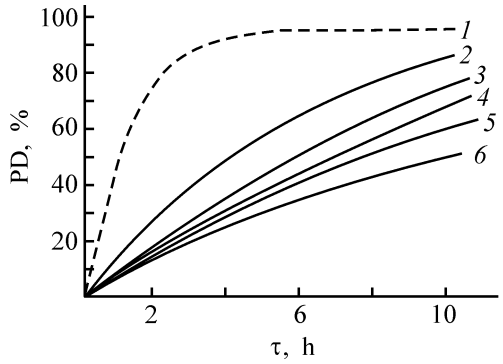
	V	5.54	+42.98

The lightfastness of azo dyes **VI**–**IX** in the acetobutyrate matrix has been studied previously both with individual dyes [4, 5] and with various dye mixtures [6]; the necessity for photostabilization of the filter dyes was revealed.



Fading curves of dye **VII** in an acetobutyrate film. (PD) Degree of photochemical degradation and (τ) time. Second component: (*1*) none, (*2*) **I**, (*3*) **II**, (*4*) **IV**, (*5*) **III**, and (*6*) **V**.

Photochemical degradation of ethylenedithiolate complexes in cellulose acetobutyrate and the photostabilizing properties of these complexes have not been studied previously.

We prepared nine film samples with individual dyes and 20 film samples with binary mixtures of an azo dye with an IR absorbent.

The photochemical degradation of dyed films was studied under conditions of accelerated photochemical aging. Samples were irradiated with a xenon lamp whose emission spectrum is similar to that of the Sun.

The rate of dye degradation in the polymeric matrix was determined from the degrees of its photochemical degradation (PD, %), measured at regular intervals (15, 30, 45 min; 1, 2, 3, ..., 10 h):

$$\mathrm{PD} = \frac{D_0 - D_i}{D_0} \times 100.$$

Here D_0 and D_i are the optical densities of the dye at the chosen wavelength, determined before irradiation and after irradiation for a definite period, respectively.

To eliminate the possible contribution from photochemical degradation of the polymer base, the electronic absorption spectra of films were measured relative to a colorless acetobutyrate film irradiated under the same conditions. The analytical wavelengths corresponded to the absorption peaks of the dyes (Tables 1, 2).

In the range of maximal absorption of IR dyes **I**–**V**, heterocyclic azo dyes have no absorption; therefore, calculation of the degree of photochemical degradation of **I**–**V** involved no problems. In the range 440–480 nm, in which the azo dyes in hand have absorption peaks, the measured optical density is the sum of the optical densities of the azo dyes and dithiolate complexes, which also exhibit certain short-wavelength absorption; the optical density of **I**–**V** in this range should be taken into account in the calculations. It was evaluated from data on photochemical degradation of individual nickel and platinum ethylenedithiolate complexes in an acetobutyrate film irradiated under the same conditions as those for the binary formulations. The results are listed in Tables 3 and 4.

Using the data in Tables 3 and 4, we plotted the fading curves for each dye in the absence and in the presence of a second component; the curves for azo dye **VIII** are shown as example in the figure.

To discuss the results, it is appropriate to use data on photochemical degradation in 1 h, because longer irradiation may cause accumulation of degradation prod-

ucts in amounts in which they affect the optical density in the short-wavelength part of the visible spectrum.

The degrees of photochemical degradation of the dye in the film in the absence (PD_{ind}) and in the presence (PD_m) of the second component were compared, and their difference ΔPD was calculated:

$$\Delta PD = PD_{ind} - PD_m.$$

ΔPD is positive when the dye lightfastness is enhanced in the presence of the second component and negative in the opposite case (Tables 3, 4).

These results show that, in cellulose acetobutyrate, as in the previously described polymers, ethylenedithiolate complexes **I**–**V** exhibit photostabilizing properties, strongly diminishing the photochemical degradation of heterocyclic azo dyes (Table 3). This effect is especially pronounced with the least lightfast dyes, xylidine derivatives of furan (**VII**) and thiophene (**IX**). These dyes, when used in combination with ethylenedithiolates, exhibit lightfastness comparable with that in the best representatives of this class, anthranilic acid derivatives **VI** and **VIII** stabilized with an intramolecular hydrogen bond. The lightfastness of **VI** and **VIII** is also enhanced appreciably in the presence of ethylenedithiolates (Table 3). The lightfastness of **I**–**V** is not affected noticeably by the presence of azo dyes (Table 4).

The photostabilizing effect of nickel and platinum ethylenedithiolate complexes is presumably due to several factors: possible coordination of the azo dye with the complex, aggregation of azo dyes under the influence of the complexes, and ability of the complexes to quench singlet oxygen [7].

EXPERIMENTAL

The procedure for laboratory preparation of polymeric film light filters was described in detail in [8].

The electronic absorption spectra were measured on an SF-16 spectrophotometer. The solvent for the dyes and polymer was a chloroform–ethanol mixture (85 : 15 by weight).

Films were irradiated on a Standard Xenon Long-Life Fade Meter XFL-1 installation for accelerated photochemical aging. The first four irradiation runs continued for 15 min, and the subsequent runs, for 1 h each, until the total irradiation time reached 10 h. After the irradiation was complete, the films were stored in the dark at room temperature for no less than 24 h, after which the electronic absorption spectrum of the film was recorded, and the degree of photochemical degradation of each component, calculated.

Table 4. Degree of photochemical degradation of ethylenedithiolate complexes **I**–**V** in films in the absence and in the presence of azo dyes **VI**–**IX** (irradiation time 1 h)

Dye		PD, %	ΔPD, %
	I	3.50	
	II	7.53	
	III	1.72	
	IV	3.30	
	V	1.06	
I +	**VI**	1.63	+1.87
	VII	5.37	–1.87
	VIII	2.67	+0.83
	IX	2.25	+1.25
II +	**VI**	2.89	+4.64
	VII	7.03	+0.50
	VIII	2.89	+4.64

	VII	2.26	–1.20
	VIII	0.34	+0.72
	IX	0.96	+0.10

The dyes were prepared by published procedures [9, 10].

CONCLUSION

Nickel and platinum ethylenedithiolate complexes are effective IR absorbents in polymeric film light filters; they also exert a photostabilizing effect on heterocyclic azo dyes in the polymeric matrix.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

N-Methacryloylaminodeoxyglucose Copolymers Containing Unsaturated Acid and Activated Ester Units

O. V. Nazarova, N. G. Fomina, E. V. Afanas'eva, and E. F. Panarin

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received June 24, 2003

Abstract—Copolymers of *N*-methacryloylaminodeoxyglucose with acrylic and methacrylic acids were prepared by radical copolymerization. The reactions of these copolymers with *p*-nitrophenol, *N*-hydroxysuccinimide, and *N*-hydroxyphthalimide in the presence of *N*,*N*'-dicyclohexylcarbodiimide were studied.

Owing to their high reactivity, polymeric activated esters show much promise for syntheses of graft and block copolymers, preparation of cross-linked polymeric structures, and modification of various biologically active substances (BASs) [1]. Much researchers' attention is attracted now by new polymeric carriers for BASs, polyvinyl saccharides and, in particular, by polymers of *N*-methacryloylaminodeoxyglucose (MAG) [2–9].

Polyvinyl saccharides are biologically active; in particular, they exhibit immunomodulating properties [7, 8]. Furthermore, *in vivo* experiments showed that, when administered to a living body, the polymers containing carbohydrate fragments as target-recognizing vectors, are selectively localized in definite organs, i.e., these units ensure directed transport of polymeric systems [10] and enhance their bioadhesion [11]. To make polyvinyl saccharides suitable as polymeric carriers, it is necessary to introduce into them highly reactive functional groups reacting with BASs under mild conditions.

The goal of this study was to develop procedures for introducing activated ester units into polyvinyl saccharides.

We tested two procedures for introducing reactive ester units into poly-MAG: (1) radical copolymerization of MAG with activated esters of unsaturated acids and (2) introduction of activated ester groups into polymers by polymer-analogous transformations.

EXPERIMENTAL

N-Methacryloylaminodeoxyglucose was prepared as described in [2]. Activated *p*-nitrophenyl (NPE) and *N*-hydroxysuccinimide (HSIE) esters of unsaturated acids (acrylic, AA; methacrylic, MAA) were prepared as described in [12, 13]. Copolymerization of MAG with unsaturated acids was performed at 60°C for 24 h, and copolymerization with activated esters, at 50°C for 1–2 h in dimethylformamide (DMF) in the presence of a radical polymerization initiator, azobis(isobutyronitrile) (AIBN). The polymers were precipitated by pouring their solutions into diethyl ether.

Reactions of MAG–unsaturated acid copolymers with hydroxy compounds (*p*-nitrophenol, NP; *N*-hydroxysuccinimide, HSI; *N*-hydroxyphthalimide, HPI) were performed in DMF in the presence of *N*,*N*'-dicyclohexylcarbodiimide (DCC) [12]. After a reaction was complete, the dicyclohexylurea precipitate was filtered off, and the polymer was isolated with diethyl ether.

The content of carboxy groups in MAG–acid copolymers was determined by potentiometric titration with 0.1 N NaOH. The content of activated ester (*N*-hydroxyphthalimide ester, HPIE; HSIE; NPE) units in the copolymers was estimated spectrophotometrically (SF-46 spectrophotometer) from the absorption of, respectively, AA HPIE units (λ_{max} = 295 nm, ε = 2100 l mol^{-1} cm^{-1}) [13], HSI anion released in aminolysis of the copolymers with 0.1 N NH_4OH (λ_{max} = 260 nm, ε = 8600 l mol^{-1} cm^{-1}) [13], and bound NP (λ_{max} = 274 nm, ε = 9500 l mol^{-1} cm^{-1}) [14]. The intrinsic viscosities of copolymers were determined with an Ubbelohde viscometer in 0.1 M Na_2SO_4 at 25°C. The molecular weight of the MAG–AA copolymer (8.0 mol % acid units) was calculated using the same parameters of the Mark–Kuhn–Houwink equation as for poly-MAG [4]:

$$[\eta] = 8.29 \times 10^{-4} M^{0.49}.$$

1070-4272/03/7610-1647 $25.00 © 2003 MAIK "Nauka/Interperiodica"

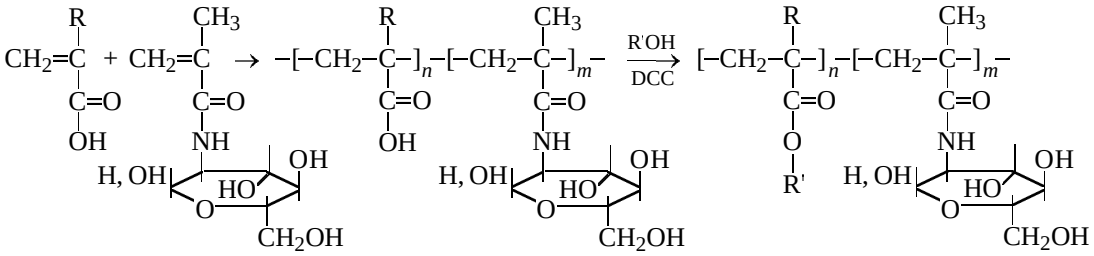
Table 1. Copolymerization of MAG (M_1) with unsaturated acids (M_2): [M_1 + M_2] = 10 wt %, [AIBN] = 3% based on [M_1 + M_2], DMF, 60°C, 24 h

Copolymer no.	Monomeric mixture		Copolymer		
	M_2	[M_2], mol %	[M_2], mol %	$[\eta]^*$, dl g^{-1}	M_η
1	AA	10	8.0	0.08	22000
2	AA	30	23.5	0.08	Not determined
3	AA	40	41.0	0.07	
4	MAA	36	27.4	0.07	″

Aminolysis of a MAG copolymer containing NPE units was monitored spectrophotometrically. A solution of the copolymer in DMF was placed in a temperature-controlled (25°C) cell (d = 0.2 cm), and a solution of an amine in DMF was added. The concentration of NPE units was 0.6×10^{-3} M, and the molar ratio [amine] : [ester units] = 150 : 1. The reaction course was monitored by a decrease with time of the optical density at the wavelength corresponding to the absorption peak of bound NP [14]. The time from mixing the reactants to starting the measurements did not exceed 10–15 s.

We failed to prepare the desired copolymers by radical copolymerization of MAG with NPE or HSIE of acrylic and methacrylic acids in the presence of AIBN. In all the cases, the polymer obtained contained no activated ester units. The MAG molecules contain hydroxy groups, in particular, a primary OH group. It is known that hydroxy compounds react with activated esters, with the reaction rate growing with temperature [15, 16]. Apparently, MAG reacts with activated esters at 50°C (conditions of radical polymerization in the presence of AIBN).

Therefore, we tested another procedure for introducing reactive groups: polymer-analogous transformations. For this purpose, we first prepared by radical copolymerization the copolymers of MAG with unsaturated acids, AA and MAA. Then these copolymers were treated with an appropriate hydroxy compound in the presence of a dehydrating agent, DCC, to obtain MAG copolymers containing activated ester (NPE, HSIE, HPIE) units:



where R = H, CH_3; R' = $-C_6H_4-NO_2$;  ,  .

Since one of the main requirements to polymeric carriers for BASs is relatively low molecular weight [17], MAG–acid copolymers were prepared at low concentrations of the monomers (10 wt %) and high concentration of the initiator (3 wt % based on the sum of the monomers). The carboxyl-containing copolymers were prepared in 93–95% yield; their characteristics are listed in Table 1. As seen from the above data, the intrinsic viscosities of the copolymers are relatively low: 0.07–0.08 dl g^{-1}. The MAG–AA copolymer containing 8 mol % acid units has M_η = 22000, which meets the requirements to polymeric carriers for BASs (Table 1, polymer no. 1).

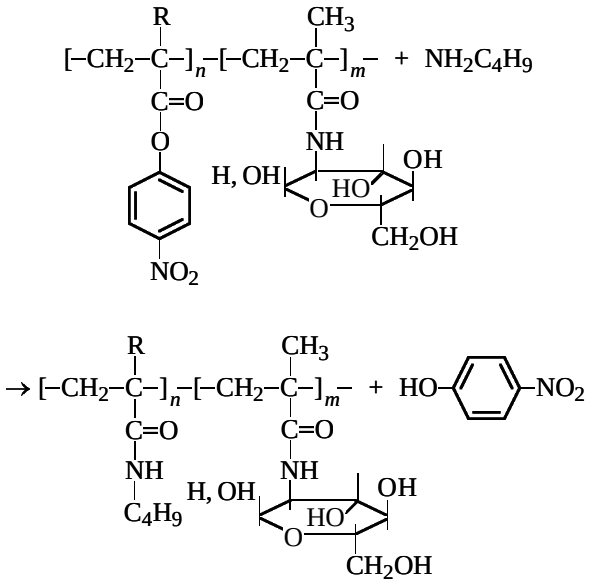
Data on reactions of MAG–acid copolymers with hydroxy compounds are listed in Table 2. In all the cases, the copolymers prepared contained activated ester units. However, the degree of esterification of carboxy groups depended on the structure of the starting copolymer. For example, the conversion of MAG–MAA copolymer (27.7 mol % acid units) in the reaction with NP (acid : NP : DCC ratio 1 : 1.2 : 1.2) is as low as 5%, whereas the conversion of the MAG–AA copolymer of similar composition (26.7 mol % acid units) under the same conditions reaches 44%. The amount of ester groups introduced into the copolymer also depends on the reactant ratio. For example, at

Table 2. Reactions of MAG–acid copolymers with hydroxy compounds (HCs)

Co-polymer no.	Starting copolymer			Reaction conditions		Reaction product		
	acid	[COOH], mol %	[η], dl g^{-1}	HC	[COOH] : [HC] : [DCC], mol %	[–O–R'], mol %	α, %	[η]*, dl g^{-1}
5	AA	23.5	0.08	NP	1 : 1.2 : 1.2	10.3	43.8	0.08
6	AA	23.5	0.08	NP	1 : 2 : 2	16.6	70.8	0.07
7	AA	23.5	0.08	NP	1 : 3.5 : 3.5	19.2	71.9	Not determined
8	AA	23.5	0.08	HPI	1 : 1 : 1	13.7	58.4	0.07
9	AA	23.5	0.08	HSI	1 : 2 : 2	14.5	62.0	0.07
10	MAA	27.7	0.07	HSI	1 : 1.2 : 1.2	1.2	4.3	Not determined
11	MAA	27.7	0.07	HSI	1 : 2 : 2	3.4	12.5	″
12	MAA	27.7	0.07	HSI	1 : 3.5 : 3.5	3.6	13.2	″

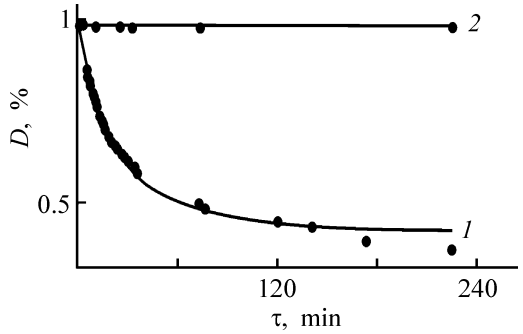
the acid : NP : DCC ratio of 1 : 2 : 2, the conversions α of the MAA and AA copolymers are 15 and 72%, respectively. However, the conversion did not increase further at larger relative amounts of NP and DCC. A similar influence of the structure of acid units and reactant ratio has been observed previously in reactions of NP with copolymers of *N*-vinylpyrrolidone (VP) with unsaturated acids [12].

Reactions of MAG–AA copolymers with HSI and HPI also proceed to high (up to 60%) conversions (Table 2). The resulting copolymers, containing activated ester units, react with amines. For example, copolymer no. 6 (MAG : AA : AA NPE = 76.5 : 6.9 : 16.6 mol %) reacts with *n*-butylamine by the scheme



with the release of free NP (λ_{max} = 320 nm), which is accompanied by a decrease in the absorption of bound NP (λ_{max} = 274 nm) [14] (see figure). The times of 20% and 50% conversion of the reactive ester groups in the reaction with the amine are 3 and 24 min, respectively, and the maximum attainable conversion is 92%. In the absence of *n*-butylamine, the intensity of the absorption band with λ_{max} = 274 nm did not change noticeably in the course of several days (see figure).

Interchain interaction of the copolymers synthesized with VP copolymers containing primary amino groups in pendant chains, e.g., with copolymers of VP and vinylamine or allylamine at 5–10 wt % concentration of the sum of the polymers, yields a gel owing to the reaction of amino and activated ester groups, as in the case of VP copolymers containing activated ester units [18].



Optical density *D* (λ_{max} = 274 nm) of a solution of copolymer no. 6 in DMF vs. time τ (*1*) in the presence and (*2*) in the absence of *n*-butylamine. Concentrations, M: NPE units 0.6×10^{-3} and *n*-butylamine 0.09.

CONCLUSION

Polymer-analogous transformations allow introduction into poly-*N*-methacryloylaminodeoxyglucose of activated ester groups reactive toward amine-containing compounds, which makes these polymers promising as polymeric carriers for biologically active substances.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Electret Effect in Compounds of Polystyrene with Aerosil

M. F. Galikhanov, D. A. Eremeev, and R. Ya. Deberdeev

Kazan State Technological Institute, Kazan, Tatarstan, Russia

Received June 9, 2003

Abstract—Coronoelectrets based on polystyrene and composites of polystyrene with Aerosil were studied.

The electret state is characteristic of virtually all insulators [1]. In recent years, the field of application of electrets, i.e., insulators producing strong electrostatic field in the surrounding space, has expanded rapidly. Their applications range from home facilities to special-purpose equipment; they include acoustic converters, dosimeters, gas filters, systems for electron focusing, elements of friction units, gaskets, systems for corrosion protection, etc. [1–3]. New fields of application of electrets have appeared recently in medicine and biotechnology [4].

For the most part, electrets with stable external electric field are produced from nonpolar polymers in which the presence of deep levels trapping charge carriers plays an important role. Impurity ions, interfaces between crystalline and amorphous phases, and free volume of the polymer serve as energy traps. However, highly stable electrets with good service characteristics can be produced only from a limited set of materials. Straight polymers as main material for electrets do not have the mechanical, thermal, and other characteristics required for their practical use.

To produce electret materials with prescribed characteristics, it is appropriate to use formulations composed of a polymeric binder and various fillers. However, the general pattern of variation of electret characteristics of polymers upon filling was not determined. As a result, progress in practical development of polymer composite electrets is ahead of their theoretical analysis. In this context, it is of interest to study the features of polarization of various composites.

EXPERIMENTAL

We used polystyrene (PS) of the PSM 115 grade [GOST (State Standard) 20282–86] with density of 1.06 g cm^{-1}, viscosity-average molecular weight of 3×10^5, and electrical resistivity of 2×10^{14} Ω m and Aerosil of the A175 grade (GOST 14922–77) with diameter of the initial aggregates of 14 nm and specific adsorption surface area of 175 ± 20 m^2 g^{-1}.

The polymer and filler were blended on laboratory microrolls at 175 ± 5°C for 3 min. Plates 1.1–1.2 mm thick were manufactured by pressing at 170 ± 5°C for 5 min (GOST 12019–66). Polymer plates were polarized in the field of a corona discharge with the use of an electrode containing 196 sharp needles uniformly arranged on a 7×7 cm^2 area. The distance between the plates and electrode was 20 mm; polarization voltage, 35 kV; polarization duration, 60 s. Before polarization, the plates were kept in a thermostat at 90°C for 10 min.

The surface potential of the electrets, V_e, was measured every 24 h for 150 days by the vibration electrode method (noncontact induction method) according to GOST 25209–82 (measuring error 0.15%). The time interval from polarization of the plate to the first measurement of its surface potential was 1 h. The electrets were stored in nonshorted state in paper pacages. The surface charge density σ_{ef} was calculated by the formula

$$\sigma_{ef} = U_c \varepsilon \varepsilon_0 / \delta,$$

where U_c is the compensation voltage; ε, the relative permittivity of the composite; ε_0, the permittivity of free space, equal to 8.854×10^{-12} F m^{-1}; δ, the electret thickness [2].

The error in σ_{ef} calculation was 0.18%.

Thermally stimulated depolarization currents were measured after 150 days of storage under linear heating at a constant rate of 5 deg min^{-1}, using an electronic recorder of small currents with special measuring cell with blocking aluminum electrodes and Teflon gasket [3]. The thermally stimulated depolarization (TSD) spectrum was recorded and visualized on a PC using NVL 03 Driver software.

The activation energy of charge relaxation, W_a (trap depth), was evaluated from the initial slope of the TSD current peak (Garlick–Gibson method) [1].

In corona polarization, when one of the polarizing electrodes is ionized air plasma, charge carriers are adsorbed on the surface of the insulator. In this case, ions either transfer their charge to the insulator and return to air or penetrate into the surface area of the insulator, where they are captured by energy traps.

Impurity ions, interface, free volume of polymer, defects of monomeric units, irregularities in the chains, and crystallite imperfections often serve as traps. Chemically active impurities, specific surface defects caused by oxidation processes, adsorbed molecules, and differences in the short-range order of molecules at the surface and in the bulk can serve as surface traps for low-energy charge carriers (shallow traps). The stability of a coronoelectret is mainly governed by the type of energy traps into which most of the injected charge carries fall (deep or shallow).

Polystyrene coronoelectrets have fairly high and stable values of the surface potential V_e (Fig. 1) and effective surface charge density σ_{ef}. It is precisely this fact that account for the researchers' interest in these materials [5–7].

A study of TSD spectra of the polystyrene coronoelectret, performed after 150 days of storage, revealed the presence of two levels capturing injected charge carriers (Fig. 2). The primary level with activation energy of charge relaxation, $W_a = 1.15 \pm 0.05$ eV, is eliminated at 125–130°C. It is likely that, at this temperature, the segmental mobility of polystyrene macromolecules becomes sufficient for liberation of injected charge carriers from structural energy traps. Indeed, at 106–110°C, polystyrene passes from glassy to hyperelastic state. Above this temperature, bulky pendant groups can fairly easily rotate, overcoming the intramolecular and intermolecular interactions. The difference between the temperatures of destruction of energy traps of this type and the glass transition point may be due to high rate of temperature variation in measurement of thermally stimulated depolarization currents, not comparable with the relaxation rate of macromolecular chains and their segments.

The secondary level capturing charge carriers, with trap depth of 1.05 ± 0.05 eV, eliminated at 160–165°C. This temperature is close to the flow point of polystyrene, above which interchain interactions in the polymer are virtually absent (Fig. 2).

Composite materials have features affecting formation and relaxation of electret charge. For example, in filling of polymers as one of the possible ways to produce electret composite materials, new structural elements that can serve as traps of charge carriers arise. These are interfaces, at which accumulation of charge carriers is caused by the difference in conductivity between the phases (Maxwell–Wagner effect), loosened adsorption layer of the polymer, and overstrained segments of macromolecules.

It is well known that radicals formed in degradation of macromolecules can act as deep traps [3]. In blending of polymers with fillers, high shear stresses arise on the rolls, which inevitably results in mechanochemical processes in the polymer. In this case, macromolecules are cleaved to form radicals.

This must result in enhancement of electret characteristics of polymeric coronoelectrets. However, a study of composites of polymers with dispersed fillers revealed that the composition of a composite exerts a complicated influence on its characteristics [3, 8–12]. Both improvement and degradation of the electret characteristics of polymer composites with increasing content of fillers were observed.

The aforesaid makes interesting a study of polymer composite coronoelectrets based on polystyrene

and dispersed fillers. Previously, electrets based on various polymers with different modifications of silicon dioxide have been studied: polymethyl methacrylate with block silica gel [10, 11], polyamide PA-6 with fiber glass [12], and polyvinyl butyral with fiber glass fabric [3]. Therefore, powdered Aerosil with general chemical formula SiO_2 was chosen as filler.

The studies showed that the presence of a filler significantly affects the electret effect in polystyrene: with increasing content of Aerosil in the composite, the surface potential and effective surface charge density measured after 150 days of storage initially increase and then decrease (Fig. 3). For all the composites studied, the surface charge is stable after 150 days of storage; therefore, a comparison of their electret characteristics at this instant of time is quite correct. A similar dependence of charge density of thermally stimulated depolarization of metal-containing polymeric electrets on the content of fiber glass fabric in polyvinyl butyral has been observed previously [3].

The increase in V_e and σ_{ef} of polystyrene upon filling with Aerosil can be accounted for by appearance in the material of new energy traps for injected charge carriers with wide energy range. A study of the TSD spectra of filled electret compounds (Fig. 2) showed the presence of new traps for injected charge carriers, which disappeared at 200–205 and 220–230°C. Most likely, these traps are due to appearance of the polymer–filler interface, since in filling the main part of new traps appear at this interface. This is also caused by the Maxwell–Wagner effect, presence of various polar groups at the silicon dioxide surface, and appearance of loosened adsorption layer at the filler surface. The observed enhancement of electret characteristics was accounted for in [3] by formation of more perfect supramolecular structures, which has a positive effect on the formation of the electret charge. This phenomenon can take place in the composites considered. The activation energies of charge relaxation from new trap levels were 1.35 ± 0.05 and 1.20 ± 0.05 eV for the electret from the polystyrene composite with 6 vol % of Aerosil.

It was found that the intensity and position of peaks of TSD currents, characteristic of neat polystyrene, vary with filling (Fig. 2). This is most likely due to the presence of adsorption layer of polymer at the filler surface with low lability; as a result, the mobility of various kinetic units of the polymer decreases and the relaxation times of its macromolecules increase. For the composite of polystyrene with 6 vol % Aerosil, W_a is 1.10 ± 0.05 and 1.95 ± 0.05 eV for primary and secondary traps for charge carriers, respectively.

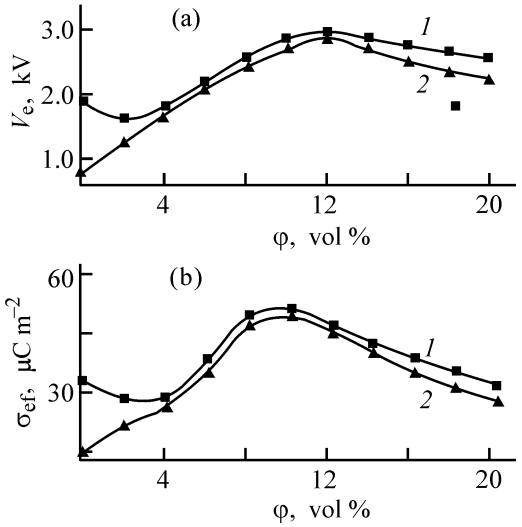

Fig. 3. (a) Surface potential V_e and (b) surface charge density σ_{ef} of coronoelectrets based on polystyrene and Aerosil vs. A175 filler content φ after (*1*) 30 and (*2*) 150 days of storage.

Raising the filler content results in an increase in the interface area and, hence, in the number of traps, which must improve the electret characteristics. Actually, for a coronoelectret based on polystyrene with 10 vol % of Aerosil W_a is 3.15 ± 0.05 and 1.75 ± 0.05 eV for tertiary and quaternary traps for charge carriers, respectively (Fig. 2).

However, with the filler content increasing further, the V_e and σ_{ef} values decrease (Fig. 3), which is unexpected. A decrease in charge with increasing filler content can be accounted for by a decrease in the amount of polarizable polymeric material: substitution of nonpolarizable filler for electretized polystyrene must inevitably affect the characteristics of coronoelectrets, which is actually observed for the dependences of V_e and σ_{ef} on the filler content (Fig. 3). In addition, even for the polystyrene composites with 10 vol % filler, the W_a values for primary and secondary trap levels for charge carriers (1.05 ± 0.05 and 1.80 ± 0.05 eV, respectively) are lower than the corresponding values for the composites with 6 vol % Aerosil. At a still higher Aerosil content, the intensities of these peaks decrease further. This can be accounted for as follows.

An increase in the total number of traps also makes greater the number of shallow traps. During polarization, shallow surface traps are saturated with injected charge carries first. An increased content of injected charge carriers in the surface layer makes higher its conductivity, which leads to high relaxation rate of the coronoelectret charge. This impairs

the electret characteristics of polystyrene composites after reaching a certain extent of filling.

Filling of polystyrene with Aerosil particles changes the characteristics of supramolecular structure formation (size, shape, and type of size distribution) and packing density, which may also lead to changes in its electret characteristics (Fig. 3).

Our results suggest that even processing of composite coronoelectrets by traditional procedures involving reprocessing of plastics at a temperature less than 190°C can yield products with electret properties, since some traps for injected charge carriers disappear above this temperature (with account of the high relaxation rates of macromolecules).

To verify this assumption, electret plates based on polystyrene compounds were kept in thermostat at 150°C, 170°C, and 190°C. Changes in the surface potentials in thermal treatment are listed in the table.

It is seen that charge relaxation is not complete, which confirms our assumption.

CONCLUSIONS

(1) In electrets based on polystyrene, two trapping levels injected charge carriers, responsible for the high and stable electret properties of the composites, were found.

(2) Addition of silicon dioxide gives rise to new trapping levels at the polymer–filler interface and changes the energy depth of the existing levels, which increases the surface potential and the effective surface charge density of polystyrene electrets. Raising the filler content above 10–12 vol % leads to deterioration of the electret characteristics of composites owing to a decrease in the amount of polarized polymeric material and increased conductivity of the surface layer, which makes faster the relaxation rate of coronoelectret charge. Electrets with prescribed characteristics can be prepared by varying the component ratio.

(3) The prepared sheet and film coronoelectrets based on composites of polystyrene with Aerosil can be processed into other articles without loss of their electret properties.

Abstract—The fluorescence intensity was studied for the scintillation formulation including 1,1,3-trimethyl-3-phenylindan and 2-phenyl-5-(4-biphenylyl)-1,3,4-oxadiazole, 2-(4'-*tert*-butylphenyl-5-(4''-biphenylyl)-1,3,4-oxadiazole, and 1,4-di(5-phenyl-2-oxazolyl)benzene. The scintillation efficiency was determined for the polymethyl methacrylate based plastic scintillator containing the above-listed compounds as luminescent additives.

2,5-Diaryl derivatives of 1,3,4-oxadiazoles are known to exhibit luminescent properties [1]. The high-intensity fluorescence and the short lifetime of the excited state of these compounds made them suitable for scintillation devices.

One of oxadiazole derivatives, 2-phenyl-5-(4-biphenylyl)-1,3,4-oxadiazole (PBD), is used as scintillation activator or luminescent additive enhancing the light pulse from plastic scintillators (PSs) based on polystyrene [2], polyvinylxylene [3], and polyvinyltoluene [4]. 2-Phenyl-5-(4-biphenylyl)-1,3,4-oxadiazole and another oxadizaole derivative, 2-(4'-*tert*-butylphenyl-5-(4''-biphenylyl)-1,3,4-oxadiazole (B-PBD), have been suggested as luminescence activators for PSs based on polymethyl methacrylate (PMMA) [5–7].

PBD and B-PBD are among the best scintillation activators. They can effectively replace *p*-terphenyl (PPP) used in liquid and plastic scintillators. PPP is superior to PBD and B-PBD in the luminescent properties (fluorescence lifetime of PPP is 0.95 s, against 1.0 s of PBD, and the quantum yield of luminescence of PPP, 0.93, against 0.83 for PBD [8]), but exerts a weaker influence on the scintillation properties of formulations. For example, the xylene solution of PBD has a light output of 59% relative to that of anthracene crystals, and the light output of a PPP solution in xylene is 48% [1]. When PBD replaces PPP in the PS based on polyvinylxylene, also containing 1,4-di(5-phenyl-2-oxazolyl)benzene (POPOP), the light output increases from 130–135 to 140–145% relative to polystyrene-based PS [3].

In this study, we attempted to use PBD B-PBD as luminescent additives to replace PPP acting as luminescence activator in the previously suggested [9] PMMA-based scintillator, also containing 1,1,3-trimethyl-3-phenylindan (TMPI) and POPOP as additives. The choice of PBD and B-PBD as luminescence activators was also governed by the fact that, similarly to PPP, they absorb light in the region of TMPI luminescence [10]. Moreover, PBD and B-PBD are more soluble than PPP in conventional scintillation solvents: Saturated toluene solution of PPP at 25°C contains 8 g l^{-1} of the luminescent additive, and that of PBD, 20 g l^{-1} [1]. PPP [11] and PBD (B-PBD) in methyl methacrylate (MMM) and PMMA proved to have the same solubilities. A better, compared with PPP, solubility of these additives must improve the scintillation characteristics of the formulations, since an increase in the concentrations of each additive tends to decrease the light flash amplitude [4].

EXPERIMENTAL

The experimental procedure was described in [1]. The scintillation characteristics of a PS are determined by the spectral-luminescent properties of all its constituent luminescent additives. 1,1,3-Trimethyl-3-phenylindan exhibits absorption and luminescence at 210–290 and 270–310 nm, respectively (Fig. 1). The absorption of PBD and B-PBD at 230–350 nm completely overlaps the luminescence of TMPI, and the medium (PMMA with TMPI additive) is transparent

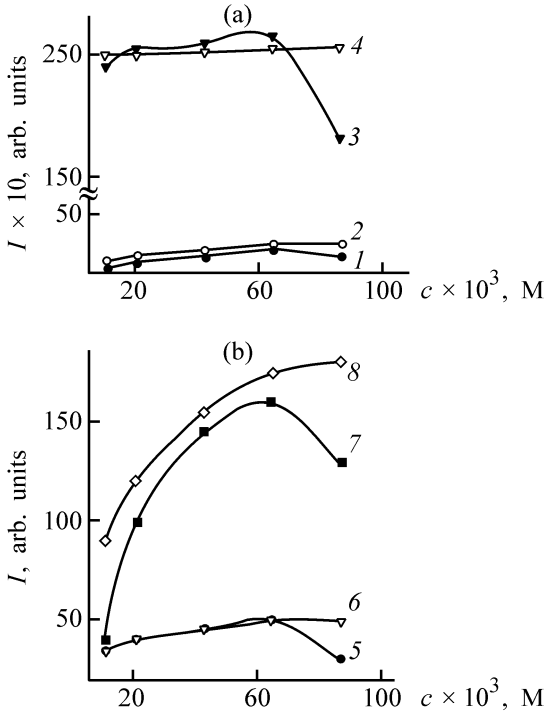

Fig. 3. Luminescence intensity *I* vs. concentration *c* in polymethyl methacrylate of (*1*, *3*, *5*, *7*) PBD and (*2*, *4*, *6*, *8*) B-PBD. (a) PBD and B-PBD at λ = 366 nm and (b) POPOP at λ = 418 nm. Excitation light wavelength λ_{exc}, nm: (*1*, *2*, *5*, *6*) 303 and (*3*, *4*, *7*, *8*) 250.

in this range. As known [1], electron-donating substituents in the *para* position of the phenyl radicals cause a bathochromic effect. This also follows from a comparison of the absorption and fluorescence spectra of PBD and B-PBD (Fig. 1). Moreover, the luminescence intensity tends to increase somewhat in going from PBD to B-PBD.

The complete overlapping of the absorption bands of PBD (B-PBD) with the luminescence bands of TMPI, as well as the high quantum yield (0.27) and short lifetime of fluorescence (8 ns) of the donor, TMPI, favors transfer of the absorbed energy, thereby converting the transferred energy to the electronic excitation energy of the molecules of the acceptor [PBD (B-PBD)]. This is also favored by higher extinction coefficients for PBD (B-PBD) absorption bands, compared with TMPI (4.5×10^4, 4.4×10^4 [1], and 1.69×10^3 l mol^{-1} cm^{-1} [10], respectively). The energy is transferred from TMPI to PBD (B-PBD) virtually without losses at a high rate, as evidenced by a decrease in the TMPI fluorescence intensity almost to zero with the PBD (B-PBD) concentration increasing to 6.5×10^{-2} M and over (Fig. 2). Based on the data from [12], we estimated the rate constants of energy transfer by the dipole-dipole mechanism (such as, e.g., singlet-singlet energy transfer between the organic molecules) at 1.27×10^{10} (1.35×10^{10}) and 6.78×10^9 l mol^{-1} s^{-1} for TMPI–PBD (B-PBD) and TMPI–PPP systems, respectively. The higher rate of energy transfer from TMPI to B-PBD and from B-PBD to POPOP, compared with that from TMPI to PBD and from PBD to POPOP, evidently intensifies the fluorescence of POPOP in the TMPI–B-PBD–POPOP system, compared with the TMPI–PBD–POPOP system irradiated at λ = 250 nm (Fig. 3).

Under excitation at λ_{exc} = 303 nm (without TMPI absorption), the fluorescence intensity of PBD dissolved in PMMA grows only slightly with increasing PBD concentration (Fig. 3a) and reaches a maximum at 1.5 wt % (6.5×10^{-2} M). Further increase in the PBD concentration decreases the luminescence intensity, i.e., there occurs concentration quenching. In the case of POPOP (Fig. 3a, curve *5*), the luminescence intensity varies with the PBD concentration in this system in a similar way. A decrease in the POPOP fluorescence intensity at PBD concentrations above 1.5% is also due to concentration quenching of the activator. Evidently, the rate of energy transfer from PBD to POPOP is comparable with, or lower than the self-quenching rate of PBD.

When a sample containing TMPI and PBD is excited at λ_{exc} = 250 nm, the PBD fluorescence intensity

increases sharply (Fig. 3a, curve *3*) and varies with increasing concentration of the luminescent additive similarly to the case of λ_{exc} = 303 nm (Fig. 3a, curve *1*). The luminescence intensity of POPOP also changes significantly (Fig. 3b, curve *7*). Unlike the case of λ_{exc} = 303 nm, light is absorbed at λ_{exc} = 250 nm by both PBD and TMPI. Therefore, in the region of the POPOP absorption, the total emission energy of PBD is due to absorption of the primary excitation energy and its acceptance from the donor, TMPI. The energy absorbed by POPOP is converted into fluorescence with higher intensity than in the case of λ_{exc} = 303 nm.

Upon introduction of a butyl group into the PBD molecule, not only the absorption and luminescence maxima shift and light emission by this compound is enhanced, but also the patterns of variation of the PBD and POPOP fluorescence intensities with the B-PBD concentration change. These dependences, unlike the case of PBD, are described by curves leveling off under excitation at λ_{exc} = 250 and λ = 303 nm (Fig. 3, curves *2*, *4*, *6*, *8*). Evidently, the transfer of the photoexcitation energy from TMPI to B-PBD and from B-PBD to POPOP is more probable than that in the case of PBD.

Transfer of the excitation energy from the secondary solvent, TMPI, to the activator, PBD (B-PBD), at a high rate and virtually without losses favors high scintillation efficiency of the polymer formulation, also containing POPOP acting as spectrum shifter. The light output of this scintillator at the optimal content of PBD and B-PBD of 1.5 wt % (6.5×10^{-2} M) is 143–145%, and in the case of a PS with the optimal PPP content (0.4%, or 1.7×10^{-2} M) and identical content of TMPI (35%, or 1.48 M) and POPOP (0.02%, or 2.75×10^{-4} M) it does not exceed 130% relative to the PS consisting of PMMA, naphthalene (15%), 2,5-diphenyloxazole (0.3%), and POPOP (0.06%) [11].

The plot of the scintillation efficiency η against the concentrations of the activators for the PMMA-based PS containing TMPI, POPOP, and PBD (B-PBD) has a maximum: η grows with the PBD (B-PBD) content increasing to 1.5 wt % (6.5×10^{-2} M), whereupon the light output decreases with increasing concentration (Fig. 4). As seen from Fig. 4, the scintillation efficiency of PS and the fluorescence intensity of the PBD activator exhibit similar trends upon variation of the PBD concentration and identical positions of the peaks and inflection points in the corresponding curves. Evidently, the luminescent properties of the additive determine its scintillation properties, and energy transfer from excited TMPI molecules to PBD

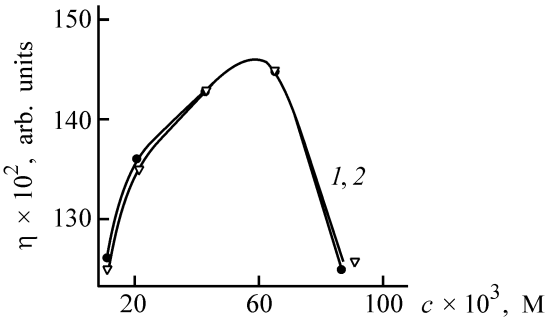

Fig. 4. Variation of the scintillation efficiency η, with the concentration *c*, of (*1*) PBD and (*2*) B-PBD.

molecules and from PBD to POPOP molecules follows the same mechanism in the cases of photo- and γ-excitation. The mechanism of energy transfer to B-PBD at B-PBD concentrations above 6.5×10^{-2} M (1.5 wt %) evidently depends on the nature of the excitation sources, as indicated by the difference in the run of the curves in this concentration range.

Plastic scintillators based on PMMA are typically prepared by free-radical polymerization of methyl methacrylate in which organic luminophores are soluble. The participation of luminophores in chain propagation and copolymerization reactions is responsible for changes in their structures, affecting the spectral characteristics and resulting in the loss of the luminescent activity. We have shown [13] that TMPI, PBD (B-PBD), and POPOP used in the scintillator of interest do not react with the propagating macroradicals: They do not inhibit the process and do not act as chain-transfer agents. These additives are present in the resulting polymer as solutes in a solid solution, and their favorable combination is responsible not only for preservation but also for sensitization of their fluorescence and scintillation.

CONCLUSIONS

(1) The photoexcitation energy is transferred from 1,1,3-trimethyl-3-phenylindan to 2-phenyl-5-(4-biphenylyl)-1,3,4-oxadiazole or 2-(4'-*tert*-butylphenyl)-5-(4''-biphenylyl)-1,3,4-oxadiazole, without losses at high rate.

(2) Polymethyl metahcrylate based plastic scintillators comprising 1,1,3-trimethyl-3-phenylindan, 2-phenyl-5-(4-biphenylyl)-1,3,4-oxadiazole or 2-(4'-*tert*-butylphenyl)-5-(4''-biphenylyl)-1,3,4-oxadiazole, and 1,4-di(5-phenyl-2-oxazolyl)benzene as luminescent additives exhibit a light output exceeding by a factor of 1.1 that of the formulation containing *p*-terphenyl in place of 1,3,4-oxadiazole derivatives.

Abstract—The effect of bifractional composition of conducting filler on the electrical and rheological properties of oligomeric compound was studied.

Conducting polymeric materials are frequently prepared by addition of conducting dispersed components [1, 2]. When a conducting component is added in amount exceeding certain fraction, a three-dimensional network of contacting particles is formed, and this structure determines the conductivity of the polymeric compound. Usually, polymeric compounds become conducting at a volume fraction of coarse filler of 23–25 vol % [3].

It is known that finely dispersed components, e.g. carbon black, tend to structurize in an oligomeric medium [4, 5] and form continuous structures extending over the entire system, making it conducting [6]. Formation of such structures obviously affects the rheological properties of the polymer, because they increase the energy of dissipation in a flowing system, i.e., the viscosity of the system grows. The volume content of the carbon black at which an oligomeric compound becomes conducting does not exceed 1 vol %.

To develop conducting polymers using conducting dispersed components, it is necessary to understand the patterns of formation of continuous networks from disperse particles in an oligomeric binder. In this study, we analyzed the rheological and electrical properties of oligomeric suspensions as influenced by an electrically conducting filler.

The structuring of carbon black consisting of coarse and fine fractions in the oligomeric dispersion medium was studied on a special rheological-conductometric device [5] equipped with a rheoviscometer of the Rheotest-2.1 type and a digital unit for data processing, interfaced to PC.

The experiments were performed using nongranulated carbon black (specific surface area 100 $m^2 g^{-1}$) and graphite (particle size 50–80 μm), with butadiene-isoprene oligomer (*M* 5000) as a dispersion phase. The formulations studied were prepared in a vacuum mixer (250 rpm, 1000 Pa) in the course of 30 min at a temperature of 60°C in the water jacket of the stirrer. The mixture was placed in the measuring cell of the rheological-conductometric device, and the cell was thermostated for 1 h. Then, the initial parameters of the device were set, the inner structure of the formulation in the measuring cell was destroyed at a shear rate of about 2×10^2 s^{-1}, and the processes occurring in the compound were studied.

The increase in the conductivity of the formulations indicated that the carbon black particles are involved in structuring and form three-dimensional (3D) conducting agglomerates extending over the entire volume of the measuring cell. As seen from microscopic data, the current passing through the formulation containing continuous networks of carbon black particles is proportional to the number of particle macrochains in the system.

Finely disporsed particles can form continuous networks extending over the entire system and affecting the macroproperties of the oligomeric compound, especially its rheological properties; primarily, the dissipation energy of the compound flow (or its viscosity) must increase. In the case of a conducting filler (e.g., carbon black), formation of 3D continuous networks would strongly affect the formulation properties, making the material conducting. Obviously,

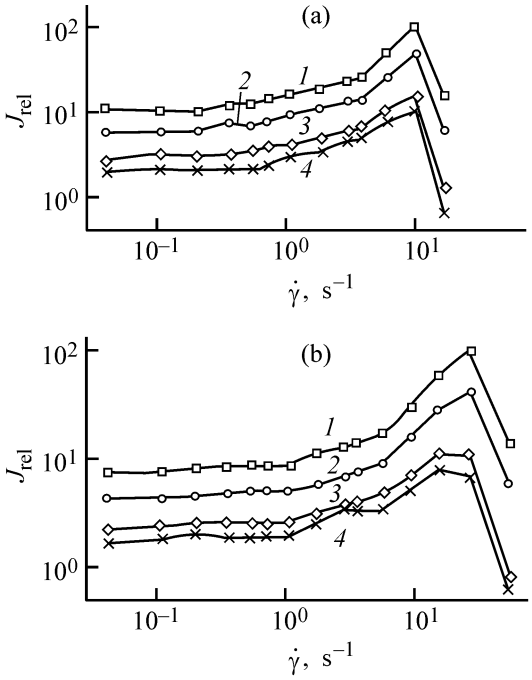

Fig. 1. Relative electrical conductivity J_{rel} of formulation containing carbon black (3 wt %) vs. shear rate $\dot{\gamma}$ at (a) 60 and (b) 80°C. Graphite content, wt %: (*1*) 20, (*2*) 10, (*3*) 5, and (*4*) 2.5.

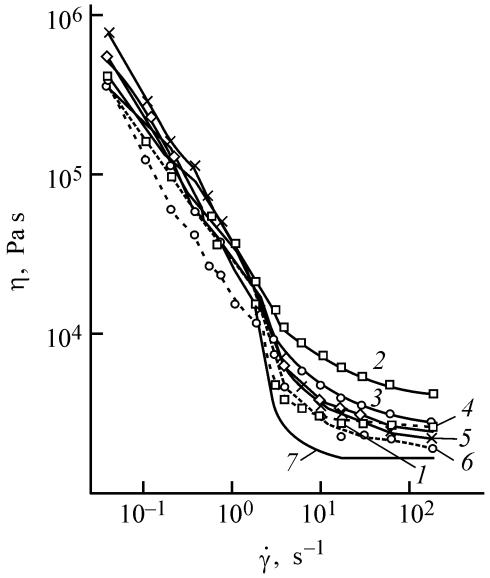

Fig. 2. Viscosity η of oligomer formulation at 60°C vs. the shear rate $\dot{\gamma}$. Graphite content, wt %: (*1*) 22, (*2*) 20, (*3*) 10, (*4*) 5, (*5*) 2.5, and (*6*) 0. Carbon black content, wt %: (*1*, *7*) 0 and (*2–6*) 3.

the length of the continuous chains must be comparable with the distance between the electrodes. Thus, the conductivity of filled polymers is a more sensitive criterion of formation of continuous 3D networks than the viscosity. A sharp increase in the system viscosity may be also due to structuring of particles without formation of networks of a size comparable with the interelectrode distance.

Thus, preparation of conducting formulations based on finely dispersed fillers requires structuring of particles into chains, whose size exceeds the particle size by many orders of the magnitude, with the number of particles in a chain exceeding thousands and tens of thousands. However, such complex systems can be easily broken. A question arises as to how the formulation properties will change upon addition of coarse conducting particles. We assume that these coarse particles can act as centers of carbon black structuring; in this case, the length of continuous carbon black chains required to form a conducting system would significantly decrease.

The dependences of the relative electrical current (i.e., the ratio of the conductivities of formulations containing a mixture of carbon black and graphite and carbon black only, other conditions being equal) are shown in Fig. 1a. We found no conductivity in the mixture containing up to 22 wt % graphite, whereas the oligomer containing 3 wt % of carbon black is a conductor (Fig. 1a). However, the conductivity of the system increases sharply upon addition of graphite to an oligomer containing carbon black (3 wt %). At increased shear rate, the internal structure of the formulation is broken and its conductivity decreases. Similar dependences obtained at higher temperature are shown in Fig. 1b. As seen, the effect of graphite becomes stronger with increasing shear rate; the maximal effect at 60°C corresponds to a shear rate of 10 s^{-1}, and that at 80°C, to 20 s^{-1}.

The influence of the filler content on the oligomer structuring is shown in Fig. 2. As seen, the viscosities of formulations containing carbon black only (curve *6*) and graphite only (curve *1*) are the lowest. The higher viscosity of the pure oligomer in comparison with the formulations containing both graphite (22 wt %) and carbon black (3 wt %) at small sheare rates is probably due to the structuring of the oligomer and the effect of the dispersed components on the resulting structures.

CONCLUSION

Coarsely dispersed filler added to an oligomeric formulation intensifies the structuring of the finely dispersed filler. Graphite when added to butadiene-isoprene oligomer simultaneously with carbon black

substantially enhances the conductivity of the system and increases its viscosity.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis and Thermal Transformations of Bis[4-(1-hydroxyethyl)phenyl] Ether Dimethacrylate

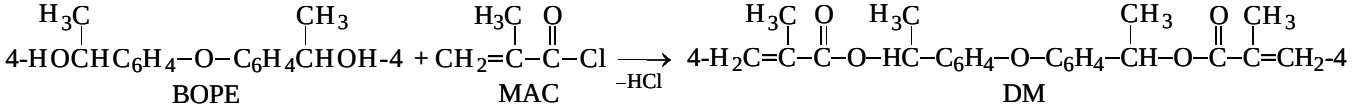
Abstract—Thermal curing of bis[4-(1-hydroxyethyl)phenyl] ether dimethacrylate was studied.

Processing of thermoreactive resins into heat-resistant polymeric materials involves a serious problem: For curing to be efficient, the curing temperature T_c should be maintained higher than the glass transition point T_g of the system being cured. In the highly viscous medium of a thickly cross-linked polymeric matrix at a temperature below T_g, curing drastically decelerates, because transport of reactants to the reaction zone becomes severely hindered. Participation of adjacent functional groups in polymer-analogous transformations might eliminate this problem [1–3].

Being a polyfunctional monomer, bis[4-(1-hydroxyethyl)phenyl] ether dimethacrylate (DM) may be of considerable interest in this respect. It is a component of Rolivsans, novel heat-resistant thermoreactive resins used in modern engineering [4–6]. Owing to the presence of unsaturated methacrylate groups, it is involved in common three-dimensional (3D) polymerization, forming network polymers similar to the well-known diol methacrylates [7–9]. However, a specific feature of DM is the presence of latent ("sleeping") fragments $-C_6H_4-CH(CH_3)-O-CO-$, allowing high-temperature rearrangement of the initial polymeric network of DM in the course of further curing at elevated temperatures. In this study, we analyzed the mechanism of thermal transformations of DM and the structure and properties of the cured products.

Bis[4-(1-hydroxyethyl)phenyl] ether dimethacrylate is formed in synthesis of Rolivsan MV-1, which is a monomer–oligomer compound prepared chemically, i.e., by transformations of a secondary aromatic diol, bis[4-(1-hydroxyethyl)phenyl] ether (BOPE), in the presence of methacrylic acid (MAA), catalyzed with strong mineral acids [10–14]. Pure DM was prepared for the first time by acylation of BOPE with methacryloyl chloride (MAC) [12, 13]. According to ozonolysis data, the content of double bonds in DM is 0.504 mol per 100 g; ester number, 272 mg KOH per gram; n_D^{20}, 1.5410; gelation time at 150°C, 2 min.



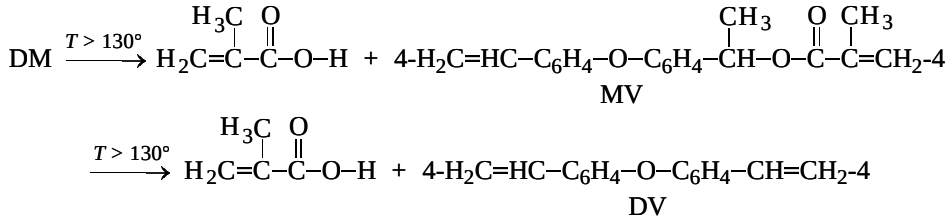
Thermal transformations of DM were studied by IR spectroscopy, differential scanning calorimetry (DSC), and elemental, thermogravimetric, and thermomechanical analyses. The IR study of DM was perfoirmed in the temperature range 140–370°C (isothermal heating at 140°C and dynamic heating of a thin film between KBr and NaCl plates at an average rate of 1.4 deg h^{-1}.

The IR spectrum of DM (Fig. 1a, curve *1*) contains absorption bands of unsaturated and aromatic groups at 3070–3060, 3030, 2975, 1630, 1600, 1500, 940, 870, and 830 cm^{-1}, of methyl and methylene groups at 2975, 2930, and 2870 cm^{-1}, and of methine groups at 2900 cm^{-1}; it also contains strong absorption bands of methacrylate ester and diphenyl ether groups at 1715 and 1240 cm^{-1}; bands at 1170, 1060, and

1070-4272/03/7610-1662 $25.00 © 2003 MAIK "Nauka/Interperiodica"

1010 cm^{-1} originate from stretching vibrations of the C–O bond in ester and ether groups.

The mechanism of thermal transformations of another monomer, 4-vinylphenyl-4-(1-methacryloyloxyethyl)phenyl ether (MV), which is also a component of Rolivsan MV-1 [12, 13, 15], has been studied previously [12, 13, 15]. DM can be expected to behave similarly (with corrections for differences in the structure and reactivity), and the following scheme of cleavage (or activation) of latent ester groups with formation of MAA, MV, and bis(4-vinylphenyl) ether (DV) can be suggested:



It should be noted that, in contrast to MV, even short (1–2 h) heating of DM at 140°C causes substantial changes in the IR spectrum (Fig. 1a, curve *2*), which are due not only to the onset of the expected 3D radical polymerization (the gelation time of DM at 140°C is as short as several minutes) but also to the cleavage of the ester groups, according to the above scheme. Dimethacrylate and bridging units of the initial network polymer, formed by it, are unstable at this temperature and start to noticeably decompose to give MAA and MV, which, in turn, decomposes to DV, MAA, and/or their units. This process gives rise in the IR spectrum of DM to a new band of out-of-plane bending vibrations of the H–C=C fragment of the 4-CH_2=CH–C_6H_4–O–C_6H_4– group at ~902 cm^{-1} [15–18]. The C=C stretching vibration band at 1630 cm^{-1} simultaneously grows in intensity. Therefore, it is not surprising that, in the initial period (1–2 h) of DM heating, the bands at 902 and 1630 cm^{-1} noticeably grow in intensity (Fig. 1a, curve *2*), compared to the starting monomer. However, further heating causes the intiensities of these bands to decrease owing to participation of the methacrylate and styrene groups in (co)polymerization (Fig. 1a, curves *3*–*5*). Therefore, upon prolonged heating of the sample at 140°C and higher temperatures, these bands gradually decrease in intensity, as also does the band at 940 cm^{-1} belonging to out-of-plane bending vibrations of the H–C= fragment of the methacrylate group (Fig. 1a, curves *1*, *2*). Thus, at high temperatures, unsaturated products formed from DM by cleavage of methacrylate groups (see above) are involved in thermal copolymerization of the system, which becomes multicomponent.

** Isothermal heating at 140°C.

Comparison of the IR spectra of DM, MV, and DV monomers (Tables 1, 2) with those of DM thermal transformation products, measured under similar conditions, shows how the degree of DM unsaturation varies in the course of slow dynamic heating in the range 130–180°C. For this purpose, we first determined the experimental intensities of the absorption bands (at 900, 940, and 1630 cm^{-1}) of DM, MV, and

DV monomers used as reference; the IR spectra were recorded under similar conditions.

Let us denote as *A* and *B* the contributions from methacrylate and styrene (4-CH_2=CH–C_5H_4–) groups to the total intensity of an absorption band of the monomer and assume these contributions to be additive. Then the spectrum of DM corresponds to 2*A*; that of MV, to *A* + *B*; and that of DV, to 2*B*. From the spectra of these three monomers, we can estimate that contribution *A* to the bands at 1630, 940, and 900 cm^{-1} is 0.12–0.13, 0.14–0.18, and 0.00, and contribution *B* to the same bands, 0.10–0.11, 0.00, and 0.14–0.18, respectively.

From these data, we can determine how the conversion c/c_0 of the CH_2=CH and CH_2=C(CH_3) groups varies in the course of DM heating. Table 1 shows that, in the range 160–180°C, the concentration of unsaturated groups of the styrene and methacrylate types in the system abruptly decreases owing to their involvement in the radical copolymerization of the system components. It should be noted that the kinetic data obtained in the isothermal (Fig. 2) and dynamic modes of DM heating are well consistent.

As for other major IR manifestations of the cleavage of ester groups in DM, Fig. 1 shows that, on heating, the methacrylate C=O absorption band at 1715 cm^{-1} gets broadened and shifted toward lower frequencies (1700–1685 cm^{-1}) corresponding to absorption of the carboxy group in MAA [15, 18]. Finally, the intensity of the methacrylate C–O stretching band at 1060 cm^{-1} abruptly decreases already at the very beginning of DM heating at 140°C. Simultaneously, the methacrylate H–C= bending band at 940 cm^{-1} gets considerably broadened and shifted owing to superposition of the carboxyl O–H bending band of MAA and/or its unit at 935 ± 15 cm^{-1}; also, broad OH stretching bands of carboxy group appear at 3570–3500 and 2700–2500 cm^{-1}, and a band of the C–O bond in carboxy group appears at 1420 cm^{-1} [19].

It could be expected that cleavage of DM according to the above scheme would be accompanied by a decrease in the content of CH_3 and CH_{tert} groups. Indeed, the intensities of the stretching vibration bands of the methyl (2980, 2930, 2870 cm^{-1}) and methylene (2890 cm^{-1}) C–H bonds and of the C–H bending vibrations (1370 cm^{-1}) appreciably decrease in the course of DM heating. A similar pattern has been observed previously in thermal transformations of other methacrylates of secondary aromatic alcohols [12, 13, 15, 18], e.g., MV [15]. In particular, it was shown that MV units in the network (co)polymer prepared by thermal polymerization of MV are also cleaved to give DV units.

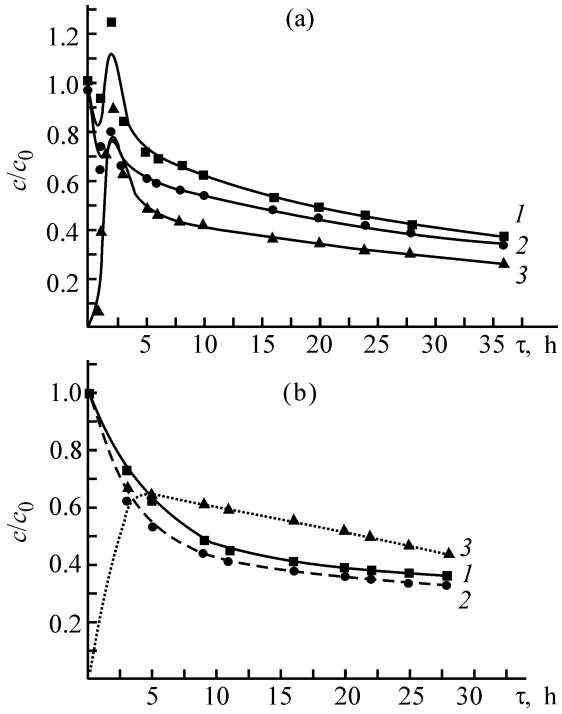

Fig. 2. Kinetics of transformations of unsaturated groups in the course of isothermal heating of DM (140°C) between (a) KBr and (b) NaCl plates. (c, c_0) Initial and running concentrations of functional groups, M. ν, cm^{-1}: (*1*) 1630 [CH_2=CH and CH_2=C(CH_3)], (*2*) 940 [CH_2=C(CH_3)], and (*3*) 902 (CH_2=CH). The c/c_0 ratios were calculated from changes in the intensities of the indicated absorption bands in the IR spectra of transformation products of DM and model monomers (MV, DV).

As the temperature is raised further to 180–200°C and more, one more parallel reaction starts to make a major contribution to the thermal transformations: formation of methacrylic anhydride (MA) units from MAA units in the network polymer, which yields substituted glutaric anhydride units. In the IR spectra of DM recorded in the course of curing, the carbonyl absorption bands at 1803 and 1755 cm^{-1}, characteristic of the anhydride group, steadily grow in intensity (Fig. 1a, curves *4*, *5*; Fig. 1b, curves *1*, *2*; Fig. 3; Table 2). To compare, glutaric anhydride shows carbonyl absorption at 1802 and 1761 cm^{-1} [19]. Naturally, as anhydride units are formed, the absorption band of carboxyl C=O group at 1690 cm^{-1} decreases in intensity.

Heating to 250–300°C causes give rise to broad bands at 1660–1680 cm^{-1} in the IR spectra of DM curing products (Fig. 1b); these bands originate from stretching vibrations of ketone carbonyl group [19].

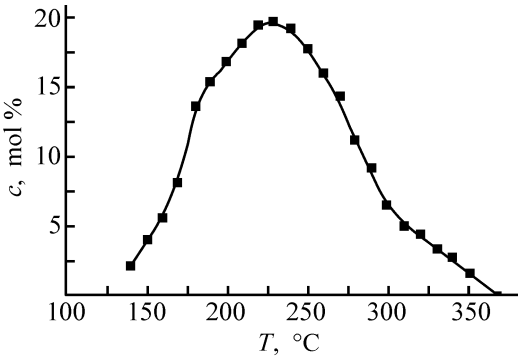

Fig. 3. Kinetics of formation of methacrylic anhydride units in the course of DM heating in the temperature range 140–370°C at average rate of ~1.4 deg min^{-1} between KBr plates: (*c*) concentration of anhydride groups and (*T*) temperature.

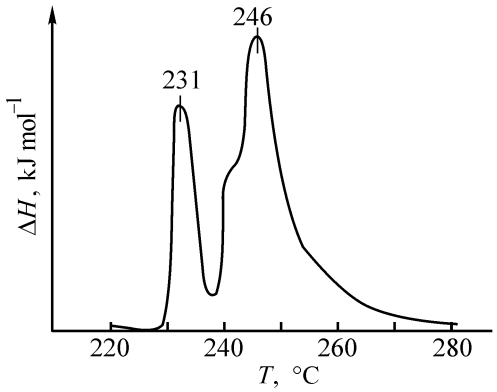

Fig. 4. Thermogram of DM curing (DSC, scanning rate 4 deg min^{-1}). (*T*) Temperature and (ΔH) thermal effect.

As shown previously in comprehensive studies of related compounds and systems by various methods [12, 13, 15, 18], these changes in the IR spectra are due to fast solid-phase Friedel–Crafts acylation of diphenyl ether groups with adjacent MA units, yielding thermally stable methylenetetralone units in the network copolymer. Figure 3 shows that the consumption of anhydride groups in polymer-analogous acylation reactions results in a fairly sharp decrease in their content in the network copolymer in the final stage of DM curing (in the temperature range 250–300°C).

The IR spectra of products of DM curing in the range 300–370°C allow evaluation of the resistance of units and some groups of the resulting network copolymer to thermal oxidative degradation in air. Figures 1b (curve *4*) and 3 show that the least thermally stable fragments of the copolymer are MA units; they degrade in the course of slow heating of the sample from 300 to 370°C. The intensities of the absorption bands of aromatic and diphenyl ether groups also gradually decrease in the course of prolonged heating, but remain relatively high even after heating to 370°C (Table 2). An exception is an appreciable growth of the band at 1600 cm^{-1}, belonging to the C=C bond in Ar and sensitive to conjugation [19]; apparently, high-temperature degradation results in the formation of polyconjugated (polycyclic) structures.

High-temperature curing of DM and related compounds [15, 18], causing cardinal structural changes as indicated by IR spectroscopy, was also studied by DSC. The observed pattern of thermal effects is consistent with the above-considered mechanism of thermal transformations of DM following from IR data, taking into account a significant difference in the heating rates (IR, 1.4 deg h^{-1}; DSC, 4 deg min^{-1}). At high heating rates, structural changes are usually manifested much more sharply than under conditions of isothermal heat treatment or slow heating.

Figure 4 shows that the exothermic peak observed at 231°C (first step of thermal transformations of DM) is apparently due to prevailing 3D (co)polymerization of methacrylate and styrene monomers. Such processes are accompanied by substantial heat release [20]. In the range 234–238°C, the heat release abruptly weakens, which may be due to prevalent contribution of concomitant endothermic cleavage of ester groups. Finally, the exothermic peaks observed at 240 and 246°C may be due to the major contribution from copolymerization of unsaturated compounds formed by DM cleavage (as shown above) and from polycyclization (formation of anhydride units from MAA units) in the final stage of DM curing (post-curing). The total thermal effect of DM transformations is about 69 kJ mol^{-1}, whereas the heat of polymerization of DV (which contains no cleavable ester groups), determined under the same conditions (kJ mol^{-1}), is considerably higher: 97 [21] or 114 [16]. Thus, the difference in the total heats of curing of DM and DV is mainly due to the fact that curing of DV involves only exothermic reactions of 3D polymerization, whereas curing of DM is accompanied, along with polymerization, by endothermic cleavage of ester groups.

The structural transformations of DM can be generally regarded as high-temperature dehydration, with water removal from the glassy polymeric matrix by molecular diffusion. Presumably, total cleavage of 1 mol of DM or its polymer (polyDM) by the above-given scheme is accompanied by release of 2 mol of MAA (or polyMAA); its transformation into the anhydride, in turn, results in release of 1 mol of H_2O:

$$\underset{\text{PolyDM}}{(C_{24}H_{26}O)_n} \xrightarrow[-H_2O]{160\text{–}230^\circ C} \underset{\text{DV–MA copolymer}}{-(C_{16}H_{14}O)_{n-m}-(C_8H_{10}O_3)_m-},$$

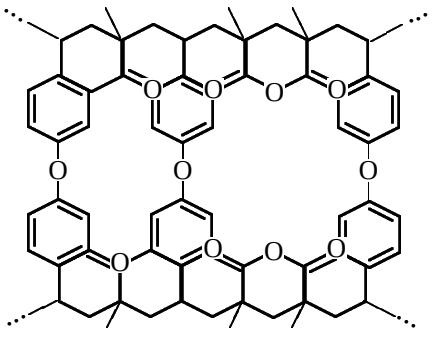
where $n = 1$, $m = 0.5$.

In this case, the molar ratio of DV and MA units in the copolymer will be 1 : 1. Then, if we assume that the high-temperature Friedel–Crafts acylation of diphenyl ether groups with adjacent anhydride groups in polymer chains to give methylenetetralone and MAA units goes to completion, then the composition of the acylated copolymer can be determined from the following scheme:

$$\underset{\text{DV–MA copolymer}}{-(C_{16}H_{14}O)_{0.5}-(C_8H_{10}O_3)_{0.5}-} \xrightarrow[-0.25H_2O]{\text{Acylation with MA}} \underset{\text{Acylated DV–MA copolymer}}{-(C_{20}H_{18}O_2)_{0.5}-(C_8H_{10}O_3)_{0.25}-}$$

Elemental analysis shows that, upon heating of DM samples to 300°C, the carbon content grows from 73.2 to 77.7%. The latter value is intermediate between the values calculated for the copolymer compositions before (76.6% C) and after (78.5% C) acylation. Calculation shows that, in the course of formation of these copolymers, transformation of carboxy groups into anhydride groups (followed in the latter case by acylation) should result in the release of 9.6 and 12.1% H_2O, respectively. However, the total amount of volatiles released in the course of dynamic (1.4 deg h^{-1}) heating of DM from 20 to 300°C does not exceed 7.7%. The fact that the amount of released water is lower than expected may be due to partial degradation (decarboxylation) of MAA and anhydride units upon prolonged heating of the samples (for more than 70 h) in the range 200–300°C. Previous mass-spectrometric studies have shown [12, 18] that, at temperatures exceeding 200°C, thermal degradation (mainyl decarboxylation) of methacrylic acid units makes a small but appreciable contribution.

Based on the above data, the polymeric structure finally formed in the course of DM curing at 250–300°C can be represented as follows:



Fast solid-phase reactions in thickly cross-linked polymeric matrices have been studied previously as applied to curing of Rolivsans [5, 6, 21], model systems [12, 13, 18], and related compounds [15, 21]. As noted above, the fact that the reactions occur in thickly cross-linked polymeric matrices at temperatures much lower than the softening point (~403°C), when the transport of reactants to the reaction zone is usually hindered, is an advantage of such systems. However, in the systems under consideration, the vibrational and rotational motion of adjacent groups is sufficiently free for the reactions to be fast [12].

The above-discussed mechanism of DM curing explains why it is possible to prepare heat-resistant polymers and plastics from this thermally unstable monomer. According to dynamic (4.5 deg min^{-1}) thermogravimetric analysis in air, the temperatures of 5 and 10% weight loss by thermally rearranged polyDM are 340 and 390°C, respectively, and the breaking bending stress of fiber glasses based on polyDM is 330 (20°C), 220 (300°C), and 50 MPa (320°C).

EXPERIMENTAL

DM was prepared according to [12, 13]; a colorless glycerol-like liquid, yield 45–50%, n_D^{20} 1.541. Found, %: C 73.20, H 6.6. Ester number (mg KOH per gram product): found 272.0; calculated 274.8.

Bis(4-vinylphenyl) ether (DV) and 4-vinylphenyl 4-(1-methacryloyloxyethyl)phenyl ether (MV) were prepared as described in [12–14].

The IR spectra were measured on a Specord 75-IR spectrometer in a thin film. Calorimetric measurements were performed with a Perkin–Elmer DSC-1B differential scanning microcalorimeter, as described in [20]. Exclusion liquid chromatography (ELC) was carried out on a GPC-Waters chromatograph at 20°C using columns packed with Ultrastyragel 500 Å and $CHCl_3$ or toluene as eluent. Dynamic thermogravimetric analysis of samples was performed on a Paulik–Paulik–Erdey MOM C derivatograph (Hungary) at a heating rate of 4.5 deg min^{-1}. The softening point was determined with a Vicat device (Institute of Macromolecular Compounds, Russian Academy of Sciences; indenter load 1 kg, indenter cross section 1 mm^2).

Fiber glasses were prepared by hot pressing of prepregs on T-10-80 fiber glass fabric at a pressure of ~1 kg cm^{-2}, with heating from 20 to 300°C at a rate of 1.4 deg min^{-1}.

CONCLUSIONS

(1) Thermal transformations of DM yield heat-resistant thermoreactive polymers; common 3D radical polymerization of DM, giving the initial thermally unstable network polymer, is accompanied by thermally initiated solid-phase consecutive-parallel reactions between adjacent groups in chains of the polymer network.

(2) Thermal transformations of DM involve a set of consecutive-parallel reactions of 3D polymerization, cleavage of ester groups of the monomeric unit in the network polymer, formation of anhydride from adjacent MAA units, acylation of diphenyl ether groups with adjacent anhydride groups, decarboxylation of MAA, and degradation of methacrylic anhydride units.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Potassium Iodide in Coloring of Polyvinyl Alcohol Film in Oxidizing Solution

N. G. Ariko and V. E. Agabekov

Institute of Chemistry of Novel Materials, Belarussian National Academy of Sciences, Minsk, Belarus

Received April 2, 2002

Abstract—Conversion of potassium iodide in polyvinyl alcohol film by its treatment in the $(NH_4)_2S_2O_8$–$CuSO_4$–KI–KCl–H_2SO_4–H_2O oxidizing solution, leading to coloring of the film with molecular iodine, was studied. The conversion mechanism was analyzed as influenced by each component of the oxidizing solution.

Iodine-colored uniaxially oriented polyvinyl alcohol (PVA) films are used in transmission, reflection, and semitransmission polarizers widely employed in production of liquid-crystal displays.

PVA films are most often colored with iodine sorbed from aqueous solution of I_2 and KI [1]. Previously [2], a new procedure has been developed in which a PVA film containing KI is colored using an $(NH_4)_2S_2O_8$–$CuSO_4$–KI–KCl–H_2SO_4–H_2O oxidizing solution. It was found that this solution is most effective if it contains simultaneously $(NH_4)_2S_2O_8$, $CuSO_4$, and KI, whereas in the absence of $CuSO_4$ or KI, the coloring efficiency drastically decreases [3].

In this study, we analyzed the coloring of a KI-containing PVA film in the course of its treatment in the oxidizing solution and the role of the solution components in the oxidation reactions proceeding in the film and solution, because published data on this matter are lacking.

EXPERIMENTAL

The polyvinyl alcohol films were cast on glass supports using a greasing-type draw plate and 11% aqueous solution of V-1N polyvinyl alcohol containing ethanol, glycerol, KI, and boric acid (5, 2.5, 0.04, and 0.1 wt %, respectively) and then dried at 24–26°C to residual moisture content of 6–7%.

To prepare a film polarizer, a dried film fixed in special clamps was placed in an aqueous oxidizing solution heated to 32 ± 2°C and containing (wt %) 0.1 $(NH_4)_2S_2O_8$, 0.1 $CuSO_4$, 0.01 KI, 17–20 KCl, and 0.1 H_2SO_4. The resulting yellow-colored film was washed with a 1% solution of boric acid H_3BO_3 at 24 ± 2°C and treated with a saturated H_3BO_3 solution heated to 42 ± 2°C. As a result, the film became blue owing to the formation of the "blue" dichroic complexes PVA–$(I_2)_n$ [4, 5]. The reaction of boric acid with polyvinyl alcohol yields boric acid esters [6], which link the polymeric chains and fix iodine in the film. Then, the film was placed in an aqueous fixing solution containing KI, CdI_2, H_3BO_3, $ZnCl_2$, and HCl (0.01, 0.1, 0.4, 15, 0.1 wt %, respectively) and washed in distilled water warmed to 24 ± 2°C. Treatment in the fixing solution made the film coloring more uniform.

To obtain an efficiently polarizing PVA film, it should be uniaxially stretched by a factor of at least 3.5–4. The wet film was fixed in a device with a lowering bar, stretched by a factor of 4, and dried in an oven for 1 h at 60 ± 5°C.

All the required solutions were prepared using pure grade reagents, ultrapure 11-5 grade concentrated H_2SO_4, and distilled water; the iodine solution was prepared from a reference formulation.

The absorption spectra of iodine-containing solutions were recorded immediately after their preparation, on a Specord UV-VIS spectrophotometer. To study the reaction kinetics of KI and $(NH_4)_2S_2O_8$, the optical density of the reaction mixture was recorded in the course of the experiment on a KFK-3 photometer. The concentrations of I_3^- and I_2 were calculated from the optical densities at 350 and 460 nm, respectively, using the extinction coefficients for I_3^- (ε_{350} = 26400 and ε_{460} = 975) and I_2 (ε_{350} = 18 and ε_{460} = 746) [7]. The measurements were performed at 20°C.

1070-4272/03/7610-1669 $25.00

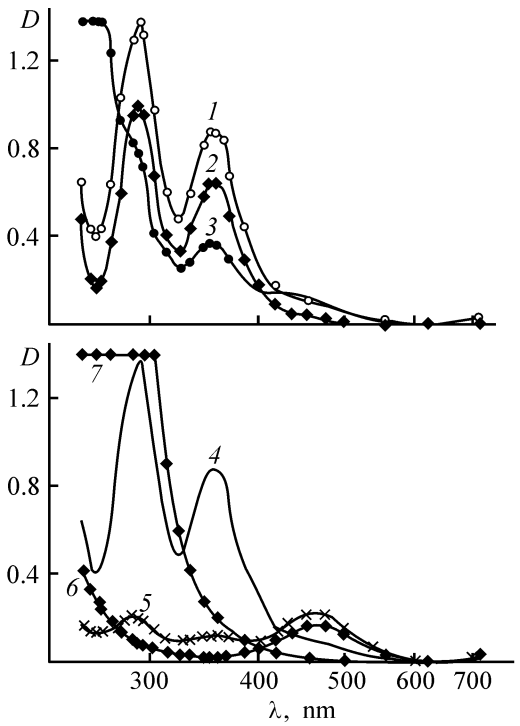

Fig. 1. Absorption spectra of iodine solutions containing (*1*) no additives and those with addition of (*2*) KI, (*3*) KCl, (*4*) $CuSO_4$, (*5*) $(NH_4)_2S_2O_8$, and (*6*) $(NH_4)_2S_2O_8$ + $CuSO_4$, and (*7*) oxidizing solution. (*D*) Optical density and (λ) wavelength. Concentration $c \times 10^4$, M: I_2 (*2*) 1.0, (*1, 3*) 1.5, and (*4–6*) 2.5; KI (*2*) 0.12; KCl (*3*) 0.13; $CuSO_4$ (*4, 6*) 8.0; and $(NH_4)_2S_2O_8$ (*5, 6*) 8.8.

The yellow coloring of the colorless PVA film upon its contact with the oxidizing solution suggests that molecular iodine is formed in its bulk. It was found that the rate and intensity of the film coloring strongly decrease in the absence of $CuSO_4$ and KI in the oxidizing solutions, whereas the greatest effect is observed when $(NH_4)_2S_2O_8$, $CuSO_4$, and KI are present simultaneously [3].

It is known that peroxydisulfate anions oxidize iodide ions by the following overall reaction [8]

$$S_2O_8^{2-} + 2I^- \rightarrow 2SO_4^{2-} + J_2. \quad (1)$$

Since the oxidizing solution contains excess peroxydisulfate anions relative to I^-, I^- must be completely converted into molecular iodine. Actually, in the course of preparation, the solution becomes brown owing to the formation of molecular iodine, but then this color disappears.

The absorption spectra of the oxidizing solution and those of iodine solutions in the absence of additives and in the presence of components of the oxidizing solution are shown in Fig. 1. The spectra of aqueous iodine solutions (Fig. 1, spectra *1–6*) exhibit three bands at 286–287 nm (I), 350–352 nm (II), and 460 nm (III), and no absorption bands are observed in the spectrum of the oxidizing solution at $\lambda > 400$ nm (Fig. 1, spectrum *7*).

According to [4, 7], absorption bands I and II belong to the anion I_3^-, and III, to molecular iodine I_2. The intensity ratio of the absorption bands in spectra 1–4 (Fig. 1) indicates that iodine occurs in these systems predominantly as complex anion I_3^-, which is formed by the reaction between I_2 and I^- present in the reference formulation:

$$I^- + I_2 \rightleftarrows I_3^-. \quad (2)$$

On introducing additional KI (Fig. 1, spectrum *2*), iodine is completely converted into I_3^-, which is confirmed by an increase in the intensity of bands I and II and by disappearance of band III. When KCl is added (Fig. 1, spectrum *3*), the absorption in the short-wavelength range becomes so intense that band I is observed as a shoulder. Copper sulfate (Fig. 1, spectrum *4*) does not affect noticeably the intensity of the absorption bands of I^- and I_3^- as compared with spectrum *1* (Fig. 1). In the presence of $(NH_4)_2S_2O_8$ oxidant (Fig. 1, spectrum *5*), absorption bands I and II gradually decrease in intensity and finally completely disappear in the course of measurements, whereas the intensity of band III increases indicating that I_3^- is converted into molecular iodine I_2. Copper sulfate strongly accelerates this process, and only the band at 460 nm typical of I_2 is observed from the very beginning (Fig. 1, spectrum *6*).

These spectral data confirm that reaction (1) proceeds in the oxidizing solution, but the oxidation of I^- is not terminated at the stage of formation of molecular iodine, because the corresponding band III is absent in the spectrum of this solution (Fig. 1, curve *7*).

To elucidate the pathways of iodine conversion in the oxidizing solution, we studied the kinetics of the reaction between KI and $(NH_4)_2S_2O_8$, catalyzed with $CuSO_4$. The concentrations of the oxidant and catalyst in this set of tests corresponded to their content in the oxidizing solution, and the concentration of potassium iodide was varied within 0.004–0.020 wt % or $(0.5–2.5) \times 10^{-3}$ M.

Immediately after mixing of the solutions [$(NH_4)_2S_2O_8$ was added to a mixture of KI and $CuSO_4$ directly in the cell of a KFK-3 photometer], a strong band at 353 nm and a broad band at 460 nm appeared in the absorption spectra; these bands belong

to complex I_3^- and molecular iodine I_2. As seen from Fig. 2, variations in the optical density D_{350} with time correspond to the changes in the content of I_3^- in solution. The peaks in the curves describing the D_{350}–t kinetic dependences indicate that the complex anion is the reaction intermediate.

The effect of the initial concentration of KI on the concentration of I_3^- formed in the initial stage of the reaction $[I_3^-]_{1\,min}$ is shown in Fig. 3; this value was calculated from D_{353} recorded 1 min after mixing of the solutions. As a matter of fact, $[I_3^-]_{1\,min}$ is the rate of oxidation of the initial iodide ions, because at this instant of time $[I^-] >> [I_3^-]$ and the rate of consumption of the complex anions is insignificant. Since the $[I_3^-]_{1\,min}$–$[KI]_0$ dependence is linear, this is a first-order reaction. The same reaction order is observed for oxidation of iodide ions with peroxydisulfate anions without catalyst [9]. This fact can be accounted for by occurrence of the reaction yielding atomic iodine:

$$\left.\begin{aligned} &I^- + S_2O_8^{2-} \rightarrow [S_2O_8^{3-}] \rightarrow I + S_2O_8^{3-},\\ &S_2O_8^{3-} \rightarrow SO_4^{2-} + SO_4^- \quad \text{or}\\ &I^- + S_2O_8^{3-} \rightarrow 2SO_4^{2-} + I. \end{aligned}\right\} \qquad (3)$$

Apparently, in the presence of a catalyst (copper compounds), the mechanism remains similar. The rate constant of the first-order reaction, $k_1 \sim 0.7 \times 10^{-3}$ s^{-1}, was calculated from the data in Fig. 3.

When the maximal concentration of triiodide anions $[I_3^-]_{max}$ is attained in the course of reaction, the major fraction of the initial iodide ions is already oxidized and, thus, the concentration of I_3^- becomes comparable with the concentration of the remaining I^- anions. The color of the reaction mixture turns from yellow to orange. At this stage, the rates of oxidation of I_3^- and I^- are comparable. The $[I_3^-]_{max}$–$[KI]_0$ dependence (Fig. 3) suggests that formation of I_3^- proceeds with two KI molecules involved [reactions (2) and (3)].

In the final stage of oxidation of potassium iodide [after passing the peak in the kinetic curves (Fig. 2)] at $[I^-] << [I_3^-]$, the formation of the complex triiodide anions stops and only their oxidation proceeds. Since formation of I_3^- does not affect noticeably the oxidation potential of the I_2/I^- couple [10], we suggest that the oxidation of I_3^- proceeds similarly to that of I^-:

$$\left.\begin{aligned} &I_3^- + S_2O_8^{2-} \xrightarrow{k_2} I_2 + I + S_2O_8^{3-},\\ &S_2O_8^{3-} \rightarrow SO_4^{2-} + SO_4^- \quad \text{or}\\ &I_3^- + S_2O_8^{3-} \rightarrow 2SO_4^{2-} + I_2 + I. \end{aligned}\right\} \qquad (4)$$

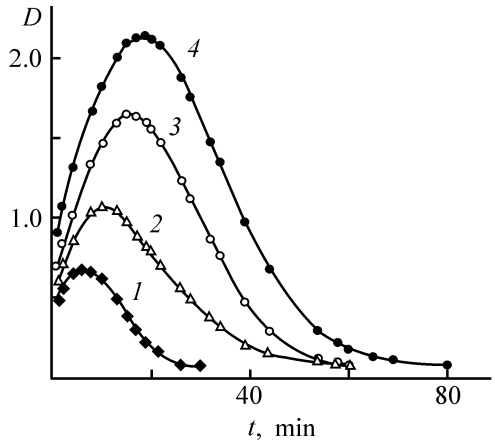

Fig. 2. Optical density D_{350} of the reaction mixture of KI and $(NH_4)_2S_2O_8$ vs. time; concentration of $(NH_4)_2S_2O_8$ 8.8×10^{-3} M. Concentration of KI $c \times 10^3$, M: (*1*) 0.8, (*2*) 1.2, (*3*) 1.4, and (*4*) 1.6.

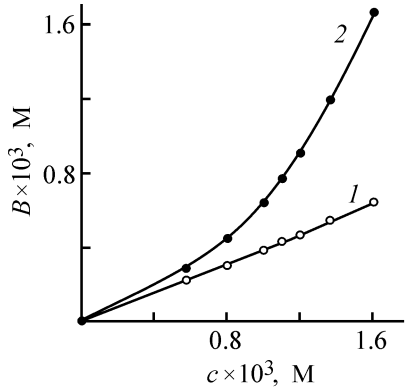

Fig. 3. Concentration of I_3^- B vs. the initial concentration c of KI in the reaction mixture. (*1*) $[I_3^-]_{1min}$ and (*2*) $[I_3^-]_{max}$.

The experimental points of the descending sections of the kinetic curves (Fig. 2) in the $\log[I_3^-]_t$–t coordinates are well fitted with straight lines, which indicates first-order oxidation of I_3^- and is consistent with the mechanism (4). The rate constant of the first-order reaction, $k_2 \approx 1.5 \times 10^{-3}$ s^{-1}, was calculated from the slopes of the $\log[I_3^-]_t$–t dependences. The constant k_1 is two times smaller than k_2, i.e., the complex anion is oxidized more readily than the initial iodide anion. Moreover, k_1 and k_2 are independent of the concentration of ammonium peroxydisulfate; at large oxidant excess, I^- and I_3^- are oxidized in solution in pseudo-first-order reactions.

The total amount of iodine formed by the instant of complete conversion of iodide and triiodide ions corresponds to the stoichiometry of the overall reaction (1) (Fig. 4).

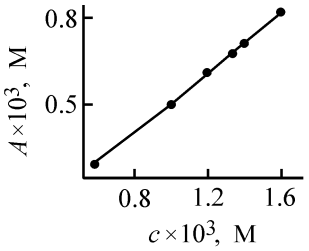

Fig. 4. Content of I_2 A vs. the initial concentration c of KI.

The acceleration effect of copper(II) on the oxidation of iodide ions by peroxydisulfate anions was studied in [10]. It was believed that copper(II) ions catalyze the oxidation, and the linear dependence of the reaction rate on the Cu^{2+} concentration was attributed to formation of the copper(II) iodide complex, which then reacts with peroxydisulfate anions:

$$\left.\begin{aligned} &Cu^{2+} + I^- \rightleftarrows CuI^+, \\ &CuI^+ + S_2O_8^{2-} \rightleftarrows [ICuS_2O_8^-], \\ &ICuS_2O_8^- \rightarrow Cu^{2+} + 2SO_4^{2-} + I^-, \\ &I^+ + I^- \rightarrow I_2. \end{aligned}\right\} \quad (5)$$

However, a study of this reaction in solutions similar to the oxidizing solution [3] showed that $S_2O_8^{2-}$ is a stronger oxidant than copper(II) ions (see table).

With $(NH_4)_2S_2O_8$ and $CuSO_4$ present simultaneously, the reaction was sharply accelerated and completed in 1–2 min. Thus, ammonium peroxydisulfate can be regarded as oxidant, and copper sulfate, as reaction catalyst. However, it was found [3] that for rapid and complete oxidation of iodide ions, Cu^{2+} should be taken not in a catalytic amount but in amount comparable with that of $S_2O_8^{2-}$ (optimal ratio 1 : 1).

It is known that the effect of silver(I), copper(II), and mercury(II) salts in redox processes is often related to counterpolarization of the oxidant molecules through partial formation of undissociated molecules of these strongly polarizing cations or complex ions with these metal cations (as central atoms) [11, 12]. The oxidative power of the undissociated molecules is the greatest. Thus, acceleration of the oxidative conversion of potassium iodide in the coloring solution is probably due to the counterpolarization of peroxydisulfate anions. Reactions (2) in the presence of $CuSO_4$ can be represented as:

$$\left.\begin{aligned} &Cu^{2+} + S_2O_8^{2-} \rightleftarrows CuS_2O_8, \\ &I^- + CuS_2O_8 \rightleftarrows [CuS_2O_8I^-], \\ &CuS_2O_8^- \rightarrow Cu^{2+} + SO_4^{2-} + SO_4^- \text{ or} \\ &CuS_2O_8^- + I^- \rightarrow Cu^{2+} + 2SO_4^{2-} + I. \end{aligned}\right\} \quad (6)$$

It is known that hydrogen ions exhibit no specific catalytic effect in a reaction between peroxydisulfate and iodide ions [8]. Actually, addition of sulfuric acid to a solution containing KI, $(NH_4)_2S_8$, and $CuSO_4$ does not accelerate the oxidation of potassium iodide.

The oxidation of potassium iodide in the presence of $(NH_4)_2S_2O_8$ and $CuSO_4$ does not stop upon formation of molecular iodine. As the reaction is continued, the intensity of the band at 460 nm gradually decreases and the orange color of the solution disappears, to the point of complete decoloration. Thus, the molecular iodine formed is oxidized by excess oxidant to the iodate ions [13]. When a reducing agent (e.g., sodium thiosulfate) is added to the decolorized solution, iodine is recovered by the reaction of IO_3^- with the reducing agent [14]. Oxidation of iodine was also found in studies of I_2 precipitation in the reaction of KI with $(NH_4)_2S_2O_8$ [12].

Thus, the oxidizing solution used for coloring of the PVA films contains, along with peroxydisulfate anions, also iodate ions, which are the products of oxidation of iodide ions. On treatment of a KI-containing PVA film with this solution, IO_3^-, being smaller than $S_2O_8^{2-}$, penetrates into the polymer and oxidizes KI. By controlling the contact time, the reaction can be terminated when the iodide ions required for the film coloring are formed in the largest amounts. The involvement of the iodate ions in the oxidation shows why sulfuric acid should be added to the coloring solution, because IO_3^- ions are more reactive in acidic solutions [8]:

$$IO_3^- + 6H^+ + 5I^- \rightarrow 3I_2 + 3H_2O. \quad (7)$$

The oxidation of potassium iodide in the film by reaction (7) provides accumulation of additional iodine in its bulk [10].

Our experimental data revealed the role of $(NH_4)_2S_2O_8$, $CuSO_4$, KI, and H_2SO_4 in the oxidizing

Oxidation of iodide ions in solution containing KCl and H_2SO_4 (17 and 0.1 wt %, respectively) (reaction time 15 min, 20 ± 0.5°C)

Component	Concentration $c \times 10^3$, M				
$(NH_4)_2S_2O_8$	8.8	8.8	–	–	–
$CuSO_4$	–	–	8.0	8.0	8.0
KI	1.2	3.0	1.2	3.0	6.0
$[I_2]_{exp}$	0.60	1.70	0.10	0.10	0.15
$[I_2]_{cal}$	0.60	1.50	0.30	0.75	1.50

solution used for coloring of PVA films with iodine. Potassium chloride is added to the solution to prevent dissolution of the films being treated and to suppress their decoloration [15]. The concentration ranges of the components in the coloring solution provide optimal accumulation of iodine in the film and, after subsequent treatment in H_3BO_3 solutions and fixing, allow preparation of polarizers with the required transmission in the 400–700 nm range and high polarizing power. At the component concentrations smaller or greater than the optimum, either increased film transmission with decreased polarizing power, or increased polarizing power with decreased transmission are observed [2].

We found that the time t of contact of the PVA film with the oxidizing solution strongly affects its coloring. Upon prolonged contact, the film is partially decolorized, affecting the optical properties of the polarizer. The dependence of the optical density of the polarizer film in the 480–800 nm range, i.e., in the absorption range typical of dichroic complexes PVA–$(I_2)_n$ [16, 17], on the contact time t is shown in Fig. 5. As seen, all the curves pass through a maximum. The decrease in the content of these complexes with time is associated with a decrease in the amount of I_2 in the film bulk due to its oxidative conversion, proceeding predominantly in the surface layer of the film. To remove excess oxidants, the film is treated in a fixing solution containing potassium and cadmium iodides and subsequently washed with distilled water.

The optimal time of treatment of the PVA film containing 0.04 wt % of KI in the oxidizing solution of given composition is 30–60 s.

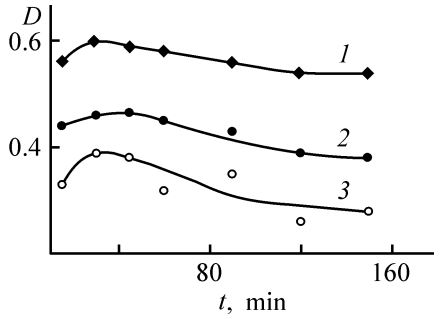

Fig. 5. Optical density D of the polarizer film as influenced by the time t of contact of the film with the oxidizing solution; film thickness 70–75 μm. Wavelength, nm: (*1*) 620, (*2*) 480, and (*3*) 800.

CONCLUSIONS

(1) Iodide ions are oxidized by ammonium peroxydisulfate to iodate ions with intermediate formation of triiodide ions and molecular iodine in the oxidizing solution containing $(NH_4)_2S_2O_8$, $CuSO_4$, KI, KCl, and H_2SO_4.

(2) During oxidative treatment of a polyvinyl alcohol film, potassium iodide occurring in the film bulk is first oxidized by iodate ions diffusing from the solution. As a result, the iodate ions provide accumulation of additional molecular iodine required to form dichroic complexes in the polymer.

(3) The coloration efficiency of the polyvinyl alcohol film is determined by the maximal accumulation of molecular iodine in its bulk and depends on the concentrations of $(NH_4)_2S_2O_8$, $CuSO_4$, and KI in the oxidizing solution and on the time of contact of the film with this solution.

Abstract—Rheological properties of dilute and moderately concentrated aqueous solutions of mixtures of methyl cellulose and hydroxypropyl cellulose and gelation in these solutions were studied. Using the solvent vapor sorption, the compatibility of the polymer pair was examined and the composition range in which the thermodynamic compatibility is realized was determined.

Characteristics of methyl cellulose (MC) solutions and films and fibers manufactured on their basis can be altered by chemical modification of the polymer. Previously it has been demonstrated that introduction of polar (cyanoethyl) and nonpolar (propyl) groups into MC macromolecules modifies the thermodynamic affinity of the polymer for water and the rheological characteristics of solutions of mixed cellulose ethers [gelation point (T_g) and cloud point (T_c) decrease] [1, 2]. Introduction of substituents containing hydroxy groups (e.g. hydroxypropyl) enhances the emulsifying capacity of the solutions and their resistance to salts and also raises the gelation point [3]. It is of scientific and practical interest to modify MC through combination with another cellulose ether, hydroxypropyl cellulose (HPC), in a common solvent, water.

Therefore, we analyzed in this study the viscous characteristics of aqueous solutions of MC–HPC mixtures, as influenced by the mixture composition and temperature, and also the gelation conditions and thermodynamic compatibility of these two polymers.

EXPERIMENTAL

In experiments, we used MC with a degree of substitution (DS) of 1.7 and degree of polymerization (DP) of 900 and HPC with molar substitution (MS) of 3 and DP 800. Mixed solutions of MC and HPC were prepared from equally concentrated stock solutions taken in various mass proportions. Distilled water was used as a solvent. The viscous characteristics of dilute solutions were measured at 20°C with an Ubbelohde viscometer. Rheological properties of concentrated solutions were studied with a Rheotest-2.1 rotation viscometer under shear stress of 3–600 Pa. The gelation point T_g was determined with a Hoeppler viscometer. The compatibility of MC and HPC was determined by the method of solvent vapor sorption on films of various compositions, formed from 2% aqueous solutions.

Viscometry is often used to characterize the interaction between two different polymers in a common solvent [4–6]. This method records the deviation of the viscosity of dilute polymer solutions from the theoretical values estimated from the weight-average viscosities of two individual polymers. The deviation can be regarded as a measure of intermolecular interactions between different polymers. In this study, to characterize intermolecular interactions between MC and HPC in aqueous solutions, we determined the intrinsic viscosity $[\eta]$ of the initial components and their mixtures. The theoretical intrinsic viscosity $[\eta]_{th}$ was estimated as

$$[\eta]_{th} = [\eta]_1 c_1/c + [\eta]_2 c_2/c, \quad (1)$$

where c is the total polymer concentration ($c = c_1 + c_2$), and c_1 and c_2, the concentrations of the first and second components.

The experimental and theoretical composition dependences of $[\eta]$ are shown in Fig. 1. The experimental curve *1* demonstrates positive deviations from ideality over the entire composition range, which is an indication of intermolecular interactions between the polymers in solutions. This can be attributed to the formation of some structures whose hydrodynamic volume is higher than the weight-average hydrodynamic volume of two individual components. The maximum deviation of $[\eta]_{exp}$ from the theoretical value is observed for the mixture with 50% HPC.

It is known that the behavior of polymer mixtures is governed by the degree of compatibility of the components. For a series of synthetic nonionic polymers, we evaluated the thermodynamic compatibility of the components in solutions on the basis of intrinsic viscosity measurements. According to the criterion suggested in [7], we used as the measure of compatibility $\Delta i/\Delta\eta_i$.

$$\Delta i/\Delta\eta_i = ([\eta]_{exp} - [\eta]_{th})/([\eta]_2 - [\eta]_1), \qquad (2)$$

where Δi is the difference between the experimental and theoretical [η] of the mixture, and $\Delta\eta_i$, the difference between [η] of the first and second components of the mixture.

For compatible polymers, this parameter is 0.1 or close to this value irrespective of the sign. Figure 1 (curve *3*) shows the dependence of $\Delta i/\Delta\eta_i$ on the composition of the MC–HPC mixture. As seen, the maximum $\Delta i/\Delta\eta_i$ is observed in a mixture containing 50% HPC, i.e., the system is incompatible in this composition range. For other compositions, the parameter $\Delta i/\Delta\eta_i$ is close to 0.1, suggesting that MC and HPC are compatible.

To examine the compatibility of MC and HPC and characterize the polymer–polymer and polymer–water interactions, we also used the solvent vapor sorption method [8]. Films prepared from the individual polymers and their mixtures were dried in a vacuum, placed in closed vessels with water, and allowed to stand under a saturated water vapor at 20°C until equilibration. Then the films were weighed, and the degree of swelling was estimated as

$$Q = (P_{swell} - P_{dry})/P_{dry}, \qquad (3)$$

where P_{dry} and P_{swell} are the weights of the dry and swollen film, respectively.

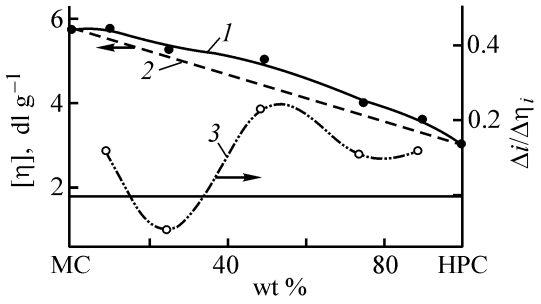

Fig. 1. (*1*) Experimental $[\eta]_{exp}$ and (*2*) theoretical $[\eta]_{th}$ intrinsic viscosities, and (*3*) $\Delta i/\Delta\eta_i$ vs. the solution composition.

Data on the sorption of water vapor on MC, HPC, and their mixtures are summarized in the table below. From the degree of swelling of the films, we estimated parameters of the polymer–solvent interaction χ_1 for MC, HPC, and their mixtures, using the Flory–Huggins equation [9].

$$\ln a_1 = \ln(p_1/p_1^0) = \ln(1 - \varphi_2) + \varphi_2 + \chi_1\varphi_2^2, \qquad (4)$$

where a_1 is the solvent activity, and p_1/p_1^0, the relative pressure of the solvent vapor.

The experiments were carried out at the saturated pressure of the solvent vapor, i.e., $a_1 = p_1/p_1^0 = 1$ and $\ln a_1 = 0$. The volume fraction of the polymer was calculated by

$$\varphi_2 = 1/[1 + (d_2/d_1)Q], \qquad (5)$$

where d_1 and d_2 are the solvent and polymer densities, respectively, and Q, the amount of the adsorbed solvent (g g^{-1}).

The sample density was determined by hydrostatic weighing in heptane. The polymer–polymer interac-

Amount of adsorbed water Q, volume fractions of the solvent φ_1 and polymer φ_2, parameters of the interactions polymer–solvent χ_1 and polymer–polymer χ_{23}, and size of the solvent associates $c_1g_1 + 1$ and their amount N_c

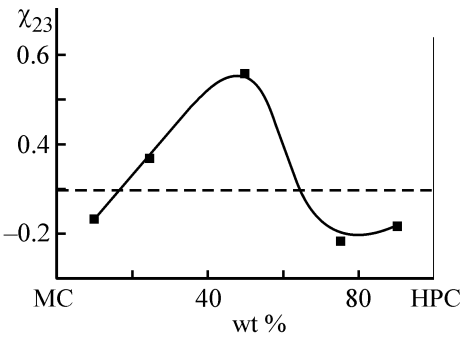

Fig. 2. Polymer–polymer interaction parameter χ_{23} vs. the solution composition.

tion parameter was estimated from the sorption data by the Patterson equation (6) [10].

$$\chi_{23} = (\chi_{12}\varphi_a + \chi_{13}\varphi_b - \chi_{1(23)})/\varphi_a\varphi_b, \quad (6)$$

where χ_{12}, χ_{13}, and $\chi_{1(23)}$ are the Flory–Huggins interaction parameters of, respectively, the individual MC and HPC and their mixtures with water; φ_a and φ_b are the volume fractions of the polymers in a mixture.

Scott has demonstrated [11] that $\chi_{23} < 0$ for compatible polymer mixtures. Therefore, any positive value of χ_{23} suggests that the polymers are incompatible. The table shows that the mixtures containing 25–50% HPC are incompatible ($\chi_{23} > 0$). For the mixtures with 10 and >75% HPC, $\chi_{23} < 0$, i.e., the systems are compatible.

It should be pointed out that data on the compatibility of NC and HPC, obtained in the solvent vapor sorption experiments, are consistent with the viscometric data obtained for dilute solutions and also with the theoretical results yielded by Eq. (2) (Fig. 1, curve *3*). As a graphic demonstration, Figure 2 shows the composition dependence of χ_{23}. As seen, both methods give nearly coincident composition ranges in which MC and HPC are compatible. Here, one should keep in mind that data on compatibility of polymers, obtained in studying properties of dilute solutions of polymer mixtures, are not always confirmed by the solvent vapor sorption method.

In the bulk of a polymer, adsorbed solvent molecules can form associates if the cohesion forces between the sorbate molecules are stronger than those between the sorbate and the polymer [12]. The average size of the associates, i.e., the number of molecules in the associate can be estimated by the Zimm–Lundberg equation (7) [12].

$$c_1 g_{11} + 1 = (1 - \varphi_1)(\partial \ln \varphi_1 / \partial \ln a_1)_{p,T}, \quad (7)$$

where g_{11} is the cluster formation integral; and c_1, φ_1, and a_1, the molar concentration, volume fraction, and activity of the solvent, respectively.

Combining the Flory–Huggins and Zimm–Lundberg equations, Starkweather has derived the following relationship for the size of associates [13]:

$$c_1 g_{11} + 1 = 1/(1 - 2\chi_1\varphi_1), \quad (8)$$

where χ_1 is the polymer–solvent interaction parameter in the Flory–Huggins equation.

The number of associates in the polymer matrix was calculated by

$$N_c = W/(c_1 g_{11} + 1), \quad (9)$$

where W is the amount of adsorbed solvent (g per 100 g dry polymer).

As seen from the table, the amount of associates and their size are larger in a mixture containing 50% HPC.

It may be suggested that the size of solvent associates and their amount are influenced by the properties and thermodynamic compatibility of macromolecules of the polymeric components constituting the mixture, as well as the morphology of the films formed. Like cellulose itself, MC and HPC are partially crystallizable polymers. With increasing fraction of amorphous zones in the polymers and their mixtures, i.e., with decreasing degree of ordering, the volume of the polymer matrix in which associates can be formed will increase. With incompatible polymers, a porous matrix appcars in film formation. This matrix has larger specific surface area and higher porosity as compared with the films prepared from the individual polymers. As the specific surface area and porosity of the films increase, the volume in which solvent associates can be formed increases too, which is supported by experimental data. Thus, the films containing 50% HPC are cloudy in their outward appearance, unlike the films of other compositions.

To gain better insight into the intermolecular interactions between macromolecules of different kinds in moderately dilute solutions, we studied the rheological characteristics of 2% MC–HPC mixtures at various temperatures.

Figure 3 shows the flow curves of the solutions studied. As seen, these solutions demonstrate an incompletely Newtonian flow behavior. At shear stresses of up to log $\tau \sim 1.8$–2.0 (τ, 10^{-1} Pa), nearly New-

tonian flow is observed, and at higher shear streses, a structural viscosity branch. With increasing HPC fraction, the viscosity of mixed solutions decreases. With the solutions heated to 50°C, the shape of the log η–*T* curves changes (Fig. 4). Above 40°C, a physical thermally reversible gel is formed, which, in turn, leads to an increase in viscosity. In a solution containing 25% HPC, we also observed gel formation accompanied by increasing viscosity. In the HPC solution (Fig. 4, curve *5*), gel formation does not occur with increasing temperature, but the solution gets turbid, suggesting phase separation (precipitation of HPC from the solution). This makes lower the polymer concentration in solution, which results in a sharper decrease in the viscosity above 40°C.

From the temperature dependences of the viscosity, we estimated the enthalpy of activation of viscous flow of the solutions E_a (at temperatures at which no gel formation is observed, i.e., at 20–40°C). From the flow curves we estimated the degree of structurization in the solutions, defined as the ratio $[(\eta_0 - \eta_1/\eta_0] \times 100$ (%), where η_0 and η_1 are the solution viscosities at $\log \tau = 1.7$ and 3.0, respectively.

Figure 5 shows the composition dependences of the viscosity, activation enthalpy of viscous flow, and degree of structurization in MC–HPC mixtures. The viscosity of the mixed solutions and degree of their structurization (curves *1* and *3*) are higher than the additive values, which can be attributed to the formation of new mixed structural elements in solutions by virtue of intermolecular interaction between like and unlike macromolecules and also to the formation of a new 3*D* system of hydrogen bonds in the solutions. The composition dependence of E_a is more complex (Fig. 5, curve *2*). Positive deviations of E_a are observed at an HPC content below 50%, and negative deviations, above 50%. The positive and negative deviations of E_a suggest the formation of different associates, depending on the nature and concentration of a predominant polymer. The evolution of the viscosity, solutions structurization, and E_a can be attributed to changes in the thermodynamic affinity of a polymer for a solvent after addition of another polymer, and also to interaction between unlike macromolecules and phase separation in the solutions, caused by the incompatibility of the polymer pair [9].

Sarkar has demonstrated [3] that introduction of hydroxypropyl groups into glucoside units of MC raises the gelation point in aqueous solutions of the mixed ether, methyl hydroxypropyl cellulose, as compared with straight MC. It may be suggested that

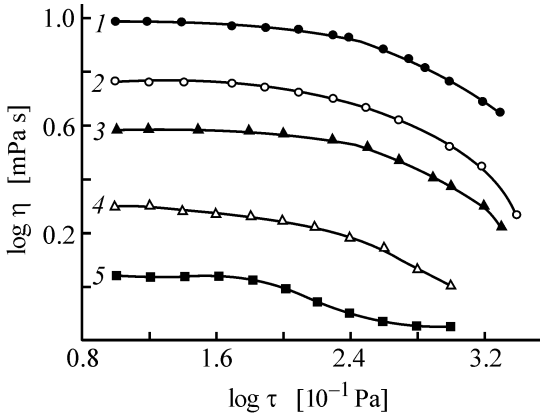

Fig. 3. Flow curves of 2% solutions at 20°C: (*1*) MC, (*2*–*4*) MC–HPC, and (*5*) HPC. (η) Viscosity and (τ) shear stress. HPC content (wt %): (*2*) 25, (*3*) 50, and (*4*) 75; the same for Fig. 4.

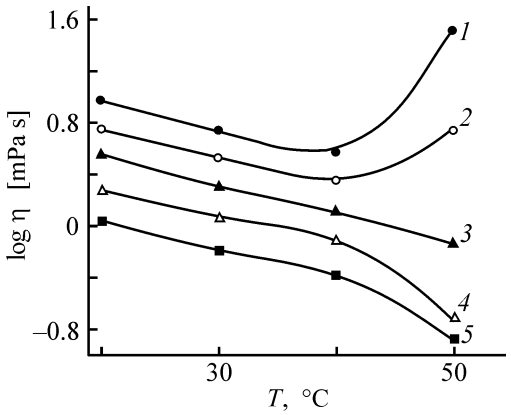

Fig. 4. Viscosity η vs. temperature *T* in solutions of (*1*) MC, (*2*–*4*) MC–HPC, and (*5*) HPC.

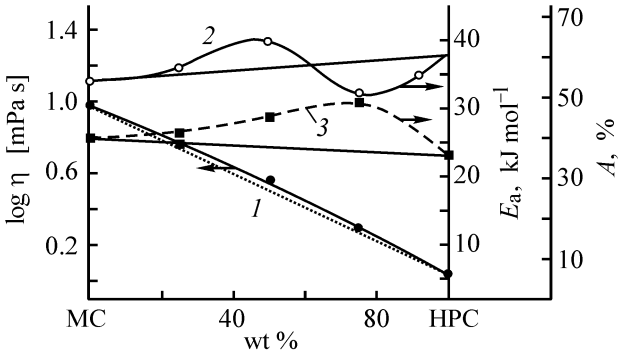

Fig. 5. (*1*) Viscosity η, (*2*) E_a, and (*3*) degree of structurization, *A*, vs. the solution composition.

the gelation point in mixed MC–HPC solutions differs from that in MC solutions, too.

The gelation (T_g) and cloud (T_{cl}) points were determined from changes in the viscosity with a Hoeppler viscometer and also photocolorimetrically with

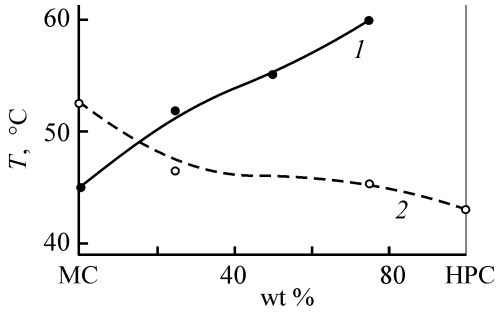

Fig. 6. (*1*) Gelation and (*2*) cloud points vs. the solution composition.

a KFK-2 laboratory concentration photocolorimeter in a temperature-controlled cell at a wavelength of 670 nm [1, 2]. The results obtained are shown in Fig. 6.

With growing HPC fraction, T_g increases and T_{cl} decreases. When heated, HPC does not form a gel [14]. Therefore, the increase in T_g is probably due to the interaction between unlike polymers in a common solvent through hydrogen bonding. As a result, the hydrophobic interaction between the trisubstituted MC units weakens, and the thermal resistance of the MC macromolecules increases. The decrease in T_{cl} is associated with increasing weight fraction of HPC which is separated from the solution on heating [14], thus increasing the solution turbidity.

CONCLUSIONS

(1) Rheological properties of dilute and moderately concentrated aqueous solutions of methyl cellulose, hydroxypropyl cellulose, and their mixtures were studied.

(2) In mixed polymer solutions, positive deviations of the solution viscosity from the theoretical values were observed, suggesting the formation of new mixed structural elements in solutions as a result of intermolecular interactions between like and unlike macromolecules and also the formation of a new 3*D* system of hydrogen bonds.

(3) The solubility of methyl cellulose and hydroxypropyl cellulose was studied by the solvent vapor sorption method at various compositions. It was found that The polymers are thermodynamically compatible in mixtures containing 10 and >75 wt % hydroxypropyl cellulose. In mixtures containing 25 to 75 wt % hydroxypropyl cellulose, the polymers are incompatible. In the polymer mixtures, adsorbed molecules of the solvent form associates, whose amount and size are the largest in an incompatible mixture containing 50% hydroxypropyl cellulose.

(4) With increasing fraction of hydroxypropyl cellulose, the gelation point increases and the cloud point decreases.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Fabrication of Microcrystalline and Powdered Cellulose from Short Flax Fiber and Flax Straw

A. M. Bochek, I. L. Shevchuk, and V. N. Lavrent'ev

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received June 24, 2003

Abstract—Conditions of manufacture of microcrystalline cellulose from variously treated short flax fibers and of powdered cellulose from flax straw were examined. The effect of fats, waxes, and pectins contained in the fibers on the kinetics of hydrolysis of the polysaccharide was studied.

Production of flax-fiber-based textile materials grows steadily. Among the problems arising in flax fiber processing in textile industry is utilization of wastes [flax stalks (boon) and short fibers] after separation of long fibers for manufacture of yarn.

Food, cosmetic, and fragrance industries widely use microcrystalline cellulose (MCC) manufactured from cotton linter or treated wood cellulose [1–3]. It is of scientific and practical interest to use short flax fibers and stalks for manufacture of microcrystalline and powdered cellulose, and also as a raw material instead of cotton linter in production of cellulose ethers and esters.

Therefore, we analyzed in this study conditions of manufacture of powdered and microcrystalline cellulose from variously treated short flax fiber and also from flax stalks. For comparison, the kinetics of hydrolysis of cotton linter was also studied.

EXPERIMENTAL

As starting materials we used short flax fiber and flax straw (from the Nevel Plant), and also cotton linter. The degree of polymerization (DP) of cellulose in the initial flax and cotton fibers was 2850 and 1600, respectively. The DP was determined viscometrically in cellulose solutions in Cadoxene.

The samples of flax fiber and straw were characterized by their chemical composition (see table). The cellulose content was determined by the Kurschner–Hoffner method [4]; lignin, by Komarov's method [4]; fats and moisture and ash contents, according to the procedures described in [4, 5]; pectins, by the calcium pectate method [5]; and nitrogen, by the Kjeldahl method, using the procedure described in [5].

Flax and cotton fibers were hydrolyzed under similar conditions. To optimize the process, flax straw was preliminarily chopped in an MN-250 knife mill and graded with a metallic sieving stack. For hydrolysis, we used the 0.1–1.0 mm fraction.

For manufacture of MCC, mineral acids (HCl, H_2SO_4, and HNO_3) are commonly used [2, 3]. In this study, the fibers were hydrolyzed in 2.5 M HCl at 105°C with mechanical stirring. In the course of hydrolysis, samples of the hydrolyzate were taken, washed with distilled water to pH 7.0, wetted with ethanol, and dried at 105°C to constant weight. The thus prepared samples were then ball-milled for 0.5 h and graded with a sieving stack. The DP was determined from the viscosity of solutions in Cadoxene. Treat-

Chemical composition of flax fibers and stalks

Component	Content, wt %	
	flax straw (flax stalks)	short fibers
Ash	2.1	1.3
Fats and waxes	2.0	1.2
Lignin	31.6	4.8
Nitrogen	Not determined	0.3
Cellulose	47.2	72.1
Pectins	2.5	1.2
Other hemicelluloses	7.8	13.9
Moisture content	6.4	5.2

ment of flax fiber to remove fats, waxes, and pectins was carried out using the procedure described in [5]. Fats and waxes were removed by treatment with an alcohol–benzene mixture in a Soxhlet apparatus. Pectins were removed by treating the defatted fibers with aqueous solutions of HCl and ammonium citrate [6].

A part of the initial flax fiber and stalks was bleached. Samples (9–10 g) were placed in a bleach liquor (500 ml) and heated at 100°C for 3 h (nitrogen bubbling) with mechanical stirring. The composition of the bleach liquor was as follows: 10 g of NaOH and 6.5 g of $Na_2S_2O_3$ in 500 ml of distilled water. The samples after bleaching were washed with distilled water to pH 7.0.

The crystallinity index was determined in pelletized samples by X-ray diffraction analysis [7] on a DRON-2 diffractometer (Cu_{K_α} radiation, Ni filter).

Figure 1 shows the kinetics of hydrolysis of the samples. In the initial samples, the DP in flax cellulose is higher than that in cotton cellulose, which is consistent with published data [5, 8]. In cotton linter, the "limiting" DP of cellulose after hydrolysis was 180, while the DP of cellulose in flax fiber decreased to 230–240. The differences in DP of cellulose in hydrolyzed samples can be attributed to spesific features of the fine structure of flax and cotton fibers and also to different sizes of crystallites of the natural polymer in the fibers.

In contrast to cotton, flax fibers contain more fats, waxes, pectins, and hemicelluloses [5, 8], which affects the hydrolysis rate. Fats and waxes prevent wetting of the fibers with aqueous HCl and also its diffusion into the fibers, affecting the time in which the limiting DP is reached. Removal of fats, waxes, and pectins increases the rate of hydrolysis of flax cellulose. As seen, treatment of flax fiber to remove the indicated components results in that the time of establishment of the limiting DP approaches that typical of cotton cellulose. It should be pointed out that any treatment of flax fiber to remove fats, pectins, and other associated compounds decreases the molecular weight of cellulose. Figure 1 shows that, in untreated fibers, the DP of cellulose is 2850. As fats and pectins were removed, the DP decreased to 2550 (curves *4–6*). After bleaching, the DP of cellulose decreased to 2650.

Figure 2 demonstrates X-ray diffraction patterns of MCC samples obtained from variously treated fibers. The crystallinity index of cotton MCC was determined to be 0.67. In MCC samples prepared from flax fiber, the crystallinity index increased as the accompanying comitant compounds were removed (from 0.64 for untreated fiber to 0.67 for bleached fiber).

The cross-sectional size L_{eff} of cellulose crystallites in flax and cotton fibers was estimated by the Debye–Scherrer method.

$$L_{\text{eff}} = 0.9\lambda/\beta\cos\theta, \quad (1)$$

where $\beta = \sqrt{\beta_o^2 - \beta_i^2}$; λ is the wavelength of Cu_{K_α} radiation (0.154 nm); θ, the diffraction angle from the 002 plane (11.25°); β, the corrected halfwidth of the reflections (002); and β_o and β_i, the observable halfwidth and instrumental broadening of the line, respectively.

In cotton MCC, L_{eff} was estimated to be 3.8 nm, which is well consistent with published data [3, 7]. In flax MCC, L_{eff} appeared to be higher (4.5–5.2 nm). These values well correlate with the above-mentioned higher DP of flax cellulose. The differences in hydrolysis kinetics between flax and cotton celluloses, and also the observed higher limiting DP of flax cellulose are caused both by the presence of accompanying compounds in flax fibers and by larger cross-sectional size of cellulose crystallites.

The crystallite size distribution in the MCC samples is shown in Fig. 3. MCC prepared from cotton linter contains no particles larger than 500 μm. In all the MCC samples, the major fraction of particles has the size ranging from 100 to 200 μm. In MCC obtained from flax fiber, we also found particles of 500 μm and more in size, which can be attributed to the presence of residues of stalks (boon) in short flax fibers. These residues have a different chemical composition and a higher resistance to hydrolysis. Furthermore, the presence of waxes and pectins in the samples has a negative effect on the disintegration rate of the dried material in the course of ball-milling before fractionation.

Conversion of the flax stalks fraction into the powdered form in treatment with HCl takes a longer time (>10 h) as compared with hydrolysis of flax fiber under the same conditions. The hydrolysis of flax stalks is decelerated at high content of lignin (see table). Therefore, we did not study the kinetics of hydrolysis of flax stalks. Based on data presented in Fig. 1, the initial flax straw fiber was treated with 2.5 M HCl for 6 h (time of establishment of the limiting DP for untreated flax fiber), and flax straw fiber after bleaching, for 2 h. Figure 4 shows the particle size distribution in the initial flax straw fiber and in that after hydrolysis. As seen, the curves differ only slightly from each other. The only observed trend is a decrease in the fraction smaller than 700 μm in size. However, the fraction >200 μm did not increase, i.e., powdered cellulose can be obtained under the experimental conditions of hydrolysis of flax straw fibers.

To conclude, MCC can be manufactured from short flax fiber, and powdered cellulose, from chopped flax straw. The cellulose samples thus obtained find use in various areas instead of MCC from cotton and wood cellulose.

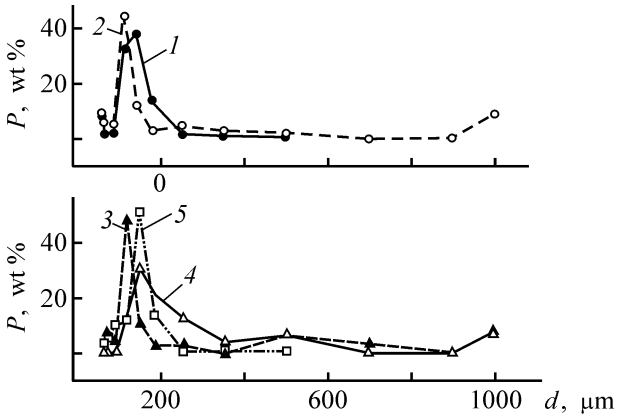

Fig. 3. Crystallite size distribution in MCC. (*P*) Fraction and (*d*) effective size; the same for Fig. 4. (*1*) Cotton fibers and (*2–5*) flax fiber: (*2*) untreated, (*3*) that after removal of fats and treatment with hot water, (*4*) after removal of fats and pectins, and (*5*) after bleaching.

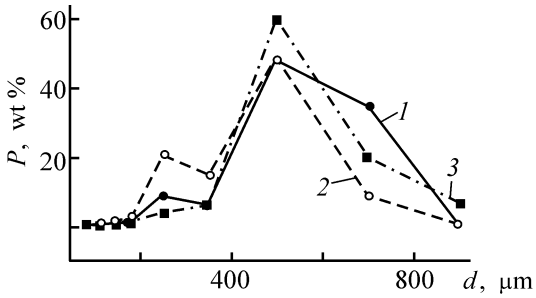

Fig. 4. Particle size distribution in flax straw fiber: (*1*) beaten initial fiber, (*2*) after hydrolysis (untreated), and (*3*) after hydrolysis (bleached).

CONCLUSIONS

(1) Conditions of manufacture of microcrystalline cellulose from short flax fiber of various cleaning grades and of powdered cellulose from flax straw are studied.

(2) The kinetics of flax cellulose hydrolysis is influenced by fats, pectins, and lignins contained in the fibers. Removal of fats, waxes, and pectins increases the hydrolysis rate.

(3) The effective cross size of the crystallites in flax fiber is larger than that in cotton fiber.

Received April 10, 2003

Abstract—The molecular composition of sulfur-containing waste from desulfurization of Tengiz (Kazakhstan) crude oil was studied by gas chromatography–mass spectrometry.

The presence of mercaptants and other aggressive sulfur-containing compounds in most of hydrocarbon raw materials from West Kazakhstan deposits gives rise to specific problems in extraction, transportation, storage, and processing, making urgent desulfurization of oils and petroleum products.

The Tengiz deposit is one of the largest oil and gas deposits in Kazakhstan. Tengiz crude oil is a high-quality light product; it, however, contains much sulfur compounds: 20–30 vol % H_2S, 0.45–1.15 wt % total sulfur, 0.001–0.009 wt % mercaptans, and 0.001–0.2 wt % sulfides and disulfides [1].

Among the existing methods for oil desulfurization, hydrorefining is the most widely used in industry. The process involves cleavage of organosulfur compounds in a medium of a hydrogen-containing gas in the presnece of catalysts, to obtain H_2S and H_2O. The major fraction of H_2S is then trapped and converted into elemental sulfur by the Claus process (oxidation on titanium oxide catalysts) or removed by base treatment.

Treatment of oil and gas to remove sulfur compounds results in formation of large amounts of a sulfur-containing waste, which inevitably leads to an environmental impact. Therefore, a study the molecular composition of the organic component of this waste is topical. Such data are also necessary for efficient utilization of processing products of high-sulfur oils.

EXPERIMENTAL

To determne the molecular composition of the organic component of the sulfur-containing waste from oil desulfurization, a 50-g sample was extracted 10 times with 800 ml of distilled water in a Soxhlet apparatus. The resulting solution (500 ml) was extracted in a separatory funnel with three 20-ml portions of ultrapure grade methylene chloride. The extract was concentrated and analyzed on a Hewlett–Packard 5890/5972 gas chromatograph–mass spectrometer. An SPB-5 (Supelco) capillary column (30 m × 0.25 mm i.d., coating thickness 0.25 μm) was used. The carrier gas was helium (linear velocity 43 cm s^{-1}). The injector and interface temperatures were 280°C. The temperature schedule of the column was as follows: 30°C, 4 min; heating to 180°C at a rate of 10 deg min^{-1}; heating to 280°C at a rate of 15 deg min^{-1}; 280°C, 5 min. The mass-spectrometric detector was used in the scan mode.

The total content of hydrocarbons in the sulfur sample was determined by extraction with carbon tetrachloride, followed by measurement of the absorption at 2940 cm^{-1} (Specord M-80 IR spectrometer, Carl Zeiss, Jena).

According to the chemical classification [2], Tengiz crude oil belongs to the mercaptan type and contains relatively low-boiling and reactive sulfur compounds (H_2S, mercaptans, disulfides). It also contains [1] derivatives of oxidized sulfur (sulfoxides, sulfones); their total content is 13.3 wt % relative to total sulfur.

In this study, we identified by gas chromatography–mass spectrometry the major components and organic impurities of the sulfur-containing waste from oil desulfurization. The chromatogram of the hexane ex-

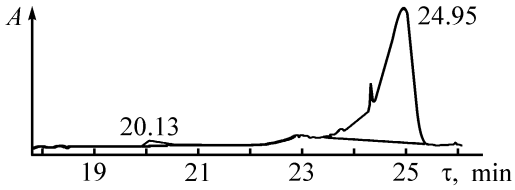

Fig. 1. Chromatogram of a hexane extract from the sulfur-containing waste from oil desulfurization. (τ) Retention time; the same for Fig. 3.

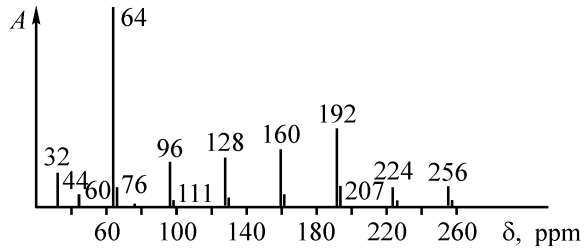

Fig. 2. Mass spectrum corresponding to the S_8 peak in the chromatogram.

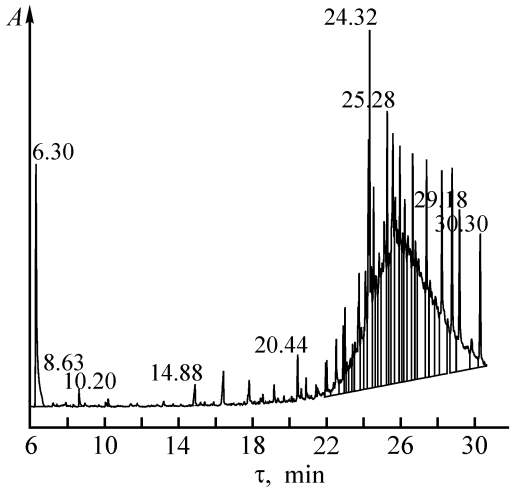

Fig. 3. Chromatogram of the organic fraction of the extract from the sulfur-containing waste.

tract of this product in hexane (Fig. 1) corresponded to the chromatogram of elemental sulfur. A relatively weak peak at τ = 20.13 min was assigned to S_6, and a strong peak at 25.95 min, to S_8. The shape of the latter peak, with broadened wing on the side of short retention times, may be due to partial transformation of this sulfur modification to a lower-molecular-weight form under the conditions of gas-chromatographic analysis. The mass spectrum (Fig. 2) is typical of sulfur; the difference between the main peaks is 32 amu, which corresponds to the atomic weight of S.

The total content of petroleum hydrocarbons in the final sulfur-containing waste was estimated by IR spectroscopy to be 23 mg kg^{-1}. In this study, we analyzed the molecular composition of hydrocarbons present in the sulfur-containing waste. We assumed that the major components of the hydrocarbon fraction must be crude oil components that remained unchanged upon desulfurization: paraffins, cycloparaffins, etc. Also of considerable interest were organic products that could be formed under the processing conditions by oxidation, dehydration, etc. Such or-

ganic compounds may be water-soluble (so-called translocation forms of hydrocarbons) and, therefore, environmentally hazardous [3].

To determine the molecular composition of oxidized (hydrophilic) petroleum products, we used in this study a special extraction procedure. The sulfur-containing waste was repeatedly extracted in a Soxhlet apparatus with water, and the resulting aqueous phase was extracted with methylene chloride. The results of chromatographic analysis of the extract thus obtained are given in the table and in Fig. 3.

As seen from the table, we identified in the sulfur-containing waste from desulfurization of high-sulfur crude oil more than 30 organic compounds, among which the major components were paraffins, saturated and unsaturated C_8–C_{19} carboxylic acids, and alicyclic compounds containing linear alkyl substituents.

A significant fraction of the organic compounds detected in the sulfur-containing waste are the initial oil components adsorbed in unchanged form on the product surface in the course of crude oil desulfurization.

At the same time, aliphatic carboxylic acids present in the sulfur-containing waste (see table) may originate from oxidation of crude oil hydrocarbons in the Claus process in the stage of H_2S oxidation, and also from transformations of the product in the course of irs prolonged storage in air under the action of atmospheric oxygen and moisture.

CONCLUSIONS

(1) The final sulfur-containing waste from desulfurization of Tengiz high-sulfur crude oil and gas contains impurities of aliphatic and cyclic organic compounds.

(2) A study by gas chromatography–mass spectrometry revealed that the hydrocarbon fraction of the product contains aliphatic carboxylic acids.

Received January 18, 2003; in final form, August 2003

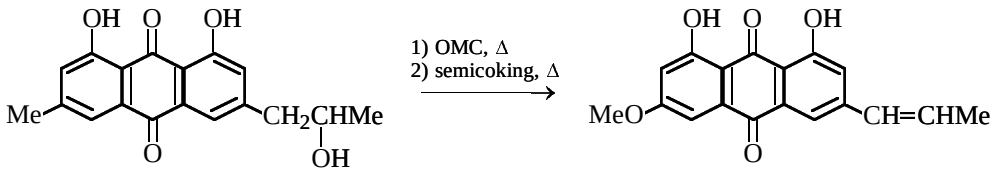
Abstract—The possible genetic relationship of anthraquinone and allied derivatives from brown coal organic matter with the starting biological material was studied.

Substituted anthaquinones, their derivatives, compounds of the anthrone and anthracene series, and also benzo- and naphthoquinones were identified by a set of physicochemical methods in extracts and semicoking tars of brown coals, with coals from the Berezovo deposit of the Kansk–Achinsk fields as example [1–10].

It is known that anthraquinone derivatives constitute the most abundant group of natural quinones, and, by now, hundreds of such compounds have been isolated, mainly from monocotyledonous and dicotyledonous flowering plants, lower fungi, and some lichens; these compounds have also been found in some insects and marine invertebrates of the Echinodermata class (sea lilies, Crinoidea) [11–20].

Virtually all natural anthraquinones contain hydroxy and methoxy groups in various positions and, frequently, methyl, propyl, isoprenyl, hydroxymethyl, aldehyde, and carboxy groups in the β-position. In plants, anthraquinones are often bound to sugars, as O- and C-glycosides [10, 11].

Comparison of the anthraquinones and related compounds that have been identified in the examined coal products with native anthraquinones shows that none of the structures identified in coals directly corresponds to native structures. Only one coal compound, dihydroxymethoxypropenylanthraquinone, can be related to nalgiovensin **I** [10, 11, 19] as dehydration product; dehydration could have occured in the course of coal formation or thermochemical transformations of the organic matter of coal (OMC) during semicoking:



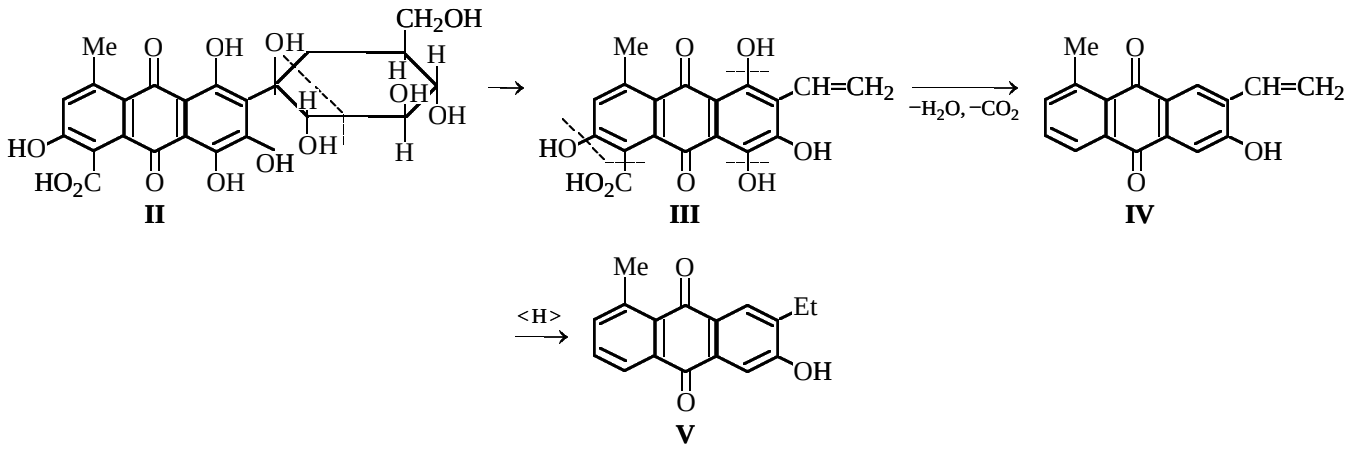
I

The other anthraquinones and related compounds contain substituents that are, as a rule, untypical of natural anthraquinones. Therefore, several possible pathways of biogeo- and thermochemical transformations of natural anthraquinone structures and several possible routes of formation of anthraquinone fragments in OMC from other native precursors in the course of coal formation and semicoking were suggested.

In the course of peat and, subsequently, coal formation, glycoside moieties of natural O- and C-anthraglycosides can partially degrade, with preservation of the anthraquinone core and its subsequent incorporation into the forming geopolymers. The same concerns anthraquinones with hydroxymethyl, hydroxypropyl, aldehyde, and isoprenyl substituents. In the course of subsequent semicoking, these fragments are elimi-

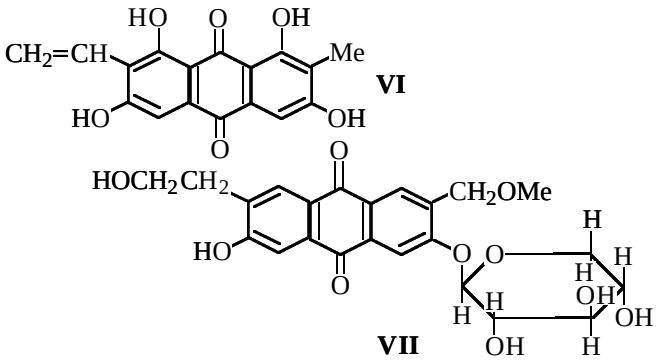
1070-4272/03/7610-1686 $25.00 © 2003 MAIK "Nauka/Interperiodica"

nated, probably with rearrangement and isomerization of substituents, to finally form structures detected in semicoking tars. This transformation pathway is apparently responsible for the appearance of vinyl and ethyl substituents in the identified anthraquinones. (+)-Carminic acid **II** [11] or related compounds could have been the starting biogenic natural anthraglycosides. Partial degradation of the glucopyranose ring in **II**, followed by decarboxylation and dehydroxylation of degradation product **III** to give **IV**, can occur in the initial step of peat genesis with participation of fungi and bacteria [13]. Subsequent transformations of the organic matter under reductive conditions in later stages of peat and coal formation may involve hydrogenation of vinyl groups to ethyl groups, to give compounds like **V**:



II **III** **IV** **V**

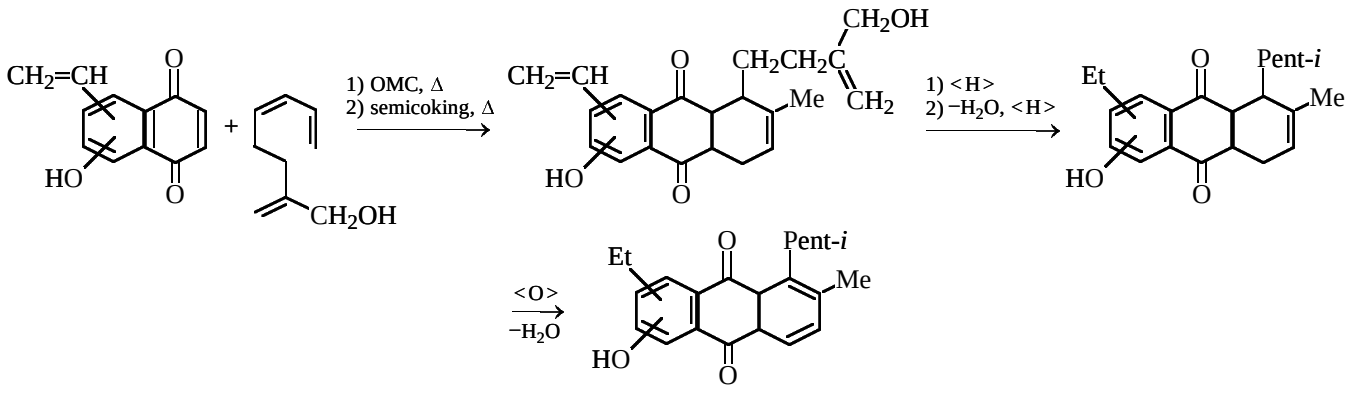
A few representatives of natural anthraquinones, e.g., sopheranin **VI** [21] and nataloin **VII** [11], contain vinyl and 2-hydroxyethyl substituents:



VI **VII**

Biogeochemical transformations of **VI** and **VII** could be similar to those shown in the scheme.

We believe that one of the main probable pathways yielding anthraquinone fragments in the course of coal formation and semicoking is the Diels–Alder reaction of natural naphtho- and benzoquinone derivatives with acyclic and monocyclic terpenes and terpenoids. It is known [19] that such reactions give 1,4,4*a*,9*a*-tetrahydroanthraquinone derivatives in high yields; these compounds are then virtually quantitatively oxidized by atmospheric oxygen to give the corresponding anthraquinones:

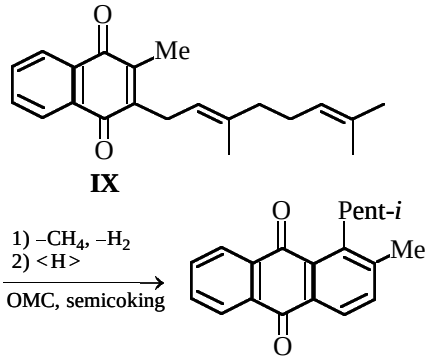


Processes of this kind may involve not only natural naphthoquinones, but also benzoquinone derivatives, and the reactions themselves may occur in the early (peat genesis) step of coal formation in the presence of atmospheric oxygen, which is necessary for oxidation of the primary products of diene synthesis, 1,4,4*a*,9*a*-tetrahydroanthraquinone derivatives, to anthraquinones.

The arising structures were subsequently either accumulated in pores of the forming macromolecular matrix of coal as a mobile phase or incorporated into the forming geopolymer via donor–acceptor, hydrogen, or ester bonds; these structures could have also undergone dehydration and hydrogenation under reductive conditions in the later steps of sedimentogenesis and diagenesis in the absence of atmospheric oxygen, which finally resulted in the transformation of hydroxyisopentadienyl and vinyl groups into isopentyl and ethyl groups.

The possibility of this pathway of anthraquinone formation in coals is supported by identification in the semicoking tars under consideration of a series of benzo- and naphthoquinone derivatives which can act as dienophiles in this process, such as juglone, fumigatin, spinulosin, 2,6-dimethoxybenzoquinone, and structures related to plumbagin, alkannin, shikonin, shikalkin, and javanicin [11, 13–16]. Among naphthoquinones, these reactions could have involved phylloquinone and menaquinone structures widely abundant in plants, and, among benzoquinones, ubiquinone and plastoquinone derivatives participating in respiration and hydrogen transfer in the course of oxidative phosphorylation [11, 13–16]. The coal products studied are also characterized by high content and diversity of native and transformed (bio- geo- and thermochemically) acyclic and monocyclic terpenes and terpenoids playing in these reactions the role of dienes and originating mainly from coniferous plants [23], which made a predominant contribution to coal-forming phytocenosis of coal [23, 24].

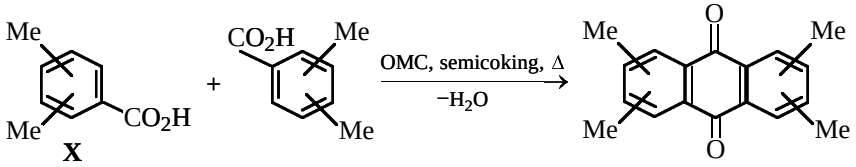
The above-mentioned phyllo- and menaquinone structures, belonging to the naphthoquinone series and widely abundant in plants, can also undergo cyclization under the conditions of coal formation and semicoking, to give anthraquinone structures containing isopentyl and methyl groups, as shown for cyclization of menaquinone-2 (**IX**) as example:

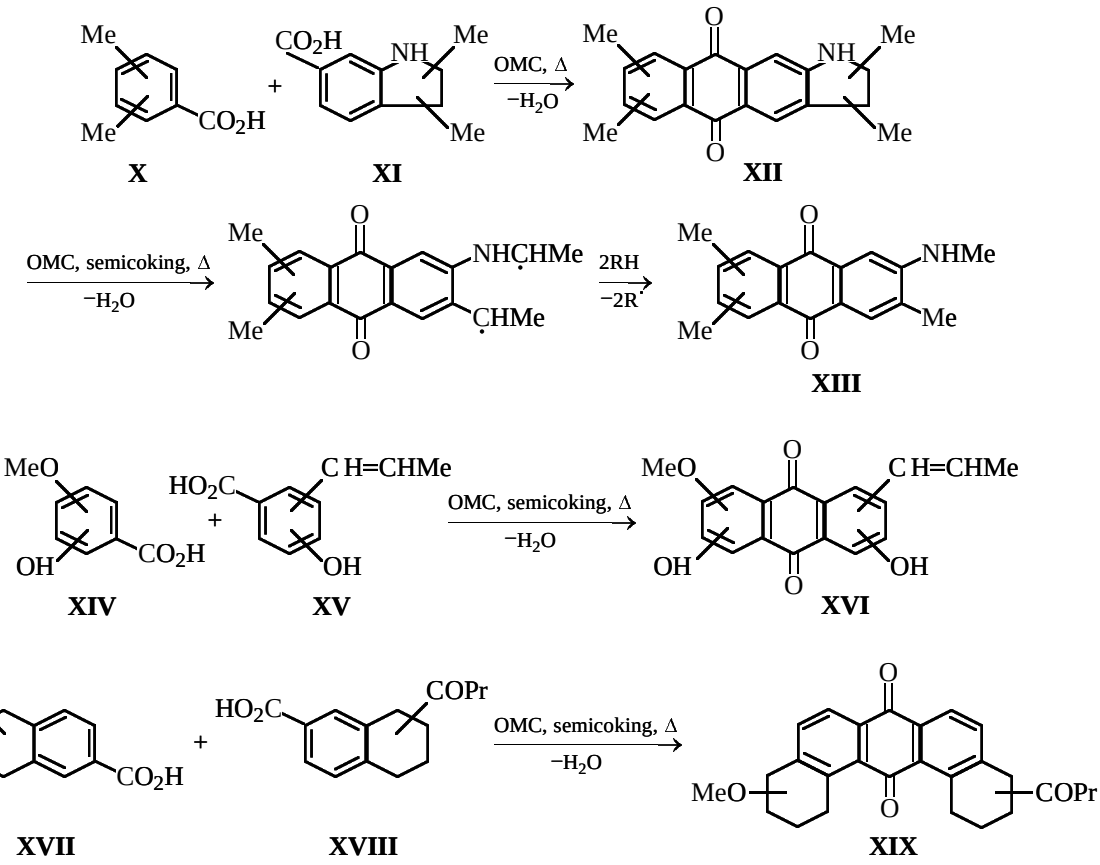


IX

Similarly, structures of ubi- and plastoquinones, belonging to the benzoquinone series, can transform into the corresponding naphthoquinones, which subsequently react with terpenoids (diene synthesis) to give anthraquinone fragments of OMC. The intermediate naphthoquinone structures can also originate from numerous substituted naphthalenes, tetralins, tetralinols, tetralindiols, and naphthols (genetically related to mono- and bicyclic sesquiterpenoids of coniferous plants), which have also been identified in various fractions of the semicoking tars studied [3–10]. Being prone to dehydrogenation, dehydration, and oxidation, these structures can be oxidized under coal weathering conditions into the corresponding naphthoquinones, which subsequently transform into anthraquinone derivatives.

Presumably, anthraquinone fragments of OMC may have also been formed by condensation of substituted benzoic acids with intermediate formation of 2-benzoylbenzoic acids [19]. These reactions occur in the presence of Lewis acids and, under the conditions of coal formation, can be catalyzed by aluminosilicates and organomineral complexes contained in the mineral matter of coal. This synthesis pathway is probable for polymethyl-, methylamino-, and pyrrolidinoanthraquinones:

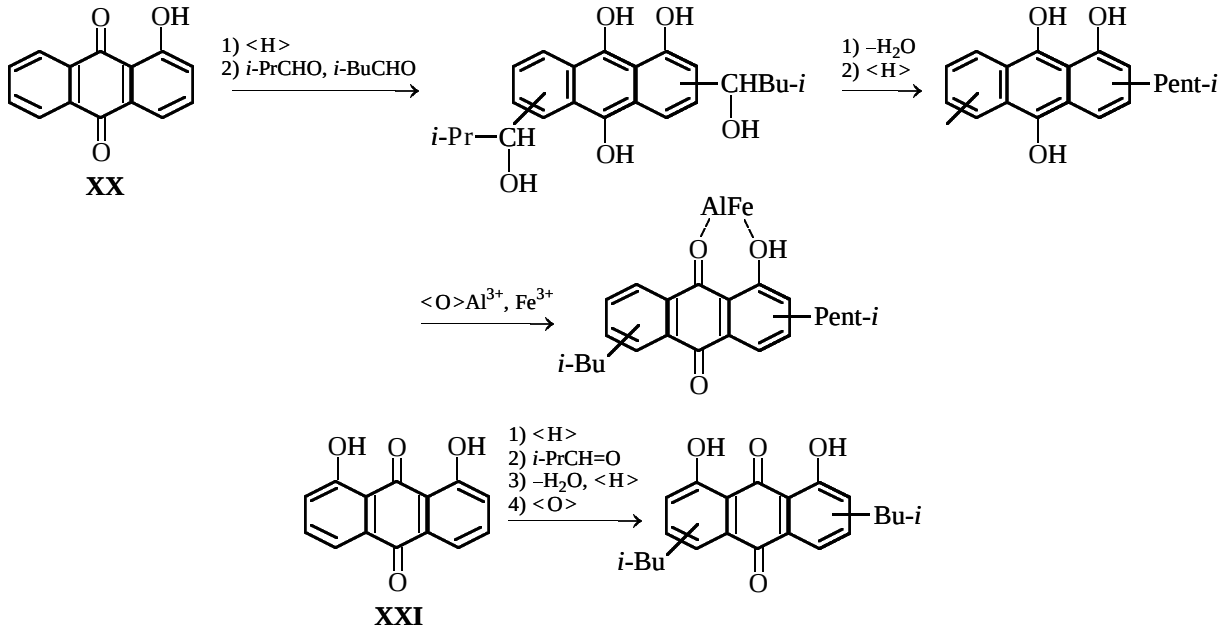




Dimethylbenzoic acid **X** may be produced by microbial oxidation of OMC in the weathering step. Dimethylindolinecarboxylic acid **XI** may have originated from biogeochemical transformations of native indole compounds, e.g., indole alkaloids. A large number of indole, indoline, and genetically related structures have been identified in various close-cut fractions of organic bases, phenols, and asphaltenes of the semicoking tar studied [3, 6, 9, 25, 26]. In the course of further semicoking, anthraquinones with the pyrrolidine ring of type **XII** can transform into anthraquinones like **XIII** by radical cleavage of the pyrrolidine ring. In turn, vanillic (**XIV**) and propenylhydroxybenzoic (**XV**) acids, which are probable precursors of structure **XVI**, are, most probably, genetically related to lignin of the initial plants involved in primary sedimentation. Tetralincarboxylic acids **XVII** and **XVIII**, probable precursors of anthraquinone **XIX**, are apparently products of biogeochemical transformations of sesquiterpenoids of coniferous plants.

Both benzoic acid itself and its substituted derivatives (*p*-hydroxybenzoic, salicylic, vanillic, syringic, β-resorcylic, protocatechuic, veratric acids, etc.) have been identified in aqueous extracts of coals [1, 3]. These acids widely occur in plants in free form and as esters. Esters of vanillic and syringic acids are components of wood lignin. Orsellic, lecanoric, and evernic acids are the most important substituted benzoic acids of lichens [13–16].

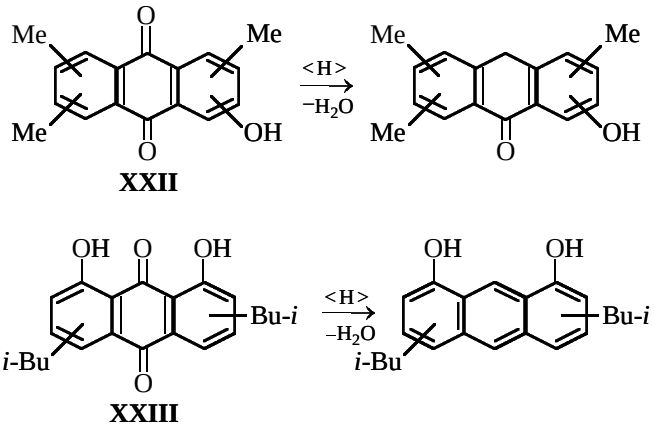
Anthraquinone fragments of OMC could have also been formed by reactions of leuco compounds (anthrahydroquinones) with aldehydes, with intermediate formation of hydroxyalkyl derivatives, which are subsequently reduced to alkylanthrahydroquinones. The latter products are then oxidized by atmospheric oxygen (e.g., in the course of coal weathering) to the corresponding alkylanthraquinones. This transformation route is known in synthetic chemistry of anthraquinone as the Marschalk reaction [19]. This reaction readily occurs with hydroxyanthrahydroquinones which, in turn, can be formed, along with the required aldehydes, from the initial natural hydroxyanthraquinones and carboxylic acids under reductive anaerobic conditions in the steps of late peat genesis and early diagenesis. 1-Hydroxy- (**XX**) and 1,8-dihydroxyanthraquinone (**XXI**) can also enter into the Marschalk reaction [11, 27] to give the corresponding coal anthraquinones:



XX

XXI

Anthrone and anthracene derivatives are apparently formed by reduction of anthraquinone precursors in anaerobic reductive steps of peat and coal formation:



XXII

XXIII

Anthraquinones **XXII** and **XXIII**, in turn, could have been formed by the above-considered reactions: condensation of benzoic acids and Marschalk reaction, respectively. Other hexahydro- and octahydroanthrone derivatives may, presumably, be products of condensation of sesquiterpenoids of coniferous plants or of the Diels–Alder reaction of benzo- and naphthoquinone derivatives with diene-containing OMC fragments, followed by reduction.

Thus, the most probable initial bioproducers of the identified coal anthraquinone structures and their possible precursors are Mesozoic evolutionary precursors of flowering plants, insects, and lower fungi, which were involved in primary degradation of the initial biomaterial in the primary peat-genesis step of coal formation, and also lichens and coniferous plants. These conclusions are confirmed by the results of earlier geochemical studies of products obtained from Kansk–Achinsk coals (composition of terpenoids, azulenes, adamantanes, and pyrone derivatives: flavonoids, coumarins, chromones, isocoumarins) and by data obtained in geological and paleontological reconstruction of primary sedimentation and subsequent transformation of the initial organic matter [23, 24, 28]. According to these data, coal formation occurred under terrigenous conditions. The main bioproducers were Mesozoic coniferous plants, with active participation of lower fungi and aerobic bacteria in primary degradation of the starting organic matter in the initial step of peat formation.

CONCLUSIONS

(1) The probable initial bioproducers of anthraquinone structures detected in lignite extracts and semicoking tars are Mesozoic evolutionary precursors of flowering plants, insects, fungi, aerobic bacteria, lichens, and coniferous plants.

(2) Possible pathways of formation of anthraquinone structures in the steps of peat and coal formation, and also in low-temperature degradation of the organic matter of coal were suggested.

Abstract—A hydrochloric acid technology for loparite processing on enlarged laboratory scale was developed. Extractive recovery of a sum of titanium(IV), niobium(V), and tantalum(V) was carried out in the continuous mode.

The domestic mineral resources of niobium, tantalum, and rare-earth elements (REE) occupy the leading position in the world in quantity, but are inferior to foreign resources in ore quality, mining conditions, and geographical-economical position. Now, Russia has the only surveyed and developed deposit of complex raw materials for manufacture of tantalum, niobium, rare-earth elements of the cerium group, and titanium: this is the Lovozero deposit of loparite.

Commercial tantalum and niobium, technical-grade titanium product, and a concentrate of REE chlorides are obtained together with radioactive elements contained in the loparite concentrate.

Loparite is a complex raw material with small amount of ballast elements (sodium and calcium), less than 10% in aggregate. Developing an efficient technology for processing of loparite will ensure a high profitability of the production process.

The chlorine technology requires chlorine gas. The sulfuric and nitric acid technologies failed to produce good results under industrial conditions [1]. The hydrofluoride technology, which is only in the laboratory stage of development, employs hydrofluoric acid, the most expensive and ecologically hazardous reagent.

In this context, it is the authors' opinion that the hydrochloric technology for loparite processing is rather promising.

Investigations in this direction were carried out in the 1960s–1970s, but failed to advance beyond the stage of laboratory development.

At present, the possibility of practical implementation of the hydrochloric acid technology of loparite is stronger. For example, attention was called in [3] to the fact that the number of investigations employing a hydrochloric medium is substantial [4]. Previously, its use in hydrometallurgical practice was hindered by the lack of necessary materials for apparatus. The appearance of new acid-resistant materials, plastics, special alloys, graphite with special impregnators, acid-resistant rubbers, and ceramics enabled use of hydrochloric acid in those cases when this is economically efficient.

The investigation performed demonstrated that treatment of the loparite concentrate with a 37% solution of hydrochloric acid at 95°C, breakdown time of 6 h, l : s = 3–5, and concentrate grain size of +0.08…+0.05 leads to >98% recovery for components soluble in HCl. The residue contains, in amount of 3–4% relative to the mass of the starting concentrate, ballast materials insoluble in hydrochloric acid: aegirine, quartz, and feldspar. The production solutions contain, depending on breakdown conditions, the following components (g l^{-1}): TiO_2 70–150, Nb_2O_5 7–35, Ta_2O_5 0.8–3.0, ΣREE 35–130. In addition, the solution contains chlorides of calcium, strontium, sodium, potassium, iron, and radioactive elements.

Extractive recovery of titanium(IV), niobium(V), and tantalum(V) with the use of octanol was developed and tested under laboratory and enlarged laboratory conditions, with these metals separated from all the accompanying impurities. The results obtained in enlarged-scale extraction experiments carried out on a box-type mixing extraction cascade, are listed

* Starting solution: ρ 1.267 g cm^{-3}, c_s 101.9 g l^{-1}, TiO_2 78 g l^{-1}, Nb_2O_5 12.16 g l^{-1}, Ta_2O_5 0.78 g l^{-1}, ΣREE 40 g l^{-1}, ThO_2 0.76 g l^{-1}, U 0.02 g l^{-1}. Extracting agent: ρ 0.924 g cm^{-3}, μ 15.85 cP. Extract: ρ 0.980 g cm^{-3}, c_s 68 g l^{-1}, HCl 3.25 M, TiO_2 76.26 g l^{-1}, Nb_2O_5 12.05 g l^{-1}, Ta_2O_5 0.067 g l^{-1}, μ 40.69 cP, ThO_2 not found, U not found. Raffinate: ρ 1.202 g cm^{-3}, TiO_2 0.475 g l^{-1}, Nb_2O_5 <0.001 g l^{-1}, Ta_2O_5 0.002 g l^{-1}, ΣREE 38 g l^{-1}, ThO_2 0.621 g l^{-1}, U 0.036 g l^{-1}.

in the table. Re-extraction was performed with water, the rate of stratification was 1.5 m h^{-1} in both cases. This value ensured a stable course of the process, and recycled extracting agent contained no impurities. The loss of niobium(V) and tantalum(V) with the raffinate was 0.008 and 0.24%, respectively. The content of ΣREE in the extract was less than 0.5 g l^{-1}. No radioactive elements were found in the re-extract.

The possibility of extractive recovery of thorium(V) from solutions after isolation of titanium(IV), niobium(V), and tantalum(V) was established; the degree of thorium(V) extraction into the organic phase in a single stage was 86%. The regeneration conditions of hydrochloric acid by extraction with octanol were determined; the acid can be partly returned by the known techniques from sodium and iron chlorides produced in the technology. The "cold chlorination" process described in [5] was tested in separation of titanium(IV) and niobium(V). The process consists in obtaining $TiCl_4$ (the most promising product for obtaining high-quality TiO_2) via the compound K_2TiCl_6. This compound is precipitated from a titanium sulfate solution saturated with KCl and HCl at 0°C. Since K_2TiCl_6 is unstable, precipitation of a more stable and less soluble compound, Cs_2TiCl_6, was also studied. The possibility of 90% extraction of titanium(IV) into precipitate was established; in this case, the loss (recoverable) of niobium(V) with the precipitate did not exceed 4%, since niobium(V) forms no double compound. Further processing of the double salt is performed by heating and evaporation of $TiCl_4$. The residue containing niobium(V) and alkali metal chlorides is recycled into the stage of precipitation of the double salt.

CONCLUSIONS

(1) The loparite concentrate is virtually completely decomposed with 37% hydrochloric acid at a temperature of 95°C at l : s = 4 : 1 in the course of 6 h.

(2) Recovery of titanium(IV), niobium(V), and tantalum(V) into the organic phase, with their separation from other elements remaining in the raffinate, was carried out on an enlarged-laboratory scale on an extraction cascade.

(3) Separation of titanium(IV) and niobium(V) contained in re-extracts is performed via precipitation of poorly soluble Cs_2TiCl_6. $TiCl_4$, which is used in manufacture of a pigment, is obtained from this compound by evaporation.

Abstract—Synthesis and some chemical properties of the Al_2O–SiO_2–P_2O_5 system activated with MnO were studied.

Presently, the interest in laser glasses remains intense. Long-term studies have shown that phosphate glasses are advantageous as regards their technological effectiveness and preservation of their working properties upon introduction of considerable amounts of an activator.

This study is concerned with the chemical properties of the K_2O–Al_2O_3–SiO_2–P_2O_5 system activated with MnO. The K_2O–Al_2O_3–SiO_2–P_2O_5 system, which contains oxides of elements belonging to different groups of the periodic system, can be used as effective glass matrix for preparing luminescent and laser materials [1–3].

The matrix was prepared by fusing potassium metaphosphates and aluminum orthophosphate with silicon oxide (of optical-glass-making grade) in a high-temperature furnace for 8 h. The matrix obtained was powdered, and then the activator was introduced in the form of MnO_2 which was reduced with ammonium tartrate to Mn^{2+} at 1200–1250°C in the course of synthesis. To preclude oxidation of Mn(II) to Mn(IV), the reduction was performed in a CO_2 atmosphere.

The activated glass was poured into a metallic ingot mold and annealed at 300°C for 4 h. The sample obtained had no visually observed coloration (MnO_2 concentration 1.8 mol %, optical density D = 0.45 at λ = 410 nm, ρ = 2.67 g cm^{-3}). The glass obtained has the composition $18K_2O$–$11Al_2O_3$–$10SiO_2$–$61P_2O_5$: MnO_2(1.8 mol %).

The electronic absorption spectrum of the potassium–alumino–silica–phosphate glass (PASPhG)–Mn^{2+} is shown in Fig. 1. The highest-intensity absorption band is peaked around 410 nm and corresponds to the $^6A_1 \rightarrow {}^4A_1$ transition, which is virtually independent of the crystal field strength. At the long-wavelength wing of this band, a weakly resolved band associated with the $^6A_1 \rightarrow {}^4T_1$ transition is observed at 540 nm.

The luminescence spectrum of (PASPhG)–Mn^{2+} (Fig. 2) has the form of a broad asymmetric band peaked at around 630 nm, with half-width of 100 nm (2600 cm^{-1}). According to the existing concepts, this type of Mn^{2+} luminescence corresponds to an octahedral configuration. The luminescence decay time is 2 ms.

The spectral, luminescence, and kinetic characteristics remain at a practically acceptable level. The developed laser matrix opens up wide opportunities for use of MnO_2 as sensitizer of REE ions in the PASPhG.

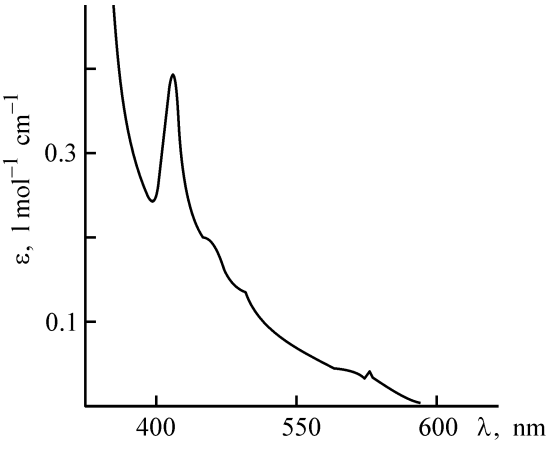

Fig. 1. Electronic absorption spectrum of Mn^{2+} in PASPhG. (ε) Molar extinction coefficient and (λ) wavelength.

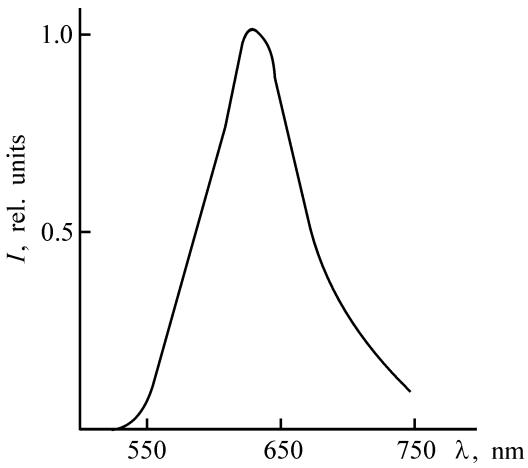

Fig. 2. Luminescence spectrum of Mn^{2+} in PASPhG. (I) Intensity and (λ) wavelength.

It has been considered for years that only REE ions (Nd^{3+}, Er^{3+}, Yb^{3+}, Ho^{3+}, etc.) can play the role of lasing ions in glassy matrices. This conclusion has been supported by a number of unsuccessful attempts to create a laser material based on a glass activated with 3*d*-element ions and, in particular, with Cr(III) ions. However, the results obtained in [4–15] made it possible to develop and manufacture a laser material based on a Ti(III)-activated glass of composition $Al(PO_3)_3$–Ti^{3+}. The given composition of the matrix appeared to have the best physicochemical properties and, in particular, the highest resistance to high-intensity laser light, which is an important characteristic of a glassy laser material.

The glass samples synthesized were irradiated with gigantic laser pulses (λ = 532 nm, incident power density of up to 100 MW cm^{-2}, pulse width 3.3×10^{-8} s), i.e., with energy of 3 J cm^{-2} at its uniform distribution over the irradiated area. The degree of resistance to light was determined from a possible decrease in the luminescence signal from a target (5 mm in diameter) subjected to a sequence of laser light pulses. It was found that, after several tens of pulses, the luminescence intensity remained unchanged. Consequently, the luminescent centers did not undergo any pronounced destruction, and no centers capable of absorbing or attenuating both the exciting and the emitted light appeared in the material. The sample in the form of a disc of diameter d = 5 mm and thickness l = 3 mm was irradiated with a gigantic pulse at the wavelength of the second harmonic of a neodymium laser, with the pumping intensity varied widely, up to the maximal value of 75 MW cm^{-2}. A single-pass lasing was obtained with this glass.

The results obtained have aroused interest in a systematic study of spectral and luminescence properties of other 3*d*-ions in glassy matrices and in analysis of the previously studied systems from the standpoint of their possible application as active media and sensitizers for lasers.

BRIEF COMMUNICATIONS

Phase Equilibria in the System $CuO–Fe_2O_3–Sb_2O_4–O_2$

B. G. Golovkin and G. V. Bazuev

Institute of Solid-State Chemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received December 17, 2002

Abstract—Results of X-ray phase analysis were used to construct the phase diagram of the system CuO–Fe_2O_3–Sb_2O_4–O_2 at 1000°C in air. Two $Cu_{2x}Fe_{4-3x}Sb_xO_6$ solid solutions ($0 \le x \le 0.154$ and $0.923 \le x \le 1$) of, respectively, hematite and bixbyite structure were identified.

A study of phase formation in the sistem Fe_2O_3–Sb_2O_4–CuO is of interest in the context of a search for catalysts for propylene [1] and butylene [2] oxidation and use of these materials in storage devices and microwave matching elements [3, 4].

In the system CuO–Fe_2O_3 in air, below 1040°C, there exists a cubic modification of copper(II) ferrite $CuFe_2O_4$ (a = 8.39 Å) transformed into a tetragonal modification (a = 8.23 Å and c = 8.70 Å) at 380°C. Above 1040°C, $CuFe_2O_4$ transforms into copper(I) ferrite $CuFe_5O_8$ with loss of oxygen. Both the ferrites and Fe_3O_4 form a continuous series of solid solutions of general formula $Cu_xFe_{3-x}O_4$ ($0 \le x \le 1$) [3–6].

In each of the systems Fe_2O_3–Sb_2O_5 and CuO–Sb_2O_5 in air, only a single compound is formed, $FeSbO_4$ with rutile structure [7] (stable up to 1270°C [8]) and $CuSb_2O_6$ with trirutile structure [7, 9]. The latter compound starts to decompose at about 1020°C to give $Cu_8Sb_2O_9$ [10].

The results obtained in studying the system Sb_2O_3–Sb_2O_5 are reviewed in [7, 11–14]. Antimony oxide Sb_2O_3 exists in two polymorphic modifications: low-temperature rhombic and high-temperature cubic, with phase transition temperature of about 500°C in inert atmosphere [11]. In air, Sb_2O_3 is oxidized at this temperature to α-Sb_2O_4, which transforms into β-Sb_2O_4 above $T \sim 1000$°C [7, 11, 12]. After calcination of hydrated antimony(V) oxide at 300°C in air, Sb_6O_{13} is first formed, which is reduced to α-Sb_2O_4 at 800°C [11] and remains stable up to about 1000°C, and then transforms into β-Sb_2O_4. At $T \sim 1200$°C, the last compound starts to dissociate to give Sb_2O_3 [11]. Anhydrous Sb_2O_5, existing in two polymorphic modifications, can be obtained solely under elevated pressure in oxygen [14].

Among ternary compounds of the given system, the previously obtained cubic complex oxide Cu_2FeSbO_6 of bixbyite structure (a = 9.5622 Å) [15, 16] is known (so-called structural type *C* typical of a number of rare-earth oxides, such as α-Mn_2O_3, etc.).

EXPERIMENTAL

As starting reagents for synthesis of samples were used analytically pure oxides CuO, Sb_2O_3, and Fe_2O_3. The samples were synthesized by the conventional ceramic technology first at 660°C (20 h) and then at 1000°C (100 h). The reaction course was monitored by means of X-ray phase analysis (XPA, DRON-2 diffractometer, Cu_{K_α} radiation). The XPA sensitivity with respect to the phases formed in the annealing products was, on the average, 0.5–1.0 wt %.

The results obtained in analysis of the annealing products are presented in the form of a phase diagram (see Fig. 1). In accordance with the published data mentioned above, antimony enters in the course of synthesis into the composition of the complex oxides $FeSbO_4$, $CuSb_2O_6$, and Cu_2FeSbO_6 in the oxidation state +5, although the oxide $Sb^{3+}Sb^{5+}O_4$ is a stable simple antimony oxide in air below 1200°C [14]. For this reason, the $CuSb_2O_6$–$FeSbO_4$–Sb_2O_4 compositions are plotted in the diagram using a nonuniform scale method [17]. In the system, two ternary phases of the general formula $Cu_{2x}Fe_{4-3x}Sb_xO_6$ were identified: the first with a homogeneity region $0 \le x \le 0.154$ (solid solution based on hematite Fe_2O_3) and the second, with Cu_2FeSbO_6 bixbyite structure, for which $0.923 \le x \le 1$. The edge compositions of the first phase are hematite Fe_2O_3 [x = 0, hexagonal crystal system, corundum structure, a = 5.032(2), c = 13.738(5) Å] and $Fe_{3.538}Cu_{0.308}Sb_{0.154}O_6$ [x = 0.154;

1070-4272/03/7610-1696 $25.00 © 2003 MAIK "Nauka/Interperiodica"

a = 5.051(2), c = 13.778(5) Å]. The edge compositions of the second phase are dark brown Cu_2FeSbO_6 (x = 1) and $Cu_{1.846}Fe_{1.231}Sb_{0.923}O_6$ [x = 0.923, a = 9.5515(7) Å]. Because the figurative points for the given solid solutions lie on the straight line connecting Cu_2FeSbO_6 and Fe_2O_3, they can be regarded as solid solutions of Cu_2FeSbO_6 in Fe_2O_3 and, *vice versa*, of Fe_2O_3 in Cu_2FeSbO_6. This suggests that antimony is present in the given solutions in the oxidation state +5.

Reducing the indices of the edge compositions of the solid solutions obtained to integers gives hematite-like $Fe_{23}Cu_2SbO_{39}$ and bixbyite-like $Cu_{12}Fe_8Sb_6O_{39}$. To elucidate the substitution scheme, they are represented as nA_2BCO_6, where A is a complex cation, and B and C are complex anions. This gives $(Fe_{11}Cu_2)_2 \times [(Fe_{13})(Fe_{11}Sb_2)]O_{78}$ and $(Cu_{12}Fe)_2[(Fe_{13})(FeSb_{12})]O_{78}$, respectively, at n = 13.

As seen from these formulas, the substitution takes place in the sublattices A and C, with the homogeneity region twice larger for hematite solid solutions.

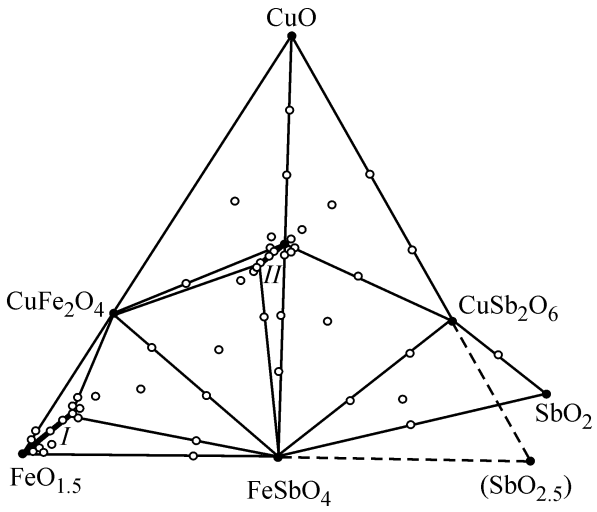
As is known [18, 19], one of Fe_2O_3 modifications is bixbyite (a = 9.393 Å) ([18, 19]). This suggests that a continuous series of $Cu_{2x}Fe_{4-3x}Sb_xO_6$ solid solution of bixbyite structure ($0 \le x \le 1$) can be formed under appropriate conditions. At the same time, hematite has a more densely packed structure, compared with bixbyite (this conclusion follows from a comparison of unit cell volumes of the Fe_2O_3 modifications being analyzed, reduced to the same formula unit). This suggests that the range of existence of hematite solid solutions can be extended under appropriate synthesis conditions.

When heated to about 1100°C, the bixbyite solid solutions obtained dissociate to give $FeSbO_4$, Fe_2O_3, and $Cu_8Sb_2O_9$ by the reaction:

$$4Cu_2FeSbO_6 \cdot mFe_2O_3 \xrightarrow{1100°C} Cu_8Sb_2O_9 + 2FeSbO_4 + (m + 1)Fe_2O_3 + 2O_2\uparrow.$$

Thermal treatment of Cu_2FeSbO_6 at 950°C under a pressure of 60 kbar did not result in any structural transformations [20]. With pressure raised to 90 kbar at the same temperature, dissociation into CuO and $FeSbO_4$ occurred.

The $Cu_9Sb_4O_{19}$ phase was synthesized at 1000°C under oxygen pressure of 10 bar in [12]. To obtain this phase, compositions of the partial system $CuO–CuSb_2O_6$ indicated in Fig. 1 were tested. For this purpose, they were subjected to additional annealing in oxygen at 950°C for 20 h under normal pressure.



Phase diagram of the system $CuO–Fe_2O_3–Sb_2O_4–O_2$ at 1000°C in air. (*I*) $Cu_{2x}Fe_{4-3x}Sb_xO_6$, $0 \le x \le 0.154$ and (*II*) $Cu_{2x}Fe_{4-3x}Sb_xO_6$, $0.923 \le x \le 1$. *Small circles* stand for the figurative points of annealed compositions.

The reaction products consisted, however, solely of a mixture of CuO and $CuSb_2O_6$.

CONCLUSION

The phase diagram of the system $CuO–Fe_2O_3–Sb_2O_4–O_2$ at 1000°C in air was constructed. In the region of the $CuO–Fe_2O_3–FeSbO_4–CuSb_2O_6$ compositions, two $Cu_{2x}Fe_{4-3x}Sb_xO_6$ solid solutions were identified: with structure of hematite (homogeneity region $0 \le x \le 0.154$) and bixbyite (homogeneity region $0.923 \le x \le 1$), in which antimony is present in the oxidation state +5. Iron(III) and copper(II) antimonates are in equilibrium with each other and with Sb_2O_4.

Abstract—Influence exerted by additives introduced into the working solution, and by iron or copper formed in electric-spark dispersion of these metals and zinc, on the quality of the products obtained in electric erosion was studied.

As noted previously [1], the attention given to the behavior of dispersed metal particles after their removal from the spark discharge zone is insufficient. This is due to the fact that the literature covers incompletely the application of the method of electric-spark dispersion of metals for obtaining highly dispersed materials, even though the working principle of the method has long been known and is employed successfully in metal working and, in particular, in electric-erosion processing of metal articles to obtain complex profiles and apertures [2, 3].

The present study is concerned with the influence exerted by additives introduced into the working solution, and by iron or copper formed in electric-spark dispersion of these metals and zinc, on the quality of the products obtained in the process.

The product quality was checked by determining its absorption capacity in gas purification to remove hydrogen sulfide. The electric-spark dispersion of metal was carried out on an installation, and using a procedure, described in [1]. The reactor was for the most part filled with zinc granules and had zinc electrodes fixed at its edges. As working solution served distilled water with various additives. Pulsed current (pulse repetition frequency 700 Hz) was passed through the reactor [4]. The product obtained in electric erosion of zinc was filtered off and dried at a temperature of 100°C.

Further, the dried product was compacted and then ground. To determining the absorbing capacity of the samples studied, the 0.25–0.50-mm fractions were taken. The sulfur absorption capacity of a sample, Q (wt %), is the amount of sulfur absorbed by unit mass of the sample in gas purification to remove H_2S, which is defined as the ratio of the sample masses (g) before and after an experiment, multiplied by 100. The sulfur absorption capacity was determined by passing a gas mixture containing hydrogen and 1.3–1.4 vol % hydrogen sulfide (which is 18–18.5 g m^{-3} in terms of elementary sulfur) through a sample bed at a rate of 5000 h^{-1}. The temperature of the sample bed was maintained at 400°C, and the gas mixture was passed to complete saturation with sulfur, i.e., until the concentrations of H_2S in the gas mixture before and after the sample became equal.

Figure 1 shows the results obtained in studying the influence exerted by the working solution components used in electric erosion on the value of Q for

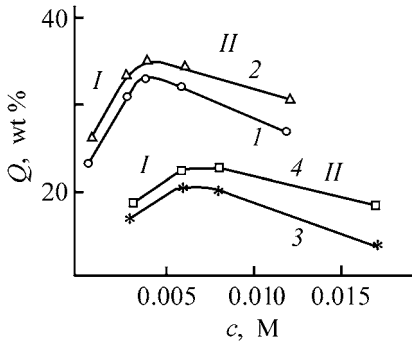

Fig. 1. Sulfur absorption capacity Q of samples prepared from products formed in electric erosion of zinc vs. concentration c of additives present in the working solution. samples prepared from products formed in electric-spark dispersion of zinc. In electric-spark dispersion of a metal, the additives introduced into the working solution are thermally decomposed in the spark discharge zone [5]. As a result, atomic oxygen, carbon and carbon-containing residues are formed (the additives present in the working solution also undergo thermal decomposition in the course of electric erosion of zinc). The atomic oxygen thus formed is involved in the formation of an oxide film on the surface of dispersed zinc [5]. It can be seen from Fig. 1 that, with increasing concentration of the additives, the sulfur absorption capacity of samples prepared from erosion products first grows and then, having reached its limiting value (portion *I*, curves *1* and *3*), starts to decrease (portion *II*). The rise in sulfur absorption capacity in portion *I* of the Q–c curve is apparently due to reduction of the oxide film on the surface of dispersed Zn particles by hydrogen from the gas mixture to be purified to remove hydrogen sulfide. Further, dispersed Zn, freed of the oxide film, reacts with H_2S to give zinc sulfide. The certain decrease in the sulfur absorption capacity of the samples (portion *II*) is possibly due to an increase in the content of compounds formed in interaction of dispersed Zn particles with other products of thermal decomposition of the additives, which are not involved in the process of gas purification to remove H_2S.

For comparison, Fig. 1 shows the sulfur absorption capacity of samples prepared from products obtained in electric erosion of zinc in a working solution containing the additives considered (curves *2* and *4*) and precalcined at 450°C. It can be seen that the manner in which the sulfur absorption capacity varies is the same as that for dried samples, with only the sulfur absorption capacities being somewhat higher. This is probably due to oxidation, during sample calcination, of a part of compounds formed in interaction of dispersed metal with other products of thermal decomposition of the additives, to give active zinc oxide. This oxide further reacts with H_2S to give ZnS [6]. Thus, analysis of the data obtained suggests that the nature of additives introduced into the working solution strongly affects the quality of products formed in electric erosion of zinc.

Interesting results were obtained in electric-spark dispersion of zinc together with iron or copper. For this purpose, minor amounts of iron or copper granules were introduced into a reactor packed with zinc granules in such a way that approximately 1.4 wt % iron or copper was dispersed together with zinc in electric erosion. A solution of oxalic acid was used as the working solution. Figure 2 shows data on sulfur absorption capacity of samples prepared from products of electric erosion of Zn (point *1*), Zn with Fe (point *2*), and Zn with Cu (point *3*). It can be seen that presence of a minor amount of Fe or Cu in the erosion product leads to a substantial increase in the sulfur absorption capacity of the samples. Thus, the quality of the product obtained markedly changes under these conditions of the electric erosion process.

It is known that one and the same compound formed from different substances exhibits varied catalytic properties. For instance, ZnO obtained by heating various zinc-containing compounds, e.g., $ZnCO_3$ and $Zn(OH)_2$, shows different sulfur absorption capacities (32.0 and 21.9 wt %), all other conditions being the same. Such a difference between the sulfur absorption capacities of the samples is commonly attributed to varied perfection of the crystal lattice of zinc oxide [7]. For example, in heating of $ZnCO_3$, its crystal lattice is already disintegrated, whereas that of the reaction product, ZnO, is not complete yet.

The increased sulfur absorption capacities of the samples prepared from erosion products containing Zn and Fe or Zn and Cu (with the amount of the two second components equal to 1.4 wt %), observed in Fig. 2, are possibly due to incorporation of a part of Fe or Cu into the crystal lattice of Zn to form defects whose amount depends on the nature of a metal being introduced. These defects may further behave as active centers in gas purification to remove H_2S, which, in the end, leads to an increase in sulfur absorption capacity.

CONCLUSION

The quality of products obtained in electric erosion is strongly affected by additives introduced into the

working solution, and also by iron or copper formed in their joint electric-spark dispersion with zinc. It is suggested that the increased sulfur absorption capacities of samples prepared from zinc erosion products containing minor amounts of iron or copper are due to incorporation of these metals into the crystal lattice of zinc to form defects that behave as active centers in gas purification.

BRIEF COMMUNICATIONS

Desulfation of Active Paste from Lead Battery Scrap with Potassium Carbonate

A. G. Morachevskii, E. V. Bochagina, and M. N. Khabachev

St. Petersburg State Polytechnical University, St. Petersburg, Russia

Received August 13, 2003

Abstract—The results obtained in studying the desulfation of the active paste from lead battery scrap with the use of an aqueous solution of potassium carbonate are discussed.

It has been repeatedly noted previously that the most ecologically efficient way to utilize sulfur in processing of the sulfate-oxide fraction of lead battery scrap is desulfation (desulfurization) with carbonates or hydroxides of alkali metals or ammonium [1–7]. The desulfation processes are based on much lower solubility products (SP) of lead(II) hydroxide or carbonate, compared with lead(II) sulfate. For example, SP of $PbSO_4$ is $10^{-7.8}$ at 25°C varies with increasing temperature only slightly [8]. At the same time, the SP values for $Pb(OH)_2$ and $PbCO_3$ are, respectively, $10^{-15.3}$ (20°C) and $10^{-13.1}$ (25°C). Physicochemical and technological studies of the process of desulfation of lead-containing materials were considered in detail in a review [9]. Desulfation with sodium carbonate solutions has been studied extensively [10–14], whereas use of potassium carbonate for this purpose is understood to lesser extent. Smirnov and co-authors noted [5] that, being a by-product in processing of nepheline raw materials, potassium carbonate is manufactured in sufficient amounts (0.31 ton of potash is produced at the Achinsk combine per 1 ton of Al_2O_3). In addition, the reaction with lead sulfate

$$PbSO_4 + K_2CO_3 = PbCO_3 + K_2SO_4 \qquad (1)$$

yields potassium sulfate, which is in high demand, compared with sodium sulfate. In [5], some parameters of the process of desulfation with K_2CO_3 were reported: process temperature 50°C, solid-to-liquid ratio (s : l) 1 : 5, process duration 2 h, degree of sulfur recovery 95%.

The same communication reported the results obtained in laboratory experiments on desulfation of the active paste from positive and negative plates of a lead battery with K_2CO_3 solutions. According to analytical data (weighing method), the starting active paste from various battery plates contained, after being washed with water and dried, 45 wt % $PbSO_4$ (14.3% SO_4^{2-}). According to X-ray phase analysis, the main components of the active paste are $PbSO_4$ (anglesite) and lead oxide PbO_2 (plattnerite, tetragonal modification), present in comparable amounts (Fig. 1a). Also, a very small amount of the orthorhombic modification (α-PbO_2), and trace amounts of PbO (tetragonal modification) and metallic lead, may be present. A mineralogical characterization of the active paste was made in [15]. It was also noted that the main components are $PbSO_4$ and PbO_2 in the tetragonal and rhombic forms.

According to the results of a sieving analysis, the starting material had average and maximum grain size of 0.17 and 0.40 mm, respectively. The amount of active paste used in each experiment was 30 g, the excess of potassium carbonate over the value required by the reaction equation was 20%, the s : l ratio was varied from 1 : 4 to 1 : 5. The experiments were carried out at a temperature of 50°C under continuous vigorous stirring. After an experiment was complete, the filtered-off mass was washed, dried at 150°C for 2 h, and the filtrate was analyzed for the content of the sulfate ion by the weighing method. A set of experiments demonstrated that, after 45 min, the degree of recovery of the sulfate ion from the active paste is, on the average, as high as 99.5%. It should be noted here that the mass of the initial weighed portion decreases, on the average, by 2 g (by 6.7%), which is somewhat higher than the value expected under assumption that only reaction (1) occurs. Together with the formation of cerussite $PbCO_3$,

1070-4272/03/7610-1702 $25.00 © 2003 MAIK "Nauka/Interperiodica"

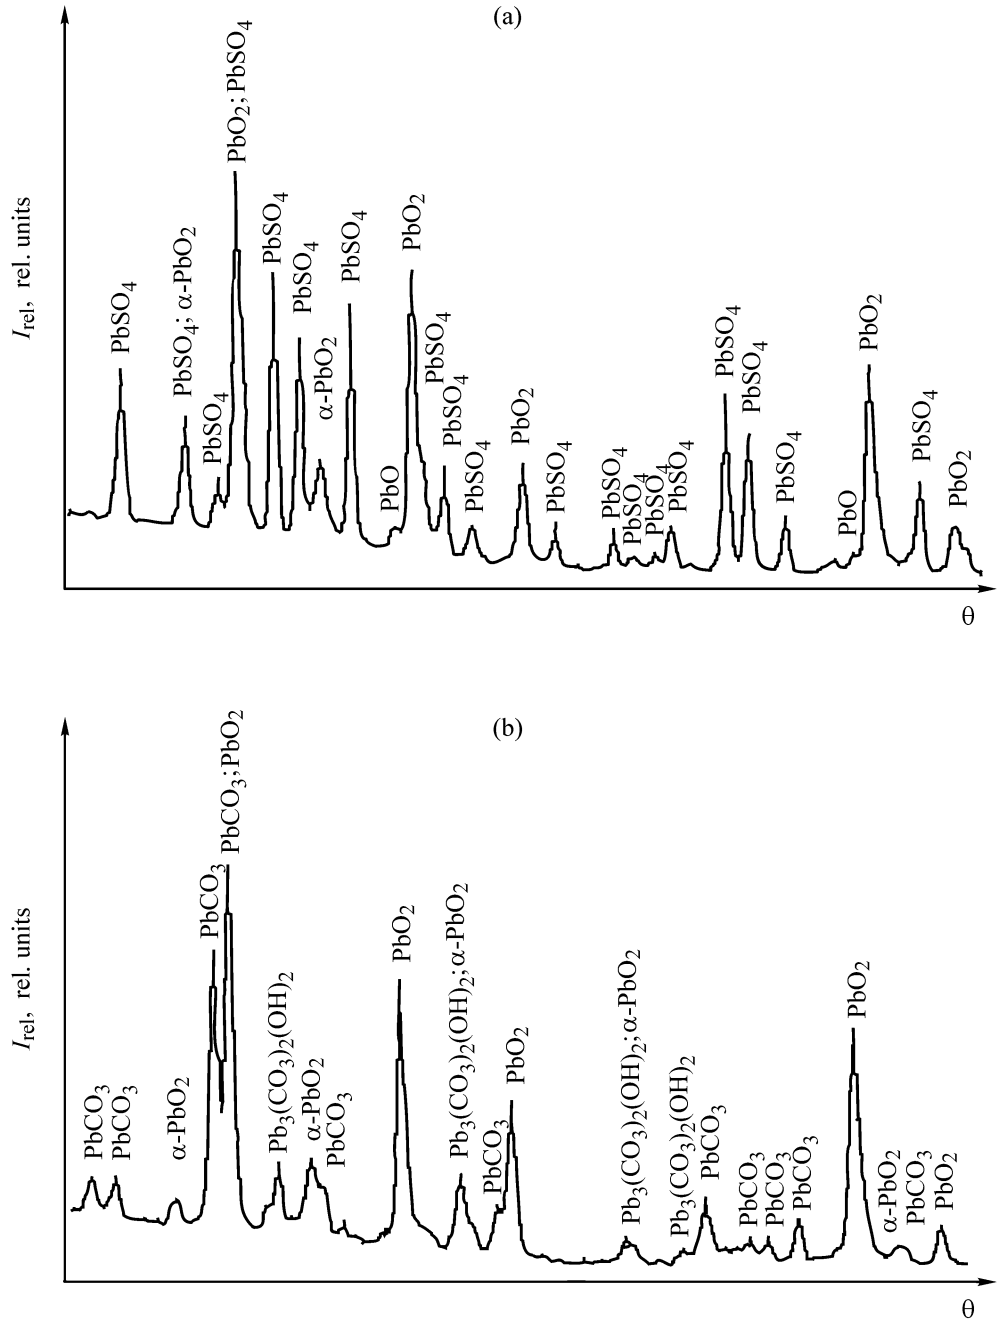

Fig. 1. X-ray diffraction patterns of (a) starting active paste and (b) that after desulfation. (I_{rel}) Relative intensity of diffraction lines and (θ) Bragg angle. The diffraction lines are assigned to the phases revealed; the content of a phase is proportional to the relative intensity of a line.

a minor amount of hydrocerussite $Pb_3(CO_3)_2(OH)_2$ is formed by the reaction [9, 16]:

$$3PbSO_4 + 4K_2CO_3 + 2H_2O = Pb_3(CO_3)_2(OH)_2 + 3K_2SO_4 + 2KHCO_3.$$

An X-ray diffraction analysis confirmed the presence of hydrocerussite in the desulfation products, in relatively small amounts, compared with those of cerussite and plattnerite. It should be noted that, in contrast to desulfation with soda, no double salt similar to the compound $NaPb_2(CO_3)_2OH$ is formed in desulfation with potash. This confirms the results obtained in [16] and in earlier investigations in this field.

In several sets of experiments, the paste being desulfated was sampled 15, 30, and 45 min after the be-

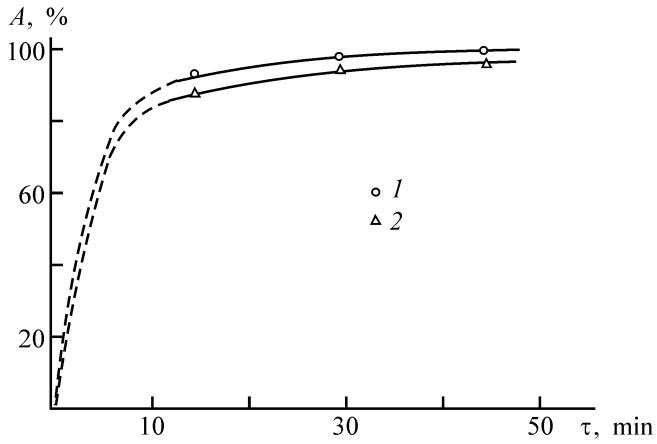

Fig. 2. Degree *A* of recovery of sulfate ions from the active paste vs. time τ. s : l: (*1*) 1 : 4 and (*2*) 1 : 5.

ginning of the process and the content of SO_4^{2-} ions in the samples was determined. As can be seen from Fig. 2, the main part of SO_4^{2-} ions pass into solution at least during the first 10 min of the process. The s : l ratio (1 : 4 or 1 : 5) has virtually no effect on the course of desulfation, with the curves coinciding to within the experimental error.

CONCLUSION

The process of desulfation of the active paste from lead battery scrap in an aqueous solution of K_2CO_3 at 50°C is fast, with the desulfation degree as high as 99.5%. The main components of the desulfated paste are cerussite $PbCO_3$ and plattnerite PbO_2. Also, a minor amount of hydrocerussite $Pb_3(CO_3)_2(OH)_2$ is present.

Wilhelm Ostwald (To 150th Anniversary of His Birthday)

The 1909 Nobel Prize Laureate in chemistry, W. Ostwald is widely known as one of founders of physical chemistry, a scientist and pedagogue, philosopher, and historian of science. He made an outstanding contribution to the development of the theory of electrolyte solutions and the theory of kinetics and catalysis. Together with J. Van't Hoff (1852–1911, 1901 Nobel Prize in chemistry), he founded the first specialized journal of physical chemistry and created a prominent international school of physical chemists. Numerous W. Ostwald's work have been translated into Russian. In 1896, W. Ostwald became a foreign corresponding member of the St. Petersburg Academy of Sciences.

Friedrich Wilhelm Ostwald was born on September 2, 1853, in Russia, in Riga, an administrative and cultural center of the former Liefland Province, into a family of Baltic Germans. His father, Gottfried Ostwald, was owner of a small barrel shop and a skillful barrel maker himself. Already when studying at Riga Realgymnasium, W. Ostwald became devoted to chemistry and, having finished his secondary education in 1872, entered the physicomathematical faculty of the University of Dorpat (now Tartu). At those years, Dorpat was a town of Liefland Province that was second in economic and cultural importance only to Riga. The studies at the university were in German (till 1889; later, in Russian). Chemistry was taught at the University of Dorpat at a sufficiently high level. The chair of chemistry was headed by professor Carl Schmidt (1822–1894), a corresponding member of the St. Petersburg Academy of Sciences since 1873. His main studies were devoted to analytical, physiological, and agricultural chemistry. As assistant at Schmidt's laboratory worked Johan Lemberg (1842–1902), also an erudite pedagogue and scientist, one of those who founded in Russia a field of science named "chemical geology." The formation of W. Ostwald's scientific view of the world was strongly affected by professor of physics A. von Oettingen (1836–1920).

In April 1875, W. Ostwald graduated from the university with a degree of a candidate of chemistry and, beginning in July of the same year, started to work as assistant at the physics laboratory of the university. Simultaneously, the young scientist commenced his

W. Ostwald, 1887.

experimental investigations. As object of study served acids and salts, whose interaction was analyzed in terms of chemical affinity. W. Ostwald chose as an experimental technique measurements of volume in the reaction of neutralization; later, he also studied other physical properties (refractive index, viscosity, electrical conductivity). In the autumn of 1877, W. Ostwald, having passed necessary examinations, presented dissertation "Volume-Chemical Study of Affinity" for the degree of master of chemistry, and already in December 1878, the degree of doctor of chemistry was conferred on him after he presented his doctoral dissertation "Volume-Chemical and Optical-Chemical Studies."

Beginning in March 1880, W. Ostwald started to work as privat-docent at C. Schmidt's chemical laboratory, but only for a short time: already in December 1881, at the age of 28, he was appointed professor of chemistry at Riga Polytechnic Institute (Polytechnicum) and started lecturing there in January 1882. Riga Polytechnicum, founded in 1862, was the oldest polytechnic educational institution of Russia. The teaching was in German, despite that students of various nationalities studied at the institute. In January 1883, W. Ostwald toured for the first time cities of

1070-4272/03/7610-1705 $25.00 © 2003 MAIK "Nauka/Interperiodica"

Germany and Switzerland and made acquaintance with the best research laboratories and leading chemists and physicists in these countries. In particular, he visited for the first time Leipzig, which was a prominent book-publishing center of that time. With account of his impressions of the trip, a new, well-equipped chemical laboratory was organized at Riga Polytechnicum in 1885. Together with being engaged in pedagogical and organizational activities, W. Ostwald paid much attention to experimental studies. In the beginning of June 1884, he received a paper by young Swedish scientist Svante Arrhenius (1859–1927, 1903 Nobel Prize in chemistry, foreign corresponding member of the St. Petersburg Academy of Sciences since 1903, honorary member of the Academy of Sciences of the USSR since 1926) "A Study of Electrical Conductivity of Electrolytes" (dissertation for the degree of doctor of philosophy). The dissertation was presented on May 26, 1884, at the University of Upsala (Sweden); however, Swedish scientists remained skeptical about Arrhenius's ideas of electrolytic dissociation. At the same time, W. Ostwald immediately understood that Arrhenius's study involved novel approaches, which can strongly affect further development of the theory of solutions and electrochemistry. Already in August 1884, W. Ostwald went to Sweden to make personal acquaintance with Arrhenius [1]. Ostwald's arrival and his support were exceedingly important for Arrhenius and his theory, and this became the beginning of close friendship between the two scientists.

In 1885, W. Ostwald carried out intensive experimental research at his laboratory. In a letter to Arrhenius (1886), he wrote: "...determined the electrical conductivity of 120 acids and performed about 2000 experiments..." [2]. During his residence in Riga (1882–1886), W. Ostwald published more than 30 experimental papers. In the spring and summer of 1886, Arrhenius worked during about six months at W. Ostwald's laboratory. Using a viscometer designed by W. Ostwald, he studied, in particular, the viscosity of dilute aqueous solutions.

In Riga, W. Ostwald completed his fundamental two-volume textbook of general chemistry, which paid much attention to advances in physical chemistry, and work on which was commenced already in Derpt. Both volumes were published in Leipzig [*Lehrbuch der allgemeinen Chemie* (Textbook of General Chemistry), 1885, vol. 1; 1887, vol. 2]. Having completed the textbook, W. Ostwald started to make preparations for publication of a new international physicochemical journal [*Zeitschrift für physikalische Chemie* (Journal of Physical Chemistry)]. W. Ostwald's initiative was supported by prominent scientists from many European countries, including D.I. Mendeleev (1834–1907) and N.A. Menshutkin (1842–1907). Already in June 1887, the first issue of the journal was published in Leipzig; W. Ostwald and J. Van't Hoff, a professor of Amsterdam University, became its editors.

As Stradins noted in his publications devoted to the Riga period of W. Ostwald's activities [3, 4], the scientific achievements of the young professor from Riga, publication of a textbook and journal by him, and his foreign trips got him international fame. In the spring of 1887, W. Ostwald was invited to fill a vacancy of a professor of physical chemistry at Leipzig University, the oldest in Germany (founded in 1409). In the autumn of 1887, W. Ostwald's commenced his pedagogical and scientific activities in Leipzig, where he managed to organize a physicochemical laboratory, which soon became a kind of center of new directions in physical chemistry: Arrhenius's theory of electrolytic dissociation, Van't Hoff's osmotic theory, and theory of catalysis. In 1888, W. Nernst (1864–1941, 1920 Nobel Prize in chemistry) was invited to work at the laboratory as assistant and started studies of the electromotive force of galvanic cells. The closest W. Ostwald's associates also included E. Beckmann (1853–1923), who suggested the design of a high-precision thermometer for determining the molecular weight of solutes by cryoscopy and ebullioscopy, and G. Bredig (1868–1944) specializing in catalysis. Long time was spent at W. Ostwald's laboratory by S. Arrhenius and P. Walden (1863–1957, academician of the St. Petersburg Academy of Sciences since 1910), who was a professor of Riga Polytechnicum and W. Ostwald's pupil.

Despite that W. Ostwald moved to Leipzig, his scientific relations with Riga were not terminated, and a number of W. Ostwald's pupils and colleagues continued earlier commenced investigations. In 1903, W. Ostwald was elected honorary member of the Riga Polytechnic Institute, first translations of his books into Russian were published in Riga. W. Ostwald's relatives also lived in Riga [3]. Particularly close were W. Ostwald's personal and scientific relationships with Walden, who wrote first W. Ostwald's biography in 1903.

W. Ostwald's laboratory in Leipzig was visited by young scientists from many European countries, USA, and Japan. The first among Russian scientists, not counting Walden, was V.A. Kistyakovskii (1865–1952, academician of the Academy of Sciences of the USSR since 1929), who graduated, with a degree of candidate, from the physicomathematical faculty

of St. Petersburg University in January 1889 and decided, on his own initiative, to continue education at W. Ostwald's laboratory in 1889–1890. Kistyakovskii was well acquainted with modern concepts of the theory of solutions, since the Planck–Arrhenius hypothesis was the subject of his graduation thesis. This was one of the first publications in Russia, in which the concepts of Arrhenius, Van't Hoff, W. Ostwald, and M. Planck (1858–1947, 1918 Nobel Prize in physics) were subjected to detailed critical analysis. In Leipzig, Kistyakovskii studied, under the supervision of W. Ostwald and Arrhenius, the electrical conductivity of aqueous solutions of a number of double salts in order to determine the composition of ions formed in dissolution of these salts. The notion of double and complex salts was introduced by W. Ostwald in 1889; in the Russian chemical literature, this notion appeared after Kistyakovskii's publication [5, 6].

In the summer of 1889, privat-docent I.A. Kablukov (1857–1942, honorary academician of the Academy of Sciences of the USSR since 1932) arrived in Leipzig, on a business trip from Moscow University [7]. He studied the electrical conductivity of hydrogen chloride solutions in various solvents. At that same time, A.V. Speranskii (1865–1919), who graduated from Moscow University in 1888 (later, professor of Kiev University), continued his education at W. Ostwald's laboratory. In different years, the following representatives of Russia worked in Leipzig: V.F. Timofeev (1858–1923), D.P. Turababa (1863–1933), A.V. Sapozhnikov (1868–1935), N.A. Shilov (1872–1930), L.V. Pisarzhevskii (1874–1938, academician of the Academy of Sciences of the USSR since 1930), and A.V. Rakovskii (1879–1941, corresponding member of the Academy of Sciences of the USSR since 1933). Young talented scientists from different countries made especially high the level of studies at the physicochemical laboratory of Leipzig University. To Kistyakovskii belongs the well-known phrase: "It is a common opinion that W. Ostwald created a prominent school of physical chemists, but, vice versa, it may be said that this prominent school created W. Ostwald" [8].

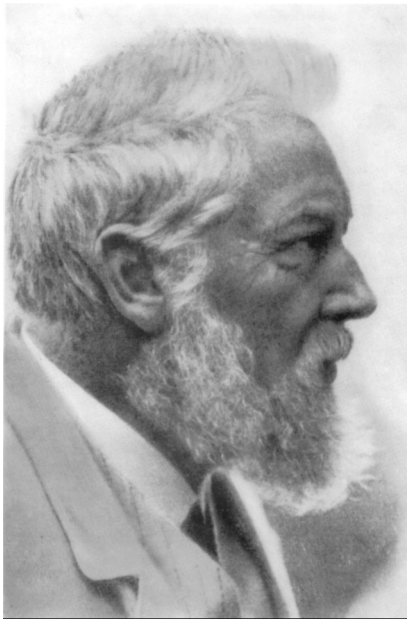
During the period from 1887 till 1906, the international school of physical chemists, headed by W. Ostwald, gave to the world science about 70 scientists, who became professors and heads of laboratories and chairs in different countries [2, 3].

Kistyakovskii in St. Petersburg and Kablukov in Russia, active supporters of new concepts of the nature of solutions, had to deal with strong opponents of the theory of electrolytic dissociation. These included leading Russian chemists of that time: Mendeleev, D.P. Konovalov (1856–1929, academician of the Academy of Sciences of the USSR since 1923), M.D. L'vov (1848–1899), N.N. Beketov (1827–1911, academician of the St. Petersburg Academy of Sciences since 1886), F.M. Flavitskii (1848–1917, professor of Kazan University, corresponding member of the St. Petersburg Academy of Sciences since 1907), and others. More tolerant and unbiased toward Arrhenius's hypothesis was Menshutkin, a professor of St. Petersburg University. Kistyakovskii and, later, Kablukov considered it their task to bring together the two different standpoints concerning the nature of solutions, based on the concept of hydration of ions and their interaction with the solvent.

In 1888, W. Ostwald established an important relationship between the degree of dissociation of an electrolyte and its concentration (Ostwald's dilution law). In 1888–1889, the scientist continued investigations of the electrical conductivity of organic acids to determine the dependence of their constant of electrolytic dissociation on the composition and structure of an acid and established important relationships between the structure and reactivity of organic molecules and studied dissociation of dibasic acids. In 1890–1892, W. Ostwald paid much attention to dyed solutions and their absorption spectra and developed a theory of acid-base indicators. Based on this and other investigations in the field of analytical chemistry, he wrote a manual *Scientific Foundations of Analytical Chemistry* (1894).

In 1889, W. Ostwald founded a series of publications, *Klassiker der exakten Wissenschaften* (Classics of Exact Science), which became widely known, and, later, *Ostwalds Klassiker der exakten Wissenschaften*, which promoted and popularized works of world's most prominent scientists. In 1893, one of W. Ostwald's teachers, professor Oettingen, finished his pedagogical and scientific activities at Dorpat University and moved, by W. Ostwald's invitation, to Leipzig to engage himself in preparation and publication of current issues of the series *Klassiker der exakten Wissenschaften*. In 1966, the 250th issue was published, devoted to W. Ostwald's works in the field of chemical affinity. In 1988, a special monograph was published in tribute of the centennial foundation anniversary of the series [9].

W. Ostwald was among those who initiated foundation of specialized research institutes to solve the most topical problems of chemistry. This idea was embodied in Germany: in 1896, the Institute of Physical Chemistry and Electrochemistry was orga-



W. Ostwald, 1927.

nized in Gottingen for Nernst, who headed the chair of physical chemistry at Gottingen University at that time. In the end of 1897, the Institute of Physical Chemistry was organized in Leipzig for W. Ostwald. The main directions of research at the institute were kinetics and catalysis. W. Ostwald commenced investigations in these fields of physical chemistry already when living in Riga. In 1890, he published an important paper "Autocatalysis," which initiated wide-scale investigations in the field of catalysis. In 1895, there appeared another paper of fundamental importance: "On the Nature of Catalytic Processes." Among the closest W. Ostwald's associates, the already mentioned Bredig studied heterogeneous catalysis. Later (in 1900–1906), extensive studies of the kinetics of homogeneous reactions were carried by M. Bodenstein (1871–1942). Shilov studied the kinetics of conjugated reactions. Results of numerous investigations were summarized by W. Ostwald in a monograph *Über Kataluse* (On Catalysis, Leipzig, 1902; Russian translation in 1903). W. Ostwald's investigations in the field of catalysis were analyzed in detail in a monograph by N.I. Rodnyi and Yu.I. Solov'ev [2].

In August 1906, W. Ostwald finished teaching at Leipzig University. The exceedingly intensive work for 20 years resulted in fatigue and strain. By that time, W. Ostwald was comfortably off and had the rank of privy councilor. Together with the numerous members of his family (three sons and two daughters) he settled at his Energetik country-house at a small town of Grossbothen approximately 30 km southwest of Leipzig.

Shortly before resigning, in the spring of 1904, W. Ostwald delivered a Faraday lecture "Compounds and Elements" at Royal Institute in London. In 1906, in the framework of the first program of exchange of scientists between Germany and the United States, W. Ostwald delivered lectures at a number of universities in USA during a year.

In 1909, as already mentioned, W. Ostwald won Nobel Prize in chemistry "... in recognition of his work on catalysis and for his investigations into the fundamental principles governing chemical equilibria and rates of reaction" [10]. The presentation of the scientist by Swedish Royal Academy of Sciences emphasized the importance of W. Ostwald's discoveries not only for the development of theory, but also for practical use, e.g., for manufacture of sulfuric acid or synthesis of indigo-based dyes. Among the scientists who nominated W. Ostwald for the Nobel Prize was Kablukov.

Having freed himself from his duties as a professor of Leipzig University and head of the Physicochemical Institute, to become a "freelance professor," W. Ostwald could deal with the issues he had always been interested in. One of these was the development of science and the role played in this process by scientific creative work of separate scientists. In 1909, W. Ostwald published a book *Grosse Männer* (Great Men, Leipzig, 1909; Russian translation in 1910), which analyzed the career of six scientists: three chemists (H. Davy, J. Liebig, Ch. Jerard) and three physicists (M. Faraday, R. Mayer, and H. Helmholtz). W. Ostwald's ideas concerning the problems associated with chemical education, influence of age on scientific activities, formation of scientific schools, and quite a number of other issues of research organization have remained topical up to now. During his entire scientific career, W. Ostwald expressed keen interest in the history of science. He studied in most detail the evolution of electrochemistry and described it in a monograph *Elektrochemie: Ihre Geschichte und Lehre* (Electrochemistry: History and Theory, 1895). Later, in 1910, W. Ostwald described the history of electrochemistry in a more popular form; in 1911, this book was translated into Russian.

W. Ostwald proceeded from the assumption that elucidating the laws governing the development of science yields a key to understanding of the present-day situation in science and must ensure deeper understanding of general aspects of the development of society [2].

Already in the late 1890s, W. Ostwald's attention was attracted by philosophical problems of natural science; the scientist's standpoint was described in

his book *Vorlesungen über Naturphilosophie* (Lectures on Natural Philosophy, 1902; Russian translation in 1903) and later publications [2]. W. Ostwald's concept of energy as fundamental principle of the physical world and scientist's skepticism toward the atomic-molecular theory have been repeatedly subjected to justified criticism [11].

W. Ostwald's scientific and organizational activities were extensive and diverse, and his creative heritage is vast. The scientist's career has been the subject of numerous publications, including a detailed autobiography (1926–1927) and recollections of his son, Walter Ostwald (1953). Sufficiently detailed evidence of biographic nature can be found in known reference books [12–14].

Wilhelm Ostwald died on April 4, 1932, at the age of 79. He became part of the history of science as one of the most outstanding natural scientists of his time.

REVIEWS

Effect of Hydrogen Bonding on Cellulose Solubility in Aqueous and Nonaqueous Solvents

A. M. Bochek

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received June 18, 2003

Abstract—Interrelation between the hydrogen bonding energy in cellulose and its solubility in aqueous and nonaqueous solvents is examined. Factors controlling the solubility and selection criteria for nonaqueous solvents for cellulose are analyzed.

Among polymers widely used in various areas of human activities, cellulose, as a steadily renewable native polymer, and its derivatives are of great importance. In this connection, development of green technologies for cellulose processing is a topical problem. Native cellulose fibers are used essentially in textile and pulp and paper industries. It is important also that cellulose and its derivatives as films, fibers, and granules are manufactured generally through polymer solutions [1, 2].

Fabrication of rayon through the xanthate, which was a common process until the mid1980s, includes the use of toxic carbon disulfide [3–6]. In the last two decades, in Russia and other countries, new solvent systems for cellulose were intensively studied as alternatives to the viscose process. Among these systems were nonaqueous (tertiary amine *N*-oxides, aprotic solvents with addition of LiCl, DMF with N_2O_4, trifluoroacetic acid, etc.) and aqueous solvents like aqueous $ZnCl_2$, NaOH, and H_3PO_4 [7–13]. Most of these solvents have not found practical use because of such reasons as toxicity and environmental hazard, limited solvency, problems arising in developing closed processes, and high power consumption in solvent regeneration.

Criteria for predicting the solvency with respect to cellulose are searched for many years. Knowledge of only the thermodynamics of the polymer–solvent interaction does not allow theoretical prediction of the solubility of cellulose in one or another solvent. The solubility of cellulose is influenced by such factors as the fiber morphology, molecular weight, degree of structurization, i.e., origin of the polymer, and also by hydrogen bonding in its structure. All these factors affect characteristics of cellulose solutions and, indirectly, the performance of the resulting fibers and films.

Therefore, it appeared advisable to summarize and correlate information on hydrogen bonding in cellulose and other factors controlling its solubility in aqueous and nonaqueous solvents, and also on the selection criteria for solvents for cellulose.

1. SOLUBILITY PARAMETER δ OF CELLULOSE AND HYDROGEN BONDING IN THE NATIVE POLYMER

The presence of one primary (C^6) and two secondary (C^2, C^3) hydroxy groups in an anhydroglucose unit of cellulose predetermines the occurrence of a system of inter- and intrachain hydrogen bonds in the native polymer. This strongly limits the range of one-component solvents suitable for practical use.

The first systematic studies of hydrogen bonding in ordered regions of the cellulose structure were reported in [14–18]. The conformations of cellulose macromolecules and hydrogen bonding in them were actively studied by Zhbankov and coworkers [19, 20]. In these works, IR absorption spectra of cellulose in the OH stretching region (3000–3700 cm^{-1}) were analyzed to elucidate the arrangement of intra- and interchain hydrogen bonds. Since introduction of instruments of new generation (FTIR spectrometers), these works have been brought up to a higher standard [21–25].

Basing on the Sarko and Blackwell's elementary unit models [26–28], Zbankov and Kozlov [20] theoretically analyzed hydrogen bonding in highly ordered regions of the cellulose structure with parallel arrangement of the cellulose chains. They considered the most stable conformations of the native cellulose chains. The results are given in Fig. 1 and Table 1.

The theoretical estimates confirmed the occurrence of two intra- and one interchain hydrogen bonds in

1070-4272/03/7611-1711$25.00

Table 1. Characteristics of hydrogen bonds in native cellulose (C1) [20]

Type of bonding	O···H distance, Å	E_h, kJ mol^{-1}
Intrachain	1.81	13.2 [26]
$O^{3'}$–H···O^5	1.86	11.5 [28]
O^2–H···$O^{6'}$	1.74	14.9
	1.91	10.0
Interchain	1.96	8.6
$O^{6'}$–H···$O^{3''}$	1.82	12.8

the elementary unit of native cellulose. Table 1 shows that the hydrogen bonding energy in cellulose ranges from 8.5 to 15.0 kJ mol^{-1}. Dissolution of cellulose requires breaking of at least all the interchain hydrogen bonds. There are a number of solvents capable of forming hydrogen bonds with the energies E_h above 13.0 kJ mol^{-1}. These are alcohols, aldehydes, amines, some aprotic solvents, etc. [29]. Water forms hydrogen bonds with E_h = 18.0–21.0 kJ mol^{-1} [29]. However, cellulose does not dissolve in water and the above-indicated solvents under any conditions, suggesting the realization of hydrogen bonds in cellulose with an energy above 21.0 kJ mol^{-1}. Naimark *et al*. [30] studied the interaction of cellulose with plasticizing aprotic and proton-donor solvents and suggested that amines can form hydrogen bonds with the OH groups of cellulose with E_h >21.0 kJ mol^{-1}.

One of the parameters characterizing intermolecular interactions in polymers is the solubility parameter δ introduced by Hildebrand in his regular solution theory [31]. Knowledge of this parameter allows prediction of the cohesion energy of a polymer E_{coh} and also of the nature of intermolecular interactions in the polymer, which may be helpful in directed search for good solvents.

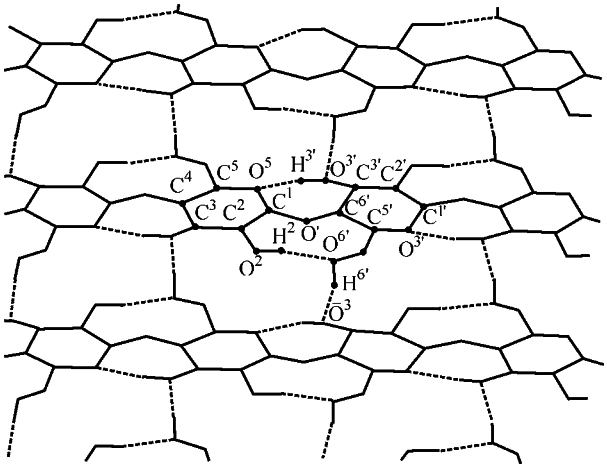

Fig. 1. Intra- and interchain hydrogen bonding in ordered regions of the structure of native cellulose [20].

From the equilibrium swelling, Thode and Guide [32] have determined δ = 28.6 (J cm^{-3})$^{0.5}$ for cellulose. In studying the plasticizing properties of solvents, Naimark *et al*. [30] obtained δ = 52.8 (J cm^{-3})$^{0.5}$, which was assigned to amorphous cellulose. The theoretical estimates obtained for some physical and physicochemical characteristics of cellulose and other polysaccharides revealed that the energy of intermolecular interaction in cellulose amounts to 207.0 kJ mol^{-1}, which corresponds to δ = 29.2 (J cm^{-3})$^{0.5}$ [33]. The cohesion energy of cellulose was reported to be 1296.0 kJ mol^{-1} [34]. Berger and Keck [35] obtained δ = 53.4 (J cm^{-3})$^{0.5}$ for cellulose in crystallites. Swelling of films of hydrated cellulose in aprotic and proton-donor solvents was studied in [36, 37]. In these works we demonstrated that knowledge of the dependences of the degree of swelling on δ of a solvent does not allow estimation of δ of cellulose.

Hansen suggested to consider the cohesion energy of solvents and polymers as a sum of three terms [38, 39]:

$$\delta = \left(\frac{E_{coh}}{V}\right)^{0.5} = \left(\frac{E_d + E_p + E_h}{V}\right)^{0.5} = (\delta_d^2 + \delta_p^2 + \delta_h^2)^{0.5}. \quad (1)$$

where E_d, E_p, and E_h are the contributions of the dispersion and dipole–dipole interactions and hydrogen bonding, respectively, to the cohesion energy; and *V*, volume.

To characterize the parameters of intermolecular interactions, primarily of hydrogen bonding, in cellulose, we proposed a new procedure for determination of the solubility parameter of cellulose and estimated for the first time the partial contributions of the dispersion (δ_d) and dipole–dipole (δ_p) interactions and hydrogen bonding (δ_h) to δ [36]. The procedure involves determination of δ of cellulose acetates with various degrees of substitution (DS) from their solubility diagrams in mixed solvents reported by Malm *et al*. [40]. The δ vs. DS plots appeared to be linear (Fig. 2). By extrapolation of these dependences to zero DS, δ, δ_d, δ_p, and δ_h were determined to be 55.7, 11.7, 35.9, and 42.2 (J cm^{-3})$^{0.5}$, respectively. The δ value thus obtained exceeds considerably that of water and other common solvents. High values of δ, δ_p, and δ_h of cellulose are caused by the features of its chemical structure, specifically, by the system of intra- and

interchain hydrogen bonds contributing significantly to E_{coh} of the polymer.

The theoretical δ as well as δ_d, δ_p, and δ_h appeared to be considerably lower than those obtained experimentally [36, 37, 41]. Discrepancies in δ of cellulose estimated by various methods are probably due to the fact that the contributions of dipole–dipole interactions and hydrogen bonding to the cohesion energy were taken into account to a different extent in each method.

From the experimental δ_h we estimated the hydrogen bonding energy to be E_h = 25.0 kJ mol^{-1} [36, 37], which is about twice that published in the literature for interchain hydrogen bonds in cellulose (Table 1). The value E_h = 25 kJ mol^{-1} is well consistent with that estimated from the shift of the OH absorption bands in IR spectra of cellulose of various origins. Sugiyama *et al*. [42] reported the frequencies of 3240 and 3270 cm^{-1} for the H-bonded OH groups in polymorphs I_α and I_β of cellulose, respectively. From these frequencies, one may estimate the corresponding E_h values using the Sokolov's equation [29]. The result is 26.1 and 23.8 kJ mol^{-1} for the bands at 3240 and 3270 cm^{-1}, respectively, which is in good agreement with E_h estimated from δ_h.

Finally, it is the high E_h typical of hydrogen bonding in cellulose (up to 25 kJ mol^{-1}) that restricts the range of solvents suitable for cellulose.

2. TERTIARY AMINE *N*-OXIDES

Many efforts were made to establish a correlation between the structure of amine oxides and their solvency with respect to cellulose. As early as in 1939, Graenacher and Sallmann have demonstrated that aliphatic and cyclic amine oxides dissolve cellulose at elevated temperature to form 7–9% solutions [43]. They have also formulated the selection criteria: oxides of tertiary amines should contain no more than 14 carbon atoms and be free from aromatic radicals. At that time, amine oxides found no practical application because of relatively low attainable cellulose concentrations. In 1969, Johnson reported on dissolution of cellulose in heterocyclic amine oxides like *N*-methylmorpholine *N*-oxide (NMMO) [44, 45]. He suggested that amine oxides are capable of breaking hydrogen bonds between the OH groups of cellulose chains even in crystalline regions of the cellulose structure by virtue of formation of stronger hydrogen bonds between the OH groups of the polymer and the oxygen atom of an oxide: Cell–O–H···O$^-$←N$^+$R$_3$.

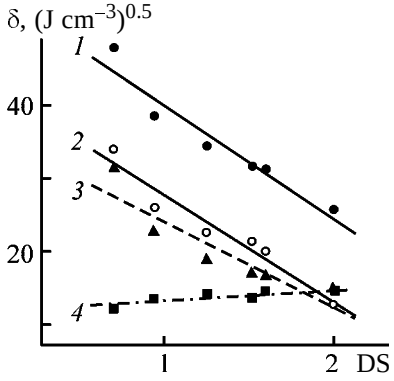

Fig. 2. (*1*) δ, (*2*) δ_h, (*3*) δ_p, and (*4*) δ_d of cellulose acetates as functions of DS [37].

In 1979–1980, Franks and Varga studied the solvency of a broad range of amine oxides of various structures (32 amine oxides) [46, 47]. They have demonstrated that the solvency of amine oxides depends on the water content of the solution and offered certain physical and chemical or, rather, structural criteria for evaluation of amine oxides as solvents for cellulose [48]: (1) *N*-Oxide should be a tertiary amine derivative; (2) preferably, a tertiary amine *N*-oxide having a cyclic molecular structure should be taken, except for triethylamine *N*-oxide (TEAO) and *N*,*N*-dimethylethanolamine *N*-oxide (DMEAO); (3) the size of the ring should be no larger than the size of the glucopyranose unit (5.15 Å); (4) amine oxide should have high dipole moment (at least 4.5 D) to be capable of breaking the hydrogen bonds between the OH groups of cellulose; and (5) solvent should contain water within a specified critical range, to dissolve cellulose at a given temperature.

Franks and Varga offered a so-called polar-steric dissolution mechanism, with special emphasis on the structure of substituents at the nitrogen atom. With the above criteria being met, the hydrophobic part of the amine oxide molecule solvates the glucopyranose unit, shielding it from the nearest neighboring units and promoting dissolution of cellulose.

However, the above-given selection criteria cannot explain different behavior of specific amine oxides with respect to cellulose. For example, NMMO dissolves cellulose, but *N*-ethylmorpholine *N*-oxide (NEMO) does not; TEAO dissolves cellulose, but trimethylamine *N*-oxide (TMAO) does not, even though having a high dipole moment (5.02 D).

Other authors [49, 50] proposed to add two more criteria to those considered above, namely, the basicity of amine oxides (pK_a ~ 5.0) and the steric factor at the nitrogen atom. Shielding of the oxygen of the

Table 2. Interaction energies of amine oxides with water (E_h) and in dimers (E_{dim}) [57]

Amine *N*-oxide	μ, D	E_h	E_{dim}	Solvency*
		kJ mol^{-1}		
TMAO	5.14	28.9	43.9	–
TEAO	4.52	25.9	40.5	+
MO	4.05	18.4		–
NMMO	4.25	25.5	26.4	+
NEMO	4.12	22.5	26.4	–

*(–) Does not dissolve and (+) dissolves.

N→O group by a substituent at the same nitrogen atom may result in the total loss of the solvency even in oxides of high polarity and basicity. Consideration of the steric factor allows understanding of the facts that NMMO dissolves cellulose, but NEMO does not. The methyl substituent is not bulky enough to shield the oxygen atom, permitting strong hydrogen bonding with the OH groups of cellulose. On the contrary, the ethyl substituent strongly shields the oxygen atom of the N→O group, hindering hydrogen bonding. Unfortunately, inclusion of the steric factor into consideration is insufficient to explain the inverse pattern observed for aliphatic amine oxides (TEAO dissolves cellulose, but TMAO does not).

Philipp and coworkers [11, 51] proposed another dissolution mechanism involving formation of a donor–acceptor transition complex. However, inclusion of such a stage into consideration allows explanation of the fact of cellulose solubility, but not its quantitative theoretical prediction.

Analyzing cellulose solubility in the framework of the donor–acceptor interaction, Tsvetkov [52] suggested that cellulose could dissolve only in solvents of high electron-donor power ($DN_{SbCl_5} > 40$). The donor number of NMMO was estimated to be just about 40 [50]. It should be pointed out that the donor number is a measure of the total interaction energy of a given solvent with $SbCl_5$, but it does not always provide information on the specific interaction of the solvent with a fixed functional group of the polymer. For example, DN_{SbCl_5} of diamines, ethylenediamine and tetramethylethylenediamine, were estimated to be 50 and 55, respectively. However, they do not dissolve cellulose [53]. Note also that *DN* of solvents can depend on the determination procedure [54].

Tsygankova *et al*. [55] have performed MNDO quantum chemical calculations of some electronic structure parameters (dipole moment, ionization potential, and electron density distribution) for a series of tertiary amine oxides both not dissolving (TMAO) and dissolving cellulose (TEAO, NMMO, and NMMO monohydrate). The authors found no significant differences in the above-indicated parameters of the electronic structure which could explain the lack of the solvency in the amine oxides that are very similar in their electronic structure to those dissolving cellulose.

Yakimanskii *et al*. [56] applied the same calculation procedure to broader ranges of amine oxides and their monohydrates and calculated a larger set of electronic characteristics. They studied the electronic structure of TMAO, TEAO, morpholine *N*-oxide (MO), NMMO, NEMO, DMEAO, and their monohydrates and also the cellulose solubility in them. The electronic structure analysis included such characteristics as the HOMO and LUMO energies, dipole moment and its derivatives, charge distribution, and $2p_x$, $2p_y$, and $2p_z$ populations. As in [55], results revealed that none of the parameters taken alone could be used as a criterion for predicting the cellulose solvency of amine oxides. It may be suggested that it is governed by some set of electronic structure parameters, each being responsible for certain contribution to the total solvent–polymer interaction energy.

The affinity of amine oxides for water can be used to elucidate their affinity for the OH groups of cellulose. Yakimanskii *et al*. [56] have estimated the energy of hydrogen bonding E_h between water and amine oxides. For completeness sake, Bochek *et al*. [57] have also estimated the cohesion energies of solvents in dimers E_{dim}. In the anhydrous state, NMMO molecules are arranged so that the dipolar N→O bonds in the adjacent molecules are antiparallel [58].

Table 2 shows that only combined analysis of the energies of hydrogen bonding of amine oxides with the OH groups (E_h), on the one hand, and the cohesion energies of amine oxides in dimers E_{dim}, on the other hand, opens the door for formulation of the selection criteria for solvents for cellulose. As shown above, cellulose is soluble in amine oxides capable of forming high-energy (>25.0 kJ mol^{-1}) hydrogen bonds with the OH groups. The value of 25 kJ mol^{-1} corresponding to the maximal hydrogen bonding energy in cellulose bounds the range of one-component solvents for cellulose. It is seen also that the ability of amine oxides to form hydrogen bonds with E_h >25 kJ mol^{-1} is a necessary but not sufficient condition to ensure cellulose solubility. It is also necessary that E_{dim} of solvents be lower than, or at least close to the indicated critical value. The enthalpy of

cellulose interaction with NMMO monohydrate was found to be ΔH_{int} = 24.6 [52, 59] and 24.1 kJ mol^{-1} [60]. The validity of these estimates is supported by the closeness of E_h and ΔH_{int} in the case of NMMO monohydrate.

As seen, E_h and E_{dim} are close to each other only in NMMO. In aliphatic TMAO and TEAO, E_{dim} is considerably higher. Cellulose dissolves in amine oxides upon heating. Although hydrogen bonding between an amine oxide and the OH groups of cellulose is an exothermic reaction, elevation of the temperature is needed to overcome the self-association and crystallization in the solvent [61]. The E_{dim} in amine oxides can be lowered also by adding certain critical amount of water, which results in reduction of the melting point of NMMO monohydrate (TEAO monohydrate is a liquid at room temperatures). It could be concluded from Table 2 that TMAO, having the highest E_h (28.9 kJ mol^{-1}) among the solvents studied, should demonstrate the highest cellulose solvency. However, this solvent has also the highest E_{dim}, and neither elevation of the temperature nor addition of water allows reduction of E_h to the desired value. It is not unlikely that some additional conditions are necessary for TMAO to provide decrease in E_{dim}.

3. AMIDE/LiCl NONAQUEOUS SOLVENT SYSTEMS

Like tertiary amine *N*-oxides, some nonaqueous solvent systems containing an aprotic solvent and LiCl can directly dissolve underivatized cellulose. The interest in such systems is initiated by the possibility of dissolution of synthetic and natural polymers other than cellulose, to obtain highly concentrated solutions convenient for formation of fibers and films.

Initially, the system dimethylacetamide (DMAA)–LiCl was employed for dissolution of proteins [62], amides [63], and chitin [64, 65]. Then, McCormic *et al*. [66] have demonstrated that DMAA–LiCl can dissolve cellulose with formation of concentrated solutions containing mesomorphic phases. Among a great number of nonaqueous salt-containing systems, only certain amides with addition of LiCl dissolve cellulose. These are DMAA, methylpyrrolidone, and hexamethylphosphoric triamide [17, 62, 67, 68]. Recent studies [69, 70] revealed that cellulose is soluble also in a series of other LiCl-containing nonaqueous systems.

Tsygankova *et al*. [71] performed quantum chemical study of the DMAA–LiCl system, including the electronic structure and geometry of the $(DMAA)_n \cdot LiCl$ complexes. They found that, at n = 3, a high negative charge is localized on the Cl^- ion of the molecular complex formed, increasing the tendency to hydrogen bonding with organic hydroxy compounds via the chloride ion.

By now, researchers offered seven mechanisms for dissolution of cellulose in the DMAA–LiCl system [10, 13, 64, 66, 69, 72]. Several authors [62, 66, 72] believe that cellulose interacts with the DMAA–LiCl complexes in which LiCl occurs in the ionic form. The thought of other authors [64, 67, 69] is that lithium chloride is in the molecular form. Yakimanskii *et al*. [73] analyzed the electronic structure of DMAA and DMF complexes with both ionic and molecular LiCl using MNDO calculations. The system DMF–LiCl, which does not dissolve cellulose under the same conditions, was selected as a reference.

Analysis of the electronic structure parameters (charge distribution, bonding energy, and dipole moments) of the complexes with LiCl in the molecular form revealed no significant differences between the corresponding parameters of the two systems, which could account for the lack of solubility in the DMF–LiCl system.

For the complexes with ionic LiCl, dissociation of LiCl in the amides should be taken into account [Eqs. (2) and (3)]. Assuming that the complexes interact with cellulose via Cl^- ion, the difference in the cellulose solvency of the systems should be attributed to the different dissociation energies (E_d).

$$DMAA \cdots LiCl \rightleftarrows [DMAA \cdots Li]^+ + Cl^-, \quad (2)$$

$$DMF \cdots LiCl \rightleftarrows [DMF \cdots Li]^+ + Cl^-. \quad (3)$$

MNDO calculations with full optimization of the geometry of the ionic complexes $[DMAA \cdots Li]^+Cl^-$ and $[DMF \cdots Li]^+Cl^-$ were performed. The E_d for reaction (2) appeared to be lower by 23.0 kJ mol^{-1} as compared to (3), i.e., LiCl more readily dissociates in DMAA. Comparison of the estimated bonding energies between water molecules and the resulting cations $[DMAA \cdots Li]^+$ and $[DMF \cdots Li]^+$ showed that they are similar, being 110.0 and 113.3 kJ mol^{-1}, respectively.

At the same LiCl concentrations in the amide solutions, the amount of reactive cations $[amide \cdots Li]^+$ will be considerably higher in DMAA, which, evidently, is responsible for the ability of the DMAA–LiCl system to dissolve cellulose [69]. This analysis

is supported by the results reported in [74], demonstrating that cellulose dissolves in both the DMAA–LiCl and DMF–LiCl systems. However, in the case of the latter system, dissolution requires activation of cellulose with liquid ammonia.

The established correlation between the cellulose solvency of the nonaqueous amide–LiCl systems and the degree of dissociation of LiCl in them confirms the concept that dissolution of cellulose proceeds through interaction with the complex amide···LiCl in which the salt occurs in the ionic form.

4. EFFECT OF PHYSICOCHEMICAL MODIFICATION ON HYDROGEN BONDING IN CELLULOSE

Solubility of cellulose in technology-relevant solvents can be realized through a decrease in its cohesion energy by virtue of weakening of the hydrogen bonding. Dissolution of cellulose in the cuprammonium solvent followed by precipitation changes the crystallinity index of the polymer [75]. Regenerated cellulose with a low crystallinity index is soluble in aqueous NaOH. The solubility considerably decreases with increasing molecular weight. Any cellulose polymorph can be fully dissolved in 5% NaOH, as demonstrated with 2% cellulose solutions [76].

The effect of modification of the system of hydrogen bonds in cellulose by steam explosion on its solubility in 9% alkali was studied in [77–80]. In these works, cellulose of various origins and polymorphs (CI, CII, and CIII) with different MWs and crystallinity indices was studied. Treatment by steam explosion produces degradation of cellulose macromolecules and partial break of intra- and interchain hydrogen bonds. The solubility of cellulose in aqueous alkali increases as MW decreases and hydrogen bonds (primarily intrachain bonds $O^5\cdots HO^{3'}$ and $O\text{–}H^2\cdots O^{6'}\text{–}H$) break. From cellulose thus treated, 4–5% solutions can be obtained, suitable for fiber formation [81].

However, this process for rayon production has not found wide use. In our opinion, the major drawbacks are low degree of polymerization ($DP < 400$) and low concentration of the resulting cellulose solutions (4–5%).

The hydrazine process for preparation of cellulose solutions [12] may also be classified with the processes based on partial breaking of hydrogen bonds in the polymer through physical impact. It is known that a series of amines, among them hydrazine, at atmospheric pressure form high-molecular-weight inclusion compounds with cellulose [82]. True solutions of cellulose can be obtained by heating the polymer in hydrazine at 100–200°C and a pressure of up to 0.7 MPa (7.0 atm). Evidently, elevated pressure modifies both the system of hydrogen bonds in cellulose and physicochemical properties of the solvent.

5. CHEMICAL MODIFICATION OF CELLULOSE

Introduction of new functional groups into cellulose macromolecules modifies the initial system of hydrogen bonds, distorts the regular arrangement of cellulose chains, and changes the supramolecular structure of the polymer toward a decrease in the macrochain ordering.

It is known [83] that a series of cellulose derivatives, viz., methyl cellulose, ethyl hydroxyethyl cellulose, hydroxyethyl cellulose, hydroxypropyl cellulose, hydroxypropyl methyl cellulose, methyl ethyl cellulose, and carboxymethyl cellulose sodium salt dissolve in water, the convenient solvent from the technological standpoint. The indicated cellulose derivatives are widely used as gelling agents, thickeners, stabilizers, and emulsifiers in food industry [1].

Introduction of the acetate groups within a rather narrow DS range from 0.4 to 1.0 makes cellulose water-soluble [84–86]. A necessary condition of solubility of cellulose acetate (CA) in water is a regular distribution of the substituents along the macrochains and in the anhydroglucose units [40, 86, 87]. Therefore, it appears advisable to analyze factors influencing the solubility of cellulose derivatives with an example of CA.

In [88] we reported the results of a comparative study of interaction of cellulose and CA of various DS with water, ethanol, and chloroform, aimed at elucidation of the effect of modification of the system of hydrogen bonds, produced in cellulose by introduction of the acetate groups, on the thermodynamic affinity of the polymers for water.

Introduction of the acetate groups into cellulose increases the difference in the surface energy γ of the polymer and a solvent, i.e., promotes hydrophobization of the polymer, thus making worse the wettability of the polymer with water and hindering the diffusion of the solvent to the polymer matrix. With further increasing DS, the difference in γ between the polymer and a solvent becomes so large that cellulose triacetate does not longer dissolve in water. It is the increase in the hydrophobicity of the polymer that determines

the DS upper limit in water-soluble cellulose acetates of 1.0.

In [88] we demonstrated that the solubility of CA in water is realized within the DS range in which δ of the polymer is equal to or lower than δ of a solvent. In this range, the polymer–solvent interaction parameter χ_1 is minimal. To obtain water-soluble CA, it is necessary to decrease the contribution of hydrogen bonding to the cohesion energy, which was dominant in the initial cellulose. Introduction of small amounts of the acetate groups (on the condition of their regular distribution in the macromolecular chains and glucose units) significantly modifies the system of hydrogen bonds typical of the initial cellulose toward a decrease in the amount and energy of these bonds, which predetermines the phenomenon of solubility in water. Further increase in the content of acetate groups is accompanied by increasing difference in the surface tension between the polymer and the solvent (hydrophobization of the polymer), resulting in the loss of solubility. Cellulose propionates obtained by a similar process are insoluble in water because of a stronger increase in their hydrophobicity [1]. Therefore, the solubility of CA in water is a result of modification of the initial system of hydrogen bonds toward a decrease in their energy and amount (supramolecular level) and also of a change in the hydrophilic–hydrophobic balance of the macromolecules (molecular level) [88].

Processes of cellulose dissolution through chemical modification include those with mineral or organic acids as solvents. In acid solutions, derivatization of cellulose occurs with formation of soluble products. Among the acid solvents are nonaqueous systems with formic acid (cellulose formate is formed as a soluble product), trifluoroacetic acid (cellulose trifluoroacetate), DMF–N_2O_4, DMF–SO_3, dimethyl sulfoxide–paraformaldehyde, and also concentrated mineral acids [7, 8].

CONCLUSION

Analysis of the literature shows that the presence of hydrogen bonds with an energy of up to 25.0 kJ mol^{-1} in cellulose strongly confines the range of solvents for this polymer. Therefore, it is rational to search for new solvent systems for cellulose in at least two directions. The first one is search for solvents capable of forming hydrogen bonds with an energy above 25 kJ mol^{-1}, taking into account that strongly polar solvents tend to association, as was demonstrated with an example of tertiary amine *N*-oxides. In nonaqueous mixed solvent systems (amide + LiCl), the solubility of cellulose is controlled by the amount of reactive cations formed and also by the polymer preactivation conditions.

Another line is to decrease the energy of hydrogen bonds in cellulose by physicochemical or chemical modification.

Received June 6, 2003

Abstract—Conditions were studied for the dissolution in HF of hydrated tantalum(V), niobium(V), and titanium(IV) oxides, which are formed by acid decomposition of loparite, and also for the selective extraction of Ta(V) with octanol from the resulting fluotitanic solutions.

One of the largest sources of titanum–rare metal raw materials in Russia, Lovozero deposit of loparite ores, is located on the Kola peninsula. As compared to conventional raw materials used abroad (pyrochlore, tantalite, columbite, etc.), rare-earth titanoniobate loparite is a lean rare-metal raw material, but at the same time it contains several valuable components: tantalum(V), niobium(V), titanium(IV), and rare earths(III). After dressing, the loparite concentrate contains (wt %) Ta_2O_5 0.60–0.65, Nb_2O_5 7–8, TiO_2 38–40, and Ln_2O_3 30–32 [1].

Growth of the production of loparite concentrate not only makes it possible to meet the demands of the existing and future applications of rare and rare-earth elements, but also allows the export of these elements. Because of the complex composition of loparite, problems arise with the separation of its useful components and their recovery as commercial products. An efficient direction in loparite processing is its acid decomposition with HNO_3 or HCl [2, 3]; in the process, rare earths(III), strontium(II), calcium(II), and other components pass into solution, whereas tantalum(V), niobium(V), and titanium(IV) are concentrated in the precipitated hydrate cake (HC) as hydrated oxides. The hydrate cake is dissolved in hydrofluoric acid with the subsequent extractive separation of tantalum(V), niobium(V), and titanium(IV) [4–7]. Hydrofluoric acid can be practically completely regenerated by pyrohydrolysis with simultaneous formation of metal oxides; the regenerated HF is recycled to the HC dissolution [2].

This work was mainly focused on HC dissolution in hydrofluoric acid with the aim to minimize HF consumption and to obtain solutions with high contents of target components, and also on the search for conditions of tantalum(V) selective extraction from the acid fluoride solution. The composition of the examined HC samples after nitric acid (HNO_3) and hydrochloric acid (HCl) breakdown is given in Table 1. Hydrate cakes were obtained in the trials of the corresponding processes [3, 8]. The presence of rare earths(III) in HC(HNO_3) results from the presence of non-decomposed loparite.

A 50-g sample was placed in a beaker equipped with a stirrer and a lid (all fluoroplastic) and filled with an HF solution (400 g l^{-1}) preheated to a specified temperature. The amount of HF corresponding to the reaction stoichiometry was calculated assuming formation of $HTaF_6$, $HNbF_6$, H_2TiOF_4, H_2SiF_6, and LnF_3 (according to [4, 9], these compounds dominate in the system under study). The dissolution was carried out in a thermostat at 20 ± 1 or 50 ± 1°C for 6 h. After filtration, the precipitate was washed with water by repulping at s : l ≈ 1 : 5, filtered off, and dried at approximately 100°C. The procedures for extraction of Ta(V) and Nb(V) from fluoride solutions and for analytical control are given in [4].

Figures 1 and 2 show that decomposition of HC(HNO_3) involves a greater amount of HF than the

Table 1. Composition of HC after loparite acid decomposition

Cake	Content, wt %				
	Ta_2O_5	Nb_2O_5	TiO_2	Ln_2O_3	SiO_2
HC(HNO_3)	0.77	10.2	51.6	5.8	2.2
HC(HCl)	0.50	8.4	63.6	–	–

1070-4272/03/7611-1720$25.00

dissolution of HC(HCl). This is apparently due to the presence of a loparite impurity in HC(HNO_3) and, as a consequence, to the formation of a precipitate of fluorides of rare-earth elements, which hampers the dissolution of hydrated oxides of rare metals in HF. Unchanged loparite can be fairly easily separated by hydroclassification [2], which will allow the consumption of HF for the decomposition of HC(HNO_3) to be reduced.

In dissolution of the two kinds of HC at HF deficiency, titanium(IV) behaves differently. According to X-ray phase analysis, HC contains an impurity TiO_2-rutile phase, and its content in HC(HCl) is higher than in HC(HNO_3). As rutile relatively difficultly dissolves in HF, the passing of the elements into the liquid phase in the course of HC(HNO_3) decomposition decreases in the order Ti(IV) > Ta(V) ≥ Nb(V), and for HC(HCl), in the order Ta(V) > Nb(V) ≥ Ti(IV).

It is interesting that, at 20°C, rare elements are recovered into solution from HC(HCl) at a low HF consumption better than at 50°C. Presumably, under the conditions of HF deficiency and of heating, Ta(V), Nb(V), and Ti(IV) fluorides are hydrolyzed to give poorly soluble oxofluorides. When the HF amount exceeds that required by the stoichiometry, which ensures sufficiently high content of free HF in the solution, the recovery of the elements into the liquid phase at 50°C is higher than at 20°C.

The behavior of Ta(V), Nb(V), and Ti(IV) during the dissolution of HC should be studied additionally. However, it should be noted that the above-mentioned features of the distribution of rare elements between the solid and liquid phases are observed only under conditions of HF deficiency. With large amounts of HF, ensuring virtually complete recovery of the target components into the liquid phase, which is of the greatest interest for technology, the difference in the distribution of Ta(V), Nb(V), and Ti(IV) is leveled out, and their behavior becomes similar.

Thus, we recommend to dissolve HC(HNO_3) and HC(HCl) at approximately 50°C, with the amount of HF being 130 and 115% of the stoichiometric amount, respectively. The solutions obtained under these conditions (with 400 g l^{-1} HF) contain (g l^{-1}) TiO_2 200–250, HF 320–340, and HF_{free} 50–75; hereinafter HF_{free} is the calculated content of HF in excess of that required for the formation of $HTaF_6$, $HNbF_6$, H_2TiOF_4, and H_2SiF_6. Tantalum(V) and niobium(V) can be most efficiently recovered from the fluotitanic solutions by extraction. In this case there is no need to add sulfuric or another inorganic acid into the system to improve the extraction and separation of tantalum(V) and niobium(V) [9], as the necessary acidity is provided by the formation of tetrafluorooxotitanic acid H_2TiOF_4 in the system [4–7].

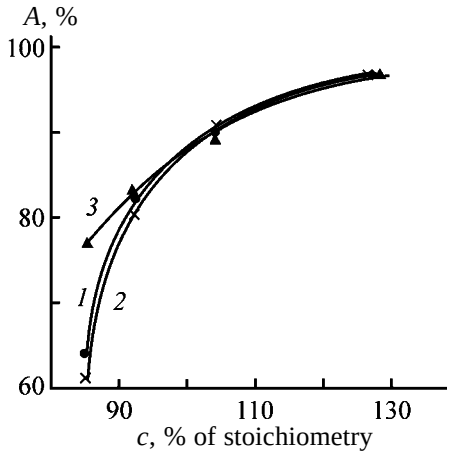

Fig. 1. Influence of HF amount taken *c* on the recovery *A* of (*1*) Ta(V), (*2*) Nb(V), and (*3*) Ti(IV) into the liquid phase from HC(HNO_3) at 50°C.

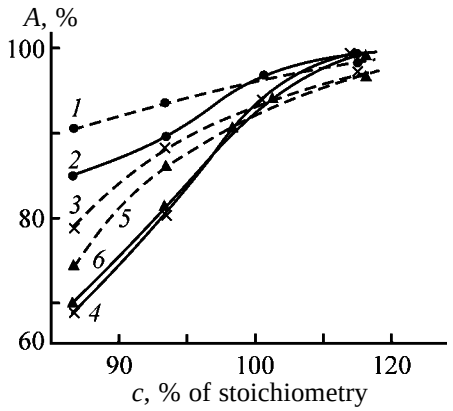

Fig. 2. Influence of HF amount taken *c* on the recovery *A* of (*1, 2*) Ta(V), (*3, 4*) Nb(V), and (*5, 6*) Ti(IV) from HC(HCl) at (*1, 3, 5*) 20 and (*2, 4, 6*) 50°C.

To recover pure tantalum(V) and niobium(V) compounds from fluotitanic solutions, we previously suggested flowsheets based on successive extraction of Ta(V) and Nb(V) with tributyl phosphate (TBP) [4, 5] or on the extraction of the sum of Ta(V) and Nb(V) with 1-octanol (OCL) followed by separation of the target components in the back-extraction stage [6, 7]. The use of OCL as an extractant is preferential, because it is more stable in an acidic medium than TBP [10].

The drawback of the flowsheet involving OCL [6, 7] is the joint extraction of Ta(V) and Nb(V). At the same time, the scheme of successive extraction of Ta(V) and Nb(V) [9] is more convenient both for controlling the process and for ensuring reproducibly high quality of the product. This flowsheet is also

13	175	–	62	328	0.5 : 1	–	84.0	3.2

characterized by smaller flows of the extractant and, correspondingly, by better economical parameters (Table 2).

After HC decomposition with hydrofluoric acid, the solutions were evaporated to the TiO_2 content of about 500 g l^{-1} to reduce flows in the extraction processing stage and to distill off excess HF which can be used for HC dissolution. However, the joint extraction of Ta(V) and Nb(V) from the evaporated solutions still takes place (Table 2, run nos. 1–3), apparently, owing to high content of both HF_{free} and H_2TiOF_4. To reduce the concentration of HF_{free} and to improve the separation of Ta(V) and Nb(V) [9], we used the simplest way of the process control [11], dilution. The twofold dilution resulted in successful selective extraction of Ta(V) (Table 2, run nos. 4–7). Under the best conditions ($V_{org} : V_{aq}$ = 0.1 : 1), 89% of Ta(V) is extracted in a single stage at insignificant recovery of Nb(V) and especially Ti(IV) (about 8 and 0.2%, respectively). With a continuous counterflow process, it is possible to extract Ta(V) virtually completely in 4–5 equilibrium steps and to obtain an extract containing 30–40 g l^{-1} Ta_2O_5.

The addition of HF to the solution from which Ta(V) was removed allows also efficient recovery of Nb(V) at a low Ti(IV) coextraction (Table 2, run nos. 9, 10, 12, and 13). Table 2 shows that an increase in the HF concentration reduces the passing of Ti(IV) into the organic phase, apparently owing to an increase in the relative content of the poorly extracted dibasic acid H_2TiF_6 [6] among fluotitanic acids. However, the drawback of the suggested process for Nb(V) extraction is the necessity of introducing large amounts of HF into the system, which makes worse the economical parameters of the process owing to the additional consumption of the expensive chemical and to an increase in flows of organic and aqueous solutions in the system. A better choice is the repeated evaporation of the solution after Ta(V) recovery to the TiO_2 content of about 500 g l^{-1} and the extraction of Nb(V) at a relatively low ratio $V_{org} : V_{aq}$ = 0.5 : 1 (Table 2, run no. 2) to obtain the extract containing up to 200 g l^{-1} Nb_2O_5. This approach allows realization of a compact process providing a high content of target components in extracts, considerably decreased consumption of chemicals (including the consumption during washing of organic phases), and reduced size of the equipment.

Thus, the data obtained allow us to offer the following principal scheme involving OCL extraction for the processing of solutions from HC decomposition: evaporation of the solution to the TiO_2 content of about 500 g l^{-1}, followed by dilution by a factor of 1.5–2; extraction of Ta(V) at $V_{org} : V_{aq} \approx 0.1 : 1$, evaporation of the aqueous solution to the TiO_2 content of 500 g l^{-1}; extraction of Nb(V) at $V_{org} : V_{aq} \approx 0.5 : 1$; and then pyrohydrolysis of the fluotitanic raffinate to obtain commercial TiO_2 and regenerate HF [2].

Impurities can be efficiently removed from Ta(V) and Nb(V) extracts by washing with fluoride solutions of these elements, aqueous solutions of HF and(or) H_2SO_4, or water, and the purified target components can be back-extracted with water [6, 7, 12, 13].

The conditions of HC dissolution and of Ta(V) and Nb(V) extraction found in this work are also suitable after slight modification for the acid (HNO_3 or HCl) decomposition of another rare-earth titanoniobate, perovskite, a high-grade deposit of which is also located on the Kola peninsula [14].

CONCLUSIONS

(1) The precipitate of hydrated Ta(V), Nb(V), and Ti(V) oxides formed by nitric or hydrochloric acid decomposition of loparite should be dissolved in HF taken in amount of 130 and 115%, respectively, relative to the amount corresponding to the stoichiometry of the formation of fluoride complexes of these elements.

(2) Conditions were found for the successive extraction of Ta(V) and Nb(V) with octanol from fluotitanic solutions to obtain extracts containing 30–40 g l^{-1} Ta_2O_5 and up to 200 g l^{-1} Nb_2O_5.

Abstract—The qualitative and quantitative composition of volatile products of zinc selenide oxidation with atmospheric oxygen was determined. The influence of the process conditions on quantitative composition of the volatile products was studied.

Oxidative roasting of ZnSe is one of ways of processing waste from its production. The advantages of this method are that it does not require sophisticated equipment and large amounts of expensive chemicals. However, published data on the oxidation of powders [1–3], polished plates [3, 4], and single crystals [5, 6] of ZnSe are ambiguous [7]. In particular, the composition of volatile products of ZnSe oxidation with oxygen is still unclear.

In this connection, our goal was to determine the quantitative composition of the volatile products of ZnSe oxidation with atmospheric oxygen and also to study how the process conditions affect their ratio. The objects of the study were wastes of ZnSe plates and spent polishing powders of various grain-size distributions from manufacture of optical components for IR engineering from polycrystalline zinc selenide.

EXPERIMENTAL

The oxidation of small (10–30 g) amounts of ZnSe without forced air circulation (installation I) was described in detail in [7].

We developed and manufactured installation II for the oxidation of large (0.5–1.5 kg) amounts of zinc selenide. It includes an inclined tubular quartz reactor of length l = 400 mm and diameter d = 50 mm and three receivers connected by ground-quartz joints. The design of the first receiver allows unloading of the formed product during operation of the installation. Owing to the inclined arrangement of the reactor and receivers, a nonforced steady-state air flow arises when the reactor is heated with a tubular resistance furnace.

Later we developed and manufactured installation III for the oxidation of 400–500 g of zinc selenide in a forced air flow (Fig. 1). The installation includes a quartz reactor (l = 1150, d = 16 mm) and two receivers. The first of them consists of a narrow part (l = 305, d = 20 mm) and a wide part (l = 370, d = 40 mm). The receiver is tightly connected to the reactor by the narrow part, and the wide part serves for collecting volatile products. The second receiver, which has the size of the wide part of the first receiver, is connected to it by ground-quartz joints. The reactor is heated with a tubular resistance furnace. The controllable air flow is created with a compressor; a special unit is arranged at the outlet to keep the flow constant. The flow rate at the reactor outlet was measured at regular intervals with a rotameter. The completeness of the condensation of volatile products was checked at the outlet of the second receiver using a qualitative test for Se(IV) with thiourea according to the technique suggested in [8].

In all experiments, the grain-size distribution of powders was determined by mesh analysis. The temperature was measured accurate to 3% using a preliminarily calibrated chromel–alumel thermocouple. The degree of ZnSe conversion was determined by a gravimetric procedure: a preliminarily weighted reactor with a weighed sample of the substance was taken from the furnace, cooled, and weighed. To analyze volatile oxidation products, the receivers were detached at regular intervals, weighed, and volatile oxidation products were withdrawn.

Volatile oxidation products were qualitatively analyzed by chemical methods. For this purpose, the products were dissolved in distilled water, and the undissolved residue was filtered off. The filtrate was treated with sodium sulfite in a hydrochloric acid medium, hydrogen sulfide, thiourea, and hydrochloric acid solution of tin(II) chloride according to the procedure suggested in [9]. In the case of the first three reagents, a red precipitate of elemental selenium was formed, which suggests the presence of SeO_3^{2-} and SeO_4^{2-} ions in solution. To determine them separately, we used tin(II) chloride, which reacts in solution only with SeO_3^{2-} ions to form a precipitate of elemental selenium at temperatures below 20°C, whereas SeO_4^{2-} ions are reduced to selenium with tin(II) chloride only on boiling the solution. The precipitate after filtration was boiled with a 1.5 M Na_2SO_3 solution, which is, according to [10], a selective solvent for selenium. The treatment of the resulting product (Na_2SeSO_3) with concentrated sulfuric acid yields a red precipitate of elemental selenium. We also used a reaction of the precipitate with cold H_2SO_{4conc}. It reacts with selenium to give a green solution ($SeSO_3$), which also forms a red precipitate of elemental selenium on dilution [11].

To determine the quantitative composition of volatile reaction products, we used a technique developed and described in detail in [12]. It involves dissolution of the weighed product in distilled water, filtration of the precipitate, and its drying and weighing.

The oxidation of zinc selenide in a nonforced air flow was carried out on installation II at 600°C, which was found to be optimal for ZnSe oxidation [7]. The weight of the ZnSe sample was 600 g, and the particle size, 0.6–2.5 mm. The qualitative analysis of volatile products by the above-described technique showed that the precipitate was elemental selenium and the filtrate, solution of H_2SeO_3 formed upon dissolution of the liberated SeO_2 in water. Therefore, the volatile product of ZnSe oxidation with atmospheric oxygen is a mixture of elemental selenium and its dioxide;

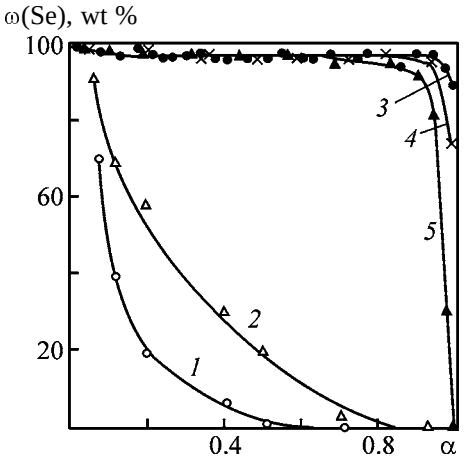

Fig. 2. Content of selenium ω(Se) in volatile products of zinc selenide oxidation with atmospheric oxygen. (α) Degree of ZnSe conversion. Oxidation on installation II in (*1*) nonforced and (*2*) forced air flow; oxidation on installation III at a flow rate (ml min^{-1}) of (*3*) 9.5, (*4*) 40, and (*5*) 110.

their ratio varies in the course of the process (Fig. 2, curve *1*). It was found previously that ZnO is a nonvolatile oxidation product [7]. Thus, we suggest the following equation for the oxidation of zinc selenide:

$$ZnSe + (1/2 + y)O_2 \rightarrow ZnO + xSe + ySeO_2.$$

where the coefficients x and y change during the process ($x + y = 1$).

As seen from Fig. 2, the content of elemental selenium in the products is high, especially in the beginning of the process. It contradicts the previous thermodynamic calculations [7], according to which SeO_2 is the main volatile product of the reaction between ZnSe and atmospheric oxygen. Furthermore, when air is passed through the reactor fully packed with the charge, the content of elemental selenium in the products is even higher (Fig. 2, curve *2*).

To account for this inconsistency, we assumed that, when SeO_2, which is a highly active oxidant, passes through a bed of unchanged ZnSe, the following reaction between these compounds is possible:

$$2ZnSe + SeO_2 \rightarrow 2ZnO + 3Se.$$

We performed a thermodynamic calculation of the system ZnSe–SeO_2 in the temperature range 500–1500 K, which confirmed the possibility of this process. The calculated equilibrium concentrations of the components (mole per total number of moles of the starting compounds) are shown in Fig. 3. It is seen from Fig. 3 that Se_2 is the major volatile product of

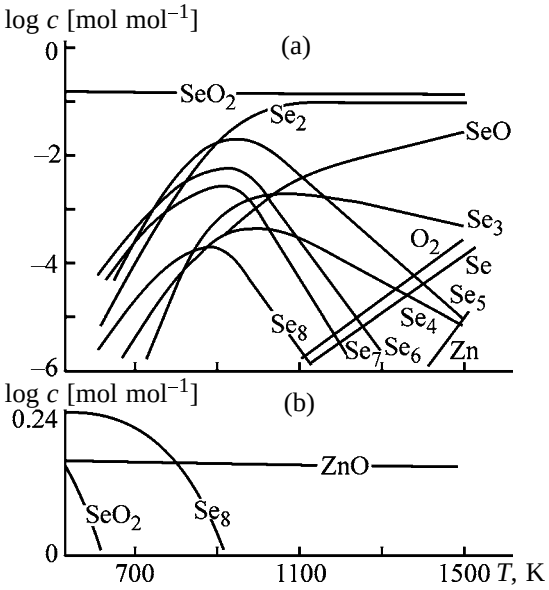

Fig. 3. Temperature dependence of the equilibrium composition of the system ZnSe–SeO_2. (*c*) Equilibrium concentration of a component. Phase: (a) gas and (b) solid.

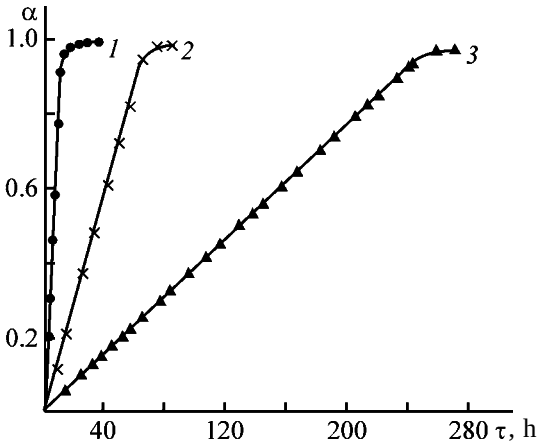

Fig. 4. Kinetic curves of ZnSe oxidation in a forced air flow: (α) degree of zinc selenide conversion and (τ) time; the same for Fig. 5. Flow rate, ml min^{-1}: (*1*) 110, (*2*) 40, and (*3*) 9.5.

the reaction. Its content in the gas phase increases in the range 600–1000 K and does not noticeably change at higher temperatures. The content of condensed selenium is maximal in the range 500–700 K and decreases to zero at 900 K. Therefore, under the conditions ensuring complete reduction of the liberated SeO_2 with ZnSe, with no excess O_2 in the flow, we can expect that the resulting volatile product will consist exclusively of elemental selenium. To check this assumption, we performed experiments on installation III.

The experiments on the oxidation of ZnSe in a forced air flow were carried out at 600°C with particles of the size 2.5–4.5 mm in the range of the air flow rate 9.5–110 ml min^{-1}. When the air flow is passed through the reactor, the oxidation initially occurs in the narrow zone in the beginning of the reactor, which can be visually monitored as a change in the color of the charge from lemon yellow (ZnSe color) to white (ZnO color). In this case, the volatile products pass through a bed of ZnSe not exposed to oxidation and react with it. In time, the length of the white zone increases (and the length of the bed of unchanged ZnSe, correspondingly, decreases), and by the end of the process the whole charge becomes a white powder. The corresponding curves of the zinc selenide conversion vs. time are flattening out straight lines (Fig. 4).

Figure 4 shows that, as the air flow rate increases, the time of complete oxidation substantially decreases, being 260, 66, and 11 h at the flow rates of 9.5, 40, and 110 ml min^{-1}, respectively. We failed to reach complete condensation of SeO_2 for flows with rates higher than 110 ml min^{-1}, at practically complete condensation of elemental selenium. In this case, we can only suggest that the SeO_2 content in the oxidation products is noticeable and also that, starting from 90–95% conversion, the product consists exclusively of SeO_2. At the flow rates of 9.5, 40, and 110 ml min^{-1}, as seen from Fig. 2, curves *3*–*5*, the content of elemental selenium is virtually the same (95–99 wt %). The difference appears only in the final parts of the curves. In this case, an increase in the flow velocity results in incomplete reducton of SeO_2, because the small segment of remaining ZnSe is passed by the flow faster. Furthermore, when the flow rate exceeds 40 ml min^{-1}, excess O_2 starts to exert an effect, namely, starts to oxidize the forming selenium, which results in an increase in the SeO_2 content in the products.

The oxidation conditions can be changed so as to obtain SeO_2 free from elemental selenium. For this purpose, forming elemental selenium should be oxidized. We suggested two oxidation modes: oxidation of the products with atmospheric oxygen at the reactor outlet and introduction of additional oxidizing agents into the air flow. We used HNO_{3conc} as the additional oxidizing agent, placing boats with it into the reactor in front of boats with the ZnSe powder. In these cases, the volatile product was pure SeO_2 containing no elemental selenium. The content of impurities in the resulting product was determined by direct atomic emission spectroscopy. The content of impurities in SeO_2 obtained by "afteroxidation" at the reactor outlet (sample 1) and in the presence of HNO_3 vapor in the flow (sample 2) is given in the table.

Content of impurities in selenium dioxide samples

Sample no.	Impurity content, wt %					
	Mg	Fe	Si	Al	Cu	Zn
1	3×10^{-5}	2×10^{-4}	2×10^{-3}	$<1\times10^{-4}$	3×10^{-5}	$<3\times10^{-4}$
2	3×10^{-5}	2×10^{-4}	3×10^{-4}	2×10^{-5}	1×10^{-5}	3×10^{-3}

Furthermore, we found that HNO_3 vapor accelerates ZnSe oxidation with atmospheric oxygen. The corresponding kinetic curves are shown in Fig. 5.

Figure 5 shows that the time of complete oxidation of ZnSe particles of size 0.6–1.5 mm at 560°C is 180 min in the absence of HNO_3 vapor and 130 min in its presence. In the case of $3.5 \times 2.7 \times 0.4$-mm plates, the time of complete oxidation is 420 and 330 min in the absence and in the presence of the acid vapor, respectively.

CONCLUSIONS

(1) The volatile products of zinc selenide oxidation with atmospheric oxygen are selenium and selenium dioxide, their ratio changing in the course of the process.

(2) Unchanged zinc selenide can react with selenium dioxide to form selenium.

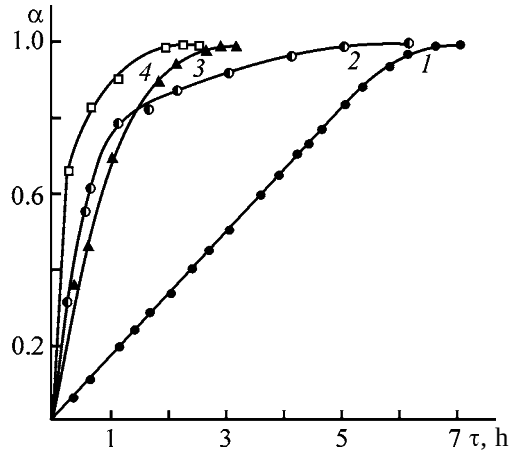

Fig. 5. Kinetic curves of the oxidation of ZnSe powders and plates in a nonforced air flow in the absence and presence of nitric acid vapor. (*1*, *2*) Plates and (*3*, *4*) powders; (*1*, *3*) without HNO_3 and (*2*, *4*) with HNO_3.

(3) Introduction of nitric acid vapor in the flow accelerates ZnSe oxidation and results in the formation of selenium dioxide free from elemental selenium.

Abstract—The integral molar excess Gibbs energy and the enthalpy of mixing of liquid alloys of the ternary system iron–nickel–cobalt at 1600°C were calculated by various methods from data on the boundary binary systems. The data for the boundary binary systems are analyzed in detail.

Calculated thermodynamic properties of liquid alloys of the ternary system Cu–Ni–Fe have been reported previously [1, 2]. Proceeding with studies of liquid metal systems, which are important for thermodynamic analysis of pyrometallurgical processes occurring in nickel production, we calculated in this work the integral molar Gibbs energy and the enthalpy of mixing of liquid alloys of the system Fe–Ni–Co at 1600°C, using different geometric models and analytical approach. The available data on thermodynamic properties of this system are limited. Velišek *et al.* [3] measured the saturated vapor pressure to determine the component activities only at 1227°C, i.e., for alloys in the solid state. In [4], a Knudsen cell and a mass spectrometer were used to determine the activity of each of the components of the ternary system within 1200–1650°C, but the system was studied solely along the section with the component ratio $x_{Fe} : x_{Ni} = 9 : 1$ (where x_i is the mole fraction of component in the alloy). The melt–vapor equilibrium for eight compositions of the ternary system Fe–Ni–Co at 1600°C was studied in [5]. The condensate composition was determined by chemical methods. The obtained data and data for binary systems, subjected to a systematic treatment, were used to obtain the equations reflecting the dependence of the vapor phase composition on the composition of the liquid phase and to calculate the coefficients of the component activity. To our knowledge, there are no other thermodynamic studies of liquid alloys of the system Fe–Ni–Co.

Analysis of the phase diagram of the Fe–Ni–Co system [6] shows that the liquid alloys will exhibit very moderate deviations from ideality. Then, it is necessary to scrutinize the data for the boundary binary systems used in calculation of the thermodynamic characteristics of the ternary system by any model. The thermodynamic properties of liquid alloys of the Fe–Ni system were repeatedly studied; the results are summarized in [1, 7–9]. Although the deviations (negative) from ideality exhibited by the Fe–Ni binary system are moderate, they markedly exceed the deviations in the other boundary systems, Fe–Co and Ni–Co, and are essentially responsible for the deviations in the Fe–Ni–Co ternary system as a whole. The comprehensive information for estimating ΔG^{ex} at 1600°C in the Fe–Ni system is presented in [10–12]. In all the three studies, the Knudsen effusion method combined with mass spectrometry was used. The results of these works agree fairly well with each other (Fig. 1). The ΔG^{ex} values (Table 1) used for calculation were chosen taking into account the recommendations from [7, 9]. The enthalpy of mixing of the Fe–Ni system was estimated using data of [10] and results [13, 14] of calorimetric measurements (Fig. 2). The calculated ΔH values were chosen based on the recommendations from [7].

The thermodynamic properties of liquid alloys of the system Fe–Co have been also repeatedly studied. Early studies are summarized in a monograph [7] and a review [15]. Analysis of the whole set of the data and evaluation of the experimental methods and other investigations suggest that the most reliable ΔG^{ex} values were obtained for the Fe–Co system at 1600°C in [16, 17]. At the same time, for estimating ΔH, we will use the data from [14, 18]. As seen from Table 1, the ΔG^{ex} and ΔH values for the Fe–Co system are of different sign, which is admissible when these thermodynamic functions are low in absolute values and the excess entropy of mixing is negative.

0.90	–1.41	–1.84	0.90	0.66	–0.59	0.90	–0.23	0.13

The thermodynamic properties of liquid alloys of the system Ni–Co are summarized in [19]. The data obtained by Tomiska *et al*. [20] using the Knudsen effusion method combined with mass spectrometry seem to be the most reliable. According to these data, in the Ni–Co system in the liquid state the activity isotherms of both components exhibit slight deviations from ideality; the Gibbs energy is negative over the entire composition range, passing through a minimum of –0.550 kJ mol^{-1} at x_{Co} = 0.528. The enthalpy of mixing is positive, with the maximal value of 0.425 kJ mol^{-1} at x_{Co} = 0.460 [20]. The ΔH values from [20] are in satisfactory agreement with the Predel and Mohs's calorimetric results [21]. At the same time, in a review [19], with due regard for [22], somewhat lower values were recommended for the enthalpy of mixing: ΔH of about 0.330 kJ mol^{-1} near the equiatomic composition. In calculation of ΔH for the ternary system, we used the data of [20] (Table 1).

In the past two decades, major attention has been paid to application of various calculation procedures to estimation of the thermodynamic properties of ternary and more complex liquid metal systems from data on boundary binary systems [18, 23–27]. Geometric models in which the integral molar properties of a ternary system are calculated using the surface of a relatively simple geometric form have found the widest application. The models can be subdivided into two groups: symmetric and asymmetric. In the first case, nonequivalent participation of the boundary binary systems is laid into the algorithm for calculating the integral property; the calculation result is, to a certain extent, dependent on the component arrangement chosen for the ternary system. In the second case, the component arrangement does not affect the

final result. Schematic geometric models are presented in Fig. 3. Schemes *I–III* illustrate the asymmetric methods of calculating the integral property. The arrangement of components commonly corresponds to the minimal deviation from the ideality exhibited by system *1–3* in calculation along the secants with the constant $x_1 : x_3$ ratio. The most widely used calculation procedure is scheme *I* (Toop method). Koehler, Muggiani, and Colinet models (*II*, *III*, and *IV*, respectively) are symmetrical with respect to the indices numbering the system components. Point *O* (Fig. 3) designates the composition of the ternary alloy for which an integral thermodynamic property is calculated. Points *A*, *B*, and *C* indicate the compositions of binary boundary systems whose integral values are used in calculations. Model *V* allows two calculation procedures using the integral values in points *A*, *B*, and *C* or in points *A*', *B*', and *C*'. As a rule, two calculation procedures are used in parallel, with the results averaged. The corresponding algorithms are given in [2, 26, 27] and are not repeated here. The calculations using all models were performed along the secants of the concentration triangle with the constant $x_{Ni} : x_{Co}$ ratio (3 : 1, 1 : 1, and 1 : 3). The calculations using all the six models yield reasonably consistent results. The average ΔG^{ex} and ΔH values for the system Fe–Ni–Co are given in Table 2, along with the average deviation. As in [2], none of the methods can be considered as inadequate. The lines of the equal ΔG^{ex} and ΔH values are shown in Figs. 4a and 4b. All the models are based on the concept that the boundary binary systems produce independent effect on the integral thermodynamic characteristic of the ternary system.

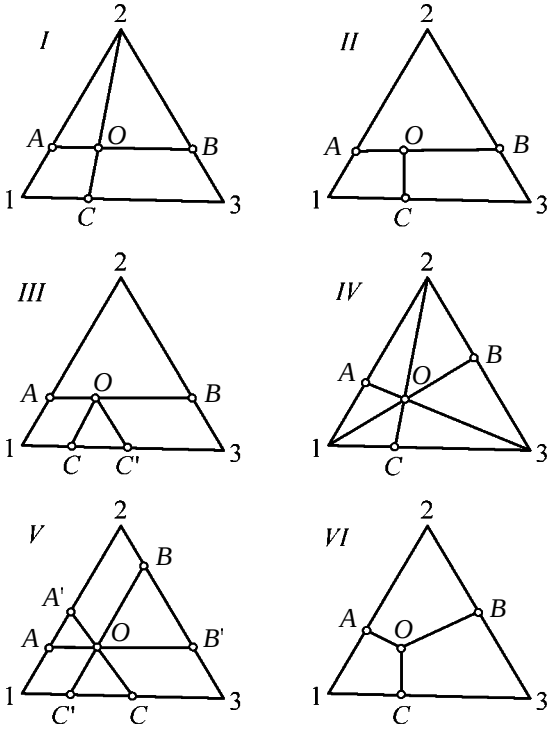

Fig. 3. Schemes of typical geometric models for calculating integral molar properties of ternary systems.

As shown previously [1, 2, 23], the dependence of ΔG^{ex} and ΔH on the composition of binary systems can be presented by the Redlich–Kister polynomials:

$$\Delta G^{ex} = x_1 x_2 [b + c(2x_1 - 1) + d(2x_1 - 1)^2,$$

$$\Delta H = x_1 x_2 [b' + c'(2x_1 - 1) + d'(2x_1 - 1)^2].$$

In the given case, x_1 and x_2 characterize the composition of the corresponding binary systems. Num-

bering and arrangement of the ternary system components, accepted by us, suggests the following designation for the binary systems: Co–Fe (1–2), Fe–Ni (2–3), and Ni–Co (3–1). Processing of experimental data from Table 1 yields the following values of the polynomial coefficients (ΔG^{ex} and ΔH, kJ mol^{-1}):

System	b	c	d
Co–Fe	5.2801	3.5035	–1.7652
Fe–Ni	–11.1043	6.1540	–0.7691
Ni–Co	–2.5158	0.0500	0.0122

System	b'	c'	d'
Co–Fe	–6.1419	–1.6528	1.5121
Fe–Ni	–17.1611	9.0480	2.5736
Ni–Co	1.6717	0.2934	–0.0074

The equations with the above coefficients describe the experimental data with a high accuracy. In this case, there is no need to describe the concentration dependences of thermodynamic functions by polynomials of the third or higher degrees.

Use of polynomials allows calculation of the limiting partial molar thermodynamic functions and the coefficients of component activity. As known [2, 23],

$$\left(\frac{\Delta G^{ex}}{x_1x_2}\right)_{x_1\to 0} = (\Delta G_1^{ex})^{\infty},$$

$$\left(\frac{\Delta G^{ex}}{x_1x_2}\right)_{x_2\to 0} = (\Delta G_2^{ex})^{\infty}.$$

Based on these expressions, without graphical plotting, we obtained the following limiting thermodynamic characteristics for the binary systems at 1600°C:

	$(\Delta G^{ex})^{\infty}$, kJ mol^{-1}	$\ln\gamma^{\infty}$	γ^{∞}
	Cobalt–iron system		
Co	–0.0114	-7.32×10^{-4}	0.999
Fe	7.018	0.451	1.569
	Iron–nickel system		
Fe	–18.027	–1.158	0.314
Ni	–5.719	–0.367	0.693
	Nickel–cobalt system		
Ni	–2.554	–0.164	0.849
Co	–2.454	–0.158	0.854

As a whole, the calculation results reasonably agree with the experimental data [7, 10, 16].

The change in the excess Gibbs energy of the ternary system can be presented as a sum of the independent contributions [1, 23]:

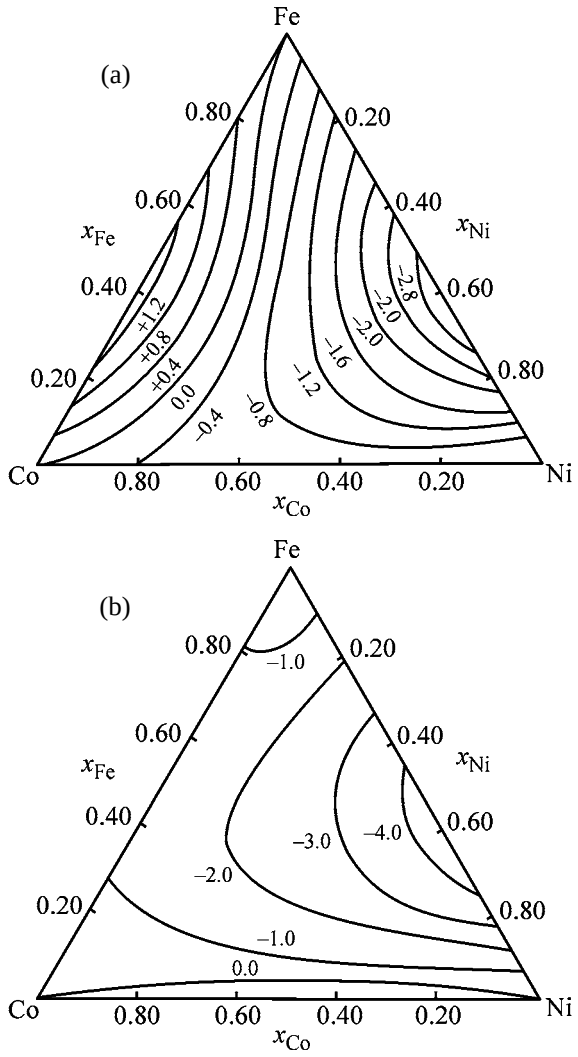

Fig. 4. Lines of the equal values of (a) integral molar excess Gibbs energy ΔG^{ex} and (b) enthalpy of mixing ΔH in alloys of the ternary system Fe–Ni–Co at 1600°C.

$$\Delta G^{ex} = \Delta G_{12}^{ex} + \Delta G_{23}^{ex} + \Delta G_{31}^{ex} + \Delta G_{123}^{ex}.$$

The first three terms can be estimated from the coefficients of the above polynomials. To estimate the ΔG_{123}^{ex} contribution, it is necessary to have data on the ternary system. At the same time, experience shows that there is no need to take into account ternary interactions. The final equation for calculating ΔG^{ex} has the form

$$\Delta G^{ex} = x_1x_2[b_{12} + c_{12}(x_1 - x_2) + d_{12}(x_1 - x_2)^2] + x_2x_3[b_{23} + c_{23}(x_2 - x_3) + d_{23}(x_2 - x_3)^2] + x_3x_1[b_{31} + c_{31}(x_3 - x_1) + d_{31}(x_3 - x_1)^2].$$

Table 3. Results of polynomial calculation of ΔG^{ex} and ΔH in the Fe–Ni–Co ternary system at 1600°C

x_{Fe}	$x_{Ni} : x_{Co} = 3 : 1$		$x_{Ni} : x_{Co} = 1 : 1$		$x_{Ni} : x_{Co} = 1 : 3$	
	ΔG^{ex}	ΔH	ΔG^{ex}	ΔH	ΔG^{ex}	ΔH
	kJ mol^{-1}					
0.20	–1.73	–2.48	–0.92	–1.75	0.02	–1.29
0.40	–1.97	–3.39	–0.90	–2.51	0.23	–1.90
0.60	–1.57	–2.80	–0.72	–2.14	0.16	–1.66
0.80	–0.84	–1.37	–0.44	–1.09	–0.02	–0.88

The terms x_1, x_2, and x_3 in this equation characterize the composition of the ternary alloy. The expression for calculating ΔH in the Fe–Ni–Co ternary system is similar, with the coefficients b', c', and d'. The results of polynomial calculation of ΔG^{ex} and ΔH are presented in Table 3.

The results of calculation by geometric models and using polynomials that reflect the contribution of binary systems are in reasonable agreement. This indirectly confirms that the values of the corresponding thermodynamic functions accepted by us for the boundary binary systems adequately reflect the real form of the surface of the thermodynamic functions of the ternary system.

CONCLUSIONS

(1) Liquid alloys of the iron–nickel–cobalt system exhibit moderate alternating deviations from ideality: at compositions adjacent to the Fe–Ni side, the integral molar excess Gibbs energy is negative, whereas at compositions adjacent to the Fe–Co side it is positive.

(2) All the six geometric models used for calculating the integral molar thermodynamic properties of the Fe–Ni–Co ternary system from data on boundary binary systems, as well as the method using the polynomials for the binary systems, yield similar results.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Calculation of Solubility of Crystalline Halides and Sulfides in Water and Acid Solutions

S. E. Shkol'nikov

Kirov State Academy of Forestry Engineering, St. Petersburg, Russia

Received February 19, 2003

Abstract—The influence of the pH of nonoxidizing acid solutions on the solubility of a number of crystalline halides and sulfides was calculated thermodynamically.

The rate of dissolution of chalcogenide materials intended for membranes of ion-selective electrodes (ISE) in various model solutions has been studied previously [1, 2]. At the same time, it is no less important to know the thermodynamic characteristic of solubility of sensor materials, which is determined by the molar concentration of the saturated solution in aqueous–organic media. The solubility is a function of temperature, structural and chemical features of a membrane, and characteristics of the liquid medium being analyzed: ionic and molecular composition, pH, and true redox potential [2].

In this study, the thermodynamic method was used to calculate the solubility under the standard conditions for a number of binary inorganic compounds in pure water at pH 7 (s^0, g l^{-1}) and in aqueous solutions of nonoxidizing acids at pH 5, 3, and 1 (for example, in HCl or HBr solutions) in the absence of similar ions and without appreciable complexation. The objects of calculation were crystalline halides of silver and thallium(I), fluorides of lanthanum and other Group II–III elements, and sulfides of silver, cadmium, lead(II), copper(II), and mercury(II), which are used [3] or show promise [1, 2] for preparation of ISE membranes.

In aqueous solution saturated with respect to a difficultly soluble electrolyte M_mA_n, a heterogeneous chemical equilibrium is attained:

$$M_mA_n(cr) \rightleftarrows mM^{n+}(s) + nA^{m-}(s), \quad (1)$$

whose thermodynamic constant

$$K_s^0 = US^T + a_M^m a_A^n = (ms^0)^m (ns^0)^n \quad (2)$$

can be used to calculate the molar solubility of a compound in pure water (s^0, M) at a less than 10^{-4} M ionic strength of a solution [4] by the formula

$$s^0 = (K_s^0/m^m n^n)^{1/(m+n)} \quad (3)$$

or Ms^0 (g l^{-1}), where M is the molar weight of a compound M_mA_n.

The K_s^0 constant was calculated using the thermodynamic relation

$$\ln K_s^0 = -\frac{\Delta G_{s,298}^0}{R \times 298} = -0.404 \Delta G_{s,298}^0, \quad (4)$$

where the standard change in the Gibbs energy $\Delta G_{s,298}^0$ for the dissolution process (1) was calculated by the equation

$$\Delta G_s^0 = m\Delta G_{f,M^{n+}}^0 + n\Delta G_{f,A^{m-}}^0 + m\Delta G_{f,M_mA_n}^0. \quad (5)$$

The ΔG_f^0 values of the ion formation in aqueous solution were taken from [5], and the ΔG_f^0 values of formation of a compound M_mA_n (cr, g) in crystalline or glassy state at 298 K were taken from a reference book [6] or calculated by known methods.

In calculation of the solubility of the M_mA_n crystals in nonoxidizing acid media by the equation

$$s^{m+n} = \frac{K_s^0}{m^m n^n f_M^m f_A^n x_A^n}, \quad (6)$$

account was made for the molar activity coefficients of M^{n+} and A^{m-} ions and the mole fraction x_A of A^{m-} free anions not bound into weak acid species (HF, HS^-, and H_2S) [4, 5].

For a heterogeneous equilibrium in a nonoxidizing

Note: (ds) Difficultly soluble and (is) virtually insoluble [8].

acid

$$MF_n(cr, g) + nH^+(s) \rightleftarrows M^{n+}(s) + nHF(s),$$

whose thermodynamic constant is $K_a = K^0_{s,MF_n}/K^n_{HF}$, the acid resistance of crystalline and glassy fluorides was calculated by formula (6) using the relationship

$$x_{F^-} = \frac{K_{HF}}{[H^+] + K_{HF}}, \quad (7)$$

whereas at pH ≤ 3, when $[H^+] > K_{HF}$, it can be calculated by the approximate formula

$$s^{n+1} = \frac{K^0_s[H^+]^n}{n^n f_M f_F^n K^n_{HF}}. \quad (8)$$

For a heterogeneous chemical equilibrium in a nonoxidizing medium,

$$M_mS_n(cr, g) + 2nH^+(s) \rightleftarrows mM^{(2n/m)+}(s) + nH_2S(s),$$

the acid resistance of the M_mS_n crystals and glasses can be calculated, taking into account that $x_{S^{2-}} \approx K_{H_2S}[H^+]^2$ at pH ≤5 and $K_{H_2S} = 2.5\times10^{-20}$ [4], by the generalized equation

$$s^{m+n} = \frac{K^0_s[H^+]^{2n}}{m^m n^n f_M^m f_S^n K^n_{H_2S}}. \quad (9)$$

The calculation results are presented in the table, where $pK^0_s = -\log K^0_s$ and P_i is the degree of ionicity (%) of the M–A chemical bond in a compound M_mA_n, determined from the difference in the electronegativites of A and M elements using the Pauling curve [7]. Table 1 shows that, for a majority of difficultly soluble compounds, the pK^0_s values calculated by Eq. (4) reasonably agree with the data from a reference book [4] (the average deviation $\Delta pK^0_s = \pm0.19$). Exceptions are cadmium and mercury(II) sulfides, for which the ΔG^0_s and K^0_s values must be refined. With increasing ionicity of silver and thallium(I) halides in the series I → Br → Cl → F, their solubility in water s^0 increases (see table). The least soluble in water are HgS, CuS, and Ag_2S crystals, in which the M–S

bonds are mainly covalent. The AgF, TlF, and BeF_2 ionic crystals have the highest solubility in water (P_i = 70–85%), with the BeF_2 solubility, like GeO_2 solubility (α, β) [8], considerably depending on the crystal structure (α-, β-, and γ-modifications). The solubility of the BeF_2 glass ($BeF_{4/2}$ structural unit) is somewhat higher than that of a stable β-BeF_2 crystal of the α-quartz hexagonal structure, but lower than that of the other BeF_2 modifications (see table).

Due to the salt effect, the solubility of silver and thallium(I) halides in nonoxidizing acid solutions increases only slightly (1.3-fold as pH is decreased from 7 to 1). As pH is decreased from 7 to 3 and from 7 to 1, the solubility increases by factors of about 2 and 44, respectively, for the fluorides MF_2 and by factors of 2.3 and 86, respectively, for MF_3. This is largely due to binding of fluoride ions into molecules of a weak acid, HF. The solubility of sulfides MS (M is Pb, Cd, Cu, or Hg) increases more appreciably, namely, by a factor of $\sim 10^7$ as pH is decreased from 7 to 3 and further by a factor of 230 as pH is decreased from 3 to 1. Therefore, PbS, LaF_3, ScF_3, CaF_2, and TlI crystals are unsuitable as ISE membranes in strongly acidic solutions. The Ag_2S, HgS, CuS, AgI, AgBr, and YF_3 crystalline membranes can be used at pH 1 (their solubility is less than 0.2 mg l^{-1}).

CONCLUSIONS

(1) The solubility of crystalline silver and thallium(I) halides increases as the degree of their ionicity grows in the series I $\rightarrow$ Br $\rightarrow$ Cl $\rightarrow$ F.

(2) As pH is decreased from 7 to 1, the solubility of silver and thallium(I) halides grows only slightly (by a factor of 1.3); that of fluorides MF_2 and MF_3, considerably (by a factor of 40–90), and that of sulfides MS (M is Pb, Cd, Cu, or Hg), to the greatest extent (by a factor of $\sim 10^9$).

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Dissolution of Palladium Deposited onto a Fibrous Carbon Cathode in Nitric Acid Solution through Operation of a Short-Circuited Electrochemical System

V. I. Varentsova and V. K. Varentsov

Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

Received April 17, 2003

Abstract—Dissolution in 3.5 M NHO_3 of palladium deposited onto a fibrous carbon electrode from hydrochloric and nitric acid solutions was studied. The factors influencing the dissolution of palladium in contact with the electrode were revealed using a model of short-circuited electrochemical system.

Dilute palladium solutions widely occur in various industries, e.g., in hydrometallurgy, in electrolytic metallurgy, and in processing of spent catalysts and nuclear fuel. Various procedures have been suggested for recovery of palladium from the forming (mainly nitric and hydrochloric acid) solutions [1, 2]. One of effective techniques is electrolysis with filtering three-dimensional electrodes and, in particular, with electrodes made of fibrous carbon materials (FCMs), which have been used previously in recovery of noble metals in hydrometallurgy and electrolytic metallurgy and in processing of spent catalysts [3–5]. In the course of electrolysis, the metals are concentrated within a fibrous carbon electrode (FCE), with 15–30 kg of metal deposited per 1 kg of FCM. Platinum-group metals are deposited from hydrochloric and nitric acid solutions with high degrees of recovery [4, 5]. However, it has been established, in the case of electrodeposition from nitric acid solutions, that palladium deposited onto an FCE dissolves after the external voltage is switched off, whereas in deposition of palladium from hydrochloric acid solutions, no dissolution is observed. A similar phenomenon of zinc dissolution in recovery of the metal from alkaline electrolytes has been reported previously [6]. It was established that zinc deposited onto an FCE dissolves in the alkaline electrolyte through operation of a short-circuited electrochemical system (SES) Zn–FCE–electrolyte.

The possibility that deposited palladium can dissolve in a nitric acid solution through operation of SES is based on the difference of standard electrode potentials of palladium and FCM. When in contact with FCM in a nitric acid solution, palladium can form an SES in which the metal undergoes anodic dissolution. Taking into account the ability of palladium to form complexes with nitrate and nitrite ions, which are always present in an HNO_3 solution [9], it may be suggested that anodic dissolution of palladium will be accompanied by formation of the corresponding complex compounds. Based on the stability constants of nitrate ($K = 1.2 \pm 0.4$ [10]) and nitrite ($K = 1.4 \times 10^{15}$ [11]) palladium(II) complexes, the anodic dissolution of palladium can be represented as

$$Pd + 4NO_2^- = Pd(NO_2)_4^{2-} + 2e, \qquad E^0 = 0.54 \text{ V}. \quad (1)$$

Cathodic reduction of nitric acid to nitrous acid and nitrogen oxides ($E_0 + 0.94$ and $+0.96$ V, respectively) and of dissolved oxygen ($E^0 = +1.229$ V) are possible on the FCM surface. Vetter [9], who studied in detail the kinetics of cathodic reduction of HNO_3 on an inert electrode, demonstrated that the final product of its reduction is nitrous acid, with the formation of nitrogen oxides N_2O_4 and NO_2 considered as intermediate stages.

The dissolution of palladium in SES may lead to the loss of the metal in its electrolytic recovery from nitric acid solutions. At the same time, this process can be used to separate and concentrate palladium in dissolution of metals deposited from the solutions mentioned above.

The aim of this study was to analyze how palladium deposited onto FCE from hydrochloric and nitric acid solutions dissolves through operation of the SES Pd–FCE–3.5 M HNO_3.

1070-4272/03/7611-1737$25.00

EXPERIMENTAL

Palladium was electrodeposited onto an FCE from model and real nitric and hydrochloric acid solutions, using the procedure, technique, and cell described in [3, 12], with solution circulated through the FCE volume at a rate of 18 ml min^{-1} and the electrode zones separated by an MK-40 ion-exchange membrane. The cathode was polarized with a B-5-49 power source. As FCE served carbonized fibrous carbon material NT-1 containing about 85 wt % graphite [3]. A perforated titanium plate was used as current lead to the FCE; platinum grid, as anode; and 2% Na_2SO_4 solution, as anolyte. The efficiency of palladium electrodeposition was evaluated by the degree of recovery $\alpha = (c_0 - c_\tau)/c_0$ and by the current efficiency

$$CE = (c_0 - c_\tau)V \times 26.8/(I\tau M_{eq}),$$

where c_0 and c_τ are the initial and final palladium(II) concentrations in solution (g l^{-1}); V, solution volume (l); I, current at which electrolysis is carried out (A); τ, experiment duration (h); 26.8 A h mol^{-1}, Faraday constant; and M_{eq}, molar mass of the metal equivalent.

Palladium electrodeposited onto the FCE was dissolved in the cell mentioned above, with a nitric acid solution pumped through the FCE volume at a prescribed rate m_v, or in a glass cell in a nonflowing 3.5 M solution of nitric acid. The amount of dissolved palladium was determined from the loss of mass by the FCE with palladium and by the atomic-absorption method from changes in the palladium(II) concentration in solution. The dissolution rate W_{Pd} of palladium deposited onto the FCE was calculated per the overall area of FCE with thickness of about 3 mm.

The content of nitrous acid was determined by permanganatometric titration by the Lunge method [13].

The dissolution of palladium deposited onto the FCE was analyzed qualitatively using the known method for modeling of a microvoltaic cell with a macrovoltaic cell [14]. The electrodes of the latter, FCM, palladium plate, or a palladium plate with palladium deposited onto it from a hydrochloric or nitric acid solution, were placed in an HNO_3 solution. The use of this method for studying the electrochemical process in the system in question is due to the macrokinetic nature of processes characterizing the FCM operation.

Since the reproducibility of the results obtained depends on the method used for pretreatment of the palladium plate surface, the surface was treated under fixed conditions: a plate was subjected to mechanical grinding, polishing on felt, and successive washing with an Na_2CO_3 solution, alcohol, and distilled water. Palladium was electrodeposited onto a palladium plate from a nitric acid solution containing 0.3 g l^{-1} Pd(II) and 3.5 M HNO_3 and from a hydrochloric acid solution containing 2 M HCl and 2.5 (solution no. 1) or 0.3 g l^{-1} Pd(II) (solution no. 3) in a nonflowing electrolyte at current density of 100 A m^{-2} in the course of 25–50 min. After electrolysis, the plate was washed with distilled water and dried in air. The amount of deposited palladium was 0.5–2.5 mg cm^{-2}.

The electrode potentials were measured relative to a saturated silver chloride electrode with an OP-265/1 pH-meter and recalculated to the hydrogen scale. The results of no less than 4–5 measurements were averaged; the mean deviation was ±20 mV in measuring the electrode potential of the palladium plate, ±40 mV for the palladium-plated plate, and ±5 mV for FCM.

A study of palladium electrodeposition onto FCM from real and model nitric and hydrochloric acid solutions demonstrated that palladium is recovered to high extent from solutions of both types (Fig. 1). The current efficiency by palladium, calculated for 90% recovery, is 5–25%; it grows with increasing concentration of palladium(II) and decreasing concentration of acid in solution and falls with increasing current density and degree of palladium recovery. The low current efficiency by palladium is due to the concurrent reduction of hydrogen ions and nitric acid.

In electrolytic recovery of palladium from real solutions, platinum metals, such as rhodium and ruthenium, are deposited together with palladium.

A study of how palladium deposited onto FCE from model solutions dissolves in 3.5 M HNO_3 revealed that the rate of dissolution of palladium electrodeposited from nitric acid is 4–6 times that in the case of palladium electrodeposition onto FCM from a hydrochloric acid solution.

Table 2 lists the results obtained in measuring the corrosion potential E_{cor} of FCE with palladium deposited onto it from nitric acid (I) and hydrochloric acid (II) solutions in the course of palladium dissolution in 3.5 M HNO_3. Table 2 shows that, in dissolution of palladium deposited from a nitric acid solution, E_{cor} grows fast with increasing time of contact with a 3.5 M HNO_3 solution. When E_{cor} reaches a value of 0.88 V, palladium starts to dissolve, as determined visually from the appearance of yellow coloration in the near-boundary layer. It was found in different

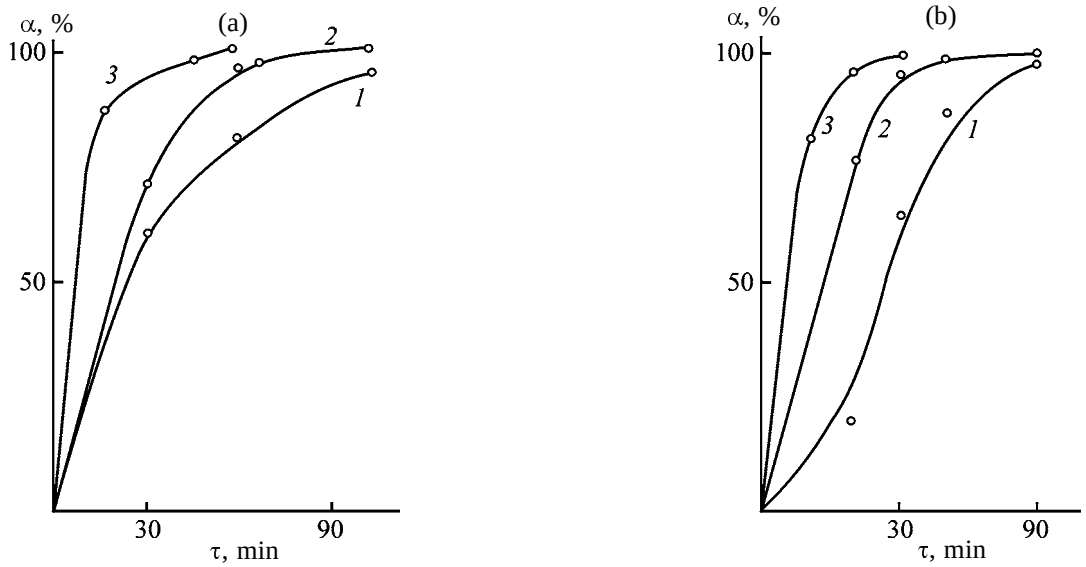

Fig. 1. Degree of electrolytic recovery α of palladium from (a) hydrochloric and (b) nitric acid solutions vs. electrolysis duration τ. (a) Overall cathode area, cm^2: (*1*) 30 and (*2*, *3*) 2. Concentration of components in spent solution from gold refining ($g\ l^{-1}$; in terms of metal): (*1*) Au 6.2, Pt 1.1, Pd 2.2, Cu 0.5, and HCl 50; (*2*, *3*) Au 3.9, Cu 0.15, Fe 1.0, Ni 0.01, Pd 0.07, Pt 0.05, Rh 0.01, Zn 0.03, and HCl 50. Current density, $A\ m^{-2}$: (*1*) 800, (*2*) 600, and (*3*) 1000. (b) Overall cathode area 2 cm^2. Model solution, $g\ l^{-1}$: Pd(II) 0.17 and HNO_3 220. Current density, $A\ m^{-2}$: (*1*) 250, (*2*) 500, and (*3*) 1000.

experiments that palladium starts to dissolve after 5–10 min of contact with the HNO_3 solution. In the case when FCM with palladium deposited from a hydrochloric acid solution is brought in contact with an HNO_3 solution, E_{cor} = 0.88 V is reached, and palladium starts to dissolve, only after keeping in the solution for 1 h, i.e., in this case, the period of time preceding palladium dissolution is much longer (40–60 min).

Figure 2 shows the stationary potentials of palladium and palladium-plated plates, $E_{st.Pd}$, as a function of the time during which the electrodes were kept in a 3.5 M HNO_3 solution. It can be seen that $E_{st.Pd}$ reaches a value of 0.94 V after the plate is kept in the HNO_3 solution for 20–30 min (curve *1*). It should be noted that $E_{st.Pd}$ grows gradually with increasing time of keeping in the HNO_3 solution. After 1.5 h, the stationary potential becomes 1.01 V, the plate surface is covered with a black palladium oxide layer, and the concentration of palladium in solution is 2.5 $mg\ l^{-1}$. The concentration of nitrous acid increases from 0.0006 (initial 3.5 M HNO_3 solution) to 0.0014 M (after 1.5 h of operation of the voltaic cell).

According to published data, $E_{st.Pd}$ is of corrosion nature in nitric acid solutions [8]. Taking into account the appearance of palladium(II) ions in solution, the rise in the concentration of nitrous acid in solution, and the values of the stability constants of nitrate and nitrite complexes of palladium(II), it may be assumed that palladium is oxidized in anodic regions to give palladium(II) nitrite complexes [reaction (1)] and surface oxides:

$$Pd + H_2O = PdO + 2H^+ + 2e, \qquad E^0 = 0.858\ V. \quad (2)$$

In the cathodic regions, nitric acid is reduced. The stationary potential of palladium-plated electrodes is more negative than the value characteristic of the palladium plate and depends on the nature of the solution from which palladium was deposited and on the palladium concentration in solution (Fig. 2, curves *2*–*4*).

Table 1. Dissolution rate W_{Pd} of palladium in the system Pd–FCM–3.5 M HNO_3. Solution volume 50 ml; amount of palladium deposited onto FCE at current density i = 1000 $A\ m^{-2}$ in 20 min equal, on the average, to 60% of the FCM mass

In the case when palladium was deposited onto the plate from a hydrochloric solution no. 2 (Fig. 1, curve *4*), no palladium was found in solution after keeping such an electrode in 3.5 M HNO_3. $E_{st.Pd}$ is more negative by about 0.8 V than the potential characteristic of the palladium plate. According to published data [15], the more negative stationary potential of palladium-plated palladium, compared to that of the palladium plate, is due to the presence of sorbed hydrogen in the cathodic deposit. The ability of metallic palladium to absorb large amounts of hydrogen gas (up to 50–70 $cm^3\ g^{-1}$ palladium) has long been known [15–17]. The issues associated with absorption and adsorption of hydrogen by palladium in the course of electrolysis (compact metal or that electrolytically deposited on various substrates: platinum, palladium, or carbon, including carbon fabrics) and with the properties of the resulting deposits were considered in [15, 17]. It was established that the amount of sorbed hydrogen is larger for electrodeposited palladium, compared to the palladium plate, and it grows with increasing dispersity of the deposit obtained, with the deposition potential shifted to the electronegative side. Depending on the electrodeposition potential, the atomic ratio H/Pd is 0.62–0.68 and may become as high as 1.1 [15, 17].

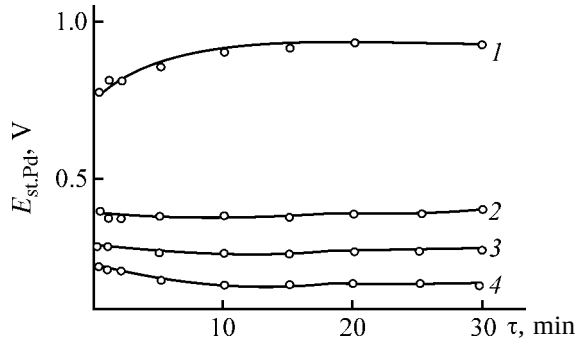

Fig. 2. Stationary electrode potential of palladium, $E_{st.Pd}$ (vs. standard hydrogen electrode), vs. time τ of keeping in 3.5 M HNO_3 solution. (*1*) Plate; (*2–4*) plate palladium-plated in (*3*) nitric acid solution and hydrochloric acid solution nos. (*2*) 1 and (*4*) 2.

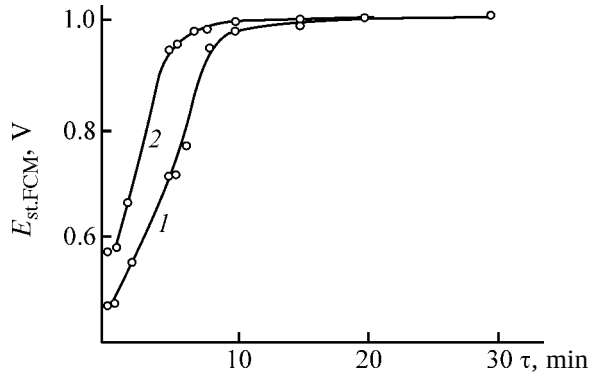

Fig. 3. Stationary electrode potential, $E_{st.FCM}$ (vs. standard hydrogen electrode), vs. time τ of keeping in a 3.5 M HNO_3 solution before (*2*) and (*1*) after cathodic treatment.

Figure 3 shows the results obtained in measuring the stationary electrode potentials of FCM, $E_{st.FCM}$. The steady-state value of the stationary potential of the initial NT-1 sample is 1.06 V. Samples subjected to cathodic treatment are characterized by longer time in which a steady-state value of $E_{st.FCM}$ is attained. Raising the time during which samples are kept in an HNO_3 solution to 2 h leads to an increase in $E_{st.FCM}$. According to published data [18, 19], the value of $E_{st.FCM}$ in nitric acid solutions is determined by the reduction of nitric acid and products of its reduction and disproportionation, and also by FCM corrosion to give surface oxides. The occurrence of oxidation processes is indicated by the shift of $E_{st.FCM}$ in the positive direction with increasing duration of contact with a nitric acid solution and also by the data of [20], according to which the mass of FCM increases and its conductivity decreases dramatically when the material is brought in contact with the same solution.

Table 3 lists the parameters characterizing the operation of a voltaic cell constituted by palladium plates and FCM: corrosion potential E_{cor}, corrosion current I_{cor}, and degrees of anodic (C_a), cathodic (C_c), and ohmic (C_{ohm}) control, calculated using the known equations [21]. The calculations were performed using E_{st} values after 30 min of keeping in a nitric acid solution (Fig. 2). Palladium was electrodeposited onto the plate from the following solutions: 2.5 $g\ l^{-1}$ Pd(II) and 2 M HCl (run no. 2), 0.3 $g\ l^{-1}$ Pd(II) and 2 M HCl (run no. 3), and 0.3 $g\ l^{-1}$ Pd(II) and 3.5 M HNO_3 (run no. 4).

	60	0.89	77.6	0.96	13.2	9.2	120

Table 1 shows that the corrosion potential of the palladium plate is 0.1 V more positive than its stationary value, and the degree of anodic control is about 92%. In the case when the plate is palladium-plated from a hydrochloric acid solution containing 2.5 g l^{-1} Pd(II), the electrical resistance in the system increases somewhat. The corrosion current increases sixfold (run no. 2); during 30 min of operation of such a voltaic cell, the concentration of palladium(I) in a solution of volume 50 ml becomes as high as 5.7 mg l^{-1}. Preliminary cathodic treatment of NT-1 has no significant effect on the operation of the voltaic cell.

If palladium was electrolytically deposited onto the plate from hydrochloric acid solution no. 2 with a low content of Pd(II) (run no. 3), then the voltaic cell initially (during the dirst 30 min) operates under cathodic control and no palladium(II) is detected in the solution. Also, the ohmic loss in the system increases substantially. These results suggest occurrence on the anode of a reaction that is not associated with palladium dissolution, does not control the operation of the voltaic cell, and makes the electrical resistance in the system much higher. This is, presumably, due to an increase in the resistance of electrolytically deposited palladium because of the hydrogen sorption and formation by palladium of compounds with hydrogen. The current characterizing the operation of this voltaic cell is the highest among the voltaic systems considered. After 60 min of operation of the voltaic cell, the electrical resistance in the system decreases considerably, the polarization of the palladium electrode becomes stronger, and ions of dissolved palladium appear in the system. All this suggests that the anodic reaction occurring during the first 30 min of operation of the voltaic cell is electrooxidation of hydrogen sorbed by the palladium deposit. The possibility of occurrence of such processes is known [17].

If palladium is electrodeposited onto the plate from a solution containing 0.3 g l^{-1} Pd(II) and 3.5 M HNO_3 (run no. 4), then an increase in the degree of cathodic control to 35–38% is only observed in the first 15 min, and the ohmic loss grows during this period of time to 16–20%, i.e., the contribution from electrooxidation of sorbed hydrogen is much lower.

It follows from the results obtained that the operation of the voltaic cell strongly depends on the type of the palladium electrode (plate or palladium-plated plate). Of importance in the latter case are the nature of the solution and the initial content of palladium(II) in the electrolyte from which palladium was deposited. These two factors determine the relative amounts of current consumed for deposition of palladium, hydrogen evolution, and reduction of HNO_3. Apparent-

ly, at the same current mode of the electrolysis process, the quantity of electricity consumed for hydrogen evolution from an electrolyte containing 0.3 g l^{-1} Pd(II) exceeds that for an electrolyte with 2.4 g l^{-1} palladium(II). In contrast to hydrochloric acid solutions, reduction of nitric acid is possible, together with reduction of palladium(II) and hydrogen ions, in electrodeposition of palladium from a nitric acid solution. In this case, the fraction of current consumed for reduction of hydrogen ions must be smaller. It follows from the values of standard potentials that mainly reactions of reduction of palladium and nitric acid occur at the cathode in a nitric acid solution, and reduction of palladium and hydrogen ions, in a hydrochloric acid solution. Therefore, the fraction of hydrogen sorbed by palladium(II) in the former case is smaller than that in the latter.

Thus, the reason for the strong difference between the rates of dissolution in nitric acid of palladium deposited from nitric and hydrochloric acid solutions is that the cathodic deposit contains sorbed hydrogen whose oxidation precedes the dissolution of palladium. If only the time of dissolution of palladium is taken into account in calculating the rate of dissolution of palladium deposited onto FCE from a hydrochloric acid solution, then the results obtained in dissolution of palladium deposited from nitric and hydrochloric acid solutions are comparable.

The dissolution of palladium deposited onto FCE from nitric acid solutions, caused by SES operation, makes it possible to quantitatively separate palladium from codeposited platinum metals. For example, electrodeposition of palladium from a model nitric acid solution containing (g l^{-1}) Pd(II) 0.110, Rh(III) 0.095, Ru(II) 0.077, and HNO_3 189 onto an NT-1 FCM gave a cathodic deposit with Pd : Rh : Ru mass ratio of 50.5 : 32.1 : 17.4. Dissolution of this deposit in 3.5 M HNO_3 without applying external voltage yielded a solution with the Pd : Rh : Ru mass ratio of 95.1 : 1.1 : 3.0 and palladium(II) concentration of 500 mg l^{-1}. In subsequent electrolytic recovery of palladium from this solution into an FCM cathode, a cathodic deposit with more than 99% palladium was obtained.

CONCLUSIONS

(1) It was shown that electrodeposition of palladium from nitric and hydrochloric acid solutions onto electrodes made of a fibrous carbon material occurs with high degree of recovery (>98%). The current efficiency by palladium is 5–25%, depending on concentrations of palladium(II) and hydrochloric acid in a solution and on current density. The low current efficiency is due to cuncurrent reduction of hydrogen ions and nitric acid.

(2) It was established that palladium deposited onto a fibrous carbon electrode dissolves in a 3.5 M HNO_3 solution with applying any external voltage through operation of a short-circuited electrochemical system constituted by Pd, fibrous carbon material, and 3.5 M HNO_3. The dissolution rate depends on the nature and composition of the solution from which palladium is deposited. The cathodic deposit obtained in electrodeposition from a nitric acid solution dissolves 4–5 times faster than that obtained from a hydrochloric acid solution.

(3) It was demonstrated, using a model short-circuited electrochemical system, that the reason for the strong difference between the rates of dissolution in nitric acid of palladium deposited from nitric and hydrochloric acid solutions is the presence in the cathodic deposit of sorbed hydrogen whose oxidation precedes the dissolution of palladium. The contribution from this process is much lower for cathodic deposits obtained in electrodeposition from nitric acid solutions.

(4) It was concluded that dissolution in a nitric acid solution of palladium on a fibrous carbon electrode through operation of a short-circuited electrochemical system can be used to enrich a solution with palladium and to separate the metal from the concomitant platinum metals.

Abstract—Growth kinetics of anodic oxide films on tantalum in a molten eutectic mixture of lithium, sodium, and potassium nitrates was studied and the influence exerted by introduction of hydroxide and chromate ions into the nitrate mixture was considered. The basic kinetic parameters of anodic oxidation of tantalum under galvanostatic conditions were determined.

Oxidation of tantalum is widely used in various fields of technology. Use of molten salts and, in particular, nitrates makes it possible to intensify anodic oxidation of Ta and to obtain oxide coatings with better service characteristics, compared with the coatings formed in aqueous electrolytes [1, 2]. It has been established that the presence of oxygen-containing ions in a melt strongly affects the kinetics of formation of oxide films on rectifying metals and their electrical properties [3, 4].

In continuation of previous investigations [2, 5], we studied the growth kinetics of anodic oxide layers on tantalum in a molten eutectic mixture of lithium (37.5 mol %), sodium (18 mol %), and potassium nitrates and the influence exerted by introduction of hydroxide and chromate ions into the nitrate melt.

EXPERIMENTAL

The study was carried out in the temperature range 413–503 K in a nitrogen atmosphere. The design of the electrochemical cell and methods used for pretreatment of nitrate salts and the electrode material have been described previously [3, 5].

Hydroxide and chromate ions were introduced into the melt in the form of KOH and Na_2CrO_4 of chemically pure grade. Na_2CrO_4 was preliminarily remelted and KOH was dehydrated by prolonged vacuum treatment in the course of heating (1.5–2.0 h) from room temperature to 800 K, with subsequent keeping at this temperature for about 3–4 h. The content of potassium hydroxide in the nitrate melt was 2 wt %; sodium chromate was introduced into the melt to saturation.

Tantalum was oxidized in the galvanostatic mode at current densities of 2.5–15 A m^{-2}. The procedure for galvanostatic measurements was described in [2, 5].

The thickness of the oxide film was determined by the capacitance technique [3, 6].

The dependences of the potential of the tantalum anode on the oxidation time for all the melts under study at different temperatures and current densities were linear. Figure 1 shows as an example the *E–i* curves obtained in the $LiNO_3$–$NaNO_3$–KNO_3–Na_2CrO_4 melt.

As is known [6], the linear run of the *E–i* curves is observed in oxidation of rectifying metals at high field strengths in the oxide film. In this case, the anodic process is limited by mass transfer of ions across the oxide layer formed on the surface of tantalum. The growth of oxide layers under conditions of high field strength in the oxide film is characterized by the de-

pendence of the ion current on the field strength, which is described by the Günther–Schulze equation [6]

$$j\eta = j_0 \exp(-W/kT) \exp(qaE_f/kT), \quad (1)$$

where j is the current density (A m^{-2}); η, current efficiency determining the fraction of the ion current j_i ($j_i = \eta j$) in the oxide; E_f, field strength (V m^{-1}); W, activation energy (eV); a, activation distance (nm); q, charge of an ion moving in the oxide (C); and j_0, constant determined by the nature of a metal (A m^{-2}).

The linear run of the dependence $\ln(j\eta)$–E_f confirms the applicability of Eq. (1) to the process under study. Figure 2 exemplifies such a dependence for the nitrate melt $LiNO_3$–$NaNO_3$–KNO_3 at several temperatures. All the dependences show similar types of behavior for all the temperatures in the range under study.

The values of η, W, a, and j_0 were found using Eq. (1) from experimental data. It was taken in the calculations that metal ions move across the oxide film. As established in [2, 5], mainly the higher oxide Ta_2O_5 is formed on the surface of tantalum being oxidized in a nitrate melt. Therefore, the density ρ (g cm^{-3}) and the dielectric constant ε of the oxide layer were taken to be, respectively, 7.93 and 27.6 [6]. The calculation results are listed in the table.

It can be seen that the current efficiency of tantalum oxidation decreases steadily in the temperature range under study. With account of Eq. (1), this indicates that the current flowing across the oxide film in electrochemical oxidation of tantalum in a nitrate melt is a sum of the ionic ($j\eta$) and electronic currents, with the share of the latter growing with temperature.

The slope of the E–t dependence (Fig. 1), which characterizes the rate of anodic oxidation of tantalum, is described by the equation

$$dE/dt = E_f d\delta/dt, \quad (2)$$

where $d\delta/dt$ is the oxidation rate (m s^{-1}); dE/dt, variation rate of the anode potential (V s^{-1}); and E_f, electric field strength in the oxide (V m^{-1}).

In this case, the variation rate of the anode potential grows with increasing density of the polarizing current and is a linear function of temperature [6].

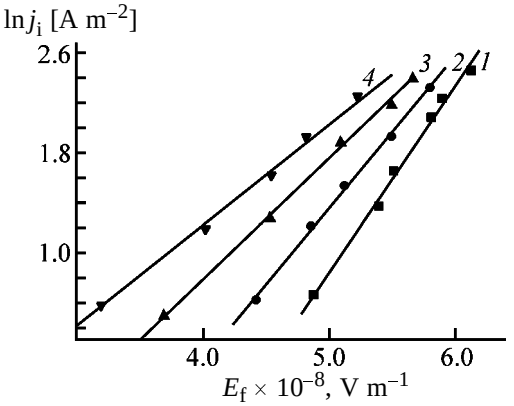

Fig. 2. $\ln j_i$ vs. electric field strength E_f in the oxide film, obtained for the $LiNO_3$–$NaNO_3$–KNO_3 melt. T, K: (*1*) 413, (*2*) 428, (*3*) 453, and (*4*) 478.

It was established that, at constant temperature, the dependence of the variation rate of the anode potential on the ionic current density is described by the equation

$$\ln(dE/dt) = n + m\ln(j\eta), \quad (3)$$

and the temperature dependence of the variation rate of the potential at current density of 1 A m^{-2}, by the empirical equation

$$(dE/dt) = c + DT. \quad (4)$$

The rates of tantalum anodizing and the coefficients of Eqs. (3) and (4) are listed in the table.

As seen from the table, the melt composition strongly affects the kinetic characteristics of tantalum anodizing. For example, the presence of hydroxide and chromate ions in a nitrate melt leads to a decrease in the current efficiency and oxidation rate of tantalum. On introduction of OH^- and CrO_4^{2-} ions into the melt, simultaneously with electrochemical oxidation of nitrate ions [7]

$$NO_3^- = NO_2 + 1/2O_2 + e, \quad (5)$$

one of the following reactions occurs [8, 9]:

$$2OH^- = H_2O + 1/2O_2 + 2e, \quad (6)$$

$$2CrO_4^{2-} = Cr_2O_7^{2-} + 1/2O_2 + 2e. \quad (7)$$

The simultaneous occurrence of reactions (5), (6) or (5), (7) should intensify tantalum oxidation. However, this is not the case. Possibly, this is due to incorporation of the anions mentioned above into the oxide film and to degradation of its dielectric properties. Apparently, addition of hydroxide ions also makes higher the corrosiveness of the melt toward Ta_2O_5. As a result, the current efficiency η and the oxidation rate $d\delta/dt$ decrease. According to [8], the activation energy W of electrochemical oxidation of tantalum in an orthophosphoric acid solution is 2.17 eV, and that in the nitrate melt $NaNO_3$–KNO_3, 1.56 eV [2]. In this study, a value of 1.3 ± 0.2 eV was obtained for the $LiNO_3$–$NaNO_3$–KNO_3 melt, in reasonable agreement with the data of [2]. Also in good agreement are the values of a and j_0 (see table), found for both the nitrate melts [2].

CONCLUSIONS

(1) Oxide layers grow on tantalum in the nitrate melts studied in accordance with the Günther–Schulze equation. The kinetic parameters of the process were determined.

(2) The current efficiency of tantalum oxidation decreases with increasing temperature.

(3) The melt composition affects the kinetic characteristics of tantalum anodizing. The presence of hydroxide and chromate ions leads to a decrease in the current efficiency and oxidation rate of tantalum.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Regeneration of Iron(III) Chloride Etching Solutions Containing Organic Additives

A. G. Belobaba, A. I. Maslii, and O. N. Shevtsova

Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

Received April 14, 2003

Abstract—The behavior of inorganic macrocomponents (Fe^{3+}, Fe^{2+}, Cu^{2+}, and Cl^{-}) and organic additives (judged from the relative concentration of total carbon) in regeneration and reuse of spent etching solutions used in fabrication of copper type-plates was studied. The conditions of electrochemical and sorption stages of the regeneration process were discussed.

Chemical etching with $FeCl_3$-based solutions is used in printing industry to obtain relief images on copper type-plates [1]. As a rule, the starting etching solution contains approximately (g l^{-1}): Fe^{3+} 90, Fe^{2+} 20, and Cu^{2+} 10. In etching a type-plate, the concentration of the oxidizing agent (Fe^{3+}) decreases and etching products (Fe^{2+} and Cu^{2+}) are accumulated. This leads to a decrease in the rate of etching and deterioration of its quality and necessitates replacement of the etching solution with its fresh portions. Since the cost of preparation of a fresh etching solution and that of utilization of spent etchant are rather high, the most natural solution of this technological and, simultaneously, environmental problem consists in regeneration and reuse of etching solutions.

The clear-cut distinction of the etching solution used in printing industry from a similar solution employed in manufacture of printed-circuit boards consists in that it contains organic additives introduced to ensure the required quality of etching. The behavior of these additives in the etching process and in regeneration of these solutions has not been studied so far. Therefore, two problems are to solved in developing the process and apparatus for regeneration of etching solutions of this kind. It is necessary to ensure the optimal mode of regeneration of inorganic components and also to study the behavior of organic additives in recycling of the etching solutions and determine the conditions under which the solutions can be purified to remove organic substances. Tackling with these problems was the aim of this study.

EXPERIMENTAL

A spent etching solution contains, in addition to $FeCl_3$, also $FeCl_2$ and $CuCl_2$. An ideal technique for regeneration of solutions of this kind is the membrane electrolysis [2, 3], since this method makes it possible to reverse, at the expense of electric power, the chemical reactions occurring in etching and thus to restore the composition of the solution without introducing into it any additional chemicals (oxidizing and reducing agents). The solution is regenerated in two stages in an electrolyzer with an anion-exchange membrane. In the first stage, the etching solution is subjected to cathodic treatment, with the result that Fe^{3+} is reduced to Fe^{2+}, and Cu^{2+}, to metallic copper:

$$FeCl_3 + e = FeCl_2 + Cl^-, \quad (1)$$

$$CuCl_2 + 2e = Cu + 2Cl^-. \quad (2)$$

The treated catholyte contains the required amount of Cu^{2+}, but the ratio of Fe^{3+} to Fe^{2+} ion concentrations is far from being normal. Therefore, anodic treatment of the solution, carried out in the second stage of regeneration, is necessary. In the process, oxidation of Fe^{2+} to Fe^{3+} and transfer of Cl^- across the membrane from the cathode chamber into the anode one leads to formation of an $FeCl_3$ solution:

$$FeCl_2 - e + Cl^- = FeCl_3. \quad (3)$$

In the course of anodic treatment, the concentration of Fe^{2+} in the anolyte decreases and that of Fe^{3+} increases. As a result, the concentrations of all the

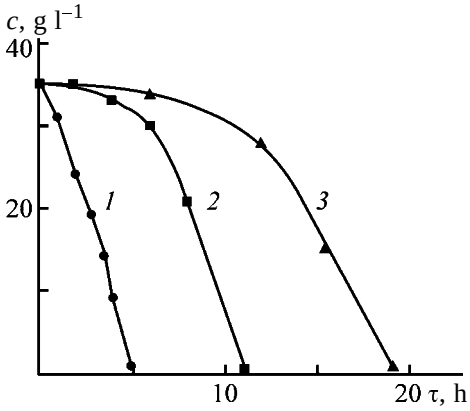

Fig. 1. Variation of the concentration c of copper(II) ions in the catholyte in the course of electrochemical regeneration at different current densities. (τ) Time. Current density (A dm^{-2}): (*1*) 1.5, (*2*) 3, and (*3*) 6.

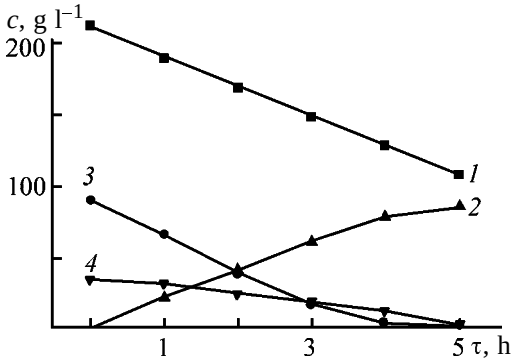

Fig. 2. Variation of the concentration *c* of catholyte macrocomponents with time τ of electrolysis. Current density i = 6 A dm^{-2}; the same for Fig. 3. Macrocomponent: (*1*) Cl^-, (*2*) Fe^{2+}, (*3*) Fe^{3+}, and (*4*) Cu^{2+}.

macrocomponents become close to those in the starting etching solution at a certain instant of time, and the solution being regenerated can be reused in etching.

A model etching solution, for which the cathodic regeneration mode was chosen, contained $FeCl_3$ and $CuCl_2$, with Fe^{3+} and Cu^{2+} concentrations of 95 and 35 g l^{-1}, respectively. An $FeCl_2$ solution (110 g l^{-1} in terms of Fe^{2+}) served as anolyte. The solutions were prepared from pure-grade chemicals and distilled water. The experiments wee performed in a membrane electrolyzer in the galvanostatic mode at current densities i of 1.5–6 A dm^{-2}. The electrode spaces were separated by an MA-40 anion-exchange membrane. The cathode was made of titanium, and the anode, of graphite. The working areas of the electrodes and the membrane were 0.36 dm^2. The solution volume in each of the chambers was 250 ml. During electrolysis, the catholyte and anolyte in the non-flow-through chambers were agitated with compressed air from a microcompressor.

In the course of regeneration, the concentrations of macrocomponents in the catholyte and anolyte, current strength, cathode and anode potentials (relative to a saturated calomel electrode), pH value, and temperature and volume of the solution were monitored. The concentrations of Fe^{3+}, Fe^{2+}, and Cl^- were determined by titration [4], and the total Cu, by the atomic-absorption method. Direct cathodic voltammetry on a renewable graphite electrode [5] was employed for proximate analysis of the solutions for these components. The concentration of organic substances in the solutions was found from the total organic carbon by the method developed in [6].

The optimal working parameters of electrolysis are to be found experimentally for any particular type of etching solution, depending on its composition. The choice is due to the necessity for satisfying simultaneously several conditions ensuring the maximum rate of copper recovery, preventing electrolyte overheating, and precluding occurrence of side electrode processes.

Figure 1 shows how the concentration of copper(II) ions in the catholyte varies in the course of electrolysis at different current densities. It can be seen that, depending on the current density, two different ways of development of the cathodic process are observed: successive and parallel reduction of Fe^{3+} and Cu^{2+}. At low current densities, these ions are reduced successively: first, mainly Fe^{3+} ions are reduced, with virtually no metallic copper recovered, and only after the concentrations of Fe^{3+} and Cu^{2+} become close, the rate of copper recovery increases. With increasing current density, the initial delay in the beginning of copper deposition shortens dramatically and virtually vanishes at i = 6 A dm^{-2}. Naturally, the reduction of Fe^{3+} leads to an increase in the concentration of Fe^{2+} (Fig. 2). Simultaneously, the concentration of Cl^- ions decreases because of their migration into the anode chamber, i.e., the process of electrochemical regeneration is described virtually quantitatively by a set of equations (1)–(3). A minor deviation from this scheme consists in the appearance of a small amount of copper ions in the anolyte (up to 1.5 g l^{-1}) in the final stage of electrolysis. This is presumably due to formation in the catholyte of negatively charged complexes of copper(I) ($CuCl_2^-$ and $CuCl_3^{2-}$) in the first stage of copper(II) discharge and to their migration across the anion-exchange membrane into the anode chamber.

Further intensification of copper recovery by raising the current density is limited, on the one hand, by

solution heating and, on the other, by side reactions of H_2 evolution at the cathode and Cl_2 evolution at the anode. The solution heating is limited by the thermal stability of the ion-exchange membrane (about 50°C). Evolution of chlorine at the anode is unacceptable environmentally, and evolution of hydrogen at the cathode is accompanied by an undesirable increase in pH in the near-cathode layer and by formation of iron and copper hydroxides. For example, during cathodic treatment at current density of 6 A dm^{-2}, the pH of the catholyte grows from 0.2 to 1–1.7, i.e., to values at which $Fe(OH)_3$ may start to form, and the solution temperature increases to 40°C (Fig. 3), approaching the maximum permissible value. In this context, raising the current density further is hardly advisable.

A pilot batch of real spent solutions was regenerated under the chosen conditions on an electromembrane installation comprising an electrolyzer, a dc power source (12 V, 50 A), a microcompressor for air bubbling in order to agitate the catholyte and anolyte, and an electronic thermometer. The cathode and anode were made of titanium and graphite, respectively. The working area of each of the electrodes was 4 dm^2, and the membrane area, 6.6 dm^2; the volumes of the catholyte and anolyte were 20 l each.

Figure 4 shows anodic and cathodic current–voltage characteristics of a real etching solution at characteristic points of its regeneration: (1) starting spent solution and the same solution after (2) cathodic and (3) anodic treatments. The voltammograms enable prompt monitoring of the regeneration process and make it possible to evaluate the concentrations of macrocomponents in the catholyte and anolyte in order to terminate at due time the solution treatment. As regards the quantitative interpretation of the curves, it should be noted that the cathodic peak at φ = 400 mV is related to reduction of Fe^{3+} to Fe^{2+}. The potential of Cu^{2+} reduction to Cu^+ lies in the same range of potentials [7], so that the peaks of Fe^{3+} and Cu^{2+} reduction virtually coincide. The second peak in the cathodic part of the voltammogram (φ = –350 mV) is associated with reduction of Cu^+ to metallic copper. In the anodic part of the voltammogram, there is a single peak at φ = 750 mV, which corresponds to oxidation of Fe^{2+} to Fe^{3+}. The voltammograms also show the potentials of side electrode reactions: evolution of Cl_2 at the anode is possible at φ ≈ 1.5–1.6 V, and that of hydrogen at the cathode, at about –(0.6–0.7) V. Comparison of the current–voltage curves in Fig. 4 shows that electrochemical regeneration ensures that the excess concentration of copper(II) is removed

from a solution and the necessary Fe^{3+}/Fe^{2+} ratio is restored.

Prolonged studies of the electrochemical regeneration demonstrated that, if the recommended current density of 6 A dm^{-2} is used, the main electrolysis parameters in processing of real etching solutions in the electromembrane setup (cathode and anode potentials, voltage drop across the membrane, and solution temperature) are close to their limiting values but do

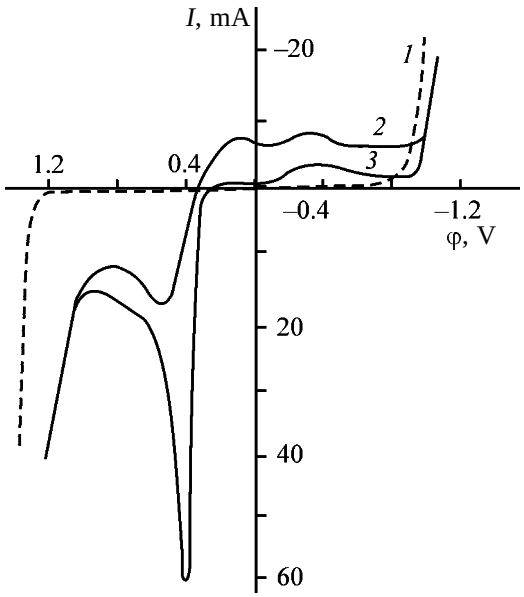

Fig. 5. Cathodic and anodic polarization curves of (*1*) supporting electrolyte (2 M NaCl + 0.15 M HCl) and solutions with addition (1 g l^{-1}) of (*2*) stabilizer and (*3*) calibrator.

not exceed them, which indicates that the regeneration mode is nearly optimal. The setup has been working in this mode for already more than three years. During this period of time, more than 10 000 l of the etching solution has been regenerated. The average processing rate of the etching solution was 12 l day^{-1}, and the energy expenditure, 0.27 kW h l^{-1}, with copper deposited at the cathode in the form of a powder and periodically removed from the titanium cathode when replacing the regenerated solution.

The prolonged experience of electrochemical regeneration of spent etching solutions in manufacture of copper type-plates demonstrated the efficiency of membrane electrolysis, which makes it possible not only to restore the etching ability of the solution, but to recover copper from it. However, it was established that the quality of the type-plates became poorer after 4–5 etching cycles, although all the macroscopic parameters of the regenerated solutions were normal.

The most probable reason for the impaired quality of etching is accumulation of organic additives or products of their degradation in the solution. The organic substances contained in a mixture of two brand-name additives, calibrator and stabilizer, are added to the solution to ensure high quality and fast etching rate.

The behavior of additives in the course of regeneration can be prognosticated qualitatively if their electrochemical activity, i.e., the ability to be oxidized or reduced at electrodes, and also their chemical stability are known. Figure 5 shows voltammograms of the supporting electrolyte, and also of the calibrator and stabilizer. It can be seen that both the organic additives are electrochemically active, i.e., exhibit peaks of both reduction and oxidation in the working range of potentials. Since it is known that one of the additives contains thiourea and formamidine disulfide (FADS), it should be mentioned that these substances are chemically unstable. For example, FADS decomposes in the course of time into thiourea, cyanamide, and sulfur [8]. Thiourea, in turn, may decompose in acid solutions to give H_2S [9]. Thus, it follows from the results presented that the organic additives used in etching are active electrochemically and unstable chemically. Therefore, they may decompose, with decomposition products accumulated both in the etching stage and in any of the two stages in electrochemical regeneration of solutions.

Quantitative monitoring of organic additives in etching solutions is strongly complicated by specific features of the etchant, highly intense coloration and high concentration of macrocomponents. Such a composition of the supporting solution made impossible use for this purpose of UV spectroscopy [8], voltammetry[1], and various chemical methods based on oxidation of organic substances (chemical consumption of oxygen, permanganate oxidizability, etc.) [10]. The only method applicable to determination of the total organic carbon is that [6] according to which organic substances contained in a solution are found from the amount of CO_2 evolved in mineralization of the etching solution in the presence of H_2O_2 and under its irradiation with UV light in a closed quartz reactor.

The changes in the concentration of the total organic carbon (g l^{-1}) in electrochemical regeneration of samples of etching solutions with low (sample 1) and high (sample 2) concentration of organic substances are presented below:

Treatment stage	Sample no. 1	Sample no. 2
Starting solution	0.25	0.95
Cathodic treatment	0.20	0.75
Anodic treatment	0.15	0.65

It can be seen that the content of organic substances decreases in both cathodic and anodic treatment of a solution. The relative degree of removal of organic additives is the higher, the lower their initial content

[1] Characteristic peaks of organic additives (Fig. 5) lie within the same range of potentials as the peaks of the macrocomponents (Fig. 4), but their intensity is much lower than that of the latter (by approximately two orders of magnitude).

Residual concentration of total organic carbon, c_{res}, in sorption purification of two samples of etching solutions with various specific charges q of Sibunit sorbent. Solution agitation by air, contact time 3 h

Sample	c_{res}, g l^{-1}, at indicated q, g l^{-1}					
	0	10	30	50	60	100
1	0.25	0.18	–	0.05	–	0.05
2	0.95	0.80	0.65	–	0.55	0.50

(70% for the lower curve and 30% for the upper one). The decrease in the recovery of organic impurities with their increasing concentration in the starting solution may be due to gradual accumulation of products formed in their conversion, which are more stable against electrochemical treatment. Anyway, it may be concluded on the basis of the aforesaid that accumulation of organic substances in high concentrations is inadvisable and it is necessary to regularly purify etching solutions to remove organic impurities.

The most appropriate technique to be used for this purpose is sorption by activated carbon, and one of the most promising sorbents is a new carbon material Sibunit [11]. This sorbent is distinguished by high mechanical, chemical, and thermal stability (1000–1500°C) and is simple in regeneration. The efficiency of sorption purification was confirmed on solutions with the maximum and minimum content of organic impurities.

The table illustrates the influence exerted by the sorbent charge on the removal of organic substances. It can be seen that the first portions of the sorbent show the most effective performance, especially in solutions with relatively low concentration of organic impurities. At Sibunit expenditure exceeding 50 g l^{-1}, the sorption slows down, and, therefore, the recommended specific expenditure of the sorbent for purification of etching solutions to remove organic substances is about 50–60 g l^{-1}.

Enlarged-scale tests of joint electrochemical and sorption regeneration of industrial $FeCl_3$-based etching solutions with organic additives gave good results as regards both the rate and quality of etching with regenerated solutions, close to those for fresh etchants.

CONCLUSIONS

(1) A study of the behavior of inorganic macrocomponents (Fe^{3+}, Fe^{2+}, Cu^{2+}, and Cl^-) and organic additives of spent etching solutions in their electrochemical regeneration and recycling of regenerated solutions demonstrated that successive cathodic and anodic treatments of etching solutions restore the concentrations of the macrocomponents to the required level and remove up to 30% of organic impurities.

(2) An integrated method for regeneration of etching solutions was developed. This method combines electrochemical and sorption stages and allows reuse of a regenerated solution, which ensures the required rate and quality of etching.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Certain Organic and Inorganic Salts on Dissolution of Zinc

V. V. Ekilik, E. A. Tugolukova, and A. G. Berezhnaya

Rostov State University, Rostov-on-Don, Russia

Received August 8, 2002; in final form, June 2003

Abstract—Dissolution of zinc in a borate buffer solution with addition of substituted pyridinium perchlorates and some inorganic salts was studied. The performance of additives in the active and passive states and in the case of local depassivation of zinc was compared using various methods, including correlation analysis.

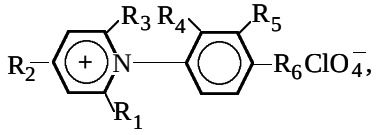
Data on additives used in anodic dissolution of zinc in borate buffer solutions are limited to aromatic amino acids and their salts [1], and also to certain inorganic compounds [2], which inhibit or promote the process.

The aim of this study was to elucidate the mechanism and character of zinc dissolution, reveal the influence of substituents in pyridinium cations, and compare the effects of organic and inorganic salts.

EXPERIMENTAL

Dissolution of zinc (99.9% Zn) was studied by measuring polarization curves with stepwise (with intervals of 30 s) increasing potential E, anodic chronoammograms at constant E, and cyclic chronovoltammograms in a borate buffer solution (pH 7.4) bubbled with purified argon. The electrode, having the form of a plate with working surface area of 1 cm^2, was conditioned with emery paper with decreasing grain size (2–0) and degreased with purified ethanol. The measurements were performed in a three-electrode cell with separated catholyte and anolyte at 25°C. Saturated silver chloride electrode was used as reference, relative to which all E values are given.

As additives were used $KClO_4$, $LiClO_4$, KCl, KBr (all salts of chemically pure grade) and pyridinium perchlorates



where $R_1 = R_2 = R_3 = CH_3$, $R_5 = R_6 = H$, $R_4 = NH_2$ (no. 1); $R_1 = R_2 = R_3 = CH_3$, $R_4 = R_6 = H$, $R_5 = NH_2$ (no. 2); $R_1 = R_2 = R_3 = CH_3$, $R_5 = R_6 = H$, $R_4 = Br$ (no. 3); $R_1 = R_2 = R_3 = C_6H_5$, $R_4 = R_6 = H$, $R_5 = NH_2$ (no. 4); $R_1 = R_2 = R_3 = C_6H_5$, $R_4 = R_5 = H$, $R_6 = NH_2$ (no. 5); $R_1 = R_2 = R_3 = C_6H_5$, $R_5 = R_6 = H$, $R_4 = Br$ (no. 6); $R_1 = R_3 =$  , $R_2 = C_6H_5$, $R_4 = R_5 = R_6 = H$ (no. 7).

The effect of the additives on the dissolution process was evaluated by the coefficient $K = i/i_1$, where i and i_1 are the process rates in, respectively, straight solution and that with an additive.

Before analyzing the influence exerted by the additives, it is appropriate to consider in brief the kinetics and mechanism of anodic dissolution of zinc.

1070-4272/03/7611-1752$25.00

In accordance with the data of [1], zinc is anodically passivated (Fig. 1) and is not subject to local passivation in the absence of additives.

The nature of the hindered stage was judged from results of potentiostatic and chronovoltammetric measurements. According to the theory of cyclic voltammetry [3], the criterion of a reversible diffusion-controlled process is the presence of linear dependences of the current densities of the anodic and cathodic peaks on the square root of the variation rate of E. Another necessary condition is that the difference of the peak potentials must not exceed $58/n$ mV, where n is the number of electrons. As can be seen from Fig. 2, only the first condition is satisfied. Consequently, the process occurs in the equilibrium mode, but is irreversible. Since E_{ap} and i_{ap} are the critical E_p and i_p of passivation, the data in Fig. 2 illustrate the role of diffusion in the transition of the metal to the passive state. The decrease in the diffusion limitations on the process with increasing potential sweep rate V causes a pronounced rise in E_{ap} and i_{ap}, i.e., hinders passivation. The important role of mass-transfer in the solid phase in formation and reduction of the oxide in passivation and activation of a copper electrode under conditions of reversible dissolution was mentioned in [4]. Presumably, the anodic peak does not correspond under the conditions considered to only equilibrium formation of zinc oxide, since metal dissolution occurs in parallel with film formation.

It should also be noted that, in the absence of an active–passive transition, no anodic peak is observed in the cyclic voltammogram, in contrast to the cathodic peak. This was demonstrated for the NiZn alloy with 20 wt % Ni, which is passive even at the potential of free corrosion, although the dependence of the current density of total passivation, i_{tp}, on $V^{1/2}$ is similar to that shown in Fig. 2.

The anodic chronoammograms in Fig. 2 describe dissolution of zinc in the active and passive states. In a straight solution, the time dependence of the rate of active dissolution is characterized by three regions: at $\tau < 50$ s, the straight lines i–$\tau^{1/2}$ (Fig. 3c) indicate, with account taken of the diffusion-kinetic mode of the process [5, 6], that the rates of the charge-transfer (i_e) and nonstationary-diffusion (i_{nd}) stages are comparable [7]; at 50 s $< \tau <$ 3 min, the straight lines i–$\tau^{-1/2}$, extrapolated to the origin of coordinates (Fig. 3b), indicate that nonstationary diffusion is the rate-limiting stage [7]; at $\tau > 5$ min, when $i \neq f$ (Fig. 3b), the process is controlled by stationary liquid-phase diffusion at a rate i_{sd}.

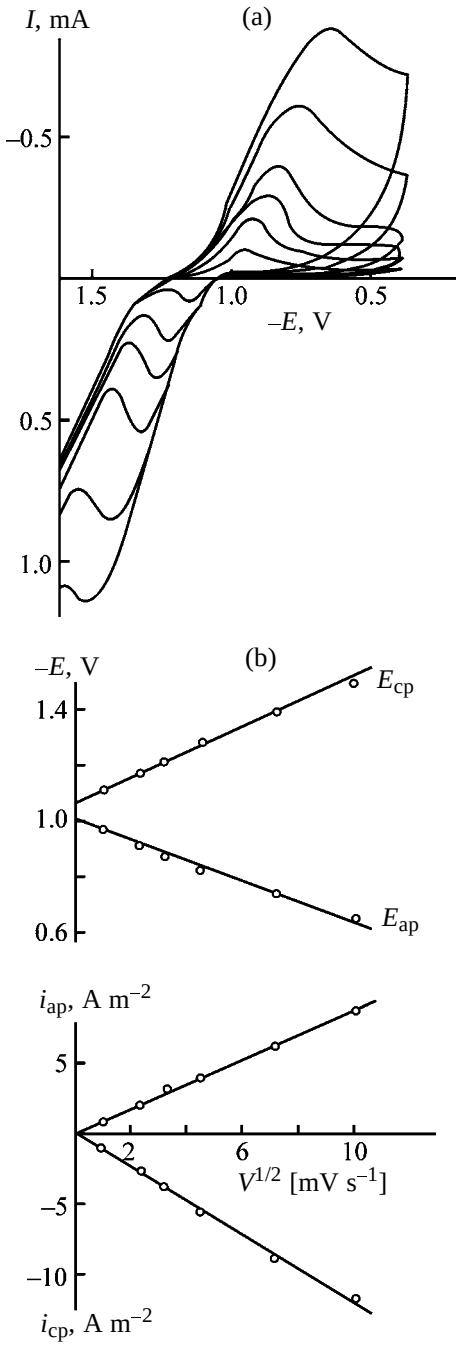

Fig. 2. (a) Chronoammograms measured in straight solution and (b) dependences of the potentials E_{cp} and E_{ap} and current densities i_{cp} and i_{ap} corresponding to cathodic and anodic peaks in the chronovoltammograms on the potential sweep rate V. Potential sweep rates (in order of increasing current in the chronovoltammogram) 1, 5, 10, 20, 50, and 100 mV s^{-1}. (I) Current and (E) potential.

For the case of reversible dissolution, the data of [7, 8] were used to obtain the dependence of i on τ and stage rates at polarization $\Delta E \gg RT/F$ in the first region:

$$i_{nd} = nF(c_S - c_0)(D/\pi\tau)^{1/2} = \gamma_1\tau^{-1/2}, \quad (3)$$

where c_S and c_0 are, respectively, the surface and volume concentrations of Zn(II), and D is the diffusion coefficient.

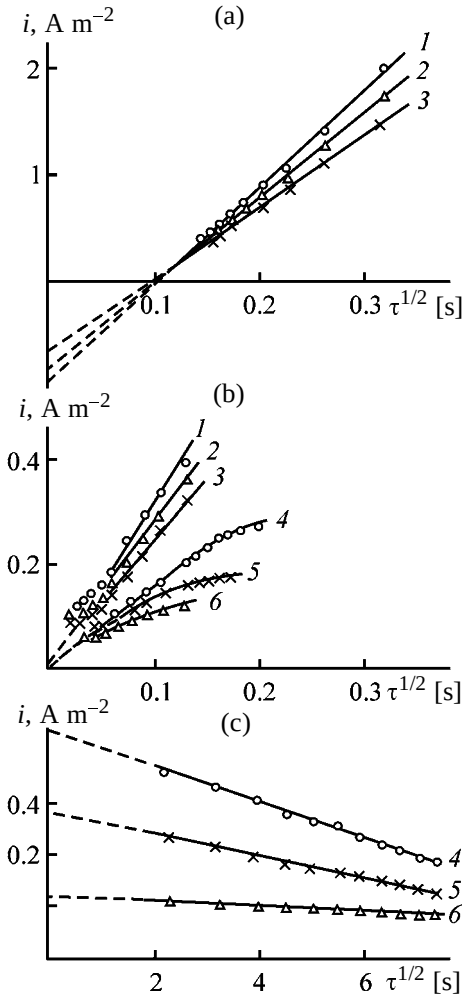

Fig. 3. Anodic chronoammograms measured in (*1*, *4*) straight solution and solutions with additive nos. (*2*, *6*) 5 and (*3*, *5*) 1. Concentration of additives 10^{-4} M; the same for Fig. 4. (*i*) Current density and (τ) time. Potential, V: (*1*–*3*) –0.5 and (*4*–*6*) –1.05. (a–c) For explanation, see text.

It follows from Eq. (2) that

$$\gamma_1 = 0.64i_e^2Q^{-1}. \quad (4)$$

The data of Fig. 3c were used to determine, using Eqs. (1)–(4), the main kinetic characteristics (Table 1).

In the second region, in which $i \approx i_{nd}$, the dependence of i on τ is described by Eq. (3), which makes it possible to find γ_2 from the straight line i–$\tau^{1/2}$ (Fig. 3b). Comparison of the values of γ_1 and γ_2 (Table 1) shows that γ decreases with time. To a first approximation, this can be attributed, in accordance with Eq. (3), to an increase in c_0 with time. Since the dissolution occurs at E = –1.05 V, which is close to E_p = –1.02 V, it can be assumed, with account of the model of concurrent processes of metal dissolution and oxygen chemisorption [9], that a passive film is formed in the course of time, which may be a second reason for a decline in γ because of the decreasing effective value of D. This conclusion is supported by the close values of steady-state i at E equal to –1.05 and –0.5 V (Fig. 3b).

When an anodic chronoammogram is measured at E = –0.5 V, weak areas of air-formed oxide are strengthened by the anodic oxide, and the decaying process of rearrangement of the oxide–hydroxide film leads to a decrease in i. It has been noted [9] that time dependences of i for other metals and of the rates of formation of surface layers on coatings are described, in the general case, by the equation

$$i = i_0 + \gamma\tau^{-\beta}, \quad (5)$$

where i_0, γ, and β are constants, with β equal to 0.5 [10, 11] or 1 [11, 12].

The process on zinc in a borate buffer solution occurs in two stages, which is indicated by two straight lines i–$\tau^{-1/2}$ (Figs. 3a, 3b); the constants of Eq. (5) are listed in Table 2. After the second stage, a steady-state current i_s is attained.

Taking into account the diffusion-kinetic control over dissolution of zinc in the active state at small τ, the role of inhibitors can be played by surfactants,

Table 2. Constants of Eq. (5) describing the anodic chronoammogram of passive dissolution of zinc

which make lower i_s, and also by film-forming and complexing agents, which diminish, respectively, the effective and true value of D. According to Table 1, substituted pyridinium perchlorates are rather versatile. They hinder both stages of the process, this being more pronounced for the charge-transfer stage, for which the values of K for additive nos. 1 and 5 are equal to, respectively, 1.5 and 3.6. The hindrance to the stationary-diffusion stage remains virtually unchanged on passing from mixed ($K \approx 1.3$) to diffusion ($K \approx 1.2$) control. The additives make longer the time during which the type of control changes (Fig. 3b). Therefore, K increases somewhat, to 1.4–1.6, in the stationary mode.

In the passive state, a certain protective effect would be expected for compounds whose particles can be incorporated into a film, changing its structure and healing its defects. Substituted pyridinium perchlorates mainly affect the value of γ, but do so to a lesser extent than in the active region, and the values of K, equal to 1.1–1.2 in the nonstationary mode, remain virtually unchanged in passing to the stationary mode (K = 1.2–1.3).

The effect of E on K for pyridinium salts was evaluated, with account of the nature of the zinc dissolution process, on the basis of polarization measurements (Table 3).

Table 3 reveals a characteristic feature of the influence exerted by the additives. The more pronounced the protective effect in the active region, the weaker the same effect in the passive region and the stronger the stimulation of local passivation. Presumably, this is due to competition of adsorption of surfactants and passivation in accordance with the model described in [9]. On areas occupied by chemisorbed inhibitor particles, chemisorption of oxygen and subsequent formation of a passivating oxide–hydroxide film are hindered. As a result, the overall influence exerted by the inhibitor and the film decreases with increasing E. This effect is the stronger, the easier the chemisorption of particles in the active region. Naturally, the weakening of the protective properties of the passive film favors local depassivation under the action of activator anions. The role of these anions can be played by ClO_4^- ions of pyridinium salts.

The regular trend in the variation of K within the series of the additive studied (Table 3) created a prerequisite for use of a correlation based on the linear free energy relationship. Here, several approaches are possible. Attempts to use reference values of σ constants of substituents for polysubstituted compounds within the additive scheme failed to give positive results. Using values of K for the stationary reaction series when performing the correlation, as it was done

Table 3. Values of K for substituted pyridinium perchlorates in relation to their structure and potential E. Concentration of additives 10^{-4} M

E* range	$-E$, V	K for indicated additive						
		no. 2	no. 3	no. 1	no. 7	no. 6	no. 4	no. 5
$E < E_p$	1.06	1.7	1.6	1.8	2.0	2.2	3.4	4.9
$E = E_p$	1.02	1.5	1.4	1.6	1.9	2.1	3.3	3.9
$E_p < E < E_{tp}$	0.96	1.5	1.6	1.7	2.0	2.1	2.7	3.1
$E = E_{tp}$	0.90	1.5	1.5	1.7	1.5	1.2	1.1	1.1

4	315	8.0	23.2
5	315	9.7	27.9

for similar compounds for the case of inhibition of acid corrosion of metals, is too formalized. Therefore, the relationship between K and some parameters of the electronic absorption spectra of dissolved additives was considered by analogy with [14, 15]. This correlation is based on the concept of surfactant chemisorption in the electronically excited state [16]. The excitation energy of π electrons is characterized by the wavelength λ of the longest-wave absorption band in the UV part of the electronic spectrum [17]. The probability of transition of the system from the ground state to excited state, determined by the oscillator strength f, is one more factor, in addition to that energy-related, which strongly affects the chemisorption. The state of polarization of the electronic transition is indicated by such a complex characteristic as

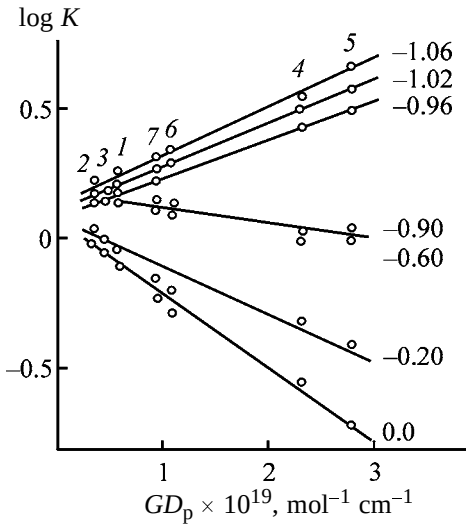

Fig. 4. log K vs. GD_p. (K) Ratio of the anode current densities in a straight solution and that with an additive; (GD_p) product of the possible degeneracy of the upper and lower states by the dipole strength of the electronic transition. Digits at lines correspond to potentials (V); the same for Fig. 5. Digits at points correspond to numbers of additives.

the product of the dipole strength of the transition, D_p, by the possible degeneracy G of the upper and lower states [18]:

$$GD_p = 0.124 \times 10^{-12} f\lambda. \quad (6)$$

The characteristics mentioned are listed in Table 4.

The correlation expressions relating K to λ and f to GD_p have the general form [13, 14]

$$\log K = \log K_{0,x} + æ_x(X - X_0), \quad (7)$$

where X stands for λ, f, or GD_p; $K_{0,x}$ and $æ_x$ are the constants of the reaction series; $\lambda_0 = 275$ nm, $f_0 = 1.4 \times 10^{-4}\ mol^{-1}\ cm^{-2}$, and $GD_p = 3.4 \times 10^{-20}\ mol^{-1}\ cm^{-1}$ are the values of the characteristics taken as standard to rule out far extrapolation of K.

The applicability of relations of the type (7) is illustrated by plots in Fig. 4, and Table 5 lists the constants of the reaction series and correlation coefficients r. The values of K for determining K_0, æ, and r are taken from Table 3.

Table 5 shows that the worst correlation is obtained between log$K$ and λ. This becomes understandable when account is taken of the fact that λ is less sensitive to the nature of substituents (Table 4) than K (Table 3). In accordance with the above-mentioned change in K on passing from active to passive zinc dissolution (Table 3), the sign of the constants æ changes to the opposite. In this same transition, a decrease in r is observed, which may be due to influence of unaccounted-for factors. In particular, the methyl-substituted additives from the beginning of the series (nos. 1–3) can more readily find their way into the forming oxide film, compared with the other, phenyl-substituted additives. To the transition mentioned corresponds a reversal of the sign of the surface charge ($E^{Zn}_{q=0} = -0.82$ V [19]) from negative to positive, which favors a π-electron interaction and can change the surface orientation of particles.

The effect of the additives strongly depends on their concentration, which was demonstrated for compound no. 2, $KClO_4$, and mixture of these (Figs. 1 and 5). At more negative E, additive no. 2 acts as an adsorption inhibitor, for which characteristic straight lines log$K$–log$c$ with slopes changing in the same direction as K were obtained (Fig. 5a). Potassium perchlorate behaves similarly up to $c = 5 \times 10^{-4}$, after which K starts to decrease. Possibly, this is due to the fact that the anions are characterized by U-shaped dependences of the rate of metal dissolution on c [20].

0.60	1.4	0.7	1.5	–0.2	–1.5	–0.5	0.797	0.884	0.917
0.20	0.9	0.9	0.9	–0.5	–4.5	–1.6	0.744	0.940	0.926
0.00	0.7	0.8	0.8	–0.8	–6.9	–2.4	0.726	0.934	0.945

When $E \approx -0.7$ V is reached, anodic-anionic activation is observed, which is especially clearly manifested at $c > 3 \times 10^{-4}$ M (Figs. 1 and 5b). After a significant rise in i in the range W from -0.35 to -0.50 V, a virtually limiting anodic current is reached.

In order to eliminate anionic effects at potentials corresponding to the active–passive transition, binary mixtures of additive no. 2 and $KClO_4$ with constant total concentration of 1 mM were studied. In the absence of K^+ ions, this would make it possible to evaluate the influence exerted by the concentration of the pyridinium cation. However, the value of K for $KClO_4$ exceeds unity (Fig. 5c). Experiments with $LiClO_4$ demonstrated that the values of K for this additive are unity in the active region and virtually coincide with those in the presence of $KClO_4$ in passivation. This suggests that ClO_4^- ions play an important part in passivation, and K^+ ions, in hindrance to active dissolution. Therefore, the effect of the mixture can be, to a first approximation, considered in terms of joint adsorption of potassium and pyridinium cations. Their mutual influence was evaluated using the known method [21]

$$\delta = K_{\text{no. 2} + KClO_4}(K_{\text{no. 2}} K_{KClO_4})^{-1}, \qquad (8)$$

where the subscripts denote the additives used.

If the coefficient of mutual influence $\delta > 1$ at $K > 1$, the effects exerted by the inhibitors are mutually enhanced. Under the conditions studied, even though the additives belong to different types of compounds, they compete and mutually weaken the influence of each other, since $\delta < 1$ (Fig. 5e). The minimum values of δ correspond to a mixture with $c_{\text{no. 2}} = c_{KClO_4} = 5 \times 10^{-4}$ M. The extreme values of K for potassium perchlorate and for the mixture are observed at this same value of c_{KClO_4}. In agreement with the above-mentioned competition between surfactant adsorption and passivation, the dependences of K of a mixture on its composition exhibit the opposite behavior in the active region and in passivation (Fig. 5d). This transition is accompanied by weakening of the competitive

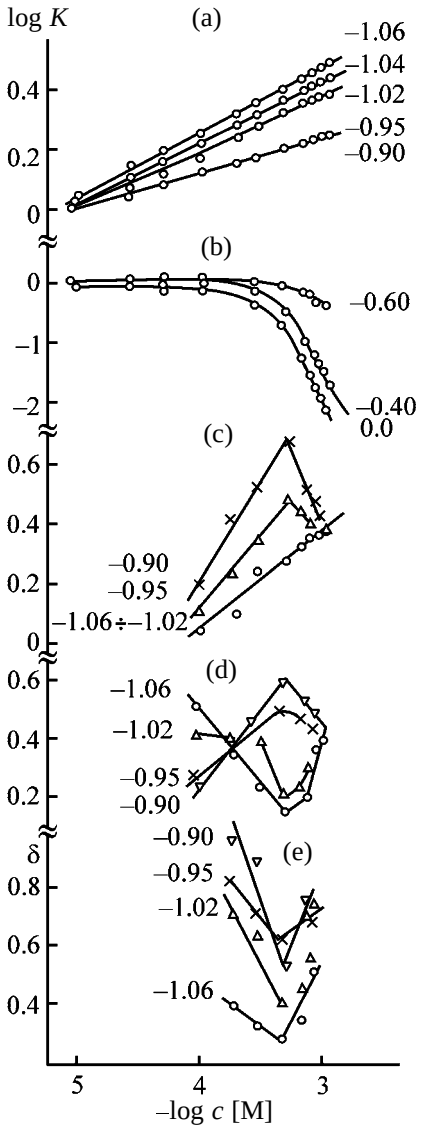

Fig. 5. log$K$ for (a, b) additive no. 2, (c) $KClO_4$, and (d) mixture of these, and also (e) δ vs. log$c$ for (a, b) additive no. 2 and (c–e) $KClO_4$. Table 6. Value of K in relation to E and nature of salt anion. Salt concentration 1 mM

$-E$, V	Value of K for indicated salts		
	$KClO_4$	KCl	KBr
1.06–1.02	2.4	2.0	1.5
0.95	2.3	4.1	4.3
0.90	2.2	1.8	3.0
0.80	2.4	2.3	3.1
0.50	0.020	0.016	0.015
0.00	0.006	0.006	0.006

action of the additives (Fig. 5e).

In the presence of KCl and KBr, the polarization curves are similar to those shown in Fig. 1 for pyridinium and potassium perchlorates; the corresponding values of K are listed in Table 6.

Compared with $KClO_4$, KCl and, especially, KBr additives hinder active dissolution to a lesser extent and are more effective in passivation; they lower the potential of local depassivation by 100 mV and accelerate somewhat this process. The limiting anodic current is virtually independent of the nature of salt.

CONCLUSIONS

(1) In the active state, zinc dissolves in the initial period of time with comparable rates of ionization and nonstationary diffusion; then the second of these becomes rate-limiting and, finally, gives way to stationary diffusion. Substituted pyridinium perchlorates hinder ionization to a greater extent.

(2) In the passive region, the time dependence of the dissolution rate is characterized by two portions. The sequence of pyridinium salts arranged in order of their increasing inhibiting action changes to the opposite one when zinc passes from the active to passive state, which is due to competition of two processes: chemisorption of additives and passivation by oxygen.

(3) It is advisable to correlate the performance of substituted pyridinium perchlorates in dissolution of zinc with parameters of the long-wave absorption band in the UV part of the electronic absorption spectrum of the dissolved additives.

(4) Mixtures of potassium and substituted pyridinium perchlorates give lower values of K in active dissolution of zinc, and higher values in passivation and in the passive state. Irrespective of the type of the process, the mixtures are characterized by mutual weakening of the influence exerted by the constituent compounds. This weakening is the most pronounced for the 1 : 1 composition.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Corrosion Behavior in Alkaline Media of Steel with Various Conversion Coatings in Concrete

G. Bikulčius, O. Girčiene, and V. Burokas

Institute of Chemistry, Vilnius, Lithuania

Received November 27, 2002; in final form, May 2003

Abstract—The corrosion behavior in alkaline media of St.3 steel with various conversion coatings in concrete was studied.

Reinforced concrete structures are widely used in construction of buildings and bridges. It is traditionally believed that steel in concrete is protected by passivation compounds formed in the strongly alkaline medium in pores (pH 12.6 at 25°C). However, carbon dioxide CO_2 present in the Earth's atmosphere enhances the corrosiveness of the medium toward reinforced concrete structures working under normal and humid conditions [1–5]. Penetration of carbon dioxide into concrete leads to its carbonation. Acid gases, e.g., SO_2, Cl_2, NO_2, etc., are frequently present in working spaces. Their interaction with concrete occurs similarly to the carbonation process. It has been established that the pH of the pore liquid decreases to 10.5 and less at high humidity in the presence of acid gases or chloride ions. It was shown in [6] that the threshold concentration of chloride ions at which iron corrosion begins depends on pH. With decreasing pH, the continuity of the protective layer on steel, which is composed of iron oxide γ-Fe_2O_3, is disturbed [1]. According to the results obtained by most of researchers, the corrosion rate of steel in carbonated concrete is the highest at periodic moistening of structures or in the case of condensate formation [2, 4, 5]. This problem has been studied extensively [6–10]. Analysis of published data makes it possible to state that steel is in the passive state only in uncarbonated concrete at low concentrations of chlorides.

Steel is commonly protected from corrosion with paint-and-varnish materials, electroplated and immersion coatings composed of Zn and its alloys, and conversion coatings deposited prior to painting. In [11], it was suggested to subject zinc coatings, in order to improve their corrosion resistance, to anodizing in solutions containing silicates, tetraborates, and alkali. The resulting anodic coating enhances by 20% the hardness of the zinc coating, exhibits good adhesion to the base, and possesses excellent corrosion-protective properties.

Conversion phosphate coatings [12–14] are films composed of difficultly soluble salts $Zn_3(PO_4)_2 \cdot 4H_2O$, $Fe_3(PO_4)_2 \cdot 2H_2O$, and $Zn_2Fe(PO_4)_2 \cdot 2H_2O$, formed in reaction of the metal with free phosphoric acid and with acidic Zn and Fe phosphates.

The phosphate layer formed improves the adhesive and protective properties of paint-and-varnish coatings and hinders corrosion when the paint film is damaged. Phosphate coatings are classified into two groups: crystalline coatings based on zinc phosphate, with mass of 1.4–7.5 g m^{-2}, and amorphous, based on the $FePO_4$, with mass of 0.2–1.4 g m^{-2}. Corrosion tests in a salt-spray chamber (5% NaCl) demonstrated that the corrosion resistance of steel with crystalline and amorphous phosphate coatings increases by a factor of several tens [15]. With properly chosen composition of the phosphating solution and conditions of its application, phosphate coatings with prescribed properties can be obtained in any particular case. Apparently, a certain structure and composition of a phosphate layer must correspond to each method of phosphating.

The aim of this study was to analyze the corrosion behavior in alkaline media of steel protected with various conversion coatings in concrete.

EXPERIMENTAL

The solutions used were prepared using analytically pure chemicals. The working electrodes were made of St.3 steel. Polarization curves were measured in the potentiodynamic mode at potential sweep rate of 0.1 mV s^{-1} in an aerated 0.1 M NaOH + 0.1 M NaCl solution at 25°C. A platinum electrode served as auxiliary electrode, and saturated silver chloride

1070-4272/03/7611-1759$25.00

Table 1. Composition of solutions and phosphating conditions

Phosphating	Composition,* M	pH	T, °C	τ, min	m, g m^{-2}

* Concentration of Se^{4+}, Cu^{2+}, and Ni^{2+} salts (color modifiers), M: F36 0.048, F16 0.35.

Ag/AgCl electrode, as reference. Prior to each measurement, samples were kept for 15 min in the solution under study. The corrosion current density was found by extrapolation of the Tafel portions of the anodic and cathodic polarization curves. Numerous studies have shown that the passivity of steel is commonly accompanied by a positive shift of the electrode potential of the metal. Therefore, the corrosion potential E_{cor} of steel in concrete can serve as indicator of its state. In measurements in concrete, the variation of E_{cor} of steel with time τ was studied. A saturated

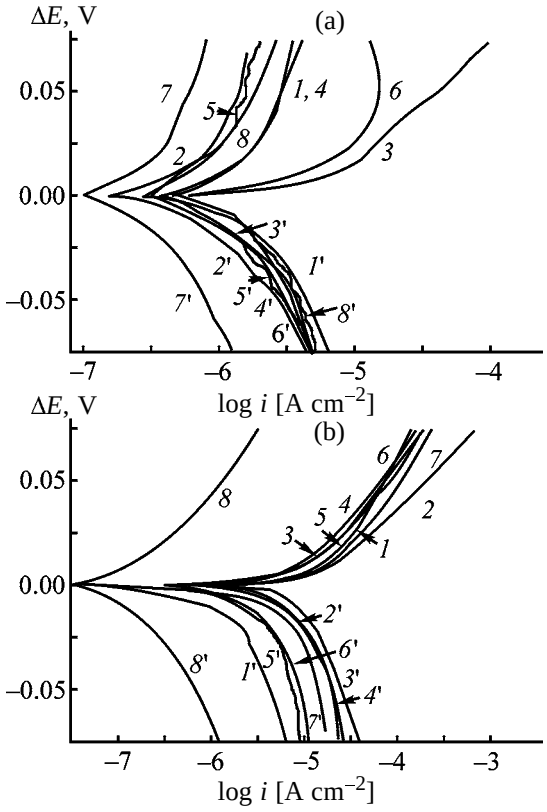

Fig. 1. (*1*–*8*) Anodic and (*1*′–*8*′) cathodic polarization curves obtained on St.3 steel in aerated 0.1 M NaOH solution containing 0.1 M NaCl at pH (a) 13 and (b) 9. Potential sweep rate V_s = 0.1 V s^{-1}. (*i*) Current density and (Δ*E*) polarization. (*1*) No coating; conversion coating: (*2*) FA–As–Al, (*3*) F16, (*4*) FA–As, (*5*) FA50(*n*), (*6*) F36, (*7*) FA50, and (*8*) F11.

$Cu/CuSO_4$ electrode served as reference. All the potentials are given in the hydrogen scale.

The composition of the electrolyte used to deposit conversion coatings onto steel plates, component concentrations, deposition modes, and coating masses are listed in Table 1.

Part of samples with amorphous phosphate coatings were dried at 100°C for 1 h (FA50), and another part remained untreated ([FA50(*n*)]. Silicate anodizing [11] of steel samples coated with FA50 was performed in a solution of composition (g l^{-1}): NaOH 30, $Na_2B_4O_7$ 90, and Na_2SiO_3, at solution temperature not exceeding 25°C in the course of 10 min with ac current of 20 A dm^{-2} for FA–As, and with ac and, additionally, pulsed current for FA–As–Al.

Reinforced concrete samples in the form of cylinders were made from portland cement of composition (%): SiO_2 21.4, Al_2O_3 3.9, Fe_2O_3 2.2, CaO 62.5, MgO 0.5, SO_3^{2-} 4.7, Na_2O 0.8, K_2O 0.6, and Cl^- 0.3, and steel reinforcement ($10 \times 10 \times 0.5$ mm St.3 steel plate). Cement cylinders 50 mm in diameter and 50 mm high were formed from a mixture with cement : sand ratio of 1 : 3 and water : cement ratio of 1 : 2. A steel plate with various conversion coatings was embedded in concrete cylinder at a height of 30 mm. Such a reinforced concrete sample was kept in a mold for 24 h. Then it was extracted, stored under laboratory conditions for 84 h, and placed in water or a 3.5% solution of NaCl in such a way that its lower part (10 mm) was submerged. With the cylinder in this position and good aeration of the external medium, diffusion of the solution into concrete is ensured, to the level of the steel plate. The potential of the steel reinforcement with various conversion coatings was measured daily over the course of 33 days. The degree of concrete carbonation was determined using the phenolphthalein indicator [12].

The values of i_{cor} of the samples under study in an aerated NaOH solution containing 0.1 M NaCl at pH 13 (Fig. 1a) and 9 (Fig. 1b), found by extrapolation of the Tafel portions of the anodic and cathodic

Table 2. Electrochemical parameters* of St.3 steel with conversion coatings in NaOH solutions containing 0.1 M NaCl

Coating	b_A, mV	b_C, mV	i_{cor}, A cm^{-2}	b_A, mV	b_C, mV	i_{cor}, A cm^{-2}
	pH 13			pH 9		
No coating	170	120	1.4×10^{-6}	72	104	1.3×10^{-5}
F16	57	158	3.2×10^{-6}	39	144	1.2×10^{-5}
FA50(*n*)	160	130	9.1×10^{-7}	56	233	8.0×10^{-6}
FA–As	125	80	8.9×10^{-7}	55	140	9.1×10^{-6}
FA–As–A1	221	76	6.8×10^{-7}	50	107	1.3×10^{-5}
F36	160	118	5.0×10^{-7}	87	105	5.4×10^{-6}
F11	106	104	4.4×10^{-7}	59	84	1.4×10^{-7}
FA50	174	76	3.0×10^{-7}	49	150	4.6×10^{-6}

* b_A and b_C are the anodic and cathodic Tafel constants.

polarization curves in the $\log i$–ΔE coordinates, are listed in Table 2. It can be seen that at pH 13 the lowest corrosion currents are observed for steel samples with F11 and FA50 coatings, and the highest, for samples without conversion coating and with F16 coating. With the solution pH decreasing to 9, i_{cor} grows by an order of magnitude for all of the samples studied (from 10^{-7}–10^{-6} A cm^{-2} at pH 13 to 10^{-6}–10^{-5} A cm^{-2} at pH 9). The only exception are samples with F11 coating, for which i_{cor} at pH 9 is 1.4×10^{-7} A dm^{-2} (Table 2). Thus, the lowest corrosion currents at pH 13 or 9 are observed for samples with conversion coatings F11 and FA50. Changes in the solution pH also affect the anodic (b_A) and cathodic (b_C) Tafel constants. At pH 13, b_A varies from 57 to 221 mV, and b_C, from 76 to 158 mV. At pH 9, b_A = 39–87 mV and b_C = 84–233 mV (Table 2).

Before carrying out measurements with steel in concrete, the rate of concrete carbonation was measured with phenolphthalein indicator. It was established experimentally that only in 7 days the pH value of the pore liquid in concrete decreased to 10 and/or less (pH ~9). The electrode potentials of samples without conversion coating and with F11, FA50, and F36 coatings, embedded in concrete, were measured in an NaOH solution (pH 13) (Fig. 2a) or 3.5% NaCl solution (pH ~9) (Fig. 2b) during 33 days.

Measurements of the dependence E_{cor}–τ for reinforced concrete samples submerged in an NaOH solution (pH 13) demonstrated that the potential of steel without conversion coating (Fig. 2a, curve *1*) decreases from 0 to –30 mV in the first 5 days, and then, during the following 28 days, gradually increases to 30 mV. A similar behavior was observed for steel with various conversion coatings. In the case of an FA50 coating (Fig. 2a, curve *4*), E_{cor} increases to 140 mV in 33 days. In the case of an F36 coating (Fig. 2a, curve *2*), E_{cor} decreases from 70 to –150 mV

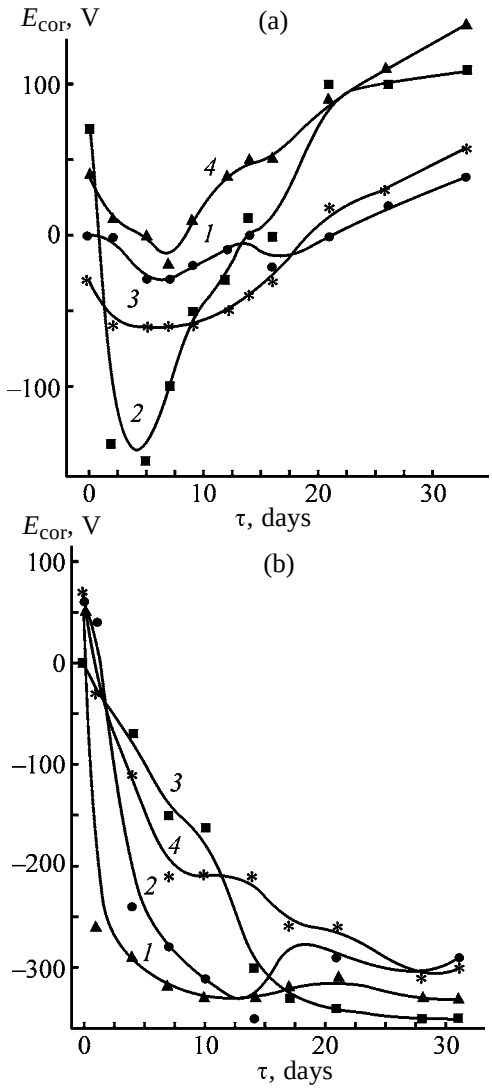

Fig. 2. Corrosion potential E_{cor} of St.3 steel with various conversion coatings in concrete vs. time τ of keeping in (a) NaOH and (b) 3.5% NaCl solutions. pH: (a) 13 and (b) 9. (*1*) Without coating; conversion coating: (*2*) F36, (*3*) F11, and (*4*) FA50.

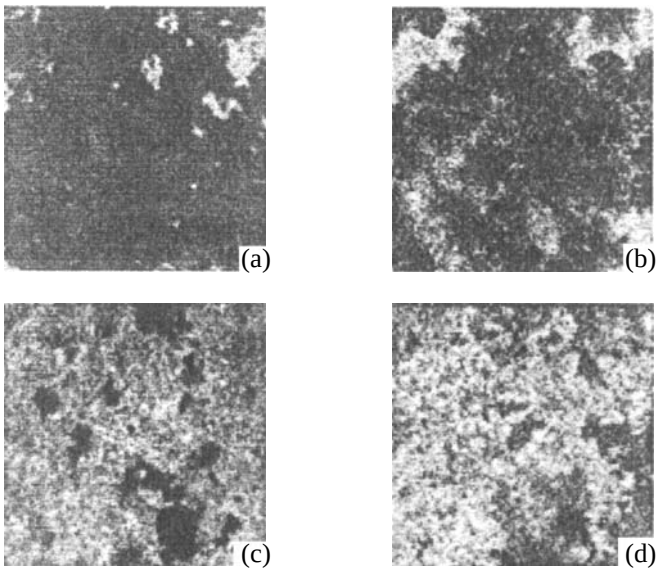

Fig. 3. Surface micrograph of St.3 with various conversion coatings after keeping in a 3.5% NaCl solution for 59 days. (a) Without coating; conversion coating: (b) F36, (c) F11, and (d) FA50.

during the first 5 days, then starts to grow to become 110 mV after 20 days of tests, and remains virtually unchanged during the subsequent 13 days. It should be noted that a steeper run of the E_{cor}–τ curve is observed in the given case. According to the results obtained, FA50 coatings show the highest corrosion resistance.

A study of the dependence E_{cor}–τ in a 3.5% NaCl solution (pH ~9) demonstrated that, in all cases, a rather steep decrease in E_{cor}, from 0–60 mV to the value ranging from –200 to –340 mV, is observed in the first 10–15 days (Fig. 2b). During the remaining 15–20 days, E_{cor} fluctuates within the range from –300 to –350 mV. However, the corrosion potential of samples with FA50 coating is more positive during 33 days than the E_{cor} of the other samples under study (Fig. 2b, curve *4*). This suggests that the FA50 coating has the best protective properties.

St.3 carbon steel can be represented, in the media under study over the whole range of potentials, as a system of the type metal–oxide or metal–metal phosphate, although the composition and structure of corrosion products may be more complex [14, 17]. It was established that the best protective properties in an NaOH solution containing no chloride ions (pH 13) are exhibited by the FA50 conversion coating (Fig. 2a, curve *4*). In a 3.5% NaCl solution (pH ~9), all the conversion coatings studied disintegrate during 33 days (Fig. 2b). However, the disintegration of the FA50 conversion coating (Fig. 2b, curve *4*) occurs at a lower rate.

Figures 3a–3d show surface micrographs of steel samples extracted from concrete after 59 days of tests in a 3.5% NaCl solution. The samples without conversion coating and with F36 coating are completely corroded (Figs. 3a, 3b). The F11 and FA50 coatings (Figs. 3c, 3d) exhibit better protective properties, and, therefore, St.3 steel is less subject to corrosion. Using the above results of the electrochemical measurements, it was established the lowest corrosion currents are observed in an NaOH solution containing 0.1 N NaCl at pH 13 and 9 for samples with F11 and FA50 conversion coatings (Table 2). A study of steel in concrete placed in water (pH 13) or 3.5% NaCl solution demonstrated that preference is to be given to FA50 coatings, since they exhibit the best protective properties.

CONCLUSIONS

(1) The lowest corrosion currents in an NaOH solution containing 0.1 M NaCl at pH 13 and 9 are observed for St.3 steel samples with conversion phosphate coatings F11 and FA50.

(2) Among the coatings studied, amorphous phosphate conversion coating FA50 ensures the best corrosion protection of a steel reinforcement in concrete placed in NaOH solution (pH 13) or 3.5% NaCl solution (pH ~9).

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Corrosion-Protective Properties of *N*-Phenacylmethylpyridinium Bromides

Kiev Polytechnic Institute, National Technical University of Ukraine, Kiev, Ukraine

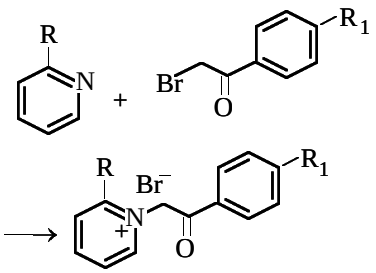
Received July 1, 2003

Abstract—The inhibiting action of *N*-phenacylmethylpyridinium bromides on corrosion of carbon steel in a 3 M sulfuric acid solution was studied. A relationship between the structure of the compounds under study and their corrosion-protective properties was revealed. Compounds ensuring high degree of corrosion protection of steel in acid media were found.

Despite that the relationship between the structure of organic compounds and their corrosion-protective properties have been studied for a relatively long time [1–3], this problem still remains topical. Particularly promising is a search for effective corrosion inhibitors among substances exhibiting the so-called intramolecular synergism [4–6]. This effect consists in that the presence of functional groups of varied nature in the inhibitor molecule enables multidimensional action on the corrosion process and ensures effective protection by the inhibitor.

As objects of study were chosen phenacylmethylpyridinium bromides **I**–**XI**, which are of interest in that they are simultaneously quaternary pyridinium salts and aromatic carbonyl compounds, i.e., belong to such types of organic compounds whose inhibiting action is well known [1, 2, 7].

Compounds **I**–**XI** were synthesized by alkylation of 2-substituted pyridines with the corresponding ω-bromoacetophenones:



I–**XI**

where R = H, CH_3, NH_2, $COCH_3$; R_1 = H, CH_3, OCH_3, Br, Cl, NO_2.

The presence in these compounds of a methylene bridge separating the pyridinium and benzoyl moieties makes it possible to act upon each of them separately by varying the substituents R and R_1 and to reveal factors positively affecting the inhibiting action of the molecule as a whole.

EXPERIMENTAL

Compounds **I**–**IV** were synthesized by published procedures; compounds **V**–**XI** were uknown previously, and their structure was confirmed by IR and ^1H NMR spectroscopy.

2-Amino-1-phenacylmethylpyridinium bromide V, 2-amino-1-(4-methylphenacyl)methylpyridinium bromide VII, 2-amino-1-(4-methoxyphenacyl)methylpyridinium bromide VIII, 2-amino-1-(4-bromophenacyl)methylpyridinium bromide IX, 2-amino-1-(4-chlorophenacyl)methylpyridinium bromide X, and 2-amino-1-(4-nitrophenacyl)methylpyridinium bromide XI. Solutions of equimolar amounts (0.02 M) of 2-aminopyridine and appropriate ω-bromoacetophenone in ethyl acetate were mixed. The reaction mixture was refluxed for 3 h for **V** and **VII** and for 5 h for **IX**–**XI**. The next day, the reaction mixture was treated with ether, and the precipitate formed was separated and recrystallized from ethanol–ether. For pyridium bromides **V** and **VII**–**XI**, the yields (%) and melting points (°C) are as follows: **V**, 82, 218–220; **VII**, 75, 191–193; **VIII**, 80, 232–234; **IX**, 77, 215–217; **X**, 82, 220–222; and **XI**, 60, 252–254.

2-Acetyl-1-phenacylmethylpyridinium bromide VI. A mixture of equimolar amounts (0.02 M) of 2-acetylpyridine and ω-bromoacetophenone was heated to 125–130°C for 20 min and treated with a minor

amount of ethanol; the precipitate formed was separated. Yield 35%, mp 198–200°C (from ethanol–ether).

To evaluate the corrosion-protective properties of the compounds under study, the hindrance factors γ and the degree *Z* of corrosion protection of steel were determined in the presence of 1×10^{-2} M of inhibitors in 3 M H_2SO_4 solutions at 20, 40, 60, and 80°C. The corrosion was monitored gravimetrically using 08KP steel samples with the working area of 14×10^{-4} m^2. The test duration was 24 h at 20°C, 2 h at 40 and 60°C, and 1 h at 80°C. Polarization curves were measured in the potentiodynamic mode at the potential sweep rate of 2 mV s^{-1} on a steel electrode in the initial and inhibited sulfuric acid solutions.

The test performed demonstrated that most of the compounds under study show noticeable inhibiting properties which are largely determined by the nature of substituents in their molecules (Table 1).

As is known [7], adsorption of quaternary pyridinium salts may occur both through electrostatic attraction of the pyridinium cation to the negatively charged metal surface and via specific π interaction of the pyridine with the metal. Attempts were made, by introducing substituents of varied electronic nature into the position 2 of the pyridine ring of **I** and thereby changing the charge on the nitrogen atom and the π-electron density of the pyridine ring, to reveal the role played by the pyridinium moiety of the molecule and evaluate the effect of the substituents introduced on the inhibiting effect of the forming compounds. It was found that, in going from **I** and **II** to the corresponding compounds with a CH_3 group heading the series of electron-donor substituents, the hindrance factor of steel corrosion grows somewhat. It increases at 20°C from 11.3 to 15.5 for compounds **I** and **III** and from 1.7 to 2.3 for **II** and **IV**. In the case of such a relatively strong electron-donor substituent as NH_2 group, the protective effect is enhanced substantially, with the corrosion hindrance factor for **V** and **XI** being 23.7 and 9.7, respectively.

This can be accounted for by the electronic influence of the amino group on the π system of the pyridine ring, which favors its π-electronic interaction with the steel surface. Also possible is the direct involvement of the amino group in free or protonated state in adsorption processes. On introducing a CH_3CO group into position 2 of the pyridine ring (compound **VI**), the corrosion hindrance factor decreases to 7.6.

It was established that the observed changes in the inhibiting action of **I, III, V**, and **VI** are strictly determined by the electronic nature of substituents R. There exists a linear relationship (r = 0.994) between the corrosion hindrance factors for these compounds and the constants σ_c^0 characterizing the combination of the mesomeric and π-induction effects of the substituents R [8]. The fact that this dependence is observed suggests that adsorption of the compounds studied onto steel at room temperature is due to π-electronic interaction of the pyridinium ring with the metal surface, favored by the presence of electron-donor substituents in the pyridinium ring. This also indicates that the amino group in **V** is not involved directly in the adsorption, and the decisive role is played by its influence on the π system of the pyridine ring.

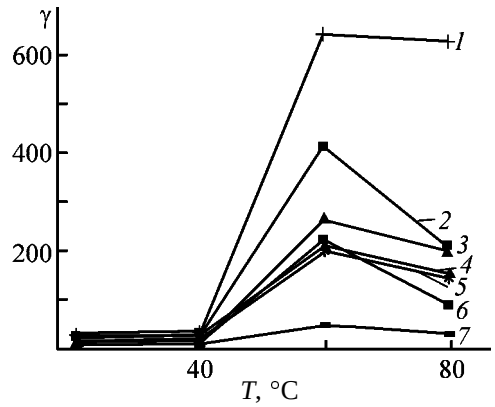

Fig. 1. Hindrance factor γ vs. temperature *T* in corrosion of 08KP steel in a 3 M solution of H_2SO_4 in the presence of 1×10^{-2} M phenacylmethylpyridinium bromides. Compound: (*1*) **VIII**, (*2*) **VII**, (*3*) **VI**, (*4*) **III**, (*5*) **V,** (*6*) **I**, and (*7*) **XI**.

It should be noted that the linear dependence γ–σ_c^0, observed for compounds **I**, **III**, **V**, and **VI**, is also preserved at 40°C, but the correlation coefficient falls in this case to 0.985. At 60°C, the inhibiting action of the compounds studied increases dramatically (Table 1), but the γ–σ_c^0 relationship is strongly disturbed, being completely eliminated at 80°C. Possibly, raising the temperature leads to manifestation in the corrosion process of a number of other factors. This may be, e.g., reorientation of molecules bound to the metal surface via the π system of the pyridinium moiety, enhancement of the role played by electrostatic interaction of pyridinium cations with the metal surface, and increasing share of the specific adsorption of compounds via the carbonyl group.

As is known [1, 2], the corrosion hindrance under the action of carbonyl compounds is mainly due to involvement of the oxygen from the carbonyl group in adsorption processes because of the presence of a substantial electron density on this atom. Electron-donor substituents make higher the nucleophilicity of the oxygen atom of the carbonyl group, thereby enhancing the donor–acceptor interaction of carbonyl compounds with the metal surface, whereas electron-acceptor substituents passivating the carbonyl group make this interaction weaker. Introduction into the *para* position of the benzene ring of **V** of CH_3 or CH_3O groups, which exhibit electron-donor effect, enhances the protective action of the inhibitor, with the result that the corrosion hindrance factor increases to 26.5 and 32.0 for **VII** and **VIII**, respectively, at 20°C. If these substituents are replaced with a bromine or chlorine atom, the corrosion-protective effect decreases dramatically, with the corrosion hindrance factor for **IX** and **X** being as low as 3.4 and 1.8, respectively.

A comparison of the protective effects of compounds **I**, **III**, and **V** and the corresponding nitro derivatives **II**, **IV**, and **XI** demonstrated that introduction of an NO_2 group into the *para* position of the benzene ring makes their inhibiting action weaker. Since the nitro group is a much stronger electron acceptor than a bromine or chlorine atom, it would be expected that the protective properties should be completely eliminated on replacing these atoms with a nitro group. However, it was found that such a replacement not only fails to make the hindrance factor lower, but even raises it substantially. For example, the corrosion hindrance factor for **XI** is 9.7.

Variation of the substituents R_1 revealed for compounds **V**, **VII**, **IX**, and **X** at 20 and 40°C a correlation between their σ_1 constants and γ values, with the correlation coefficients equal to, respectively, 0.998 and 0.990. The exception are compounds **VIII** and **XI**. Possibly, the substituents R_1 in these compounds are involved, in addition to exerting influence on the carbonyl group and the π system of the benzene ring, in some other processes. For **VIII**, this may be, e.g., independent involvement of the MeO group in the free or protonated form in adsorption, whereas in **XI**, as also in **II** and **IV**, the observed corrosion hindrance, probably, results from the combined influence exerted on corrosion both by these compounds themselves and by the corresponding amino compounds, which could be formed under the experimental conditions.

The results of the corrosion tests demonstrated that, with the temperature increasing to 60°C, the inhibiting action of most of the compounds studied increases substantially (Table 1) and remains rather high at 80°C. The observed temperature dependence of the inhibiting effect of the compounds studied (Fig. 1) is probably associated with a change in the mechanism of their adsorption onto the metal and a transition from physical (or first-order specific) adsorption to chemisorption as a result of the enhanced donor–acceptor interaction between the carbonyl oxygen and *d* levels of iron. A certain decrease in the inhibiting action of some compounds at 80°C is possibly due to desorption of inhibitors from the metal surface, resulting from the high rate of metal dissolution at this temperature.

Voltammetric measurements on steel in the presence of compounds **V**, **VIII**, and **XI** demonstrated that these compounds are inhibitors of mixed type, which inhibit both the cathodic and anodic reactions of the corrosion (Fig. 2). Under stationary conditions, they

affect the process to a greater extent by shifting the free corrosion potential E_f of steel in the positive direction. The hindrance factors calculated from the intersection of the Tafel portions of polarization curves for **V**, **VIII**, and **XI** are, respectively, 22.5, 29.2, and 4.0, and those for **V** and **VIII** are close to those obtained from gravimetric measurements (Table 1).

The nature of substituents in these compounds strongly affects the run of the cathodic polarization curves, and to a lesser extent, that of the anodic curves. The influence of compound **XI** containing a nitro group on the cathodic reaction is low, which may be due to its partial reduction on the steel surface. The extent to which compound **XI** affects the cathodic reaction of steel corrosion decreases markedly when the electrode potential is shifted in the negative direction, which may also be due to the reduction of **XI**. Inhibitors **V** and **VIII** enhance substantially the electrode polarization of the cathodic reaction of the corrosion process, thereby markedly changing the run of the cathodic curves at high polarizations. When the electrode potential is shifted in the negative direction, inhibition of the cathodic reaction of the corrosion process is enhanced in their presence. This can be accounted for by an increase in adsorption of **V** and **VIII** onto steel and their reorientation on the metal surface, which ensures formation of a more closely packed protective layer of an inhibitor [7].

The strongest influence on the rate of acid corrosion of metals is commonly exerted by the energetic ($\gamma_{\Delta\Psi_1}$) and blocking (γ_θ) inhibition effects, whose contribution to the overall corrosion hindrance factor can be calculated using a system of equations reported in [7]. The corrosion hindrance associated with the appearance of an additional step of potential, $\Delta\Psi_1$, can be calculated using simple kinetic relations taking into account the Tafel slopes of the polarization curves, b_c and b_a, and the shift of the free corrosion potential, ΔE_f, caused by the inhibitor (Table 2).

A comparison of the experimental (γ_e) and calculated (γ_c) hindrance factors demonstrated that the compounds studied hinder acid corrosion of steel mainly by the energetic mechanism, and the effect of blocking of the metal surface is only of secondary importance in their presence. As also for other cation-like compounds, this is probably due to the presence in the phenacylmethylpyridinium bromides of pyridinium cations ensuring the appearance at the metal–solution interface of a positive adsorption step of potential. The excess of γ_c over γ_e, observed for some compounds, is possibly due to the influence exerted on ΔE_f by a number of additional factors: conjugated reduction of oxygen, occurring in an acid medium in the presence of effective inhibitors; selective adsorption of surfactants on active centers of the metal; etc.

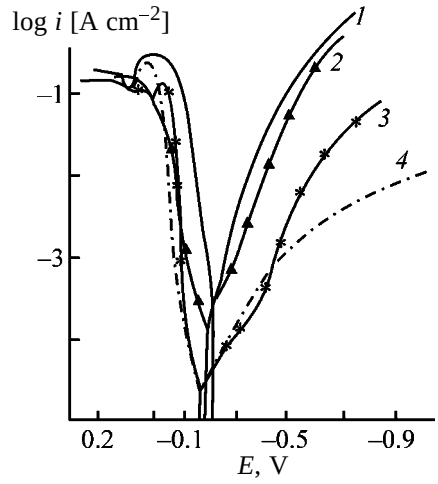

Fig. 2. Polarization curves measured on 08KP steel in a 3 M solution of H_2SO_4 at 20°C in the presence of 1×10^{-2} M phenacylmethylpyridinium bromides. (*i*) Current density and (*E*) potential (vs. standard hydrogen electrode). (*1*) Supporting electrolyte solution; compound: (*2*) **XI**, (*3*) **VIII**, and (*4*) **V**.

CONCLUSIONS

(1) Phenacylmethylpyridinium bromides are effective inhibitors of acid corrosion of steel, whose protective action depends on the nature of substituents present in these compounds.

(2) The inhibiting properties of the compounds under study are enhanced by electron-donor sub-

Table 2. Experimental (γ_e) and calculated (γ_c) corrosion hindrance factors for 08KP steel in a 3 M solution of H_2SO_4 in the presence of **V**, **VIII**, **IX**, and **XI**

Compound	*c*, M	E_f, mV	γ_e	γ_c^*
V	1×10^{-2}	60	23.7	26.8

	4×10^{-3}	31	7.8	5.4

* It was taken in calculations that $\gamma_c = 10^{K\Delta\Psi}1$, $K = b_c/b_0(b_a + b_c)$, $\Delta\Psi_1 = \Delta E_c/[1 - b_c b_a/b_0(b_a + b_c)]$, where b_c and b_a are the Tafel slopes of the cathodic and anodic polarization curves in a 3 M solution of H_2SO_4, $b_0 = 2.3RT/F$ [7].

stituents introduced both in the pyridinium and in benzoyl moieties of their molecules and weakened by electron-acceptor substituents. The key role in the corrosion-protective action of the compounds under study at room temperature is the pyridinium moiety, with the corrosion hindrance by the energetic inhibition mechanism, and the benzoyl moiety of the molecule ensures their chemisorption and high performance at elevated temperatures. Such a polyfunctionality of phenacylmethylpyridinium bromides allows them to preserve their strong inhibiting action in a 3 M solution of sulfuric acid in a wide range of solution temperatures (20–80°C).

(3) The most effective of the compounds studied are 2-amino-1-phenacylmethylpyridinium bromide **V**, 2-amino-1-(4-methylphenacyl)methylpyridinium bromide **VII**, and 2-amino-1-(4-methoxyphenacyl) methylpyridinium bromide **VIII**.

CATALYSIS

Synthesis of a Mixed Catalyst for Sulfuric Acid Production Using Various Wastes

L. A. Nefedova, S. A. Lavrishcheva, E. I. Dobkina, and S. M. Kuznetsova

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 13, 2003

Abstract—The structure of mixed catalysts for sulfuric acid production, with various types of raw materials as supports, was studied by electron microscopy.

Sulfuric acid is widely used in production of mineral fertilizers, dyes, explosives, and other chemical products. One of the main directions in the progress of sulfuric acid technology is development of new more effective catalysts and optimization of the existing catalysts [1].

Mixed catalysts for sulfuric acid production of the SVD type are the most widely used in our country. They contain vanadium in the highest oxidation state, alkaline promoters, and natural diatomite as support [2]. However, an urgent problem is extension of the scope of raw materials, in particular, replacement of natural diatomite by other materials. Furthermore, the problem of utilization of spent catalysts becomes more and more pressing. Finally, to increase the final conversion of sulfur dioxide and the productivity of contact apparatus, it is necessary to develop improved catalysts active at both high and low temperatures. This study is aimed at solving the above problems.

To study what types of raw materials could be appropriate as supports, we prepared three samples (Table 1): sample nos. 1 and 2 were prepared from diatomite of the Inza deposit, and sample no. 3, from the waste from electrothermal smelting of crystalline silicon Si_w (98–99% SiO_2, trace amounts of alkali metal oxides, and Al_2O_3). Into sample nos. 2 and 3, we additionally introduced the spent contact mass of SVD catalysts. The catalysts were prepared similarly to SVD, by dry mixing of components [diatomite support and vanadium(V) oxide] and promoters [alkali metal oxides]. Apart from traditional promoter, K_2O, we used a rubidium promoter (rubidium production waste). After molding, the catalysts were dried and then calcined for 4 h at 550°C.

The results (Table 1) show that sample no. 2 has the optimal content of components in the charge, ensuring the maximal activity over the entire temperature range. The high activity of this catalyst at 485 and 420°C arises from additional introduction of a rubidium promoter, which makes lower the viscosity of the molten active component and decreases the degree of the vanadium(V) reduction [1, 2].

Apparently, the low activity of the catalyst based on Inza diatomite (sample no. 1) without additional promoter may be due to the high Al_2O_3 content (up to 12 wt %) in this raw material. As a result, potassium ions of the molten active component are removed from the melt in the form of potash alum, and crystalline V_2O_5 is separated [1, 2].

Owing to a unique combination of alkali metal oxides in the silicate waste, the catalyst based on spent SVD and Si_w (sample no. 3) is active in a wide temperature range even without additional promotion.

Table 1. Characterization of support samples

Sample no.	Charge composition, wt %					Activity X, % at indicated T, °C

* (ρ_{true}) True density, (ρ_{app}) apparent density, and (V_{por}) pore volume.

As known, the chemical composition is not the only factor determining the catalyst activity. The activity also depends on the inner surface area determined by the pore structure [2]. Therefore, we studied the pore structure of the samples synthesized by different procedures.

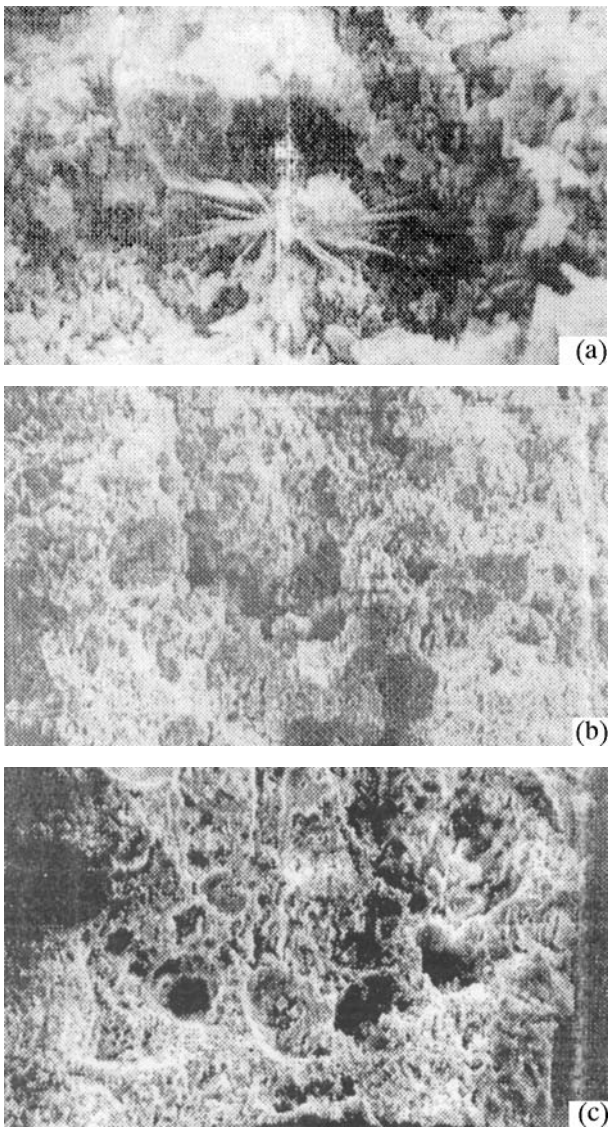

Fig. 1. Electron micrographs of sample nos. (a) 1, (b) 2, and (c) 3. Magnification 500×.

The data obtained by mercury porosimetry are presented in Table 2.

As seen, the catalysts have a multidisperse structure [1–3]. Coarse pores ensuring access of reagents and back diffusion of reaction products are present along with small pores making the corresponding contribution to the surface area.

The pore structure was also studied by electron microscopy on a Napolab 7 scanning electron microscope (Opton, Germany). The electron micrographs of the catalyst based on Inza diatomite (sample no. 1) and the catalyst into which SVD spent contact mass and a rubidium promoter were additionally introduced (sample no. 2) are shown in Fig. 1.

The electron-microscopic study shows that, for the sample synthesized from Inza diatomite without additional introduction of SVD spent catalyst and a rubidium promoter, the distribution of the active component throughout the catalyst grain is nonuniform (Fig. 1a). Owing to higher content of M_2O_3 oxides in the Inza diatomite, potassium ions of the melt are removed from the melt in the form of potash alum, and crystalline V_2O_5 is separated.

The surface tension forces accompanying crystallization of the active component cause the melt to move toward crystallization centers. After heat treatment, agglomerations of the active component crystals reside in the place of drops (Fig. 1a, the center of micrograph).

As compared to the sample prepared without spent contact mass and a rubidium promoter, the modified catalyst (sample no. 2) has a coarser-pore structure (Fig. 1b).

The electron-microscopic examination of the catalyst containing silicate waste (sample no. 3, Fig. 1c) shows that its pores are coarser than those in sample no. 1 but smaller than those in catalyst no. 2.

The distribution of elements of the catalyst active components, V and K ions in particular, over the support surface was studied on an electron-beam scanning microscope with a Kevex microanalyzer.

In the case of the catalyst synthesized without spent SVD and a rubidium promoter (sample no. 1), the distribution of K and V ions over the polished section is nonuniform (Fig. 2, I).

The catalyst modified with a rubidium promoter (sample no. 2) is more uniform (Fig. 2, II). This is

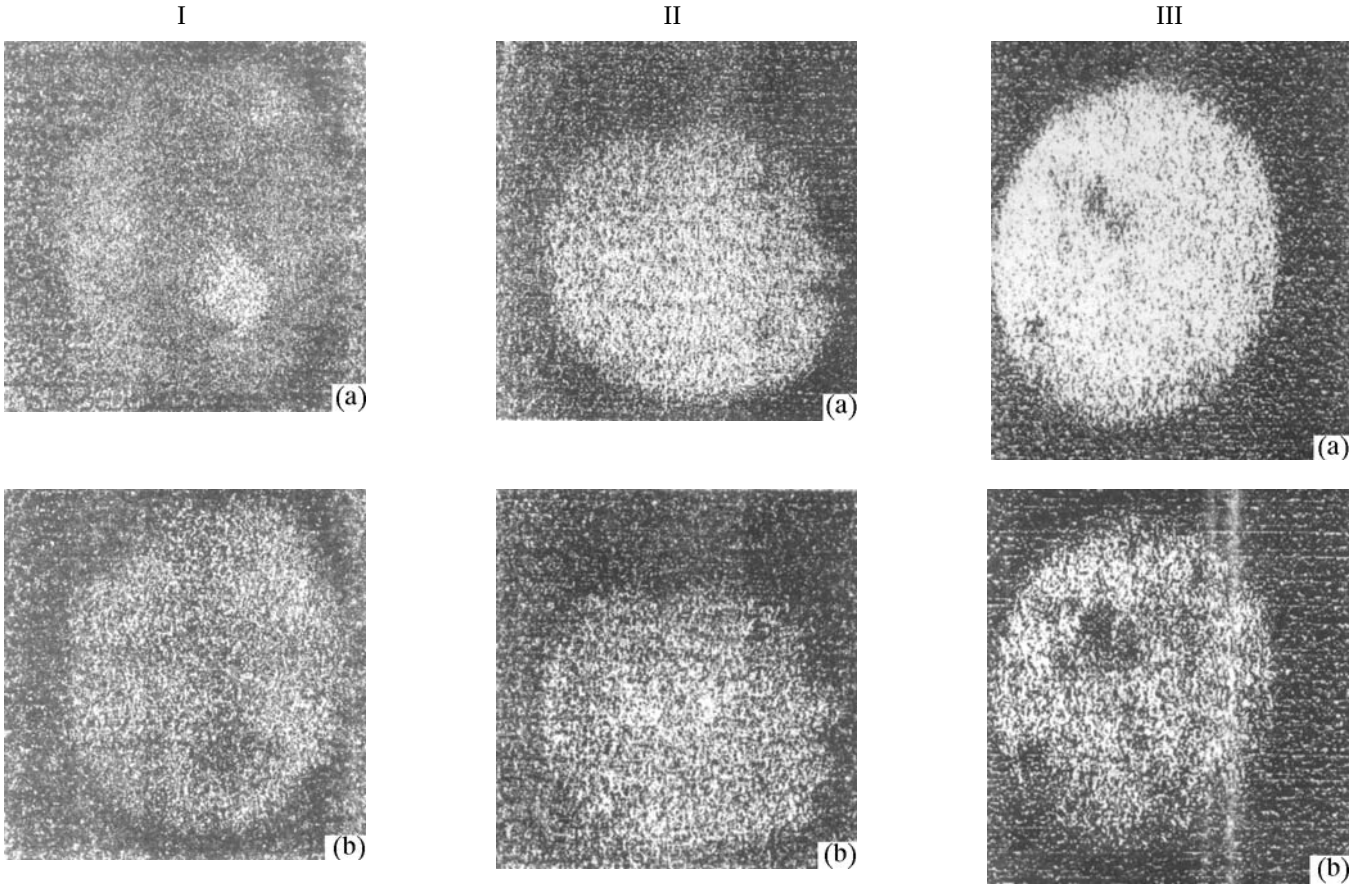

Fig. 2. The distribution of (a) vanadium and (b) potassium elements throughout the catalyst grain. Sample no.: (I) 1, (II) 2, and (III) 3.

apparently due to the lower content of Inza diatomite and, correspondingly, of M_2O_3 oxides.

The same pattern is observed with the catalyst containing a silicate component (sample no. 3; Fig. 2, III). Probably, the presence of alkali metal oxides in Si_w completely compensates the negative effect produced by the minor amount of Al_2O_3 present in it. Moreover, alkali metal oxides present in a large amount lower the melting point and viscosity of the active component, which results in its uniform distribution over the inner surface.

Thus, we have prepared catalysts (sample nos. 2 and 3) active in a wide temperature range ($X_{420°C}$ = 50–53, $X_{485°C}$ = 87–88%) owing to unique chemical composition, multidisperse pore structure, and uniform distribution of the active component over the inner surface of grains.

Hence, partial or complete replacement of diatomite by other raw materials seems feasible; it would also favor the waste utilization.

CONCLUSIONS

(1) A possibility of using silicate promoter (waste) as a new support for SVD catalyst was examined. It is appropriate to introduce rubidium production waste as promoter. (2) The catalysts synthesized are active in a wide temperature range ($X_{420°C}$ = 50–53, $X_{485°C}$ = 87–88%) owing to unique chemical composition, multidisperse pore structure, and uniform distribution of the active component over the inner surface of grains.

CATALYSIS

Influence of Preparation Conditions on Properties of a Copper-Containing Catalyst for Electrocatalytic Oxidation of Acetone

Yu. V. Tsarev, A. E. Dmitriev, and V. V. Kostrov

Ivanovo State University of Chemical Engineering, Ivanovo, Russia

Received April 3, 2003

Abstract—Stages of synthesis of a copper-containing catalyst for electrocatalytic oxidation of acetone in waste gases were studied. The course of the extrusion and calcination and their influence on electrocatalytic oxidation of acetone on the catalyst synthesized were analyzed.

Traditionally, waste gases and air are purified to remove volatile organic compounds (VOCs) by thermal afterburning, catalytic oxidation, sorption, and a sorption-catalytic method [1]. Together with the conventional methods, such techniques as, e.g., VOC oxidation in barrier discharge plasma are also used [2]. Thermal afterburning and sorption purification to remove VOC involve high maintenance expenditure, secondary pollution of the environment with nitrogen oxides, and difficult utilization of the caught components. Advantageous in this regard are sorption-catalytic and catalytic methods, including catalytic oxidation of VOCs under nonstationary conditions [3]. Platinum or oxide (less expensive) catalysts are used in oxidation. As oxide catalysts commonly serve catalysts containing copper(II) and manganese(IV) oxides [4]. Supported catalysts are fabricated using oxides of aluminum, titanium, etc. Activated carbon is occasionally used as support [5]. In this study, primary attention is given to analysis of synthesis stages of a copper-containing catalyst for electrocatalytic decontamination of hydrocarbon-containing gases, which is prepared using technical carbon (TC) as support.

The catalyst was prepared using TC of PM-750 brand. Molded TC grains were impregnated with $Cu(NO_3)_2$ solutions of concentration 100–200 g l^{-1} and mixed with basic copper carbonate $(CuOH)_2CO_3$, with the subsequent addition of a plasticizer (1.25–5.00% solution of polyvinyl alcohol). Further, the catalyst was molded at the optimal molding humidity in the form of grains 0.5–1 mm in size, and the grains were calcined in a CO_2 flow at 350°C.

The rheological characteristics of the molding paste were determined with a plasticity meter with an in-parallel-shifted plate of the Tolstoy design. The structural-mechanical characteristics were calculated from kinetic curves of deformation development and served as a basis for making a complete structural-mechanical analysis of disperse systems and obtaining information about the viscoelastoplastic properties and stability of dispersed structures in the molding paste. The strains were calculated using the Maxwell–Shvedov–Kelvin equation. The strains are related to $P = 1 \times 10^5$ Pa and $\tau = 1000$ s. The sum of relative elastic, viscoelastic, and plastic deformations served to determine to which of the six structural-mechanical types by S.P. Nechiporenko belongs a given molding paste [6].

A thermogravimetric analysis of catalyst samples was carried out on a Q-1500D derivatograph at a heating rate of 5 deg min^{-1}. As a model gas mixture served air containing 1–2 g m^{-3} acetone vapor. The concentration of acetone in the gas–air mixture was determined by nephelometry on a KFK-2MP photoelectrocolorimeter at a wavelength of 320 nm [7]. The conversion of acetone on the catalyst samples synthesized was determined in an isothermal plug-flow reactor. The tests were performed with ac electric voltage applied to the catalyst. The total specific surface area of the catalysts was determined on a Tsvet-211 sorption meter [8]. The surface area of the catalysts was measured by low-temperature selective sorption of helium. The sorption measurements were performed in pulsed mode at –136°C. An X-ray phase analysis of the catalyst samples was carried out on a DRON-UM1 diffractometer with a CuK_α tube (λ = 0.154 nm). The interplanar spacings d were calculated using RFA software written in BASIC. The compounds obtained were identified on the basis of their

Relaxation period θ, s^{-1}	2500	1050	658
Fraction of elastic strain ε_{el}, %	38.7	25.6	14.6
Fraction of viscoelastic strain ε_{ve}, %	32.9	25.6	6.26
Fraction of plastic strain ε_{pl}, %	28.4	48.8	79.1

interplanar spacings and comparison of these with the published data [8]. Changes in the phase composition of the samples, depending on their preparation conditions, were judged from the intensity of the most characteristic reflections. The products formed in electrocatalytic oxidation were determined by their absorption with hexane and analysis of the resulting mixture on a SATURN-2000R gas chromatograph–mass spectrometer.

Since molding of TC-based grains is rather a complicated task, the rheological characteristics of the catalyst samples (40% CuO and 60% TC) were studied in relation to the content of the plasticizer, polyvinyl alcohol (PVC). The results obtained by experimental data processing are listed in Table 1 and shown in Fig. 1. It is demonstrated that, with the content of PVC from 5.0 wt % for sample *A* and to 2.5 and 1.25 wt % for samples *B* and *C*, respectively, the structural-mechanical type of the catalyst paste prepared for extrusion changes correspondingly. Sample *A*, which can be related to zero structural-mechanical type, is characterized by medium values of the elastic and viscoelastic moduli (0.48 MPa, 0.56 MPa) and relaxation period of 2500 s^{-1}. Samples *B* and *C* can be related to fourth and fifth structural-mechanical types, in which plastic deformations predominate. Sample *B* is characterized by medium value of the elastic and viscoelastic moduli (3.0 MPa) and relaxation period of 1050 s^{-1}, and sample *C*, by high values of the elastic and viscoelastic moduli (3.43, 8.01 MPa) and short relaxation period (658 s^{-1}). The best sample for extrusion molding is sample *A* of the catalyst of zero structural-mechanical type. For the given sample, the relative elastic, viscoelastic, and plastic strains lie within the range of optimal values (shown by the circle in Fig. 1).

To determine conditions of thermal treatment of the catalyst samples synthesized, they were studied by thermogravimetry. The results obtained in thermogravimetric measurements are shown in Figs. 2 and 3. The experimental data suggest that, for the catalyst samples impregnated with copper nitrate solutions, the decomposition temperature of copper nitrate decreases from 180–220 to 60–90°C (Figs. 2a, 2b). This is, in all probability, due to the presence of highly dispersed TC, which can accelerate the process in question. By contrast, for the catalyst samples prepared by mixing TC with basic copper carbonate $(CuO)_2CO_3$ (Fig. 3), the decomposition temperature of the basic Cu(II) carbonate increases somewhat from 260 to 330°C. All the catalysts prepared are characterized (Figs. 2, 3) by weight loss in the temperature range 350–900°C, which is due to burning-out of TC contained in a sample. The catalyst samples prepared by impregnation with a copper nitrate solution start to lose weight

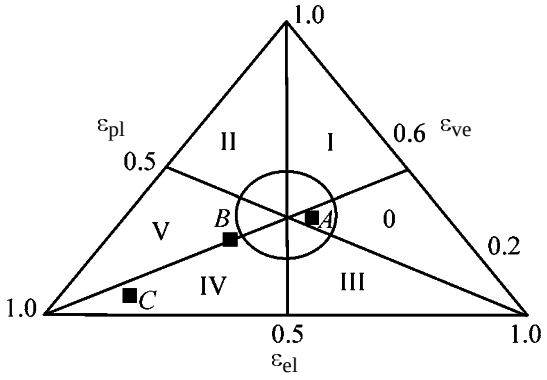

Fig. 1. Diagram of development of viscoelastoplastic strains in the catalyst samples prepared. (ε_{el}, ε_{pl}, ε_{ve}) Fractions of elastic, plastic, and viscoelastic strains, respectively. PVC content (wt %): (*A*) 5.0, (*B*) 2.5, and (*C*) 1.25.

Samples impregnated at 80°C for 1 h with $Cu(NO_3)_2$ solution (g l^{-1}): (*1*) 200, (*2*) 150, and (*3*) 100; (*4*) $Cu(NO_3)_2$ sample.

at temperatures 100–150°C lower than those for samples obtained by mixing with the basic Cu(II) carbonate $(CuOH)_2CO_3$.

In the experiments, the specific surface area of the catalyst samples was determined. The experimental data (Table 2, Figs. 4 and 5) indicate that the decrease in the degree of acetone conversion on catalyst samples calcined at high temperature is not caused by catalyst caking, since the specific surface areas of the samples calcined at 350 and 700°C are the same. The high specific surface area of the catalyst sample containing 60 wt % CuO is, in all probability, due to decomposition of basic Cu(II) carbonate, whose content in the catalyst is high. The specific surface area (35 $m^2 g^{-1}$) of the catalyst sample containing no copper oxide is virtually equal to the specific surface area of the starting TC (35 $m^2 g^{-1}$), which indicates the absence of any pronounced influence of the mixing and molding procedures on the specific surface area of the catalyst.

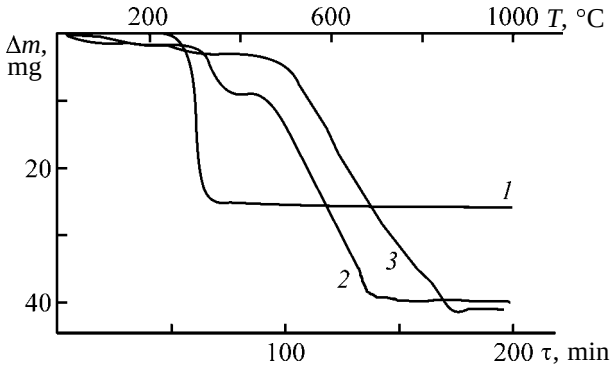

Fig. 3. TG curves of catalyst samples obtained by mixing TC with basic copper(II) carbonate. $(CuOH)_2CO_3$ content (wt %): (*1*) 100, (*2*) 40, and (*3*) 10.

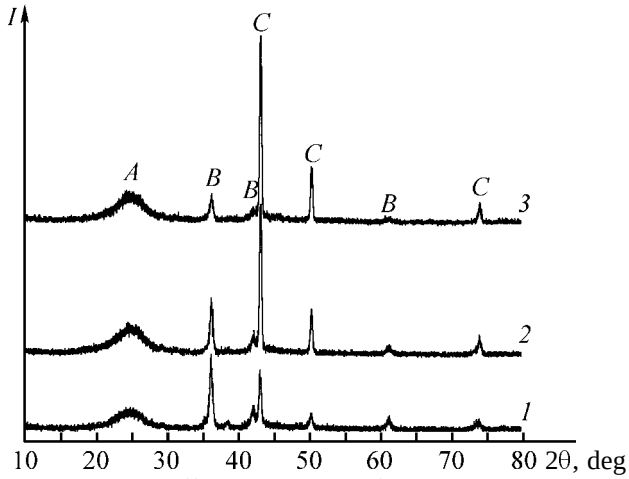

Fig. 4. X-ray diffraction patterns of a catalyst sample containing 20 wt % CuO, calcined at (*1*) 350, (*2*) 500, and (*3*) 700°C. (*I*) Intensity and (θ) Bragg angle. (*A*) TC, (*B*) CuO (Cu_2O), and (*C*) metallic copper.

To determine the phase composition of the catalyst samples synthesized, they were subjected to X-ray phase analysis. Samples with 20% content of the active component, calcined at 350, 500, and 700°C, were studied. Comparison of the experimental diffraction patterns (Fig. 4) with reference data for various compounds showed that the samples contained crystalline CuO (*B*; 2θ = 62°) or Cu_2O (*B*, 2θ = 36°). With increasing calcination temperature, the amount

Table 2. Specific surface area of catalyst samples

Sample no.	Calcination temperature, °C	CuO, %	S_{sp}, $m^2 g^{-1}$
1	700	20	28
2	500	20	37
3	350	20	28
4 (TC)	–	0	38
5	350	60	47
6 (TC)	350	0	35

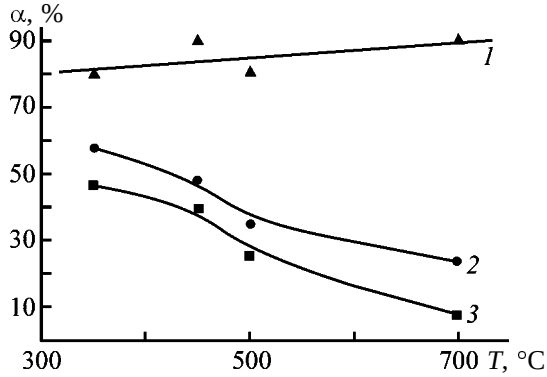

Fig. 5. Degree of acetone conversion α vs. calcination temperature *T* of the catalyst. Input electric power (W cm^{-3}): (*1*) 4, (*2*) 2, and (*3*) 0.6.

of the crystalline phase of these compounds decreases, since the intensities of peaks characteristic of these compounds become lower. The decrease in the amount of copper oxides is due to their reduction in a catalyst at high temperature to metallic copper (*C*; 2θ 43°, 51°). Correspondingly, in the X-ray diffraction patterns the intensity of peaks associated with metallic copper grows with temperature. The catalyst support, TC (*A*), in the catalyst is in amorphous or weakly crystalline state, which can be judged from the halo corresponding to a diffraction angle 2θ = 25°.

A study of the extent to which acetone is converted on the catalyst samples obtained demonstrated (Fig. 5) that, for specific input electric power of less than 2 W cm^{-3}, the degree of acetone conversion decreases with increasing catalyst calcination temperature. Consequently, a conclusion can be made that, in electrocatalytic oxidation of acetone, the CuO and Cu_2O phases enhance the influence exerted by the electric power. The phase of metallic copper has no effect on electrocatalytic oxidation of acetone. For input electric power exceeding 2 W cm^{-3}, the calcination temperature does not affect the degree of acetone conversion on the catalyst. This can accounted for by the prevalent influence of the electric component at high specific input power. These modes are characterized by predominance of plasma-enhanced catalytic processes, since effects characteristic of plasma formation are observed under these conditions.

CONCLUSIONS

(1) Rheological characteristics of catalyst samples were obtained, which indicate that making lower the percentage content of plasticizer (polyvinyl alcohol) impairs viscoelastoplastic properties of the catalysts.

(2) Thermogravimetric studies of the samples yielded information about the temperatures of decomposition of copper nitrate and basic Cu(II) carbonate and of burning-out of technical-grade carbon, which makes it possible to select calcination conditions for copper-containing catalysts synthesized on the basis of technical-grade carbon.

(3) The calcination temperature has no effect on the specific surface area of the samples, since this parameter is the same, and equal to 28 m^2 cm^{-3}, for samples calcined at 350 and 700°C.

(4) An X-ray phase analysis revealed that the decrease in the catalytic activity of the catalyst samples with increasing calcination temperature is due to reduction processes occurring in the catalyst at high temperatures and leading to formation of metallic copper, which is inactive in acetone oxidation.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Mathematical Simulation of Ozonosphere Perturbations in Spacecraft Launches

O. V. Yatsenko

Don State Technical University, Rostov-on-Don, Russia

Received March 13, 2003

Abstract—Factorial analysis of the results obtained in numerical simulation of ozone layer depletion by spacecraft was carried out. The mechanism, chemical agents, and kinetic characteristics responsible for the dynamics of ozone level in the perturbed region were studied. A mathematical model of the processes, intended for engineering-ecological estimates, was suggested.

The topicality of structural-informational development of mathematical models (MM) of ozone layer depletion by spacecraft is due to a significant rise in the anthropogenic impact of this kind. The principal factors in this case are the following: steadily increasing number of launches and their increasingly diverse geography; use of phased-out solid-propellant carrier rockets for injection of objects into upper layers of the atmosphere and into space; possibility of successful use in the near future of an aerospace plane intended to simplify the procedure dramatically and raise the intensity of space flights. In the situation at hand, the simulating capacities of the existing models and, in particular, those described in [1–3] are insufficient. However, the capacity of modern personal computers and the possibilities of information technologies enable improvement of these models both in their mathematical structure and in the database for simulation.

A detailed analysis of studies concerned with destruction of the ozone layer by launches of carrier rockets was made in [1]. It is admitted that the most important factor of the influence exerted by carrier rockets on the photochemistry of the ozone layer is the trail cloud formed via mixing of the propulsive jet with background gases. Another important result [1] is associated with analysis of modern MMs of photochemical processes in a stratosphere perturbed by spacecraft. According to [1], most of MMs of this kind are characterized by common structural-informational imperfections and/or limitations: (1) simplified mathematical formulation of the kinetics–diffusion problem or the so-called box model of photochemical transformations and turbulent transfer of reagents in the rocket trail; (2) inclusion into the kinetic scheme of a comparatively small number of reactions dominating in the photochemistry of unperturbed stratosphere and supposedly retaining their relative significance in the case when the stratosphere is perturbed by spacecraft. Therefore, it is impossible to obtain, in terms of the known MMs, answers to a number of questions concerning, in particular, the adequacy of the modeling process itself and of the identification of physicochemical mechanisms involved in breakdown and regeneration of the stratospheric O_3. For example, a detailed MM of photochemical processes in the ozonosphere was suggested in [2]. Based on the model of [2], a set of computer simulations [3] was performed in order to determine the scale-dynamic characteristics of perturbations in launches of Proton carrier rockets, which use 1,1-dimethylhydrazine and N_2O_4 as propellant components. However, beyond the scope of these studies remained the problems associated with mechanisms by which the rocket trail acts upon the ozonosphere and with the adequacy of MM to real processes, whose understanding becomes increasingly important because of the rise in the number of launches and the growing diversity of carrier rockets and propellants used.

The present study is devoted to (1) essential structural improvement of the models [2, 3]; (2) assessment of the adequacy of the modified MM and prototype models [1–3] to real processes of ozone breakdown in the rocket trail; (3) identification of mechanisms of ozone loss in the trail cloud of liquid-propellant rockets; (4) construction of a minimum MM [4] for practical estimates of parametric perturbations of the ozonosphere and radiation field, caused by launches of various types of liquid-propellant rockets.

1070-4272/03/7611-1776$25.00

A structural modification of the diffusion model [3] consists in using a transfer–dissipation equation of more general form: first, the box model is replaced by a discrete diffusion one, and, second, the initial gas-dynamic stage of interaction between the propulsive jet and the ambient gas is taken into account. This shifts the start of simulation from the instant of termination of the gas-dynamic expansion–deceleration–mixing of the propulsive jet with stratospheric gases in the model [3] to the beginning of exhaust of combustion products from nozzles.

The discrete diffusion model assumes that, by the instant of exhaust, the component concentrations in the rocket trail are characterized by step-like distribution along the jet radius. The model considers N concentric ranges uniform in chemical composition and temperature, bounded by circles with radii R_1, $R_1 \times 2^{1/2}$, ..., $R_1 N^{1/2}$ and evolving following the same law $R_n = R_1(t) N^{1/2}$, $n = 1 \ldots N$. In the case, the masses of gas within the zones thus defined can be considered always the same with accuracy sufficient for the purposes mentioned, and the initial concentrations of ith combustion product in nth zone, c'_{in}, can be specified by the distribution

$$c'_{in} = c'_{i1} \frac{e^{-2(n-1)N}}{e^{2/N} - e^{4/N-2}}. \quad (1)$$

Apparently, the box model of diffusion [3] is a particular case of the step-like or discrete diffusion model at $N = 1$.

The preserved simulation limitations of the model, which are determined by the nature of atmospheric turbulence [3, 5], constitute several hours for forecast longevity. Thus, the suggested MM can describe parametric perturbations with fast photochemistry, to which belong perturbations of the ozone layer by liquid-propellant rockets.

The discrete diffusion MM of interaction between the propulsive jet trail and substances of the stratosphere is expressed by the equations

$$\frac{dc_{in}}{dt} = f(c_{kn}, T_n) + [(c_{in-1} - 2c_{in} + c_{in+1})/2 + (0.44\pi R_n)^{-1} (m/u_0\rho)^{1/2} c'_{in}] \frac{d\ln V}{dt}, \quad (2)$$

$$\frac{dT_n}{dt} = \frac{1}{C_V} \Sigma f_i(c_{kn}, T_n) \Delta H_i + [(T_{n-1} - 2T_n + T_{n+1})/2 + (0.44\pi R_n)^{-1} (m/u_0\rho)^{1/2} T'_n] \frac{d\ln V}{dt}, \quad (3)$$

$$\frac{dc_{iN+1}}{dt} = f_i(c_{kN+1}, T), \quad (4)$$

$$c_{i0} = c_{i2}, \quad \frac{d\ln V}{dt} = \frac{d\ln V_n}{dt} = 2\frac{d\ln R_n}{dt},$$

$$R_1 = \{[R_0 + (0.22/w)(mu_0/\rho)^{1/2} \ln(1 + wt/R_0)^{2/3}] + (\xi t/3)\}^{3/2},$$

where $n = 1 \ldots N$ is the number of a chemically and thermodynamically uniform region, with $n = N + 1$ corresponding to unperturbed stratosphere; c_{in}, f_i, and ΔH_i, concentration, rate of formation (decomposition) in chemical reactions, and standard heat of formation of ith substance, respectively; T_n, temperature; C_V, specific heat of the stratospheric gas; $R_n(t) = R_1(t) n^{1/2}$, radius, and $V_n = V_n(t)$, running volume of nth zone contaminated by the rocket trail; m, u_0, and ρ, flow rate of the propellant, outflow velocity of the propulsive jet, and density of ambient air, respectively; w and ξ, rocket motion velocity and coefficient of turbulent dissipation of the solar energy [3]; R_0, radius of the channel displaced by the rocket; the primed concentration and temperature variables correspond to the parameters of the propulsive jet proper, which are imparted to the stratosphere through deceleration–mixing.

In contrast to the models of [1, 3], Eqs. (1)–(4) contain terms related to the initial gas-dynamic stage of formation of the contaminated region. After the initial stage of evolution of the discharge is over, MMs (1)–(4) reduce to the model of [3]. It is important that the chemical unit of the model is nonisothermal: changes in the temperature in the reaction zone are affected not only by mixing processes, but also by energy parameters of the occurring chemical transformations, which determine the kinetics of the initial gas-dynamic stage of interaction.

The constants of photoreactions forming the material flows f_i in Eqs. (2)–(4) were calculated preliminarily and used in simulating the evolution of the rocket trail in the form taking into account the diurnal variations in solar illumination [3]:

$$\left.\begin{aligned} k_k^{ph}(H,t) &= k_k^{ph0}(H) \sin^2(\pi l/\tau), \quad 2n\tau < t < 2n\tau + \tau, \\ k_k^{ph}(H,t) &= 0, \quad 2n\tau + \tau < t < 2n\tau + 2\tau, \end{aligned}\right\} \quad (5)$$

where $k_k^{ph0}(H)$ is the effective constant of kth photochemical reaction at the instant of time corresponding

Relative content of a component in the propulsive jet of liquid-propellant rockets

Note: All other components of the propulsive jet affect the kinetics of O_3 breakdown insignificantly, as demonstrated below.

to the highest solar altitude, i.e., at noon; H is the altitude; $\tau = 24$ h.

The possibility of such a solution of the problem is due to the fact that the perturbation of the ozone layer in launches of liquid-propellant rockets is insignificant, which allows use of unperturbed constants of photoreactions and radiation field of the Sun. The resulting limitations mainly refer to the level of O_3 perturbation, which must not exceed 20%. Stronger perturbations lead to a shift of the O_3 concentration maximum, enhanced heating of lower lying layers, and disturbance of stratification; possibly, they cause vertical mixing. The fact that the perturbation level of the ozonosphere in launches of liquid-propellant rockets is insufficient for initiating the above processes has been confirmed by many numerical calculations, e.g., in [1, 3].

The informational improvement of the previous models consists in that both the range of photochemical reactions taken into account and the variety of propellants allowed by the numerical simulation become wider. In particular, each of the reactions described in [3] is now accompanied by a reverse reaction and the constants of oppositely directed transformations are thermodynamically matched. The final kinetic scheme of photoinduced transformations comprises 932 reactions between 74 components and photons in the wavelength range 180–700 nm.

Among the possible fuel–oxidant pairs, MM considers, together with the traditional pair 1,1-dimethylhydrazine + N_2O_4, also $N_2H_4 + N_2O_4$, $H_2 + O_2$, and $C_{14}H_{30} + O_2$. The chemical composition of the propulsive jet, calculated on the assumption of complete combustion of the components, partial dissociation of products, and "frozen" reactions in gas exhaust from the nozzle, is presented in the table (for components essential for the kinetics of ozone transformations).

The improvements of the model extended the range of its validity, as regards the temporal factor, to the instant of propulsive gas exhaust from the nozzle, and, as regards the variety of vehicles and nature of their impact on the ozonosphere, to possibility of adequate description of all the potential hazards among the modern and the most promising spacecraft. This makes it possible to use this model for revealing and classifying the threats to the state of the ozone layer, resulting from the economic use of the space and upper atmosphere, and to develop recommendations for reducing the environmental risk and damage inflicted by impacts of this kind.

The MM was tested for mathematical adequacy and correctness of its computer implementation in accordance with a complex procedure [3]. The correctness of mathematical formulation, reliability of the information database, and adequacy of software were verified. Model calculations of the known parameters of the ozonosphere and, in particular, the altitude profiles of minor gas components of the stratosphere (MGCS), and comparison of the results obtained with data of other authors confirm that the model suggested is well substantiated and reliable.

Practically important results obtained in testing the predecessors of the given MM [2, 3, 6] are the following: (1) altitude profiles of some poorly studied MGCS (Figs. 1a, 1b) [2, 3], calculated for the first time; (2) solution of the disputable issue concerning the diurnal kinetics of NO_2 in the ozone layer and the elementary reactions governing this kinetics [6]; (3) establishment of the important role played by excited O_2^* species in the kinetics of stratospheric ozone [2]; (4) substantiation of the validity of dividing the model into two independent submodels, of radiation-induced transfer and chemical kinetics, and also calculation of the effective constants of photoreactions [2]; and (5) evaluation of the impact of a single launch of a Proton-type rocket [6] (Figs. 2a, 2b).

Fundamentally new results obtained in terms of models (1)–(5) are the following: (1) the initial gasdynamic stage of formation of the trail cloud is in-

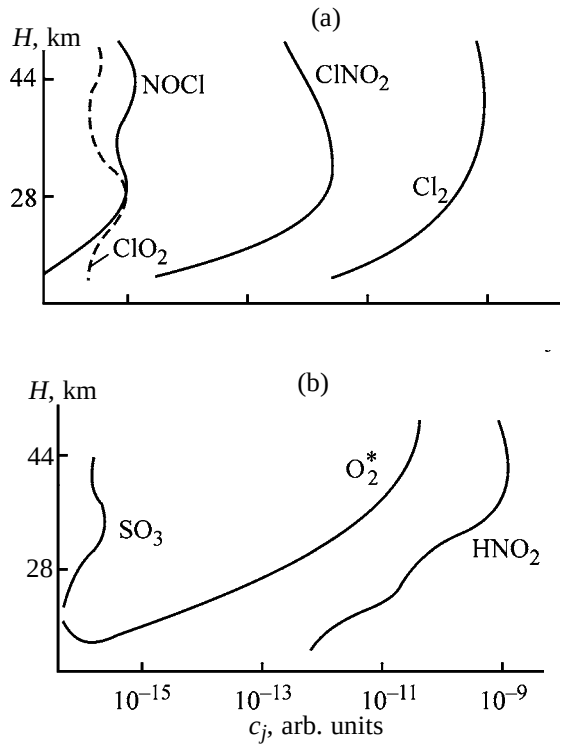

Fig. 1. Altitude (daytime) profiles of poorly studied components of the stratosphere. The O_2^* concentration is reduced by a factor of 10. (*H*) Altitude and (c_j) relative concentration of a component.

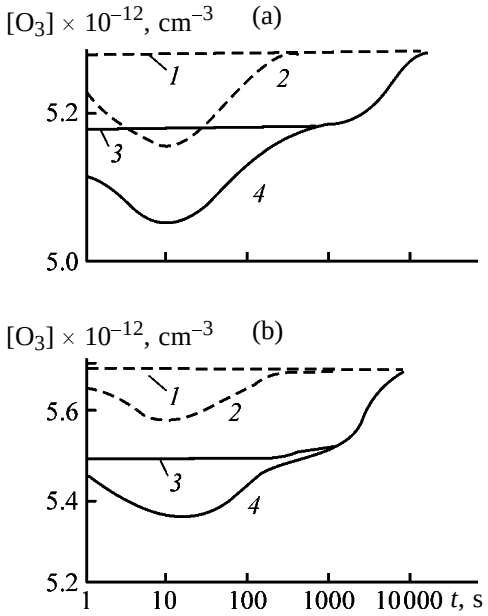

Fig. 2. Dynamics of the ozone concentration [O_3] in the stratosphere upon a single rocket launch at altitudes of (a) 25 and (b) 30 km. (*t*) Time. Curves *2* and *4* describe the evolution of the ozone concentration in a region of stratosphere contaminated when a rocket passed it at noon and midnight, respectively; curves *1* and *3* determine the dynamics of diurnal variations of [O_3] in unperturbed stratosphere (curve *1*, beginning at midnight; curve *2*, at noon).

significant for the overall process of O_3 breakdown; (2) box models are applicable to solution of the problem of evolution of the rocket trail in the stratosphere; (3) temperature perturbations in the rocket trail are insignificant; (4) the models developed can be used as tools for computer simulation of multiple launches of diverse types of liquid-propellant rockets; (5) the physicochemical mechanism of O_3 breakdown by combustion products of liquid propellants can be identified; (6) the influence of a number of components in the propulsive jet on the kinetics of atmospheric ozone is insignificant; (7) simplified MM for rough calculations and estimates can be constructed.

Result 1 was obtained in a set of calculations in terms of models (1)–(5) with $N = 1$ and that described in [3]. By the instants of time corresponding to 1–3 s after exhaust of the propulsive jet, the gas-dynamic parameters and the chemical composition of the contaminated region, yielded by models (1)–(5), approached to within ~30% the values obtained by analytical estimates and chosen as initial conditions in calculating identical perturbation in terms of the model of [3]. In later stages, the kinetic curves obtained in terms of models (1)–(5) and [3] for all the components important for the photochemistry of ozone coincided within the calculation error. This indicates that the chemistry of O_3 loss is not affected by fast processes in the initial gas-dynamic stage of formation of a rocket trail and, simultaneously, confirms the validity of the simplified MMs of the kinetics–diffusion type [1, 3].

Fact 2 was established by comparing the results of calculations with identical initial conditions (of perturbation) and $N = 1$, 3, and 5. This comparison suggests that raising the number of individually considered zones does not reveal any new effects. Conversely, it becomes possible, for liquid-propellant rockets, to detail the results of simulations in terms of the box model *a posteriori*, by analytical methods of mathematical physics. It is noteworthy that this fact is due to the relative small perturbations of the stratosphere kinetics in single launches of typical liquid-propellant rockets. In practice, using the box model saves computational resources, e.g., by shortening 100-fold the time in which a solution is found numerically by passing from $N = 5$ to $N = 1$ and obviating numerous concomitant difficulties.

The smallness of the temperature component of the

stratospheric perturbations on completion of the jet deceleration–mixing stage, mentioned above as result 3 and expressed as a short-time cooling of the trail cloud by fractions of a degree, is also a consequence of the low level and short duration of the initiating impact.

Practical result 4, obtained in terms of specialized CASE-technologies of physicochemical kinetics [3], consists of a software for widely used personal computers, which implements the concepts of the present study, and the most important results [1–3]. In computer implementation of the MM, the function of a source is developed both for simulations of several repeated launches from the same site and for varied physical nature of a contaminant and method of its introduction. In this stage, the following forms of the source function are allowed: hypersonic propulsive jet, liquid drop dispersed in flight, explosion cloud, and combinations of these. The first type of source corresponds to the goals of the present study; second, to contamination of the ozonosphere with unburned components of liquid propellants; and third, to products of their forced explosive elimination.

Result 5 and the ensuing results 6 and 7 are aimed at avoiding, wherever possible, complicated simulations and at replacing them with approximate analytical calculations or simple calculations on personal computers using the standard engineering mathematics software.

The principal hypothesis underlying the model of O_3 breakdown is as follows. The propulsive exhaust of rockets contains one or several components of those exerting predominant influence on the loss of O_3 under natural conditions, with the concentrations of these components in the rocket trail much exceeding the background values. As a result of strongly accelerated loss of O_3, its concentration in the perturbed zone is "adjusted" to the concentration of the ozone-depleting components, with the relative deviation of the ozone concentration from the unperturbed level being comparatively low (≤20%). Since the level of ozonosphere perturbation by components depleting O_3 is assumed to be rather high, its decrease cannot occur exclusively via stratospheric chemistry, being also determined by turbulent dissipation of the trail cloud.

To the above hypothesis, qualitatively accounting for the kinetic of perturbed O_3 in Fig. 2, corresponds, in the simplest variant, the equation

$$\frac{d[\tilde{O}_3]}{dt} = -\frac{k[O_3]_0 c_0}{(1+bt)^3} - \frac{3b[\tilde{O}_3]}{1+bt}, \qquad (6)$$

where c_0 is the effective initial concentration of ozone, which is assumed to be comparatively stable chemically or long-lived; k, the rate constant of O_3 loss; $b = \xi/3R_{gd}^{2/3}$, the constant of turbulent smearing of the trail [3]; R_{gd}, the rocket trail radius upon completion of the gas-dynamic deceleration of the jet; $[\tilde{O}_3] = [O_3] - [O_3]_0$, the deviation of the ozone concentration from the background value $[O_3]_0$.

A solution to (5) is given by

$$[\tilde{O}_3] = \frac{[\tilde{O}_3]_0 - k[O_3]_0 c_0 t}{(1+bt)^3}, \qquad (7)$$

where $[\tilde{O}_3]$ is the primary nonchemical, through dilution of the stratosphere by combustion products, deviation of the ozone concentration from the background value, and c_0 is the initial concentration of the depleting agent.

According to Eq. (7), the degree and dynamics of O_3 perturbation are affected by three parameters: level of perturbation by ozone-depleting agent (agents) and time factors responsible for removal of the depleting agent via chemical reactions and turbulent dissipation. The competition of the reactions of O_3 loss and diffusion forms the temporal dynamics of perturbed ozone, qualitatively coinciding with that in Figs. 2a and 2b.

Finer formulations also take into account the chemical loss and/or generation of the ozone-depleting substance by means of an analytical equation similar to (6). In particular, detailed analysis of the numerical solution for Proton rocket requires that the mechanism (6) should be discarded for the following reasons. In MM (6), the minimum concentration of O_3 occurs at the instant of time $t^*_{gd} = 1/2b$, corresponding to the characteristic duration of turbulent dissipation of the rocket trail. For rockets of the type under consideration, the gas-dynamic scale t^*_{gd} varies from 65 s at altitude of 20 km to 190 s at the upper boundary of the stratosphere. Direct integration of Eqs. (1)–(5) leads to much shorter times of extremal concentration of ozone, from 10 to 75 s, respectively. Thus, the O_3-depleting agent is a highly active substance, which enters into various reactions at a severalfold higher rate, compared with its dissipation in a purely mechanical way.

The apparent mathematical formulation of the case described is as follows:

$$\frac{d[\tilde{O}_3]}{dt} = -k[O_3]_0 c_0 - \frac{3b[\tilde{O}_3]}{1+bt}, \qquad (8)$$

$$\frac{dc}{dt} = -k_1 c_\Sigma c - k_2 c^2 - \frac{3bc}{1+bt}, \quad c(0) = c_0 \qquad (9)$$

(k_1 and k_2 are the rate constants of chemical loss of the depleting substance, and $k_1 c_\Sigma$ is the effective relative rate of depleting agent loss in first-order reactions). These equations reflect both the adjustment of the O_3 kinetics to that of the depleting agent and the kinetics of depleting agent proper, which is consumed in bimolecular first- and second-order reactions with rate constant $t^*_{ch.k} = (k_1 c_\Sigma + k_2 c_0)^{-1}$. Solutions to Eqs. (8) and (9) can be obtained in finite form in the case of predominance of one of the mechanisms of depleting agent loss, i.e., at $k_1 c_\Sigma \gg k_2 c_0$, or, vice versa, $k_1 c_\Sigma \ll k_2 c_0$. In particular, for chemical loss of depleting agent via a first-order reaction, the dynamics of ozone is given by

$$[\tilde{O}_3] = \frac{k[\tilde{O}_3]_0 c_0 (e^{-k_1 c_\Sigma t} - 1)(k_1 c_\Sigma)^{-1} + [\tilde{O}_3]_0}{(1+bt)^3}. \qquad (10)$$

It can be readily seen that the results of (7) and (10) coincide at short times; however, it follows from Eq. (10) that, at $t \approx t^*_{ch.k}$, the decrease in the concentration of the depleting agent switches off the loss channel. In other words, the characteristic lifetime of ozone-destroying substances is included in the key parameters of the problem. A similar situation takes place for loss of depleting agent in binary recombination.

Model (9), (10), combined with kinetic curves and input data of [3], makes it possible to reliably identify as main O_3-depleting agents the following two species: OH and NO radicals. Both these species (i) contain valence-unsaturated atom, (ii) have radical structure and, correspondingly, high chemical activity, and (iii) are present in propellant combustion products and in the propulsive jet in amounts much exceeding the background.

For the first stage of a Proton carrier rocket, the perturbation in NO is about 200%, and that in OH exceeds four orders of magnitude. With account of the relative importance of both the channels and the corresponding reaction constants, this makes it possible to completely disregard the chemical loss of NO and regard as the main channel of OH removal from the stratosphere the bimolecular reactions of the type OH + OH $\rightarrow$ Products, with the characteristic constant $k_2 \approx 10^{-11}$ cm^3 s^{-1}. It is also possible to obtain the extremal time for the state of depleted ozonosphere, $t^*_{ch.k} \approx 10$–30 s, in good agreement with the results of a numerical simulation [3, 6]. It should be noted that this result contradicts the conclusion of [1] about the dominating role of NO in the breakdown of stratospheric ozone. However, the authors of [1] used simplified kinetic schemes of the chemical cycles in the stratosphere and also the integration procedure based on splitting of the problem by the small-parameter method, which is unacceptable in the case of large strongly nonlinear systems.

When the second stage of the rocket is working, the amount of discharged OH decreases, and there is no discharge of NO at all. However, the relative perturbation of the concentration profile at altitudes of 40–45 km and its duration in daytime launches are greater, which is due to outstripping decrease in the efficiency of OH elimination by chemical reactions in view of the high rarefaction of the atmosphere upon opening at high altitude of a channel for photochemical reproduction of OH from water, hydrogen peroxide, and other products of binary reactions between OH radicals. This tendency is confirmed by comparison of the constants of photochemical and purely chemical reactions with OH [2] at different altitudes.

The significance of the influence exerted by OH and NO radicals discharged by a rocket on the breakdown kinetics of stratospheric ozone was verified both via perturbation of the initial data (regular for the candidates for depleting agents and random for all other components of propulsive exhausts) and by numerical characterization of the leading (in the sense of material circulation) reactions involving O_3.

It is noteworthy that, for a chemically stable depleting agent, e.g., a chlorine-containing substance, Eqs. (6) and (7) should be used as the working MM, with the instant of the minimum content of ozone in the rocket trail determined exclusively by transfer process; models (6), (7) and (8)–(10) well account for the results of detailed computer simulations [3, 6] and give estimates of the O_3 perturbation by liquid-propellant rocket, which are one to one and a half orders of magnitude lower than those predicted by [7]. The possible reason for these discrepancies is the imperfect algorithmic implementation of the MM and strongly limited kinetic schemes of atmospheric transformations [7] as compared to the models used in [2, 3, 6], which manifest themselves in a distortion of the physical meaning and dynamic characteristics of the perturbation process.

Figures 3a and 3b show the dynamics of an integral perturbation of O_3 at altitudes in the range 20–50 km, caused by a single launch of a Proton rocket, which is calculated in terms of MM (1)–(5). It can be seen that the impact has local nature, is short, and its level is

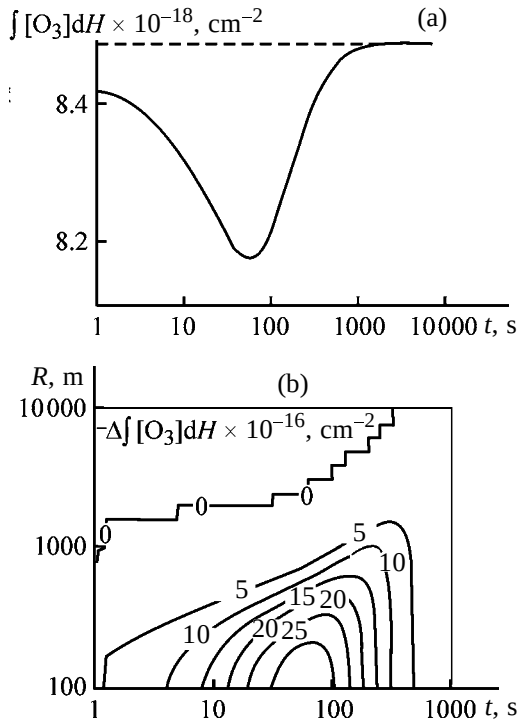

Fig. 3. Variation in space and time of the total content of ozone in the stratosphere in a single rocket launch. ($\int[O_3]dH$) Integral perturbation of ozone content along height, (R) radius of the contaminated zone, and (t) time. (a) Dynamics obtained in the box approximation [calculation by (1)–(5) at $N = 1$] and (b) that according to discrete-diffusion model (1)–(5) at $N = 5$.

low, which fully justifies the phenomenological assumptions made in constructing the MM. Nonlocal impact and dissipation processes depress the level and make longer the duration of an integral (over the range 20–50 km) perturbation to ~4% and 70 s, respectively (see, for comparison, the local perturbation parameters in Figs. 2a and 2b).

It is also important that the result of action of different fuel–oxidant pairs is qualitatively the same, and the perturbation level is proportional to the amount of OH radicals discharged.

The validity of the simplified approach (8)–(10) was confirmed by results of a test numerical simulation for a Proton rocket with kerosene–oxygen fuel: the error in the reproduction by the model of the data of detailed computations in terms of MM (1)–(5) does not exceed 20%. This allows use of elementary models of the type (8)–(10) for evaluation of the integrated impact of multiple launches of liquid-propellant rockets by various scenarios.

The inapplicability of the models presented here to direct simulation of the kinetics of the ozonosphere perturbed by solid-propellant rockets is due to the fact that, in this case, the main combustion products are chlorine-containing substances which catalyze ozone breakdown and, therefore, are not subject to chemical loss within the ozone layer. Here, the mechanisms by which the perturbation is localized and subsequently dissipated are processes of global atmospheric circulation, and, therefore, parametric estimates of the impact are to be based on a knowledge of the corresponding space and time scales. In this case, the decrease in the content of ozone in the atmosphere is found in terms of a simpler model [2], which disregards local turbulent transfer, but, simultaneously, assumes a higher (corresponding to the perturbation level) concentration of chlorine as an MGCS component, compared to the background.

Detailed calculations of the O_3 concentration fields, induced both by single and by multiple launches of liquid-propellant rockets of the same and different types, can be performed not only using MM (1)–(5) at $N = 5$ and more, but also in terms of a box approximation and elementary models of the (8)–(10) type, with subsequent smearing of the steplike profile into a Gaussian curve. The calculation errors associated with such an approach do not exceed 20%.

CONCLUSIONS

(1) The mathematical model of perturbations in the stratosphere, caused by rocket launches, was modified and used to identify the mechanism of ozone breakdown by combustion products of liquid propellants and suggest methods for approximate engineering-ecological estimates of the scale and level of impacts of this kind for various operation scenarios.

(2) A computer simulation confirmed, on the whole, the validity of the previously employed simulation models, made wider the range of situations that can be simulated, and, simultaneously, enabled more detailed simulation.

(3) The insignificant impact of liquid-propellant rockets on the stratospheric chemistry and, in particular, the ozone cycle was confirmed.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Flocculation Power of Chitosan and Its Derivatives in Mixtures with Anionic Flocculants

V. A. Izvozchikova, N. V. Pastukhova, S. A. Ryabov, Yu. D. Semchikov, L. A. Smirnova, and A. E. Mochalova

Lobachevsky Nizhni Novgorod State University, Nizhni Novgorod, Russia

Received October 28, 2002

Abstract—The flocculation properties of chitosan (cationic component) and its copolymers with (meth)acrylic acid were studied. The flocculation power of grafted chitosan copolymers with dimethylaminoethyl methacrylate in mixtures with an anionic polyacrylic flocculant was evaluated.

In most cases, treatment of industrial and domestic wastewaters is based on flocculation of negatively charged dispersions [1]. The range of cationic flocculants commercially produced in Russia is limited to synthetic (co)polymers based on amino derivatives of acrylic and methacrylic acids, vinylpyridines, and polyethylene amines. Expansion of the assortment and performance of cationic flocculants is still urgent. In this respect, much promise is shown by chitosan [CTS, β-(1 → 4)-2-amino-2-deoxy-*D*-glucose], the product of deacetylation of the natural polymer chitin. Chitosan is widespread in nature; it comes second after cellulose among polysacharides, and it can form chelates [2].

In this work, we studied the flocculation power of CTS, grafted copolymer of chitosan with dimethylaminoethyl methacrylate (DMAEM) dimethyl sulfate and their mixtures with anionic polyacrylic flocculant (PAF, copolymer of acrylamide with sodium methacrylate). The latter product is probably a terpolymer due to partial uncontrolled hydrolysis of acrylamide units.

EXPERIMENTAL

In our work we used CTS* (molecular weight 1.4×10^5, degree of deacetylation 0.82), grafted copolymer of CTS with DMAEM dimethyl sulfate prepared by radical polymerization [3], and PAF.

The flocculant solutions were prepared by dissolution of CTS and its copolymer in 1–2% aqueous acetic acid, and PAF was dissolved in water.

The flocculation power of compounds was studied using model and real systems. The model systems were dispersions of clay, kaolin, and Redoxide dye in water with the concentration of the dispersed phase of 0.5 wt %; industrial and domestic wastewaters were used as real systems.

The flocculation power was evaluated spectrophotometrically by changes in the optical transmission (%) of the suspension with time. The aqueous suspensions were prepared by dispersion of the appropriate system in distilled water for 30 min with stirring at 180–200 rpm. Then, the suspensions were placed into a cell of an FEK-M photocolorimeter, the required amount of a flocculant was added, the mixture was stirred, and the optical transmission of the system was recorded.

First we determined the optimal concentrations of polymeric flocculants and found that it was $\sim 10^{-3}$, $\sim 10^{-4}$, and 10^{-6}% for CTS, its grafted copolymer, and PAF, respectively. At higher concentrations, the dispersions are stabilized. This is confirmed by the data given in Fig. 1, which suggest that the grafted copolymer is the most effective single-component flocculant.

The flocculating power of macromolecular compounds can be enhanced by "double addition" of the flocculant [1]. It is considered that agglomerates formed on adding the first portion of the polymer solution become coarser upon addition of the second portion; as a result, the clarification rate of the dispersion is higher than at the single-stage procedure. It seemed advisable to use different compounds, e.g., cationic and anionic flocculants in the first and second stages, respectively. We suggested that the formation of interpolymeric complexes between a cationic poly-

* Purchased from the Sonat Company, Moscow, Russia.

1070-4272/03/7611-1784$25.00

mer sorbed on dispersed particles and linear macromolecules of an anionic flocculant would increase the efficiency of the dispersion sedimentation [3]. Such a structure can be described as a "bunch on the branch". Thus, the dispersions were treated by three different modes: (1) copolymers were added simultaneously, (2) CTS was added before PAF, or (3) PAF was added before CTS.

The performance of various flocculants in clarification of the clay suspensions is illustrated in Fig. 2. As seen, the flocculant mixtures showed higher flocculation performance as compared to individual components, and the best result was observed for mode 1 (CTS : DMAEM = 5 : 1). We proposed that, in this case, labile networks of macromolecules of the grafted (cationic) and random (anionic) copolymers are formed, and the dispersed particles are trapped by this network and aggregate in it. It should be taken into account that these networks do not spread through the whole solution, and their size is comparable with the size of the particle aggregates. We found that the above mixture acts as efficient flocculant at pH 2–9.

Based on the data obtained for model systems, we tested the flocculant mixtures in clarification of the industrial and domestic wastewaters.

The electrokinetic potential of the disperse phase in wastewaters was determined by electrophoresis using a Ken device. It was found that the colloidal particles were negatively charged and the electrokinetic potential was about 70 mV. This fact explains high stability of industrial wastewaters; they are stable without flocculation and clarification for several months (D = 2–3). Since the dispersed particles are negatively charged, first the cationic and then the anionic flocculants were added. It should be noted that, in contrast to the model tests, no clarification was observed on adding the flocculant mixture. Upon addition of CTS or its grafted copolymer, coarse "curdled" bunches were formed, which did not precipitate in 1 h. After addition of the anionic flocculant, we observed the densification of the initial loose aggregates and their sedimentation in 3–4 min (Fig. 3). Apparently, in this case, the coagulation–flocculation mechanism is realized providing formation of the structures of "bunch on the branch" type. Since the light transmission of the industrial wastewaters was very low ($D \gg 1$ depending on the tank), the flocculation efficiency of the double-stage addition of the polymers in question was estimated at 14–26 depending on the molecular weight of the flocculants:

$$\tau = V/V_0 - 1,$$

where V and V_0 are the clarification rates of the dispersion in the presence of flocculant and without it, respectively.

CONCLUSIONS

(1) The flocculation powers of chitosan and its grafted copolymer with dimethylaminoethyl methacrylate dimethyl sulfate in their mixtures with anionic acrylic polymer were compared, and a synergistic effect was revealed. To attain the highest flocculation power, the flocculants should be added successively, first the cationic and then the anionic polymers.

(2) The clarification efficiency of the industrial wastewaters is 14–26.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Reduction of 4-Nitrosodiphenylamine with Sodium Hydroxy- and Aminoalkanesulfinates

Yu. V. Polenov, E. V. Egorova, and S. G. Ryazantseva

Ivanovo State Chemical Engineering University, Ivanovo, Russia

Received March 13, 2003

Abstract—The kinetics of reduction of 4-nitrosodiphenylamine with sodium alkanesulfinates were studied, and the reaction mechanism was suggested.

Reduction of 4-nitrosodiphenylamine (NDPA) to 4-aminodiphenylamine (ADPA) is of great practical importance, since ADPA is an intermediate product in preparation of antioxidants. In particular, condensation of ADPA with acetone yields 4-isopropylaminodiphenylamine (commercial name Diafen FP) [1], which is thermal stabilizer for polyethylene, polystyrene, and synthetic rubber, inhibitor of tarring of motor fuel, and stabilizer of leaded gasolines. In recent years, derivatives of alkanesulfinic acids containing various substituents at the first carbon atom were found to be highly promising in reduction of organic nitro and nitroso compounds. The feature of these compounds is the presence of abnormally long C–S bond, which under certain conditions ruptures to form active intermediates having high reducing power: SO_2^{2-} and $S_2O_4^{2-}$ ions and $\dot{S}O_2^-$ radical anions [2]. The use of sodium hydroxymethylsulfinate as a reducing agent allows preparation of ADPA from NDPA in almost quantitative yield [3]. The mechanism of this reaction was thoroughly studied. It was shown that the initial substance can be reduced both with sulfoxylate anions and directly with hydroxymethanesulfinate molecules [4]. The absence of side reactions allows reliable determination of the rate constants of the stages involving decomposition of the reducing agent and the reaction of sulfoxylate anions with the oxidant. These parameters can be used for optimizing processes involving such reducing agents.

In this connection, it is appropriate to study the possibility of NDPA reduction with derivatives of alkanesulfinic acids with the aim to compare their reactivity and performance and also to elucidate the process mechanism.

EXPERIMENTAL

NDPA was prepared by threefold recrystallization of the commercial product from ethanol.

Sodium hydroxymethanesulfinate (SHMS), sodium hydroxyethanesulfinate (SHES), and sodium aminomethanesulfinate (SAMS) used as reducing agents were prepared by the procedures described in [5, 6]. The concentrations of their solutions were determined by iodometric titration [7].

NDPA was reduced directly in the colorimeter cell, which was placed into a temperature-controlled jacket connected to a UT-2 thermostat (the temperature was maintained with the accuracy of ±0.5°C). The reaction rate was determined by measuring the optical density of the NDPA solution at λ = 400 nm, which corresponds to the absorption maximum in its electronic spectrum. It was found preliminarily that the reaction products and the reducing agent do not absorb light at this wavelength. The optical density was measured on a KFK-2 spectrophotometer equipped with an Shch-1516 digital dc voltmeter.

All kinetic measurements were carried out at more than thousand-fold excess of the reducing agent, which provides practically constant concentration of the reducing agent in the course of the experiment.

Preliminary experiments showed that the reaction of NDPA with SHMS in aqueous alkaline solution yields a compound that can be isolated by distillation in a vacuum at approximately 200°C. The melting point of this compound is 66–67°C, the half-wave reduction potential on a dropping mercury electrode $E_{1/2}$ = –0.23 V (anodic wave), and the appearance of the product corresponds to published data for ADPA [8, 9].

To determine the stoichiometry of the reaction between SHMS and NDPA, we mixed the solutions of these compounds in 1 M aqueous NaOH. The resulting mixture was kept under argon at 73°C until decolorization, after which the SHMS content was determined iodometrically.

1070-4272/03/7611-1787$25.00

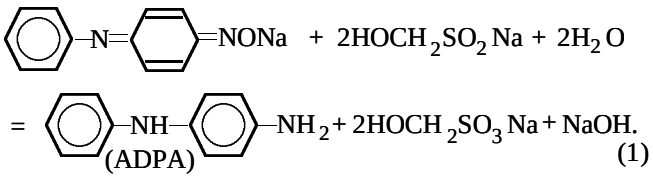
Table 1. Determination of the stoichiometric ratio of the reactants in reduction of NDPA with SHMS. Initial amount of NDPA 0.0147 mol

ν^{*}_{SHMS}	ADPA obtained	ν^{**}_{SHMS}	NDPA : SHMS*	Yield of ADPA, %
mole				
0.7178	0.0138	0.0799	1 : 1.9	94
0.1078	0.0145	0.0769	1 : 2.1	99
0.1051	0.0145	0.0742	1 : 2.1	99

* Before reaction.
** After reaction.

Table 1 shows that, under these conditions, ADPA is formed in quantitative yield, with the ratio of the reacted NDPA and SHMS being 1 : 2. Qualitative analysis showed that, in the course of reduction, sulfite sulfur is formed.

These results suggest the stoichiometric reaction equation



(1)

SHMS and SAMS are analogs of sodium hydroxymethanesulfinate [1]. Hence, there is good reason to believe that the reduction of NDPA with SHES and SAMS proceeds by a stoichiometric equation similar to Eq. (1).

The kinetic curves of NDPA reduction with various reducing agents are shown in Fig. 1. Contrary to reduction of 2-nitro-2'-hydroxy-5'-methylazobenzene (NAB) [10], the reaction between alkanesulfinates and NDPA proceeds without an induction period, with the reaction order with respect to the oxidant being fractional.

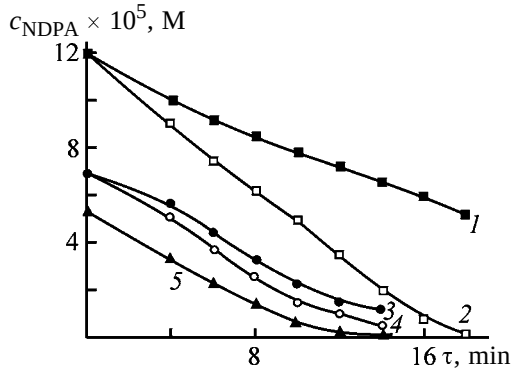


Fig. 1. Kinetic curves of NDPA reduction. (c_{NDPA}) NDPA concentration; (τ) time. (*1*, *2*) SHMS, 309 K, c_{red} = 0.5519, c_{OH^-} = 0.37 M; (*3*, *4*) SHES, 303 K, c_{red} = 0.071, c_{OH^-} = 0.6 M; (*5*) SAMS, 313 K, c_{red} = 0.414, c_{OH^-} = 1.02 M. (*2*, *4*, *5*) In the absence of additives; addition of the corresponding aldehyde, M: (*1*) 0.21 and (*3*) 0.02.

It is well known that reactions involving SHMS are inhibited by formaldehyde. This is due to the fact that the reducing species in some cases are not the molecules of the reducing agent but the products of their decomposition, sulfoxylate ions, formed by the reversible reaction [1]

$$HOCH_2SO_2^- \rightleftarrows HSO_2^- + CH_2O. \quad (2)$$

Addition of formaldehyde and acetaldehyde inhibits the reaction in question (Fig. 1, curves *1* and *3*), and at sufficiently high concentrations of the additives the reaction order with respect to NDPA becomes equal to 1 (Fig. 2a).

However, attempts to completely inhibit the reaction by adding aldehydes, as in the case of NAB and indigocarmine, failed [10, 11]. For example, in reduction of SHMS, the reaction rate on adding formaldehyde decreases by 60% at maximum, and with further addition of formaldehyde it remains constant. For SAMS, according to the equation of its decomposition with rupture of the C–S bond, aminomethanol should be an additive shifting the equilibrium to formation of nondissociated reducing agent molecules:

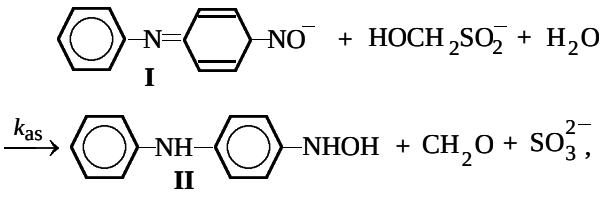
$$NH_2CH_2SO_2^- + OH^- \rightleftarrows SO_2^- + NH_2CH_2OH. \quad (3)$$

Aminomethanol does not exist in the free state [12]; therefore, it is impossible to carry out experiments with its addition to SAMS.

For all the reducing agents studied, the reaction rate varies in direct proportion to the concentration of the reducing agent (Fig. 2b) both in the presence of aldehydes and without them.

The above experimental data suggest that reduction of NDPA with derivatives of alkanesulfinic acids proceeds by two parallel pathways: direct reaction of NDPA with molecules of reducing agent (associative pathway) and reaction with the products of decomposition of reducing agent molecules, sulfoxylate anions (dissociative pathway). Based on the above and also published data [13], which note that the nitroso group is reduced in steps, we can propose the following reaction pattern (for SHMS as an example):

Associative pathway



(4)

$$\mathbf{II} + HOCH_2SO_2^- \rightarrow ADPA + HOCH_2SO_3^{2-}. \quad (5)$$

Dissociative pathway

$$HOCH_2SO_2^- + OH^- \underset{-k_1}{\overset{k_1}{\rightleftarrows}} SO_2^{2-} + CH_2(OH)_2,^1 \quad (6)$$

$$\mathbf{I} + HSO_2^- + 2H_2O \xrightarrow{k_2} \mathbf{II} + SO_3^{2-}, \quad (7)$$

$$\mathbf{II} + HSO_2^- + 2H_2O \rightarrow ADPA + HSO_3^{2-}. \quad (8)$$

Since in the presence of aldehyde the reaction order with respect to the reducing agent and NDPA is equal to 1, we can assume that, in the associative pathway, reaction (4) will be the limiting stage and the subsequent fast stage (5) will not affect the overall rate of the process. The first reaction order with respect to the reducing agent in the absence of aldehyde additions and the inhibiting effect of the aldehydes suggest, by analogy with reduction of NAB, that in reduction by the dissociative pathway the limiting stage is cleavage of the reducing agent molecules (6). Applying the steady-state concentration method to stages (6) and (7), and considering the associative pathway, we obtain the kinetic equation

$$v_{ov} = -\frac{dc_{NDPA}}{dt} = v_{dis} + v_{as} = \frac{k_1 k_2 c_{NDPA} c_r c_{OH^-}}{k_{-1} c_a + k_2 c_{NDPA}} + k_{as} c_{NDPA} c_r, \quad (9)$$

where v_{ov}, v_{dis}, and v_{as} are the overall reaction rate and the reaction rates by dissociative and associative pathways, respectively (mol l^{-1} s^{-1}); c_{NDPA}, c_{OH^-}, c_r, and c_a are concentrations of NDPA, hydroxide ions, reducing agent, and aldehyde (or aminomethanol), respectively (M); k_1 and k_{-1} are the rate constants of stage (6) (l mol^{-1} s^{-1}); k_2 and k_{as} are the rate constants of stages (7) and (4), respectively (l mol^{-1} s^{-1}).

Equation (6) can be experimentally verified for the reducing agents studied by analogy with reduction of NAB with SHMS [10].

[1] Methylene glycol is hydrated form of formaldehyde in alkali solution.

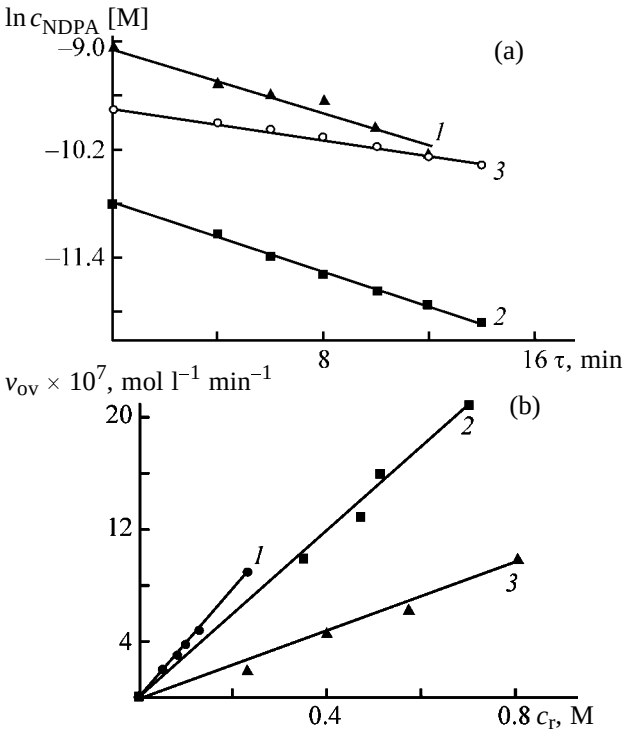


Fig. 2. Dependences of (a) $\ln c_{NDPA}$ on duration of NDPA reduction τ and (b) the reaction rate v_{ov} on concentrations of the reducing agents c_r: (a) (*1*) SHMS, 309 K, c_r = 0.5519, c_{OH^-} = 0.37, c_a = 0.21 M; (*2*) SHES, 303 K, c_r = 0.0634, c_{OH^-} = 0.17, c_a = 0.013 M; (*3*) SAMS, 303 K, c_r = 0.4088, c_{OH^-} = 0.86 M. (b) (*1*) SHES, 283 K, c_{OH^-} = 0.5, $c_{NDPA} = 2.5 \times 10^{-5}$, $c_a = 5 \times 10^{-5}$ M; (*2*) SAMS, 303 K, c_{OH^-} = 0.75, $c_{NDPA} = 2 \times 10^{-5}$; (*3*) SHMS, 308 K, c_{OH^-} = 0.37, $c_{NDPA} = 2.5 \times 10^{-5}$, c_a = 0.21 M.

For this purpose, based on the results of experiments performed at aldehyde concentrations sufficient to suppress pathways (6)–(8), we found k_{as} values (Table 2). Then, from the difference between the overall rate v_{ov} and the rate by the associative pathway v_{as}, we evaluated the reaction rates by the dissociative pathway v_{dis}, entering into the linear form of the kinetic equation

$$\frac{1}{v_{dis}} = A + \frac{Bc_a}{c_{NDPA}}, \quad (10)$$

Table 2. Kinetic parameters of NDPA reduction with sodium alkanesulfinates

Reducing agent	T = 283 K		T = 293 K	
	k_{as}	k_1	k_{as}	k_1
	l mol^{-1} s^{-1}			
SHMS	9.5×10^{-4}	1.13×10^{-9}	1.3×10^{-3}	2.5×10^{-9}
SHES	1.13×10^{-3}	2.2×10^{-7}	5.5×10^{-3}	3.5×10^{-6}
SAMS	6.7×10^{-5}	6.7×10^{-9}	3.17×10^{-4}	1.43×10^{-8}

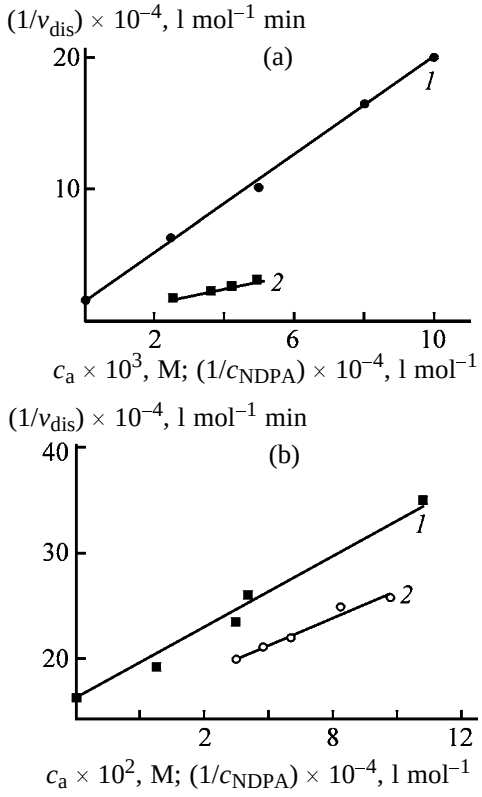

Fig. 3. Reciprocal reaction rate by dissociative pathway $1/v_{dis}$ as a function of (*1*) concentration of aldehydes c_a and (*2*) reciprocal concentration of NDPA $1/c_{NDPA}$: (a) SHES, 283 K; c_r = 0.1064, c_{OH^-} = 1.8; (*1*) $c_{NDPA} = 2.5 \times 10^{-5}$, (*2*) c_a 3.6×10^{-3} M; (b) SHMS, 308 K; c_r = 0.5519, c_{OH^-} = 0.37; (*1*) $c_{NDPA} = 6 \times 10^{-5}$, (*2*) $c_a = 3.6 \times 10^{-2}$ M.

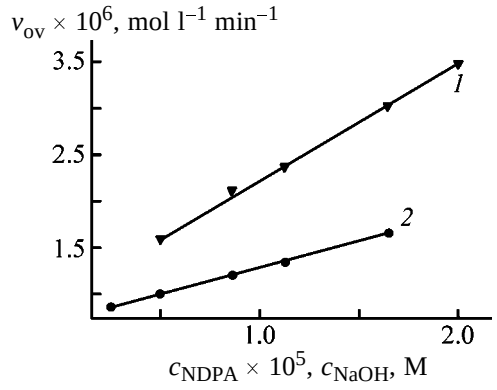

Fig. 4. Rate of NDPA reduction with HAMS v_{ov} as a function of (*1*) NDPA concentration c_{NDPA} and (*2*) concentration of hydroxide ions c_{OH^-} at 303 K. c_r (*1*) 0.468 and (*2*) 0.409; (*1*) c_{OH^-} = 0.75; (*2*) $c_{NDPA} = 2 \times 10^{-5}$ M.

where $A = 1/(k_1 c_r c_{OH^-})$, $B = k_1/(k_1 k_2 c_r c_{OH^-})$.

The linearity of the plots in the coordinates $1/v_{dis}$–c_a at c_{NDPA} and c_{OH^-} = const and $1/v_{dis}$–$1/c_{NDPA}$ at c_a and c_{OH^-} = const (Fig. 3) confirms the validity of Eq. (10).

Table 3. Kinetic parameters of NDPA reduction with SAMS

T, K	$v_{ov} = f(c_{OH^-})$		$v_{ov} = f(c_{NDPA})$	
	$k_{as} \times 10^3$	$k_1 \times 10^8$	$k_{as} \times 10^3$	$k_1 \times 10^8$
	l mol^{-1} s^{-1}			
303	1.5 ± 0.3	2.3 ± 0.6	1.1 ± 0.2	4.0 ± 1.0
308	2.6 ± 0.3	4.0 ± 1.0	2.5 ± 0.5	4.0 ± 1.0
313	6.0 ± 1.0	6.0 ± 1.0	4.0 ± 0.8	6.0 ± 2.0

Table 4. Angular coefficients of dependences $v_{ov} = f(c_r)$ for NDPA reduction with SAMS

T, K	Angular coefficient	
	evaluation by Eq. (1)	experimental
303	3.02×10^{-6}	2.88×10^{-6}
308	6.14×10^{-6}	5.2×10^{-6}
313	7.01×10^{-6}	7.86×10^{-6}

From the initial ordinates of the above linear dependences, equal to the parameter *A* in Eq. (10), we evaluated the rate constants k_1 (Table 2).

As mentioned above, it is impossible to study how aminomethanol inhibits NDPA reduction with SAMS by shifting the equilibrium of decomposition of SAMS molecules by reaction (3). However, the experimental data obtained suggest that two-pathway scheme of reduction is realized in the case of this reducing agent also and it is possible to determine the same kinetic parameters that as in the case of SHMS and SHES.

The dependences of the rate of NDPA reduction with SAMS on the concentrations of NaOH and NDPA are shown in Fig. 4. The observed linear dependences with positive initial coordinates are in good agreement with the kinetic model proposed. Assuming that $k_{-1} c_a \ll k_2 c_{NDPA}$, Eq. (9) is simplified:

$$v_{ov} = k_1 c_r c_{OH^-} + k_{as} c_{NDPA} c_r. \qquad (11)$$

The equation adequately describes the experimental data presented in Figs. 2 and 4.

The rate constants and activation energies were evaluated by least-squares treatment of these dependences for various concentrations of the reducing agent and sodium hydroxide and various temperatures (Table 3). Using the rate constants listed in Table 3,

we evaluated the angular coefficient of the dependence $v_{ov} = f(c_r)$ by Eq. (11) and compared with the experimental data (Fig. 2b) (Table 4). Satisfactory agreement of these results additionally confirms the adequacy of the proposed kinetic model. From the temperature dependences of the rate constants listed in Table 3, we evaluated the activation energies for the associative and dissociative pathways to be 106 ± 10 and 53 ± 2 kJ mol^{-1}, respectively.

It should be noted in conclusion that the found rate constants k_1 (Table 2) characterize the ease of the rupture of the C–S bond in alkanesulfinate molecule. From the above data, the reducing agents can be ranked in the following order with respect to stability: SHES < SAMS < SHMS.

CONCLUSION

Based on the kinetic data for reduction of 4-nitrosodiphenylamine with sodium hydroxymethanesulfinate, sodium hydroxyethanesulfinate, and sodium aminomethanesulfinate, the kinetic equations were obtained. These equations suggest that the reaction proceeds by two parallel pathways: direct reaction of the substrate with reducing agent molecule (associative pathway) and reaction with the product of reducing agent decomposition, sulfoxylate anion (dissociative pathway).

Received April 4, 2003

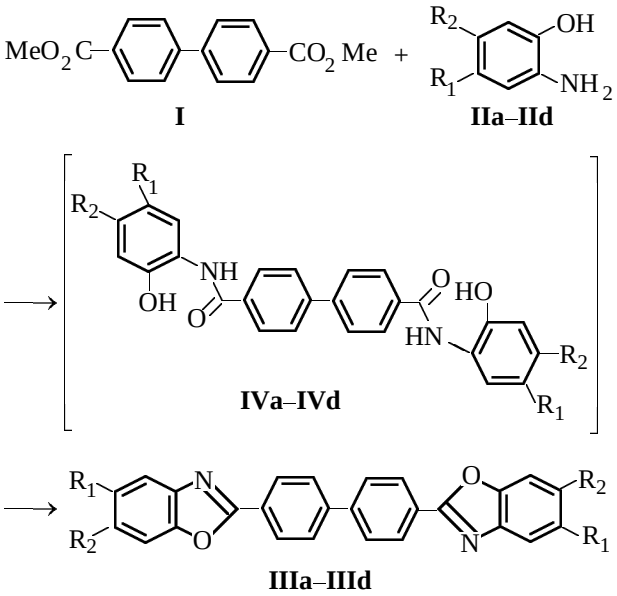
Abstract—An attempt was made to prepare 4,4'-bis[5-alkyl(aryl)benzoxazol-2-yl]biphenyls by reaction of dimethyl 4,4'-biphenyldicarboxylate with substituted *o*-aminophenols in a high-boiling solvent in the presence of boric acid.

Compounds containing an oxazole fragment exhibit a set of valuable properties [1]. In particular, benzoxazoles are used in production of heat-resistant polymers [2], scintillators [3, 4], and fluorescent whiteners [5–7]. Of considerable interest as optical whiteners are bis(benzoxazoles) in which benzoxazole cores are linked via an ethylene, aromatic, or heterocyclic bridge. These compounds exhibit high heat resistance and lightfastness; they are used for whitening of virtually all polymeric materials. Synthesis of new compounds of this series and their study in the context of specific applications remain urgent problems.

Studies on synthesis of substituted benzoxazol-2-yl compounds in which benzoxazole cores are linked to biphenyl are relatively few [8, 9], although introduction of an additional aromatic core into the conjugation chain should enhance the whitening effect. One of promising routes to bis(benzoxazoles) containing a biphenyl bridge is that starting from dimethyl 4,4'-biphenyldicarboxylate **I**, which became a cheap and readily available substance after development of an efficient procedure for its recovery from dimethyl terephthalate production waste [10]. The known procedures for preparing 4,4'-bis(benzoxazol-2-yl)biphenyl derivatives are based on condensation of 4,4'-biphenyldicarboxylic acid or its chloride with substituted *o*-aminophenols. The reaction is performed in two steps (formation of acid arylamides followed by cyclodehydration) or in one step, with polyphosphoric acid used as solvent and cyclizing agent. The yields of the target products, depending on the solvent and cyclizing agent used, did not exceed 68% [9]. Isolation of the pure target product involves prolonged (many hours) extraction, which is a significant drawback.

The goal of this study was development of a procedure for preparing 4,4'-bis[5-alkyl(aryl)benzoxazol-2-yl]biphenyls ensuring high yield and purity of the target product, involving no aggressive cyclization agents and sophisticated purification procedures, and starting from readily avaliable ester **I**. We studied the reactions of **I** with various *o*-aminophenols **IIa**–**IId** in high-boiling solvents in the presence of boric acid [11] (Table 1).

4,4'-Bis(benzoxazol-2-yl)biphenyl derivatives were prepared by the scheme



The characteristics of **IIIa**–**IIId** are listed in Table 2.

As solvents we used dimethylformamide, dimethylacetamide (DMA), diheptyl ether, diphenyl ether, and

Dinil (a mixture of 26.5% biphenyl and 73.5 δiphenyl ether). In amide solvents and diheptyl ether, the reaction is very slow, because their boiling point is too low for the efficient reaction. Table 1 shows that the ratio between ester **I** and boric acid strongly affects the yield of bis(benzoxazoles) **IIIa**–**IIId**. Complete conversion is attained with an equimolar amount of the catalyst. At lower concentrations of boric acid and optimal reaction temperatures, the yield is as low as 63%. The reaction can be accelerated by adding an equimolar amount of pyridine; in this case, the maximal yield at 250–260°C is attained in 10–12 h. The highest yield of **IIIa**–**IIId** is attained in diphenyl ether (91%) or Dinil (92%) at the component ratio **I** : (**IIa**–**IId**) : pyridine : Dinil = 1 : 2 : 1 : 5 and 100 mol % amount of boric acid.

Compounds **IIIa**–**IIId** can be readily isolated from the reaction mixture as follows. The mixture is cooled to 150–180°C, diluted with DMA, refluxed for 2 h, and then cooled to 80–90°C. Under these conditions, the reaction product crystallizes. It is filtered off and washed on the filter with hot DMA. Compounds **IIIa**–**IIId** are colorless or light yellowish powders insoluble in water and aqueous acids and alkalis and sparingly soluble in organic solvents.

The reaction mechanism involves initial formation of amides **IVa**–**IVd** followed by their cyclization with formation of the benzoxazole fragment, as demonstrated by the example of reaction of **I** with **IIa**. The IR spectrum of the intermediate amide **IVa** contains NH stretching bands at 3320 and 3270 cm^{-1}, NH bending band at 1560 cm^{-1}, and amide $\nu_{C=O}$ band at 1680 cm^{-1}.

The composition of benzoxazoles **IIIa**–**IIId** was confirmed by elemental analysis, and their structure was determined by IR and ^1H NMR spectroscopy.

The IR spectra are consistent with the suggested structures. Transformation of **I** into **IIIa**–**IIId** results in disappearance of a strong band at 1730 cm^{-1} and appearance of a strong band at 1565–1580 cm^{-1}, with the bands of aromatic structures being preserved. The band at 1565–1580 cm^{-1} belongs to vibrations of the –N=C–O– fragment in the ring [12]. A strong band at 1470–1480 cm^{-1} is apparently due to conjugation of the biphenyl fragment with the benzoxazole core of the molecule. The stretching vibration bands of the C–H bonds of the aromatic rings are observed at 3060–3020 cm^{-1}.

In the ^1H NMR spectra of **IIIa**–**IIId**, the protons of the biphenyl fragment give doublets at 7.73–7.78 (4H) and 8.15–8.21 ppm (4H), with the coupling constant of 8.0 Hz. The benzoxazolyl protons give multiplets at 7.15–7.60 ppm (4,6,7-H, 6H). The C^5–CH_3 protons in **IVa** give a singlet at 2.24 ppm; C^6–CH_3 protons in **IVd**, a singlet at 2.26 ppm; C^5–$C(CH_3)_3$ protons in **IIIc**, a singlet at 1.08 ppm (18H); and C^5–Ph protons in **IIIb**, a multiplet at 6.92–7.38 ppm (10H). Bis(benzoxazoles) **IIIa**–**IIId** are luminophores emitting in the blue range, with the fluorescence maximum at 435–440 nm (Table 1).

EXPERIMENTAL

The ^1H NMR spectra were recorded on a Tesla BS-587A spectrometer (100 MHz, internal reference HMDSO, δ scale, solvent CF_3COOD). The IR spectra were taken on a Specord M-80 spectrophotometer in the range 400–4000 cm^{-1} using KBr pellets. The fluorescence spectra were measured on a Fluorat 02-Panorama spectrometer, λ_{exc} = 350 nm. The melting points were measured with a Boetius stage.

The reaction progress was monitored, and the product purity checked, by TLC on Silufol DC-Plastikfolien Rieselgel 60 F_{254} plates, eluent toluene–ether, 3 : 1.

4,4'-Bis[5-alkyl(aryl)benzoxazol-2-yl]biphenyls IIIa–IIId. The reaction vessel was charged with 30.0 g (0.11 mol) of ester **I**, 0.22 mol of substituted aminophenol **IIa**–**IId**, 100 ml of Dinil, 10 ml of pyridine, and 6.2 g (0.1 mol) of boric acid; a nitrogen flow was passed. The mixture was heated with continuous stirring to 160–170°C and kept at this temperature for 3 h until the volatiles (methanol, water, pyridine, etc.) were completely distilled off. Then the temperature was raised to 250–260°C and kept at this level for 10–12 h. After the reaction completion, the mixture was cooled to 150–180°C, diluted with 100 ml of DMA, and refluxed for 2 h. After cooling to 80–90°C, the precipitate was filtered off, washed on the filter with hot DMA, and dried in a vacuum.

CONCLUSIONS

(1) 4,4'-Bis[5-alkyl(aryl)benzoxazol-2-yl]biphenyls are formed in quantitative yield by the reactions of dimethyl 4,4'-biphenyldicarboxylate with substituted *o*-aminophenols in a high-boiling solvent (diphenyl ether or Dinil) in the presence of boric acid and pyridine at 250–260°C for 10–12 h.

(2) High-purity substituted bis(benzoxazoles) can be prepared by this procedure in one step in high yield.

Abstract—The possibility of converting dehydroabietic acid into the chloride by treatment with $SOCl_2$, PCl_3, and PCl_5 was examined.

Diterpenic (resin) acids are monocarboxylic acids of the hydrophenanthrene series; their only available source is rosin. Their reactions involve the hydrophenanthrene core (especially owing to the presence of conjugated double bonds) and carboxy group. Therefore, it is possible to prepare from rosin diverse valuable derivatives.

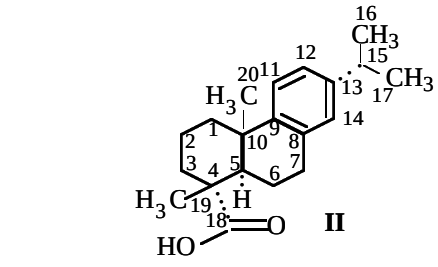
The chemical structure and properties of the main representatives of resin acids and their most important derivatives have been comprehensively studied [1–3]. A distinctive feature of resin acids is the presence of the carboxy group at the tertiary carbon atom. Therefore, with resin acids, many reactions characteristic of aliphatic carboxylic acids (formation of esters, salts, amides, nitriles, etc.) are sterically hindered and require severe conditions: high temperatures close to the decomposition point (280–300°C), elevated pressure, etc.

The reactivity of carboxylic acids can be enhanced by converting the carboxy group into a more reactive group. In this connection, it seems promising to prepare resin acid anhydrides and chlorides, which can be converted into the required derivatives more readily than the initial acids.

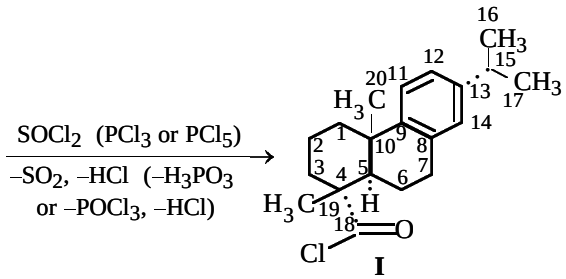
However, preparation of resin acid anhydrides also involves certain problems, since the reaction requires contact of two carboxy groups at tertiary carbon atoms [4]. Furthermore, anhydrides are less reactive than acid chlorides.

Data on synthesis and properties of resin acid chlorides are scarce and contradictory. In particular, crystalline tetrahydroabietic chloride (mp 69.5°C) was prepared by the reaction of the acid with thionyl chloride [5]. Treatment of levopimaric acid with PCl_3 in the presence of pyridine gave the corresponding acid chloride; it, however, was not isolated pure [6]. Preparation of abietic and dehydroabietic chlorides was attempted in [4, 7, 8]. It was noted that treatment of abietic acid with $SOCl_2$ gave virtually no acid chloride; therefore, subsequent experiments were performed with PCl_5 as halogenating agent. The purity of the resulting abietic and dehydroabietic chlorides isolated as viscous oily liquids was low (50–75 wt % main substance). Goryaev *et al.* [9] reported that $SOCl_2$ did chlorinate dehydroabietic acid; the product was obtained as yellow oil decomposing during distillation and was identified by IR spectroscopy.

Here we report on the synthesis of dehydroabietic chloride **I** in 90–98% yield by treatment of dehydroabietic acid **II** with $SOCl_2$, PCl_3, or PCl_5:



II



I

1070-4272/03/7611-1795$25.00

The rates of formation of chloride **I** with different chlorinating agents differ considerably. On mixing of **II** with PCl_5 at room temperature, the reaction is so fast that variation of the reactant concentrations cannot be monitored. With $SOCl_2$ and PCl_3, the reaction rates are comparable and depend on temperature. The reaction progress was monitored by IR spectroscopy: The concentration of **I** in reaction mixture samples taken at definite intervals was evaluated from the growing intensity of the C=O band of the chloride at 1790 cm^{-1}, with simultaneous monitoring of a decrease in the intensity of the carboxyl C=O band at 1690 cm^{-1}.

The experimental data are satisfactorily fitted by the kinetic equation of an irreversible second-order reaction. The apparent reaction constants calculated from this equation ($k_{app} \times 10^5$, l mol^{-1} s^{-1}) are as follows (with the temperature, °C, given in parentheses): $SOCl_2$, 6.2 ± 0.3 (40), 32.9 ± 1.8 (50), 50.0 ± 2.9 (60), and 78.9 ± 3.4 (70); PCl_3, 4.1 ± 0.2 (30), 6.0 ± 0.3 (40), 31.1 ± 1.4 (50), and 72.9 ± 3.5 (60). The apparent activation energies of the reactions of **II** with $SOCl_2$ and PCl_3 are 73 ± 1 and 86 ± 1 kJ mol^{-1}, respectively.

The main substance content in the resulting chloride **I** is 99.2–99.5% (GLC data). It is a light-colored highly viscous slowly crystallizing liquid. The product is stable in storage in a sealed vessel; it crystallizes within 30–40 days. The crystals of **I** isolated by double recrystallization from acetone and single recrystallization from hexane melt at 44.5–45°C. The molecular weight of the product, according to mass spectrometry, is 318.17522, which corresponds to the formula $C_{20}H_{27}ClO$ (318.17503). The weight fraction of chlorine, determined according to [10], is 10.4% (calculated for $C_{20}H_{27}ClO$ 11.2%).

The UV spectrum of **I** contains well-defined bands at about 268 and 275 nm, characteristic of acid **II** and corresponding to absorption of the aromatic core. The IR spectrum of **I** contains a pronounced band at 1790 cm^{-1}, corresponding to absorption of the C=O bond in acyl chlorides [11] and absent in the spectrum of **II**.

The ^1H NMR spectra of **I** and **II** are virtually identical; some differences are observed in the ^{13}C NMR spectra.

Chloride **I** is not noticeably hydrolyzed in the cold, which allows removal of excess halogenating agents and the mineral acids forming in the synthesis by washing with water. Compound **I** is readily soluble in toluene, trichloroethylene, carbon tetrachloride, diethyl ether, and dioxane. The product is thermally stable and starts to decompose at a measurable rate only at 140°C; it enters into reactions typical of all acid chlorides.

The results of this study were used for developing a commercial process for production of resin acid chlorides and their mixtures.

EXPERIMENTAL

Dehydroabietic acid **II** was isolated by recrystallization [12] from disproportionated oleoresin rosin commercially produced according to TU (Technical Specifications) 13-00281074-265–95, revision 1. We used acid **II** with mp 172°C (mp 172.5–173°C [13]) containing 98 wt % main substance (GLC data). The halogenating agents and other chemicals were of chemically pure or analytically pure grade and were used without additional purification.

The IR spectrum was recorded in CCl_4 on a Perkin–Elmer 1310 spectrophotometer (NaCl cells, layer thickness 1.05 mm), and the UV spectrum, on a Specord M-40 spectrophotometer in hexane. The ^1H and ^{13}C NMR spectra were recorded on a Bruker AC-200 spectrometer in $CDCl_3$, and the mass spectra, on a Finnigan MAT-8200 spectrometer.

The melting point was determined in a capillary according to GOST (State Standard) 14618.12–78 with a PTP device.

Resin acid methyl esters were analyzed by GLC (Chrom 5 device) following the procedure described in [14, 15], using methyl margarate as internal reference. The relative error of single analysis at a confidence level of 0.95 was within ±2%. The results of five replicate runs were averaged. The mixture components were identified by addition of authentic reference samples and by comparison of the relative retention time with published data.

Reaction of dehydroabietic acid II with $SOCl_2$. Acid **II** (10 g, 0.033 mol) was gradually added to a solution of 6.6 g (0.056 mol) of $SOCl_2$ in 50 ml of toluene. The solution was stirred for 20 h at 20°C, after which the solvent and excess $SOCl_2$ were distilled off at a pressure of 0.08 MPa. The remaining yellow-brown viscous oil (10.3 g, yield 97.3%) was stored at 20–25°C for 30 days. After double recrystallization from acetone and single recrystallization from hexane, crystalline product **I** was obtained; mp 44.5–45°C. IR spectrum, ν, cm^{-1}: 1790 (C=O).

^{13}C NMR spectrum of acid **II**, δ, ppm: 37.8 t (C^1), 18.4 t (C^2), 36.6 t (C^3), 47.3 s (C^4), 44.4 d (C^5), 21.6 t (C^6), 29.8 t (C^7), 134.5 s (C^8), 146.6 s (C^9), 36.7 s (C^{10}), 123.9 d (C^{11}), 123.7 d (C^{12}), 145.6 s (C^{13}), 126.7 d (C^{14}), 33.3 d (C^{15}), 23.8 q (C^{16}, C^{17}), 185.3 s (C^{18}), 16.1 q (C^{19}), 25.0 q (C^{20}).

Reaction of dehydroabietic acid II with PCl_3. Acid **II** (10 g, 0.033 mmol) was gradually added to a solution of 3.1 g (0.023 mol) of PCl_3 in 40 ml of toluene. The reaction was performed for 20 h at room temperature. Then the mixture was washed with water, $NaHCO_3$ solution (two times), and again water to neutral reaction of the wash waters. The toluene solution was dried over Na_2SO_4, after which the solvent was removed at a pressure of 0.08 MPa. Compound **I** was obtained as a viscous oily product (yield 9.8 g, 92.5%) which did not crystallize even on adding a seed. The IR spectrum of the product contained a band at 1790 cm^{-1} characteristic of acyl chlorides [11]. Other functional groups were not revealed spectrophotometrically.

Reaction of dehydroabietic acid II with PCl_5. A solution of 5 g (0.017 mol) of **II** in 25 ml of diethyl ether was added to 5 g (0.024 mol) of PCl_5 over a period of 2 h. The mixture was allowed to stand for 20 h at room temperature. Then it was washed with water, $NaHCO_3$ solution (two times), and again water to neutral reaction of the wash waters. The ether layer was dried over Na_2SO_4, and the solvent was distilled off at a pressure of 0.08 MPa. The remaining acid chloride **I** was a light yellow viscous mass which did not crystallize even on adding a seed. The IR spectrum of the product contained a band at 1790 cm^{-1} characteristic of acyl chlorides [11]. Other functional groups were not revealed.

CONCLUSION

Dehydroabietic chloride (yield 90–98%; main substance content 99.2–99.5 wt %, GLC data; mp 45°C) was prepared by treatment of dehydroabietic acid with PCl_3, PCl_5, or $SOCl_2$.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermodynamics of Oligomerization of Glutaric Aldehyde with Amino Acids

N. P. Kuznetsova, O. A. Pisarev, R. N. Mishaeva, and L. R. Gudkin

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received July 3, 2003

Abstract—Condensation of glutaric aldehyde with amino acids to form oligomers of glutaric aldehyde was studied by differential microcalorimetry and analysis for the functional groups.

Carbonyl–amine reactions are important biochemical reactions used, in particular, for chemical modification of proteins with glutaric aldehyde (GA). The mechanism of this process is poorly understood owing to a complex structure of peptides and a great number of possible reaction pathways. In this work we studied this process with an example of simpler systems.

Condensation of bifunctional GA with amino acids involves several parallel fast steps. In neutral aqueous solutions, the aldehyde group of GA reacts with the nonionized amino group of an amino acid to form Schiff base (rate constant $\sim 4 \times 10^{-3}$ s^{-1}). Parallel aldol condensation of the second aldehyde group of GA, activated by the first reaction, stabilizes the Schiff base. This reaction yields α,β-unsaturated GA oligomers with conjugated ethylene and aldehyde double bonds. Trimers of GA are mainly formed (rate constant $\sim 0.2 \times 10^{-3}$ s^{-1}) [1, 2].

When the molar ratio of functional groups [CHO/NH_2] ranges from 0.5 to ~4–6, single amino group is spent per three aldehyde group to form GA oligomer with three aldehyde and one carboxy groups:

$$\underset{\text{Amino acid}}{HOOC–R–NH_2} + 3\underset{\text{GA}}{[O=CH–(CH_2)_3–HC=O]}$$

$$HOOC–R–N=CH–(CH_2)_3–[\underset{\displaystyle HC=O}{\underset{|}{HC}}=C–(CH_2)_2]_2–HC=O$$

At a large GA excess ($[CHO/NH_2]_0 \gg 4$ mol/mol), 5–6 aldehyde groups and more are spent per a reacted amino group [5].

Our pervious study shows that, in aqueous neutral solutions of GA, a zwitterion of amino acid is rapidly deprotonated (recharged) to form the nucleophilic nonionized aminogroup, which is atypical for neutral solutions of free amino acids. The rate constant of deprotonation of the zwitterion (0.1–0.2 s^{-1}) is higher by three orders of magnitude than that of its condensation. The resulting amino acid anions containing carboxy group can catalyze oligomerization of GA bound to the amino acid. With excess GA, pure GA oligomers can be formed in the solution.

To determine the conditions under which GA is condensed with amino acids by only two main pathways, namely, Schiff base formation and GA oligomerization, we used microcalorimetry and chemical analysis of the functional groups of the products.

EXPERIMENTAL

Reaction of GA with differently charged amino acids [glycine (monoaminoacetic acid), lysine (α,ε-diaminocaproic acid), and glutamic acid (α-aminoglutaric acid) was studied at 21°C in neutral aqueous solutions at the molar ratio of aldehyde and amino groups $[CHO/NH_2]_0$ ranging from 0.5 to 7.0 mol/mol. The amino acid concentration and the volume of the reaction mixture were constant. The reactants were mixed and samples of the reaction mixture were taken at definite time intervals. The content of free amino groups was determined by reaction with 2,4,6-trinitrobenzenesulfonic acid [6], and the content of aldehyde groups, by differential pH-metry with hydroxylamine hydrochloride [7]. The number of functional groups converted into stable Schiff bases was estimated by the difference between the initial and current ($[\Delta CHO]_t$, $[\Delta NH_2]_t$) content of these groups. Commercial 25% aqueous solution of GA was purified on activated carbon. The purity was estimated from the ratio of optical densities at two wavelengths D_{235}/D_{280} =

* Fraction of $[CHO]_t$ spent for Schiff base formation in aldol condensation.

0.4–0.5, measured on an SF-26 spectrophotometer. Glutaric aldehyde was stored in an acidified (pH 3) aqueous solution at 4°C. Under these conditions, GA was in the monomeric and hydrated forms.

The heat effects of the reaction of GA with glycine were determined by microcalorimetry on a DAK 1-1 calorimeter at 21°C and 101.3 kPa. The reagent mixer was described in [8]. The differential heat effects in time t, ΔH_t, were estimated from the areas under the microcalorimetric curves measured from zero time to time t:

$$\Delta H_t = \int_0^t \Delta H \mathrm{d}t.$$

The integral heat effects ΔH_0 were determined after the stationary thermal conditions were attained, by integration in the range from 0 to t_{eq}. The calculations were performed by the equation

$$\Delta H_0 = \int_0^{t_{eq}} \Delta H \mathrm{d}t.$$

The determination error of the heat effects at the 95% confidence level was ±2%.

The number of amino groups of amino acids, reacted in time t, $[\Delta NH_2]_t$, should be equal to that of stable aldimine bonds of the Schiff base. Superstoichiometric consumption of aldehyde groups $[\Delta CHO]_t - [\Delta NH_2]_t$ can be due to GA oligomerization. As seen from Table 1, at the initial ratio of the aldehyde groups and amino groups of lysine (α,ε-diaminocaproic acid) and glycine (monoaminoacetic acid) $[CHO/NH_2]_0$ = 4–5 mol/mol, the ratio of reacted groups $[\Delta CHO/\Delta NH_2]_t$ remains constant (~3 mol/mol) up to the reaction completion. About 70% of amino groups are spent within the first 10–20 min and 84–86%, within 1 h.

About 30% of reacted aldehyde groups are spent for formation of stable Schiff bases with the amino acid; the other 70% are involved in aldol condensation of GA. Data for the GA–glutamic acid system are given for comparison. The presence of two carboxy groups at the α- and γ-positions can substantially decelerate conversion of this acid into nucleopilic agent with nonionized amino group. At the same time, the Schiff base derived from a dibasic acid catalyses more strongly the GA oligomerization in solution. In this case, the Schiff base formation is inhibited and 90% of GA is spent for aldol condensation within

* Differential thermal effect.

10 min. This can be due to the third reaction: oligomerization of GA (at its excess in the reaction mixture) in the solution, catalyzed by the carboxyl-containing products. It should be noted that the GA pentamer bonded with glutamic acid was isolated by gel chromatography from the products of reaction of GA with glutamic acid [5]. The other aldehyde groups may be involved in GA oligomerization in the solution. When the products of condensation of the amino acid with GA oligomers are accumulated in a large amount in the solution, the remaining aldehyde groups can be spent for formation of condensation products free of aldehyde groups.

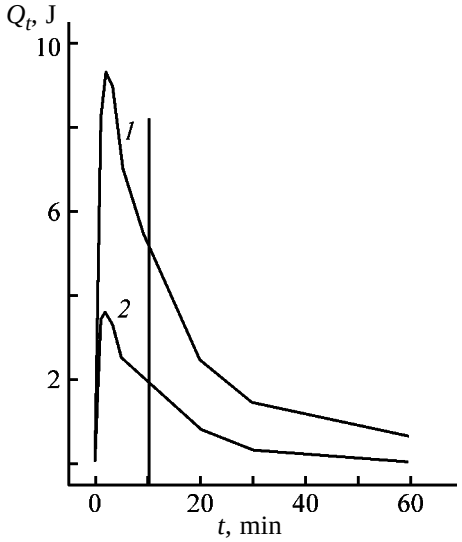

Fig. 1. Heat of reaction Q_t of GA with glycine at 21°C as a function of time *t*. Initial ratio of the functional groups of the reactants $[CHO/NH_2]_0$ (mol/mol): (*1*) 0.5 and (*2*) 4.0.

The results of the study of condensation of GA with glycine at the ratio of the functional groups of the reactants $[CHO/NH_2]_0$ from 0.5 to 7 mol/mol are presented in Table 2. When the ratio is small (0.5 and 1.0), GA is completely consumed in 10 and 30 min, respectively. The ratio between reacted aldehyde groups of GA and reacted amino groups of glycine $[\Delta CHO/\Delta NH_2]_t$ 10 min after the reaction start is 5–7 at $[CHO/NH_2]_0$ = 7.0 and 3 at lower initial ratio.

We studied condensation of GA with glycine by differential microcalorimetry. In these experiments, the time dependence of the reaction enthalpy was measured at different concentrations of the initial components. In all cases, the reaction is exothermic. The differential heat effect of the reaction at the initial ratio of the functional groups of the components of 5 and smaller (Tables 1, 2) can be normalized to the number of moles of the resulting GA–glycine oligomer (gly–GA_3, molecular weight 293). The time dependence of the reaction enthalpy is shown in Fig. 1. The heat release is maximal in 1–2 min after the reaction start. The reaction is complete in 1 h. The time

dependence of the differential enthalpy ΔH_t of the reaction of GA with glycine is shown in Fig. 2. At the initial ratio of the functional groups from 0.5 to 4, the shape of the curves within the first 10 min is similar (excluding the ratio of 2 and 7 mol/mol), which indicates the similar reaction mechanism is all these cases. At longer reaction time, the curves diverge owing to occurrence of various side reactions. It should be noted that the differential enthalpy ΔH_t measured in the first 10 min ranges from 50 to 75% of the total heat effect ΔH_0 (Table 3).

The integral ΔH corresponding to the equilibrium reaction mixture (in ca. 1 h) can be normalized to the amounts (moles) of both the GA–glycine oligomer (gly–GA_3) and glycine amino groups converted into the Schiff bases. The resulting dependences of ΔH_0 on the initial number of the aldehyde and amino groups are shown in Fig. 3. Curve *1* shows how the enthalpy changes assuming that only the Schiff bases are formed. Curve *2* is the dependence assuming that the reaction yields only the product of condensation of glycine with GA trimer. The minimal enthalpy, equal in the both cases, is registered at the initial ratio of the functional groups $[CHO/NH_2]_0 = 2$ (or in the range from 1 to 4 mol/mol/). Outside this range, the curves go apart owing to parallel occurrence of side reactions. At the glycine excess (the left branch of the curve), glycine can be added to the double bonds of the condensation product (Michael reaction). At high GA content in the initial mixture (right branch of the curve), the reaction products containing carboxy groups catalyze oligomerization of GA in the solution, which is not the case in solutions of pure GA.

The difference between ΔH_0 of the two curves can be assigned to the enthalpy of aldol condensation to form GA oligomers.

In the course of the reaction, a dynamic equilibrium between initial reactants and reaction products is attained. The rate constant of formation of the glycine–GA trimer derivative can be calculated at all reaction times by the equation:

$$K_{bind} = [gly–GA_3]/[gly]_{free}[GA]_{free}.$$

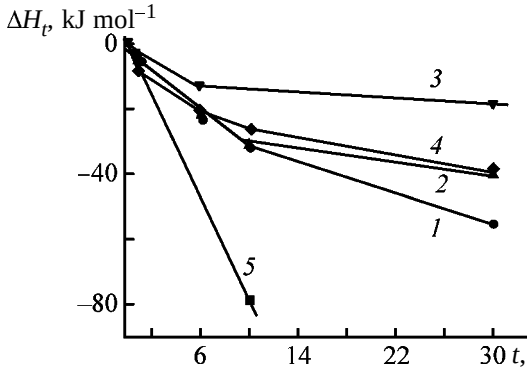

Fig. 2. Differential enthalpy ΔH_t of the reaction of GA with glycine as a function of reaction time t. Initial molar ratio of the functional groups of the reactants $[CHO/NH_2]_0$: (*1*) 0.5, (*2*) 1.0, (*3*) 2.0, (*4*) 4.0, and (*5*) 7.0.

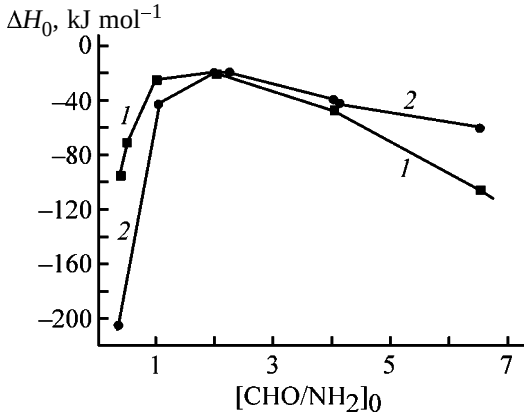

Fig. 3. Integral enthalpy ΔH_0 of the reaction of GA with glycione as a function of the initial molar ratio of the functional groups of the reactants $[CHO/NH_2]_0$. T = 21°C, t = 1 h. ΔH_0 normalized to the (*1*) number of moles of spent amino groups of glycine and (*2*) number of moles of the condensation product of glycine with GA trimer (gly–GA_3).

The Gibbs energy of the reaction was calculated from this constant by the equation $\Delta G = -RT\ln K_{bind}$, and the reaction entropy, by the equation $\Delta G = \Delta H - T\Delta S$. The results are summarized in Table 3. In the course of the reaction, K_{bind} increases and hence $-\Delta G$ also increases. The dependences of ΔH_t and $-T\Delta S$ on the ratio of the functional groups are similar. The negative values of these functions are minimal at $[CHO/NH_2]_0$ = 2 mol/mol. Probably, htis ratio is the most favorable for formation of pure gly–GA_3.

CONCLUSIONS

(1) Oligomerization of glutraic aldehyde with amino acids was studied by differential microcalorimetry and analysis for aldehyde and amino groups. Pure condensation product of amino acid (glycine) with the trimer of glutaric aldehyde is formed at the initial ratio of the functional groups of the reactants of 2 or the ratio of [glutaric aldehyde]/[glycine] = 1.0 mol/mol.

(2) At the ratio of the functional groups from 0.5 to 5 mol/mol, two parallel reactions, formation of stable Schiff bases from glutaric aldehyde and the amino acid and oligomerization of glutaric aldehyde catalyzed by the reaction products containing carboxy groups, mainly occur within the first 10–20 min of the process.

Abstract—The dependence of the electrical conductivity of a platinum-containing polymeric nanocomposite on the number of sorption–reduction cycles was studied, as well as its thermal properties.

Nanoparticles, whose properties differ from those of macroparticles, are widely used in electrocatalysis, photocatalysis, electrophotography, as components of magnetic memory, etc. [1–3]. For example, the use of electrodes coated with polymeric films with immobilized platinum group metal nanoparticles [4, 5] increases the currents of hydrogen and oxygen liberation from aqueous solutions at relatively low content of the platinum metal catalyst. The structure of matrices usually used for preparing metal-containing polymeric nanocomposites consists of a system of interpenetrating pores providing higher specific surface area and easy penetration of reagents in the bulk of the matrix and determining the growth conditions of the metal particles. Among these materials are porous polyethylene prepared by localized crazing [6], perfluoroalkanelsulfonic acid (Nafion trade name) with communicating ionic regions (nonuniformities) formed by sulfonate groups [7], cross-linked polyacrylates with carboxy functional groups, etc. Catalytically active metal nanoparticles are introduced by sorption and reduction of the metal ions in a porous polymeric matrix (PPm) which can be considered as nanoreactor [8]. Immobilization of growing particles on the polymer prevents their aggregation. Association of the metal cation with functional groups of the polymer plays an important role in the formation of nanoparticles [9].

In this work, we used a polymeric matrix prepared by copolymerization of methyl methacrylate (MMA) with potassium methacrylate (KMA) in the presence of polyethylene glycol (PEG) as an inert solvent and blowing agent. The polymerization product is a gel whose porous structure is formed by phase separation via macro- and microsyneresis [10]. The parameters of the porous structure are controlled by variation of the component ratio in the initial mixture. At a high degree of dilution of the ionic monomer (KMA) with a mixture of MMA and PEG, the growing gel is collapsed into a microgel at the critical point of phase separation, i.e., macrosyneresis occurs. In this case, polyethylene glycol acts as a dispersion medium.

In the course of polymerization, the polymeric particles agglomerate to form a heterogeneous gel consisting of the blowing agent and copolymer. In the course of polymerization at a high concentration of the ionic monomer forming salt cross-links, the liquid phase of PEG, at a definite density of cross-links, forms dispersed drops inside the growing gel, i.e., microsyneresis occurs. In this case, PEG is partially retained in the gel phase owing to formation of hydrogen bonds between OH groups of PEG and the oxygen atoms of the carboxy groups of the copolymer. The growing structure also contains two continuous phases: blowing agent and the copolymer.

Porous materials prepared by macro- and microsyneresis of polymeric gels have different pore size distribution. Pores formed in the course of macrosyneresis are larger [10]. Since the blowing agent forms a continuous phase, it can be extracted from the matrix to form a porous polymer which exhibits cation-exchange properties owing to the presence of carboxy groups.

In this work we studied sorption and reduction of platinum(IV) ions in porous polyacrylate matrices of different structures. The properties of the polymeric matrix before and after platinum reduction and proper-

ties of the platinum-containing polymeric nanocomposites were also studied.

EXPERIMENTAL

The porous polymeric matrix was prepared by block copolymerization of MMA with KMA at 70°C in the presence of PEG-200 polyethylene glycol and using benzoyl peroxide as an initiator. Polyethylene glycol was extracted with water in a Soxhlet apparatus for 10 h. The thickness of the resulting copolymers was 15 mm. Platinum cations were sorbed on PPM from aqueous solutions of platinum(IV) chloride at room temperature and then were reduced to metal with hydrazine hydrate by the Paal procedure. The electrical conductivity of the composites σ (S cm^{-1}) was measured with an E-711 apparatus operating at 1000 Hz ac current. The IR spectra of thin wet films were recorded on a Specord-M80 spectrometer. To determine the platinum content, the nanocomposites were pyrolyzed at 800°C, and metallic platinum was dissolved. The platinum content was determined photometrically on a KFK-3 photometer by the relatively sensitive procedure with tin chloride [11]. Thermal analysis curves of the initial and the platinum-containing polymeric matrices were recorded on a Q-1500 MOM derivatoraph (Hungary) in air. The samples (40–45 mg) were heated from 25 to 700°C at a rate of 10 deg min^{1}. X-ray diffraction patterns were obtained on a D8 GADDS diffractometer (Bruker) in the range 2θ = 5°–75° using CuK_α radiation. The particle size was calculated by the Debye–Scherrer equation [12]. The content of CO_2^- groups in the polymer was determined by potentiometric titration.

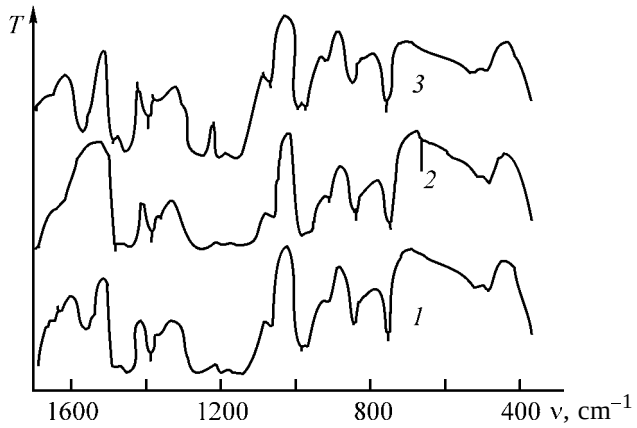

Fig. 1. IR spectra: (*T*) transmission and (ν) wave number. Matrix: (*1*) polymeric, (*2*) with sorbed platinum, and (*3*) with reduced platinum.

The polymeric samples were prepared at different [MMA] : [PEG] ratios and different content of carboxy groups, determined by the KMA concentration in the initial mixture. At high KMA concentrations (Table 1, sample nos. 2 and 3), the phases are separated in the system by the microsyneresis mechanism to form mainly micropores invisible with an electron microscope. At a low salt concentration, the macroporous structure is formed by macrosyneresis.

Platinum nanoparticles were prepared in the polymer bulk in two steps: (1) sorption of $PtCl_4$ from aqueous solution at room temperature, followed by sorption of the reducing agent (hydrazine hydrate) from toluene solution at 5°C, and (2) reduction of platinum ions by flash heating of the polymer in hexane to 60°C.

This procedure was used to exclude migration of platinum(IV) ions to the reduction front, causing nonuniform distribution of platinum nanoparticles in the bulk of the polymer. Polymeric composites were washed with distilled water to remove the reduction products. We experimentally found that the time required to attain the equilibrium in the PPM–$PtCl_4$ solution system depended on the syneresis type: 2 h for sample nos. 2 and 3 and 30 min for sample no. 1.

In solutions, $PtCl_4$ forms an acid, $H_2[PtCl_4(OH)_2]$. It is unclear how this complex anion is sorbed on the polymer exhibiting cation-exchange properties. We suggest that one or two OH groups of the anion are substituted with the carboxy groups of the polymer. In the IR spectrum of PPM (Fig. 1), the band of free CO_2^- groups is present at 1560 cm^{-1}. After coordina-

tion of the platinum complex anions, this band completely disappears and the band of coordinated CO_2^- group appears at 1640 cm^{-1}. After reduction to metallic platinum, the band at 1560 cm^{-1} appears again, i.e., noncoordinated carboxy groups are regenerated and can be involved in repeated chemisorption. As seen from Table 1, the concentration of the CO_2^- ion-exchange groups is lower than the sorption capacity of the matrix for platinum ions. Probably, platinum chloride is also absorbed in the polymeric matrix by a mechanism other than ion exchange. This assumption is confirmed by the fact that the IR spectrum of PPM kept in an aqueous solution of $PtCl_4$ contains the band at 670 cm^{-1} assigned to the stretching vibrations of the Pt–Cl bond of the complex anion. The pore structure of the polymer affects the mobility of these weakly bonded anions and hence affects the size of platinum nanoparticles.

Hexachloroplatinic acid is reduced with hydrazine hydrate by the following reaction:

$$H_2[PtCl_4(OH)_2] + N_2H_4 \cdot H_2O$$

$$\rightarrow N_2H_5H[PtCl_4(OH)_2]$$

$$\rightarrow H[PtN_2H_4Cl_3(OH)_2] \rightarrow Pt(0) + N_2\uparrow.$$

Nitrogen is liberated from the pores of the polymeric matrix and nanoparticles of metallic platinum are formed. Dispersions of metal-containing polymeric composites in 2-methoxyethanol are stable for several months.

The typical X-ray diffraction pattern of the polymeric matrix containing 10 wt % Pt is shown in Fig. 2. The fact that only platinum reflections and board reflections of the polymer at 13.8° and 30° are present in the pattern suggests the absence of side products. The average size of crystallites calculated from the (111) reflection is 4 nm. The particle size is almost independent of both the polymer structure and its sorption capacity. Since the equilibrium in the PPM–PCl_4 solution is attained slowly, the mobility of platinum ions sorbed by the non-ion-exchange mechanism is strongly restricted. Hence, surface complexes between platinum ions and carboxyate anions of the polymer can be considered as dissociated to a negligible extent, compared to bulk aqueous solution.

Since the CO_2^- groups are regenerated after platinum reduction, repeated sorption–reduction cycles of platinum(IV) ions are possible. The electrical conductivity of the nanocomposite increases with increasing

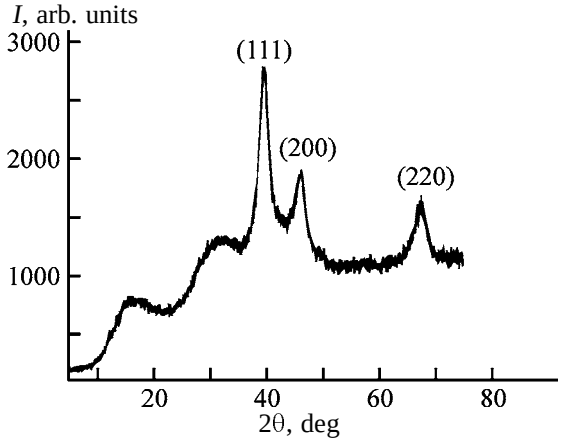

Fig. 2. Typical X-ray diffraction pattern of platinum-containing nanocomposite. (*I*) Intensity and (θ) Bragg angle.

content of platinum nanoparticles, which is important for preparing electrodes from these materials. The results of the first four sorption–reduction cycles are presented in Table 2. As seen from Table 2, the electrical conductivity of the composite increases with increasing content of platinum nanoparticles. However, the value of the conductivity indicates that the percolation threshold was not reached.

We studied the thermal properties of the polymeric matrix and platinum–polymer composites. The most intense thermal degradation of PPM by depolymerization [13] was observed at 340–370°C. At the same time, thermal analysis curves of the platinum nanocomposites contain a strong exothermic peak in this range, which is absent in the thermal analysis curves of pure polyacrylates. This is probably due to platinum-catalyzed oxidation with atmospheric oxygen of the monomer formed by depolymerization. The maximum of thermal degradation of the PPM is shifted to 390–420°C. Thermolysis of PPM is completed at 670°C. The weight loss of the platinum nanocomposite stops at 460°C. Its decomposition products contain carbon compounds.

Table 2. Sorption–reduction cycles of platinum in sample no. 1

Cycle no.	σ, S cm^{-1}	Pt concentration, mmol g^{-1} of polymer
1	3.8×10^{-4}	0.72
2	1.9×10^{-3}	0.79
3	1.9×10^{-3}	1.17
4	2.3×10^{-3}	2.1

CONCLUSIONS

(1) Platinum-containing polymeric nanocomposites were prepared by sorption and reduction of platinum ions in the bulk of porous polyacrylates with different structures.

(2) The average size of platinum particles, determined by X-ray diffraction, is 4 nm.

Abstract—Evaporation of binary aqueous–organic mixtures through composite membranes with coatings based on polyelectrolytic complexes including different combinations of polyelectrolytic polycations and polyanions was studied. The possibility of efficient dehydration of organic solvents by their pervaporation was demonstrated.

Production of organic solvents (aliphatic alcohols, ketones, esters, etc.) includes their dehydration in the final stage. This procedure is complicated by the fact that these organic solvents form, as a rule, aqueous azeotropic mixtures. In the common processes, dehydration of these organic solvents is carried out by power-consuming distillation combined with additional chemical treatment. At the same time, it is known that organic solvents, including azeotropic mixtures, can be dehydrated by pervaporation (evaporation through membranes of diffusion type). The dehydration by this technique is less power-consuming and is carried out without chemical treatment at lower temperature.

When preparing pervaporation membranes, the following hydrophilic polymers are used: some cellulose derivatives, polyacrylic acid (PAA), polyvinyl alcohol, aromatic polyimides, and polyamides and their derivatives [1–5]. These polymers contain specific ionic or nonionic functional groups (hydroxy, sulfo, carboxy, amino) which are responsible for selective transfer of water molecules through pervaporation membranes. Published data show that the most efficient in dehydration of organic compounds by pervaporation are membranes with coating films based on polyelectrolytic complexes (PECs) consisting of polycations and polyanions.

The principles of the choice of polyanions and polycations suitable for preparing polyelectrolytic pervaporation membranes, procedures for their preparation, and structural features and permeability of the membranes were discussed in [6–12]. These works showed also that the pervaporation membranes prepared from PECs of similar chemical composition can considerably differ in their permeability. This difference can be caused by differences in the content of polycation and polyanion in the polyelectrolytic complex, in their molecular weights, in the time of membrane preparation (in advance or immediately before pervaporation), in the temperature of thermal treatment, and in other factors. The permeability and selectivity of pervaporation membranes is influenced by procedures used for their preparation. In this work we used the composite membranes (CMs) with coating films based on known and new PECs obtained by different combinations of polycations and polyanions.

EXPERIMENTAL

Polyanion-containing agents used in our experiments were as follows: PAA with molecular weight (MW) 1×10^7, sulfoethyl cellulose (SEC) with MM 240×10^3 and the degree of sulfonation γ 41 or 100 (per 100 glucose units), carboxymethyl cellulose (CMC) with MW 91.5×10^3 and γ = 46, and poly(2-acrylamido-2-methylpropane)sulfonic acid (PSA) with MW 4×10^6. Chitosan (Ch) with MW 185×10^3 (degree of deacetylation 80%) and quaternized poly(2-dimethylaminoethyl) methacrylate (PDM) with MW of 14×10^6 were used as sources of polycations.

When preparing the composite membranes, commercial ultrafilter based on UMP-20 aromatic polyamide was used as support.

The PAA/Ch stoichiometric polyelectrolytic complex and the complexes with the PAA/Ch ratios of 2/1 and 1/2 were prepared using 0.1–0.2 and 0.5–1.0%

1070-4272/03/7611-1807$25.00

solutions of PAA and Ch, respectively, in 30% aqueous acetic acid.

To prepare the composite membranes based on PECs in advance, a thin layer of aqueous PEC of appropriate composition was applied to a support, which was followed by drying, keeping in excess of distilled water for 1 day, and repeated drying [8]. Hereinafter, the membranes prepared in advance will be referred to as the homogeneous composite membranes.

The PAA/Ch composite membranes can be prepared also immediately before pervaporation. In this case, a thin layer of 0.1–0.2% aqueous PAA was applied to the support surface and dried at 20°C, after which this layer was coated with a thin layer of 0.5–1.0% Ch in 2% aqueous acetic acid. The resulting coating film was kept for appropriate time and then dried. Hereinafter, the membranes of this type will be referred to as the laminated membranes.

In our experiments we also used the laminated selective composite membranes based on other composite polyelectrolytic complexes: PDM/SEC (prepared from 0.1–0.2% aqueous PDM and 0.5–10% aqueous SEC), PDM/CMC (prepared from 0.2% aqueous PDM and 1.5% aqueous CMC), and a ternary PSA/PDM/PAA membrane (prepared from 0.2% aqueous PSA, PDM, and PAA). When preparing these complexes, the separate components were applied to the support in the order corresponding to their position in the complex designation. The composite membranes with coatings based on single polymers were used as references.

All the experiments on pervaporation of aqueous–organic solutions were carried out on a temperature-controlled laboratory device with stirring at the residual pressure above the membrane of 0.2 mbar. The effective surface area of the membranes was 6.2 cm^2. The vaporous permeate that passed through a membrane was condensed in a trap cooled with liquid nitrogen. The condensate was weighed, and the transmembrane vapor flow rate ($\prod$, kg m^{-2} h^{-1}) was calculated.

In our experiments we studied dehydration of binary aqueous–organic (ethanol, 2-propanol, acetone, methyl ethyl ketone, ethyl acetate, and methyl acetate) mixtures with water content of up to 55 wt %. The permeate composition was determined by refractometric or chromatographic (0.5-m column packed with Porapak Q) methods. The selectivity factor of the pervaporation separation was calculated by the equation

$$\alpha = (X_A/X_B)/(Y_A/Y_B),$$

where X_A and X_B are the weight content of water and organic substance in the permeate, and Y_A and Y_B are the weight content of water and organic substance in the initial aqueous–organic mixture.

It is known that Ch/PAA poyelectrolytic complexes can be used for preparing efficient homogeneous pervaporation membranes [8, 11]. For example, the stoichiometric and nonstoichiometric complexes of this type were used as 50-μm coatings in pervaporation of aqueous 2-propanol or dioxane to remove water [11]. These experiments showed that, with membranes containing PAA with MW 2×10^5, only nonstoichiometric membranes [Ch/PAA ratios 2/1, 1/2 and 1/3] exhibit high dehydration power. In contrast, according to the data reported in [8], the membranes of both types, homogeneous and laminated, based on stoichiometric Ch/PAA complexes, exhibit high selectivity in pervaporation of aqueous ethanol of approximately azeotropic composition to remove water. It was shown also that, with increasing PAA molecular weight from 9×10^4 to 45×10^4, the separation factor significantly increases, whereas the vapor flow rate decreases. In evaporation of water–ethanol mixtures through the membranes based on polyelectrolytic complexes of PAA and several polymeric quaternary ammonium salts [10], the permeability and selectivity increase with increasing PAA molecular weight (to 4×10^6).

In this work we prepared polyelectrolytic complexes of different types from ultra-high-molecular-weight PAA, PSA, and PDM. The pervaporation characteristics of homogeneous PAA/Ch membranes with the PAA/Ch ratios of 2/1, 1/1, and 1/2 are listed in Table 1. This table also gives the pervaporation characteristics of known PAA/Ch homogeneous membranes with PAA of different molecular weights and characteristics of membranes prepared from PAA and Ch as single component, which are of interest because there are published data on similar membranes [1, 2, 13].

The comparison of the data on separation of water–ethanol mixtures by evaporation through our composite membrane no. 1 and its known analog no. 2 (Table 1) shows that these membranes have comparable selectivity factors α, but the evaporation rate through our membrane is noticeably higher. We believe that the advantage of membrane no. 1 is caused, all factors being the same, by smaller thickness of its coating due to ultrahigh molecular weight of PAA in its composition. The decisive role of this factor is confirmed by the pervaporation data reported in [10, 13] where the membranes based on PAA of identical molecular weight as single component (Table 1, CM no. 8) and in combination with various polymeric

bases were studied. These data show (Table 1, CM no. 3) that the membrane based on stoichiometric PEC exhibits low selectivity for water–2-propanol mixture. The similar negative effect found in [7] was attributed to breakdown of stoichiometric CMs in aqueous solutions enriched in 2-propanol. Table 1 (CM nos. 7, 9 and 11) shows that the selectivity of membranes with coatings prepared from PAA as single component considerably exceeds that of the membranes prepared from non-cross-linked chitosan. It should be noted that the selectivity of membranes based on chitosan or polyacrylic acid of relatively low molecular weight can be improved by their chemical cross-linking (Table 1, CM no. 12). The membranes based on PAA with molecular weight exceeding 1×10^6 exhibit fairly high selectivity without cross-linking [1, 8]. Thus, when preparing pervaporation membranes based on individual PAA or on its polyelectrolytic complexes, the use of PAA of ultrahigh molecular weight is preferable.

We found that, in pervaporation of a water–acetone mixture through homogeneous membranes with coating film prepared from stoichiometric PEC or individual PAA, the dehydration of acetone is highly efficient (Table 1, CM nos. 4 and 9). These results are consistent with the basic relations concerning contribution of the thermodynamic factors to the pervaporation selectivity. The main factor responsible for efficient separation of water from ethanol and acetone in pervaporation of water–ethanol (acetone) mixtures is the difference between the water permittivity (80.1) and that of ethanol and acetone (24.3 and 20.7, respectively). In pervaporation of aqueous–organic mixtures with identical water content, the dehydration is the more efficient, the larger the difference between water and the organic component in polarity. With lowering polarity of the organic component, its interaction with the polar coating weakens and, therefore, the selectivity of dehydration is improved. It should be noted that the efficiency of the pervaporative separation is also a function of the difference in the diffusion coefficients of the compounds being separated. In pervaporative dehydration, this factor is controlled by the difference between kinetic diameters of organic and water molecules, among which the kinetic diameter of water molecule, as a rule, is smaller.

It was of interest to study the difference between the pervaporation characteristics of membranes with homogeneous and laminated coating films. These effects were studied in evaporation of water–acetone mixtures with widely varied water content through stoichiometric PAA/Ch membranes (Figs. 1, 2).

The PAA/Ch composite membranes (homogeneous and laminated) used in our experiments exhibit high permeability and selectivity. As seen from Fig. 1, the acetone content in the permeate does not exceed 1 wt % at widely varied initial water content. This figure shows that the efficiency of separation of water–acetone mixtures by pervaporation (curve *1*) considerably exceeds the separation efficiency in a common open evaporation (curve *2*).

The pervaporation is also less power-consuming process than open evaporation, especially in separation of aqueous–organic mixtures with low water content. This is due to the fact that, in distillation, all

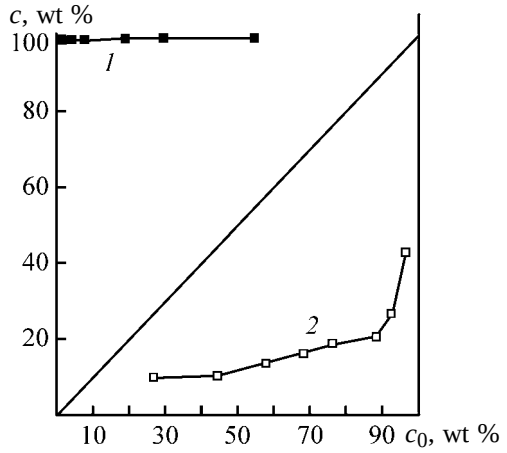

Fig. 1. Water content c in (*1*) permeate (evaporation through PAA/Ch membrane irrespective of the membrane type) and (*2*) in the vapor phase (common open evaporation) as a function of the initial water content c_0 in the water–acetone mixture at 20°C.

volatile components are transferred to the vapor phase, whereas in pervaporation water molecules are selectively transferred through the membrane.

Figure 2 shows that, with increasing water content in the water–acetone mixture, the transmembrane vapor flow increases and the pervaporation selectivity decreases. Under these conditions, the PAA/Ch laminated membrane exhibits higher selectivity and lower permeability than homogeneous membranes (Fig. 2, curves *4* and *3*, respectively). These data show that the procedures used for preparing pervaporation membranes affect their permeability and selectivity.

It should be noted that, when preparing the laminated membranes, it is difficult to control their chemical composition and the layer thickness. In this case, we can only suggest the polyelectrolytic complexes are formed, because these membranes, like stoichiometric homogeneous membranes, ensure efficient water removal from water–acetone mixture with a water content of 50% and more. At the same time the membranes prepared from individual PAA are suitable for dehydration only at low water content in acetone (Table 1). When the water content exceeds 20 wt %, these membranes completely lose their selectivity.

When preparing the PAA/Ch laminated coating film, a thin layer of PAA/Ch polyelectrolyte complex is formed over the layer of unchanged PAA. Although this membrane has reduced permeability, when water–acetone mixture passes through its multilayer structure, the selective transfer of water molecules is reached at widely varied water content in the initial mixture. The similar selectivity is attained by the membranes prepared from individual PAA (Table 1). In this case, the selectivity for water can be attributed to formation of hydrogen bonds between PAA and the surface polar molecules of the polyamide support. It will be shown below that, with less polar polyacrylonitrile used as support instead of polyamide, the permeability increases to a level close to that of the homogeneous membranes.

Comparison of procedures used for preparing homogeneous and laminated pervaporation membranes shows that, as a whole, the membranes with laminated coatings are preferable. The main drawbacks of preparing the homogeneous membranes are the necessity of using concentrated acidic PAA and Ch solutions and prolonged washing of the resulting coatings with water. Therefore, in further experiments we used the PAA/Ch laminated membranes.

The lamination technique provides especial advantage in preparing PDM/SEC, PDM/CMC, and PSA/PDM/PAA membranes containing components unstable even in weakly acidic solutions. The presence of polyelectrolytic complexes in the multilayer coating films is confirmed by the fact that, in application of individual anionic (except for PAA) and cationic polymeric agents to a support, the selective pervaporation membranes are not formed. Of particular interest are the laminated membranes with ternary PSA/PDM/PAA coatings consisting of ultra-high-molecular-weight polymeric components. This coating can be applied to a support as a very thin 0.1-μm uniform film exhibiting high permeability. In this coating, the polycationic layer (PDM) is located between two polyanionic layers of different types. We believe that the PSA/PDM and PDM/PAA polyelectrolytic complexes are formed at interfaces.

* Applied to polyacrylonitrile support. ** Prepared from SEC and poly(dimethyldiallylammonium chloride) [9].

Our experimantal data on pervaporative separation of acetone-rich water–acetone mixtures with laminated composite membranes of different compositions are listed in Table 2. To evaluate the generalized characteristic of the membrane performance reflecting both the selectivity and permeability, we used the productivity factor $\alpha\Pi$. Table 2 shows that this factor, being approximately identical for CM nos. 1–3, noticeably increases in going to PDM/CMC membranes, and for ternary membrane PSA/PDM/PAA it becomes commensurable with that of the best of known analogs (Table 2, CM no. 6).

We found that the productivity factor of PAA/Ch laminated membrane with the coating applied to a polyacrylonitrile support with porous chracteristics close to those of the polyamide ultrafilter (Table 2, CM nos. 1–1) exceeds the productivity factor of PAA/Ch membrane with the coating applied to a polyamide support (Table 2, CM no. 1). The productivity factor of this membrane also exceeds that of the PAA/Ch homogeneous membrane (1140 kg m^{-2} h^{-1}) (CM no. 4, Table 1). We believe that these effects are caused by the fact that PAA interacts with the polyacrylonitrile support more weakly than with the polyamide support. Thus, the chemical features of a support material substantially influence the membrane productivity factor. We do not rule out also that high permeability of ternary composite membrane no. 5 (Table 2) is caused not only by its small thickness and ultrahigh molecular weight of its polymeric constituents, but also by the order of application of the laminated coating film to the polyamide support.

The service life of a pervaporation membrane was determined in long-term (530 h) evaporation of a water (1.5 wt%)–acetone mixture through laminated membrane no. 2 (Table 2). In these experiments, the removal of methanol traces present in acetone (130 ppm) was monitored by IR spectroscopy. This problem is important from practical viewpoint. Our tests showed that the membrane exhibits the stable permeability in the course of long-term pervaporation. Upon successive evaporation of the water–acetone mixture through three identical membranes, the water and methanol contents were decreased to 0.3 wt % and 80 ppm, respectively.

The published data on pervaporative dehydration of organic solvents mainly concern water–aliphatic alcohol mixtures. At the same time, it was of interest to elucidate whether the pervaporation can be used for dehydration of a wider set of organic solvents, including aqueous azeotropic mixtures. With this aim, we studied water removal from aqueous 2-propanol, methyl ethyl ketone (MEK), methyl acetate, and ethyl acetate (EtAc) by their evaporation through several laminated composite membranes (Table 3).

Table 3 shows that the most versatile are the membranes with the coating based on the PAA/Ch complex. These membranes efficiently dehydrate all the aqueous–organic mixtures studied by us. The permeability of these membranes for water, all other factors being the same, depends on the nature of the organic solvent. For organic solvents under consideration, the membrane permeability decreases in the order EtAc > acetone > ethanol. We believe that the decrease in

permeability is caused by formation of water associates with ethanol and acetone and their lack in the case of ethyl acetate. The similar effects were found in [4] for membranes with the coating prepared from a sulfonated aromatic polyamide. Table 3 shows also that, in evaporation of the aqueous–organic mixtures through a PSA/PDM/PAA ternary laminated membrane, especially efficient dehydration is reached for acetone and MEK.

CONCLUSIONS

(1) New types of composite pervaporation membranes ensuring the efficient dehydration of aliphatic alcohols, ketones, and esters were prepared by different combinations of polyanions and polycations.

(2) The permeability and selectivity of the pervaporation membranes is a function of the polyelectrolyte complex type, molecular weight of polyanions and polycations, and chemical features of polymeric support material.

(3) The permeation characteristics of the pervaporation membranes with coating films prepared from ultra-high-molecular-weight polyacrylic acid and Chitosan is a function of procedure of preparing the polyelectrolytic complex.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Rheological and Electrophysical Properties of Dispersions Based on Thermally Treated Magnetite and Aqueous Emulsions of Water-Soluble Polymers in Transformer Oil

T. G. Lazareva and E. V. Shinkareva

Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received April 23, 2003

Abstract—Rheological, electrophysical, and sorption properties of magnetite dispersions modified with water-soluble polymers were studied as influenced by the temperature of heat treatment in the 300–600°C range.

Composites sensitive to mechanical and magnetic fields can be prepared from fluid systems with dispersed fillers modified with water-soluble polymers. Such materials can be used as antivibrators, acoustic sensors, measurement devices, and shock absorbers [1]. Filler particles are modified by sorption of water-soluble polymer on their surface; in this case, additional treatment, such as heating or water sorption, can affect the filler properties. It is known that thermal treatment can affect the crystal structure of the polymer or cause more profound degradation with formation of new bonds. The oxidation and degradation processes begin on heating in air to 170–220°C, whereas the carbon structure is formed at temperatures higher than 500°C.

Previously, we studied the rheological properties of magnetite dispersions in transformer oil as influenced by conditions of the filler surface modification with water vapor and solutions of water-soluble polymers such as polyvinyl alcohol (PVA) and carboxymethyl cellulose [2]. We proposed that modification of the magnetite surface with water-soluble polymers plasticized with water molecules can yield systems exhibiting both plasticity and dilatancy, which is due to the formation of a network of hydrogen bonds in the mechanical field and subsequent structuring of the system with increasing shear stress, with anisotropic orientation of filler particles.

In this work we studied the rheological, electrophysical, and sorption properties of magnetite dispersions modified with a water-soluble polymer as influenced by the temperature of heat treatment (300–600°C).

EXPERIMENTAL

In our work we used dry transformer oil as dispersion medium and finely ground pure-grade magnetite (5–10 μm particle size) dried at 100±5°C for 5 h. Modification was performed as follows: magnetite was mixed with 5 and 20% solutions of PVA (16/1 brand) and a 0.5% solution of carboxymethyl cellulose (Na-CMC, 70/300 brand); the PVA–magnetite ratio was 5 and 10, and the Na-CMC–magnetite ratio, 2.5 (bath ratio). The mixtures were dried at 100±5°C for 5 h and treated for 2 h at 300–600°C. Then, the sorption of water vapor by the resulting magnetite composites was studied. These samples were stored at ambient temperature for 20 days in desiccators at the relative humidity of 30, 60, 80, and 100%, maintained by saturated solutions of appropriate salts.

The viscosity was measured on a Rheotest-2 rotary viscometer in the shear rate range 3–1312 s^{-1} (5 wt % solution concentration).

The conductivity of dispersions based on the pretreated composite of magnetite and water-soluble polymer was measured on an HI 9032 (Hanna Instruments) stationary conductometer at 20±5°C.

The dependences of the viscosity η of 5% magnetite dispersions modified with 5% PVA solution and treated at 300–600°C on the shear rate τ_v are shown in Fig. 1. As seen, thermal treatment of modified magnetite does not affect the modes of the fluid flow as compared to the untreated filler. The viscosity of such fluid systems increases up to a certain limit; such systems exhibit the dilatancy. Sorption of water vapor by the treated magnetite–PVA composite changes the fluid flow mode: η decreases with increasing τ_v. As a result, the viscosity at small shear rates increases; the higher the water content, the greater the system viscosity. After heating to 300°C at sorption degree of 2.2%, the maximal viscosity η_{max} is 32 mPa s, and at 600°C and sorption degree of 10.4%, 55 mPa s. At a shear stress >1 Pa, the viscosity is independent of

1070-4272/03/7611-1813$25.00

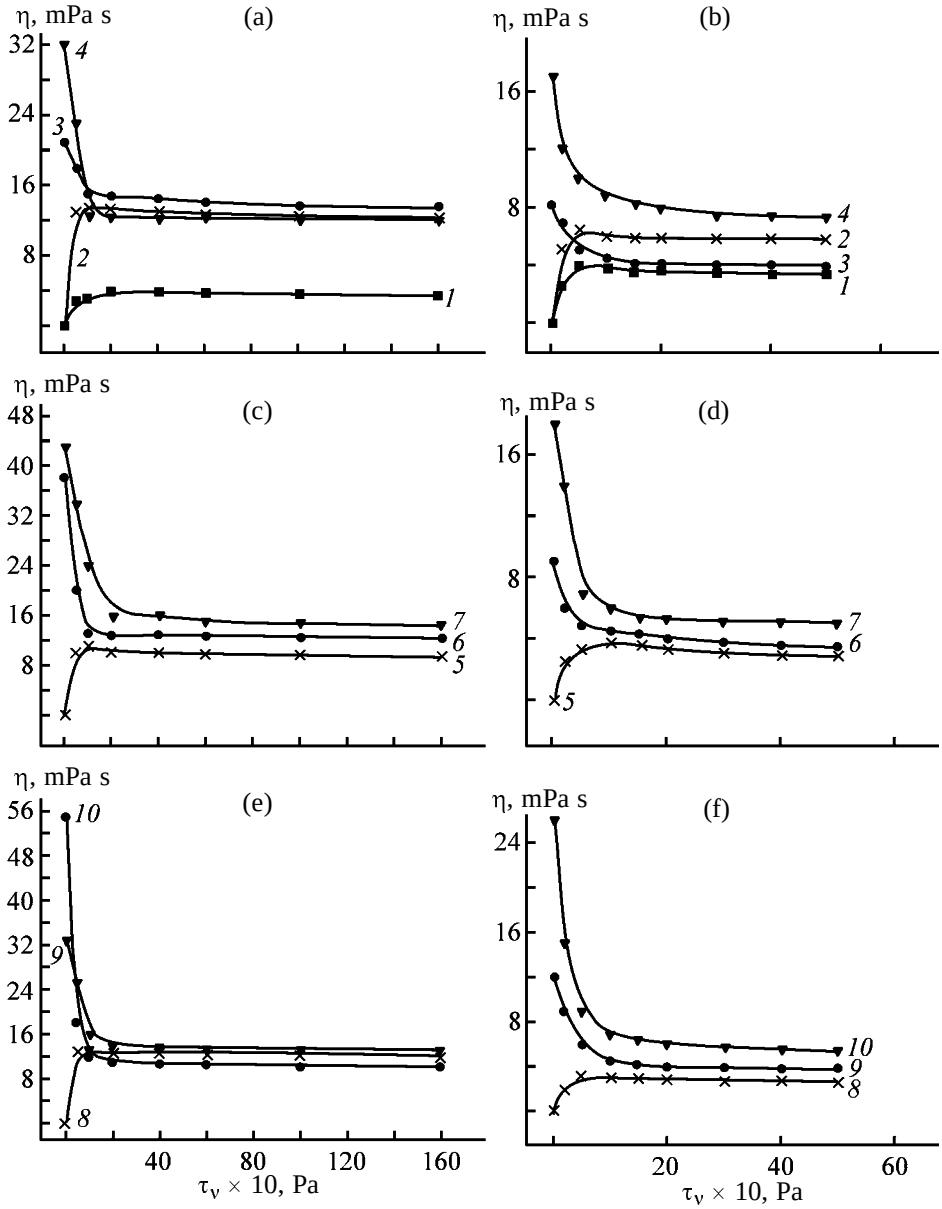

Fig. 1. Dynamic viscosity η as a function of the shear stress τ_v at (a, c, e) 30 and (b, d, f) 70°C for 5 wt % magnetite dispersion in transformer oil. Magnetite modified with 5% PVA solution. Filler: (*1*) untreated, (*2*, *5*, *8*) thermally treated, and (*3*, *4*, *6*, *7*, *9*, *10*) thermally treated and modified with water vapor; the same for Fig. 2. Temperature of thermal treatment, °C: (*2*–*4*) 300, (*5*–*7*) 400, and (*8*–*10*) 600; the same for Fig. 2. Water content, %: (*3*) 1.0, (*4*) 2.25, (*6*) 1.58, (*7*) 9.84, (*9*) 2.20, and (*10*) 10.43.

the water vapor sorption by filler particles. The thermal treatment of the magnetite–PVA composite with steam provides formation of the structure more sensitive to water vapor and causes a significant increase in the system viscosity. It should be noted that the flow curves recorded for 5%-magnetite dispersions modified with 20% PVA, heated to 300–600°C, and plasticized with water molecules are similar to those given above.

The dependences of the viscosity η of 5% magnetite dispersions modified with 0.5% Na-CMC solution and treated at 300–600°C on the shear rate τ_v are shown in Fig. 2. As seen, thermal treatment at 300°C of the magnetite–Na-CMC composites does not affect the shape of the flow curves; the viscosity η increases up to certain limit. With increasing temperature to 400–600°C, the shape of the flow curves of magnetite dispersion changes, and a maximum appears at τ_v = 0.2–0.5 Pa; there are sections in which the fluid viscosity decreases (plasticity) or increases (dilatancy). With penetration of additional water molecules in the magnetite–Na-CMC composite treated at 300–600°C,

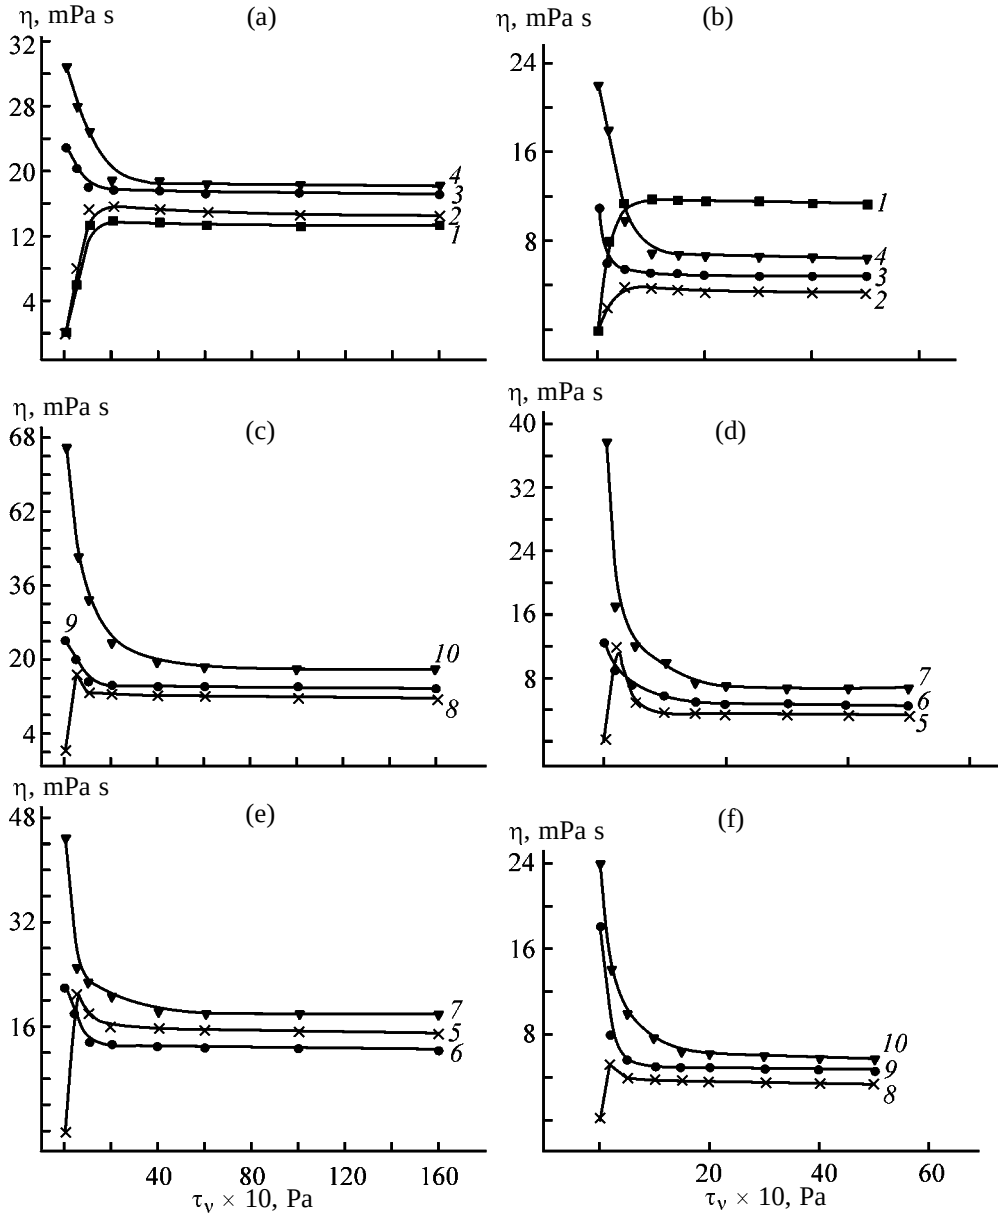

Fig. 2. Dynamic viscosity η as a function of the shear stress τ_v at (a, c, e) 30 and (b, d, f) 70°C for 5 wt % magnetite dispersion in transformer oil. Magnetite modified with 0.5% Na-CMC solution. Water content, %: (*3*) 0.7, (*4*) 1.8, (*6*) 1.4, (*7*) 1.9, (*9*) 1.34, and (*10*) 4.0.

the flow mode strongly changes. With increasing shear stress, the dispersion viscosity decreases. However, at small shear stresses (up to 2×10^{-2} Pa) the system viscosity first increases and then decreases, in contrast to untreated filler and magnetite–Na-CMC composite plasticized with water molecules, for which the peak in the flow curves is observed at greater τ_v (up to 2–4 Pa). Upon heating of magnetite modified with 0.5% Na-CMC solution at 300°C and subsequent treatment with water vapor (1.8% water content), the viscosity increases to 33 mPa s at maximum (system temperature 30°C); upon heating to 400°C, at 1.9% water content, to 45 mPa s, and upon heating to 600°C, at 4.0% water content, to 66 mPa s.

The thermal treatment of the magnetite–water-soluble polymer system affects it hydrophilicity. The sorption capacity of the thermally treated samples is greater than that of the untreated sample, and this effect is observed in the entire water vapor pressure range studied. The greatest increase in the sorption capacity is observed after heating to 600°C. In this case, the sorption of water vapor in the magnetite–PVA system comprises 2.2% (30% relative humidity)

and 10.4% (80%), whereas for magnetite–Na-CMC composites it is 1.3 (30%) and 4.0% (80%). With decreasing treatment temperature to 300°C, the sorption capacity decreases, but it remains higher than that of the untreated filler. The sorption capacity with respect to water vapor of the magnetite–PVA composites is 1.0 (30) and 2.25 (80%) and of the magnetite–Na-CMC, 0.7 (30%) and 1.8 (80%) (Table 1). The effects observed are probably due to changes in the nature of intra- and intermolecular interactions and to related changes in the molecular mobility in the thermally treated magnetite–water-soluble polymer composites, and also to the formation of a carbon structure.

Table 2. Conductivity of dispersions based on thermally treated magnetite–water-soluble polymer composite

Modifying agent	Treatment temperature, °C	Specific conductivity, μS cm^{-1}
5% solution of PVA, 16/1 brand	100	133.5
	300	158.7
	400	215.8
	600	366.9
20% solution of PVA, 16/1 brand	100	132.6
	300	154.6
	400	224.3
	600	425.8
0.5% solution of Na-CMC, 70/300 brand	100	132.9
	300	129.5
	400	147.6
	600	230.4

We also studied the suitability of the dispersions based on thermally treated magnetite–water-soluble polymer composites as conducting materials. For example, thermal treatment of the filler in air at 300–600°C increases its conductivity (Table 2).

Thus, our experimental data suggest that the structural and rheological properties of the magnetite–water-soluble polymer system can be controlled by additional thermal treatment and sorption of water vapor.

CONCLUSION

Thermal treatment at 300–600°C and sorption of water vapor increase the conductivity of magnetite particles modified with water-soluble polymers and change the flow mode of fluids based on them under the mechanical stress. As a result, the systems exhibiting both plasticity and dilatancy are formed depending on modification conditions, which allows preparation of systems with controlled flow mode in the mechanical field.

Abstract—A study was made of the elastic and dissipative properties of epoxy-phenolic network polymers in which the ratio of the chemical and physical cross-links was controlled by varying the ratio of epoxy and phenol groups in the initial compositions.

Machine building development demands nonmetallic polymer composite materials (PCMs) characterized by high elasticity and strength. Specific conditions of exploitation of articles manufactured from PCMs pose additional requirements on them. They must exhibit high dynamic and static fatigue resistance, high fracture resistance, and other characteristics associated with the ability of the polymer matrix (PM) in PCMs to dissipate the mechanical loading energy [1]. This necessitates directed control of the elastic and relaxation (dissipative) properties of not only articles manufactured from composites as integral structures [2, 3] but also of the PM in separate.

The aim of this work was to elucidate how the chemical and physical networks affect formation of the elastic and relaxation properties of epoxy-phenolic polymers (EPPs) when the ratio of different cross-linking bonds is varied by varying the ratio of the epoxy and phenol groups in the initial composition being cured.

EXPERIMENTAL

We studied an epoxy-phenolic compound based on resorcinol diglycidyl ether (RDGE) purified by vacuum distillation and an SF-0113 novolac phenol–formaldehyde resin (PFR) [TU (Technical Specifications) 6-05-031-509–74] with a drop point T_d = 75–90°C and a free phenol content under 0.5 wt % [4]. As tertiary amine we used *N*,*N*-diethylaniline efficiently accelerating reactions of epoxides with phenol and secondary alcohol groups [5].

The elastic and relaxation dynamic characteristics of EPPs were studied by the bending resonance vibration method on a setup similar to that described in [6]. The static mechanical characteristics, i.e., tensile strength σ_t, Young modulus E_t, and breaking strain ε_t, were determined on a 1231-U tensile-testing machine at the clamp movement rate of 1 mm min^{-1}. The samples for testing were molded in vacuum molds supplied with dumbbell-like fluoroplastic inserts (to damp the shrinkage strains) with a 30-mm-long working unit. Prior to tests, the samples were annealed for 3 h in VM-1 vacuum oil at 160°C, which was followed by cooling at a 0.2 deg min^{-1} rate. The annealing was controlled with a polarization setup. The surface fracture energy γ (identified with the fracture viscosity [7]) was estimated by cleaving trapezoidal samples having a longitudinal groove according to the procedure described in [8, 9].

Three-dimensional cross-linking of network epoxy polymers occurring in the glassy state at room temperature is effected by various bonds: chemical covalent (stable) and physical (labile at the given temperature). The labile physical bonds linking the chemical structure elements are so important that one can speak of a network of physical bonds having its own specific features and governing, for a significant part, the set of physicomechanical properties of epoxy polymers. Among physical labile bonds, the most important are hydrogen bonds characterized by a cohesion energy of 29–40 kJ mol^{-1} [10]. Cured epoxy resins contain abundant secondary alcohol groups yielded by opening of epoxy rings in polycondensa-

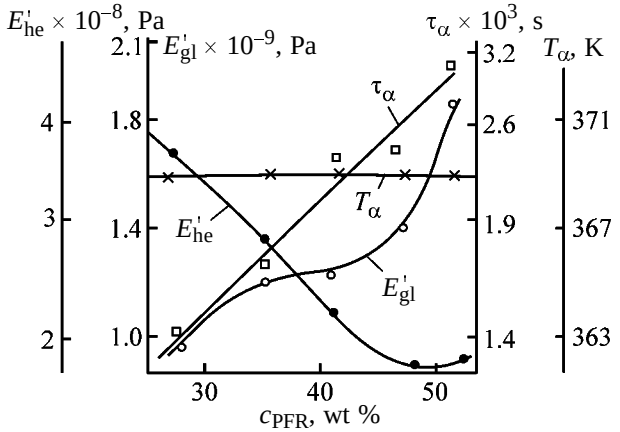

Fig. 1. Variation of the shear modulus in hyperelastic (E'_{he}) and glassy (E'_{gl}) states, α-transition temperature T_α, and α-transition relaxation time τ_α with the content of PFR c_{PFR} in epoxy-phenolic compound.

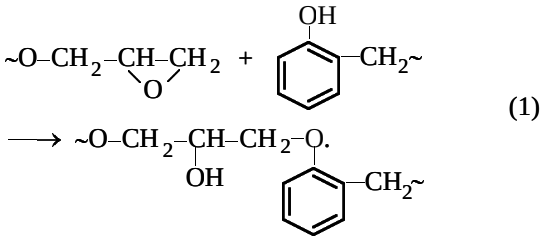
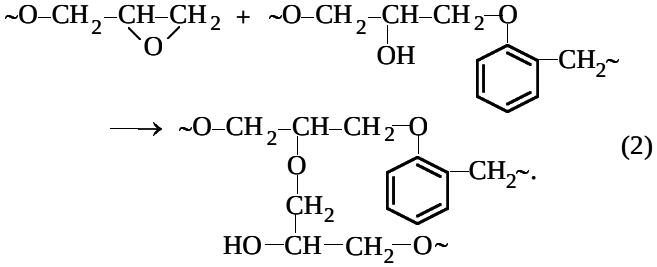
tion. Thus, the hydrogen bonds formed by these groups can be treated as the major effective cross-linking sites of the labile physical network, supplementing the chemical linking of the structural elements of the polymer.

A specific feature of curing of epoxy resins with polyphenols, in particular, PFRs [11], is that it allows control of the content of the secondary alcohol groups and, thereby, the number of effective linking sites of the physical network. For example, at equimolar ratio of the epoxy and phenol groups in the initial compound, the epoxy groups at moderate temperatures react, for the most part, with phenol groups, if the latter are sterically accessible [12]:



(1)

When taken in excess over the phenol groups, the epoxy groups can also react with the secondary alcohol groups, especially at elevated temperatures and in the presence of tertiary amines catalyzing this reaction [5]:



(2)

In this case, a chemical cross-link appears instead of a secondary alcohol group, which is a linking site of a labile physical network. Evidently, with increasing mass fraction of PFR, the density of the chemical cross-links should decrease, and the number of the physical linking sites, increase. It should be noted that, in this work, in the presence of *N*,*N*-diethylaniline and at stepwise increase in the curing temperature, virtually all the epoxy and phenol groups reacted. This enabled more correct elucidation of how the contents of different types of bonds providing three-dimensional cross-linking (physical and chemical; their contents vary in opposite directions) affect the behavior of EPPs under mechanical loading in different modes. With a view to development of polymeric materials exhibiting high strength when subjected to dynamic and static loads, it is important, above all, to elucidate how the changes in the nature of the cross-linking bonds affect the energy of the cohesion interaction of the structural units and their energy dissipation ability. It is believed [13] that these factors make the greatest contribution to the resistance of polymeric materials to high mechanical loads.

The EPP samples with varied content of PFR were subjected to mechanical tests of two kinds, dynamic and static. In the first case, we studied the temperature dependences of the dynamic elasticity modulus E' and the mechanical loss tangent $\tan\delta$. Figure 1 shows that, with increasing PFR content in the initial composition, the dynamic elasticity modulus tends to increase in the glassy state (E'_{gl}, 300 K) and to decrease in the hyperelastic state of EPP (E'_{he}, 420 K). These findings are in line with the views on the deciding influence of the physical bonds on the glassy state and of the chemical bonds on the hyperelastic state of network polymers [6].

It should be noted that other researchers also reported that the dynamic elasticity moduli in the glassy and hyperelastic states vary in the opposite directions [14, 15] in the case of epoxy–amine polymers in which the cross-linking density of the chemical network was controlled by varying the structure of the initial epoxy oligomer. It was supposed [14, 15] that increasing the distance separating the chemical cross-linking sites in epoxy polymers characterized by a high cross-linking density tends to increase the number of physical contacts. In our case, increase in the content of the secondary alcohol groups in parallel with increase in the distance separating the cross-links tends to additionally enhance the effect exerted by physical links.

Thus, increase in the dynamic elasticity modulus in

the glassy state with increasing PFR content and, consequently, the number of labile physical links indicate that the cohesion energy of interaction between the structural units of EPPs grows [16].

The dissipative properties of EPPs can be assessed from their relaxation spectra using different parameters. The first parameter is the internal friction background (IFB) for which one conventionally takes the mechanical loss tangent measured at room temperature, $\tan\delta_{25}$, i.e., at the temperature at which the strength of these polymers is tested. The IFB can serve as an indicator of the structural organization and intermolecular interaction in polymers [17]. The second parameter is the energy dissipated during the α-relaxation process [18] involving large-scale segmental molecular motion. This parameter is conventionally estimated as the intensity (or height) of the α peak in the maximum, i.e., as $\tan\delta_{max}$, or, more precisely, as the α-peak area, which is approximated by the product of $\tan\delta_{max}$ by the FWHM of the α peak $\Delta_{1/2}$ [18]. The energy dissipated during the α process can also be estimated indirectly, using the parameters of segmental mobility of the PM such as, e.g., the effective activation energy U_α [19] or the α-relaxation time τ_α [20]. Notably, the energy dissipated during the α process can affect the room-temperature strength of the PM [20].

Since it is difficult to correctly estimate $\Delta_{1/2}$ and U_α, we took $\tan\delta_{25}$, $\tan\delta_{max}$, and τ_α as relaxation (dissipation) dynamic indicators.

Figure 2 shows that, with decreasing PFR content, i.e., with increasing number of the chemical cross-links, $\tan\delta_{25}$ and, hence, the IFB tend to linearly grow. This is in line with the observed decline in the dynamic elasticity modulus in the glassy state and, evidently, means that the local molecular mobility tends to grow with increasing number of the chemical bonds owing to weakening of the intermolecular interaction [6]. At the same time, $\tan\delta_{max}$ tends to linearly decline with increasing number of the chemical cross-links, and this is accompanied by a decrease in the α-process peak area. This could also be due to a decrease in the large-scale segmental molecular mobility owing to an increase in the density of the chemical cross-links. However, this contradicts the following data. First, the temperature corresponding to the α-peak maximum remains virtually unchanged (Fig. 1), while it is known [21, 22] that the glass transition point of epoxy polymers typically increases with increasing chemical cross-linking density. Evidently, this is due to mutual compensation of the opposite changes in the number of different types of

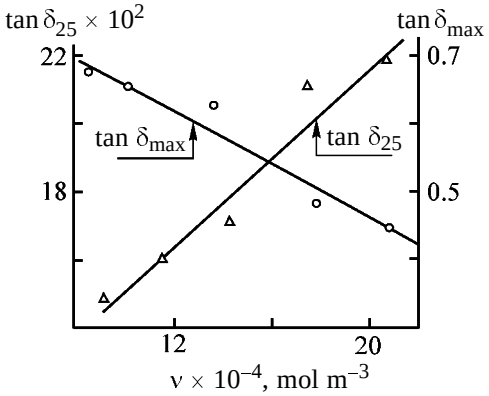


Fig. 2. Variation of the mechanical loss tangent at room temperature ($\tan\delta_{25}$) and in the α-transition maximum ($\tan\delta_{max}$) with the number of the chemical cross-links ν.

cross-links (and, possibly, to increase in the content of the aromatic rings in the PFR structure).

Second, the τ_α parameters calculated from the resonance condition in the α-peak maximum tend to decrease with increasing number of the chemical cross-links (Fig. 1). This means that the segmental molecular mobility, on the contrary, tends to grow with increasing density of the chemical cross-links. Therefore, a decrease in the mechanical losses (weakening of the dissipative properties) during the α process with increasing chemical cross-linking density is due to increase, rather than decrease, in the molecular mobility because of weakening of the intermolecular interaction. In turn, enhancement of the dissipative properties of EPPs with increasing number of labile physical cross-links is, evidently, due to increase in the effective size of the kinetic units of the α-relaxation process owing to increase in the interchain cooperativity of the segmental motion.

Thus, the dynamic mechanical tests showed that, with increasing PFR content in the initial composition, i.e., with increasing number of physical and decreasing number of chemical cross-links, not only the dynamic elasticity moduli in the glassy and hyperelastic states, but also the mechanical loss tangent in the glassy state (IFB) and in the region of the α transition from the glassy to hyperelastic state vary in the opposite directions. In transition from the glassy to hyperelastic state, the cohesion and dissipative properties of EPPs vary in the opposite directions.

Static tensile tests yielded the following characteristics: E_t, σ_t, ε_t, and γ. Figure 3 shows that, with increasing PFE content, σ_t, ε_t, and γ tend to increase, and E_t remains unchanged.

Let us attempt to analyze in a simplified way these results using the known Griffits formula of the critical

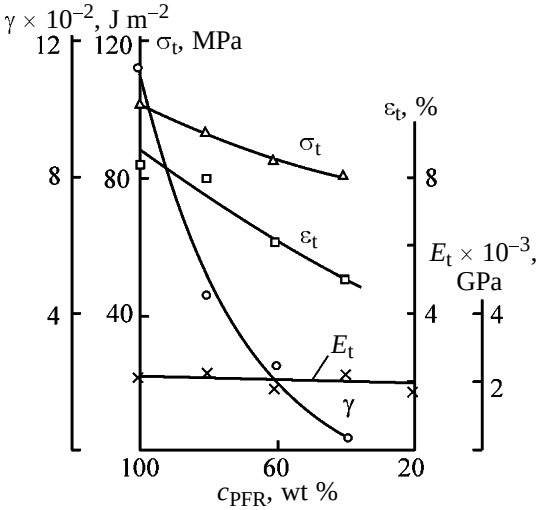

Fig. 3. Variation of the physicomechanical properties of epoxy-phenolic polymers: surface fracture energy γ, tensile strength σ_t, breaking strain ε_t, and Young modulus E_t, with the PFR content c_{PFR} in the epoxy-phenolic composition.

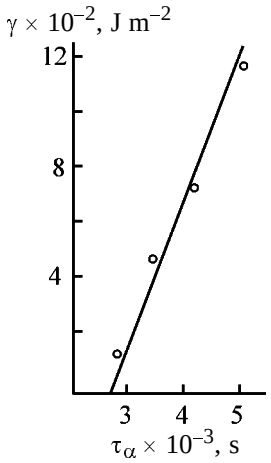

Fig. 4. Variation of the surface fracture energy γ with the α-transition relaxation time τ_α.

strength [13]

$$\sigma_c r = 2E\gamma/\pi l_{cr},$$

where E is the Young modulus; γ, specific surface energy; and l_{cr}, critical defect size.

This formula interrelates the major parameters governing the strength of solid materials: elasticity parameter E, relaxation (dissipative) parameter represented by γ [13] (identified, according to the published data, with the fracture viscosity [7, 9]), and the parameter l_{cr} characterizing the structure defects. The latter parameter was calculated by substituting into formula (1) the experimental E_t, σ_t, and γ values. It should be noted that l_{cr} is directly proportional to γ.

The fact that the relaxation and structural parameters vary in the same direction (as early reported in [5, 8]), in combination with larger l_{cr} parameters incomparable with the sizes of the supramolecular formations in EPPs [12], can suggest that l_{cr} characterizes the size of the critical structural defect in the preruptured, rather than in the initial, state. Hence, the above-mentioned correlation can have the following physical sense at the micromechanical level: The stronger the relaxation (dissipative) properties of PMs, the greater external mechanical load applied to the material is required for preliminary initiation of the catastrophic rupture event via rapid growth of the propagating main crack forming a new surface and the greater deformation work is spent for the preliminary growth of the greatest structural defect to the critical size or for preliminary opening of the crack to the critical state. This deformation energy should be added to the surface fracture energy proper.

Thus, the specific surface fracture energy of polymers reflects, to a significant extent, the relaxation ability of the material, i.e., its ability for viscous dissipation of mechanical energy at the top of the propagating crack owing to plastic deformation of the adjacent regions.

Notably, there is no correlation between the strength parameters and IFB, and there is a linear correlation between γ and τ_α (Fig. 4). The physical sense of this correlation at the molecular level, evidently, consists in the following. Despite low (room) temperature of static cleavage tests, large-scale molecular motion substantially contributes to fracture via forced plastic flows at the mouth of the propagating crack. The greater the effective sizes of the kinetic units participating in the relaxation process, the greater volume they occupy (the greater proportion of the fluctuation free volume they need [23]), the greater should be the volume of the plastic zone at the top of the propagating crack, and the greater the dissipated energy.

Thus, increase in the number of labile physical cross-links and the parallel decrease in the number of the chemical cross-links are responsible for the EPP fracture delocalization at the microlevel. This means that larger microvolumes of the material are involved into fracture (increase in γ and l_{cr}). At the macrolevel, this is manifested in growth of ε_t and also of the total deformation energy A_d including the fracture energy, which is estimated from the integral area enclosed by the fracture curve [5]. Therefore, in the case of static tests, the suggested approach involving variation of different types of cross-links in EPP also affords more efficient dissipation of the mechanical energy. Evi-

dently, increase in the EPP strength with increasing PFR content is due to enhancement of the dissipative properties of these polymers.

CONCLUSIONS

(1) Dynamic tests showed that increase in the content of phenol–formaldehyde resins in epoxy-phenolic polymers tends to increase eventually the content of labile physical and decrease the content of stable chemical cross-links in the resulting three-dimensional network polymer.

(2) Dynamic and static tests suggest enhancement of the elastic and dissipative properties of these polymers in the glassy state and their weakening in the hyperelastic state.

(3) Analysis of the role of the dissipative properties of epoxy-phenolic polymers at the local and large-scale (segmental) levels of the molecular mobility of the polymer matrix during fracture upon extension of these materials shows the following. Articles subjected to large dynamic loads need the maximal amount of labile physical bonds and, thus, the maximal content of phenol–formaldehyde resins. Articles operating at elevated temperatures, when the deciding role is played by chemical covalent bonds, need a reduced content of phenol–formaldehyde resins and, thus, an increased density of the chemical cross-links.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Formation of Strength Properties of Model Glue Joints Based on Epoxy–Amine Binders Cured by Polycondensation Mechanism

Yu. N. Smirnov and V. N. Korotkov

Institute for Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received May 22, 2002; in final form, September 2003

Abstract—The kinetics of formation of strength properties were studied for a model glue joint based on epoxy–amine binder cured by the polycondensation mechanism at various temperatures. The binder curing kinetics were monitored. In the course of curing, shrinkage defects were studied and the glue joint fracture surface was examined.

In [1–3], we attempted chemical designing of high-strength epoxy-amine binders (EABs) for fiber glass plastics by combining the structural contributions from polycondensation and polymerization curing mechanisms. It was shown in [1, 3] that, with attaining the optimal structural microheterogeneity of the materials combined, this markedly enhances the cohesion strength of EABs, particularly their breaking strain, and also the fracture work. This makes these materials especially attractive as binders for composites [4]. However, high cohesion strength of the polymer matrix in a composite should be combined with high adhesion strength with respect to the reinforcing filler surface [5]. Studying the adhesion strength formation during composite molding is essential for chemical designing of high-strength fiber glass plastics. It is important to elucidate how different structural contributions from the combined different three-dimensional cross-linking processes affect the origination, number, and size of shrinkage and thermal defects, the corresponding strains, and their relaxation processes.

As known [6–8], in models simulating the three-dimensionally strained state of the matrix in composite materials, shrinkage strains arising in the course of curing of epoxy systems are responsible for shrinkage defects of the cohesion, adhesion, and mixed types. The type and pattern of evolution of shrinkage defects in the course of curing depend on the sequence of the two processes cross-linking the polymer matrix, namely, gelation (formation of a network of chemical bonds) and glass transition (formation of a network of labile physical bonds). As known [9, 10], the sequence of these processes is governed by the curing temperature, as well as by the chemical composition of the binder [11].

The aim of this work was to elucidate how the shrinkage defects and relaxation (dissipative) properties of the base epoxy–amine compound cured by the polycondensation mechanism affect formation of the strength properties of the model composites and their fracture in the course of curing. This is particularly important in view of the fact that shrinkage defects arising immediately during formation of articles from composite materials (CMs) are able of transformation in the course of cooling under thermal strains into extremely dangerous defects such as critical Griffits defects [12]. The latter stimulate further cohesion and adhesion fracture processes in CM articles operating under loads.

EXPERIMENTAL

Strength properties of the composites were studied with a glue joint model (GJM) obtained by gluing two $60 \times 25 \times 6$-mm glass plates. The plates were arranged crosswise and separated with an insert made of a fluoroplastic film to control the glue seam thickness (~120 μm). A hole cut in the insert allowed control of the glue joint area (d = 5 mm). The binder was poured into the hole in the insert, and the plates were pressed with a 250-g load and placed into a special stand and then into an oven. After keeping in the oven for a certain time, a batch of six samples was cooled to room

1070-4272/03/7611-1822$25.00

temperature. The remaining samples were cooled for some more time. Some samples were glued with pure epoxy resins without curing agent. The resins were heated to 120°C, poured into the hole in the insert, whereupon the plates were laid, pressed with a load, and cooled at a rate of 0.5 deg min^{-1}. The tensile strength of the glue joint σ_{glue} was determined at 20°C by extending the GJM with cross-shaped clamps at a rate of 3 mm min^{-1}. The average σ_{glue} was estimated from the data obtained in tests with six samples.

As the basic binder we used a compound based on ED-20 epoxy–4,4'-isopropylidenediphenol resin and *m*-phenylenediamine (*m*-PDA). The curing kinetics of the individual binder were studied calorimetrically on an EK-2 low-inertia calorimeter [13], using a torsion pendulum (torsion mass 9 g; a 60-mm-long VM-1 glass thread containing 25 wt % binder as the working unit); on a Rheotest-II viscometer [plate–cone design; gelation time at various temperatures was determined by extrapolating the linear section, corresponding to a sharp viscosity growth, to the abscissa (time axis) and, additionally, as the time of achievement of a conventional viscosity of 4000 P]; and tensometrically, on a setup described in [14].

Shrinkage defects were observed immediately during the isothermal synthesis in long glass tubes [8], when chemical shrinkage in the middle of the tubes creates an all-sided extended state [15] similar to the strained state of a matrix in a fibrous composite [7]. A fairly high adhesion between the system being cured and the glass surface afforded the initial shrinkage cohesion defects which further, under certain conditions, evolved into adhesion exfoliates.

Figure 1 presents typical kinetic plots of σ_{glue} for the ED-20 + *m*-PDA binder at curing temperatures lower than the limiting glass transition point for this system (155°C).

Unexpectedly, the run of these curves proved to significantly differ from that of the curing kinetic curves. For example, a characteristic feature of the time dependence of σ_{glue} was a maximum in the initial stage of the binder curing, preceding the gelation stage (the corresponding gelation onset time is indicated in the abscissa with arrows). Notably, the subsequent sections are characterized by steadily low σ_{glue}. At the same time, further growth and attainment of saturation by the σ_{glue} vs. time plot seems to naturally stem from development and further inhibition of the binder curing due to its vitrification (hardening). Figure 1 shows that the time of attainment of the maximum, σ_{glue}^{max}, tends to decrease and the corresponding σ_{glue}^{max}, σ_{glue}^{min}, and $\sigma_{glue}^{\leftarrow\infty}$, to increase with increasing experimental temperature T_{cur}. At T_{cur} = 100°C (Fig. 1, curve *3*), the previously observed σ_{glue} maximum is virtually degenerated. Notably, similar nontrivial variation of the glue joint strength was revealed for binders with other compositions such as, e.g., *N*,*N*,*N*',*N*'-tetraglycidyl-3,3'-dichloro-4,4'-diaminodiphenylmethane (EKhD grade)–aniline, ED-20–4,4'-diaminodicyclohexylmethane, and ED-20–benzyldimethylamine.

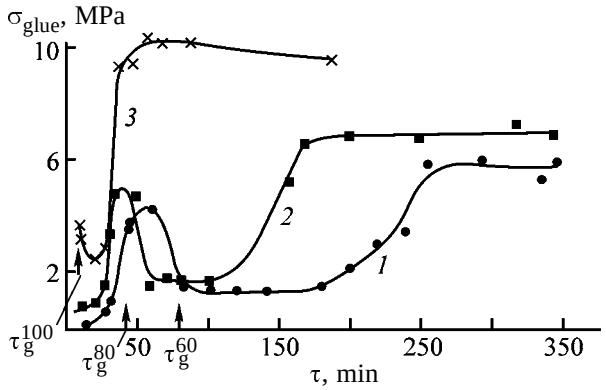

Fig. 1. Glue joint strength σ_{glue} as a function of the curing time τ. (τ_g) Gelation time; the same for Fig. 2. *T*, °C: (*1*) 60, (*2*) 80, and (*3*) 100.

Curing was studied at temperatures of 40–120°C differing from both the test temperature (20°C) and the limiting glass transition point (155°C). Therefore, when analyzing the pattern of variation of the glue joint strength in the course of curing, it is necessary to take into account the fact that the binder in the GJM before the tests can generally change its physical state by five different pathways: liquid state (LS) at $T_{cur} \rightarrow$ LS at T_{test}, LS at $T_{cur} \rightarrow$ glassy state (GS) at T_{test}, LS at $T_{cur} \rightarrow$ hyperelastic state (HES) at $T_{cur} \rightarrow$ HES at T_{test}, LS at $T_{cur} \rightarrow$ HES at $T_{cur} \rightarrow$ GS at T_{test}, LS at $T_{cur} \rightarrow$ GS at $T_{cur} \rightarrow$ GS at T_{test}.

Realization of particular pathway depends on the sequence of the two cross-linking processes, gelation and glass formation, for a given composition of the binder and specific curing and test temperatures.

The glue joint strength should be determined, above all, by the physical state of the binder in GJM at T_{test} (LS, HES, or GS) governing the elasticity modulus on GJM extension. However, essential is also the final physical state of the binder at T_{cur}, which determines the nature of the transition on cooling to T_{test} and, hence, the free excess volume and its distribution over holes (voids) [16, 17], as well as the residual (shrinkage and particularly thermal) internal stresses. Thus, σ_{glue} can vary in the course of curing

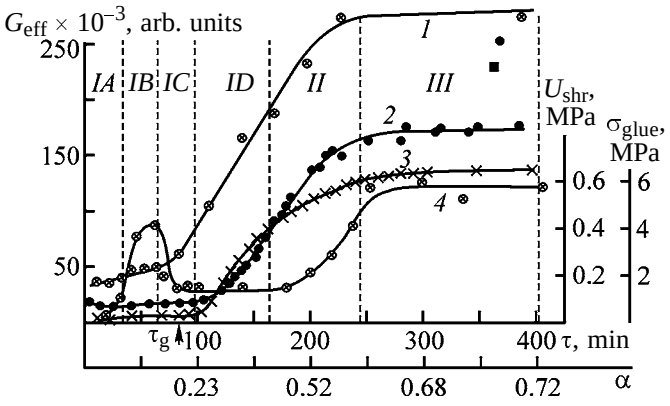

Fig. 2. Variation of the effective elasticity modulus G_{eff} at (*1*) 20°C (G_{eff}^{20}) and (*2*) 60°C (G_{eff}^{60}), and (*3*) shrinkage stresses U_{shr} and (*4*) glue strength σ_{glue} with time τ and conversion α. Fracture time intervals: (*IA–ID*) cohesion, (*II*) cohesion–adhesion, and (*III*) adhesion.

not only with the conversion of the functional groups and cross-linking density but also with the physical history of the binder in GJM.

Figure 2 combines the results of the kinetic studies at T_{cur} = 60°C. It should be noted that, to distinguish more clearly between the two cross-linking processes, we studied gelation in separate, on a highly sensitive rotation viscometer. The kinetic viscosity curves exhibited a typical run [18, 19] and consisted of two sections corresponding to slow and fast viscosity growth, respectively. The gelation onset time τ_g^T (T is the temperature, °C) in these curves was estimated by extrapolating to abscissa (time axis) the linear section corresponding to fast growth. In Figs. 1 and 2, the respective τ_g^T values are shown with arrows at the abscissa, and the corresponding temperatures are indicated. Glass transition (hardening) of the binder at room and other temperatures was studied with a less sensitive torsion pendulum adjusted to recording changes in the torsion rigidity of the thread due to the liquid–glass transition only. The growth of the binder viscosity in the initial curing stages is due to enhancement of its dissipative properties (the ability of dissipating energy during the relaxation process) in the liquid state. In this work, we did not estimate the dissipative (relaxation) properties of the binder in the hyperelastic and glassy states and gave them only general consideration. Curve *1* in Fig. 2 shows how the effective elasticity modulus at room temperature, G_{eff}^{20}, varies with swinging of the thread of the torsion pendulum at room temperature. Notably, in these experiments the set of impregnated threads was kept at 60°C for a certain time. Next, one of the threads was cooled for a certain time to room temperature, at which G_{eff}^{20} was measured.

Curve *2* in Fig. 2 shows how the elasticity modulus at T_{cur} = 60°C, G_{eff}^{60}, varies with thread swinging. The G_{eff}^{60} growth onset at τ = ~115 min corresponds to the glass transition onset. Notably, this time coincides with the hardening time determined for the system by the method of penetration of a glass rod into the binder being cured. The attainment of saturation by curve *2* at τ = ~240 min suggests that glass transition virtually terminates at this curing temperature.

To elucidate how the physical state (LS, HES, or GS) of the binder in the GJM affects the glue joint strength in various stages of the chemical and physical cross-linking, we will analyze the whole set of the kinetic data and also the pattern of fracture of the glue interlayer in the GJM. This pattern can be derived from optical studies of the fracture surface image at ×10 magnification. Notably, in the course of curing the loaded GJM undergoes fracture of three major types: (*I*) cohesion, (*II*) cohesion–adhesion, and (*III*) adhesion. These fracture types generally correspond to the defects arising from spontaneous fracture of the binder due to shrinkage strains directly at T_{cur} [6–8]. Thermal strains in the course of cooling and the external load do not principally affect the GJM fracture pattern at T_{test}.

In early curing stages (until ~30 min), the binder at T_{cur} and T_{test} occurs in the viscous-flow LS, and upon cooling its viscosity increases only. The cohesion fracture of GJM has a liquid nature. During separation of the plates, bubbles are formed and degrade (Fig. 3a). The time interval corresponding to this type of cohesion fracture is designated in Fig. 2 as section *IA*. A minor σ_{glue} growth is due to the viscosity growth in the course of curing.

Within 35–60 min, the binder at T_{cur} and T_{test} also occurs in the LS. Upon cooling to T_{test}, the viscosity markedly increases, but the G_{eff}^{20} growth rate remains unchanged (Fig. 2, curve *1*). The cohesion fracture in this stage has a plastic nature and is characterized by weakly manifested surface relief features. This fracture type is illustrated in Fig. 3b, and its corresponding time interval is indicated as section *IB* in Fig. 2. This section is characterized by a major primary growth of the glue joint strength.

In the 65–90 min interval, the binder, occurring in the LS at T_{cur}, exhibits the onset of transition to the solid state upon cooling. A fairly sharp inflection appears in curve *1*. At T_{cur}, the viscosity begins to rapidly grow to a conventional value of 4000 P (at 60°C

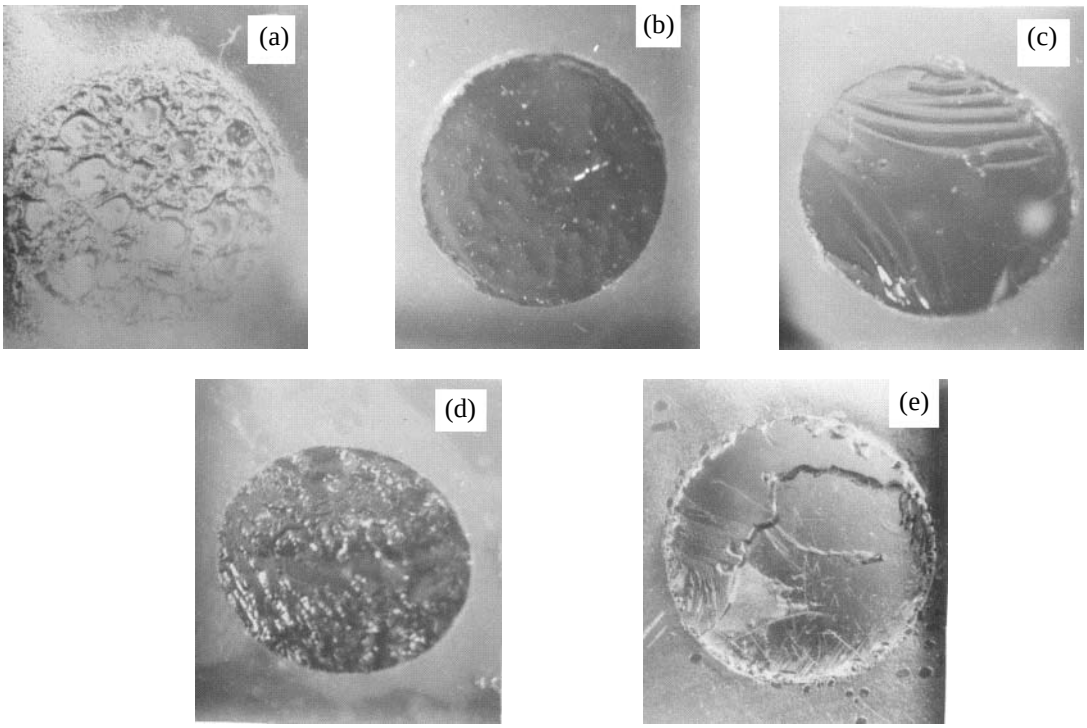

Fig. 3. GJM fracture surface image. τ, min: (a) 0–25, (b) 25–65, (c) 65–90, and (d) 90–160, and (e) 160–240.

within 83 min); no growth of shrinkage stresses is observed (Fig. 2, curve *3*). Shrinkage defects in the tubular model samples do not form yet, but the glue joint strength drastically decreases. From the time at which σ_{glue} begins to decrease till that at which it attains saturation, fracture is brittle by nature and exhibits clear shear bands typical for GJMs glued with low-molecular-weight glassy substances (e.g., ED-8 glassy epoxy resin). This fracture type is illustrated by Fig. 3c, and its corresponding time interval is indicated as section *IC* in Fig. 2. The inflection in curve *1*, transformation of the binder into brittle state, and a sharp decrease in the glue strength directly indicate the onset of glass transition of the binder at T_{test}. Notably, this is the first physical transition in the binder manifested at room temperature. The conversion of the binder attained by that time can be treated as critical for attaining the GS of the binder (α_{ph1}) [19]. This parameter is of practical importance for predicting the life of intermediate prepregs in storage.

To tentatively analyze variation of the glue joint strength within the *IA*–*IC* intervals, we will take advantage of the Griffits formula for the critical strength σ_{cr} [12]:

$$\sigma_{cr} = (2E\gamma/\pi l_{cr})^{1/2}$$

were E is Young modulus; γ, specific surface energy; and l_{cr}, critical defect size.

This formula interrelates the major factors governing the strength of solid materials: elasticity factor E, the l_{cr} factor characterizing the structural defectiveness, and the γ-relaxation (dissipative) factor (according to Berry [12]). This equation was already used for analyzing the glue joint strength of elastomers [21]. It suggests that a sharp increase in the glue joint strength in going from section *IA* to *IB* cannot be due only to enhancement of the flexible properties of the binder, as the G_{eff}^{20} growth rate in curve *1* (Fig. 2) remains unchanged. Thus, with invariant structural defectiveness factor, the growth of the glue joint strength should, evidently, be due to growth of the dissipative factor γ (owing to the binder viscosity growth). At the same time, a sharp decrease in the glue joint strength in going from section *IB* to *IC* (when the fracture mechanism changed from plastic to brittle) should, evidently, be attributed to a decrease in the dissipative factor owing to the change in the physical state of the glue interlayer. It should be noted that transition from plastic to brittle fracture means transition from fracture involving relaxation processes characterized by viscous energy dissipation and, correspondingly, large γ values, to fracture characterized by small γ values, which are virtually equal to the energy of new surface formation proper.

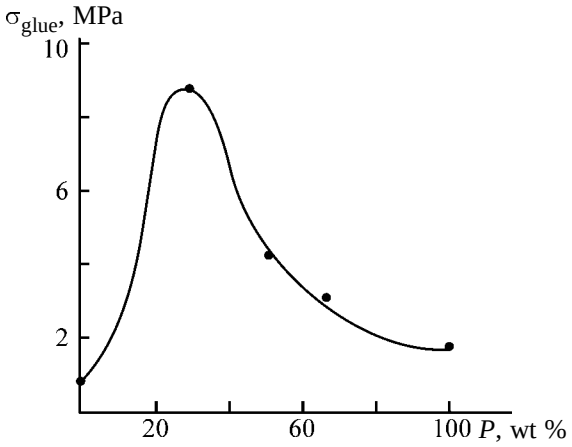

Fig. 4. Variation of the glue joint strength σ_{glue} with the content P of ED-16 and ED-8 epoxy resins.

The changes in the physical state of the binder in early curing stages were reproduced by plates glued with straight epoxy resins ED-16 (simulating a highly viscous liquid medium) and ED-8 (simulating fully glassy medium at room temperature).

Figure 4 shows that, on varying the ED-16-to-ED-8 resin ratio, σ_{glue} passes through a prominent maximum at 25 wt % of ED-8, with σ_{glue} being fairly high at a maximum.

Thus, the changes in the glue joint strength and in the GJM fracture pattern in the *IA*–*IC* intervals can be treated as due to the changes in the physical state of the binder at T_{test} owing to partial chemical transformations of the initial compound, namely, formation of linear chains or local microgels, rather than to the onset of the chemical cross-linking with formation of a macrogel. The microgels can be formed in the case of microheterogeneous chemical cross-linking.

It is believed [22] that formation of microgel structures is much less probable (and, correspondingly, the degree of microheterogeneity of the network structure is smaller) in the case of polycondensation than in the case of radical polymerization [23]. However, under the actual conditions [low curing temperature and high viscosity, sharply increasing during vitrification (hardening) of the binder], the probability of microheterogeneous cross-linking of the binder should be fairly high [24–26]. The microheterogeneous nature of the network structure of the binder in the HES can be responsible for microheterogeneous structure of the binder in the GS upon cooling, when locally vitrified microvolumes of the binder can be distributed in a highly viscous liquid medium and act as viscous energy dissipation sites. Their growth in number before complete transition of the binder to the glassy state (which can be treated as percolation) should initially favor substantial enhancement of the dissipative properties of the binder followed by their weakening upon transition of the binder to completely solid (brittle) state. This process resembles fracture of amorphous-crystalline polymers depending on the size and number of crystallites [27].

Within 90–180 min (*ID*, *II*), the observed pattern of variation of the glue joint strength was unexpected. Despite doubling of the conversion of the functional groups within this interval, σ_{glue} remains unchanged. The GJM fracture in this interval is plastic by nature, when the microrelief features of the fracture surface are more pronounced (Fig. 3d; Fig. 2, section *II*). At the same time, in the case of the tubular model samples, shrinkage stresses begin to grow at T_{cur}, and shrinkage defects appear. Also, glass transition of the binder begins and intensively develops at T_{cur} (G_{eff}^{60} grows; Fig. 2, curve *2*). Within this time interval, a secondary physical transition is manifested in the binder due to formation of a macronetwork of physical bonds (glass formation) at T_{cur}. The critical degree of the transition was estimated at 0.63. At T_{test}, the elasticity of the binder in the GS continues to substantially grow (curve *1*).

The reasons for the lack of growth of the glue joint strength in the time interval of interest still remain to be fully understood. The above-presented formula suggests two major factors responsible for the σ_{glue} invariance. The growth of the elasticity factor and the constancy of the relaxation factor can involve the compensation growth of the defectiveness factor (including growth of the sizes of the defects and internal strains localized in their vicinity). This is in line with the growth of the number and size of the shrinkage defects and shrinkage stresses observed within the interval of interest in the case of tubular model samples. The growth of the elasticity factor can also be compensated by a decrease in the relaxation factor. However, this seems less probable in the considered stage of the physical and chemical cross-linking of the binder when the gel fraction has already started to form. In terms of the model of microheterogeneous cross-linking of the binder, γ can be treated as constant, under assumption that a uniform macronetwork structure has not yet formed in this stage. The binder consists of unlinked microgels and at T_{cur} occurs essentially in a highly viscous LS, rather than in the HES. Upon cooling, the binder entirely transforms to the GS with presumably globular structure. Evidently, this specifically predetermines the cohesion fracture mechanism for GJM, with prominent surface microrelief features. The glass formation in the binder,

which began at T_{cur}, is accompanied by "freezing-out" of the mobility of the largest microstructure units. This, evidently, is responsible for even greater localization of the chemical cross-linking and yields microstructure units with a small dimensionality, with the concentration of elastically active chains remaining virtually unchanged.

Within the time interval from the glass transition onset (115 min) to virtual completion (260–270 min), the conversion of the functional groups of the binder increases from 0.3 to 0.65. Nevertheless, the final macrostructurization (monolithization) of the binder can proceed as a physical process of vitrification of a microheterogeneous medium by formation of physical intermolecular contacts between glassy microvolumes based on the most strongly cross-linked microgels that already lost their mobility, rather than as a chemical process of formation of an infinite network of covalent bonds. Evidently, at low curing temperatures, the onset of monolithization of the binder, i.e., formation of a macronetwork of physical bonds or macrovitrification at T_{cur}, is specifically responsible for the secondary growth of the glue joint strength.

At higher curing temperatures, the secondary growth of σ_{glue}, taking into account the growth of the elasticity factor E and defectiveness factor l_{cr}, can be due to the outrunning enhancement of the dissipative properties of the binder owing to accelerated growth of the gel fraction content.

Notably, the section corresponding to rapid secondary growth of σ_{glue} begins approximately in the middle of the section corresponding to the G_{eff}^{60} growth at T_{cur}. The enhancement of the elastic properties of the binder during glass formation owing to chemical cross-linking is similar, in principle, to that of elastic dynamic properties of network polymers during glass transition upon cooling. In the latter case, the average change in the elastic properties during glass transition typically corresponds to the maximum mechanical losses in the polymer [28]. The enhancement of the dissipative properties and, correspondingly, of the binder strength is specifically responsible for transition from cohesion to adhesion fracture for GJM, as suggested by the appearance of adhesion defects in the transition region *II* in Fig. 3e, observed in tubular model samples.

After the GJM fracture changes eventually to adhesion mechanism (~240 min, α = 0.62) until attaining the limiting conversion at 60°C (α_∞ = 0.72, ~420 min), the growth of the elasticity moduli in swinging at 20 and 60°C virtually terminates, as well as the growth of shrinkage stresses and glue joint strength, but in tubular samples the adhesion defects continue to slowly grow. Transformation of the functional groups of the binder and growth of the content of the gel fraction seem to be responsible for further enhancement of the strength of the binder and, thus, of the GJM. But the limiting stage of the GJM fracture is fracture along the glass–binder interface. The above-presented formula suggests that, with a constant elasticity factor, the growth of the relaxation factor is compensated by that of the defectiveness factor (with the adhesion defects dominating). Also, further growth of the degree of the binder curing in the glassy state can deteriorate the relaxation characteristics of the glue interlayer, enhance localization of stresses near the glass–binder interface, and increase the importance of the adhesion factors.

Evidently, the adhesion contribution to the GJM strength and the adhesion defects are specifically responsible for a fairly low limiting glue joint strength. For the actual curing temperature range and glue composition range, it was estimated at 6–20 MPa, and the strength of the binders proper, at 60–90 MPa. This requires paying particular attention to strengthening of the glass–gluing seam interface in further studies.

CONCLUSIONS

(1) With ED-20–*m*-phenylenediamine compound cured by the polycondensation mechanism as a binder, the glue joint exhibits substantially nonmonotonic variation of the strength during isothermal curing. This is due to the action of two relaxation processes in the glue interlayer (vitrification of the binder at room and curing temperatures) and gelation, as well as to changes in the fracture mechanism of the model glue joint.

(2) The first strength maximum for the model glue joint corresponds to transition of the binder from the viscous-flow to glassy state. It is due to the action of two competitive factors: enhancement of the dissipative properties due to viscosity growth because of proceeding of the curing reaction and hardening and, correspondingly, transformation of the binder to brittle state at the test temperature. These findings are interpreted in terms of the model of microheterogeneous cross-linking of the binder.

(3) A fairly long section characterized by a low and virtually constant σ_{glue}^{min} value is, evidently, due to growth of the contribution from shrinkage defects and stresses.

(4) The revealed initial growth and further decline of the strength of the model glue joints is of practical importance: Forced cooling of glued and, correspondingly, glass fiber plastic articles in the appropriate time interval can produce dangerous defects irremovable by further heating.

(5) Worsened relaxation characteristics of the binder and concentration of thermal stresses at the glass–polymer interface predetermines inevitable transition to adhesion fracture of the model glue joints, thus decreasing the overall strength of the glue joint.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Uranyl Sulfoxide Complexes as Photoinitiators of Polymerization of Methyl Methacrylate and Epoxy Acrylate Oligomers

E. M. Battalov, G. V. Leplyanin, and Yu. I. Murinov

Received April 16, 2003

Abstract—Photoinitiation activity of uranyl sulfoxide complexes in polymerization of methyl methacrylate and epoxy acrylate derived from ED-16 and acrylic acid, and also the postirradiation effects in photopolymerization of these monomers were studied.

The behavior of uranyl salts in radical polymerization is of interest. These compounds are inactive in the thermal initiation of polymerization, but they are fairly active photoinitiators [1]. In this work, we studied photopolymerization of methyl methacrylate (MMA) initiated with uranyl sulfoxide complexes, which are infinitely soluble in MMA monomer.

EXPERIMENTAL

Methyl methacrylate was purified to remove the stabilizer by the method described in [3]. Uranyl sulfoxide complexes were synthesized by the method of [3]. Polymerization was performed in the bulk at a temperature controlled with ±0.05°C accuracy. The photopolymerization kinetics was studied dilatomertically with molybdenum glass dilatometers. Epoxy acrylate polymer was synthesized as in [4]. A PRK-4 mercury lamp was used as a UV source; the distance between the light source and reactor was 14 cm in all experiments. The dynamic viscosity was measured with a Rheotest 2.1 device. The spectra of the samples were recorded on a Specord UV VIS spectrophotometer.

Whyte and Melville were the first who studied uranyl salts as photopolymerization initiators [5]. They found that, at low concentrations of uranyl sulfate, the rate of photopolymerization of vinyl acetate and methacrylic acid is proportional to the square root of the salt concentration. Okamura and Motoyama [6] confirmed this dependence when studying vinyl acetate photopolymerization activated with uranyl nitrate and oxalate in the systems with water and acetic acid. They observed reduction of U(VI) to U(IV) and assumed the following reaction scheme taking into account the presence of water:

$$UO_2^{2+} + 2H_2O \rightarrow U^{4+} + 2OH^- + 2OH^{\cdot}.$$

Simionescu *et al.* [7] studied photopolymerization of acrylonitrile in the presence of uranyl salts and found that the initiation activity decreases in the series $UO_2SO_4 > UO_2(OAc)_2 > UO_2(NO_3)_2$.

Polymerization occurs by radical mechanism, and the polymer obtained has amorphous structure. The subsequent studies [8–10] on using uranyl salts as polymerization photoinitiators were aimed at comprehensive elucidation of the initiation mechanism.

The kinetic curves of MMA polymerization in the presence of uranyl nitrate sulfoxide complex under UV irradiation are shown in Fig. 1. As seen, the polymerization rate increases by a factor of approximately

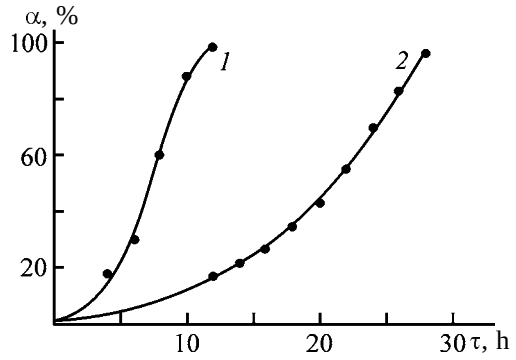

Fig. 1. Kinetic curves of MMA polymerization at 50°C (*1*) in the presence of 0.05 wt % $UO_2(NO_3)_2 \cdot 2$DASO (DASO is diamyl sulfoxide) and (*2*) without additions. (α) Conversion and (τ) time; the same for Fig. 4.

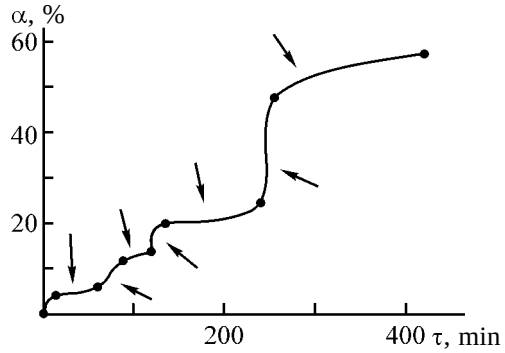

Fig. 3. Kinetics of MMA photopolymerization in the presence of 0.05 wt % $UO_2(NO_3)_2 \cdot 2DASO$ under the irradiation at λ = 430 nm (arrows bottom-up) and λ = 600 nm (arrows top-down) at 50°C. (α) Conversion and (τ) time.

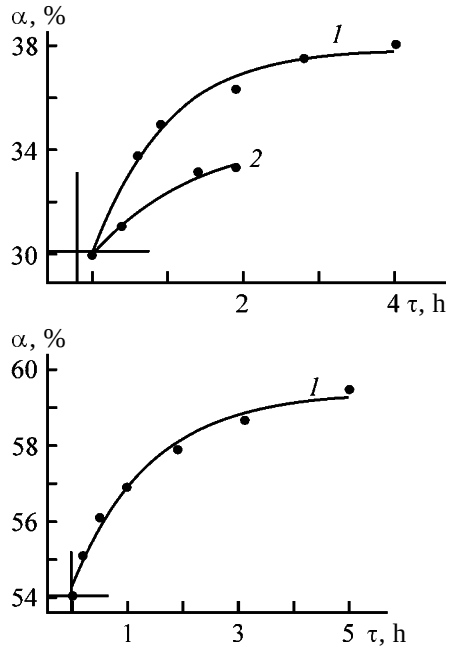

Fig. 4. Kinetic curves of postirradiation effects in MMA polymerization at 50°C in the presence of 0.5 wt % (*1*) $UO_2 \cdot (NO_3)_2 \cdot 2DASO$ and (*2*) diacetyl at various conversions.

2, i.e., this complex exhibits photoinitiation activity. The photoinitiation mechanism probably involves sensitization of polymerization of vinyl monomers with uranyl (sulfate, nitrate, oxalate, etc.) and was discussed previously in numerous papers [5–10]. The following photoinitiation mechanism presented in [6] is apparently the most realistic:

$$UO_2^{++} \xrightarrow{+h\nu} [UO_2^{++}]^*, \quad (1)$$

$$[UO_2^{++}]^* \rightarrow UO_2^{++} + \Delta, \quad (2)$$

$$[UO_2^{++}]^* \rightarrow UO_2^{++} + h\nu^1, \quad (3)$$

$$[UO_2^{++}]^* + M \rightarrow [UO_2^{++} + M]^*, \quad (4)$$

$$[UO_2^{++} + M]^* \rightarrow UO_2^{++} + M^*, \quad (5)$$

$$[UO_2^{++} + M]^* \rightarrow UO_2^{++} + R^*, \quad (6)$$

$$M^* + M \rightarrow 2R_1^{\cdot}, \quad (7)$$

$$M^* \rightarrow \Delta^1, \quad (8)$$

$$R_1^{\cdot} + M \rightarrow R_2^{\cdot}, \quad (9)$$

$$R_m^* + R_n^* \rightarrow P_m + P_n. \quad (10)$$

Photoinitiation occurs only under the action of light with λ = 430 nm, which is absorbed by the central atom of the complex (Fig. 2). The kinetic curves of MMA polymerization in the presence of a uranyl nitrate sulfoxide complex under irradiation with light at 430 and 600 nm are shown in Fig. 3. As seen, the rate of MMA polymerization in the presence of the amy sulfoxide complex under irradiation by light with the wavelength in the region of uranyl absorption (Fig. 2) is higher compared to irradiation at the wavelength of the ligand absorption. This suggests the major role of uranyl in the polymerization initiation. Probably, sensitization with uranyl complexes proceeds just by the above scheme. The stepwise character of polymerization under irradiation by light with different wavelengths suggests different polymerization rates and the possibility of performing the reaction in the controllable mode.

It should be noted that the MMA polymerization in the presence of uranyl complexes is accompanied by strong postirradiation effects. For comparison, the postirradiation effect of such well-known photoinitiator as diacetyl is shown in Fig. 4. The reason of this effect is poorly understood.

Afterpolymerization is also characteristic for epoxy acrylate oligomers, e.g., ED-16-AA (products of reaction of diepoxide ED-16 with acrylic acid) after short UV irradiation, especially in the presence of uranyl

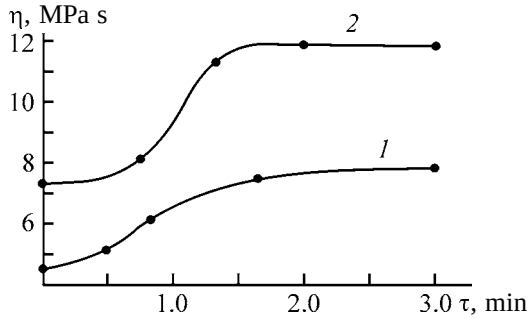

Fig. 5. Kinetic curves of dynamic viscosity η of epoxy acrylate oligomer ED-16-AA after UV irradiation for 15 s in the presence of (*1*) 1.0 wt % benzophenone and (*2*) 0.08 wt % $UO_2(NO_3)_2 \cdot 2DASO$ at 60°C. (τ) Time; the same for Fig. 6.

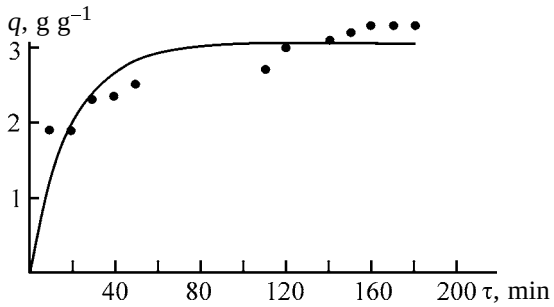

Fig. 6. Kinetics of swelling *q* in trichloroethylene of epoxy acrylate polymer ED-16–AA prepared in the presence of uranyl nitrate sulfoxide complex. UV irradiation of the initial oligomer 15 min.

nitrate sulfoxide complex (Fig. 5). Benzophenone as a photoinitiator gives a weaker postirradiation effect. Variation of the dynamic viscosity of this oligomer in time after 15 s of preliminary UV irradiation is an indirect evidence of postpolymerization in the presence of photoinitiators. In the system studied, there are no mechanisms other than postpolymerization under the action of long-lived radicals that could be responsible for variation of the dynamic viscosity.

The kinetics of swelling of the epoxy acrylate polymer prepared by photopolymerization in the presence of uranyl nitrate complex with petroleum sulfoxides is shown in Fig. 6. As seen, this polymer weakly swells in trichloroethylene and is classed with cross-linked products.

Thus, uranyl sulfoxide complexes are photoinitiators of MMA polymerization and of photoinduced cross-linking of epoxy acrylate oligomers. Cross-linked polymeric products are formed under irradiarion of epoxy acrylate oligomers in the presence of uranyl sulfoxide complexes. Polymerization of both MMA and epoxy acrylate oligomers is accompanied by increased postirradiation effects as compared to standard photoinitiators (dibenzoyl, diacetyl, benzophenone).

CONCLUSIONS

(1) Uranyl sulfoxyde complexes are fairly efficient photoinitiators of polymerization of methyl methacrylate and epoxy acrylate oligomer.

(2) The monomers studied show increased afterpolymerization effect.

(3) The polymerization rate can be controlled by varying the irradiation wavelength.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Diffusion Modification of Polymethyl Methacrylate with Oligoglycol Acrylates

L. A. Abdrakhmanova, V. Kh. Fakhrutdinova, and V. G. Khozin

Kazan State Architectural and Building Academy, Kazan, Tatarstan, Russia

Received June 18, 2003

Abstract—The structural transformations of oligoglycol acrylates in the surface layers of polymethyl methacrylate were studied.

Surface bursting resulting in development of cracks with the depth of 1–2 mm and more ("silver" formation) is characteristic of polymethyl methacrylate (PMMA) plexiglass. Under conditions of artificial and natural aging, evaporation of low-molecular-weight substances, and action of various factors, significant defects are formed, altering the physicomechanical, optical, and other characteristics of plexiglasses. Factors deteriorating the strength of the surface layer of glass play an extremely important part in appearance of "silver." The appearance of "silver" is especially affected by almost all organic solvents.

The real method of strengthening the surface layers is creation of gradient interpenetrating networks (IPNs) [1–3], blends of three-dimensional polymers in which concentrations of components vary through the cross section of the sample. Introduction of oligoglycol acrylates of various structures, polymers based on which are characterized by increased softening point and hardness [4], into the surface layers of PMMA allows production of materials of the gradient semi-IPN type with enhanced performance.

Diffusion swelling of PMMA in oligoglycol acrylates, ethylene glycol dimethacrylate (EGDMA), triethylene glycol dimethacrylate (TEGDMA), and polyethylene glycol dimethacrylate (PEGDMA), was carried out at 37, 42, and 50°C. The degree of swelling of PMMA in the oligomers is presented in Table 1. The kinetic curves of PMMA swelling in acrylates at 50°C are shown in Fig. 1.

Table 1 shows that, with increasing molecular weight (correspondingly, with decreasing fraction of acrylate groups in oligomer molecules), the degree of swelling increases. Apparently, the rate of polymerization of oligoglycol acrylates increases with decreasing their molecular weight, which results in an increase in the viscosity of oligoglycol acrylates in the course of diffusion and, correspondingly, in a decrease in swelling.

To identify the spectra of the gradient PMMA, we recorded the IR spectra of polyglycol acrylates prepared by polymerization of the corresponding oligomers. The spectra of the diffusion-modified PMMA at various depths of the samples were obtained by laser spectroscopy.

The characteristic bands for polyglycol acrylates based on EGDMA are 1639 and 1283 cm^{-1}, up to 1283.5 for PEGMA, and 1283.6 cm^{-1} for TEGMA. The band at 988.2 cm^{-1} in the spectrum of PMMA was selected as the reference for calculations.

Processing of the spectra and determination of the intensity ratio of the characteristic bands to the reference band at 988.2 cm^{-1} at various depths from the sample surface allowed determination of the relative content of oligomers in the surface layers of the samples. The results are presented in Table 2.

As follows from Table 2, the dependence of the oligomer concentration on the depth of its penetration into the PMMA matrix has a maximum (Fig. 2). For

Table 1. Degree of swelling of PMMA α in oligomers

Table 2. Relative content of oligomers in the surface layers of PMMA (swelling at 50°C)

Distance from the sample surface, μm	Intensity ratio of the characteristic bands to the band at 988.2 cm^{-1}		
	EGDMA	TEGDMA	PEGDMA
2	1.50	–	–
5	1.50	–	–
10	1.60	–	–
30	1.80	–	2.60
50	1.85	2.45	1.15
60	1.85	2.30	0.07
100	1.60	1.98	Absent
200	0.90	0.95	″
240	0.70	0.75	″
500	0.22	0.30	″
540	0.18	Absent	″

TEGDMA and PEGDMA, the range of variation is narrow, since in the surface layers we failed to reveal the band characteristic for PMMA (988.2 cm^{-1}).

The data obtained show that, the higher the molecular weight of oligoglycol acrylate, the smaller the depth of its penetration into the PMMA matrix. A comparison of these data with the results listed in Table 2 suggests higher local concentration of the oligomers with the higher molecular weight (PEGDMA and TEGDMA) in the surface layers, since the greater degree of swelling corresponds to the smaller penetration depth.

To explain why the dependence of the oligomer concentration on the penetration depth has a maximum, we studied structural transformations of oligoglycol acrylates in the surface layers of PMMA. To identify the resulting structures, we recorded the ^1H NMR spectra.

The treatment of the ^1H NMR spectra and determination of the intensity ratio of the characteristic signals to the reference signal confirmed polymerization of the oligomer in the surface layers, which is observed only when a "threshold" concentration of the oligomer in the surface layer is reached. The local concentration of the oligomer in the surface layers at which polymerization begins is approximately 15–20 wt %; this corresponds to the degree of swelling of the polymer in oligoglycol acrylate of 6–9 wt %. With a further increase in the degree of swelling, the fraction of nonpolymerized oligomer in the surface layers decreases owing to its conversion into the network polymer (Fig. 3).

Polymerization of the oligomer is also confirmed by the results of studying the molecular mobility in the surface layers of PMMA. At the degree of swelling more than 10%, the mobility of the oligomeric component decreases (Fig. 4) owing to curing. With increasing degree of swelling, the fraction of the component corresponding to the mobility of oligomer in

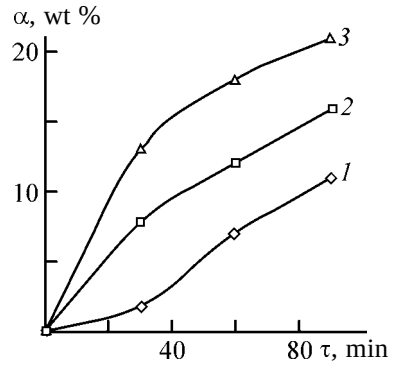

Fig. 1. Kinetic curves of PMMA swelling in oligoglycol acrylates at 50°C: (α) degree of swelling and (τ) time. (*1*) EGDMA, (*2*) TEGDMA, and (*3*) PEGDMA; the same for Fig. 2.

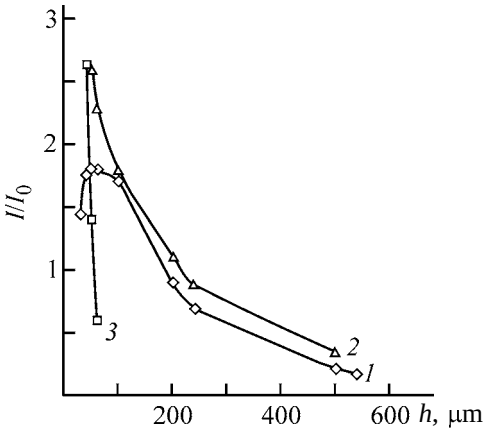

Fig. 2. Relative content of oligomers in the surface layers of PMMA from the evidence of laser Raman spectroscopy (the 1283.2 cm^{-1}/988.2 cm^{-1} intensity ratio). (I/I_0) Relative intensity and (*h*) penetration depth.

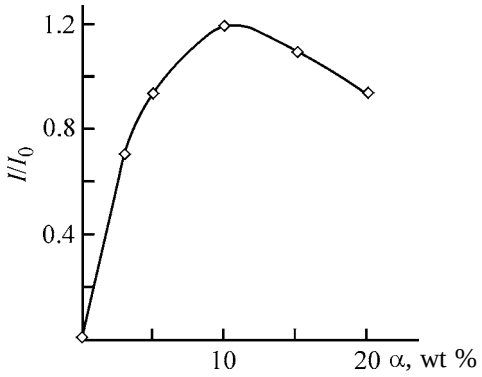

Fig. 3. Relative content of EGDMA (from the evidence of ^{1}H NMR) as a function of the degree of swelling of PMMA α. (I/I_0) Relative intensity.

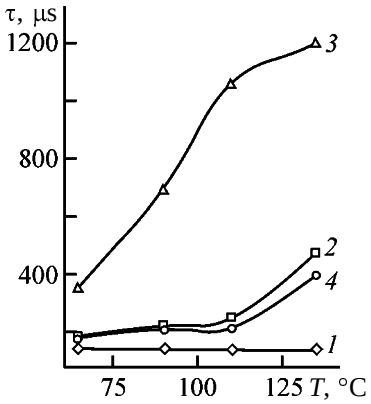

Fig. 4. Transverse spin–spin relaxation time τ of the surface layers of PMMA modified with EGMA at 50°C as a function of temperature *T*. Degree of swelling (wt %): (*1*) 1.9, (*2*) 3.6, (*3*) 8.1, and (*4*) 20; the same for Fig. 5.

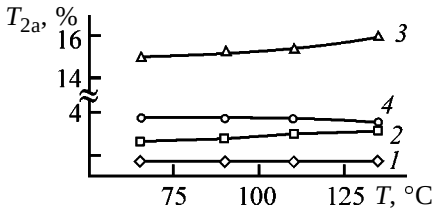

Fig. 5. Population of the mobile component T_{2a} of surface layers of PMMA modified with EGMA at 50°C as a function of temperature *T*.

PMMA increases to the threshold concentration and then starts to decrease (Fig. 5).

Thus, the forming structure of gradient polymers is largely governed by the depth of penetration of the oligomeric modifying agent into the surface layer and the degree of its curing in this layer.

EXPERIMENTAL

In the experiments we used PMMA of the Altuglas brand with the following physicochemical characteristics: d = 1188 kg m^{-3}, n_D^{20} = 1.4900, T_g = 100°C; EGDMA with d = 1080 kg m^{-3} and n_D^{20} = 1.4540; TEGDMA with d = 1092 kg m^{-3} and n_D^{20} = 1.4600; PEGDMA with d = 1099 kg m^{-3} and n_D^{20} = 1.4900; benzoyl peroxide in the amount of 0.3% (with respect to oligoglycol acrylate) was used as polymerization initiator.

The structure of gradient PMMA was analyzed by IR and laser spectroscopy. The IR spectra were recorded on a Perkin–Elmer 2000 FI-IR spectrometer.

The spectra of diffusion-modified PMMA at various depths of the samples were obtained by the laser spectroscopy on a Raman DILOR XY spectrometer with multichannel detection, equipped with a microscope and a video image (excitation of platinum at 458 μm, XYZ with manual or automatic monitoring of excitation zone). The composition of gradient layers was studied at various depths from the surface up to 550 μm (with a step of 1 μm in the automatic mode).

To study the molecular mobility in the surface layers of PMMA (samples of surface layers of modified PMMA in powdered form), we used pulse NMR at 64 MHz.

The ^{1}H NMR spectra were recorded on a Bruker spectrometer operating at 100 MHz using acetone-d_6 as a solvent.

CONCLUSIONS

(1) With increasing molecular weight (correspondingly, with decreasing fraction of acrylate groups in oligomer molecules), the degree of swelling of polymethyl methacrylate in oligomers increases. For ethylene glycol dimethylacrylate, the oligomer concentration as a function of the depth of its penetration into the polymethyl methacrylate matrix passes through a maximum.

(2) Polymerization of oligomers in the polymethyl methacrylate matrix is observed only when their threshold concentration in the surface layers, approximately 15–20 wt %, is reached.

Received May 6, 2003

Abstract—Solid, optically transparent polymers with a high (up to 25 wt %) content of coordination-bound rare-earth elements were prepared by curing glycidyl esters of phosphorus acids with rare-earth metal salts.

There are two main lines in the use of metal compounds in preparation of epoxy polymers [1–3]. Salts and other metal compounds catalyze curing of epoxy oligomers [1, 2] and can be latent hardeners, e.g., for preparation of single-component epoxy compounds. Large amounts of metal ions can improve such properties of epoxy polymers as adhesion, bending strength, crack resistance, water absorption, and softening point [2, 3]. Nevertheless, introduction of metal ions into epoxy resins is complicated because of low solubility of their inorganic compounds (oxides, salts). This problem is usually solved using salts with organic anions or metal complexes. However, introduction of noticeable amounts of large organic ions and molecules together with metals can worsen the polymer parameters and requires special study.

Among metal ions introduced into epoxy polymers, we can emphasize rare-earth elements (REE). REE-containing polymers arouse growing interest, which is caused by the possibility of producing various optical devices (waveguides, optical amplifiers, lasers) on their base [4]. The use of epoxides as polymeric matrices is caused by a set of their favorable physicomechanical properties providing good performance. However, polymers prepared by curing of commercial epoxy–4,4'-isopropylidenediphenol oligomers show insufficient optical characteristics, softening point, and refractoriness.

It was shown previously that polymers based on glycidyl esters of phosphorus acids (GEP) combine high physicomechanical and thermal properties and refractoriness with good optical characteristics [5–8]. In addition, phosphoryl groups in GEP molecules can form additional coordination bonds with multicharged metal ions (including REE ions), similarly to trialkyl phosphates, which are well-known extractants [9]. This suggests the possibility of introducing large amounts of REE ions into such epoxy polymers.

In this work we studied formation of GEP-based solid, optically transparent polymers with required refractive index and high (up to 25 wt %) concentrations of coordination-bound REE ions.

EXPERIMENTAL

GEPs of the general formula

$$RP(OCH_2CH{-}CH_2)_2,$$
$$\quad\|\quad\quad\quad\backslash\ /$$
$$\quad O\quad\quad\quad\ O$$

where R is $(OCH_2CH{-}CH_2)_2$ (**I**), OCH_3 (**II**), CH_3 (**III**), synthesized as in [10] and analytically pure or chemically pure grade REE chlorides, nitrates, and sulfates (Y, Sc, La, Pr, Nd, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu) were used.

Glycidyl esters of phosphorus acids were dried by water distillation in a vacuum for 1 h at 60–70°C. The REE salts were used in the form of crystal hydrates or dehydrated samples. Polymers were prepared by stirring at 25°C phosphorus-containing glycidyl ester with REE salt in 100 : (0.5–50) weight ratio (as calculated for cation content) until the salt completely dissolved; curing was performed at 40–80°C.

The viscosity of mixtures of REE salt and GEP was determined according to GOST 10587–84 as the time of outflow of a definite volume of the mixture through a VPZh-1 viscometer capillary with a diameter from 0.54 to 5.1 mm.

* Content as calculated for cation.

The glass transition point T_g was determined by a thermomechanical method with a PTB-1 device. The heating rate was 50 deg h^{-1} at static loading (P = 9.8–39.2 N) of cylindrical samples 8 mm in diameter and 11 mm high.

The hardness of samples was measured with a PMT-3 microdurometer.

The IR spectra of samples were recorded on a Specord IR-75 spectrometer, and UV-VIS spectra, on a Lambda EZ210 (Perkin–Elmer) spectrophotometer.

After mixing metal salt with phosphorus-containing glycidyl esters **I**–**III**, the viscosity of the system gradually increases. The process rate depends on the salt content, cation, anion, GEP structure, temperature, and moisture content. The time dependences of the viscosity of REE salt–**I** mixtures for two concentrations of holmium and ytterbium nitrates are shown in Fig. 1. With gadolinium salts as examples, the gel time is presented in the table as a function of curing temperature, anion, and GEP structure. As seen, the gel time decreases in the orders **III** > **II** > **I** and sulfate > chloride > nitrate. The temperature rise and increase in salt concentration also accelerate gelation. In the series of REE cations, no regular trends in the curing rates were revealed.

The curing was monitored by IR spectroscopy. The IR spectra of gadolinium sulfate solution in triglycidyl

phosphate and of the cured polymer are shown in Fig. 2. Metal ions open the epoxy ring, which follows from disappearance of the band at 920 cm^{-1}. Simultaneously, new bands at 1640 and 1290 cm^{-1} appear. The first of them can be assigned to vibrations of C–O–M bonds [11] formed by opening of the epoxy ring with REE ion. The band at 1290 cm^{-1} belongs to ether bonds C–O–C.

In the presence of REE ions, two mechanisms of epoxy ring opening are possible. At a low cation content, catalytic homopolymerization (with formation of C–O–C ether bonds) proceeds. At high REE salt concentrations, along with homopolymerization, epoxy ring opening can occur by binding of the metal ion (with formation of C–O–M bonds) and growth of the polymer chain. It was established by DSC that small (0.5–5 wt parts) amounts of REE triflates catalyze DGEBA polymerization with complete cross-linking at 120– 200°C [12]. From the temperature dependences of the dielectric loss tangent, we determined the glass transition points of polymers: 108.8, 95.1, 124.8, 110.5, and 93.1°C for the samples prepared with Yb^{3+}, La^{3+}, Ce^{4+}, Dy^{3+}, and Sm^{3+}, respectively.

It was found that the intensity ratio of the bands at 1290 and 1640 cm^{-1} decreases as the REE content increases. This shows that homopolymerization, prevailing at a low content of metal ions [12], gives way to the metal-coordination mechanism at high REE concentrations.

Reactions of **I**–**III** with REE salts yield hard polymers with the hardness of 130–150 MPa (see table).

The polymers prepared were studied thermomechanically. Figure 3 shows the thermomechanical curves of triglycidyl phosphate cured at 40°C with various amounts of yttrium nitrate. As seen, the glass transition point increases and deformation decreases with increasing salt concentration. The T_g values found from thermomechanical curves are also listed in the table.

The table shows that, for metal-coordinated polymers based on bi- and trifunctional GEPs, T_g differs only slightly. At low metal concentrations, this can be caused by the fact that in homopolymerization, characteristic for this concentration range, the three functional groups of triglycidyl phosphate are not fully converted. This is indicated by relatively low glass transition points. At high concentrations of metal ions, small differences in the glass transition and hardness for bi- and trifunctional GEPs can be explained by the fact that the thickness of the polymer network is determined by cross-links produced by coordination

with REE salts exhibit high transparency with 98–99% transmittance in the visible range for the materials based on La^{3+}, Y^{3+}, Sc^{4+}, Yb^{3+}, Tb^{3+}, Gd^{3+}, and Lu^{3+}. For the materials with REE ions absorbing in the visible range, we recorded the corresponding spectra. Some of them for liquid and cured REE-containing samples are shown in Fig. 4. As seen, curing does not affect the location and width of bands and weakly affects the background absorption. The spectra obtained have a better resolution as compared to the spectra given in [13] for glasses doped with the same REE, which are used as fiber amplifiers and lasers [14]. Thus, epoxy polymers doped with REE show promise as optical materials.

CONCLUSIONS

(1) The possibility of formation of metal-coordinated polymers in reaction of glycidyl esters of phosphorus acids with REE salts was demonstrated.

(2) Polymers obtained were characterized by electronic and IR spectroscopy and thermomechanically.

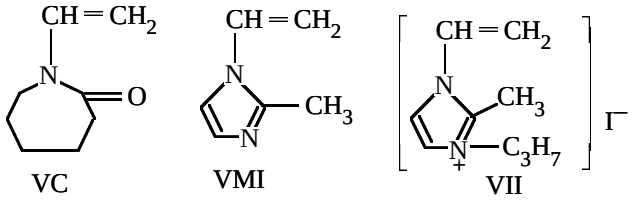
Abstract—Flocculation of a latex of SKS-30 ARK commercial rubber with homopolymers and copolymers of *N*-vinylcaprolactam, 1-vinyl-2-methylimidazole, and its quaternization product was studied. The flocculating power of the nonionic polymers in acid solution was evaluated. The performance of the copolymers grows with increasing content of cationic units in the macromolecules and on adding an acid.

An urgent problem in rubber production is development of methods of salt-free coagulation of latexes with synthetic and natural polymers, including proteins [1, 2]. An important advantage of coagulants based on natural products is that they are nontoxic and environmentally friendly. Protein hydrolyzates used as coagulating additives in industry [3, 4] are unstable in storage and nonuniform in composition; they also have other drawbacks. The undesirable properties of protein products are partially eliminated by performing coagulation with addition of salts. Promising coagulants for latexes are synthetic polymers with an amide (peptide) bond, containing ionic groups in the macrochain. These groups enhance the coagulation power of macromolecular compounds.

It is known [5] that polymers based on *N*-vinylcaprolactam (VC), containing an amide bond in the ring, are low-toxic and capable of complexation; their aqueous solutions have the lower critical solution point in the temperature interval of functioning of living bodies. Lozinskii *et al.* prepared a "protein-like copolymer" from VC and 1-vinylimidazole [6] with the structure resembling that of a globular protein. It was shown previously that 2-methylimidazole (MI) used in production of drugs, polymeric materials, and other products is suitable for latex coagulation [7].

In this work, we studied coagulation of a latex of SKS-30 ARK commercial rubber with a VC homopolymer and its copolymers with *N*-vinylimidazoles. As comonomers we used 1-vinyl-2-methylimidazole (VMI) and 1-vinyl-2-methyl-3-propylimidazolium iodide (VII). This choice was governed by the ease of preparing these monomers from readily available 2-methylimidazole (MI).



VC VMI VII

EXPERIMENTAL

VC (mp 33–34°C, bp 92–93°C/1 mm Hg) was prepared from caprolactam, acetaldehyde, and alcohol by the procedure described in [8]. VMI was prepared by thermal dehydration of 1-(2'-hydroxyethyl)-2-methylimidazole with a mixture of KOH and NaOH (1 : 1 by weight) at 150–160°C in the presence of hydroquinone. Fractionation yielded VMI with bp 64–66°C at 4 mm Hg and n_D 1.5250, which agrees with reference data [9].

Synthesis of 1-(2'-hydroxyethyl)-2-methylimidazole involved the reaction of MI with oxirane in DMF. Vacuum fractionation of the reaction mixture gives a product with mp 64–65°C (from ethyl acetate).

VII was prepared by quaternization of VMI with propyl iodide. A solution of VMI in absolute ethyl acetate was mixed with C_3H_7I at 5°C, stirred for 1 h, and allowed to stand for 12 h at the same temperature. The product was recrystallized from isobutyl alcohol and dried in a vacuum; mp 129–130°C, in agreement with published data [10].

1070-4272/03/7611-1839$25.00

Poly-*N*-vinylcaprolactam (PVC) and poly-1-vinyl-2-methylimidazole (PVMI) were prepared by radical polymerization in isopropanol at 70°C. The monomer concentration was 3.0 M, and the initiator [azobis(isobutyronitrile), AIBN] concentration, 3.0×10^{-2} M. Under such conditions, we prepared PVC with $M_\eta = 2.65 \times 10^4$, and at [VC] = 4.5 M, with $M_\eta = 8.2 \times 10^4$. PVC with $M_\eta = 3.5 \times 10^4$ was prepared by polymerization in benzene solution at 50°C for 5 h at [AIBN] = 1.5×10^{-2} M. The polymers were precipitated with hexane and vacuum-dried at 55–60°C. The molecular weights M_η were calculated from the intrinsic viscosities [η] by the formula $[\eta] = 1.5 \times 10^{-4} M_\eta^{0.68}$ [5]. PVMI had [η] = 0.17 dl g^{-1} in C_2H_5OH at 25°C.

The radical copolymerization of VC with VII was performed in ethanol, and that with VMI, in isopropanol (total concentration of comonomers 1 M) under conditions of thermal initiation (70°C, [AIBN] = 1×10^{-2} M). The mole fractions of the comonomers in the mixture were varied from 0.1 to 0.9. The products were precipitated with hexane and dried similarly to the homopolymers. Over the entire composition range, [η] of the homopolymers was 0.10–0.12 dl g^{-1} (for VC–VII in CH_3OH and VC–VMI in H_2O) at 25°C.

The copolymer compositions were determined by IR spectroscopy, from the intensity ratio of the absorption bands in the regions of 1635 (C=O vibrations of the VC units) and 1440 cm^{-1} (vibrations of the imidazole ring [11]).

Coagulation experiments were performed with a latex of commercial SKS-30 ARK rubber prepared with an emulsifying system based on disproportionated tall oil [12].

The coagulation power of the polymeric products was evaluated gravimetrically (by the weight of the coagulum formed) and visually (by the serum transparency). Coagulation was performed in a stirred flask containing 20 ml of a latex solution containing 1% dispersed phase (dry residue 18.65%). After thermostating at room temperature, the prescribed amount of an aqueous solution of a polymer was added with stirring. The consumption of the acidifying agent (2.0% sulfuric acid) was 15 kg t^{-1} rubber. The resulting coagulum was separated from the serum, washed with water, and dried to constant weight at 75–80°C.

Experiments on latex coagulation were performed with PVC (M_η 26.5×10^3 and 3.5×10^6) and with VC–VMI (VC mole fraction 0.57) and VC–VII (VC mole fraction 0.57 and 0.66) copolymers.

Since data on VC (M_1)–VII copolymers are lacking, we studied their radical copolymerization in ethanol under conditions of thermal initiation. From the data on composition of the copolymers obtained at low (up to 5–7%) conversions, we calculated analytically [13] the apparent copolymerization constants: $r_1 = 0.54 \pm 0.07$ and $r_2 = 0.03 \pm 0.02$. Thus, r_1 and r_2 differ considerably, with VII showing relatively low ($r_2 \approx 0$) activity. This is due to the fact that VII is charged, which prevents its addition to the propagating macroradical bearing like-charged units and favors addition of VC units.

We found that VC–VII copolymers with the VC mole fraction exceeding 0.55 are water-soluble like PVC of widely varied M_η. As the content of VC units decreases, the products become water-insoluble because of increased content of hydrophobic VII units.

The coagulation performance of the polymers was evaluated from the rubber flocculation curves, i.e., from the dependences of the weight fraction φ of the recovered polymer on the flocculant concentration *c*.

VC homopolymers differing in M_η and the VC–VMI copolymer without acidification showed no flocculating power. Nonionic PVMI tested for comparison behaved similarly. The curves of rubber recovery with PVC, PVMI (Fig. 1a), and VC–VMI copolymer (Fig. 1b, curve *8*) pass through a maximum (flocculation optimum), i.e., their shape is typical of flocculation of negatively charged sols (including latexes) with nonionic polymers and cationic polyelectrolytes [14, 15]. A decrease in the efficiency of rubber recovery at flocculant concentrations above the optimum is accounted for, according to the existing concepts [16], by restabilization of the system due to recharging of particles (addition of polyelectrolytes) and/or formation on their surface of a dense layer of adsorbed hydrophilic macromolecules, exerting a stabilizing effect (addition of nonionic polymeric flocculants).

The appearance of the flocculating power in an acidic solution may be due to two factors. First, the aggregative stability of the latex decreases owing to hydrolysis of carboxyl-containing surfactants (salts of fatty and other acids) to form insoluble and virtually nondissociating carboxylic acids showing no protective effect. In the process, the charge and potential of the particles and the thickness of the electrical double layer should decrease. As a result, the particles become able to approach each other to a distance at which the thickness of the adsorption layer of the macromolecules is sufficient for formation of interparticle bridges [16].

Second, the flocculating effect of PVC and VC–VMI copolymer, and also of PVMI in an acid solution may be associated with appearance of positively charged sites in the macromolecules due to protonation. In polymers containing VMI units, the protonation can occur at nucleophilic pyridine-like nitrogen atoms of the imidazole ring [17]. The protonation of azoles at the nitrogen atoms containing lone electron pairs in interaction with mineral acids is indicated in [18]. This is also suggested by the previously revealed [7] dramatic enhancement of the coagulating power of 2-methylimidazole in acid solution upon addition of increasing amounts of sulfuric acid.

In PVC and its copolymers, the possible protonation site in acid solutions is the C=O group of lactam units. This process was detected experimentally with a related polymer, polyvinylpyrrolidone [19], by NMR spectroscopy. According to [19], in acid solutions, at pH < 4, the ^{13}C NMR signal of the carbonyl carbon atom is regularly shifted downfield with increasing acidity. This suggests an increase in its positive charge and may be due to protonation of the carbonyl oxygen atom. Protonation of PVC is confirmed by certain experimental data. For example, with hydrogen ions in the latex replaced by Na^+ ions in an equimolar amount, the flocculation efficiency is extremely low, φ = 1–3% (Fig. 1, curve *4*). Hence, specifically appearance of cationic groups in PVC macromolecules, rather than an increase in the ionic strength of the medium, is the decisive factor responsible for coagulation. The efficiency of rubber recovery is also very low when an acid is added without a flocculant, whereas an increase in the acid concentration in the presence of PVC causes a sharp growth of φ (Fig. 1, curves *9* and *10*), presumably due to increasing protonation of the polymer macromolecules.

Thus, PVC (like PVMI) in acid solutions acquires the properties of a cationic polyelectrolyte. Its addition to a latex under these conditions should result in chemical binding of surfactant (stabilizer) anions with the cationic centers of flocculant macromolecules to form insoluble ionic complexes exhibiting no stabilizing effect. Such an interaction was detected nephelometrically in the presence of an acid in aqueous solutions of a mixture of PVC with Leukanol[1] [a nonhydrolyzable (in contrast to soaps) stabilizer present in latexes] (Fig. 2). Figure 2 shows that, as the acid concentration is increased, the turbidity first grows slightly and then sharply, suggesting formation of particles

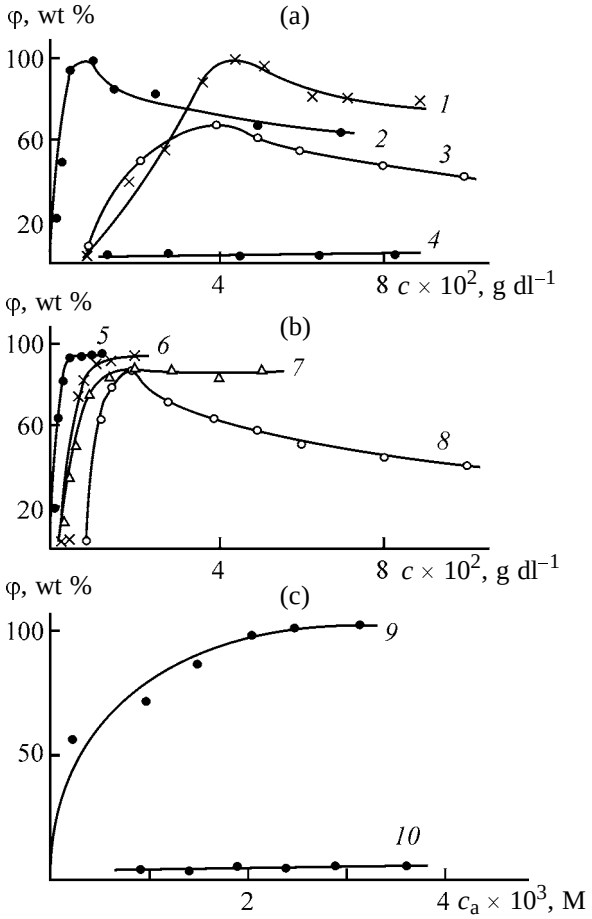


Fig. 1. Weight percentage of the recovered rubber φ as a function of the concentration of (a) homopolymers (*c*), (b) copolymers (*c*), and (c) acid (c_a). (*1*, *4*) PVC (M_η = 3.5×10^6), (*2*) PVMI, (*3*) PVC ($M_\eta = 2.65 \times 10^4$), (*5*, *7*) VC (mole fraction 0.66)–VII copolymer, (*6*) VC (mole fraction 0.57)–VII copolymer, (*8*) VC (mole fraction 0.57)–VMI copolymer, and (*9*) PVC ($M_\eta = 8.2 \times 10^4$). (*4*) NaCl concentration 3×10^{-3} M. H_2SO_4 concentration, M: (*1–3*, *5*, *8*) 1.5×10^{-3} and (*4*, *6*, *7*) 0. PVC concentration ($M_\eta = 8.2 \times 10^4$): (*9*) 2.2×10^{-3} and (*10*) 0.

of the insoluble oligomer–polymer complex [20]. In the absence of an acid, no interaction is observed in a wide range of Leukanol concentrations (Fig. 2, curve *2*).

It should be noted that, at the acid concentrations used in flocculation experiments (Fig. 2, point in curve *2* denoted with a circle), there is no noticeable increase in the turbidity. This fact apparently suggests that, under these conditions, the degree of protonation is low and the concentration of the forming complex is below the solubility limit at which the new phase starts to precipitate.

Thus, appearance of positive charges in polymer

[1] A mixture of sodium salts of an oligomeric product formed by condensation of β-naphthalenesulfonic acid with formaldehyde.

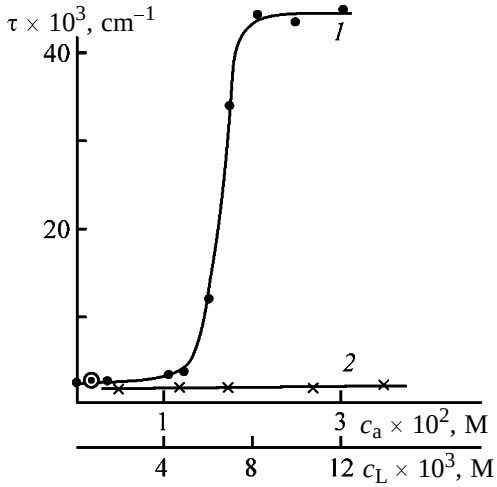

Fig. 2. Turbidity τ (*1*) of solution of PVC (M_η = 8.2 × 10^4)–Leukanol mixture (3.6 × 10^{-3} M each) as a function of H_2SO_4 concentration c_a and (*2*) of PVC solution (3.6 × 10^{-3} M) as a function of the Leukanol concentration c_L in the absence of the acid.

macrochains in acid solutions results in manifestation of the neutralization mechanism of flocculation, along with the bridging mechanism. The neutralization mechanism involves binding of surfactant (stabilizer) anions with cationic groups of the flocculant macromolecules.

Comparison of the curves for PVC and PVMI (Fig. 1a) shows that the polymer with an imidazole ring exhibits a stronger flocculating effect. This is indicated by the fact that the optimal flocculating concentration of PVMI (9.4 × 10^{-3} g dl^{-1}) is considerably lower than that of PVC (3.9 × 10^{-2} and 5.3 × 10^{-2} g dl^{-1} for samples with M_η = 2.65 × 10^4 and 3.5 × 10^6, respectively). The higher flocculating activity of PVMI and VC–VMI copolymers is due to the presence in the macromolecules of more basic imidazole rings which are protonated in acid solutions more efficiently than caprolactam units.

The influence of the molecular weight of the polymers on their flocculating effect was considered with PVC samples differing in M_η by a factor of more than 1000. We found that the floculation efficiency noticeably grew with increasing average molecular weight of PVC (with the sample having M_η = 3.5 × 10^6, the coagulum yield in the flocculation optimum is 100%, whereas with the relatively low-molecular-weight sample it is about 70%). Such a trend is characteristic of nonionic and weakly charged polymers (with which PVC in a weakly acidic solution can be classed) and is not observed with highly charged polyelectrolytes [15, 16].

Copolymers of VC with VII exhibit a higher flocculating power compared to PVC. Figure 1 (curves *5*–*7*) show that, on adding VC–VII copolymers to the latex, the yield of the recovered rubber sharply grows, reaching a virtually constant limiting value, φ_∞, starting from a certain critical concentration c_∞ of each copolymer. The flocculating power grows (c_∞ decreases, φ_∞ increases) on acidification (Fig. 1, curves *5* and *7*) and with increasing content of VII units in the macromolecules (curves *6*, *7*). This is due to an increase in the number of cationic groups in macrochains, which enhances the contribution of the neutralization factor to the latex destabilization. Furthermore, there is no restabilization branch in the flocculation curves obtained with the copolymers. This suggests a decrease in the adsorbability of copolymer macromolecules with hydrophilic charged groups. In the ascending portions of the flocculation curves, the adsorption of macromolecules is provided by electrostatic forces. After neutralization of the surface charge, such phenomena as further adsorption, densification of the adsorption layer of macromolecules, and enhancement of its protective function cease to be manifested, and the system remains strongly destabilized with excess copolymer also.

Thus, coagulation of a latex of a synthetic rubber can be effected with nonionic PVC and VC–VMI copolymer in acid solutions; copolymers of VC with a cationic monomer, VII, exhibit a flocculating effect in the absence of acid also, and this effect is enhanced upon acidification.

CONCLUSIONS

(1) Products of homopolymerization of *N*-vinylcaprolactam with a wide range of molecular weights and water-soluble copolymers with 1-vinyl-2-methylimidazole and 1-vinyl-2-methylpropylimidazolium iodide exhibit flocculating power and can be used for recovery of a synthetic rubber from a latex.

(2) Copolymers of *N*-vinylcaprolactam with *N*-vinylimidazole derivatives exhibit stronger flocculating effect than poly-*N*-vinylcaprolactam.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation and Properties of Polymers Derived from Epoxy Resins and Oligochelatotitanophenylenesiloxanes

Abstract—Oligochelatotitanophenylenesiloxanes of various structures were suggested as curing agents for epoxy resins. The compound formulas and curing conditions were chosen so as to ensure the maximal degree of cross-linking and hence the best physicomechanical properties of the polymers.

Preparation of polymers derived from epoxy resins and oligochelatotitanoarylenesiloxanes of the general formula

$$-[Ti(Ch)_2-O-Si(CH_3)_2-Ar-Si(CH_3)_2-O]_n-, \quad (1)$$

where Ch is a chelating ligand and Ar is phenylene, *p,p'*-diphenylene, or *p,p'*-oxydiphenylene, was reported in [1].

In this work we studied the reactions of oligochelatotitanoarylenesiloxanes with epoxy resins and the properties of the resulting polymers as influenced by the chemical structure of the curing agent and its content in the compound.

Experiments were performed with ED-20 epoxy–4,4'-isopropylidenediphenol resin (epoxide number 21.3), which was purified by filtration followed by vacuum drying, and oligochelatotitanoarylenesiloxanes prepared by heterofunctional condensation of bis(dimethoxysilyl)benzene with appropriate bis(chelato)dialkoxytitanium [2]. The characteristics of the oligochelatotitanoarylenesiloxanes prepared are listed in Table 1.

We found that the compounds containing various amounts of oligochelatotitanoarylenesiloxanes do not lose solubility after prolonged (for up to a year) storage at room temperature. However, in the course of storage, as in the case of epoxy–titanopolyether compounds [3, 4], their viscosity grows, though to a considerably lesser extent (Fig. 1). This may be due both to chemical reactions of the epoxy groups with the functional groups of the curing agent and to intermolecular interaction of the components [4, 5].

Curing of epoxy–chelatotitanophenylenesiloxane compounds starts at a noticeable rate at 160–200°C depending on the structure of the curing agent and its content in the compound. The process is manifested as a sharp ascent in the DTA curves [6]. Since curing of epoxy resins is an exothermic process, the compounds were heated stepwise from 150 to 200 or 220°C depending on the curing agent content. The curing time at each temperature was varied from 1 to 6 h, so as to ensure the maximal degree of cross-linking (content of soluble fraction ≤2%) and obtain high-quality cavity-free samples (Table 2).

The reaction of oligochelatotitanoarylenesiloxanes with the epoxy resin was studied by IR spectroscopy. Compounds were heated in a chosen stepwise curing mode, and at each temperature samples were taken to record the spectrum. Changes in the spectra became noticeable at 170°C. The bands at 920 and 865 cm^{-1}, characteristic of the epoxy group [7], decreased in intensity and fully disappeared at 200°C. In the range 900–920 cm^{-1}, there are also bands originating from

** (I) 150°C, 1 h; 160°C, 1 h; 170°C, 1 h; 180°C, 3 h; 190°C, 3 h; 210°C, 1 h; 220°C, 3 h; (II) 150°C, 4 h; 160°C, 3 h; 170°C, 3 h; 180°C, 3 h; 190°C, 3 h; 200°C, 3 h; (III) 150°C, 1 h; 160°C, 1 h; 170°C, 1 h; 180°C, 3 h; 190°C, 3 h; 200°C, 6 h.

the stretching vibrations of the ≡Si–O– bond in the ≡Ti–O–Si≡ fragment [8]. The absence of bands at 920 and 865 cm^{-1} in the spectra of the cured samples shows that not only the epoxy groups but also the ≡Ti–O–Si≡ groups are fully consumed. Also, in the compounds with the oligomers containing acetylacetonate (**I**) and dibenzoylmethanate (**II**) ligands at titanium, the bands at 1720 and 1745 cm^{-1}, usually characteristic of carbonyl groups in esters and ketones [7], appear at 170°C and grow in intensity on further heating. Similar changes in the spectra were observed on heating of a model mixture of dibutoxytitanium bis(acetylacetonate) or bis(dibenzoylmethanate) with phenyl glycidyl ether under similar conditions (temperature, time). The bands at 1720–1745 cm^{-1} continued to grow even after full consumption of the epoxy

groups. The bands characteristic of the oxirane ring virtually fully disappear in the presence of even catalytic amounts of the chelate component. With the oligomer containing 8-quinolinolato substituent (**III**), no absorption appears at 1720–1745 cm^{-1}.

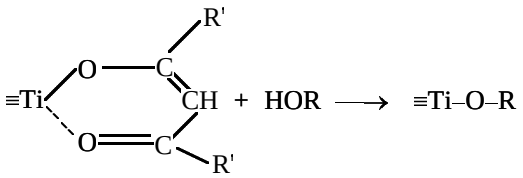
The changes observed in the IR spectra suggest that curing of the epoxy resin with oligochelatotitanoarylenesiloxanes involves the reaction of epoxy groups with the ≡Ti–O–Si≡ bonds by the following scheme:

$$-[Ti(Ch)_2-O-Si(CH_3)_2-Ar-Si(CH_3)_2-O]_n- + n\underset{\backslash\ O\ /}{CH_2-CHR'} \quad (2)$$
$$\rightarrow -[Ti(Ch)_2OCH(R')-CH_2O-Si(CH_3)_2ArSi(CH_3)_2-O]_n-,$$

and also polymerization of epoxy groups.

The suggested scheme of the reaction of the epoxy resin with oligochelatotitanoarylenesiloxanes is confirmed by an increase in absorption in the range 1040–1140 cm^{-1}, characteristic of compounds containing ≡Si–O–C≡ and ≡C–O–C≡ fragments [7].

Yatluk *et al.* showed [9] that heating of titanium complexes with β-dicarbonyl compounds to 150–200°C causes transformations of the chelating ligand to give ketones and esters. They are formed by Claisen retrocondensation of free ligands which, in turn, are released in reaction with alcohols formed by decomposition of the alkoxy groups in the titanium complex. Similar transformations probably occur when the OH groups of the epoxy resin react with the chelating ligand of the curing agent. Initially the epoxy resin adds to the curing agent molecule, displacing the chelating ligand:



$$+ R'CC(=O)CHR'OH, \quad (3)$$

where R is the epoxy resin residue; R' = CH_3, C_6H_5.

Then the resin reacts with the free ligand along the pathway of Claisen retrocondensation:

$$R'-COCH_2COR' + HR \rightarrow R'COOR + CH_3COR' \quad (4)$$

This process accounts for appearance of the ester absorption bands in the spectra of the cured product. The forming ketones, acetone or acetophenone, are apparently removed from the sample in the course of curing. It was shown for the acetylacetonate curing agent that curing is accompanied by up to 1.3% weight loss, in agreement with data of [9].

The density of the polymeric network was calculated from the thermomechanical curves by the method described in [10]. The results of calculating the molecular weight M_s of the chain segment between the cross-linking points are listed in Table 2. Depending on the composition and structure of the curing agent, M_s varies from 470 to 1130; the minimal values of M_s and hence the thickest networks are provided by the compounds containing 6–10 mol of the resin per mole of the curing agent.

This conclusion agrees with the dielectric properties of the cured polymer samples. The maximum in the temperature and frequency dependences of tanδ corresponds to the region of dipole-segmental loss, as it is manifested above the glass transition point of the polymers. From these data, we calculated the relaxation time logτ and the activation energy ΔG^* of the dipole-segmental process [3, 11]. The results are listed in Table 2. It is seen that, in the examined range of the polymer compositions, the least mobile networks (largest logτ and ΔG^*) are formed in curing of the compounds containing 6.6–10 mol of the resin per mole of the curing agent.

The thickest polymer networks, as a rule, determine the highest glass transition points T_g. The concentration dependence of T_g^d calculated from the temperature and frequency dependence of tanδ for the polymers derived from oligomer **II** is shown in Fig. 2. The same figure shows the T_g^t values (superscripts d and t refer to data obtained by the dielectric and thermomechanical data, respectively). The heights of the high elasticity plateaus, D_{he}, found from the thermomechanical curves, are plotted in Fig. 3. In all the cases, $T_g^t > T_g^d$, which is due to relaxation phenomena in the polymers. Despite similar mechanisms of the dielectric and mechanical phenomena, the nature of glass transition in these cases is different. Large loads permanently acting on a sample hamper relaxation in polymer and cause accumulation of strains, shifting the glass transition point (determined from the thermomechanical curves) to higher temperatures [12]. At the same time, T_g^d is determined by extrapolation of the temperatures at which tanδ (at a given frequency) is maximal to a frequency of 1 Hz. Hence, T_g^d corresponds to the temperature of structural glass transition corresponding to the equilibrium conditions. However, both methods show that high values of T_g and low

values of D_{he} are exhibited by polymers obtained by curing of a compound whose composition provides formation of the thickest network (10 mol of the resin per mole of the curing agent).

The physicomechanical properties of the polymers are listed in Table 2. The bending (σ_b) and tensile (σ_t) strength is plotted vs. composition in Fig. 4. It is seen that the dependences pass through maxima at the molar ratio of 8–10 mol of the resin per mole of the curing agent, i.e., at the compound formulas ensuring formation of the thickest network. Figure 4 also shows that, for the polymers derived from **II**, the strength maximum is slightly shifted toward higher resin content. The polymers derived from **I** have the highest σ_b and σ_t values. In the composition range differing from the optimum, the polymers also exhibit high strength. At a higher content of the curing agent, the stronger polymers are obtained with **I**, and at a lower content, with **I**.

For the polymers derived from **III**, there is no clear correlation between the properties and compound formula, which may be due to an additional effect of the nitrogen-containing ligand on the curing [13].

Thus, our studies showed that the polymers derived from the epoxy resin and oligochelatotitanophenylenesiloxanes have the highest density of cross-linking and the best physicomechanical characteristics at the molar ratio of the resin to the curing agent of 6.6–10. In this composition range, the physicomechanical properties of the polymers are similar to those of epoxy–titanopolyether polymers [3, 14]. At the same time, the polymers derived from the epoxy resin and oligochelatotitanophenylenesiloxanes have higher (by 90° on the average) softening point.

To accelerate curing of epoxy–chelatotitanophenylenesiloxane compounds, we used accelerators differing in the chemical nature: 2,4,6-tris(dimethylaminomethyl)phenol (UP-606/2), NaI, and a complex of dibenzo-18-crown-6 with KI (DBC). These catalysts were added in amount of 1 wt % to the compounds, which allowed the maximal temperature to be decreased by 40–50°C, and the curing time, by a factor of 2–3. The properties of the polymers obtained from one of the compounds with **II** in the presence of catalysts are listed in Table 3. It is seen that the physicomechanical properties of the products are similar to those of the polymers of the same compositions obtained without a catalyst. The softening point of the polymers and the working life of the compounds decrease (the latter, from 6 to 1 month).

The epoxy–chelatotitanophenylenesiloxane compounds were used as bases of adhesives for gluing ferrite–Sitall (devitrified glass) rods. The strength of the glued rods at static cantilever bending, σ_{cb}, is given in Table 3. It is seen that the strength of rod gluing with the compounds under consideration is as high as with epoxy–titanopolyether compounds [15].

* (IV) Heating from 20 to 150°C over a period of 2 h; 150°C, 3 h; (V) 120°C, 1 h; 130°C, 1 h; 140°C, 1 h; 150°C, 1 h; 160°C, 2 h; (II) see Table 2.

at 80°C for 30–40 min. The compounds contained 5–30 wt % curing agent, which corresponds to 33.7–2.7 mol of the resin per mole of the curing agent.

The viscosity η of the compounds was measured by the falling ball method at 25°C.

The IR spectra of the initial components, compounds kept at definite temperatures for definite periods, and cured polymers were measured on a UR-20 spectrophotometer with KBr, NaCl, and LiF prisms; the samples were prepared as mulls in mineral oil or 2% solutions in CH_2Cl_2.

The DTA curves were recorded on an OD-102 derivatograph at a heating rate of 5 deg min^{-1} in air.

The soluble fraction in the cured samples was determined by prolonged extraction with acetone in a Soxhlet apparatus.

The compression (σ_c), tensile (σ_t), and bending (σ_b) strength was determined with FM-250 and ZDM-5/91 tensile-testing machines, and the specific impact resilience a, on an MK-05 pendulum impact machine.

Thermomechanical measurements were performed on a device with a constant load of 8 kg cm^{-2}. The thermomechanical curves are plots of the strain D (%) vs. temperature. From these plots, we determined the glass transition point of the polymers T_g^t and estimated the height of the high elasticity plateau D_{he} [16]. The Vicat softening point T_V was determined on the same device as the temperature at which a rod with a tip area of 1 mm^2 sank into a sample to a depth of 1 mm under a load of 5 kg.

The dielectric properties (dielectric loss tangent $\tan\delta$ and dielectric permittivity ε') were determined with a TR-9701 bridge in the frequency range 0.5–200 kHz at 20–200°C.

CONCLUSIONS

(1) Oligochelatotitanophenylenesiloxanes prepared by heterofunctional condensation of bis(dimethyloxysilyl)benzene with appropriate bis(chelato)dialkoxytitanium were used as curing agents for ED-20 epoxy–4,4'-isopropylidenediphenol resin.

(2) Reactions of epoxy groups with functional groups of the curing agents were studied by IR spectroscopy. Conditions ensuring formation of the maximally cross-linked polymers were found.

(3) The best properties are exhibited by the polymers prepared from compounds with the molar ratio of the resin to the curing agent of 6.6–10.

(4) Adhesives based on epoxy–chelatotitanophenylenesiloxanes ensure high strength of glued ferrite–Sitall rods.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Concentration and Molecular Characteristics of Copolymers of Acrylamide with Sodium Acrylate on the Thoms Effect in Oil-in-Water Emulsions

V. A. Myagchenkov and S. V. Chichkanov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received April 12, 2003

Abstract—The effect of the concentration and molecular parameters of random copolymers of acrylamide and sodium acrylate on their performance as additives reducing the hydraulic resistance of turbulent flows in oil-in-water emulsions is quantitatively studied.

Water-soluble acrylamide (co)polymers are widely used in various stages of petroleum recovery, transportation, and refinery, particularly, as functional additives to control wellbore shale or to extend bentonite clay, as friction reducers to improve the performance of drilling facilities and transportation pipelines, and also for smoothing the profile of water injection well, oil dewatering and desalination, clean-up of equipment and pipelines to remove paraffin deposits, oily water clarification, etc. [1–3].

High-molecular-weight ionic and nonionic acrylamide (co)polymers prove to be among the most effective polymeric additives for reducing the hydraulic resistance of turbulent flows in oil-in-water and water-in-oil emulsions (Thoms effect) [1, 4]. The performance of polymeric additives as antiturbulence agents depends on a number of parameters, primarily on the polymer concentration and molecular characteristics [5, 6].

In this work, for such compositionally complex dispersion systems as oil-in-water (O/W) dispersions, we analyzed how the molecular weight (M) and M polydispersity of the polymeric additive, anionic acrylamide copolymer, influences the Thoms effect. It should be pointed out that the available information on the influence of the M polydispersity on the performance of copolymers as antiturbulence additives is limited, being not always correct [5, 6]. Only the behavior of cationic acrylamide copolymer in aqueous dispersions was studied systematically [7].

In this connection, one should take into account the fact that many chemical and physicochemical properties (including the Thoms effect) of copolymers depend not only on M and M polydispersity, but also on the mean composition of macromolecules $\bar{\alpha}$ and α polydispersity [8]. This problem, typical of common methods used for synthesis of random copolymers, such as ion and radical copolymerization and polymer-analogous reactions [9], was not given due attention in interpreting experimental data on the Thoms effect in dispersions containing random copolymers as additives.

An additional argue for the necessity of consideration of the influence of $\bar{\alpha}$ and α polydispersity on the resultant macroscopic Thoms effect in oil emulsions with ionic random copolymers of acrylamide and sodium acrylate as additives is that these parameters strongly affect the conformation state of the macroanions. In this work, in order to *a priori* exclude the effect of such characteristics of a polymeric additive as the $\bar{\alpha}$ and α polydispersity on the turbulent flow of oil emulsions, we used an unconventional method, mild ultrasonic disintegration (USD), for synthesis of the copolymer samples [10, 11].

EXPERIMENTAL

Anionic acrylamide copolymers differing in M, but similar in $\bar{\alpha}$ and α polydispersity were synthesized using USD from Alcoflood 1175A random copolymer of acrylamide and sodium acrylate [M_0 10.8×10^6; α 21.5% (weight percentage of ionic groups)]. As in [11, 12], USD synthesis of the copolymers was carried out with an UZDN-1 ultrasonic disintegrator at a frequency of 22×10^3 Hz in 0.1 M aqueous solution under specially selected mild conditions. In experiments we varied the ultrasonic field power and exposure time. Without taking into account the type of

1070-4272/03/7611-1850$25.00

terminal groups and chemical nature (acrylate or amide) of the polymer units where the macromolecular chain is broken, a simplified mechanism of ultrasonic disintegration in synthesis of the copolymer samples with various M can be presented as

$$\text{–(–A–)}_n\text{–(–B–)}_m\text{–} \rightarrow \text{–(–A–)}_{n_1}\text{–(–B–)}_{m_1}\text{–}$$
$$+ \text{–(–A–)}_{n_2}\text{–(–B–)}_{m_2}\text{–} + \cdots + \text{–(–A–)}_{n_1}\text{–(–B–)}_{m_1}\text{–}$$
$$+ \cdots + \text{–(–A–)}_{n_k}\text{–(–B–)}_{m_k}\text{–} + \dot{Z},$$

where A = CH_2–$\underset{\displaystyle CONH_2}{\underset{|}{CH}}$; B = –$CH_2$–$\underset{\displaystyle COO^-Na^+}{\underset{|}{CH}}$; $\dot{Z}$ are radicals inactive with respect to the rupture of the skeleton carbon–carbon bonds, whose nature appears to be inessential in analysis of general relationships of USD; $\sum_{i=1}^{k} n_i = n$, and $\sum_{i=1}^{k} m_i = m$.

As expected, with increasing exposure time, the number of breaks per macromolecule increased, and the degree of polymerization ($n_i + m_i$) of the polymer fragments formed in the course of USD decreased.

Mild conditions that were selected for USD allowed exclusion from consideration of such difficultly controllable reactions involving functional groups of the macromolecules as depolymerization and interchain interaction. It was demonstrated in particular experiments that USD of random copolymers of acrylamide and sodium acrylates could be interpreted in terms of the theory of random polymer degradation without depolymerization [13, 14]. Particularly, according to [13], the M polydispersity of USD products [estimated using the degradation scheme as the difference in ($n_i + m_i$) for the whole set of k fractions of the investigated copolymer] should follow the Flory statistics, and, therefore, the Schultz parameter $F = 1$ [14]. The USD procedure used permitted separation of eight samples with the maximal ($M_{max} = M_0$) and minimal (M_{min}) molecular weights differing by more than two orders of magnitude. The M_x of copolymer samples obtained in the course of USD was estimated by Eq. (1) using the initial sample with $M = M_0$ and $[\eta] = [\eta]_0$ as a reference ([η] is the intrinsic viscosity in 0.5 M NaCl).

$$M_x = M_0([\eta]_x/[\eta]_0)^{1/a}, \quad (1)$$

where a is the exponent in the Staudinger–Mark–Houwink equation (2).

$$[\eta] = kM^a. \quad (2)$$

We assumed $a = 0.814$ for all the samples of copolymers of acrylamide and sodium acrylate with $\alpha = 21.5\%$ [15].

For all the copolymers separated in the course of USD, $M_x \geq M_{min} = 0.08 \times 10^6$, suggesting that, for any fraction of any sample, $n_i + m_i > 500$. In accordance with concepts of the binary copolymerization theory [8, 16], the above inequality is equivalent, to a first approximation, to the fulfillment of relationships (3) for copolymer samples obtained upon USD.

$$\frac{n_1}{n_1 + m_1} = \frac{n_2}{n_2 + m_2} = \cdots = \frac{n_i}{n_i + m_i} = \cdots = \frac{n_k}{n_k + m_k}$$
$$= \frac{n}{n + m}. \quad (3)$$

It follows from these equalities that all the random copolymers of acrylamide and sodium acrylate obtained upon USD are identical not only in $\bar{\alpha}$, but also in the compositional nonuniformity, i.e., α polydispersity [8].

Also we used the ultrasonic disintegrator to obtain stable 10% O/W emulsions from dewatered and degassed crude oil (Aptugai oilfield, Perm oblast). Into a 300-ml conical flask containing fixed volumes of oil and water, a stabilizer was added in amount of 2% relative to the oil volume. The mixture was stirred for a short time on a magnetic stirrer and ultrasonicated for 15 min. As demonstrated by the microscopic data, the resulting emulsions were quite uniform with the particle size ranging from 0.7 to 1 μm, and no remarkable separation of the emulsion was observed in 10 days.

The performance of a polymeric antiturbulence additive in complex dispersion systems like oil emulsions can be correctly evaluated from the difference between the linear flow velocities across a capillary with (v) and without the additive (v_0) using a relative dimensionless parameter T [17]:

$$T = (v - v_0)/v_0. \quad (4)$$

The optimal capillary size for measuring the Thoms effect T in oil emulsions was determined in special experiments to be 0.5×38 mm (Reynolds number of water $Re = 5.2 \times 10^3$). Therefore, we measured the weights of emulsions with (m) and without (m_0) the additive, passed through the capillary in 30 s. The weights were measured on an A&D single-arm electronic balance (Japan). Under these conditions, Eq. (4)

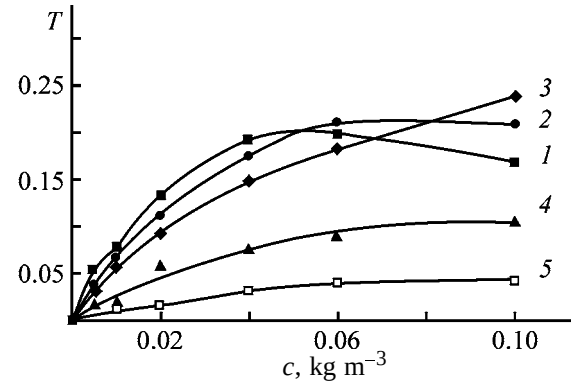

Fig. 1. Thoms effect T as a function of the concentration c of anionic acrylamide copolymers with various M. $M \times 10^{-6}$: (*1*) 10.80, (*2*) 5.08, (*3*) 3.30, (*4*) 1.07, and (*5*) 0.83.

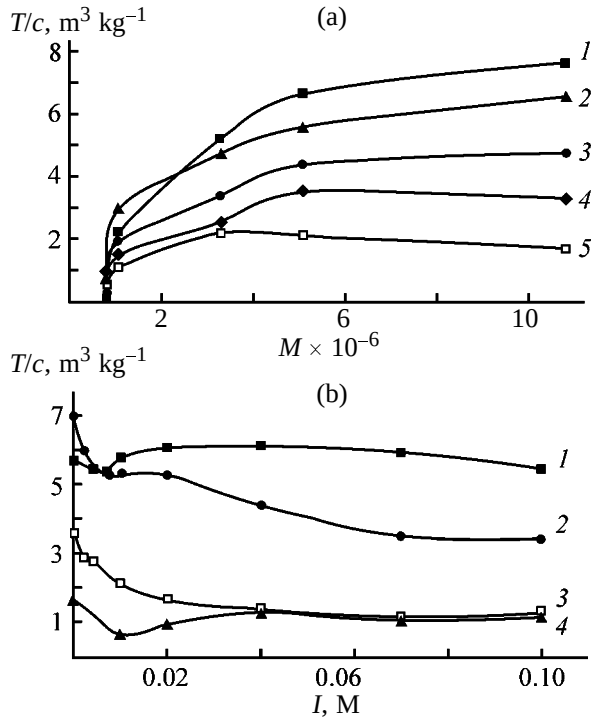

Fig. 2. Reduced Thoms effect T/c as a function of (a) molecular weight M of copolymers at various concentrations and (b) solution ionic strength I at c = 0.1 kg m^{-3}. (a) c (kg m^{-3}): (*1*) 0.01, (*2*) 0.02, (*3*) 0.04, (*4*) 0.06, and (*5*) 0.1. (b) $M \times 10^{-6}$: (*1*) 10.8, (*2*) 5.08, (*3*) 1.07, and (*4*) 0.83.

can be rewritten as

$$T = (m - m_0)/m_0. \quad (5)$$

To elucidate the performance of a specific (co)polymer as an antiturbulence additive for oil emulsions, it is necessary to analyze the effects of at least the (co)polymer concentration c and M on T. The concentration dependences of T are shown in Fig. 1 for several samples of anionic acrylamide copolymers with various M. As seen, the general concepts of the Thoms effect theory [5, 7] are valid in oil emulsions also, i.e., T increases with increasing c and M. To gain a better insight into the rheology of oil emulsions with polymeric additives, it was advisable to study the effect of each next portion of the additive on the macroscopic effect. In so doing, we pass from the parameter T to the reduced Thoms effect $\gamma = T/c$ [7, 14]. It is obvious that the higher γ, the higher the efficiency of a fixed portion of a polymeric antiturbulence additive, all other conditions being equal. As an illustration, Fig. 2 shows the reduced Thoms effect as a function of M for various concentrations of the polymeric additive. With increasing c, γ regularly decreases, especially in the case of the highest-molecular-weight sample with $M = M_0$, i.e., as c increases, the antiturbulence effect of the next portions of the additive decreases. It is clear from these results that the concentration dependence of the reduced Thoms effect should be necessarily taken into account in optimization of high-speed pipeline transportation of oil emulsions containing polymeric additives.

In recovery and transportation of crude oil as an O/W emulsion, the dispersion medium contains various electrolytes, primarily, salts, whose concentration amounts to several percents [18]. Therefore, the effect of the ionic strength on T is of not only scientific, but also practical interest. In this work we used NaCl as a supporting electrolyte. As seen from Fig. 2, T in O/W emulsions depends on the ionic strength of the dispersion medium, the dependence being less pronounced as compared to aqueous solutions [19]. In the emulsions, the electrolytic effect is reflected, most likely, in modification of the electrical double layer around the stabilized particles of the dispersed phase.

Figure 3 clearly shows the trend in the specific viscosity of O/W emulsions containing anionic acrylamide copolymers with various M and also the electrolyte. The adsorption coefficient β of anionic acrylamide copolymers in O/W emulsions was estimated from the viscometric data using Eq. (6)

$$\beta = \frac{\eta_{sp}^0 - \eta_{sp}}{\eta_{sp}^0} \frac{c}{S_{sp}(1 - q)}, \quad (6)$$

where S_{sp} is the specific surface area of 1 m^3 of the dispersed particles (for spherical particles $S_{sp} = 3/R$, where R is the particle radius); η_{sp}^0 and η_{sp}, specific viscosities of aqueous solutions of the copolymers (c = 0.1 kg m^{-3}) before and after contact with the

dispersed particles, respectively; and q, volume fraction of the aqueous phase in the emulsion.

The coefficient β thus obtained appeared to be comparatively small (2×10^{-2} mg m^{-2}). It is natural to attribute such a low β in O/W emulsions to strong electrostatic repulsion between similarly charged macroanions of the copolymer and anions of the stabilizer forming an adsorption layer of the potential-determining ions on the surface of the dispersed particles. Furthermore, the quite high T and $\gamma = T/c$ in O/W emulsions in the presence of the anionic acrylamide copolymers give an additional, indirect evidence in favor of this concept.

Except for [7], the extensive literature on various aspects of the Thoms effect contains practically no systematic quantitative information of the influence of the M polydispersity and compositional polydispersity on T. In this work, the samples of random copolymers of acrylamide with sodium acrylate were identical in $\bar{\alpha}$ and α polydispersity. Therefore, no fundamental problems could arise in preparing systems with fixed $\overline{M} = 3.3 \times 10^6$ and various M polydispersity. The composition of the systems with $\overline{M} = 3.3 \times 10^6$ was estimated as in [7]. As a quantitative criterion for evaluation of the M polydispersity of the copolymers we used the Schultz parameter F [7, 19] defined as

$$F = (\overline{M}_w/\overline{M}_n) - 1 = \sum_{i=1}^{k} \omega_1 M_1 \sum_{i=1}^{k} (\omega_i/M_i) - 1, \quad (7)$$

where $\overline{M}_w$ and $\overline{M}_n$ are the weight-average and number-average molecular weights of the systems, and ω_i, weight fraction of the ith component of the mixture, i.e., of a copolymer with $M = M_i$ (k is the number of copolymer kinds in the mixture).

Higher F in a given mixture compared to the reference is indicative of its greater M polydispersity.

The concentration dependences of T are given in Fig. 4 for a series of the most typical copolymer mixtures with fixed $\overline{M} = 3.3 \times 10^6$. It is clearly seen that the resultant macroscopic Thoms effect correlates with the M polydispersity of oil-in-water emulsions.

In Fig. 5, the Thoms effect is plotted as a function of the Schultz parameter F in O/W emulsions at various ionic strengths. The presence of a maximum and a minimum in this plot suggests complexity of the turbulent flow mode in this system, which is reflected primarily in nonadditive contributions of copolymers with various M to the resultant macroscopic Thoms effect. Knowingly not touching upon a very complicated and in a number of points debatable mechanism

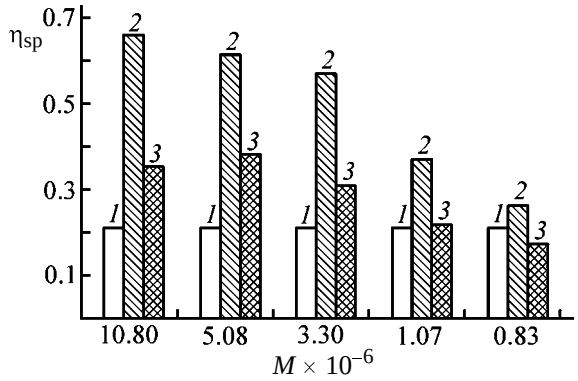

Fig. 3. Specific viscosity histogram for the system oil emulsion–polymer–electrolyte: (*1*) emulsion, (*2*) emulsion–polymer (0.1 kg m^{-3}), and (*3*) emulsion–polymer (0.1 kg m^{-3})–electrolyte (0.1 M NaCl).

of turbulent flow of O/W emulsions in multicomponent systems with water-soluble anionic acrylamide copolymer additives, it may be established that, apart from traditional control tools of the process, there is an unconventional approach based on control of the M and α polydispersities of a copolymer additive [7]. Without question, carrying out intensive experimental and theoretical studies in this direction will promote development and application of optimal regimes of high-speed pipeline transportation of oil emulsions with additives based on water-soluble acrylamide (co)polymers.

CONCLUSION

Samples of copolymers identical in the composition and polydispersity, but having different molecular weights were obtained by ultrasonic disintegration of macromolecules at the skeleton carbon–carbon bonds.

Precipitation of Titanium(IV) and Iron(III) Phosphates from Sulfuric Acid Solutions

L. G. Gerasimova and M. V. Maslova

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received March 13, 2003

Abstract—Conditions for the precipitation of phosphates from solutions of titanium(IV) sulfate containing iron(III) were studied. The precipitation of components and the mechanism of the phase formation in the system under study were considered in relation to the $TiO_2 : Fe_2O_3$ ratio in the starting solution.

Titanium(IV) phosphates are well-known synthetic products used for obtaining high-quality white paper and light-resistant plastics, for filling construction and paintwork materials, and also as sorbents. Each of these fields imposes specific demands on the composition and properties of the product, which depend on the composition of the raw materials and conditions of the synthesis.

Titanium(IV) phosphates are usually obtained from sulfuric-hydrochloric acid titanium-containing solutions by adding phosphoric acid [1–3]. If process solutions containing impurities of other ions apart from titanium(IV) are used for this purpose, the target product can be contaminated with these impurities because of the equal solubility of their phosphates or of their sorption on the surface of the titanium phosphate precipitate.

In this work we studied the conditions for the precipitation of titanium(IV) and iron(III) phosphates from sulfuric acid solutions containing various quantities of these components. Such solutions are obtained by the sulfuric acid processing of titanium-containing raw materials: sphene, perovskite, and ilmenite. In particular, sphene solutions intended for obtaining pigment titanium dioxide by thermal hydrolysis contain 150–250 g l^{-1} TiO_2 and up to 5 g l^{-1} Fe_2O_3; perovskite solutions, up to 20 g l^{-1} Fe_2O_3; and ilmenite solutions, up to 100 g l^{-1} Fe_2O_3 [4–6]. Wastewater to be treated contains up to 10 g l^{-1} TiO_2 and from 5 to 80 g l^{-1} iron (in terms of Fe_2O_3).

The following data were the prerequisites for our study. Titanium(IV) forms a hydrated solid phase on adding H_3PO_4 to its solutions over a wide range of their concentration and acidity. The number of aqua groups in the precipitate depends on the conditions of its preparation [7, 8]. At the same time, hydrated iron(III) phosphates under the action of phosphoric acid are precipitated from sulfuric acid solutions to a small extent [9–11]. The mechanism of the formation of the phosphate solid phase in mixed iron–titanium solutions is poorly understood.

In our study we used a titanium(IV) sulfate solution (concentrations of TiO_2 and H_2SO_4 1.75 and 4.25 M, respectively) prepared by dissolving titanium(IV) hydroxide in sulfuric acid, and also a solution of iron(III) sulfate (Fe_2O_3 concentration 0.625 M). We stirred the solutions (the starting volume of the solutions corresponded to a specified $TiO_2 : Fe_2O_3$ ratio) for 30 min and added concentrated H_2SO_4 up to 4.5 M. We used 81% solution of H_3PO_4 as a precipitant. Its consumption corresponded to the molar ratio $(TiO_2 + Fe_2O_3) : P_2O_5 = 1 : 1$. We added phosphoric acid to the solution under study gradually over a period of 0.5–1 h with stirring and heating (T = 80°C). Then the suspension was allowed to stand for 2 h, after which the precipitate was separated from the liquid phase and washed with water to pH 7. We determined the composition of the liquid phase (the contents of TiO_2, Fe_2O_3, and P_2O_5) by chemical analysis, and the composition of the solid phase, by the X-ray spectral analysis. For this purpose, we calcined the precipitates at 800°C. We studied the structure of the precipitates by optical microscopy, IR spectroscopy, and X-ray phase analysis.

Figure 1 shows the effect of the starting composition of the solution on the degree of passing of the components into the precipitate on adding H_3PO_4. The TiO_2/Fe_2O_3 concentration ratio was chosen as the characteristic of the solution.

* In the starting solution.

In the range of titanium(IV) concentrations in the solution corresponding to the ratio TiO_2/Fe_2O_3 = 4–20 (the Fe_2O_3 concentration is 0.0625 M and does not change), at the above-noted H_3PO_4 consumption, titanium(IV) is precipitated almost completely. For TiO_2/Fe_2O_3 = 4, the degree of iron(III) precipitation increases from 30 to 55% (in terms of Fe_2O_3) as the titanium(IV) concentration in the solution increases. Under similar conditions, no precipitate is formed from the solution of pure iron(III) sulfate. We emphasize that about 50% of H_3PO_4 (in terms of P_2O_5) is not involved in the reaction and remains in the liquid phase. For a low titanium(IV) concentration in the solution under study (0.125 M in terms of TiO_2) and the ratio TiO_2/Fe_2O_3 = 0.25–0.5, the phosphate precipitate contains from 3 to 7% Fe_2O_3. The degree of titanium(IV) precipitation decreases as the concentration of iron(III) increases.

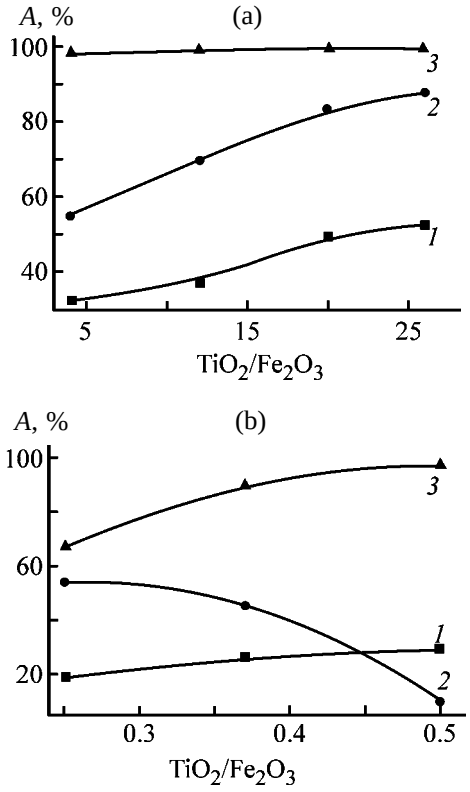

Fig. 1. Degree of precipitation of the main components *A* as a function of the TiO_2/Fe_2O_3 molar ratio in solution. Content in the starting solution, M: (a) Fe_2O_3 0.065 and (b) TiO_2 0.125. (*1*) Fe_2O_3, (*2*) P_2O_5, and (*3*) TiO_2.

On the basis of the data from [12, 13], we may state that titanium(IV) and iron(III) are combined into a pseudocomplex in sulfate solutions. Its presence affects the titanium(IV) precipitation and the composition of the resulting precipitate. The data of crystallooptical analysis suggest that the precipitates consist of two phases. The impurity phase seems to be based on the iron–titanium complex (its study was beyond the scope of this work). Since the degree of iron(III) precipitation is lower than the maximal degree, we can suggest that the composition and stability of such complexes depend on the composition of the starting mixed solutions. As the titanium(IV) concentration in the starting mixture increases, the amount of iron(III) bound to titanium(IV) and, as a consequence, the degree of iron(III) precipitation grow also. In the case of a considerable excess of iron(III) relative to titanium(IV), the stability of iron–titanium complexes increases, which hampers the formation and further precipitation of hydrated titanium phosphate. In this case, the degree of iron(III) precipitation is about 25% (in terms of Fe_2O_3).

The compositions of the precipitates isolated from the iron–titanium sulfate system under study on adding phosphoric acid are given in the table. Since the precipitates are very poorly crystallized, the X-ray and IR data do not offer a sufficiently precise information on their phase composition and character of bonds. Therefore, we determined the composition of the

precipitates by chemical analysis. The samples were first dried at 105°C and then calcined at 850°C. In so doing, we determined the moisture content and calcination loss (see table).

Comparison of the compositions of the filtrates obtained after separating the phosphate precipitate and of the final products allows the following conclusions. At a high starting concentration of TiO_2, iron(III) precipitated from the solution has a low solubility in water; its content in the final product corresponds to the degree of its precipitation in the presence of H_3PO_4. The content of iron(III) precipitated from the solutions with its high concentration does not correlate with the degree of its precipitation. Iron(III) seems to be sorbed on the active surface of the phosphate precipitate, and its washing with water results in its desorption and passing into washing water.

CONCLUSION

On adding orthophosphoric acid into iron–titanium sulfuric acid solutions, precipitates are formed over a wide range of titanium(IV) and iron(III) concentrations. These precipitates consist mainly of hydrated titanium(IV) phosphate with an impurity of iron(III) phosphate, which does not exceed 0.66% in terms of Fe_2O_3. At a high iron(III) concentration in the solution, it is sorbed on the surface of hydrated titanium(IV) phosphate particles. However, the sorption involves no chemical reaction. The data obtained can be used for separating titanium(IV) and iron(III) in acid sulfate solutions.

Choice of a Stabilizer for the Reaction of KOH with Hydrogen Peroxide To Produce Potassium Superoxide

N. F. Gladyshev, S. I. Dvoretskii, D. V. Zhdanov, M. A. Ul'yanova, and Yu. A. Ferapontov

Tambov Research Chemical Institute, Federal State Unitary Enterprise, Tambov, Russia

Received April 1, 2003

Abstract—A stabilizer for the reaction of KOH and H_2O_2 yielding potassium superoxide was proposed. The stabilizer does not affect the main consumer properties of the regenerative product based on KO_2.

Potassium superoxide KO_2 is the most widely used substance for self-contained human respiratory apparatus. The use of KO_2 is based on its capability to chemisorb moist carbon dioxide, generating oxygen required for breathing [1].

Development of a new process for KO_2 production involved certain problems related to the process conditions and qualitative composition of the final product. One of these problems is considered in this paper.

EXPERIMENTAL

According to the suggested process [1–4], potassium superoxide is produced from potassium hydroxide and hydrogen peroxide by their mixing in the molar ratio $H_2O_2 : KOH = 1.75 : 1$ with subsequent disproportionation of the intermediate adduct $K_2O_2 \cdot 2H_2O_2$ in a spray-type reactor. The process can be described by the following reaction equations:

$$2KOH + 3H_2O_2 = K_2O_2 \cdot 2H_2O_2 + 2H_2O, \quad (1)$$

$$K_2O_2 \cdot 2H_2O_2 = 2KO_2 + 2H_2O. \quad (2)$$

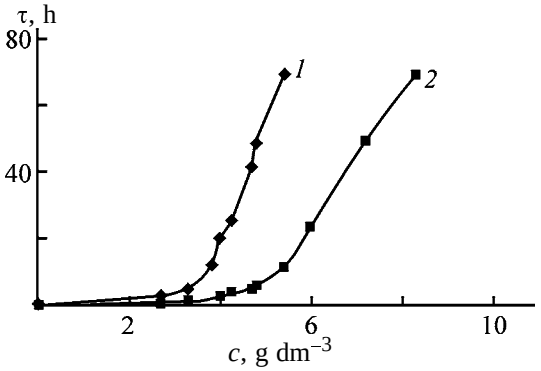
The reaction of hydrogen peroxide with potassium hydroxide is strongly exothermic under normal conditions and is accompanied by decomposition of the peroxide products and evolution of atomic oxygen. Therefore, to carry out the process, it is necessary either to cool the reaction area, which requires additional power consumption, or to add a stabilizer. By the stability of various solutions of peroxide compounds is meant the capability to preserve their available oxygen (decrease in the absolute content of available oxygen should not exceed 0.5 wt %) for a long time.

The best stabilizers of concentrated alkaline solutions of H_2O_2 are $Na_4P_2O_7$, magnesium salts of mineral acids, and certain organic compounds [5–10].

Up to now, there are no strict scientific principles for the choice of stabilizers for H_2O_2 solutions preventing their decomposition [6]. Therefore, the stabilizers are mainly chosen empirically depending on the composition of a particular solution containing H_2O_2 or other peroxides. Since H_2O_2 alkaline solution is used further for obtaining potassium superoxide and the regenerative product thereof, the suitable stabilizers should meet certain requirements concerning their toxicity, thermal stability, chemical resistance to atomic oxygen, etc. Organic compounds are unsuitable as stabilizers for H_2O_2 alkaline solutions because of the possibility of their oxidation with potassium superoxide, accompanied by burning and explosion. Among inorganic salts, magnesium sulfate and $Na_4P_2O_7$ are the best stabilizers of H_2O_2 alkaline solutions. These compounds were used in this work to obtain potassium superoxide and the regenerative product thereof.

A specified amount of a stabilizer was dissolved in a 50% H_2O_2 solution. The solution was placed in a reactor cooled with tap water stream, and a 50% KOH solution was added slowly with stirring. We found that KOH reacts with H_2O_2 under these conditions without decomposition of peroxide products (simple acid–base interaction) at the molar ratios $H_2O_2 : MgSO_4 \geq 700 : 1$ and $H_2O_2 : Na_4P_2O_7 \geq 590 : 1$. According to the chemical analysis [11], the available oxygen content in the resulting solution is close to that calculated theoretically. It is known from the literature that each stabilizer has its own critical concentration up to which it is effective. A greater amount of the stabilizer could even promote peroxide solution decomposition [7]. Furthermore, the process being developed for producing KO_2 requires that the H_2O_2 alkaline solutions be stable for no less than one day. Therefore, to choose the optimal concentration of a stabilizer for

1070-4272/03/7611-1858$25.00



Time τ of stability of H_2O_2 alkaline solution as a function of the stabilizer concentration *c*: (*1*) $MgSO_4$ and (*2*) $Na_4P_2O_7$.

the H_2O_2 alkaline solution, we studied how the time of stability of the resulting solution depends on the stabilizer content in the starting H_2O_2 solution. The results are shown in the figure.

These data show that the amount of $MgSO_4$ per unit volume of the starting H_2O_2 solution, required for the stabilization of the reaction between H_2O_2 and KOH and for the further storage of the resulting solution, is less than that of sodium diphosphate, all other things being equal. Therefore, $MgSO_4$ is preferable as the stabilizer. In addition, $MgSO_4$ is more readily available and cheaper than $Na_4P_2O_7$.

According to the experimental data [2], $MgSO_4$ does not affect the qualitative composition of the final product, i.e., when hydrogen peroxide stabilized with $MgSO_4$ is used, the product obtained by the above-described technique is the same as the product obtained from H_2O_2 without adding magnesium sulfate (all other factors being the same). This conclusion is confirmed by chemical analysis.

It was found that, with magnesium sulfate used as a stabilizer for the reaction of H_2O_2 with KOH, granulated KOH could be used instead of the 50% KOH solution. In this case, peroxide products did not decompose either.

Our experiments showed that, with time, the resulting H_2O_2 alkaline solution acquired a distinct yellow color suggesting the presence of superoxide ion. That is, colorless diamagnetic peroxide ions O_2^{2-} disproportionate directly in the solution to give colored paramagnetic superoxide ions O_2^-. We found no indications on this phenomenon in the available literature. Kazarnovskii [12] studied this process only for solid compounds. To confirm the occurrence of this process in solution, we started the magnetic susceptibility measurements. The preliminary results confirm the presence of diamagnetic ions in the resulting H_2O_2 alkaline solutions. It should be noted that superoxide ions remain stable in aqueous solution under study for a rrelatively long time. This is important, because all superoxides are known to readily decompose on contact with water to the corresponding alkali with oxygen evolution.

CONCLUSIONS

(1) A study of the stability of potassium peroxide peroxosolvate solutions by chemical analysis showed that the solution stabilized with $MgSO_4$ (in the molar ratio $MgSO_4 : H_2O_2 = 1 : 750$) remains stable for one day at temperatures of up to 25°C.

(2) Diamagnetic peroxide ions O_2^{2-} disproportionate to give paramagnetic superoxide ions O_2^- directly in solution.

Optimization of *tert*-Butyl Perbenzoate Purification

I. A. Solodova, I. P. Gorokhova, V. V. Zakhvatov, G. M. Salikhova, E. V. Maryanina, and Ch. B. Medvedeva

Kazan'orgsintez Open Joint-Stock Company, Kazan, Tatarstan, Russia

Received March 26, 2003

Abstract—Purification of *tert*-butyl perbenzoate with an $Na_2S_2O_5$ solution was studied.

tert-Butyl perbenzoate (TBPB) is widely used as high-temperature polymerization initiator in production of polyethylene, polystyrene, and vinyl acetate plastics. The quality of commercial TBPB is determined by its purity, i.e., by the degree of removal of numerous impurities: *tert*-butyl hydroperoxide (TBHP), di-*tert*-butyl peroxide (DTBP), benzoic acid (BA), *tert*-butyl alcohol (TBA), benzotrichloride (BTC), etc.

The major impurities in TBPB prepared by the two-step procedure [1] are DTBP, TBHP, and BA. In the first step (preparation of TBHP sodium salt), DTBP is removed by washing with benzine in which DTBP dissolves better than TBHP sodium salt. In the second step, TBPB is prepared from TBHP sodium salt and benzoyl chloride; the product is purified to remove TBHP with an NaOH solution [1]. The TBHP sodium salt formed in the process is removed from TBPB by subsequent washings with water. In practice, to obtain TBPB meeting TU (Technical Specifications) 6-05-1997–85 (main substance content no less than 98.5%, TBHP content no more than 0.1%), the reaction product is usually washed with five or six portions of NaOH solution and four portions of water to pH 6–8.

This procedure is time-consuming (it takes a half of the total time for the whole cycle of TBPB production). Therefore, development of a more efficient procedure for TBPB purification is an urgent problem.

The use of a sulfite buffer solution for washing of hydroxy-*tert*-alkyl peroxyesters is mentioned in patents [2, 3], mainly devoted to synthesis of peroxides.

In this work we studied purification of TBPB with an $Na_2S_2O_5$ solution.

tert-Butyl perbenzoate was washed with 33 wt % NaOH solution. The alkali content in the product being purified was 2.6 wt %. The number of alkaline washing runs n_{OH^-} was varied from 0 to 5. After that, TBPB was washed with one portion of 8% $Na_2S_2O_5$ and up to four portions of water.

In the course of purification, we determined the TBHP content before and after purification and monitored the pH of the aqueous extract. The purified TBPB was analyzed for the content of the main sub-

stance, TBHP, and BA. TBPB was determined by iodometric titration in the presence of $CuCl_2$ in isopropyl alcohol–acetic acid; TBHP, by iodometric titration in methanol–toluene in the presence of pyridine; and BA, by high-frequency titration with an alkali solution. The analytical data are listed in the table.

Purification with an $Na_2S_2O_5$ solution without preliminary washings with NaOH is inefficient, as it leads to a decrease in the main substance content. Apparently, in an acid solution, TBPB decomposes to form benzoyl chloride, which is subsequently hydrolyzed to BA.

The table shows that, as the number of OH^- washing runs is increased, the TBHP content in TBPB decreases. The required level of purity is attained only after $n_{OH^-} = 5$. If OH^- washing is followed by treatment with an $Na_2S_2O_5$ solution, one alkaline washing is sufficient to attain the required purity. This is probably due to the fact that, on the one hand, in alkaline washings NaOH binds free TBHP, and, on the other hand, alkaline medium promotes hydrolysis of TBPB to TBHP and BA. This assumption is also confirmed by the fact that treatment with an $Na_2S_2O_5$ solution decreases the BA content in TBPB. Washing of TBPB with an $Na_2S_2O_5$ solution decreases the pH of the TBPB being purified from 11.0 to 5.4–6.2, which makes washing of TBPB with water more efficient and allows the number of washing runs to be decreased.

Thus, purification of TBPB with an $Na_2S_2O_5$ solution in combination with alkaline washings is more efficient, as it improves the purity of the commercial product and reduces the purification time and the volume of wash waters.

The purification procedure developed can be recommended for commercial use.

CONCLUSION

Treatment of *tert*-butyl perbenzoate with an $Na_2S_2O_5$ solution improves the quality of the commercial product and reduces the purification time.

Effect of Transition Metal Diketonates on Oxidation of Sunflower-Seed Oil

Zh. V. Shmyreva, L. V. Moiseeva, L. F. Ponomareva, Yu. E. Zelenskaya, and T. Yu. Dolgova

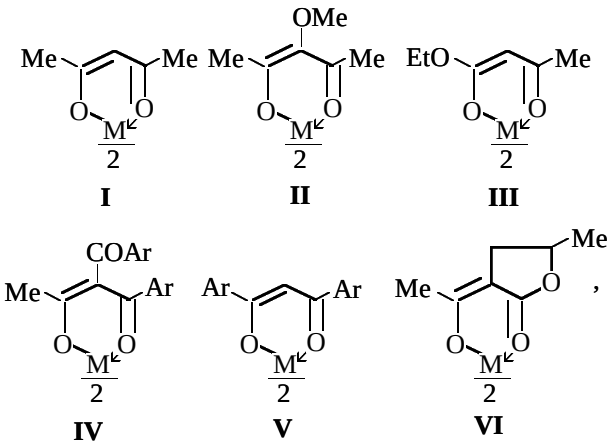
Voronezh State University, Voronezh, Russia

Received June 2, 2003

Abstract—Effect of transition metal (Mn, Fe, Co, Ni, Cu, Zn) diketonates on oxidation of sunflower-seed oil with atmospheric oxygen was studied.

Among a number of transition metal complexes, diketonates are of interest due to capability to catalyze oxidation of hydrocarbons. It is known that the catalysis direction can change, with oxidation catalysts becoming inhibitors.

In this work, the data on the effect of 20 transition metal (Mn, Fe, Co, Ni, Cu, Zn) β-diketonates of series **I**–**VI** on the catalysis direction in oxidation of sunflower-seed oil with atmospheric oxygen were summarized and correlated to reveal how the activity depends on the ligand structure and metal type:



where **I** are complexes with acetylacetone; **II**, with metoxyacetylacetone; **III**, with acetoacetic ester; **IV**, with acetylbenzoylmethane; **V**, with dibenzoylmethane; and **VI**, with α-aceto-γ-methyl-γ-butyrolactone chelates.

The choice of the oxidation substrate was determined by its practical significance in study of oxidative degradation of edible oils and pharmaceuticals [1]. For series **I**–**VI**, by an example of copper and nickel complexes, we considered the effect of ligand, and for series **I** and **VI**, the effect of metal type. The relative activity constant K_{rel} determined as

$$K = \omega_{O_2(chel)}/\omega_{O_2(oil)},$$

where $\omega_{O_2(chel)}$ is the rate of atmospheric oxygen uptake at substrate oxidation in the presence of metal complex and $\omega_{O_2(oil)}$ the rate of oxygen uptake without additives (ml min^{-1}), is the quantitative characteristic of the metal complex catalytic activity.

In other words, K_{rel} is a factor by which the rate of oxygen uptake with a definite volume of the substrate changes in the presence of a metal diketonate. Correspondingly, the inequality $K_{rel} > 1$ indicates a positive catalytic effect of the metal complex, and $K_{rel} < 1$, inhibiting effect (negative catalysis). The data obtained are listed in Tables 1 and 2.

Comparison of K_{rel} for copper and nickel chelates **I**–**VI** reveals higher sensitivity of the nickel complexes to the ligand structure as compared to copper complexes. For example, for Ni-**III** and Ni-**IV**, the activity gets inverted ($K_{rel} < 1$), while copper chelates with all ligands show only positive catalytic activity. It is interesting that, whereas the Cu-**IV** complex

Table 1. Influence of the ligand structure on the catalytic activity of Cu and Ni diketonates **I**–**VI**

M	K_{rel}					
	I	**II**	**III**	**IV**	**V**	**VI**
Cu	2.5	3.2	3.2	1.3	3.1	2.7
Ni	1.4	1.3	0.7	2.8	1.3	0.2

1070-4272/03/7611-1862$25.00

Table 2. Influence of the metal type on the chelate activity in oxidation of sunflower-seed oil

Diketonate	K_{rel}					
	Mn	Fe	Co	Ni	Cu	Zn
I	2.8	1.8	4.4	1.4	2.5	0.7
VI	0.4	0.2	0.3	0.2	2.7	0.6

show decreased activity, the Ni-**IV** complex exhibits increased activity. For the Ni-**III** and Ni-**VI** chelates, $K_{rel} < 1$, indicating activity inversion.

A previous study of the activity of transition metal chelates with **VI** [2] in oxidation of dehydroabietic acid reveal a substantial dependence of the oxidation rate on the metal type.

The relative activities of series **I**–**VI** are compared in Table 2. As seen, K_{rel} sharply decreases for complexes with **VI**, excluding the copper chelate, i.e., the activity inversion takes place virtually irrespective of the metal. In the case of complexes **I**, the activity of chelates decreases in the order Co > Mn > Cu > Fe > Ni, Zn, which mainly agrees with data of [3]. It is known [4] that the electrode potential of the metal ion and the complex stability are factors determining the catalytic activity of the chelate. For acetylacetonates **I**, the activity variation does not correlate with any of the above parameters.

Thus, for diketonates studied, the variation of the ligand structure can be accompanied by changes in the direction of catalytic activity in sunflower-seed oil oxidation, which substantially broadens possible applications of these complexes.

EXPERIMENTAL

The synthesis of transition metal chelates and their structures are described in [5]. Acetylacetonates **I** were prepared similarly. Metal chelates with **II**–**V** were prepared as in [6].

The metal chelate activity was estimated in oxidation of the unrefined sunflower-seed oil with atmospheric oxygen without initiator at $60 \pm 0.1°C$; A metal chelate concentration did not exceed 10^{-3} M. The measurement results were treated by the method described in [7]. For all measurements, $r \geq 0.97$, which shows that the volume of oxygen taken up v_{O_2} linearly depends on time:

$$v_{O_2} = f(\tau) \equiv y = kx + b,$$

where x is the time of uptake; y, amount of oxygen taken up; and k, proportionality coefficient, $k = \tan\alpha = dv_{O_2}/d\tau = \omega_{O_2}$, where ω_{O_2} is the rate of oxygen uptake.

CONCLUSIONS

The catalytic activity of transition metal β-diketonates in oxidation of sunflower-seed oil with atmospheric oxygen was studied, and high activity of copper chelates, independent of the ligand structure, was revealed. The possibility of inversion of the catalytic activity depending of the metal chelate structure was found.

Chromatographic Properties of Silica Gel Packing Materials as Influenced by Polymeric Coating

S. S. Airapetyan and A. G. Khachatryan

Yerevan State University, Yerevan, Armenia

Received December 3, 2002; in final form, May 2003

Abstract—Some chromatographic properties of microspheric silica gels coated with copolymer of polystyrene, *p*-divinylbenzene, and allyl alcohol were studied. The measurements were performed by reverse-phase high-performance liquid chromatography using modified C_8 and C_{18} phases with secondary silanization with trimethylchlorosilane.

Development of new procedures improving structural and chromatographic parameters of packing materials for chromatographic columns, including silica gel, remains urgent. At present, it seems impossible to propose a principally novel process for preparing packing materials based on silica gel for high-performance liquid chromatography (HPLC) to meet all the chromatographic requirements. Therefore, another approach is preferred: modification of known systems, e.g., coating of the silica gel surface with a polymeric material. As a result, systems exhibiting the properties of both silica gel and coating polymer are obtained. This can decrease or even completely eliminate the solubility of silica gel, making it applicable in aqueous and, especially, in alkaline aqueous solutions.

Several procedures are used to deposit polymeric layers on silica gel supports [1–11], macroporous glasses [12, 13], and diatomite [14]. Coating of non-silica gel supports (e.g., aluminum oxide, zirconium dioxide, and carbon glass) with polymeric layers is described in [15]. For this purpose, both natural [3, 4, 10, 11] and synthetic [1, 2, 5–9, 12–15] polymers are used.

In some works on polymeric coatings, primary attention is given to covalent binding of the polymeric coating with a support surface [8–11]. At the same time, it is believed [1] that there is no pronounced difference between systems with polymeric coatings bound to the support surface and encapsulating this surface.

In this work we studied the possibility of improving some chromatographic properties of packing materials based on silica gel microspheres by their coating with an appropriate polymer.

EXPERIMENTAL

As starting materials for column packing we used microspheric silica gels (MSs) prepared by hydrothermal modification of the initial MS, which, in turn, was obtained by the procedure given in [16].

The modes of hydrothermal treatment (HT) of the initial MS for preparing macroporous samples and the pore properties of the resulting silica gels are listed in Table 1. The size distribution of these MSs are shown in the figure.

The polymeric layer was applied to MS by polymerization of an adsorption layer of the monomer mixture in the presence of benzoyl peroxide (BP), whose content was about 3–5 wt % of the total weight of monomers. The porous support was impregnated with a solution of the monomer mixture in acetone with subsequent removal of the solvent at room temperature. The polymerization initiator PB was added simultaneously with the monomers, providing poly-

merization in the sample bulk. After solvent removal, the resulting dry powder was transferred into a sealed flask and placed in an oven.

Polymerization was carried out in an oven in two stages: first the sample was heated at 80–85°C for 8–10 h and then at 130°C for 3–4 h. The resulting sorbent was washed with hot dimethylformamide (DMF) to remove the homopolymers and initial monomers and dried with acetone on the filter. Then, the sorbent was modified with silanes to prepare C_8 and C_{18} phases on the surface according to [1], with additional silanization with trimethylchlorosilane (TMCS).

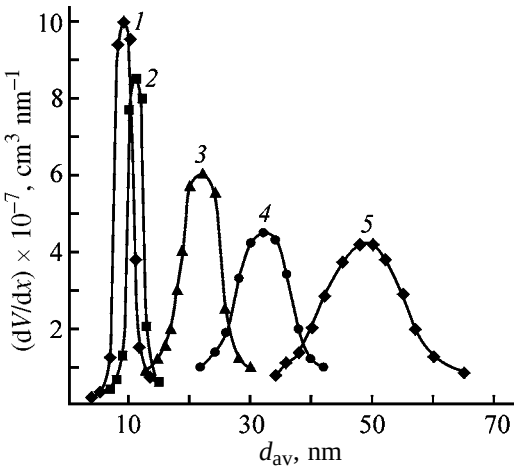
We used chemically pure grade styrene, allyl alcohol, and *p*-divinylbenzene (12 : 5 : 3 monomer weight ratio), chemically pure grade acetone, and chromatographic grade acetonitrile, water, and test mixture (uracil, benzene, and toluene).

The pore characteristics were determined by mercury porosimetry (Pore Sizer 9300 porosimeter) and by sorption of benzene vapor.

The HPLC analysis was performed on a Biotronic BI 8100 device equipped with a Spectro Monitor 5000 detector based on a photodiode matrix and a UV detector (λ = 254 nm); the flow rate of the mobile phase in all the tests was 1 ml min^{-1}. In the tests, we used the 4.6 × 150-mm columns; the other chromatographic parameters are listed in Table 2. As a test mixture we used the mixture of uracil, benzene, and toluene with $x : y : z$ weight ratio.

As seen from the figure, in preparation of the wide-pore MS samples by hydrothermal treatment of the initial silica gel, the pore size distribution becomes broader, which affects the chromatographic properties.

The performance of the columns packed with MS containing C_8 phase with respect to toluene sharply decreases on passing from Si-100 + C_8 (52480 TP m^{-1}) to Si-200 + C_8 (38693 TP m^{-1}), with the difference of 13788 TP m^{-1}, whereas on passing from Si-200 + C_8 to Si-500 + C_8 the difference is only 3501 TP m^{-1} (Table 2). This fact indicates that the main structural changes occur on substitution of Si-100 by Si-200. After attainment of the Si-200 structure, further structural changes on passing to Si-500 do not significantly affect the performance of the columns packed with these MSs. Similar trends are observed with benzene.



Pore distribution dV/dx in MS with respect to the pore size d_{av} determined by mercury porosimetry. (*1*) Initial MS; HT conditions: (*2*) pH 7.5, 100°C, 2 h; (*3*) pH 8.0, 120°C, 2 h; (*4*) pH 8.0, 150°C, 2 h; and (*5*) pH 8.0, 200°C, 4h.

The average increase in the column performance with respect to toluene after coating of the silica gel packing with a polymeric layer is about 20 000 TP m^{-1}, i.e., the column performance is improved by a factor of 1.5.

As seen from Table 2, on passing from Si-100 + polymer + C_8 to Si-200 + polymer + C_8, the column performance decreases by 6800 TP m^{-1}, which comprises 11.7 and 13.2% of the performance of the columns based on Si-100 + polymer + C_8 and Si-200 + polymer + C_8, respectively. At the same time, on passing from Si-100 + C_8 to Si-200 + C_8, the difference is 13 787 TP m^{-1} or 26.3%. In going from Si-200 + polymer + C_8 to Si-300 + polymer + C_8 and finally to Si-500 + polymer + C_8, the difference in performance is 4820 and 2942 TP m^{-1}, respectively. This suggests that the polymeric coating levels the differences in the sorbent structure after its hydrothermal modification, and no sharp drop in the column performance on passing from Si-100 + polymer + C_8 to Si-200 + polymer + C_8 packing material is observed. Moreover, on passing from Si-200 + polymer + C_8 to Si-500 + polymer + C_8, the column performance smoothly decreases, whereas in the case of Si-200 + C_8–Si-500 + C_8, such a trend is not observed.

On passing from Si-200 + C_{18} to Si-200 + polymer + C_{18}, the column performance with respect to toluene increases by a factor of 1.28 (16 821 TP m^{-1}). This fact suggests that the C_{18} phase improves the silica gel structure owing to the increase in hydrophobicity (the C_{18} phase is more hydrophobic than the C_8 phase) and in the content of organic phase on the silica gel surface.

The increase in the column performance after coating with the polymer is due to more uniform size distribution, because in this case polymer closes the finer pores.

The sorption capacity k of the columns packed with polymer-coated silica gel should obviously decrease because the pore volume and specific surface area of silica gel decrease with increasing amount of the polymer deposited. The decrease in the specific surface area depends on the silica gel structure and, to a lesser extent, on the content of the polymeric coating.

We found that, for deposition of the polymeric coating, it is advisable to use silica gel with a more open structure (with a greater pore volume, ≥ 0.75 cm^3 g^{-1}).

CONCLUSIONS

(1) The quality of the packing materials for high-performance liquid chromatography based on microspheric silica gels is improved by deposition of a polymeric layer on their surface; on average, the column performance increases by a factor of 1.5.

(2) Certain decrease in the capacity of the columns based on these sorbents is due to the decrease in the pore volume and specific surface area with increasing content of the polymer deposited.

Calix[4]resorcinols as Stabilizers for Rubber Stocks Based on Butadiene–Acrylonitrile Rubbers

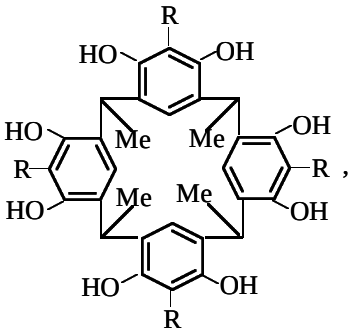
Abstract—Modification of tetramethylcalix[4]resorcinol with dimethylaminomethyl and 3,5-di-*tert*-butyl-4-hydroxybenzyl fragments was studied. The antioxidative activity of these macrocyclic stabilizers in rubber stocks based on butadiene–acrylonitrile rubber was examined.

Phenolic stabilizers are relatively little used in rubber stocks, as they are apparently inferior in the protective effect to *p*-phenylenediamine derivatives. At the same time, a major advantage of phenolic stabilizers is that, in contrast to amines, they do not alter or alter only slightly the color of rubber items; also, they are nontoxic and low-volatile and are difficultly washed out.

Macrocyclic phenolic stabilizers, in particular, calix[4]resorcinols, are a new group of phenolic stabilizers. Tetramethylcalix[4]resorcinol **I** appeared to be suitable as antioxidant for vulcanized rubbers based on butadiene–acrylonitrile rubbers [1, 2].

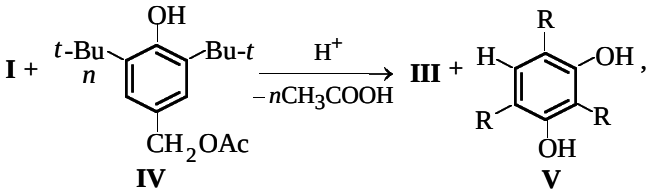
In this work we studied the antioxidative activity exhibited in rubber stocks based on butadiene–acrylonitrile rubbers by modified tetramethylcalix[4]resorcinols **II** and **III** containing in *o*-positions of the aromatic rings dimethylaminomethyl or 3,5-di-*tert*-butyl-4-hydroxybenzyl fragments:



where R = H (**I**), CH_2NMe_2 (**II**), or $CH_2C_6H_2(Bu\text{-}t)_2$-3,5-OH-4 (**III**).

It is known that introduction of dimethylaminomethyl groups into the molecule of **I** appreciably facilitates its oxidation [3]. Therefore, compound **II** should be a much more effective trap of peroxy radicals, compared to unsubstituted calixarene **I**.

Compound **III** contains phenolic groups differing in the reactivity. This should enhance the inhibiting performance in radical oxidation processes. Stabilizer **III** was prepared by the reaction of **I** with 3,5-di-*tert*-butyl-4-hydroxybenzyl acetate **IV** in the presence of formic acid. The mixture formed in the course of the reaction contains 70% calixarene **III** and 30% 2,4,6-tris(3,5-di-*tert*-butyl-4-hydroxybenzyl)resorcinol **V**:



where R = $CH_2C_6H_2(Bu\text{-}t)_2$-3,5-OH-4.

It was shown previously [4] that, in the presence of strong mineral acids ($HClO_4$, H_2SO_4), the content of **III** in the reaction mixture does not exceed 30%.

The compositions of commercial rubber stocks containing as stabilizers *N*-isopropyl-*N*'-phenyl-*p*-phenylenediamine (Diafen FP) or its mixture with 2,2,4-trimethyl-1,2-dihydroquinoline (Acetonanil),

Carbon black	120	40
EDOS plasticizer	45	–
Sulfur	–	1.5
Stabilizer	4	2

* Sulfenamide Ts is *N*-cyclohexyl-2-benzothiazolylsulfenamide; Thiuram D, tetramethylthiuram disulfide; EDOS plasticizer, a mixture based on dioxane alcohols; stabilizer, compounds **I**–**III**, **V**, **III** + **V**, Diafen FP, or Acetonanil.

calixarenes **I**–**III**, benzylated resorcinol **V**, and a mixture of **III** and **V** obtained in the course of the reaction of **I** with **IV** are listed in Table 1. The results of physicomechanical tests of these stocks are listed in Table 2. The performance of the stabilizers was evaluated by relative changes in the nominal tensile strength σ, relative elongation at break ε, and elongation set θ, occurring upon thermal oxidative aging.

Table 2 shows that, in the rubber stock of thiuram vulcanization with a high filler content, modified calixarenes **II** and **III** somewhat surpass **II** and Diafen FP (amine stabilizers) as regards preservation of σ, but are inferior to the latter additives with respect to preservation of ε. In the rubber stock of sulfur vulcanization with a low filler content, exhibiting better physicomechanical properties, calixarenes **II** and **III** inhibit thermal oxidative degradation more effectively than **I** and are comparable in this respect with Diafen FP (Table 2).

EXPERIMENTAL

In our study, we used commercial samples of butadiene–acrylonitrile rubbers SKN-18 and SKN-26. Rubber stocks were prepared in two steps with a Brabender plasticorder with the mixing chamber volume of 50 cm^3. In the first step, the rubber, carbon black, and other components, except the vulcanizing group, were mixed at 130°C. In the second step, the vulcanizing group was added. The total mixing time was 7 min, and the rotor rotation rate, 35 rpm. The rubber stocks based on SKN-18 and SKN-26 were vulcanized at 143°C for 30 and 40 min, respectively.

Physicomechanical tests were performed with a Tensometer T-10 tensile-testing machine (Monsanto).

The ^{1}H NMR spectra were recorded on a Varian Gemini-200 spectrometer (200 MHz) relative to residual protons of deuterated solvents.

4,6,10,12,16,18,22,24-Octahydroxy-5,11,17,19-tetra(3,5-di-*tert*-butyl-4-hydroxybenzyl)-2,8,14,20-tetramethylpentacyclo[19.3.1.1^{3,7}.1^{9,13}.1^{15,19}]octacosa-1(25),3,5,7(28),9,11,13(27),15,17,19(26),21,23-dodecaene III. Formic acid (65 ml) was added to a solution of 3 g (5.5 mmol) of **I** and 6.9 g (24.8 mmol) of **IV** in 55 ml of acetone. The mixture was allowed to stand at 20°C for 1 day. Then it was poured into 100 ml of water, and an $NaHCO_3$ solution was added to pH 5–6. A mixture of products (7.75 g) was obtained, containing, according to the ^{1}H NMR spectrum, compounds **V** and **III** in a molar ratio of 3 : 7. It was dissolved in 25 ml of benzene, and 170 ml of hexane was added. Compound **III** was obtained; yield

4,6,10,12,16,18,22,24-Octahydroxy-5,11,17,19-tetrakis(dimethylaminomethyl)-2,8,14,20-tetramethylpentacyclo[19.3.1.1^{3,7}.1^{9,13}.1^{15,19}]octacosa-1(25),3,5,7(28),9,11,13(27),15,17,19(26),21,23-dodecaene II and 2,4,6-tris(3,5-di-*tert*-butyl-4-hydroxybenzyl)resorcinol V were prepared as described in [5] and [6], respectively.

CONCLUSION

Modification of tetramethylcalix[4]resorcinol with dimethylaminomethyl and 3,5-di-*tert*-butyl-4-hydroxybenzyl fragments afforded macrocyclic stabilizers with enhanced antioxidative activity, exceeding that of the starting tetramethylcalix[4]resorcinol, toward rubber stocks based on butadiene–acrylonitrile rubbers.

Research Institute of Physicochemical Problems, Belarussian State University, Minsk, Belarus

Received July 1, 2003

Abstract—Sulfonation of petroleum polymeric resins based on the C_9 fraction with various suilfonatic agents was studied, and procedure was developed for preparing sulfonated resins. The possibility of using sulfo resins as effective plasticizers for concrete was examined.

Sulfonation of hydrocarbon polymers is one of effective modification procedures extending the application field of these materials. Introduction of sulfo groups makes polymers hydrophilic, which allows their use as water-soluble components of various formulations.

Efficient sulfonation procedures were developed for polymers and copolymers of ethylene and styrene [1–3]. In the case of petroleum polymeric resins (PPSs), which are multicomponent systems involving about ten kinds of monomeric units, sulfonation procedures virtually have not been studied. Petroleum polymeric resins are today one of the most promising and cheapest synthetic substitutes of vegetable oils and rosins. These products are prepared from by-products of oil pyrolysis and are widely used in production of synthetic drying oils, oil–resin lacquers, and components of various paint-and-varnish, adhesive, rubber, and other formulations. However, PPR-based products are, as a rule, soluble only in aromatic hydrocarbons and alkyl halides and insoluble in water, which restricts their applications. Modification of PPRs by sulfonation will give environmentally friendlier water-soluble film-forming agents and plasticizers.

Our studies resulted in development of a waste-free process for production of PPRs and petroleum polymerizate (PP), an analog of petroleum polymeric drying oil, by cationic polymerization of the C_9 fraction. There products are intended for use as film-forming agents in paint-and-varnish production [4–6].

The goal of this work was to study sulfonation of PPRs and prepare from them a plasticizing additive to cement mortars.

Published data and preliminary experiments on sulfonation of styrene oligomer (molecular weight 1000–3000) revealed the regular trends and optimal conditions of the process and allows us to find the best sulfonating agents (SAs) for PPRs of molecular weights 500 and 800 [7].

Sulfonation was performed under mild conditions (at 0–35°C) in a halogenated hydrocarbon solvent. As sulfonating agents we used 10–34% oleum, liquid SO_3, acetyl sulfate, chlorosulfonic and sulfuric acids, and 2 : 1 and 1 : 1 SO_3–dioxane complexes. The latter agents appeared to be the most effective. The complex $2SO_3 \cdot$dioxane was prepared at 0–5°C in a reactor equipped with a power-driven stirrer, a dropping funnel, and a thermometer, by slowly adding 1,4-dioxane to a solution of SO_3 in chloroform. To the resulting complex of SO_3 with dioxane or to another SA, a solution of PPR or PP in chloroform was added over a period of 2–3 h with vigorous stirring. After adding the whole amount of PPR (or PP), the mixture was stirred for an additional 1 h and then diluted with water and neutralized with sodium carbonate. The aqueous and organic layers were separated in a separatory funnel. The aqueous layer was filtered and dialyzed for 24 h. The purified solution was evaporated on a rotary evaporator to obtain sulfo-PPR (SPPR).

The influence of the reactant ratio on the SPPR yield and content of HSO_3 groups is illustrated by the table. Sulfonation of PPR with sulfuric acid yields a product that is virtually insoluble in water, probably owing to formation of sulfone derivatives. With acetyl sulfate, oleum, or liquid SO_3 used as sulfonating agents, partially water-soluble products were obtained, but their yield and content of sulfo groups were lower as compared to the resins sulfonated with SO_3–dioxane complexes and chlorosulfonic acid.

The reactant ratio noticeably affects the content of

** In run nos. 4 and 5, PP containing 70 and 80 wt % PPR, respectively, was sulfonated.

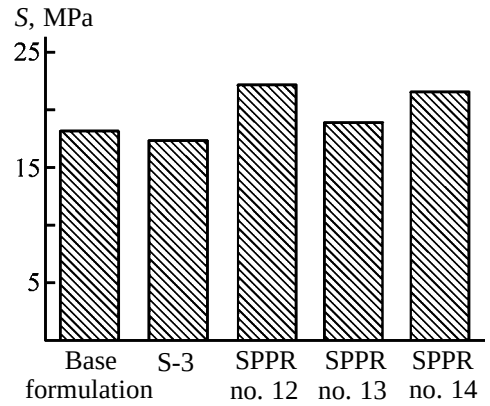
the sulfo groups introduced and the yield of the water-soluble resin (run nos. 1–3). The product containing the sulfo group in each monomeric unit can be prepared only with excess sulfonating agent (run nos. 3–10). Sulfonation of PPR with a SO_3–dioxane complex at less than 2 : 1 SA : PPR ratio gives a water-soluble product in a lower yield (run no. 1); therefore, it is appropriate to use the complex $2SO_3 \cdot$dioxane at the SA : PPR weight ratio from 2 : 1 to 5 : 1. With chlorosulfonic acid used for sulfonation (run nos. 9 and 10), the SPPR yield is lower than in run nos. 6–8, at comparable degree of sulfonation. In sulfonation of the resin of molecular weight 500 with oleum, the SPPR yield is considerably lower compared to sulfonation with a complex of SO_3 with dioxane, but the content of HSO_3 groups is higher by a factor of almost 2 (run nos. 3, 11). In sulfonation of petroleum polymerizate, the SPPR yield strongly depends on the resin concentration, whereas the content of sulfo groups is virtually the same (run nos. 3–5).

SPPR sample nos. 6–10 were tested as plasticizers for cement mortars.[1] The results showed that these SPPRs ensure the same or even higher mobility of mortars, compared to S-3 superplasticizer. Sulfo resins enhance the early strength of concrete to a greater extent (at equal mortar mobility), whereas plasticizers behaving as surfactants (including S-3) cause an opposite effect (the strength of concrete after 3-day setting is shown in the figure). Furthermore, SPPR additives accelerate setting and alter the hardening kinetics.

[1] Experiments were performed under the guidance of V.V. Tur (Brest State Technical University).

We also found that the plasticizing effect of SPPRs strongly depends on their degree of sulfonation, decreasing as the content of sulfo groups grows. The best results were obtained with SPPR no. 6. Electron microscopic examination suggests that sulfo resin molecules favor an increase in the content of crystallization centers and make the size of ettringite crystals and their distribution in the cement stone structure more uniform.

As compared to nonplasticized samples and those plasticized with S-3, the concretes obtained with SPPR additives are more uniform; they have higher density and considerably lower autogenic shrinkage strain [8].



Effect of plasticizer on the compression strength S of concrete. SPPR sample nos. 12–14 were prepared by sulfonation of PPR (M_n = 600) with the complex $2SO_3 \cdot$dioxane, HSO_3Cl, and SO_3, respectively; content of HSO_3 groups 2, 2, and 3 mmol g^{-1}, respectively.

CONCLUSIONS

(1) A procedure was developed for sulfonation of petroleum polymeric resins and petroleum polymerizate with various sulfonating agents (a complex of SO_3 with 1,4-dioxane, chlorosulfonic acid, oleum), allowing control of the content of sulfo groups in the product. Samples of water-soluble sulfo resins with the molecular weight of 1000–1500 and different degrees of sulfonation were prepared.

(2) The sulfonated petroleum polymeric resins can be used as effective concrete plasticizers.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

175 Years of Manufacture of Platinum Metals in Russia

The history of platinum manufacture in Russia and the development of research in this field have been the subject of several papers [1–6]; however, all of these cover the period of time before the 1940s. For various reasons, the manufacture of these metals in later period has not been discussed. Here we consider, after a brief review of the main stages of development of the manufacture of platinum-group metals on the basis of the Ural deposits, materials related to manufacture of platinum and concomitant elements from sulfide copper–nickel ores of the Norilsk deposit.

As far back as the early XVIII century, the Europe was well aware of the existence of platinum, which was imported from South America only. The annual production and consumption of platinum were within 320–560 kg. In Russia, platinum-containing samples of osmious iridium were found in gold fields of Upper Iset and Neiva districts in the Urals only in 1819. This stimulated further prospecting for platinum deposits. Purely platinum placers were discovered in the Gornaya Blagodat district in 1824, and in Nizhni Tagil district in the Urals in 1825. By order of the minister of finance, count E.F. Kankrin (1774–1845), who stimulated in every possible way prospecting for, and mining of platinum, all the metal ("raw" platinum) was delivered to St. Petersburg. Samples were analyzed at the laboratory of the Mining Military College (now Mining Institute) by V.V. Lyubarskii (1795–1852). Previously, in 1823, he also analyzed samples of osmious iridium. Having graduated from the Mining Military College in 1816, Lyubarskii worked for several years at laboratories of Ural plants, and then, in 1820–1827, at the laboratory of the Mining Military College, which was rebuilt and expanded in 1826 and later merged with the laboratory of the Department of Mining and Salt Affairs to become United Laboratory of the Department of Mining and Salt Affairs, Mining Military College, and Mining Apothecary [7]. The new laboratory was headed by P.G. Sobolevskii (1781–1841), who played an outstanding part in the development of processes for industrial refining of platinum and production of ductile platinum [7–9]. Sobolevskii graduated from a military educational institution (1798) and then was first in military and then in state service; in 1817–1824, he was an engineer at the Kama–Votkinsk iron-making plant, and in 1819, became manager of the plant. In 1824, Sobolevskii returned to St. Petersburg and took part in the organization of the United Laboratory and remained its head till the end of his life. For his scientific merits, he was elected corresponding member of the St. Petersburg Academy of Sciences in 1830.

Sobolevskii and Lyubarskii developed a relatively simple, but, at the same time, rather efficient method for refining of raw platinum and its conversion into ductile metal and laid foundations of powder metallurgy [10]. From May till November 1826, about 1600 kg of raw platinum was processed. In 1828, export and trading of raw platinum were prohibited. In the same year, Russia started mintage of platinum coins, which continued till 1845. During this period of time, the production of raw platinum markedly increased, to become 3490 kg in 1843. Before that time, platinum and its compounds had been studied in Russia by A.A. Musin-Pushkin (1760–1805), a chemist, mineralogist, honorary member of the St. Petersburg Academy of Sciences (since 1796), and vice-president of Berg Kollegiya (Mining Board) [11]. In 1797–1805, he published 23 papers devoted to platinum and suggested an original method for production of ductile platinum. Musin-Pushkin's studies favored the development of methods for analysis and refining of platinum metals in Russia.

To the most important events associated with studies of platinum metals belongs the discovery of ruthenium in 1844 by K.K. Klaus (1796–1864), a professor of Kazan University. Klaus started research in chemistry of platinum metals, which led to this discovery, in 1841. Having headed the chair of pharmacy at Dorpat University on returning in 1852 to his native Dorpat (now Tartu, Estonia), he continued studies in chemistry of ruthenium, osmium, and other platinum-group metals [12, 13]. Klaus wrote fundamental monographs *Issledovaniya ostatkov Ural'skoi platinovoi rudy i metalla ruteniya* (Studies of Residues of Ural Platinum Ore and Ruthenium Metal, 1845) and *Materialy k khimii platinovykh metallov* (Materials for Chemistry of Platinum Metals, 1854). The first of these was awarded the Demidov prize by the St. Petersburg Academy of Sciences. A hundred years after,

1070-4272/03/7611-1873$25.00

K.K. Klaus.

Klaus's works were republished in the series *Klassiki nauki* (Classics of Science).

Klaus suggested new techniques for refining of platinum metals, described methods for their tests for purity, considered properties of a large number of compounds of these metals, and suggested procedures for analysis of "platinum residues." In contrast to his predecessors, who studied separate problems of chemistry and metallurgy of platinum, Klaus created the chemistry of platinum metals of that time [4].

From 1841 till 1867, platinum was refined at St. Petersburg Mint. After mintage of platinum coins was terminated (June 1845), export of platinum obligatorily refined at the Mint was allowed. Thus, the refining works continued to exist in Russia, but it terminated in 1867 when export of raw platinum was allowed.

In 1879, platinum refining was commenced in limited amounts (130–150 kg in a year) at the Tentelevskii chemical plant (St. Petersburg). However, this plant, and also another small plant refining platinum in St. Petersburg, belonged to foreigners. About 10–13% of platinum produced at the Urals was refined. As noted in [4], 92% of investment into the Ural platinum industry belonged to foreigners. At the same time, the Ural platinum fields gave more than 90% of world's platinum.

Quite a number of known Russian geologists were engaged in studies of platinum deposits in the Urals. A.A. Inostrantsev (1843–1919), a professor of St. Petersburg University, published in 1893–1894 studies of bedrock deposits in the Nizhni Tagil district. By that time, only placer deposits were used in the Urals. Bedrock deposits, whose disintegration produced placers, had not been studied. The geology of bedrock deposits was also the subject of a study by Academician A.P. Karpinskii (1846–1936), published in 1893. During many years, the platinum deposits of the Urals were studied by N.K. Vysotskii (1864–1932), a geologist from St. Petersburg. The platinum deposits of the Nizhni Tagil district were described in a paper by N.A. Zavaritskii (1884–1952), published in 1909. A number of Ural platinum deposits were described by F.Yu. Levinson-Lessing (1861–1939), a professor of St. Petersburg Polytechnic Institute, in his publications of 1909–1910.

In the field of chemical analysis of minerals containing platinum metals, much was done by B.G. Karpov (1870–1940). Having graduated from the St. Petersburg University (1896) with first-degree diploma, he started to work as chemist-analyst at the Geological Committee (St. Petersburg). Already in 1900, Karpov established for the first time, together with A.A. Antipov (1858–1911), the presence of uranium in the geological material from Fergana province. In the same year, he was sent to a business trip abroad for further improvement of his skills and worked at H. Le Chatelier's laboratory (1850–1936) in Paris. Beginning in 1907, Karpov specialized in analysis of platinum metals. He wrote a manual *O metodakh analiza samorodnoi platiny* (On Methods for Analysis of Native Platinum) and made several hundred analyses of both native platinum and platinum ores from Ural deposits [4, 14].

In the late XIX century, Professor N.S. Kurnakov (1860–1941, academician since 1913) carried out at the chemical laboratory of the Mining Institute studies in chemistry of complex compounds of platinum-group metals [6, 15, 16]. Already the first scientist's communication devoted to this subject, on "products of thiourea combination with platinum salts" (1889), aroused much interest among chemists. The results of the study were included by D.I. Mendeleev (1834–1907) in the fifth edition of *Osnovy khimii* (Fundamentals of Chemistry). Later (1889–1893), these studies were continued. It was emphasized in the monograph [15] that Kurnakov was the first among Russian scientists to appreciate the coordination theory of A. Werner (1866–1919), an outstanding Swiss chemist, later a Nobel Prize laureate (1913). The results of Kurnakov's studies in the field of chemistry of complex compounds were summarized in a separate collection of works [17].

At the turn of the XX century, it became clear that chemistry of platinum metals is intimately associated with chemistry of coordination compounds. Platinum metals form various complex compounds characterized by high stability. Already in the beginning of the XX century, investigations carried out by L.A. Chugaev shifted the center of research in the field of complex compounds and also in chemistry of platinum metals to Russia [6]. Chugaev graduated from the natural department of the physicomathematical faculty at Moscow University in 1895. The initial period of his scientific activities was devoted to studies of organic compounds. In 1903, Chugaev defended his master dissertation "Studies in the Field of Terpenes and Camphor." However, his doctoral dissertation "Studies in the Field of Complex Compounds" (1906) was devoted to synthesis and studies of properties of compounds formed by a number of metals, including platinum and palladium, with imides and α-dioximes. In the following years, Chugaev's interests were focused exclusively on the chemistry of coordination compounds. Chugaev was a professor of the Moscow Higher Technical School (1904–1908) and extraordinary (since 1908) and ordinary (since 1911) professor of the St. Petersburg University [18].

As already noted, Russia was the main supplier of platinum to the world market at the beginning of the XX century, but platinum refining was not performed on due scale. The question of necessity for organization of industrial refining of Ural raw platinum was raised by Russian scientists more than once; however, this was hindered by the existing Russia's treaty commitments. The export of raw platinum was completely prohibited only after the beginning of World War I.

In July 1914, the government made a contract with the management of the Joint-Stock Society of Nikolae-Pavda mining district to build and equip in accordance with the requirements of modern technology a refining plant in Yekaterinburg with annual output capacity of no less than 450 poods (~7400 kg) and manufacture simple articles from refined platinum [5, 6, 19]. The government surrendered its rights to build a state-owned plant for platinum refining to the joint-stock society.

In February 1915, the Permanent commission for analysis of natural productive forces of Russia (KEPS) was organized by decision of the Academy of Sciences, and Academician V.I. Vernadsky (1863–1945) was appointed its chairman, and Academician Kurnakov, its vice-chairman. In his keynote address devoted to the goals of the Commission, Vernadsky mentioned that, for Russia's natural resources to be used properly, "it is necessary to go Russia's own way without using as prescriptions the achievements of the West or America... We must search not only for sources of new natural productive forces in our country, but also for methods and procedures for their use, and devise these methods" [20].

L.A. Chugaev.

N.N. Baraboshkin.

In August 1915, the Nikolae-Pavda joint-stock society invited mining engineer N.N. Baraboshkin (1880–1935) to head work on building of a refining plant in Yekaterinburg. N.N. Baraboshkin entered the Mining Institute in St. Petersburg in 1899 and graduated therefrom in 1914, having worked during his education period in gold and platinum fields of the Urals and Siberia and at other metallurgical plants. Beginning in 1911, he made a great number of analy-

O.E. Zvyagintsev.

ses of platinum metals at a laboratory of the Mining Institute. Karpov's paper [21] mentions that "It is necessary to mention as one of the most outstanding representatives of Kurnakov's analytical school N.N. Baraboshkin, who applied to the greatest extent his analytical talents to studies of analysis of platinum ore and products of its processing. These studies... brought to him honorable fame and key position at... the refining plant." In 1914–1915 at the Mining Institute, N.N. Baraboshkin was engaged, together with N.I. Podkopaev (1872–1930), in improvement of methods for platinum refining, with the result that the Klaus–Baraboshkin method was devised and later used for a long time at the refining plant [6, 22]. At the beginning of 1916, a temporary laboratory for refining and production of technical-grade spongy platinum, headed by N.N. Baraboshkin, was put into operation. In October of the same year, the construction of the first Russia's refining plant was, for the most part, finished. The commonly accepted official data of its starting-up is October 10 (23), 1916, when the Ministry of Trade and Industries approved a special "Instruction" regulating all aspects of the functioning of the new plant. From November 1916 till November 1917, 900 kg of platinum was refined; by the beginning of 1918, the output capacity of the refining plant reached 400 kg of platinum per month and increased gradually. However, on February 6 (19), 1918, the plant was nationalized and soon was closed. The civil war suspended work on platinum refining, but the plant was not evacuated and all the equipment remained intact. Mainly owing to N.N. Baraboshkin's efforts, the refining plant resumed its work in the spring of 1920. Soon, other metals started to be produced together with platinum: palladium in 1922, iridium in 1923, rhodium in 1925, osmium in 1927, and ruthenium in 1930. Manufacture of extra-brand platinum was started in 1928, melting of platinum to obtain platinum bullion, in 1923, and manufacture of platinum alloys and fabrication of articles from platinum and platinum alloys, in 1928.

Professor N.N. Baraboshkin was one of organizers of higher metallurgical education in the Urals, headed metallurgical chairs at the Ural Polytechnic Institute, and dealt with a wide variety of issues related to manufacture of copper and nickel at plants of the Ural region [19, 23–25].

The achievements in refining of platinum and associated metals were closely related to wide-scale studies carried out, in the first place, in Petrograd. On Chugaev's initiative supported by academicians Kurnakov and A.E. Fersman (1883–1945), the Institute of Platinum and Other Noble Metals (Platinum Institute) was organized in Petrograd in April 1918 [26, 27]. This made it possible to unite specialists working in the field of chemistry of platinum metals at laboratories of the University, Mining and Polytechnic Institutes, and some other institutions. The explanatory memorandum devoted to the organization of the institute read: "Platinum-group metals, i.e., platinum, iridium, rhodium, palladium, osmium, and ruthenium, constitute the exclusive national treasure of the Russian state, since more than 95% of the whole world's production of placer platinum falls on Russia..." [4]. Chugaev was appointed the first director of the Platinum Institute. The aims of the Institute, formulated by its director, were diverse and extensive, with the development of methods for separation of platinum and associated metals and their manufacture in pure state occupying the first place [28]. After the untimely death of Chugaev in September 1922, Kurnakov was elected director of the Institute. During the entire period of his scientific activities, Kurnakov was incessantly interested in platinum and other platinum-group metals: in their complex compounds, manufacture technology, alloys on their base, and use of the metals and alloys in various fields of technology.

In 1922, the State Association of plants producing and processing platinum, Uralplatina of VSNKh (Supreme Council for National Economy), was created. In agreement with this association, the Platinum Institute engaged itself in a number of investigations in the field of refining and analysis of platinum metals. To accomplish these tasks, two commissions were organized at the Institute: that of refining, headed by

Kurnakov, and analytical, headed by Karpov. A number of known specialists working at the Platinum Institute were, simultaneously, members of both the commissions: S.F. Zhemchuzhnyi (1873–1929), O.E. Zvyagintsev (1894–1967), and V.V. Lebedinskii (1888–1956). A detailed report about the activities of the Platinum Analytical Commission can be found in [21]. A major contribution to the organization of joint work of Uralplatina and the Platinum Institute was made by Zvyagintsev, an engineer at Uralplatina in 1922 to 1926 and later one of the leading Russian specialists in chemistry, geochemistry, and technology of platinum metals, the author of a number of monographs and books on history of chemistry [29].

In 1923–1925, KEPS, Russian Academy of Sciences, initiated publication of capital work of N.K. Vysotskii [30], devoted to deposits, production, and refining of platinum in Russia. Results obtained in studies carried out by staff members of the Institute of Platinum and in other investigations in the field of chemistry of platinum metals appeared on regular basis in *Izvestiya Instituta* (Transactions of the Institute), which started to be published in 1920.

In 1919, in lower reaches of the Yenisei River, beyond the Polar circle, prospecting for deposits of coal and other minerals was commenced, with only rather scarce relevant information available. The expedition was led by N.N. Urvantsev (1893–1985), a young mining engineer and graduate of the Tomsk Technological Institute [31]. The systematic studies carried out in the following years on the southern periphery of the Taimyr tundra led to discovery of a coal field and deposits of copper–nickel ores containing platinoids, which constituted the mineral and energy base for Norilsk mining-and-smelting combine. The decision to construct the combine was made by the Council of People's Comissars of the USSR on June 23, 1935. The implementation of the plan was entrusted to Chief Administration of Prison Camps (GULAG). The exceedingly severe climate of the Polar region made construction under the ever-frost conditions a very complicated task. Nevertheless, first hundreds of tons of raw nickel were obtained in 1939, production of electrolytic nickel commenced in the spring of 1942, that of electrolytic copper, in 1943, and that of cobalt, in 1944. As nickel and copper were produced, platinoid-containing sludges were accumulated.

On April 7, 1939, the country's leadership made a decision to construct a refining plant in Krasnoyarsk. The construction and functioning of the plant were also entrusted (till 1953) to NKVD (People's Comissariat for Internal Affairs). The construction site was chosen with participation of Zvyagintsev. The design was made by specialists of the Soyuznikel'olovoproekt Institute (now Gipronikel' Institute, St. Petersburg), with participation of specialists from the Institute of General and Inorganic Chemistry, Russian Academy of Sciences, and Mining Institute. Professors N.P. Aseev (1871–1952), K.F. Beloglazov (1887–1951), N.S. Greiver (1900–1971), and Yu.V. Morachevskii (1894–1961) took part in extensive studies of the behavior of platinum metals in processing of sulfide copper–nickel ores, carried out at the Leningrad Mining Institute.

The refining plant in Krasnoyarsk was constructed in severe war years; however, already in November 1942, the first batch of sludges formed in nickel electrolysis was delivered to the plant for processing. On March 23, 1943, first platinum (1291 g) and palladium (3235 g) were produced on the pilot installation from Norilsk sludges. This date is considered the birthday of the Krasnoyarsk Refining Plant (Krasnoyarsk Plant of Nonferrous Metals since 1967). On June 1, 1943, the plant commenced manufacture of finished products in conformity with the established State plan. In May 1944, manufacture of rhodium was started. In January 1945, the main shop for refining of platinum and palladium was put into operation and large-scale manufacture of these metals was commenced. In 1946–1947, melting of platinum and palladium was made possible and manufacture of these metals in the form of bullion was organized. In November 1946, recovery of ruthenium by distillation with ammonium persulfate was started. In 1948, processing of Ural placer platinum and secondary raw materials containing precious metals was organized. In May 1950, a technology for electrochemical recovery of gold from solutions to give commercial technical-grade metal was developed. In 1952, a method for electrochemical recovery of rhodium from solutions of its pure salt was introduced into practice [32].

In September 1994, Russia's largest goldsmith's work was created, and in 1996, and effective technology for gold and silver refining was developed.

Together with the traditional research centers at which sulfide copper–nickel ores and chemistry of platinum-group metals were studied, scientists and specialists exiled to Krasnoyarsk (professors I.Ya. Bashilov and S.M. Anisimov) or detained there (professors R.L. Myuller and V.V. Nedler, engineers K.K. Beloglazov, A.P. Sergeev, A.N. Fedorova, and others) much helped to staff members of the plant during its early years, in 1943–1953, in developing

the technology for processing of novel types of raw materials and refining of platinum metals.

I.Ya. Bashilov (1892–1953) studied at the Petrograd Polytechnic Institute. Already in 1921, he, together with V.G. Khlopin (1890–1950, member of the Academy of Sciences of the USSR since 1939), developed and implemented a technology for production of radium and other valuable components (uranium, vanadium) from the ore delivered from Central Asia (Fergana). In 1932, he created and headed the chair of rare metals at the Moscow Institute of Fine Chemical Technology. In the same tear, Bashilov was appointed scientific supervisor of the Institute of Rare Metals (Giredmet). In August 1938, professor Bashilov, one of those who organized the industry of radioactive and rare metals in Russia, was groundlessly repressed and, on finishing his detention term in June 1943, sent to Krasnoyarsk, to the refining plant [32–35]. First, he worked as researcher and then as head of the research department of the Central factory laboratory. Despite the previous conviction, which was not expunged, Bashilov was awarded a State Prize in 1948. Already after the scientist's death, the decision of the Special Board of NKVD of February 14, 1939, was repealed by the Supreme Court of the USSR on January 30, 1957 "because of the absence of a crime."

S.M. Anisimov (1901–1970), a disciple of a prominent metallurgist V.Ya. Mostovich (1880–1935) and a professor of the North-Caucasian Mining-and-Smelting Institute (Vladikavkaz), was repressed in 1941, served his sentence at Norilsk labor camps, and then worked at the Krasnoyarsk Refining Plant. He did much in organizing at the plant an assay laboratory for analyzing raw, and other industrial, materials with low content of noble metals. Anisimov paid much attention to training plant's staff members for assay techniques and carried out a number of technological studies [32]. In 1954, Anisimov was fully rehabilitated, returned to Vladikavkaz, and headed the chair of metallurgy of noble and rare metals at the same institute as before.

Head of the chair of electrochemistry at Leningrad University, professor R.L. Myuller (1899–1964) was sentenced to 10 years of imprisonment for "anti-Soviet propaganda" [36, 37]. In 1946–1949, Myuller demonstrated, together with specialists from the plant, the possibility of using electrochemical methods in various stages of the refining process. A shop for fractional electrolysis operated at the plant for a long time. Such methods as cathodic deposition of metallic rhodium from solutions of hexachlororhodic acid and electrochemical purification of iridium solutions proved to be successful [32].

In 1956, after full rehabilitation, Myuller resumed his rather successful scientific activities at the Leningrad University.

V.V. Nedler (1908–1997), a known physicist-spectroscopist from Moscow, served his four years term of imprisonment in Krasnoyarsk. His contribution to implementation of spectral analysis at the plant and personnel training is invaluable. In the early 1950s, spectral analysis became the most important method for monitoring processes, testing the quality of finished products, and analyzing other materials at a plant. On returning to Moscow, Nedler, a doctor of chemical science, professor, and State Prize laureate, worked successfully at Giredmet Institute for many years [38]. The organization at the plant of a research department, which actually functioned as an applied-research institute, was much assisted by scientists from the Institute of General and Inorganic Chemistry, Academy of Sciences of the USSR: Academician I.I. Chernyaev, corresponding members of the Academy of Sciences of the USSR Lebedinskii and N.K. Pshenitsyn, Professor A.M. Rubinshtein, and, especially, Professor Zvyagintsev. I.I. Chernyaev (1893–1966), a disciple and follower of Chugaev, graduated from the Petrograd University in 1915, worked at the Institute of Platinum in 1918–1934 and at the Institute of General and Inorganic Chemistry, Academy of Sciences of the USSR beginning in 1934; in 1941–1966 he was director of the Institute. Chernyaev was a prominent specialist in chemistry of complex compounds and discoverer of the *trans* effect. The methods for osmium recovery from ore and production of high-purity platinum, developed by Chernyaev, are used in the industry. Beginning in 1918, Lebedinskii and N.K. Pshenitsyn (1891–1961), graduates from St. Petersburg (Petrograd) University and Chugaev's disciples, worked at the Institute of Platinum and at the Institute of General and Inorganic Chemistry, Academy of Sciences of the USSR. The main Lebedinskii's investigations were devoted to methods for production and refining of rhodium. Pshenitsyn made a major contribution to analytical chemistry of platinum metals and developed an industrial method for iridium recovery [16, 26].

Of promise and interest are investigations in the field of electrocrystallization and refining of platinum metals with molten electrolytes, carried out the most extensively at the Institute of High-Temperature Electrochemistry, Russian Academy of Sciences, Yekaterinburg and also at the Yekaterinburg Plant for Proc-

essing of Nonferrous Metals (former Refining Plant). These studies were initiated and supervised by Academician A.N. Baraboshkin (1925–1995), N.N. Baraboshkin's son [39].

Platinum-group metals play an important part both in monetary reserves of states an in quite a number of diverse, and newest branches of technology [40]. Platinum metals, and also their alloys and compounds, are irreplaceable in electronics, radio engineering, instrument building, chemical and petrochemical industries, space and nuclear engineering, medicine, and goldsmith's works. Platinum and platinum–rhenium catalysts are used in manufacture of high-octane gasoline and numerous monomers for manufacture of synthetic rubber and other synthetic materials. Platinum metals and their alloys are used in fuel cells, microelectronics, growth of single crystals of precious gems, and special glass making. Alloys of platinum with rhodium and palladium neutralize noxious components of exhaust gases of internal combustion engines.

By the end of the XX century, the share of Russia and Republic of South Africa (RSA) exceeds 92% of world's production of platinum metals and 96% of their resources [41]. However, the structures of resources and production in these countries differ significantly. Platinum predominates in RSA ores and its output is approximately twice that of palladium. By contrast, the palladium resources in raw materials in Russia much exceed those of platinum, and, therefore, producing a comparable amount of palladium, our country lags far behind RSA (by a factor of more than 4.5) in production of platinum. An analysis of the world market of platinum metals in the 1990s was made in [41]. During the period from 1993 to 1998, the world consumption of platinum-group metals increased by 74% (from 263 to 458 tons), and that of platinum, by 41.7% (from 126 to 179 tons).

In Russia, more than 98% of the proven resources of platinum-group metals is concentrated in the Arctic zone, with more than 95% of these metals manufactured from sulfide copper–nickel ores of the Norilsk industrial region [40, 42, 43]. The factors determining the unique properties of Norilsk platinoid–copper–nickel ores have been analyzed by D.A. Dodin *et al*. [43, 44]. However, the fraction and quality of ores rich in platinum metals delivered to the Norilsk mining-and-smelting combine decreases gradually. In this context, much attention is given by the program "Platinum of Russia" (1992) to studies of new, untypical of Russia, kinds of platinum-containing raw materials [40, 44–46].

Russia possesses sufficient natural resources for extending the existing, and creating new, sources of raw materials for production of platinum metals and raising their manufacture in order to ensure the leading position in the world market in the XXI century.

BOOK REVIEWS

Tarasov, A.V., Besser, A.D., Mal'tsev, V.I., and Sorokina, V.S., *Metallurgicheskaya pererabotka vtorichnogo svintsovogo syr'ya* (Metallurgical Processing of Secondary Lead)

Tarasov, A.V., Ed., Moscow: Gintsvetmet, 2003, 224 pp.

In the recent decade, exceedingly close attention has been given in all the economically developed countries to utilization of lead battery scrap. This problem, which is very important economically and environmentally, is made particularly pressing by the global rise in the number of automobiles and other vehicles using lead batteries, high toxicity of lead, and depletion of lead ore deposits. By the end of the XX century, the annual world's output of lead exceeded 6 million tons, with no less than 55% of the whole manufactured amount of lead constituted by secondary metal, which is mainly obtained in processing of spent lead batteries. No less than 70% of lead produced in the world is consumed in manufacture of lead batteries. On the completeness of collection and utilization of battery scrap depends the possibility of satisfying the demand of the world's leading countries for lead. The aforesaid refers to Russia in full measure.

The monograph by A.V. Tarasov and co-authors comprises a foreword, introduction, eight chapters, and bibliographic list containing 243 references to various publications.

A brief foreword (p. 6) notes that the short supply of lead and its alloys in Russia was among the reasons for decrease in manufacture of lead batteries and their increased import. The introduction (pp. 7 and 8) justly emphasizes that the overall expenditure for manufacture of lead and its alloys and compounds from secondary lead raw materials and the impact of the methods for its processing on the environment are much lower than that in their production from ore raw materials. Provided that an efficient system for battery collection and processing is organized, the dependence of Russia on imported lead and its alloys and concentrates can be eliminated.

Chapter 1 of the monograph (pp. 9–14) analyzes data on the present state of manufacture and consumption of lead. Unfortunately, data on the dynamics of manufacture and consumption of lead in Russia in the last decade, the more so for the earlier period, are virtually lacking. Chapter 2 (pp. 15–21) characterizes secondary lead-containing raw materials. The main attention is given to lead battery scrap and wastes of battery plants. These kinds of secondary lead can be processed together. Chapter 3 (pp. 22–48) is devoted to preparation of secondary lead-containing raw materials for the basic metallurgical procedures. The chapter considers transportation of lead batteries, discharge and processing of electrolyte, cropping of batteries into fractions, desulfurization (desulfation) of the oxide–sulfate fraction with caustic soda or soda ash, manufacture of commercial sodium sulfate as by-product, and utilization of organic components of battery scrap.

Chapter 4 (pp. 48–81) discusses the main processes occurring in pyrometallurgical processing of secondary lead and the appropriate apparatus. Unfortunately, the authors fail to present with due clarity the physicochemical essence of reduction processes and do not use the known results of numerous studies of these processes. The same chapter considers slags and mattes, typically produced in manufacture of lead by pyrometallurgical methods, and smelting processes in furnaces of various types. Chapter 5 (pp. 81–161), occupying the central place in the monograph, describes the basic flowsheets for processing of secondary lead-containing raw materials: melting of uncropped lead batteries in shaft furnaces after discharge of electrolyte, melting of separate fractions of lead battery scrap in reverberatory or rotating furnaces, electrosmelting, and other known procedures. The authors give numerous examples from domestic and foreign practice.

Chapter 6 (pp. 161–185) describes processes for refining of lead obtained from secondary raw materials. The authors restrict the consideration to analysis of widely known procedures for pyrometallurgical purification to remove antimony, arsenic, tin, and

1070-4272/03/7611-1881$25.00

copper impurities and of electrolytic refining with a hydrofluorosilicic electrolyte. New promising procedures specially developed for refining of secondary lead are not discussed in the monograph. Chapter 7 (pp. 185–204) presents information about hydrometallurgical methods for processing of battery scrap. Chapter 8 (pp. 204–211) considers environmental and economical aspects of lead manufacture from secondary raw materials.

Numerous deviations from the commonly accepted rules of bibliographic description may hinder use of the, on the whole, rather informative list of references.

The monograph by Tarasov and co-authors will be indubitably of interest for specialists working at research and development organizations dealing with processing of secondary lead-containing raw materials.

INFORMATION

Jubilee Scientific Conference "Gerasimov Readings"

In tribute of the centennial anniversary of the birthday of Yakov Ivanovich Gerasimov (23.09.1903–17.03.1983), a known physical chemist, corresponding member of the Academy of Sciences of the USSR, and laureate of a State Prize, the jubilee scientific conference "Gerasimov Readings" was held at the Lomonosov State University in Moscow on September 29–30, 2003. The conference was organized by the Chemical Faculty of Moscow State University (MGU), Scientific Council of the Russian Academy of Sciences for Chemical Thermodynamics and Thermochemistry, and Scientific Council of the Russian Academy of Sciences for Physicochemical Foundations of Semiconductor Materials Science, with financial support by the Russian Foundation for Basic Research and a number of other institutions. The organizing committee of the conference was headed by the Dean of the Chemical Faculty, Academician V.V. Lunin and his deputies, Academician Yu.D. Tret'yakov and Professor G.F. Voronin.

The scientific program included seven plenary reports, poster sessions in six sections, and round table on use of computers in chemical research and teaching of chemistry. Lunin and Tret'yakov took part in the opening session of the conference. The report by N.A. Smirnova (St. Petersburg State University) "Thermodynamics of Complex Fluid Systems at St. Petersburg University: Research and Teaching" was devoted to a wide variety of thermodynamic problems dealt with at the Chemical Faculty of St. Petersburg State University. Particular attention was given to thermodynamics of solutions of various kinds and to thermodynamics of surface phenomena. O.M. Poltorak (MGU) considered in his report the problems associated with teaching of chemical thermodynamics within the modern course in physical chemistry. The report by Voronin (MGU) "Unused Possibilities of Chemical Thermodynamics" analyzed the main directions of development of chemical thermodynamics in the XX century. J. Hertz (Université Henry Poincarè, Nancy I, France), a known scientist in the field of thermochemistry of metal alloys, considered in his report the basic research in the field of thermodynamics, mainly carried out in the XIX century by Carnot, Clapeyron, Thomson, Clausius, Gibbs, Ostwald, Le Chatelier, Duhem, de Dondet, Boltzmann, and Planck. In particular detail were considered the activities of Sadi Carnot (1796–1832), a French engineer and physicist, one of the founders of thermodynamics.

The report by F.A. Kuznetsov (Institute of Inorganic Chemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk) was devoted to the role of chemical thermodynamics in semiconductor materials science. The report by Yu.V. Tsvetkov (Baikov Institute of Metallurgy and Materials Science, Russian Academy of Sciences, Moscow) considered Ya.I. Gerasimov's studies in the field of theoretical metallurgy and their influence on the subsequent research. The author developed (together with E.K. Kazenas) a procedure and apparatus used to obtain experimental data on thermodynamics of evaporation and dissociation of oxides of a great number of metals. Studying the thermodynamics of transfer of components of the metallurgical raw materials into the gas phase is of particular importance for the development of plasma metallurgy. E.P. Ageev (MGU) illustrated his report devoted to the career and research activities of Gerasimov by a large number of interesting photographs.

Numerous poster reports were grouped into six sections: (I) general and academic problems of chemistry and chemical thermodynamics; (II) thermodynamic properties of substances; (III) phase equilibria and transformations; (IV) physical chemistry of solutions and melts; (V) theoretical and semiempirical methods for calculation and evaluation of physicochemical parameters of substances; and (VI) adsorption, kinetics, and catalysis. Abstracts of papers of the jubilee scientific conference "Gerasimov Readings" were published as a separate edition.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Liquid Fertilizers Based on Dolomite, Nitric Acid, and Ammonia

A. Sviklas and R. Shlinkshene

Kaunas Technological University, Lithuania

Received May 6, 2003

Abstract—Solubility in the system $Ca(NO_3)_2$–$Mg(NO_3)_2$–NH_4NO_3–H_2O was studied by the visual-polythermic method. The crystallization curves and the chemical composition of the solid phase were determined. The chemical composition of solutions with crystallization temperature of 0°C was calculated. A technological scheme for production of liquid fertilizers containing nitrogen, calcium, and magnesium was proposed.

The world's production of concentrated combined fertilizers, e.g., nitroammophosphates, increases, whereas the fraction of fertilizers with secondary macronutrient elements decreases. Cultivation of a number of agricultural cultures involves deficiency of bound calcium, magnesium, and sulfur [1–3], which is partially compensated for by use of nitrophoska and superphosphates. However, in many cases it is more expedient to use liquid fertilizers. Of particular interest is use of dolomite[1] $CaCO_3 \cdot MgCO_3$, which contains up to 30% CaO and 20% MgO, as a raw material for manufacture of liquid fertilizers containing calcium and magnesium.

The agrochemical efficiency of chemically unprocessed dolomite is low, as it is almost insoluble in water. Milled dolomite is used in agriculture only for neutralization of acid soils.

Products formed in dolomite processing with orthophosphoric acid can be used as fertilizers in neutral or alkaline soils [5]. Production of suspended fertilizers by reacting dolomite with various inorganic compounds has been reported [6, 7]. However, calcium and magnesium phosphates are virtually not used in production of liquid fertilizers at all because of their low solubility [8].

Readily water-soluble calcium and magnesium nitrates obtained by decomposition of dolomite with nitric acid can be the best components of calcium- and magnesium-containing liquid fertilizers. There are published data on application of the product formed in the reaction between dolomite and nitric acid as an additive in the production of ammonium nitrate [9]. However, data on phase equilibria in the ternary systems $M(NO_3)_2$–NH_4NO_3–H_2O (M = Ca, Mg) and $Ca(NO_3)_2$–$Mg(NO_3)_2$–H_2O systems [10–14] are insufficient for creating liquid calcium-, magnesium-, and nitrogen-containing fertilizers.

The aim of this study was to analyze the possibility of manufacturing liquid fertilizers containing simultaneously nitrogen, calcium, and magnesium by decomposition of dolomite with nitric acid, with the subsequent neutralization of the resulting product with ammonia water.

To achieve this objective, it was necessary to study the solubility in the system $Ca(NO_3)_2$–$Mg(NO_3)_2$–NH_4NO_3–H_2O, to determine the chemical composition of liquid calcium, magnesium, and nitrogen-containing fertilizers, and to suggest a technological scheme for manufacture of liquid fertilizers.

To study the solubility, we used analytically pure $Ca(NO_3)_2 \cdot 4H_2O$, $Mg(NO_3)_2 \cdot 6H_2O$, and NH_4NO_3 and distilled water.

The content of calcium, magnesium, iron, and aluminum in terms of their oxides was determined by chelatometry; that of ammonia nitrogen, by the formaldehyde method; and that of nitric nitrogen, by the permanganate method. The concentration of silicon oxide and the amount of crystallization water were determined gravimetrically [15, 16].

[1] There are deposits of dolomite (about 180 million cubic meters) in northern Lithuania [4], but this mineral is virtually not used in agriculture as a fertilizer.

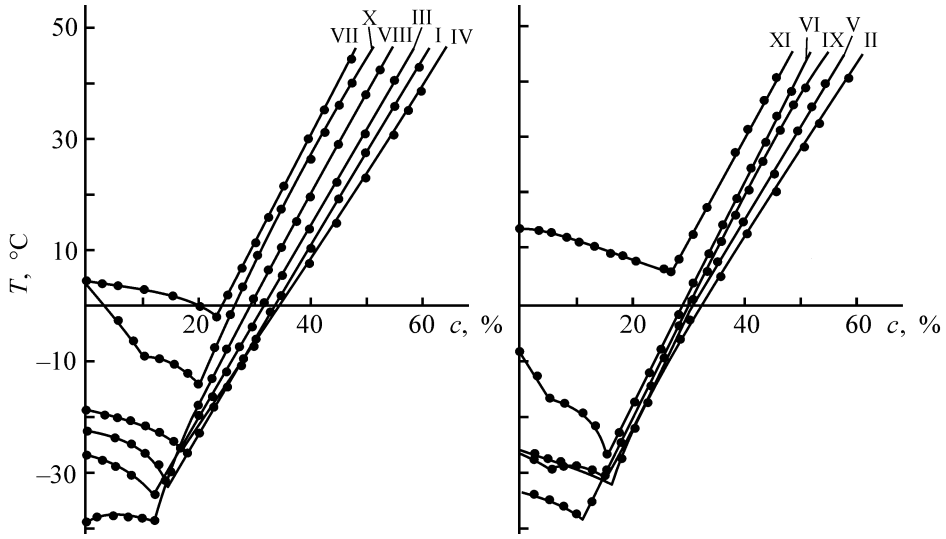

Fig. 1. Polythermal sections I–XI of solutions of the system $Ca(NO_3)_2$–$Mg(NO_3)_2$–NH_4NO_3–H_2O. (T) Temperature and (c) content of NH_4NO_3.

The following physicochemical methods of analysis were used in the study: atomic-absorption electrothermopyrographic spectrometry (Perkin–Elmer Zeeman 3030 spectrometer [17, 18]), IR spectrometry (Specord M-80 spectrometer, KBr pellets, compaction duration 5 min [19]), thermogravimetry (Du Pont Instruments 990 Thermal Analyzer, heating rate 10 deg min [20]), and X-ray phase analysis (DRON-3 instrument with a cobalt anode, range of diffraction angles 0–166.5°, measurement error not exceeding 0.5% [21]).

To obtain liquid fertilizers under laboratory conditions, we used technical-grade nitric acid (58%), ammonia water (25%), and dolomite[2] containing 53.21% $CaCO_3$ and 42.88% $MgCO_3$. The content of admixtures in dolomite was as follows (wt %): Fe_2O_3 1.71, Al_2O_3 0.10, SiO_2 2.10, Mn 1.76×10^{-2}, Zn 2.71×10^{-2}, Cr 1.54×10^{-3}, Cu 3.34×10^{-4}, Ni 2.81×10^{-4}, Co 8.51×10^{-4}, Mo 2.50×10^{-4}, Cd 9.79×10^{-5}, Pb 4.69×10^{-6}, Se $< 1 \times 10^{-6}$, and Hg $< 1 \times 10^{-6}$. The crystallization temperatures of solutions were determined by visual-polythermic method [22].

Table 1. Chemical composition of sections of the system $Ca(NO_3)_2 + Mg(NO_3)_2 + H_2O \rightarrow NH_4NO_3$

Section	Composition, wt %

Taking into account the composition of dolomite (ratio of calcium and magnesium oxides), we studied the dependence of the crystallization temperature of solutions with varied ratio of calcium and magnesium nitrates on the concentration of ammonium nitrate (0 to 60%) in the temperature range from full freezing up to 40°C. The solubility in 11 sections $x Ca(NO_3)_2 + y Mg(NO_3)_2 + z H_2O \rightarrow NH_4NO_3$ (Table 1) was determined by the visual-polythermic method.

Polythermal sections I–XI are shown graphically in Fig. 1. The crystallization curves in the selected range of concentrations and temperatures had one or two inflection points associated with phase transitions.

Using a centrifuge-refrigerator (at low crystallization temperatures T_{cr}) or a Nutsche filters (at crystallization temperatures higher than 0°C), we isolated the crystals obtained at the temperatures corresponding to the inflection points and in characteristic ranges of polytherms and then subjected them to chemical and instrumental analysis. An examination of the obtained experimental and published [10–14] data

[2] Pyatrashunai (northern Lithuania).

Table 2. Chemical composition of solutions and solid phases in the system $Ca(NO_3)_2$–$Mg(NO_3)_2$–NH_4NO_3–H_2O

on the solubility in the ternary systems $M(NO_3)_2$–NH_4NO_3–H_2O (M = Ca, Mg) and $Ca(NO_3)_2$–$Mg(NO_3)_2$–H_2O demonstrated that binary crystal hydrates are formed as a result of the crystallization. Table 2 shows, as an example, results of chemical analysis of the solid phase in section III at crystallization temperature of 0°C.

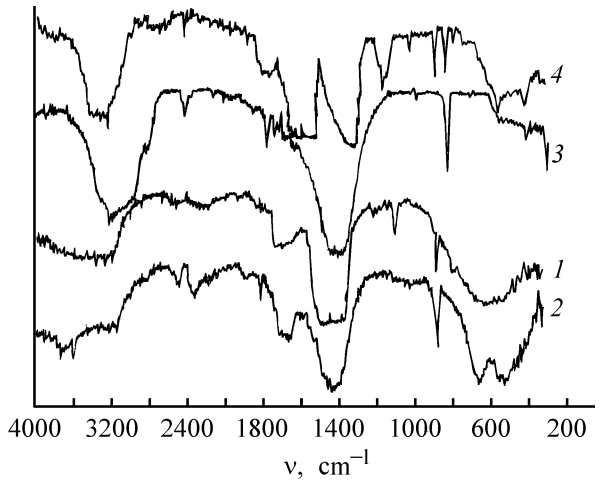

Fig. 2. IR spectra of (*1*) $Ca(NO_3)_2 \cdot 4H_2O$, (*2*) $Mg(NO_3)_2 \cdot 6H_2O$, (*3*) NH_4NO_3, and (*4*) solid phase in section III of the system $Ca(NO_3)_2$–$Mg(NO_3)_2$–NH_4NO_3–H_2O at crystallization temperature of 0°C. (ν) Wave number.

	24.00	16.00	20.00	40.00	–14.0	Mg · 6H + Ca · 3H + A · Ca · 2H
XI	25.87	14.78	26.10	33.25	+6.3	Mg · 6H + Ca · 3H + A · Ca · 4H

* I is ice; A, NH_4NO_3; Mg · 6H, $Mg(NO_3)_2 \cdot 6H_2O$; Mg · 9H, $Mg(NO_3)_2 \cdot 9H_2O$; Ca · 3H, $Ca(NO_3)_2 \cdot 3H_2O$; Ca · 4H, $Ca(NO_3)_2 \cdot 4H_2O$; A · Ca · 2H, $NH_4NO_3 \cdot Ca(NO_3)_2 \cdot 2H_2O$; A · Ca · 3H, $NH_4NO_3 \cdot Ca(NO_3)_2 \cdot 3H_2O$; A · Ca · 4H, $NH_4NO_3 \cdot Ca(NO_3)_2 \cdot 4H_2O$.

contain absorption peaks of the NO_3^- group at 750–1050 and 1330–1420 cm^{-1}, and the spectrum of ammonium nitrate (Fig. 2, curve *3*), that of the NH_4^+ group at 3100 cm^{-1}. These vibrations are characteristic of pure components of the system, but, with certain deviations, they can also be seen in the spectrum of the solid phase being analyzed (Fig. 2, curve *4*).

The DTG curves of pure compounds (Fig. 3, curves *1–3*) show dips corresponding to endothermic effects: 95, 300, and 410–460°C for $Mg(NO_3)_2 \cdot 6H_2O$; 40, 140–160, and 500°C for $Ca(NO_3)_2 \cdot 4H_2O$; 100, 130, 170, and 205°C for NH_4NO_3. The same dips at temperatures slightly changed owing to the formation of crystal hydrates of binary salts were found in the DTG curves of the compound under analysis (Fig. 3, curve *4*).

A comparison of the interplanar spacings in the X-ray diffraction patterns of the substance under analysis (Fig. 4, curve *4*) and pure substances (Fig. 4, curves *1–3*) revealed certain disagreements. It is necessary to note that the X-ray diffraction pattern of the solid phase contains all the main peaks with *d/n* values (Å): 1.190, 0.305, and 0.231 for calcium nitrate; 0.359, 0.268, and 0.236 for magnesium nitrate; 0.483, 0.398, and 0.222 for ammonium nitrate. Thus, we can conclude that binary salts containing calcium and magnesium crystal hydrates and also ammonium nitrate are present in the solid phase.

A comparison of the results of chemical and instrumental analyses with published data on the solubility of salt systems identified the following compounds in the solid phase: NH_4NO_3, $Mg(NO_3)_2 \cdot 6H_2O$, $Mg(NO_3)_2 \cdot 9H_2O$, $Ca(NO_3)_2 \cdot 3H_2O$, $Ca(NO_3)_2 \cdot 4H_2O$, $NH_4NO_3 \cdot Ca(NO_3)_2 \cdot 2H_2O$, $NH_4NO_3 \cdot Ca(NO_3)_2 \cdot 3H_2O$, and $NH_4NO_3 \cdot Ca(NO_3)_2 \cdot 4H_2O$. The characteristics of inflection points in the range studied in the system $Ca(NO_3)_2$–$Mg(NO_3)_2$–NH_4NO_3–H_2O are shown in Table 3.

It is seen that the crystallization temperature at the transition points varies widely, within the range –38.5…+6.3°C. The crystallization temperature at inflections in various sections grows with increasing concentration of ammonium.

Using the data obtained (isotherm 0°C), we found that the maximum concentration of nutrients in solutions with various N : CaO : MgO ratios is as follows (%): N (total) 16.13, CaO 7.59, MgO and 5.06 (Table 4). For the CaO : MgO ratio corresponding to dolomite, higher concentrations of nutrients are observed in the solution containing (wt %): NH_4NO_3 28.20, 17.95 $Ca(NO_3)_2$, 15.80 $Mg(NO_3)_2$, and 38.05 H_2O (pH 4.4). The chemical composition, concentra-

tions of nutrients, and pH of solutions having crystallization temperature of 0°C are listed in Table 4.

According to the data obtained, the mixture containing 16% bound nitrogen, 6% calcium (in terms of CaO), and 4% magnesium (in terms of MgO) is the optimal liquid fertilizer among those prepared by decomposition of dolomite with nitric acid, followed by treatment of the resulting acid product with ammonia water. As the temperature of saturated solutions increases, the concentration of nutrients grows only slightly. At 20 and 30°C the effect of salting-out of calcium and magnesium nitrates manifests itself. Thus, summer solutions are distinguished by increased concentration of nitrogen, but lowered concentrations of CaO and MgO.

Samples of liquid fertilizers that contain calcium, magnesium, and bound nitrogen were prepared under laboratory conditions, and their physicochemical properties were studied. Dolomite was decomposed under the optimal conditions reported in [23]: the highest degree of decomposition is reached with 45–55% HNO_3, 0.5–1.0-mm dolomite fraction, reaction dura-

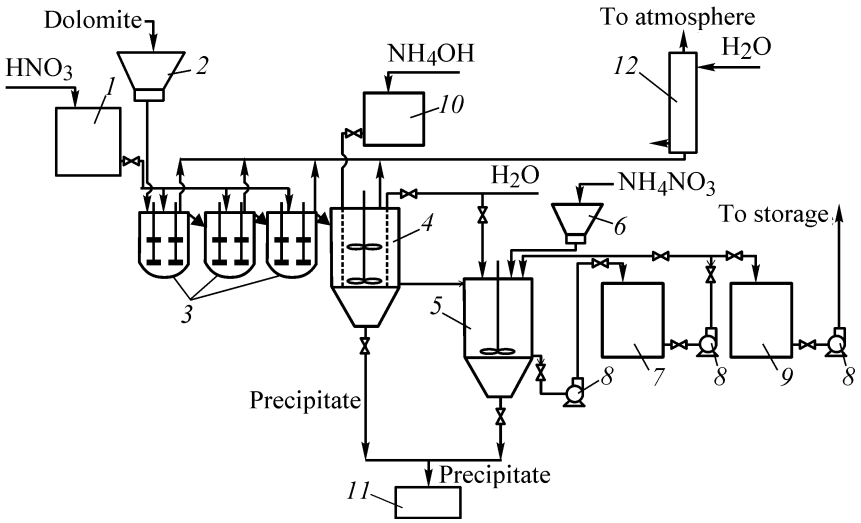

Fig. 5. Technological scheme of production of liquid fertilizers from dolomite, nitric acid, and ammonia: (*1*) tank for nitric acid, (*2*) bunker with dolomite, (*3*) reactors with elliptical bottom, (*4*) neutralization vessel, (*5*) coagulation vessel, (*6*) bunker with ammonium nitrate, (*7*) intermediate tank, (*8*) rotary pumps, (*9*) vessel for fertilizers, (*10*) tank with ammonia water, (*11*) slime bunker, and (*12*) packed absorber.

tion of 40–60 min, temperature of 50–60°C, and HNO_3 consumption of 120% relative to the stoichiometry. The product of dolomite decomposition with nitric acid contained, after its neutralization with ammonia, an aqueous solution of ammonium, calcium, and magnesium nitrates.

The main physicochemical parameters of this liquid fertilizer were as follows: crystallization temperature –3.3°C, pH 5.4, density 1281 kg cm^{-3}, dynamic viscosity 5.47 P, refractive index 1.440, and electrical conductivity 0.109 S cm^{-1}. Apparently, these parameters conform to the commonly accepted requirements to liquid fertilizers. Such a liquid fertilizer can be used as a special fertilizer for hothouse cultures, flowers, and fruit cultures.

We distinguished the following main technological stages of production of liquid fertilizers: decomposition of dolomite with nitric acid, neutralization of acidic solution, its standardizing with respect to nitrogen content, removal of precipitate, and conservation. A technological scheme for production of liquid fertilizers (Fig. 5) was supported on the basis of the results obtained.

CONCLUSIONS

(1) A study of solubility in the system $Ca(NO_3)_2$–$Mg(NO_3)_2$–NH_4NO_3–H_2O revealed the chemical composition of liquid fertilizers (%): NH_4NO_3 28.20, $Ca(NO_3)_2$ 17.95, $Mg(NO_3)_2$ 15.80, and H_2O 38.05. This chemical composition corresponds to the liquid-fertilizer brand 16-0-0-6CaO-4 MgO.

(2) A technological scheme for production of liquid nitrogen-, calcium-, and magnesium-containing fertilizers was supported.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Technology for Joint Production of Bromine and Lithium Bromide from Brines from Siberian Platform

Received April 8, 2003

Abstract—Two methods for obtaining bromine and lithium bromide from highly mineralized brines enriched with lithium- and bromine-containing compounds, with Li : Br atomic ratio of 0.4–0.8, were studied. These methods are based on a combination of the technique for production of bromine and sorption recovery of lithium from brines to give eluates, LiCl solutions.

Lithium bromide is an expensive reagent in short supply, which is in high demand in the market of lithium products. The prospects for high demand for this compound is mainly associated with its use in refrigeration engineering and in manufacture of heat pumps.

Most of the existing industrial techniques for manufacture of LiBr are based on the reaction of lithium hydroxide or carbonate with hydrobromic acid [1, 2] or elementary bromine in an aqueous medium in the presence of a reducing agent, e.g., hydrogen peroxide [3] or ammonia [4]. The common shortcoming of these methods is the high cost of LiBr obtained, which is due to the fact that expensive commercial lithium compounds, hydrobromic acid, and liquid bromine are used in the process. At present, HBr and Br_2 are manufactured in Russia in limited amounts and mainly from imported raw materials. In this context, development of more economic methods for production of LiBr from new kinds of raw materials is rather a topical task.

As comparatively low-cost and available raw material for production of both liquid Br_2 and LiBr can serve highly mineralized brines from the Siberian platform, which contain considerable amounts of compounds of lithium and bromine simultaneously. The lithium to bromine atomic ratio in brines of this type is 0.4–0.8, and, therefore, only part of bromine contained in a brine, rather than its whole amount, is required for obtaining LiBr. The remaining part can be used to manufacture liquid Br_2 as commercial product.

The most promising technique for processing of brines of this kind is that combining two main technological procedures: production of bromine and selective recovery of lithium ions to give lithium products. Of the known industrially used techniques for manufacture of bromine, the best applicable to the case in question is that based on steam induced desorption of elementary bromine after oxidation of bromide ions with chlorine. However, an important shortcoming of this technique is the necessity for use of liquefied chlorine, which is ecologically unsafe and involves difficulties in its transportation, storage, and use. To improve the ecological and economic characteristics of this technique, the authors suggest to oxidize bromide ions with chlorine obtained by anodic oxidation of chlorine ions contained in the brine, rather than with liquefied chlorine. Such a technology, based on electrochemical oxidation of Br^- ions with anodic chlorine, combined with steam-induced desorption of the Br_2 formed, is, presumably, the most promising for large-scale manufacture of Br_2[1] [5].

A sorption technique based on use of an inorganic lithium-selective sorbent $LiCl \cdot 2Al(OH)_3 \cdot mH_2O$ (DGAL-Cl) has been developed for recovery of lithi-

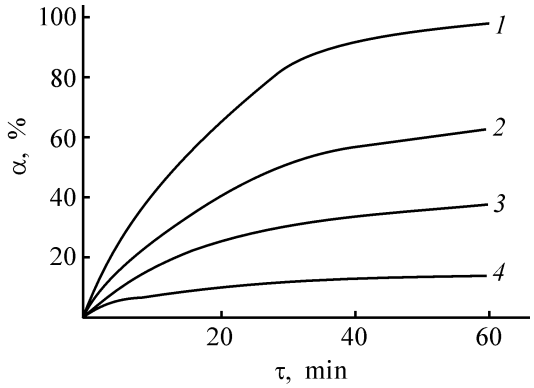

Fig. 1. Kinetic curves for the degree α of bromine absorption by LiOH solution in the presence of a reducing agent from bromine–air mixture with varied content of Br_2. (τ) Time. Br_2 content $c \times 10^2$ in air (g l^{-1}): (*1*) 25.7, (*2*) 16.2, (*3*) 9.7, and (*4*) 3.7.

um ions from highly mineralized brines [6]. In this method, lithium ions are recovered from the brine in the form of a selective-sorption eluate, a dilute LiCl solution with concentration of 7–10 kg m^{-3}, which contains a certain admixture of calcium and magnesium compounds removable by an appropriate purification procedure.

In elaboration of the techniques developed for recovery of lithium and bromine ions from brines of the Znamenskoe deposit (Irkutsk oblast), two new technological procedures were suggested for joint production of LiBr and elementary bromine. The first of these combines a procedure for manufacture of bromine and that for production of LiOH or Li_2CO_3 from selective-sorption eluates. A LiOH solution can be obtained by electrochemical conversion of a lithium chloride solution or its mixture with lithium carbonate [7, 8], and Li_2CO_3 slurry, by carbonization of a LiOH solution with carbon dioxide. Lithium bromide is obtained by bromination of lithium hydroxide or carbonate. As a brominating agent in the given method serves bromine vapor evolving from bromine water formed in isolation of bromine in the stage of steam desorption [1].

The second variant also includes a technique for production of liquid bromine; however, it is suggested to obtain LiBr directly from selective-sorption eluates (LiCl solutions) by ion exchange in desorption of lithium ions from the cation-exchange resin with a hydrobromic acid solution obtained by reduction of liquid bromine in an aqueous medium. Thus, the aim of this study was to make comparative analysis of the two suggested technological procedures for joint production of Br_2 and LiBr from natural brines.

EXPERIMENTAL

Laboratory studies were carried out with model solutions imitating the composition of a brine[2] with average composition (g l^{-1}): LiCl 2.5, NaCl 6.1, KCl 8.2, $MgCl_2$ 115, $CaCl_2$ 335, and Br^- 9.3; Li : Br atomic ratio 0.5. In studying multicomponent systems containing Br^0, Br^-, and Cl^-, analysis of solutions and the gas phase was performed using methods commonly accepted in manufacture of bromine [9]. The content of chloride ions in solutions was determined by mercurimetric titration, and that of calcium and magnesium ions, by trilonometry [10]; lithium ions were analyzed by flame photometry on an SP-9 spectrophotometer [11].

The first technological variant employs bromine water as a brominating agent. To obtain bromine vapor, bromine water was placed in a flask thermostated at 50°C. The flask was connected to absorbing vessels filled, depending on the aim of an experiment, with LiOH solution or Li_2CO_3 slurry. Bromine vapor was driven-off from bromine water with air from a compressor, with the content of bromine in the bromine–air mixture varied from 0.04 to 0.26 kg m^{-3}. The concentration of the LiOH solution was 50 g l^{-1}, the liquid to solid phase ratio (l : s) in the Li_2CO_3 slurry was varied from 3 to 11. As a reducing agent was used carbamide, with its amount varied in the range 0.75–1.5 relative to that required by the stoichiometry for reduction of elementary bromine to the bromide ion in accordance with the equations describing the chemical reactions

$$3Li_2CO_3 + 3Br_2 + CO(NH_2)_2 = 6LiBr + N_2\uparrow + 4CO_2\uparrow + 2H_2O, \quad (1)$$

$$6LiOH + 3Br_2 + CO(NH_2)_2 = 6LiBr + N_2\uparrow + CO_2\uparrow + 5H_2O. \quad (2)$$

As is known, the rate of bromine absorption by solutions of alkali or alkali metal carbonates is determined by the resistance of the boundary gas layer [1], being proportional to the bromine concentration in the gas phase. Figure 1 shows kinetic curves for the degree of bromine absorption by a LiOH solution from a bromine–air mixture with varied content of Br_2. As would be expected, the process is the faster and the degree of bromine absorption the greater, the higher the bromine concentration in the bromine–air mixture. The isotherm of bromine absorption is linear in the concentration range under study.

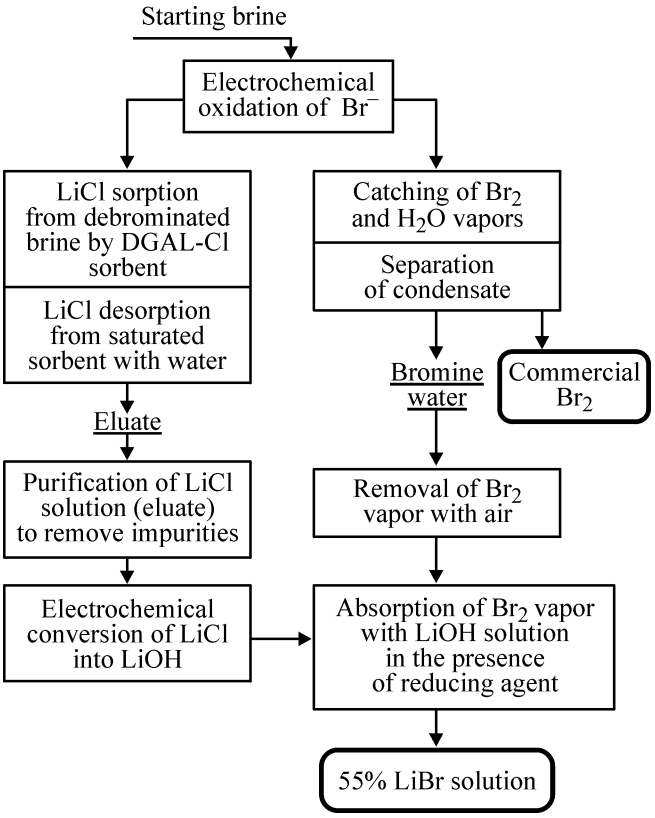
[2] Znamenskoe deposit (Irkutsk oblast).

With Li_2CO_3 slurry used to obtain lithium bromide, it was established that the concentration of the resulting LiBr solution increases with decreasing l : s ratio in the slurry, which is indicated by the data presented below:

The l : s ratio in slurry	11	7	4	3
LiBr concentration, g l^{-1}	125	246	381	440

Consequently, the l : s ratio is to be lowered for obtaining more concentrated LiBr solutions.

In the experiments, highly concentrated LiBr solutions with concentration of 400 g l^{-1} and more were obtained from saturated LiOH solutions and Li_2CO_3 slurry. In both cases, a certain excess of a reducing agent, about 20% relative to the stoichiometry of reactions (1) and (2), is necessary for more complete absorption of the bromine vapor. On the basis of the studies performed, technological Scheme 1 for obtaining LiBr with bromine vapor used as brominating agent has been developed [12].



Scheme 1.

The second method for producing LiBr directly from eluates obtained from brine as LiCl solutions is based on sorption of lithium ions by a KU-2×8 cation-exchange resin in the H^+ form, with its subsequent desorption with hydrobromic acid to give a LiBr solution. Laboratory studies were carried out with model LiCl solutions in distilled water, with the concentration of lithium ions in the solutions varied from 3 to 1500 mg l^{-1}. Sorption was performed at room temperature in a glass column 60 mm high and 1.09 cm in diameter, packed with 50 cm^3 of KU-2 × 8 cation-exchange resin at bed height of 54 cm. The kinetics of sorption of lithium ions by the cation-exchange resin was studied by the dynamic method. A solution to be passed through the sorption stage was fed from below upwards by a dosage pump, with the linear flow velocity W of the solution varied from 7.4 to 26 m h^{-1}. The cation-exchange resin saturated with lithium ions was washed to remove chloride ions with demineralized water, after which lithium ions were desorbed with a HBr solution. The process in which LiBr is obtained can be described by the following ion-exchange reactions

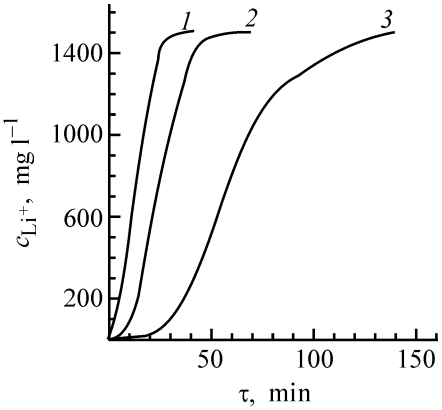


Fig. 2. Output curves of lithium ion sorption by KU-2×8 cation-exchange resin at different linear flow velocities of the solution. (c_{Li^+}) Concentration of Li^+ ions and (τ) time. W (m h^{-1}): (*1*) 26, (*2*) 15, and (*3*) 7.4.

$$R\text{–}H^+ + Li^+_{sol} \rightarrow R\text{–}Li^+ + H^+_{sol}, \quad (3)$$

$$R\text{–}Li^+ + H^+_{sol} \rightarrow R\text{–}H^+ + Li^+_{sol}. \quad (4)$$

In the initial stage of dynamic studies, output curves of lithium ion sorption by the cation-exchange resin were obtained at different flow velocities of a LiBr solution with concentration of 9.2 g l^{-1}, which corresponded to lithium ion concentration of 1500 mg l^{-1}. The dependences obtained (Fig. 2) made it possible to determine the time necessary for complete saturation of the cation-exchange resin and its dynamic exchange capacity (DEC), and to calculate the working zone height $H_{w.z}$ for each case. The sorption was performed in the plug-flow mode, which made it pos-

Table 1. Basic parameters of the process of lithium ion sorption by KU-2×8 cationite

15.0	60	1.61	0.77
26.0	35	1.58	0.89

Table 2. Basic technological characteristics of the process of lithium ion desorption from saturated cationite with HBr solutions

c_{HBr}, M	Degree of Li ion desorption, %	Concentration of the resulting LiBr solution, g l^{-1}	Degree of utilization of the desorbing solution, %
0.7	41.0	62.5	99.2
1.5	72.0	129.3	99.2
2.0	98.5	174.0	100
2.2	98.8	184.6	96.5
2.5	98.9	187.2	86.1

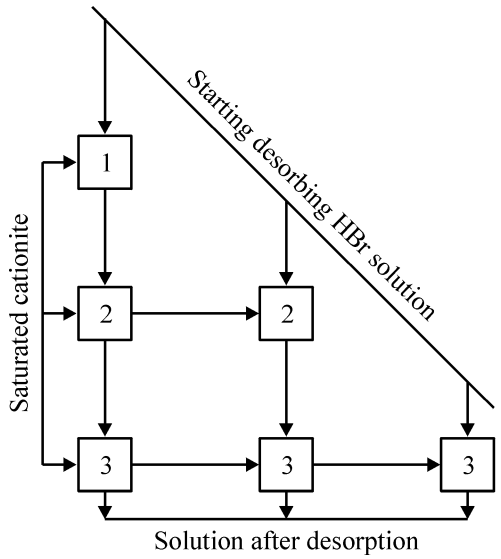
sible to use in the calculations the Michaels–Treible formula [13]:

$$H_{w.z} = H_b \frac{\tau_{eq} - \tau_{br}}{\tau_{eq} - (1 - \phi)(\tau_{eq} - \tau_{br})},$$

where H_b is the height of the fixed bed of the cation-exchange resin (m); τ_{eq}, the time in which a concentration equal to $0.95\,c_{in}$ appears after the cationite bed (h); τ_{br}, the time in which a breakthrough concentration equal to $0.05\,c_{in}$ appears after the cationite bed (h); ϕ, the symmetry parameter of the curve.

It was established in the experiments that raising W leads to an increase in $H_{w.z}$, with the dependence being linear. As expected, the capacity characteristics of the cation-exchange resin decrease somewhat, as also does the degree of lithium ion sorption from solutions, with increasing flow rate of the solution. It should be added that the dynamic exchange capacity of the cation-exchange resin in the concentration range of lithium ions in LiCl solutions (3–1500 mg l^{-1}), used in this study, remains virtually constant, being equal to 1.6 mg-equiv ml^{-1} (Table 1).

Lithium ions were desorbed from the cationite in three stages with HBr solutions at l : s = 1 : 1 for each stage by Scheme 2 modeling the process of continuous counterflow desorption (horizontal arrows denote the flow of the cation-exchange resin, and vertical arrows, that of the desorbing HBr solution). It was established experimentally that the optimal HBr concentration in the desorbing solutions is 2.0–2.2 M. As can be seen from the data in Table 2, only this concentration ensures the most complete (~99%) recovery of lithium ions from the cation-exchange resin and the maximum concentration of LiBr in the final desorbate. Use of more concentrated hydrobromic acid solutions for desorption of lithium ions is inexpedient because of the low extent of their utilization.

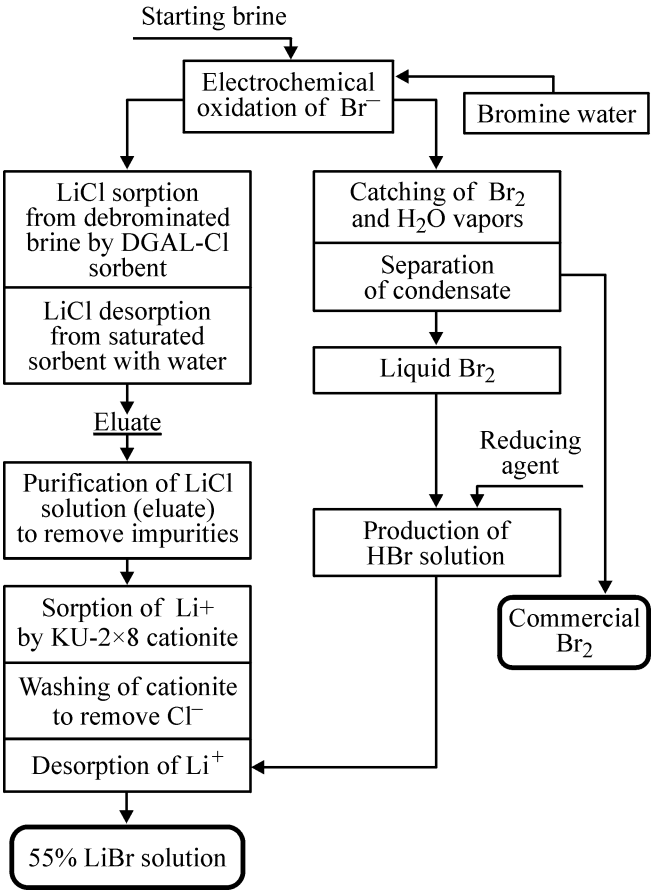


Scheme 2.

HBr solutions of required concentration were obtained by reacting elementary bromine with a reducing agent in an aqueous medium. The most appropriate reducing agents for this purpose are hydrazine, carbamide, and their derivatives, which form as a result of a redox reaction inert gaseous substances, N_2 and CO_2:

$$2Br_2 + N_2H_4 = 4HBr + N_2\uparrow. \quad (5)$$

The synthesis was carried out at room temperature under conditions of continuous metering-out of liquid bromine and agitation of the reaction mass until its total decoloration, which indicated the completion of the reaction. It was established experimentally that reaction (5) proceeds in strict conformity with the stoichiometry, with no excess of reagents required. This method for obtaining lithium bromide has been patented [14], its technological flowsheet is represented by Scheme 3. A solution of hydrobromic acid was used as brominating agent [14].



Scheme 3.

As already mentioned, both the methods yield two commercial products, Br_2 and LiBr, within a single technological scheme. It should be noted that, on the whole, the second method for LiBr manufacture directly from selective-sorption eluates obtained in the initial stages of brine processing is simpler and less expensive than the first technique, which involves power-intensive stages of LiOH or Li_2CO_3 production, which require intricate equipment. As for the choice of the optimal method for obtaining LiBr, it is determined by specific features and conditions of a particular production shop being designed or by availability of low-cost Li_2CO_3.

Combined schemes for joint production of Br_2 and LiBr from brines make it possible to lower substantially the manufacturing cost of the products obtained.

CONCLUSIONS

(1) Two variants of a technology for joint production of Br_2 and LiBr with bromine vapor or hydrobromic acid as brominating agents were developed.

(2) The second technique, which does not require additional expenditure for conversion of LiCl into LiOH or Li_2CO_3 for catching of bromine vapor, is simpler and less expensive.

Received July 16, 2003

Abstract—Dynamic gas extraction of osmium tetroxide from aqueous solutions was studied. The possibility of shortening substantially the duration of the stage of gas-extraction recovery of OsO_4 by reasonable choice of temperature, flow rate of extracting gas, and sample volume was also considered. The coefficients of OsO_4 distribution between the aqueous and gas phases were determined in the temperature range 20–90°C.

The absence of highly selective reagents for photometric determination of osmium and its low concentrations in objects to be analyzed create a need for preliminary concentration and separation of osmium from accompanying admixtures [1–3]. The unique property of osmium to form a volatile tetroxide is most commonly used to separate it from other metals. Osmium is frequently isolated as tetroxide by evaporation or gas extraction. Gas-extraction separation of osmium from other metals is in considerable use not only in analytic practice but also in industrial production of this metal [2, 4].

The search for more perfect schemes for distilling off osmium tetroxide has resulted in that a procedure for gas-diffusion recovery of osmium has been developed [5]. However, this scheme failed to solve the major problem of sample preparation for the determination of osmium, since it could not make shorter the time required for osmium isolation, which commonly takes more than an hour [2, 4, 5]. The possibility of optimizing the stage of osmium recovery in the form of its tetroxide is limited by the lack of published data on the coefficients of OsO_4 distribution in the liquid–gas system over a wide temperature range or any quantitative information about the effect of various factors on the efficiency of gas-extraction recovery.

The aim of this study was to search for the conditions under which the time of gas-extraction recovery of osmium is the shortest by revealing factors that affect the coefficients of osmium tetroxide distribution between the aqueous and gas phases.

EXPERIMENTAL

The osmium concentration in solution was determined by a spectrophotometric method based on the formation of a colored complex of osmium with thiourea [1]. We measured the optical density of colored solutions at a wavelength of 480 nm on a Karl Zeiss Specord M 40 spectrophotometer (Jena, Germany).

We prepared working aqueous solutions of OsO_4 immediately before experiments by saturating aqueous phases with OsO_4 vapor. For this purpose, we bubbled air through an alkaline solution of OsO_4, prepared from a standard solution in Richter's apparatus, and directed the resulting air flow into Zaitsev's absorbing apparatus filled with distilled water or sulfuric acid solution, depending on the required composition of the aqueous phase. The concentration of osmium in the thus prepared working solutions was determined spectrophotometrically by the above-mentioned procedure with the use of thiourea.

We determined the coefficients of OsO_4 distribution in the gas–liquid system by the known procedure, which determines the decrease in the component concentration in the working solution after passing a specified volume of an extracting gas through this solution [6]. Zaitsev's absorbing apparatus (bubbler) with the working solution was placed in a liquid thermostat, with temperature maintained constant to within ±0.1°C. To maintain a constant flow rate of the extracting gas (air or nitrogen) through the bubbler, we used a gas flow controller from the gas preparation unit of a gas chromatograph. The flow rate of the extracting gas

1070-4272/03/7612-1896 $25.00 © 2003 MAIK "Nauka/Interperiodica"

was measured with a soap-film flowmeter and maintained constant using a rotameter at the bubbler inlet. We measured the time with a stop-watch. The coefficient of OsO_4 distribution was calculated by the formula: [6]

$$K = W_G t/[V_L \ln(c_L^0/c_L)]. \quad (1)$$

Here K is the distribution coefficient, equal to the ratio of the OsO_4 concentration in the liquid phase to its concentration in the gas phase at equilibrium; W_G, the volumetric flow rate of the extracting gas ($cm^3\ min^{-1}$); t, the duration of bubbling (min); V_L, the solution volume (cm^3); c_L^0 and c_L, the starting and final concentrations of OsO_4 in the working solution ($mg\ l^{-1}$).

The relative error in determining K by the above-mentioned procedure is, with account of the error in measuring the flow rate of the extracting gas and other quantities appearing in formula (1), 5% at number of measurements $n = 4$ and confidence coefficient $P = 0.95$.

In the general case, the distribution coefficient of any component in a liquid–gas system depends on its concentration. The nonlinearity of the interphase distribution isotherm becomes significant at a certain concentration of the component, when the nonideal nature of the solution begins to show itself. For extremely diluted solutions, which corresponds to an overwhelming majority of cases of gas-extraction recovery of osmium from solutions, the concentration dependence of the distribution coefficient can, as a rule, be disregarded [6]. Our experiments showed that the coefficient of OsO_4 distribution between the aqueous and gas phases is independent of the OsO_4 concentration in aqueous solutions over the whole concentration range (30–500 $mg\ l^{-1}$), and its numerical value at 20°C is 950 ± 50. In this case, K is independent of which extracting gas (air or nitrogen) is used for OsO_4 extraction.

It has been shown previously that, for liquid–gas systems, the distribution coefficient of a volatile substance with limited solubility in a liquid can be rather easily estimated *a priory* if the saturated vapor pressure and the solubility of the substance at a given temperature are known [7]:

$$K = RTdP_0. \quad (2)$$

Here R is the universal gas constant ($dm^3\ Pa\ mol^{-1}\ K^{-1}$); T, temperature (K); P_0, the saturated vapor pressure at the temperature specified (Pa); d, the solubility of the substance in the liquid at this temperature ($mol\ dm^{-3}$).

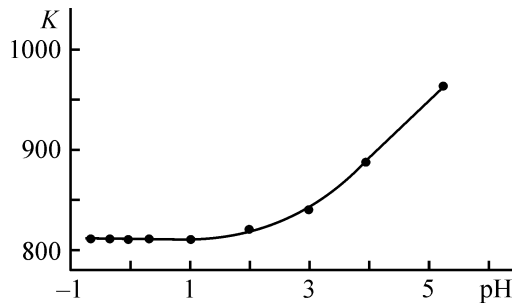

Fig. 1. Effect of pH on the coefficient of OsO_4 distribution K between aqueous and gas phases at 20°C.

Below, the coefficients of OsO_4 distribution in a water–air system, found experimentally and calculated by formula (2) on the basis of published data on OsO_4 properties [8], are compared:

T, °C	K_{exp}	K_{calc}
18	990 ± 50	910
25	720 ± 40	680

Taking into account that formula (2) is based on the assumption that the phases are ideal, we can conclude that the correspondence between the experimental and calculated K values is reasonable.

The most important factors affecting K are the nature of the liquid phase and the temperature, whereas the nature of the gas phase, in which intermolecular interaction forces are negligibly small, hardly affects this parameter. Figure 1 shows how the coefficient of OsO_4 distribution depends on the pH value of aqueous solutions. As would be expected with account of the weakly acid properties of osmium tetroxide ($K_1 = 6.3 \times 10^{-3}$, $K_2 = 6.8 \times 10^{-13}$), K is virtually independent of the hydrogen ion concentration within the pH range in which OsO_4 is almost completely in the molecular form.

It is a common knowledge that raising the temperature leads to a substantial decrease in K and to a corresponding increase in the efficiency of gas-extraction recovery. The table illustrates the effect of temperature on the coefficients of OsO_4 distribution. In addition to data for purely aqueous solutions, the table lists those for a sulfuric acid solution, since various forms of osmium in aqueous solutions are rather frequently oxidized to OsO_4 in a sulfuric acid medium. It can be seen from the table that heating from room temperature to 90°C results in a decrease in the distribution coefficient by almost a factor of 30 for both neutral and sulfuric acid solutions. The temperature

Coefficients of OsO_4 distribution, K, in the liquid–gas system at various temperatures

dependences of the distribution coefficient (Fig. 2) are close to the theoretical dependences. They are straight lines in the $\ln K$–$1/T$ coordinates.

The flow rate of the extracting gas is one more factor, in addition to an increase in temperature, that can intensify the gas-extraction recovery. All other conditions being the same, the higher the flow rate of the extracting gas, the greater the amount of a volatile component extracted from a solution in unit time. However, raising the flow rate of the extracting gas through a solution being analyzed is reasonable only to those values at which the interphase equilibrium in the liquid–gas system has enough time to be attained. Figure 3 shows how the flow rate of the extracting gas affects the distribution coefficient calculated by formula (1) in terms of the equilibrium model of dynamic gas extraction.

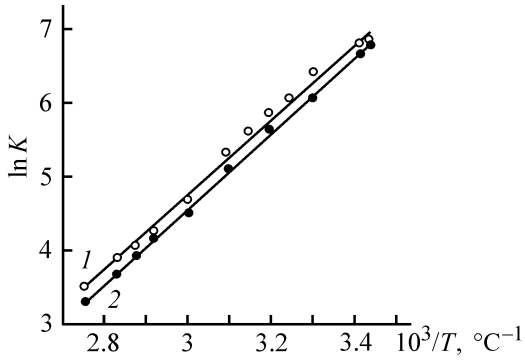

Fig. 2. Logarithm of the coefficient of OsO_4 distribution in the liquid–gas system, $\ln K$, vs. temperature T. (*1*) Distilled water and (*2*) 1 M solution of H_2SO_4.

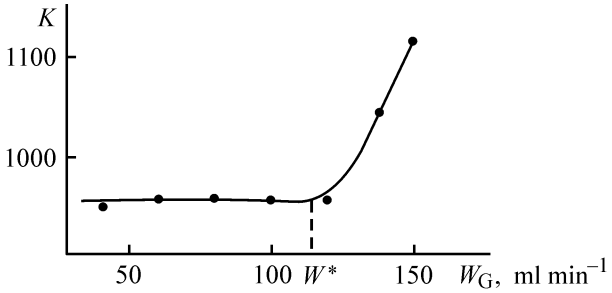

Fig. 3. Effect of the flow rate W_G of the extracting gas on the coefficient K of OsO_4 distribution between aqueous and gas phases. V_L = 2.0 ml, temperature 20°C.

As follows from Fig. 3, K is independent of the flow rate of the extracting gas, W_G, at $W_G \le 120$ ml min^{-1}. At greater flow rates, K starts to increase with W_G. This circumstance indicates that the interphase equilibrium has no enough time to be attained in this region. Similar dependences were obtained for other solution volumes V_L in the bubbler in the range 1–10 ml. The only difference is that the value of W_G^*, at which deviation from the equilibrium conditions of gas-extraction recovery begins, varies in direct proportion to the solution volume.

The ratio V_L/W_G is the time during which the extracting gas is in contact with the bulk of the solution. On this basis, we can conclude that the minimum time required for an equilibrium interphase distribution of OsO_4 to be established between the liquid and gas phases is $V_L/W_G^* = 2.0$ ml : 120 ml min^{-1} = 1 s.

Using the equilibrium model of dynamic gas extraction and the resulting formula (1), we can calculate the time R necessary for a prescribed degree of gas-extraction recovery of OsO_4 from the solution to be attained:

$$R = (1 - c_L/c_L^0). \quad (3)$$

Substituting c_L/c_L^0 from Eq. (3) into formula (1) and making simple rearrangements, we obtain

$$t = (KV_L/W_G)\ln[1/(1 - R)]. \quad (4)$$

If we set the flow rate of the extracting gas as $W_G = W_G^*$ and take into account that $V_L/W_G^* = 1$ s, we obtain the following approximate relationships for calculating the necessary duration t (s) of the stage of gas-extraction recovery of OsO_4 from aqueous solutions:

$$t \approx 3K \quad (\text{for } R = 0.95), \quad (5)$$

$$t \approx 4.6K \quad (\text{for } R = 0.999). \quad (6)$$

To verify the validity of expressions (5) and (6), we found experimentally the time necessary for 95%

recovery of OsO_4 from 5 and 10 ml of 1 M sulfuric acid solution at 90°C (K = 27) and air flow rates of 300 and 600 ml min^{-1}, respectively. In both cases, this time was 90 ± 5 s, in satisfactory agreement with the calculated value (81 s).

CONCLUSION

The duration of the stage of gas-extraction recovery of osmium from aqueous solutions in the form of its volatile tetroxide does not exceed several minutes at reasonable choice of temperature, flow rate of extracting gas, and sample volume. This creates favorable conditions for development of fast procedures for photometric determination of osmium in aqueous media and, in particular, that for flow-through injection analysis.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Monolithic Silica Gel in Alkaline Medium

Abstract—The influence exerted by the basicity and nucleophilicity of a number of organic amines on the formation of a monolithic silica gel by the organic sol-gel method was studied.

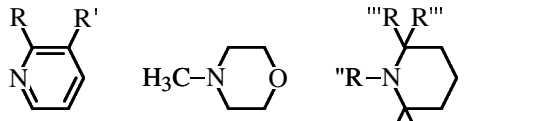
During several years, the fundamental aspects of tetramethoxysilane (TMOS) hydrolysis and polycondensation of the forming compounds have been studied in order to obtain a monolithic silica gel SiO_2. The composition of the sol–gel system ensuring the formation of a three-dimensional network with minimum content of organic impurities has been optimized by varying the chemical nature of DCCA (drying control chemical additives) reagents introduced into the system [1], catalysts [2], and solvents of the sol–gel process [3]. However, acid-catalyzed sol–gel synthesis was considered in all cases.

Catalysis of an organic sol–gel process in an alkaline medium was described in [4], mainly with the aim to synthesize nanodispersed SiO_2 particles [5, 6]. However, only few publications have been concerned with the fundamental aspects of formation of a monolithic SiO_2 gel in the presence of bases [7, 8], with catalysis performed in both cases by adding an ammonia solution to the sol–gel system. In [9], the influence exerted by a number of organic amines on TMOS hydrolysis and polycondensation of the forming compounds was studied in order to obtain monodisperse SiO_2 nanoparticles. In this case, the catalytic process occurs under conditions of strong dilution of TMOS with water and ethanol (TMOS : water : ethanol ≈ 1 : 25 : 100), which is favorable for formation of an ensemble of dispersed particles [4].

In the present study, the influence exerted by basicity and nucleophilicity of a number of organic amines on TMOS hydrolysis and polycondensation of the forming compounds under conditions of a limited amount of water and ethanol relative to that of the forming SiO_2 gel was analyzed, possibility of synthesizing a monolithic gel under the given conditions was determined, and preparative methods for this synthesis were developed.

EXPERIMENTAL

For a study of TMOS hydrolysis and polycondensation of the forming compounds under alkaline conditions the following chemically and thermally stable aromatic amines were chosen: 3-fluoropyridine (**1a**), pyridine (**1b**), and 2-picoline (**1c**), and tertiary cyclic amines: 4-methyl morpholine (**1d**), 1-methylpiperidine (**1e**), and 1-ethyl-2,2,6,6-tetramethylpiperidine (**1f**):



1a–**1c** **1d** **1e**, **1f**

where R = H, R' = F (**1a**); R = R' = H (**1b**); R = CH_3, R' = H (**1c**); R" = CH_3, R"' = H (**1e**); R" = C_2H_5, R"' = CH_3 (**1f**).

The choice of the amines used is not accidental. This becomes apparent when comparing the ionization constants of their conjugated acids, pK_a:

$$:NR_3 + H_2 \rightleftarrows HN^+R_3 + OH^-.$$

The boiling points and pK_a constants of these amines are listed below [for comparison, the corresponding constants for ammonia (**1g**) are also presented]:

Amine	pK_a	bp, °C
1a	3.0 [10]	30–31/4 mm
1b	5.247 [10]	115
1c	5.997 [10]	128
1d	7.41 [11]	115.4
1e	9.97 [12]	106
1f	11.13 [13]*	82–83/10 mm
1g	9.25 [14]	

* The pK_a value is given for 1,2,2,6,6-pentamethylpiperidine; for 1-ethyl-2,2,6,6-tetramethylpiperidine the pK_a value must be about the same or somewhat higher.

1070-4272/03/7612-1904 $25.00 © 2003 MAIK "Nauka/Interperiodica"

All the compounds used, TMOS and the amines, were purified by distillation on a rectification column with efficiency of 10 theoretical plates in a vacuum with residual pressure of 760–10 mm Hg. Compounds **1b**–**1e** are commercial preparations; trifluoropyridine **1a** and 1-ethyl-2,2,6,6-tetramethylpiperidine **1f** were synthesized using the procedures described in [15] and [16], respectively.

To prepare sol–gel systems **1a**–**1g**, TMOS (1 equiv), ethanol (1 equiv), and a catalyst were mixed in the order specified above and water was added under vigorous agitation with a magnetic stirrer. In the case of pyridine **1b**, 2-picoline **1c**, or 2-fluoropyridine **1a**, water was added at room temperature; for more basic amines, 4-methyl morpholine **1d**, 1-methylpiperidine **1e**, 1-ethyl-2,2,6,6-tetramethylpiperidine **1f**, or ammonia **1g**, this was done under cooling to –10°C. The ratios of amines **1a**–**1g** used as catalysts in preparing the corresponding gels **2a**–**2g** are listed below:

Gel	**2a**	**2b**	**2c**	**2d**	**2e**	**2f**	**2g**
Amine	**1a**	**1b**	**1c**	**1d**	**1e**	**1f**	**1g**
Ratio	0.1	0.1	0.1	0.02	0.01	0.01	0.01

The resulting solutions were placed in hermetically sealed polypropylene test tubes 15 mm in diameter (5 test tubes for each gel) and heated at 70°C for 6 days. Then the hermetic stoppers of the test tubes were replaced with stoppers with apertures (1 mm in diameter) and humid gels were dried in the following temperature mode: heating from 70 to 80°C in 2 h, keeping at 80°C for 22 h, heating from 80 to 100°C in 2 h, keeping at 100°C for 22 h, heating from 100 to 120°C in 2 h, and keeping at 120°C for 20 h. Gels **2b** and **2f** were additionally heated in glass test tubes from 120 to 150°C in 5 h and kept at this temperature for 20 h. This yielded samples **3b** and **3f**.

For the resulting gels **1a**–**1g**, the open porosity W_{op} and apparent density d_{app} (Archimedes method, with toluene as saturating fluid) were determined. The gelation point t (h) was found at 70°C as the time after which the sol lost its fluidity. The hardness of the samples was measured on a PMT-3 microhardness meter. Derivatograms were measured on a Q-1500D derivatograph (Hungary) in the temperature range extending to 1000°C at heating rate of 20 deg min^{-1}. The percentage content of SiO_2 in the gels obtained was determined gravimetrically, and the content of carbon was found by measuring the electrical conductivity of a $Ba(OH)_2$ solution serving as absorber of CO_2 formed upon burning the samples in oxygen. An electron-microscopic study of the gels was performed on an EM-125 instrument at accelerating voltage of 75 kV with cellulose–carbon replicas prepared on freshly cleaved surfaces of the gels obtained. The porous structure of the samples was studied by analyzing adsorption–desorption isotherms of ethanol on a McBain spring vacuum balance [17].

Physicochemical characteristics of the gels obtained

Sol–gel system	t, h	SiO_2, %	C, %	d_{app}, g cm^{-3}	W_{op}, %	Hardness, kg mm^{-2}
2a	0.77	88	2.05	1.07	46.8	32.6
2b	0.18	89.5	3.35	0.73	63.2	11.1
3b	–	92.4	4.10	0.61	69.4	9.8
2c	0.13	90	4.55	0.66	66.7	15.7
2d	0.02	92	1.75	–	–	9.4
2e	<0.01	91	1.45	0.58	71.3	9.2
2f	<0.01	91	2.70	0.65	67.9	15.4
3f	–	93	2.50	–	–	–
2g	<0.01	94	1.0	–	–	10.0

Samples **2a** and **2b** were monolithic transparent cylinders; systems **2c**, **2d**, and **3b**, somewhat opalescent partly cracked cylinders; systems **2e**–**2g** and **3f**, completely cracked samples.

The table lists the physicochemical characteristics of the resulting gels.

It can be seen from the table that the density and hardness of the samples synthesized decreases and their porosity increases as the basicity of the amines used as catalysts becomes higher. In this case, the content of SiO_2 in the gel matrix shows, according to the derivatographic data in Fig. 1, the opposite trend, i.e., grows, with the gelation time t of the sol-gel system simultaneously decreasing. Such a change in t in going from sample **2a** to samples **2e**–**2g**, which even occurs upon a pronounced decrease in the amine concentration, can be readily accounted for by an increase in the rates of reactions of hydrolysis of the $Si–OCH_3$ bond [4].

$$\equiv Si–OCH_3 + H_2O \xrightarrow{OH^-} \equiv Si–OH + CH_3OH \quad (1)$$

and condensation of the forming silanols into siloxanes [4]

$$\equiv Si–OH + HO–Si\equiv \underset{(III)}{\overset{(II)}{\rightleftarrows}} \equiv Si–O–Si\equiv + H_2O.$$

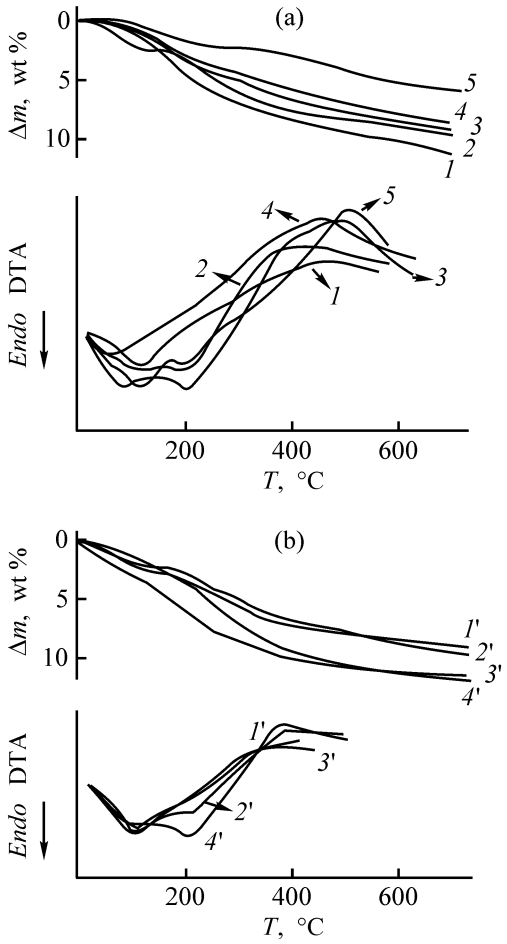


Fig. 1. DTA and TG data for (*1*–*5*, respectively) gels **2a**–**2c**, **2e**, **2g** and (*1'*–*4'*, respectively) gels **2b**, **2f** and **3b**, **3f**. (Δm) Mass loss and (T) temperature.

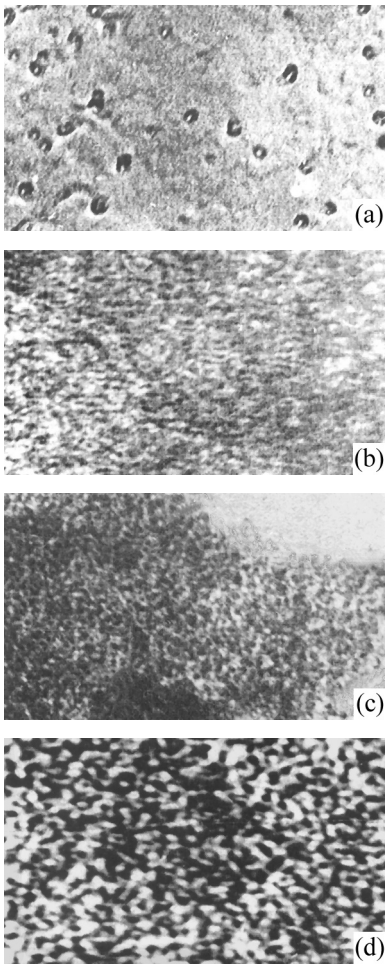

Fig. 2. Electron micrographs of gels (a) **2a**, (b) **2b**, (c) **2e**, and (d) **2f**. Magnification 120000.

Of much more interest is analysis of DTA curves (Fig. 1a) in order to determine the content of SiO_2 and carbon in the gel matrix (see table). As can be seen from an analysis of the intensities of these curves in the temperature range 400–600°C, which correspond to exothermic effects of burning-out of unhydrolyzed methoxy groups in the gel matrix, the number of these groups is the greatest when strongly basic amines are used as catalysts of the sol–gel process, i.e., in samples **2e** and **2g**. The rise in the intensity of this band in the case of gel **2f**, with a simultaneous increase in the content of carbon, should be attributed to lower volatility of amine **1f** as compared with the other bases used. In contrast to the other bases, amine **1f** simply remains in the gel matrix upon its being dried. In this case, the total amount of carbon in these samples (see table) is much lower than that in samples **2b** and **2c**. It seems reasonable to assume that the main part of carbon in the last two gels is contained in the form of volatile organic compounds remaining in the gel matrix after drying. Indeed, the DTA curves of these gels show two extrema [in contrast to the DTA curves of gels **2e** and **2g**] related to intense endothermic evaporation effects.

Comprehensive quantitative analysis of gels **2a**–**2g** is rather complicated; however, analysis of DTA curves and general considerations lead to the following conclusions. Apparently, residual amounts of methanol, water, and catalyst, retained in pores of the matrix by strong hydrogen bonds, remain in the gels after drying at 120°C. To their removal from the structure corresponds the first endothermic effect in the DTA curves of gels **2a**–**2g**. The second endothermic effect, probably, corresponds to removal of volatile organic compounds of silicon, which are formed when amines **1b** or **1c** are used as catalysts of the sol–gel process. These compounds are, apparently, characterized by low molecular weight, which allows them to easily leave a matrix being heated.

Such a disproportionation of alkoxysilanes to give the starting TMOS or low-molecular-weight siloxane has been described when studying the mechanisms of the sol–gel process [18]. When strong bases are used, no low-molecular-weight siloxanes are formed. In this case, it can be seen from the DTA curves that the evaporation of the solvents of the sol–gel process is immediately followed by burning-out of methoxylyl groups ≡Si–OM.

Finally, the attribution of the existence of the second dip in the DTA curves just to the process of evaporation of volatile siloxanes (rather than to evaporation of the excess amount of an amine used) can be confirmed by analysis of data for gels **2a**–**2c**. The content of carbon in the matrix of sample **2a** is much lower than that in gels **2b** and **2c**, although the volatilities of 3-fluoropyridine, pyridine, and 2-picoline are about the same. The second dip in the DTA curve, which is characteristic of gel **2b**, is virtually not observed at all in gel **3b** (Fig. 1b), with the content of carbon in the gel matrix remaining virtually unchanged. It is apparent that, in this case, volatile siloxanes are simply transformed into siloxanes with higher molecular mass. In passing from gel **2f** to gel **3f**, the run of the corresponding DTA curves is not changed (Fig. 1b).

Gels **2b** and **2c** still remain monolithic, whereas with stronger bases used as catalysts of the sol–gel process [gels **2d**–**2g**], the samples obtained completely crack in drying despite the increased amount of SiO_2 in the gel matrix and lowered content of carbon. The reason for such a behavior of the samples synthesized can be understood when studying their microstructure (Figs. 2 and 3).

It follows from the electron micrographs of gels **2a**, **2b**, **2e**, and **2f** in Fig. 2 that the monolithic structure of gel **2a**, which is, on the whole, characteristic of the sol–gel process in an acid medium, contrasts with the cellular structure of gel **2b** and even looser structure of gels **2e** and **2f**. These distinctions become even more apparent when studying the porosity of the samples synthesized (Fig. 3). Analysis of the data in Fig. 3 shows a clearly pronounced dependence of the pore size distribution on the basicity of a catalyst for different sol–gel systems. For comparison, data for a sol–gel process performed in the presence of acetic acid are show (Fig. 3, curve *1*).

The mechanisms of sol–gel processes of TMOS hydrolysis and polycondensation of the resulting compounds and those by which particles of colloid silica are formed have been described in detail [4, 19]. Apparently, gel **2a** is formed by the polymeric mechanism, which is characteristic of processes occurring in the acid medium, and gels **2d**–**2g**, by the corpuscular mechanism, in which the possibility of coarsening of SiO_2 particles is due to the occurrence of reaction (III). The mechanism by which gels **2b** and **2c** are formed has intermediate nature, with the Si–O–Si bonds between separate particles partly preserved, which is responsible for the monolithic character of gels **2b** and **2c**. The number of Si–O–Si bonds is small, and it is this fact that accounts for the low density and hardness of these monoliths. The use in the process of a sterically hindered base with lowered nucleophilicity, amine **1f**, does not lead to any significant changes in the parameters of the resulting gel **2f**, in contrast to the sol–gel process of TMOS hydrolysis and polycondensation of the forming compounds under conditions of strong TMOS dilution with water and ethanol [9].

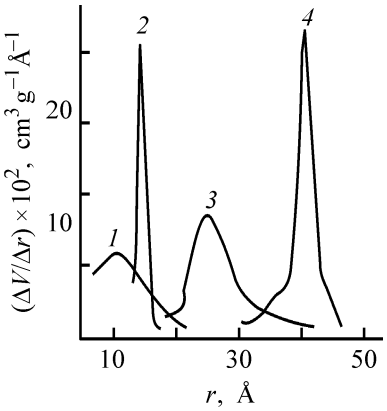

Fig. 3. Curves describing pore volume V distribution with respect to pore radii r for (*2*–*4*, respectively) gels **2a**, **2b**, and **2d**. (*1*) Sol–gel process in acid medium (acetic acid).

CONCLUSIONS

(1) A novel method for synthesis of porous SiO_2 xerogels is suggested. This method employs amines as catalysts, with the pore size controlled by the basicity of a catalyst used.

(2) Irrespective of the concentration of tetramethoxysilane, the mechanism of the sol–gel process is determined solely by the nature of a catalyst. In the case of weakly basic amines, a mixed polymeric–corpuscular mechanism is operative, which enables synthesis of monolithic SiO_2 xerogels.

(3) In alkaline catalysis under the action of strong bases, the dispersed phase has the form of an ensemble of weakly bound SiO_2 particles, which gives no way of obtaining monolithic samples.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Simple Criterion of Thermodynamic Similarity for Molecular Inorganic Compounds

I. B. Sladkov

St. Petersburg State Technical University, St. Petersburg, Russia

Received November 12, 2002; in final form, October 2003

Abstract—The new determining criterion of thermodynamic similarity was suggested and used to obtain correlations that ensure reliable prediction of the physicochemical properties of molecular inorganic compounds on the basis of a single experimental characteristic of a substance, its boiling temperature.

The accumulation of reference information lags far behind the needs of science and technology for data on the physicochemical properties of substances. Because the experimental determination of properties is frequently a complicated task, it becomes even more important to determine the lacking data by calculation. Presently, such methods use the thermodynamic similarity theory as a theoretical basis [1].

The similarity theory originates from the reduced Van der Waals equation, from which the law of corresponding states follows. The concept of the corresponding states, which appeared as a consequence of the reduced Van der Waals equation, further became separated from the particular form of the equation of state and transformed into a method for prediction of the physicochemical properties of substances in terms of the similarity theory [2].

The similarity theory is based on the generalized form of the reduced equation of state

$$Y_{red} = f(T_{red}, V_{red}), \quad (1)$$

where Y_{red} is an invariant that represents the dimensionless form of the property to be determined using the law of the corresponding states. Such an invariant may be a dimensionless combination of any physicochemical properties.

Equation (1) means that, in terms of the dimensionless parameters, the physicochemical behavior of similar substances must be identical. This gives reason to believe that Eq. (1) is the criterion equation of thermodynamic similarity. The criterion equation in the form (1) is referred to as the two-parameter form of the law of corresponding states.

As is known from the similarity theory, criterion equations can be applied solely to identical objects. Correspondingly, Eq. (1) is only applicable to thermodynamically similar substances.

To judge whether or not the thermodynamic similarity is the case, one commonly uses the dimensionless parameters named the determining criteria of thermodynamic similarity. In the absence of such criteria, Eq. (1) has a very narrow applicability range, being solely suitable for small groups of substances exhibiting rather rigorous thermodynamic similarity. To extend the applicability range of Eq. (1), a determining criterion A is introduced as its additional argument to give a three-parameter form of the law of corresponding states

$$Y_{red} = f(T_{red}, V_{red}, A). \quad (2)$$

Establishing the determining criteria of thermodynamic similarity is a rather complicated task. It is this circumstance that explains why more than half a century passed between the formulation of the law of corresponding states and its practical application (in the form of methods for approximate calculation of physicochemical properties). In the mid-1950s, several criteria of the same kind were suggested, among which the Pitzer acentric factor gained the widest acceptance [3]. The correlations developed on the basis of the acentric factor have found wide application for predicting properties of organic substances.

The use of the acentric factor in the case of inorganic molecular compounds meets certain difficulties, which are caused both by the specific features of the prediction method [4] and by the fact that the correlations based on the acentric factor cannot be applied to strongly polar substances and associated liquids [3].

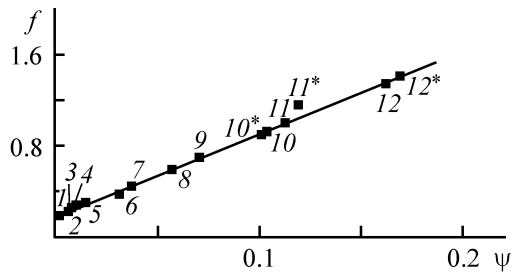

Fig. 1. Relation between the criteria f and ψ. *Digits at points* denote the sample nos. in Table 1, and *digits with asterisk*, those in Table 2; the same for Figs. 2 and 3.

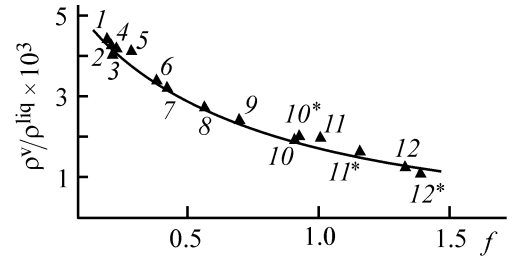

Fig. 2. Relation between the criterion f and the vapor to liquid density ratio ρ^{v}/ρ^{liq} at the boiling point.

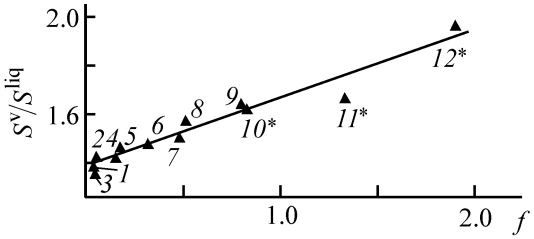

Fig. 3. Relation between the criterion f and the ratio of the standard entropies of gas and liquid, S^{v}/S^{liq}.

It has been suggested to use in characterizing the thermodynamic similarity of inorganic molecular compounds the determining criterion named the factor of complexity of the intermolecular interaction (ψ-factor) [5]. This factor is calculated from the boiling temperature T_b and the molar volume of a liquid at the boiling point, V_b ($cm^3\ mol^{-1}$):

$$\psi = 0.01 \ln T_b - 0.122 \ln V_b + 0.006.$$

A number of correlations have been developed on the basis of the ψ-factor for predicting the physicochemical properties of molecular inorganic liquids [6]. Many of these allow calculation of physicochemical properties with nearly experimental error.

Although data on the molar volume of a liquid at its boiling point are available for many substances (e.g., in a reference book [6]), the boiling points of a molecular liquid is its most readily available characteristic. Accordingly, it would be of particular importance to have, for little-studied substances, a determining criterion that could be calculated solely from the boiling point of a substance under consideration.

The method used to establish the ψ-factor [5] was applied to obtain a new determining criterion of thermodynamic similarity, defined by the equation

$$f = \ln T_b - 1.1 \ln \Pi - 4. \quad (3)$$

It should be emphasized that the parachor Π is calculated from data on the parachor increments for different elements. The calculation procedure and all the necessary tabulated data were reported in [6].

Prior to considering the calculation of physicochemical properties with the use of the criterion f, let us note that the determining criteria f and ψ are correlated (Fig. 1), with high correlation factor ($R = 0.9967$):

$$f = 7.3\psi + 0.2.$$

The existence of the above correlation is of major practical importance, because it allows estimation of the polarity of a little-studied substance on the basis of the only experimental parameter, its boiling temperature. The values of the ψ-factor, which characterize the boundaries between substances with different polarities, can be used to obtain the following values of the criterion f for characterizing the polarity: $0 < f < 0.5$ for nonpolar and weakly polar substances (e.g., $SiCl_4$ and BBr_3), $0.5 < f < 0.9$ for moderately polar substances (e.g., $CrCl_2O_2$ and IF_5), and $f > 0.9$ for strongly polar substances (e.g., HCl and NH_3).

Being the determining criterion of thermodynamic similarity, the parameter f must correlate with the invariants of the physicochemical properties. This is well confirmed both graphically (Figs. 2 and 3) and by the analytical relations (4)–(9) presented below.

Let us list the expressions derived for calculating various physicochemical properties with the use of the parameter f as the determining criterion.

Molar volume of a liquid at its boiling point

$$V_b = (-6.2f + 31.2)\Pi^{0.94}. \quad (4)$$

Critical temperature

$$T_{cr} = T_b/(0.667 - 0.055f^{0.5}). \quad (5)$$

Table 1. Physicochemical properties of substances

It can be readily seen that, at $f \to 0$, Eq. (5) transforms into the known Guldberg rule, which is observed for nonpolar substances.

Critical volume

$$V_{cr} = V_b(2.69 + 0.05f). \quad (6)$$

At $f \to 0$, Eq. (6) yields the known Hertz rule, which is valid for nonpolar substances.

Van der Waals constant

$$b = V_b(0.2f + 1.12). \quad (7)$$

Critical pressure

$$P_{cr} = 1.039\,T_{cr}/b. \quad (8)$$

Enthalpy of vaporization at the boiling point

$$\Delta H_b = RT_b \ln(10.255T_{cr}/b)/(1 - T_b/T_{cr}). \quad (9)$$

The potentialities of the new criterion are illustrated for 12 substances belonging to different classes and having different polarities. The physicochemical properties of these substances were taken from a reference book [6] (see Table 1). The mean errors in calculating the above properties by Eqs. (4)–(9) are listed in Table 2.

The data presented show that the calculated and the experimental values are in good agreement. It is important to note that the prediction error is virtually polarity-independent.

The data array was expanded to 50 substances.[1] All the data necessary for calculation were taken from

[1] The 50 substances whose properties were included into the expanded data array are the following: CH_4, B_2H_6, GeH_4, SnH_4, CF_4, MoF_6, WF_6, UF_6, BCl_3, CCl_4, $TiCl_4$, PCl_3, PCl_5, $BiCl_3$, S_2Cl_2, $MoCl_5$, PBr_3, $SmBr_4$, BI_3, SiI_4, CCl_3F, CBr_2F_2, $CBrF_3$, $SiBrCl_3$, $SiBr_2Cl_2$, $PClF_2$, PCl_2F, $NClF_2$, $SiHBr_3$, PCl_3O, PBr_3O, SCl_2O, ClO_3F, WCl_4O, and CO; the remaining 15 substances are listed in Tables 1 and 4.

Table 3. Verification of the accuracy of the methods used for calculating physicochemical properties

a reference book [6]. As can be seen from Table 3, that a 4-fold extension of the data array leaves virtually unchanged the error in prediction of the physicochemical properties considered. This points to high reliability of the data on the error of the correlations presented.

The criterion suggested can also be used for predicting the thermodynamic properties of substances. For example, there is a clearly pronounced correlation between the ratio S^{liq}/S^g of the standard entropies (at 298 K) of a substance in the liquid and gaseous states and the parameter f (Fig. 2). This correlation, expressed by

$$S^{liq}/S^g = (0.18f^2 + 1.385), \quad (10)$$

can be used to predict the entropy of a phase state of a substance (liquid or gas) from the entropy of the other state. The errors of such a prediction are listed in Table 4. Here, the set of substances is somewhat different from that of Table 1, because some substances (SO_2, HCl, NH_3) do not exist in the liquid state at T = 298 K and P = 1 atm (101 325 Pa).

Molecular inorganic compounds with widely different intermolecular interactions are represented in the set of the substances studied, including nonpolar, moderately polar, and highly polar substances. For all these substances, the criterion suggested ensures rather high accuracy of prediction of their physicochemical properties.

To gain clearer insight into the potentialities of the criterion suggested, it is appropriate to consider the limiting case of prediction, when substances with the most complex intermolecular interaction are under study. To such substances belong associated liquids, which are characterized by the presence of hydrogen bonds and high values of the acentric factor. The errors in calculating the critical parameters for such substances are listed in Table 5. It can be seen that there is no unambiguous pattern in this case: the calculation error may be either low or rather large (this mainly refers to the critical pressure).

The increase in error is presumably due to poorer accuracy in calculating the parachor (for substances with hydrogen bonds the additivity of the parachor is violated) and, consequently, the parameter f. At the same time, with account of the fact that prediction of physicochemical properties with the use of the parameter suggested is based on the only input property (boiling point), application of the parameter f to the above substances, too, may be of practical importance.

CONCLUSIONS

(1) A determining criterion that considerably extends the potentialities of the thermodynamic similar-

ity theory for prediction of physicochemical properties of little-studied substances was suggested.

(2) The similarity criterion was used to obtain the correlations that ensure reliable prediction of physicochemical properties on the basis of the only characteristic of a substance, its boiling temperature.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Calculation of the Enthalpy of Sublimation by the QSPR Method with the Use of a Fragment Approach

Abstract—The enthalpies of sublimation of organic compounds belonging to various classes were studied for the first time in terms of the fragment approach based on the QSPR (Quantitative Structure–Property Relationships) method. The applicability of this technique to calculation of this parameter was demonstrated and a model that makes it possible to predict the enthalpy of sublimation of compounds on the basis of descriptors taking into account the fragment composition of a molecule was suggested.

The enthalpy of sublimation, $\Delta_{sub}H$, is the enthalpy of a transition of a substance from the solid state directly (without melting) to the gaseous state [1]. This property is of certain practical interest for the chemistry of the crystalline state and, in particular, for resolving the problems associated with dispersion of dyes and discoloration of materials, and such ecological problems as transport of organic contaminants in the atmosphere, etc. [1–5]. Determining the enthalpy of sublimation, $\Delta_{sub}H$, or other thermodynamic parameters experimentally requires application of expensive and time-consuming procedures. Therefore, considerable attention has been given in the literature both to theoretical calculational techniques and to empirical QSPR (Quantitative Structure–Property Relationships) methods for estimating these characteristics. For example, the enthalpies of sublimation have been obtained by calculating crystal packings [1–3]. For QSPR, methods of regression analysis [1], neural networks [1], and 3D-QSAR (CoMFA) [4, 5] methods have been used. In the case of a regression analysis with learning sample containing 62 compounds (control sample of 10 compounds), a three-parameter equation has been obtained, in which the number of carbon atoms, and also the number of donors and acceptors of the hydrogen bond, were used as descriptors [1].

In 1990, the FRAGMENT software was developed. This program can generate sets of fragments: chains (1–9 atoms), cycles (3–6-membered), and several types of branched fragments [6–11]. Each atom in a fragment is designated in dependence on the type of atom, the number of H atoms bonded to it, and the bonding environment, which makes it possible to take into account in adaptable manner the multiple bonds, functions, heteroatoms, etc. The FRAGMENT program has been successfully used in the QSAR/QSPR software package EMMA [11–19] and neural-network software package NASAWIN [20–23].

In previous studies concerned with QSAR/QSPR [(Quantitative Structure–Activity Relationships)/(Quantitative Structure–Property Relationships)], fragment descriptors have been widely used both for QSPR (chromatographic retention indices [18], boiling point [18], polarizability [24], density, viscosity, and saturated vapor pressure [25] for widely diverse classes of compounds) and for QSAR [11, 19]. A point of principle should be noted: if a set of compounds is sufficiently large for constructing a statistically significant model, then any topological index can be replaced with a set of fragment descriptors [26]. The advantage of fragment descriptors consists in the clearness and easy structural interpretation of the results of QSAR/QSPR. In this study, fragment descriptors are used to carry out a QSPR analysis of the enthalpy of sublimation.

As model experimental database of the enthalpies of sublimation (Database 1) were chosen the data reported in [1]: learning sample of 62 compounds and control sample of 10 structures (compound nos. 63–72). The complete sample comprised molecules with known crystal structure, which contain C, H, O, and N atoms, including aliphatic and aromatic hydrocarbons, their oxo and aza derivatives, carboxylic acids, amide and amino acids, cyanides, quinones, and heterocycles. The input and verification of Database 1

1070-4272/03/7612-1914 $25.00 © 2003 MAIK "Nauka/Interperiodica"

were performed using MEOW and BASTET software [24]. The advantage of the given sample of compounds is that the enthalpies of sublimation can be calculated for this set in three ways: (1) by theoretical calculation of crystal packings (with the statistical parameters $n = 62$, $r^2 = 0.971$, $s = 0.939$ kcal mol^{-1}, maximum error 3.5 kcal mol^{-1}), (2) by regression analysis (with the following statistical parameters: three descriptors, $n = 62$, $r^2 = 0.92$, $s = 1.6$ kcal mol^{-1}, maximum error 8.9 kcal mol^{-1}, average error of prognosis 2.8 kcal mol^{-1}), and (3) with a neural network (with the following parameters for the best model: seven hidden neurons, $n = 62$, $r^2 = 0.865$, $s = 2.2$ kcal mol^{-1}, maximum error 10.1 kcal mol^{-1}, average error of prognosis 36 kcal mol^{-1}). This constitutes a sound basis for comparison, even though the sample is not too large.

The MEOW and BASTET software was used to create Database 2 (88 compounds), by adding to Database 1 experimental data of [2] and excluding duplicates, and Database 3 (104 compounds), by adding to Database 2 experimental data of [4] for chlorinated diphenyls (15 structures) and excluding duplicates. The inclusion of chlorinated phenyls is due both to the importance of this type of compounds, which find wide application as insulating materials and fire retardants, and to the desire to extend the structural diversity of the sample by covering chlorine-containing compounds.

The QSPR modeling was performed using QSAR software EMMA [18, 19] and NASAWIN [20–22]. The fragment descriptors were calculated by FRAGMENT software (modified version distinguished by a greater number of types of fragments and more versatile classification of atoms [11, 23]), with the following restrictions imposed: chain length was 1–6; fragment descriptors were selected both automatically and manually; in selecting mutually correlated descriptors, those correlated to the greatest extent with the property were chosen.

Let us consider the comparative results of QSPR. The table lists characteristics of the models devel-

Statistical parameters of QSPR models for the enthalpy of sublimation, based on fragment descriptors for Databases 1–3

* Model no. 1: descriptor 1: fr_1 is the number of arbitrary atoms; descriptors 2, 3: fr_2, fr_3 are the numbers of fragments of the types =CR−OH and N_{sp^3}−C=O, respectively; descriptor 4; fr_4 is te number of simple bonds in a molecule, •−•; descriptors 5–8: fr_5, fr_6, fr_7, fr_8 are the numbers of fragments of the types RC_{Ar}÷$C_{Ar}H$÷$C_{Ar}H$÷$C_{Ar}R$, NH_2, •=•−•−•−•=•, and CH_3, respectively.

** Model no. 2: descriptor 1: fr_1 is the number of arbitrary atoms; descriptors 2–10: fr_2, fr3, fr_4, fr_5, fr_6, fr_7, fr_8, fr_9, fr_{10} are the numbers of fragments of the types =CR−OH, N_{sp^3}−C=O, CH_2−CH_2−CH_2−CH_2, =CR−C_{Ar}(÷$C_{Ar}H$)$_2$, =CR−CH_2, C_{Ar}−C_{Ar}(÷$C_{Ar}R$)$_2$, C−C−C−C=, •−•−•−•−•÷•, C−C−C−C=O, respectively.

*** Model no. 3: descriptor 1: fr_1 is the number of arbitrary atoms; descriptors 2–10: fr_2, fr_3, fr_4, fr_5, fr_6, fr_7, fr_8, fr_9, fr_{10} are the numbers of fragments of the types =CR−OH, N_{sp^3}−C=O, CH_2−CH_2−CH_2−CH_2, =CR−C_{Ar}(÷$C_{Ar}H$)$_2$, C_{Ar}−C_{Ar}(÷$C_{Ar}R$)$_2$, =CR−CH_2, C−C−C−C−C, •−•−•−•÷•, C−C−O−C=O, respectively.

oped on the basis of the fragment descriptors. First, a QSPR model was constructed (see table, Model no. 1) using the same sample as that in [1], i.e., 62 compounds were taken as learning sample and 10 compounds (63–72) for prognosis purposes (Database 1). It can be seen from the table that a satisfactory statistics, which is comparable with that in [1] and provides a reasonable prognosis (Model no. 1), is obtained with fragment descriptors 3–5. Interestingly, descriptor 1 (number of nonhydrogen atoms) models the first descriptor of [1], and the following two fragment descriptors indirectly model the number of centers forming hydrogen bonds (as in [1]).

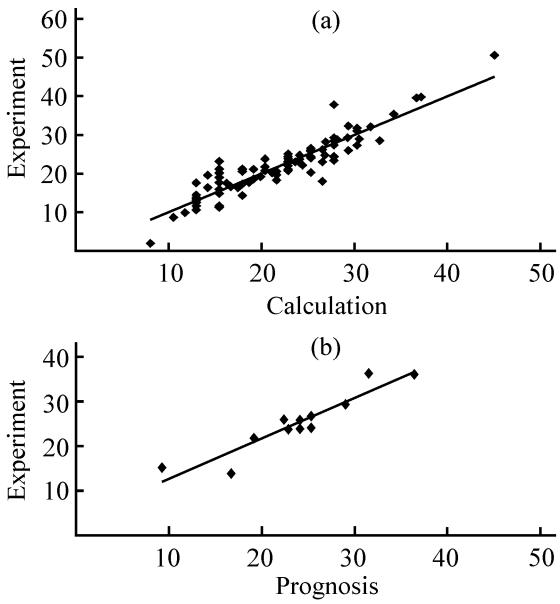
It is also of interest that formic acid (15.2 kcal mol^{-1} for learning sample) and adamantane (14.30 kcal mol^{-1} for control sample) fall out of the correlation, irrespective of the number of descriptors. In other words, fragment descriptors fail to reflect structural features of these compounds, which are important for prognostication of the enthalpy of sublimation.

Formic acid is the first member of the homologous series of acids, with Database 1 containing data (kcal mol^{-1}) for acetic (16.3), propionic (17.7), oleic (19.2), and valeric acids (20.2). In going from formic to valeric acid, the enthalpy of sublimation shows monotonic linear variation, which, presumably, obviates the question of experimental error in determining the value of $\Delta_{sub}H$ and may be due to the fact that the models include no descriptors that would reflect the tendency toward variation of the enthalpy of sublimation in the series of carboxylic acids.

It is noteworthy that adamantane has nearly spherical molecule and is highly volatile, and the absence of its derivatives and analogues from the learning sample leads to unsatisfactory prognosis. It should be emphasized in this context that, despite separate discussions, no rigorous scientific approach to the division of a sample into learning and control samples has been reported in the literature.

Naturally, with Database 3 available, it was of interest to obtain a QSPR model, using an extended learning sample. For this purpose, compound nos. 1–62 (Database 1), 73–88 (Database 2), and 13 compounds of the series of chlorinated diphenyls were used as a learning sample. The control sample included, in accordance with [1], the same 10 compounds (63–72), but was supplemented with three compounds belonging to the series of chlorinated diphenyls: two compounds used for prognostication in [4], namely, 2,2',5-trichlorodiphenyl (23.8 kcal mol^{-1}) and 2,2',5,5'-tetrachlorodiphenyl (24.1 kcal mol^{-1}), and also 2,2',3,3',4,4',6-heptachlorodiphenyl (29.3 kcal mol^{-1}). Thus, the learning sample comprised 91 compounds, and the control sample, 13 compounds. The QSPR model constructed (see table, Model no. 2) is distinguished by good prognosticating capacity, which exceeds that of Model no. 2 and makes it possible to predict the property under study for compounds belonging to the series of chlorinated diphenyls. The average error of prognostication varies from 2.4 kcal mol^{-1} (model based on three descriptors) to 2.7 kcal mol^{-1} (model based on eight descriptors).

It is also of interest that compound no. 70 (dimethylglyoxime, 23.2 kcal mol^{-1}), which falls out of the correlation for the control sample, remains in this position upon inclusion of a varied number of descriptors into the model. This fact may indicate that either the experimental data are to be refined or this compound (dihydroxylated diazadiene) is to a certain extent unique among the structures in Database 3.



Scatter diagram of calculated and experimental enthalpies of sublimation (kcal mol^{-1}) for (a) learning and (b) control samples of Database 3 in accordance with the linear-regression model [Eq. (1)].

Finally, the above consideration of the structures that fall out of the correlation gave rise to an idea to change the learning and control samples in the following way: two structures, adamantane and dimethylglyoxime were transferred from the control to the learning sample, and formic acid, contrariwise, from the learning to the control sample. Thus, the learning sample comprised 92 compounds, and the control sample, 12 compounds. The QSPR model constructed (see table, Model no. 3) has the best prognosticating capacity, compared with the set of the linear-regression models described.

The equation corresponding to the model based on three fragment descriptors (Model no. 3), which is characterized by the maximum value of the Fisher criterion and high prognosticating capacity, is presented below

$$\Delta_{sub}H_{calc} = +5.57 + 1.23fr_1 + 6.92fr_2 + 6.95fr_3, \quad (1)$$

$n = 104$, $r^2 = 0.8540$, $s = 2.97$, F = 160, average error (absolute value) of prognostication 2.16 kcal mol^{-1}, where fr_1 is the number of any nonhydrogen atoms, •; fr_2, the number of fragments of the type =CR–OH; fr_3, the number of fragments of the type N_{sp^3}–C=O.

The figure shows the scatter of the experimental and calculated enthalpies of sublimation, which agrees with the given model.

The maximum errors in prognostication of the enthalpy of sublimation (kcal mol^{-1}) are observed for formic acid (5.9) and pentaerythritol tetranitrate (4.8); for the learning sample, octadecane (10), dibenzoylmethane (8.6), dimethylglyoxime (7.7), and nitrogen (6) fall out of the correlation. The deviations from the correlation for formic acid and dimethylglyoxime remain the same, which supports the above explanations for both these cases.

In the next stage, the applicability of the fragment approach to prognostication of the enthalpies of sublimation of organic compounds with QSPR models constructed using artificial neural networks was analyzed [27]. A three-layer feed-forward back-propagation neural network produced using the software package NASAWIN [28] was chosen for this purpose. The input layer of the network comprised eight neurons in accordance with the number of descriptors preliminarily selected using a procedure for step-by-step linear regression analysis of descriptors. Two neurons were placed in the internal layer, since their greater number leads, when working with the given database, to strong "overlearning," and smaller number, to construction of a model that does not differ fundamentally from the linear-regression model. The output layer comprised a single neuron that corresponded to the property being prognosticated. As the learning algorithm was taken the "generalized delta rule" [27], with the learning rate parameter equal to 0.25 and learning "instant" parameter of 0.9. The learning process was terminated when the minimum prognostication error was achieved for the control sample.

The differences between the statistical parameters of linear-regression and neural-network models obtained on the basis of the same fragment descriptors are insignificant. At the same time, inclusion of descriptors selected as a result of the neural-network procedure makes it possible to improve the quality of the models. For example, it was possible to construct, for the learning and control samples of the linear-regression Model no. 3 (see table), a model with the best prognosticating capacity among all the models obtained (average prognostication error 1.66 kcal mol^{-1}, $R^2 = 0.8308$, $RMS_{learn} = 3.9364$, $RMS_{progn} = 2.1964$). The model is based on eight descriptors: descriptor 1: fr_1, –• (number of nonhydrogen atoms); descriptors 2–8: fr_2, fr_3, fr_4, fr_5, fr_6, fr_7, fr_8, the number of fragments of the type =CR–OH, N_{sp^3}–C=O, •–•=• (chain of three arbitrary atoms), $C_{Ar}÷C_{Ar}R÷C_{Ar}$ (÷ is an aromatic bond), CH_3–C–C, CH_2–(C=)–OR, CH_2–CH_2–CH_2, respectively.

As in the preceding cases, the strongest deviations from correlation in the control sample are characteristic of pentaerythritol tetranitrite (5.34 kcal mol^{-1}) and formic acid (1.95 kcal mol^{-1}).

Thus, the enthalpies of sublimation of organic compounds belonging to various classes were studied for the first time using the fragment approach based on the QSPR method. It was shown that the models for calculation of the enthalpy of sublimation, obtained using this technique, have parameters comparable with, and, in some cases, exceeding those of the regression equations reported in the literature. In other words, the model suggested makes it possible to prognosticate the enthalpy of sublimation of compounds with the use of descriptors taking into account the fragment composition of a molecule.

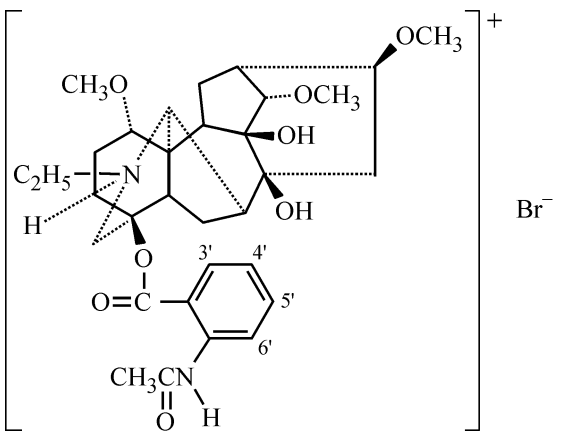
Abstract—Isothermal calorimetry was applied to study the heats of dissolution of lappaconitine hydrobromide at varied dilution. The data obtained were used to calculate the standard enthalpy of dissolution of $C_{32}H_{44}N_2O_8 \cdot HBr$ in an infinitely diluted (standard) aqueous solution. The heats of combustion and melting of $C_{32}H_{44}N_2O_8 \cdot HBr$ were calculated using approximate methods. A combination of experimental and calculation techniques was used to find the standard heats of formation of lappaconitine hydrobromide and its 33 analogues.

Studying the thermochemical and thermodynamic properties of alkaloids is of certain theoretical and practical interest for directed synthesis of these compounds with prescribed properties.

The alkaloid lappaconitine is an ester of triatomic amino alcohol lappaconine and *N*-acetylanthranilic acid; the structural formula of lappaconitine hydrobromide (allapinine) is given below [1]:



It should be emphasized that, until now, neither experimental nor estimated values of the thermochemical and thermodynamic constants of this theoretically and practically important alkaloid and its derivatives are available in the literature.

In view of the aforesaid, the aim of this study was to analyze experimentally the thermochemical properties of lappaconitine hydrobromide and to use the data obtained to find, by combining calculation procedures, the standard enthalpies of formation of $C_{32}H_{44}N_2O_8 \cdot HBr$ and its analogues.

The enthalpy of dissolution of lappaconitine hydrobromide $C_{32}H_{44}N_2O_8 \cdot HBr$ in water was studied calorimetrically under isothermal conditions on a DAK-1-1A calorimeter. The theory of, and procedure for a calorimetric study were described in detail in [2–5]. The DAK-1-1A commercial differential automated calorimeter has the following main technical characteristics: working temperatures 25–200°C, cartridge volume 8 cm^3, error in measuring heat release energy ≤20 μW. The calorimeter measures the integral heat flux outgoing from the calorimetric cartridge, in which a substance is being dissolved, through the differentially connected thermocouples and the massive central unit of the microcalorimeter. The rated error in determining the heat effects is ±2.0%.

The experimental errors and the uniformity of variance in determining the heat effects were calculated using the Student and Bartlett criteria.

The heat of combustion of lappaconitine hydrobromide was calculated using the Karas and Frost methods [7], and the heat of fusion was found from an empirical equation recommended in [8].

The values of $\Delta_f H^0_{298.15}$ for analogues of $C_{32}H_{44}N_2O_8 \cdot HBr$ were calculated using the system of enthalpy increments for anions [9, 10].

EXPERIMENTAL

The commercial lappaconitine hydrobromide chosen for the calorimetric study (M = 665.6 g mol^{-1} [11]) was of analytically pure grade (>99.0% main substance) and had melting point of 225°C (with decomposition), in conformity with the data of [11].

The homology-based technique was used to index the powder X-ray diffraction pattern of $C_{32}H_{44}N_2O_8 \cdot HBr$. It was found that $C_{32}H_{44}N_2O_8 \cdot HBr$ crystallyzes in the tetragonal system with the following lattice constants: a = 12.26, c = 10.72 Å; V^0 = 1611.3 Å^3; Z = 2; $\rho_{X\text{-ray}}$ = 1.41, and ρ_{pycn} = 1.38 ± 0.04 g cm^{-3}.

The enthalpy of dissolution of lappaconitine hydrobromide in water was determined experimentally at dilutions of 1 : 36000, 1 : 44000, and 1 : 50000 (moles of a salt : moles of water) with automated heat compensation. The heat effects were recorded with a KSP-4 potentiometer and, simultaneously, with an IP-4 high-precision integrator. A substance under study (weighed on an analytical balance to the fourth decimal place) was introduced in a metallic ampule, which was then inserted into a metallic cartridge with the solvent. The time of preliminary thermostating of the solvent and the substance was 2 h. The zero drift of the integrator did not exceed 3 units in the last digit position in 100 s. The substance under study dissolved when the ampule was submerged in the solvent.

The instrument was tested by measuring the heat of dissolution of thrice-recrystallized KCl at dilutions of 1 : 1600, 1 : 2400, and 1 : 3200 (moles of a salt : moles of water). The resulting averaged heat of KCl dissolution in water at 25°C (17860 ± 283 J mol^{-1}) was in satisfactory agreement with the recommended values (17577 ± 34 [13] and 17489 ± 371 [14] J mol^{-1}), obtained at the same temperature with accuracy of 1.6 and 2.0%, respectively.

Table 1 lists the calorimetrically determined heats of lappaconitine hydrobromide dissolution at various dilutions.

The experimentally found enthalpies of dissolution of $C_{32}H_{44}N_2O_8 \cdot HBr$ at varied dilution were further used for calculating the ΔH^0 of its dissolution at standard (infinite) dilution. A mathematical processing of the experimental data established that the dependence of the enthalpy of dissolution (kJ mol^{-1}) on the molal concentration $\sqrt{m}$ is described, similarly to [15], by the equation

$$\Delta H^m_{diss} C_{32}H_{44}N_2O_8 \cdot HBr = 6.02 - 93.13\sqrt{m}. \quad (1)$$

Table 1. Heat effect and molar enthalpy of $C_{32}H_{44}N_2O_8 \cdot HBr$ dissolution in water at varied dilution*

* Dilution, mole of a salt : mole of H_2O; the same for Table 2.

By solving this equation, the standard enthalpy of lappaconitine hydrobromide dissolution in an infinitely diluted aqueous solution was found to be 6.02 ± 0.17 kJ mol^{-1}. This value is of great theoretical and practical importance for calculating the standard heats of formation of various lappaconitine derivatives.

Further, the enthalpies of interaction between an aqueous solution of $C_{32}H_{44}N_2O_8 \cdot HBr$ and crystalline silver nitrate were determined in the reaction

$$C_{32}H_{44}N_2O_8 \cdot HBr\ (\text{solution},\ nH_2O) + AgNO_3(\text{s.}) = C_{32}H_{44}N_2O_8H^+\ (\text{solution},\ nH_2O) + NO_3^-\ (\text{solution},\ nH_2O) + AgBr(\text{s.}) - \Delta H^0_{int}. \quad (2)$$

1.442 (1.444)	8 (7)

* Published data [16] are given in parentheses.

The $AgNO_3$ crystals subjected to a calorimetric study were of analytically pure grade. Table 2 lists the results obtained in determining the ΔH^0 of the interaction.

The mass of the resulting crystalline precipitate of AgBr had, after its being dried, a mass totally corresponding to the theoretical yield. This indicates that lappaconitine hydrobromide completely dissociated upon dissolution in water. The same conclusion follows from X-ray diffraction data for AgBr (Table 3) formed in reaction (2), which were in full agreement with reference data [16].

To calculate $\Delta_f H^0_{298.15}$ for $C_{32}H_{44}N_2O_8 \cdot HBr$, its standard heat of combustion was evaluated using the Karas and Frost methods [7], which are the most appropriate techniques for taking into account the contributions of different groups to the heat of combustion. The resulting averaged heat of $C_{32}H_{44}N_2O_8 \cdot HBr$ combustion was –18 318 ± 619 kJ mol^{-1}, with relative calculation error of 3.4%. The standard enthalpy of formation of (molten) $C_{32}H_{44}N_2O_8 \cdot HBr$ was calculated from the ΔH^0 of combustion by the Hess cycle by the reaction

$$2C_{32}H_{44}N_2O_8 \cdot HBr_{(l)} + 78.5O_{2(g)} = 64CO_{2(g)} + 45H_2O_{(l)} + 2N_{2(g)} + Br_{2(g)} \quad (3)$$

to be –718 kJ mol^{-1}. It should be emphasized that the Karas and Frost methods are only applicable to calculation of ΔH^0 of combustion of liquid hydrocarbons. The data required for calculating $\Delta_f H^0_{298.15}$ of $C_{32}H_{44}N_2O_8 \cdot HBr_{(l)}$ by scheme (3), with the exception of ΔH^0 of combustion, were taken from [17].

In view of the fact that lappaconitine hydrobromide is in the crystalline state at 298.15 K, its $\Delta_f H^0_{298.15}$ is to be calculated for the solid state. For this purpose, ΔH^0_{melt} of $C_{32}H_{44}N_2O_8 \cdot HBr$ was estimated using the empirical equation [8]:

$$\Delta H^0_{melt} = 44.4T_{melt} - 4400, \quad (4)$$

which is commonly used for strongly polar halide compounds. The value of ΔH^0_{melt} of $C_{32}H_{44}N_2O_8 \cdot HBr$, found using Eq. (4), is 17.7 kJ mol^{-1}. The equation

$$\Delta_f H^0_{298.15}C_{32}H_{44}N_2O_8 \cdot HBr_{(s)} = \Delta_f H^0_{298.15}C_{32}H_{44}N_2O_8 \cdot HBr_{(l)} - \Delta H^0_{melt} \quad (5)$$

was used to calculate the standard enthalpy of $C_{32}H_{44}N_2O_8 \cdot HBr_{(cr)}$ formation to be –736.0 kJ mol^{-1}.

Further, the ΔH^0 of $C_{32}H_{44}N_2O_8 \cdot HBr$ dissolution at infinite dilution (6.02 kJ mol^{-1}) was used to calculate the standard enthalpy of $C_{32}H_{44}N_2O_8 \cdot HBr$ formation in the standard aqueous solution by the equation

$$\Delta_f H^0_{298.15}C_{32}H_{44}N_2O_8 \cdot HBr \text{ (solution, } H_2O\text{, standard state)} = \Delta_f H^0_{298.15}C_{32}H_{44}N_2O_8 \cdot HBr_{(s)} + \Delta H^0_{solv} \quad (6)$$

to be –730 kJ mol^{-1}. The relation

$$\Delta_f H^0_{298.15}C_{32}H_{44}N_2O_8H^+ \text{ (solution, } H_2O\text{, standard state)} = \Delta_f H^0_{298.15}C_{32}H_{44}N_2O_8 \cdot HBr \text{ (solution, } H_2O\text{, standard state)} - \Delta_f H^0_{298.15}Br^- \text{ (solution, } H_2O\text{, standard state)}, \quad (7)$$

was used to calculate, on the basis of the data obtained and the reference value of $\Delta_f H^0_{298.15}$ (solution, H_2O, standard state), the standard enthalpy of formation of the $[C_{32}H_{44}N_2O_8H]^+$ ion in a standard aqueous solution to be –599.0 kJ mol^{-1}. The value obtained by the calculation was used to calculate $\Delta_f H^0_{298.15}$ for other lappaconitine derivatives. In [9, 10], a system of thermochemical enthalpy increments was developed. This system makes it possible to calculate standard heats of formation of compounds in the crystalline state by the equation

$$\Delta_f H^0_{298.15}M_m(X_\alpha O_\beta)_n = [m\Delta_f H^0_{298.15}(M^{n+}, \text{ solution, } H_2O, \text{ standard state})]K + n\Delta_f H^i_{298.15})X_\alpha O_\beta^{m-}, \quad (8)$$

where $\Delta_f H^i_{298.15}$ is the enthalpy increment for the anion, and K is the proportionality factor.

To calculate $\Delta_f H^0_{298.15}$ of the compounds by Eq. (8), it suffices to know the $\Delta_f H^0_{298.15}$ (solution, H_2O, standard state) of the cation, whereas the coefficients K and $\Delta_f H^i_{298.15}$ for the anions are tabulated; the accuracy of the calculation is ±5.0%. For the lappaconitine derivatives, Eq. (8) can be represented as (for the example of $C_{32}H_{44}N_2O_8 \cdot HNO_3$):

$$\Delta_f H^0_{298.15}C_{32}H_{44}N_2O_8 \cdot HNO_{3(s)} = [\Delta_f H^0_{298.15}C_{32}H_{44}N_2O_8H^+ \text{ (solution, } H_2O\text{, standard state)}]K + \Delta_f H^i_{298.15}NO_3^-. \quad (9)$$

Table 4 lists the values of $-\Delta_f H^0_{298.15}$ for 33 lappaconitine derivatives, calculated using Eq. (9).

CONCLUSIONS

(1) The enthalpies of lappaconitine hydrobromide dissolution in water at varied dilution were determined experimentally for the first time. The values obtained were used to calculate by indirect methods the standard enthalpy of $C_{32}H_{44}N_2O_8 \cdot HBr$ dissolution, $\Delta_f H^0_{298.15}$ of $[C_{32}H_{44}N_2O_8H]^+$ (solution, H_2O, standard state), standard enthalpy of formation of molten and crystalline $C_{32}H_{44}N_2O_8 \cdot HBr$, its heat of combustion, and heat of fusion.

(2) The standard heats of formation of 33 lappaconitine derivatives were calculated.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Heavy Metals from Model Solutions with Amine-Containing Chemisorption Polyamide Fiber

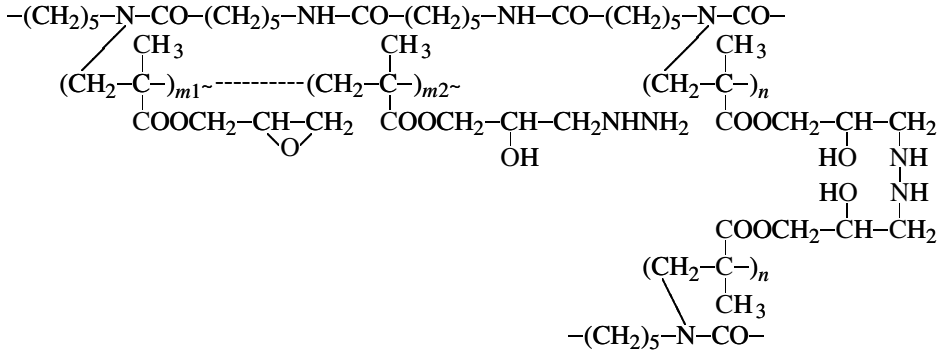
Abstract—Sorption of Cu(II), Ni(II), Zn(II), and Cr(VI) ions with POLAN-OG sorbent was studied. The capacity and kinetic characteristics of the sorbent in hydrochloric acid and chloride solutions were determined.

Complexing ion exchangers occupy a leading position among sorption-active polymeric materials. Their use is diverse, from waste-free high technologies to solution of environmental problems. Recently, there has been a steady trend toward use of fibrous complexing sorbents for concentration and recovery of microelements from aqueous media and process solutions in analytical monitoring. The fibrous materials based on cellulose, polyacrylonitrile, polyvinyl alcohol, polycaproamide (PCA) and their copolymers show high performance in recovery of heavy metals, including platinum group metals, and radionuclides [1, 2]. In addition, they exhibit higher kinetic characteristics as compared to granulated or porous sorbents [3]; metals sorbed can be relatively readily desorbed with acids, and these sorbents can be used repeatedly in sorption–desorption cycles.

It is known [4] that the complexing properties of polymeric ion exchangers depend not only on the kind offunctional groups, but also on the polarizability of atoms bound to these groups, distribution of ligand groups along the polymer chain, and other factors. This allows preparation of fibrous complexing ion exchangers with a wide spectrum of the sorption properties, in particular, by polymer-analogous transformations. A variety of fibrous chemisorption materials (fibers, nonwoven materials, cloths) allow variation of the chemisorption equipment design.

Commercially available fibrous sorbents do not meet the demand for such materials in solving environmental problems, both in assortment and in production volume. Therefore, synthesis of new sorption fibers, study of their properties, and assessment of specific application fields are topical. In this study, we examined the sorption properties and kinetics of sorption of heavy metal ions with chemisorption polyamide fiber POLAN-OG. This material differs from the known chemisorption fibers in the chemical composition, structure, nature of functionally active groups, and advanced production technology.

A fibrous sorbent with the static exchange capacity (SEC) with respect to HCl of 1.73 mmol mol^{-1} was prepared by polymer-analogous transformation of polycaproamide (PCA) fiber with grafted polyglycidyl methacrylate (PGMA) under the action of aqueous hydrazine hydrate [5]. The chemisorption fiber has the following chemical structure.



1070-4272/03/7612-1925 $25.00 © 2003 MAIK "Nauka/Interperiodica"

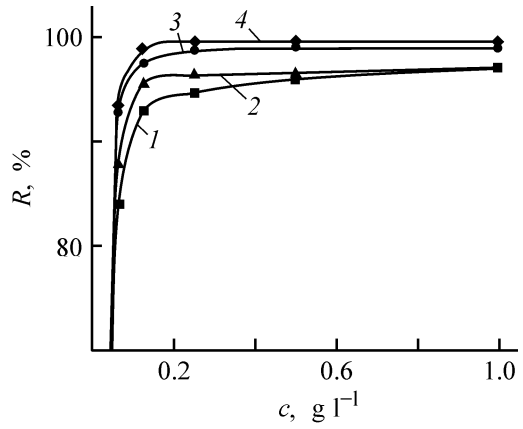


Fig. 1. Degree of recovery of metal ions, *R*, from solutions with amine-containing polyamide fiber vs. heavy metal ion concentration *c*. Sorption conditions: sorption time 60 min, *L*/*S* ratio 100, pH 5. Ion recovered: (*1*) Cu(II), (*2*) Cr(VI), (*3*) Ni(II), and (*4*) Zn(II).

Ionogenic functional groups NH and NH_2 in the coordination-active (deprotonated) state form the outer coordination sphere and play the role of ligands toward ions being sorbed.

Electron-microscopic studies have shown [1] that grafted PMGA is distributed over the surface of the polycaproamide fiber. Therefore, the chemically active hydrazide groups introduced are accessible in chemisorption, and the mass exchange is fast. In addition, hydrophobic grafted chains of carbon-chain PMGA protect the fibrous PCA matrix and thus increase the sorbent resistance toward aggressive media. The use of physically active grafted copolymers, e.g., PCA–PMGA as the starting material in obtaining fibrous chemisorbents, has a number of technological advantages as compared to widely described chemisorption fibers based on random copolymers (fibers of VION type [6]): problems with preparing the fiber from copolymers with insufficient fiberforming ability and necessity for cross-linking of such fibers to make them insoluble are eliminated [1, 7].

Although certain processes for treatment of wastewater from electroplating shops have been developed, and there are a lot of publications on this issue [8–11], the problem of efficient removal of heavy metal ions to the level of maximum permissible concentration remains urgent. In this study, we studied the sorption of transition metal ions [Cu(II), Ni(II), Zn(II), and Cr(VI)] contained in the process solutions of electroplating shops with PCA–PMGA copolymers.

The sorption was performed under static conditions from model solutions with metal ion concentrations of 1 g l^{-1} and lower at a solution volume (ml) to fibrous sorbent weight (g) ratio (*L*/*S*) equal to 100. The content of metal ions in the solution was determined spectrophotometrically with a Specord M-40 spectrophotometer. The optical density ε of the solution with introduced reagent picramine before and after addition of fibrous sorbent was measured at λ = 550 nm and solution layer thickness *l* = 5 cm. The content of sorbed metal ions was determined using a calibration plot.

The static capacity of the fibrous sorbent (g g^{-1}) was found by the formula

$$\mathrm{SC} = \frac{(c_0 - c_1)V}{p \times 1000},$$

where c_0 is the initial metal ion concentration, (g l^{-1}); c_1, the metal ion concentration after sorption (g l^{-1}); *V*, the solution volume (ml); and *p*, the sorbent weight (g).

The specific surface area (S_{sp}) of the chemisorption fiber was determined gravimetrically (in a desiccator) with water vapor as adsorbate [12]. To compare the values of S_{sp} obtained by the sorption method in the dessicator and on a device equipped with a Mackbain balance [13], we used polycaproamide fiber as reference. The S_{sp} value was found to be 66 $m^2 g^{-1}$, in good agreement with the reference value of 70 $m^2 g^{-1}$.

We found that the fibrous sorbent exhibits high absorptive power with respect to Ni(II) and Zn(II) even in dilute solutions (0.125 g l^{-1}) (Fig. 1). The degree of metal ion recovery *R* reaches 99%, which makes expedient use of the POLAN-OG fiber in sorption of trace amounts of these metals. A somewhat lower *R*, 93 and 95.5%, was obtained for solutions containing Cu(II) and Cr(VI) ions, respectively, at their concentration of 0.125 g l^{-1}.

At solution volume to fibrous sorbent weight ratios of 50–500 and metal ion concentration of 0.1 g l^{-1}, the *R* value decreases only slightly with increasing solution volume. Upon a tenfold increase in the *L*/*S* ratio, *R* decreases by 3%, at most, from 99.6 to 96.6%. This trend is preserved for all the solutions studied.

The sorption efficiency substantially depends on the sorption kinetics. The kinetic curves of sorption of Cu(II), Ni(II), and Cr(VI) ions are shown in

Figs. 2a–2c. The equilibrium distribution of metal ions between the fiber and solution is reached in a short time (20–30 min) within a wide range of concentrations at room temperature. Such a short time is due to the high specific surface area of the chemisorbent, 40 $m^2 g^{-1}$, and to the fact that chemically active groups are mostly situated in the surface layers of the fiber [1]. The degree of metal ion recovery reaches high values, 98% for Cu(II) and Cr(VI) and 100% for the other ions studied, in sorption from 1 $g l^{-1}$ solutions.

The high degree of Cu(II) recovery (99% in 30 min) is also achieved in sorption from solutions with concentrationstypical of natural water, 0.001–0.0005 $mg l^{-1}$ [maximum permissible concentration of Cu(II) in water of fish ponds is 0.001 $mg l^{-1}$], which demonstrates high sorption characteristics of this fibrous chemisorbent. Since wastewater from electroplating shops may differ not only in composition, but also in acidity, the effect of pH on the metal ion sorption should be studied. In addition, it is known that the main part of basic ligand groups have strong affinity for hydrogen ions, since the energy of the $L^- \rightarrow H^+$ coordination bond is higher than that of the $L^- \rightarrow M^{n+}$ bond. This leads to substantial influence of the H^+ concentration on complexation of ionogenic groups. The $R = f(\text{pH})$ curves (Fig. 3) show that, under the conditions studied, the sorption of 3*d*-element ions is the most efficient within the pH 5–7 range. The degree of metal ion recovery sharply decreases to 20–40% with increasing solution acidity. This is caused by a decrease in the concentration of coordination-active (nonprotonated) ionogenic groups in the fiber phase and by a change in their electron-donor properties. Since the chemisorption fiber was used in the sorption process in the OH form, the solution pH increased owing to partial transfer of OH^- ions to the solution in complexation.

The change in color of the complexing ion exchanger allows quantitative estimation of the sorption of Cu(II) and Ni(II) ions. At pH > 5, the degree of metal ion recovery is higher, and accordingly, the intensity of color of the fibrous chemisorbent increases as compared to the color of the sorbent at pH < 5. In accordance with the known coordination properties of transition metal ions [Cu(II), Ni(II), Zn(II)] [14] in the systems studied, ML_4 complexes are formed in the course of sorption on the fiber containing NH and NH_2 groups. Because of the polymeric structure of the fiber ligand groups, their irregular distribution along the chain, and the heterogeneity of the system in which the metal ions are recovered, interchain complex formation (rather than intramolecular coordination) is the most probable:

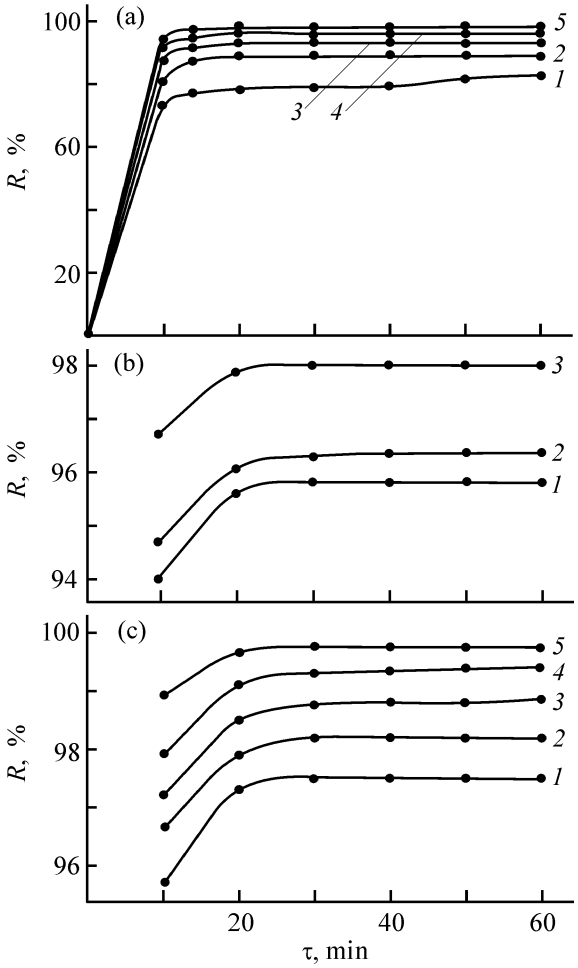

Fig. 2. Kinetics of sorption of (a) Cu(II), (b) Cr(VI), and (c) Ni(II) with chemisorption polyamide fiber. Sorption conditions: *L*/*S* ratio 100, pH 5. (*R*) Degree of metal ion recovery and (τ) sorption time. Concentration ($g l^{-1}$): Cu(II) and Ni(II), (*1*) 0.0625, (*2*) 0.125, (*3*) 0.25, (*4*) 0.5, and (*5*) 1.0; Cr(VI), (*1*) 0.125, (*2*) 0.5, and (*3*) 1.0.

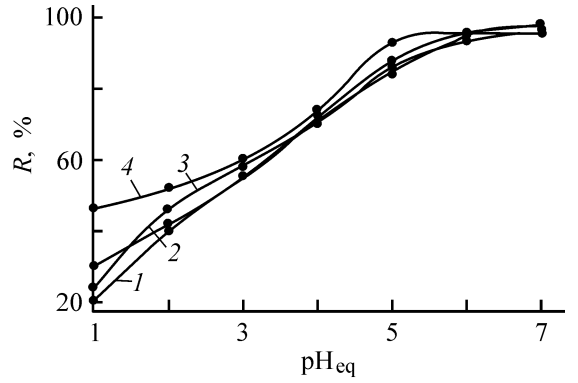

Fig. 3. Degree of transition metal ion recovery *R* with amine-containing fibrous chemisorbent as a function of pH. Sorption conditions: sorption time 24 h, *L*/*S* ratio 100, metal ion concentration 1.0 $g l^{-1}$. Ion being recovered: (*1*) Cu(II), (*2*) Ni(II), (*3*) Zn(II), and (*4*) Cr(VI).

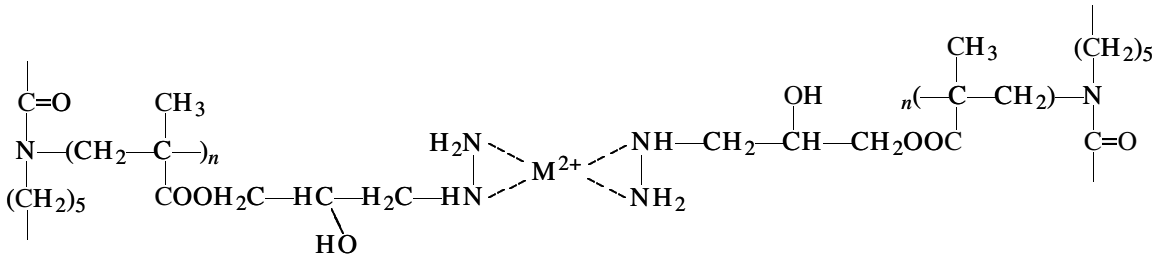

The complexation in sorption of Cr(VI) involves chromium reduction to Cr(III), which is probably due to the presence of hydrazide groups, which exhibit reductive properties ($E^0_{Cr_2O_7^{2-}/2Cr^{3+}}$ = 1.33 V and $E^0_{N_2H_4/N_2}$ = –1.16 V). Initially, the fiber becomes brown and then it acquires a dingy green color, which is characteristic of Cr(III) complexes. The brown color is probably due to mixing of the orange-red color of the $Cr_2O_7^{2-}$ ion and green color of Cr(III) formed by partial reduction of Cr(VI) on the sorbent. The reduction of $Cr_2O_7^{2-}$ ion on the surface of POLAN-OG fibrous sorbent has not been studied previously.

One of parameters of sorption with complexing ion exchangers is the distribution coefficient of the metal ion in the sorbent–sorbate system, which gives important information about the applicability of a chemisorbent.

The distribution coefficients of metal ions, *D*, calculated for sorption at various equilibrium pH values are listed in the table. The table shows that, for all the metal ions studied, *D* values grow with increasing pH. The highest *D* values were obtained for Zn(II) and Cr(VI) at pH 7.

To estimate the selectivity of sorption with the fibrous sorbent studied, we recovered metal ions from aqueous solution containing a mixture of Cu(II), Ni(II), Zn(II), and Cr(VI) in the concentration of 0.25 g l^{-1}. The *D* values obtained are listed below.

Ion	Cu^{2+}	Ni^{2+}	Zn^{2+}	Cr(VI)
$D \times 10^{-3}$, ml g^{-1}	9.9	9.8	9.9	9.4

As seen, the POLAN-OG fiber virtually equally sorbs all the metal ions studied (the *D* values do not differ substantially) and hence does not exhibit selectivity in this system. The distribution coefficients increase, as the metal ion concentration decreases, which is caused by the shift of the reaction equilibrium toward complexation.

The sorption capacity (SC) of POLAN-OG fiber measured for 1 g l^{-1} solutions is given below.

Ion	Cu^{2+}	Ni^{2+}	Zn^{2+}	Cr(VI)
SC, mg g^{-1}	98.36	99.24	99.44	98.40
SC, mmol g^{-1}	1.54	1.69	1.52	1.89

As seen, the POLAN-OG fibrous sorbent is characterized by fairly high SC with respect to 3*d*-element ions. It is inferior to POLIORGS-35 fiber in sorption of copper(II), but its SC with respect to zinc and nickel is considerably higher, by a factor of 1.5 and 2, respectively [2]. The degree of water decontamination to remove zinc ions is comparable with that obtained with VION chemisorption fiber [16]. The SC of POLAN-OG fiber increases in the order Zn(II) < Cu(II) < Ni(II) < Cr(VI).

CONCLUSIONS

(1) Fibrous complexing ion exchangers based on a graft copolymer of polycaproamide and polyglycidyl methacrylate, which contains hydrazide groups (POLAN-OG), has sorption capacity with respect to Cu(II), Ni(II), Zn(II), and Cr(VI) ions of about 1.52–1.89 mmol g^{-1} and virtually quantitatively (97–

Distribution coefficients of heavy metal ions at various pH (sorption conditions: sorption time 24 h, *L*/*S* ratio 100, metal ion concentration 1 g l^{-1})

Ion	$D \times 10^{-2}$, ml g^{-1}, at indicated pH						
	1	2	3	4	5	6	7
Cu^{2+}	0.25	0.67	1.22	2.45	6.69	16.7	32.3
Ni^{2+}	0.43	0.72	1.22	2.45	6.14	19.0	19.0
Zn^{2+}	0.32	0.85	1.38	2.57	7.33	19.0	49.9
Cr(VI)	0.85	1.08	1.50	2.89	13.3	24.0	32.3

100%) recovers them from 0.5–1.0 g l^{-1} aqueous solutions.

(2) A scheme of coordination binding of metal ions with nitrogen-containing ligand groups of the polymeric chemisorption fiber is suggested.

(3) The POLAN-OG fiber exhibits no selectivity with respect to copper(II), nickel(II), chromium(VI), and zinc(II) ions and can be recommended for their group recovery or for metal ion sorption from individual solutions.

Abstract—The influence of cobalt on processes that occur in a nickel oxide electrode of a nickel–zinc battery, fabricated from spherical nickel hydroxide on foamed nickel support, was studied.

A considerable progress has been made recently in improving the nickel oxide electrode (NOE) of the conventional power cells with alkaline electrolyte (nickel–cadmium and nickel–metal hydride). This resulted from simultaneous optimization of the morphological and electrochemical parameters of nickel hydroxide by imparting spherical shape to its particles and by modifying its structure with cobalt additives [1].

The electrodes made of spherical nickel hydroxide show better working capacity when charged and discharged in intensive modes and have stable electrochemical parameters in cycling. The anodic oxidation of the active paste of NOE, which contains incorporated cobalt compounds, occurs at low current expenditure for oxygen evolution, especially with lithium added simultaneously [2]. It was noticed that the strongest increase in the NOE activity is achieved in the presence of cobalt compounds.

It has been established, when analyzing the mechanism by which cobalt affects the NOE properties, that its incorporation into the structure of nickel hydroxides changes the nature of protonic bonds in it, which is accompanied by delocalization of protons [3].

In more recent studies [4, 5], the specific properties of nickel hydroxide modified with cobalt are accounted for by the formation, in the course of NOE forming, of intercalation compounds $Ni_{1-x}Co_xOOH$ (at x = 0.03–0.28), whose conductivity is higher by three orders of magnitude than that of $Ni(OH)_2$. This intercalation compound is revealed by Raman spectroscopy (its presence in $Ni(OH)_2$ can be judged from the intensity of the line at 515 cm^{-1} [4]). The dependence of the electron (proton) exchange on cobalt content per nickel atom in conversion from $Ni(OH)_2$ to NiOOH is described by a curve peaked at 1.1–1.2, the values attained at Co/(Ni + Co) = 0.07. This result was obtained in studying electrodes made of highly dispersed spherical $Ni(OH)_2$ (particle size 250 Å [4]. Virtually the whole amount of spherical $Ni(OH)_2$ used in power cells consists of particles with radii ranging from several to 20–30 μm. In this case, the exchange is characterized by values of 0.85–0.95 [1].

EXPERIMENTAL

In this study, we analyzed specific features of processes occurring on NOE made of spherical nickel hydroxide in NTs-25 nickel–zinc (NZ) batteries. Nickel hydroxide used in the study contained 5–6% cobalt and 3% zinc. Zinc, which is the conventional additive to spherical nickel hydroxide, is introduced to prevent formation in the course of charging of the gamma phase of NiOOH, which has irregular and easily destructible structure.

The active paste was deposited onto a foamed nickel support, and then the electrodes were compacted and dried.

A degree of compaction of the assembly that is necessary for stable reversible operation of the negative electrode was ensured when assembling batteries with the NOE under study, in contrast to the case of metal-ceramic (MC) electrodes. This was done by varying the relative thicknesses and capacities of the positive and negative electrodes at the their constant total thickness in the assembly and by using an appropriate set of separators.

Table 1. Parameters of the NTs-25 batteries under study, with a positive electrode made of spherical nickel hydroxide and containing cobalt as additive

Variant of assembly	Electrode thickness, mm		Number of electrodes in an assmebly		Theoretical capacity, A h		Ratio of Zn/NOE capacities
	Zn	NOE	Zn	NOE	Zn	NOE	
I	1.25	0.95 × 2	8	7	95	50	1.9
II	1.25	0.80 × 2	9	9	107	46	2.3
III	1.25 × 2	0.95 × 2	4 × 2 + 2	5	118	36	3.3

For most of the batteries under study, the NOE on a foamed nickel support had the same thickness as the MC electrodes; in some experiments, we used thinner electrodes, with their number in the battery assembly changed simultaneously. The positive electrodes were used in pairs.

The negative electrodes in differently assembled batteries were of the same design, but contained different amounts of the active paste.

For this purpose, the middle electrodes in the assembly of type III were paired. The electrolyte volume was 105 ml for all types of batteries. The basic parameters of the batteries are listed in Table 1.

Since the zinc electrode is insensitive to the forming modes, the primary goal of the study was to optimize the forming modes for the positive electrodes.

A study of the properties of $Ni_{1-x}Co_xOOH$ compounds revealed that they are formed under conditions of anodic polarization of an NOE containing $Co(OH)_2$ as additive at rather high oxidation rates (currents of 0.1–0.5 A) [5]. In this case, the oxidation occurs to give an intercalation compound with mosaic structure. The intercalated compound also remains stable under steady-state conditions and in the case of cathodic polarization of the NOE, but is reduced to give $Co(OH)_2$ when the potential is lowered to 0.1–0.0 V (relative to the Hg/HgO electrode in the same solution) [5]. Further lowering of the NOE potential is accompanied by even deeper reduction of cobalt hydroxide. As a result, metallic cobalt, which is inactive under the conditions of operation of the positive electrode, can be formed in the NOE at negative potentials.

Based on the results of electrochemical, X-ray diffraction, and electron-microscopic studies, it was recommended in [5] to charge NOE made of spherical nickel hydroxide in rather intensive modes, with excess charge imparted in the forming cycles, and to discharge it without allowing the final potential of the positive electrode to decrease below a certain value. As noted in studies devoted to this problem, a high degree of its charging is achieved in 2–3 cycles, with the capacity equal to 150% of the theoretical value in terms of the Ni^{2+} to Ni^{3+} conversion imparted in each cycle [1].

The data of [6] clearly show that the NOE of the type considered should be formed with excess charge imparted. In this study, the effect of cobalt on the processes occurring in the electrode was studied using potentiodynamic cycling, with the potential varied stepwise. This allowed evaluation of the contribution from each individual process in charging of the electrode, depending on the amount of cobalt added, conditions of its introduction, and forming mode.

In charging of the electrode under study, which was made of spherical nickel by its codeposition with cobalt hydroxide, Co(II) is converted to Co(III) in the first cycle, with the structural transformation and oxidation of a part of nickel occurring simultaneously. In the process, the capacity spent for formation of the intercalation compound is approximately twice that necessary for charging of cobalt.

In the course of the subsequent discharge, the capacity spent for the formation of this complex is not returned, since the complex is not reduced under the standard operation conditions. In addition, the final period of charging is accompanied by oxygen evolution. All these circumstances lead to discrepancy between the capacity imparted in the first charging and the discharge capacity.

In the second cycle, charging occurs more effectively at lower potential, which is due to the influence exerted by cobalt intercalation. However, in this case too, the whole amount of the active paste is only involved in the process after an excess charge is imparted, compared with the value calculated for the Ni(II) to Ni(III) conversion [6].

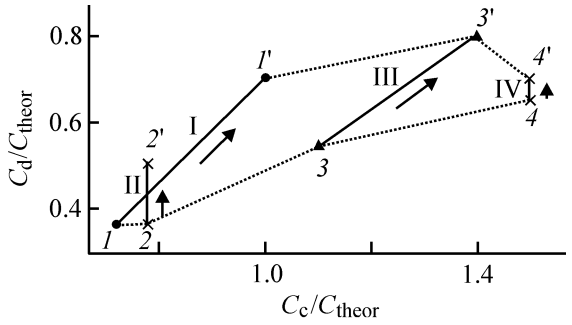

Fig. 1. Effect of charging capacity on the coefficient of utilization of the active paste in an NOE made of spherical nickel hydroxide in forming of NTs-25 batteries in modes I–IV. (C_d/C_{theor}) Ratio of discharge to theoretical capacity and (C_c/C_{theor}) ratio of charging to theoretical capacity; the same for Fig. 2. Cycle: (*1*–*4*) first and (*1*'–*4*') second.

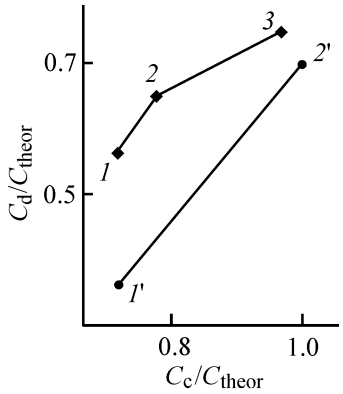

Fig. 2. Coefficient of utilization of the active paste of NOE made of spherical nickel hydroxide with varied density vs. charging capacity in forming of NTs-25 batteries. Cycle no.: (*1*, *1*') first, (*2*, *2*') second, and (*3*) third. NOE density (g cm^{-3}): (*1*–*3*) 2.7 and (*1*'–*2*') 2.5.

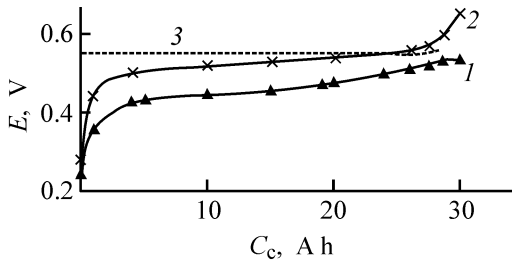

Fig. 3. Variation with cycling of the potential E of NOE (*1*) with and (*2*) without cobalt and (*3*) potential of oxygen evolution. Charging current 5 A. (C_c) Charging capacity.

The concepts concerning the conversion conditions and further effective influence of cobalt on the electrochemical processes on NOE, formulated for the case of nickel-metal hydride batteries, were taken into account when studying the NZ battery only in the part regarding the inadmissibility of overcharging of the zinc electrode. The forming modes with different ratios of charging to theoretical capacity C_c/C_{theor} were chosen based on the negative to positive electrode capacity ratios in Table 1. The results obtained, summarized in Fig. 1, refer to a 0.95–1-mm-thick NOE with active paste density of 2.5 g cm^{-3}.

The first charging of the batteries was done with currents corresponding to $0.06-0.1\,C$, i.e., in more prolonged modes as compared with those recommended in [5]. This is due to the considerable thickness of the electrodes used in NZ batteries. Four forming modes were tested, which differed in the charging capacities C_c/C_{theor}. The largest coefficient of utilization of the active paste in the first cycle (0.65) was achieved after imparting a charge capacity of $1.5\,C_{theor}$ (forming variant IV). After the second charging, the maximum value of C_c/C_{theor}, equal to 0.8, was obtained after a charging capacity of $1.4\,C_{theor}$ was imparted in the course of 8–10 h (Fig. 1, variant III).

The coefficient of utilization of the active paste in the first forming cycle grows with its density increasing to 2.7 g cm^{-3} (Fig. 2). This is presumably due to improvement of the conductivity in the solid phase. However, the degree of charging increased in the second cycle only slightly and, therefore, a third forming cycle was required. But even in this case, the current utilization coefficient was lower than the maximum value obtained at active paste density of 2.5 g cm^{-3} (Fig. 1, variant III).

The forming mode at which the capacities equal to 1.1 and $1.4\,C_{teor}$ are imparted in, respectively, the first and second cycles was chosen on the basis of the results obtained. The degree of charging of the active paste, obtained in this case, is 0.8, which is much lower than that in nickel–cadmium and nickel–metal hydride batteries ($0.95\,C_{rat}$). The possible reason is that zincate ions are incorporated into the structure of nickel hydroxide from the electrolyte, thereby being involved in the conversion of the active paste [7]. In the first cycle, when the electrolyte if free of zincate ions, the degree of NOE charging grows steadily with increasing charging capacity, but the effect achieved tends to disappear in the second cycle.

In the subsequent cycling of NZ batteries, the utilization coefficient of the active paste remains at the level reached, and the effect of zincate ions is not manifested during a certain period. This makes it possible to reveal specific features of the processes associated with cobalt intercalation. The stationary potential of an NOE containing cobalt additive is shifted toward negative values relative to that for NOE made of pure nickel hydroxide. Correspondingly, their charging potentials (Fig. 3) and the battery voltages are different, too [7, 8].

Another specific feature of an NOE modified with cobalt is its ability, acquired in the course of forming, to be charged in more intensive modes. The current utilization is the highest at a final charging potential of 0.52–0.54 V (battery voltage 1.92–1.93 V), which is lower than the 0.55–0.6 V potential (battery voltage 1.98–2.05 V) commonly used for charging of batteries with NOE containing no cobalt additive. Despite that the NOE capacity continues to grow with increasing final charging potential, the current utilization coefficient decreases and, simultaneously, the consumption of current for oxygen evolution increases.

The tolerance to fast charging is the important advantage of NZ batteries with NOE made of spherical nickel hydroxide, which is topical for power cells intended for vehicles. With a 0.6–0.8-mm-thick NOE, batteries of this kind can be charged in 2–5 h.

The results obtained in studying deep discharge of NOE, at which the NOE potential shifts toward negative values as far as the potential of hydrogen evolution (–1.1 V), which corresponds to a battery voltage of 0–0.1 V (Fig. 4), are characteristic of the transformations occurring with cobalt compounds. A charging that follows a deep discharge occurs at a lower potential equal to 0.35–0.37 V (battery voltage 1.75 V) in its initial stage, which confirms that NOE oxidation proceeds by another mechanism. In the cycle following the deep discharge, the NOE capacity decreases by 15–20 %.

Repeated deep discharges of the batteries are accompanied by further decrease in the NOE capacity, which points to gradual degradation of its active paste [8]. If the final discharge potential is not allowed to be lower than the minimum value of 0–0.1 V (battery voltage 1.2 V), the electrochemical characteristics of NOE remain constant during a long time, i.e., the forming intercalation compound $Ni_{1-x}Co_xOOH$ is not decomposed under these conditions.

Apart from the phenomena considered, which are associated with intercalation processes, the electrode made of spherical nickel hydroxide reveals other essential features imparting new properties to this electrode. A very important result illustrating the specificity of the processes occurring on NOE made of spherical nickel hydroxide was obtained in [7, 8]. In cycling of NZ batteries, the uniformity of the active paste distribution over the zinc electrode surface was considerably improved, compared with that in a battery with MC-supported NOE. No tendency toward "loss of shape" was observed on the negative electrode after 200 cycles [8]. At the same time, in batteries with an NOE on an MC support, tested under the analogous conditions, the loss of active paste in the upper part of the electrode surface is commonly as great as 50% [9].

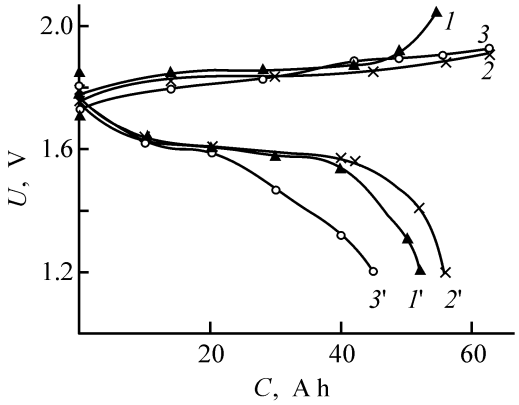

Fig. 4. Variation of the potential U in the course of (*1*–*3*) charging and (*1*'–*3*') discharge of an NTs-25 battery, following the discharge to a voltage of (*2*, *2*') 1.2 V and (*3*–*3*') 0.0–0.1 V. (*C*) capacity. (*1*, *1*') Control cycle.

The reasons for zinc redistribution on the negative electrode of an NZ battery being cycled have been studied extensively. The observed loss of shape is commonly attributed to processes occurring on the zinc electrode itself or in the electrolyte, without taking into account the effect of NOE. Only in [9], data were obtained, indicating that this phenomenon is certainly associated with the nonuniformity of current distribution over the NOE surface. This nonuniformity is responsible for a similar current distribution over the surface of the negative electrode, too, and, eventually, leads to dissolution of zinc in the upper part of the electrode and to its local passivation.

A clearly pronounced improvement of the state of the zinc electrode in its joint operation with NOE made of spherical nickel hydroxide, all other factors being the same, can be accounted for by specific features of the processes occurring on the positive electrode of this type. The high conductivity of the active paste in the presence of cobalt, established in [4, 5], plays a certain role in the changes observed, by making less significant the difference in conductivity between $Ni(OH)_2$ and NiOOH. At the same time, the observed effect cannot be accounted for solely by this factor, since introduction of other electrically conducting additives into NOE (e.g., graphite) does not lead to any results of this kind.

Probably, the observed ability of cobalt additives to level the current distribution over the surface of NOE can be attributed to the effect produced by cobalt on the intercalation hysteresis of protons

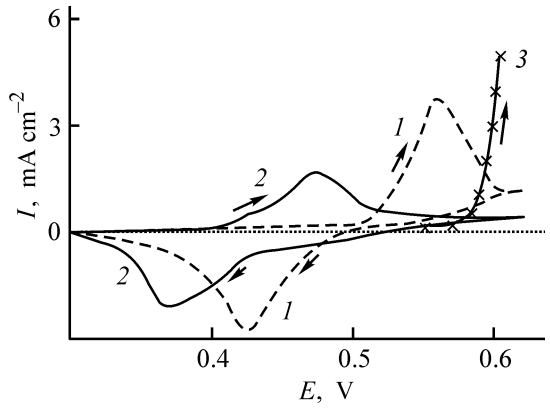

Fig. 5. Cyclic voltammetric curves for NOE (*1*) not containing and (*2*) containing cobalt as additive [10] and (*3*) curve for oxygen evolution. (*I*) Current and (*E*) potential.

under conditions of its anodic and cathodic polarization [10].

We established in this study that the voltammetric charging–discharge hysteresis loops are shifted, upon incorporation of cobalt into the NOE structure, to lower potentials by approximately 120 mV, with the distance between their peaks decreasing from 90 mV (for "pure" NOE) to 50 mV (for an electrode containing cobalt hydroxide). This shift makes the difference between the potentials of NOE oxidation and oxygen evolution greater, which creates more favorable conditions for separation of these processes in battery charging.

The voltammetric curves (*1, 2*) obtained in studying the hysteresis of protons on NOE with and without cobalt [10] are shown schematically in Fig. 5. The values of current refer solely to the *I–E* curve for oxygen evolution, since, according to the authors' data, the position of the peak, a critical parameter for the problem under consideration, is independent of the potential sweep rate and current. The anodic and cathodic portions of the voltammetric curves are shifted by 0.085 V toward positive values, with account taken of the change in the potential of the mercury oxide reference electrode on passing from a 1 M KOH electrolyte used in [10] to a 7 M KOH electrolyte in the present study. The voltammetric curves show that, in principle, the intercalation hysteresis of protons can affect the current distribution in the case of anodic polarization of NOE.

It can be seen that, for pure NOE containing no cobalt (Fig. 5, curve *1*), the peak potential of the anodic current is approximately the same as the potential of the onset of oxygen evolution (Fig. 5, curve *3*). In this case, the oppositely varying currents consumed for the main and side processes cancel out each other to a certain extent in the most overcharged region. In this region, the total current remains constant or increases only slightly, whereas the fraction of current consumed for oxygen evolution grows.

For NOE containing cobalt as an additive, the peak potential of the anodic polarization current on the voltammetric curve is shifted to more negative values (Fig. 5, curve *2*). Therefore, the decrease in current is not compensated for by oxygen evolution. In this case, a decrease in current in a certain area of the electrode must be accompanied by an increase in current in its less charged areas, whose potential is still lower than the value corresponding to the peak in the voltammetric curve, i.e., the currents will be equalized automatically.

The difference in the positions of the peak potentials of the anodic and cathodic currents in the voltammetric curves (Fig. 5) is in agreement with the data according to which the discharge potential (Fig. 3) of batteries with NOE modified with cobalt is lower than that of batteries with NOE containing no cobalt [7, 8].

CONCLUSIONS

(1) Nickel–zinc batteries with a nickel oxide electrode made of spherical nickel hydroxide acquired new properties associated with the intercalation effect of the cobalt additive contained in nickel hydroxide. The conversion of nickel hydroxide to an electrically conducting intercalation compound made it possible to charge the nickel oxide electrode in shorter modes, with high coefficient of current utilization for the main process and its insignificant consumption for oxygen evolution.

(2) The best separation of the main and side processes is provided by the shift of the stationary potential of the nickel hydroxide electrode made of spherical nickel hydroxide toward negative values, compared with the potential of pure nickel hydroxide electrode. This makes the difference between the potentials of the main oxidation process and oxygen evolution larger.

(3) The change in the voltammetric characteristic of the nickel oxide electrode, caused by the effect of cobalt intercalation on the hysteresis of protons, makes the anodic current distribution over the electrode surface more uniform. This leads to a more uniform distribution of the current density over the surface of the zinc electrode, too, and decelerates the processes leading to loss of its shape.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Potential and Current Distributions in Chlorine Diaphragm Electrolyzers with Gas Removal from the Back Side of External Electrodes and Possibility of Electrolysis Intensification

G. G. Tul'skii, A. K. Gorbachev, and A. Yu. Brovin

Khar'kovskii Politekhnicheskii Institut National Technical University, Kharkov, Ukraine

Received August 21, 2002; in final form, September 2003

Abstract—The cell voltage balance components of monopolar and bipolar electrolyzers were analyzed on the basis of calculations in terms of a mathematical model of the potential and current distributions along the cell height and tests of a laboratory electrolyzer of industrial height. Ways to diminish energy expenditure and to intensify diaphragm electrolysis of aqueous sodium chloride solutions were substantiated theoretically and experimentally.

Further improvement of the electrochemical production of chlorine and sodium hydroxide by diaphragm electrolysis of aqueous sodium chloride solutions remains a topical task, since about 50% of the world output of these products is manufactured in this way. Therefore, despite the fact that membrane electrolysis of aqueous sodium chloride solutions [1] is a promising technique, improving the diaphragm electrolysis is of practical and theoretical interest.

In [2, 3], a procedure was suggested for calculating the potential and current distributions along the height of vertical diaphragm chlorine electrolyzers with account of the gas-filling of the anolyte. The influence exerted by the electrical resistance of the current-carrying support of the anode on the potential and current distributions along the height of a vertical chlorine electrolyzer, in which an asbestos diaphragm is deposited on the cathode grid, hydrogen is removed from the back side of the grid cathode, and chlorine is released into the interelectrode space (BGK-50 and DM-50 electrolyzers).

However, a no less important factor that affects the potential and current distributions and, moreover, hinders intensification of electrolysis is the gas-filling of the anolyte [3]. A possible way to diminish the effect of gas-filling on the current distribution along the electrolyzer height is to remove chlorine from the back side of a gas-permeable external electrode, as this is done in membrane electrolyzers [1]. For this purpose, it was suggested in [4] to use an additional diaphragm tightly pressed against the external perforated or gridlike anode.

The aim of our study was to analyze the potential and current distributions along the height of a vertical diaphragm chlorine electrolyzer with gas removal from the back side of external electrodes and to assess the possibility of intensifying further the electrolysis of aqueous sodium chloride solutions and diminishing the specific power consumption in this process.

The equivalent electrical circuit of such a cell is shown in Fig. 1. To develop a mathematical model of the electrolyzer, we divide a cell with parallel electrodes into n parts, as this was done in [2], and regard each part as a closed electric circuit with current supply at $x = 0$ for all the circuits. Therefore, the voltage applied to this circuit is the same for all the circuits and equal to the voltage across the cell. The dependence of the polarization on current density in a narrow range of variation of this parameter (1000–2000 A m^{-2}) can be approximated with a straight line. In this case, the voltage balance at any point x along the height of a monopolar cell with gas removal from the back side of the external electrodes is constituted by the following components

$$E = E^{eq}_{Cl_2/Cl^-} - E^{eq}_{H_2O/H_2} + \eta_{Cl_2} + \eta_{H_2} + U_d + U_{ad} + U_{el} + E_{diff} + U_a + U_c + U_{cont}, \quad (1)$$

where $E^{eq}_{Cl_2/Cl^-}$ and $E^{eq}_{H_2O/H_2}$ are the equilibrium electrode potentials; η_{Cl_2} and η_{H_2}, the overvoltages of

1070-4272/03/7612-1936 $25.00 © 2003 MAIK "Nauka/Interperiodica"

chlorine and hydrogen evolution; U_d, U_{ad}, and U_{el}, the voltage drops across the main (cathode) diaphragm, additional (anode) diaphragm, and electrolyte, respectively; E_{diff}, the diffusion potential; U_a, U_c, and U_{cont}, the voltage drops across the anode, cathode, and contacts, respectively.

According to published data [5–7], the dependence of the overvoltage of gas evolution on the current density is described by the equations

$$\eta_{Cl_2} = 0.100 + 0.028\log i_a, \quad (2)$$

$$\eta_{H_2} = 0.240 + 0.100\log i_c, \quad (3)$$

where i_a and i_c are the cathode and anode current densities.

As in [2], these equations can be approximated with a linear dependence in a narrow range of current densities (250–3000 A m^{-2}) of practical interest. Using the least-squares procedure, we obtained the following equations

$$\eta_{Cl_2} = \Delta E_a + p_a i_a = 0.051 + 0.130 i_a, \quad (4)$$

$$\eta_{H_2} = \Delta E_c + p_c i_c = 0.286 + 0.340 i_c, \quad (5)$$

where ΔE_a and ΔE_c are the constant components of the anode and cathode polarization, and p_a and p_c are the coefficients of their variable components (Ω cm^2).

According to the equivalent circuit (Fig. 1), a current I_0 is applied to the anode at point $x = 0$. Taking into account the fact that the conditions and parameters of electrolysis are the same across the cell width, we can relate the current load to unit anode width. Let us denote the current flowing across the cross-section of the anode at a height x from the point of current supply by I; then, we have the following expression for the current flowing through the electrolyte, I_{el}

$$I_{el} = I_0 - I. \quad (6)$$

The density of the current flowing through the electrolyte at any point x along the electrode height is given by

$$i = \frac{dI_{el}}{dx} = -\frac{dI}{dx}. \quad (7)$$

Taking into account (7), we can rewrite Eqs. (4) and (5) as

$$\eta_{Cl_2} = \Delta E_a - p_a\frac{dI}{dx} = 0.051 - 0.130\frac{dI}{dx}, \quad (8)$$

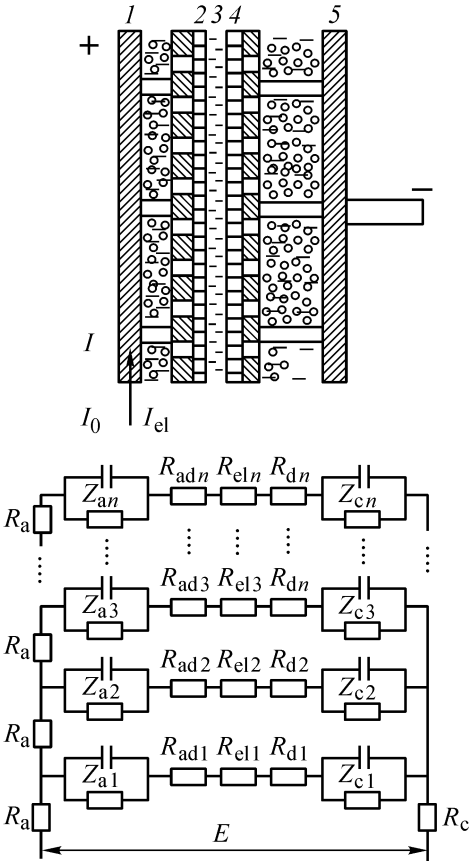

Fig. 1. Equivalent electrical circuit of a monopolar cell with gas removal from the back side of gas-permeable electrodes. (*1*) External grid anode, (*2*) additional anode diaphragm, (*3*) anolyte, (*4*) diaphragm, and (*5*) external grid cathode; the same for Fig. 4.

$$\eta_{H_2} = \Delta E_c - p_c\frac{dI}{dx} = 0.086 - 0.340\frac{dI}{dx}. \quad (9)$$

The equation for the voltage drop across the anolyte at its zero gas-filling takes the form

$$U_{el} = -\frac{dI}{dx}R_0, \quad (10)$$

where R_0 is the reduced resistance of the anolyte at zero gas-filling (Ω cm^2).

The voltage drop across the diaphragm is given by

$$U_d = -\frac{dI}{dx}R_d, \quad (11)$$

where R_d is the reduced resistance of the diaphragm (Ω cm^2).

The voltage drop across the additional (anode) diaphragm is given by

$$U_{ad} = -\frac{dI}{dx}R_{ad}, \quad (12)$$

where R_{ad} is the reduced resistance of the additional diaphragm ($\Omega\,cm^2$).

Using Ohm's law for an anode fragment of unit height, we obtain

$$\frac{dU_a}{dx} = IR_a, \quad (13)$$

where R_a is the electrical resistance of this fragment.

Integrating expression (13), we obtain an equation that describes the ohmic loss of voltage along the anode height:

$$U_a = R_a\int_0^x I\,dx. \quad (14)$$

Substitution of the values of the voltage balance components (8)–(12) and (14) into Eq. (1) gives

$$E - E_{const} = R_a\int_0^x I\,dx - \frac{dI}{dx}(p_a + p_c + R_{diff} + R_{ad} + R_0), \quad (15)$$

where $E_{const} = E^{eq}_{Cl_2/Cl^-} - E^{eq}_{H_2O/H_2} + E_{diff} + \Delta E_a + \Delta E_c + \Delta U_c + U_{cont}$ is the overall voltage balance constant.

Differentiating Eq. (15) and making certain rearrangements, we have

$$\frac{d^2I}{dx^2} = I\sqrt{\frac{R_a}{p_a + p_c + R_{diff} + R_{ad} + R_0}} = \beta^2 I. \quad (16)$$

The solution to a differential equation of this kind is the function

$$I = A\,ch\,\beta x + B\,sh\,\beta x, \quad (17)$$

where A and B are coefficients found from boundary conditions;

$$\beta = \sqrt{\frac{R_a}{p_a + p_c + R_{diff} + R_{ad} + R_0}}. \quad (18)$$

At $x = 0$ I $= I_0$, $A = I_0$; at $x = h$ $I = 0$, $B = -I_0\dfrac{\cosh\beta h}{\sinh\beta h}$.

Substituting the values of A and B into Eq. (17), we obtain an equation that can be used for calculating the current density

$$I = I_0\frac{\sinh[\beta(h - x)]}{\sinh\beta}. \quad (19)$$

Differentiating (19), we have the following equation for the current density

$$-\frac{dI}{dx} = i = \beta I_0\frac{\sinh[\beta(h - x)]}{\sinh\beta}. \quad (20)$$

Substituting I from Eq. (19) into Eq. (14), we obtain the dependence of voltage drop on x along the anode height for the boundary conditions $x = 0$, $U_a = 0$

$$U_a = \frac{I_0R_a}{\beta\sinh\beta h}\{\cosh\beta x - \cosh[\beta(h - x)]\}. \quad (21)$$

The relations (19)–(21) make it possible to calculate how the current, current density, and voltage drop across the anode vary along the height of a monopolar cell with gas removal from the back side of gas-permeable electrodes.

Using the mathematical model obtained, we studied the potential and current distributions along the height of an electrolyzer cell with gas removal from the back side of gas-permeable electrodes on laboratory electrolyzers of industrial height ($H \approx 900$ mm) with units of BGK-50/25 and DM-50 industrial electrolyzers. The design of a laboratory electrolyzer was described in [3].

A new feature in the design of the laboratory electrolyzer is that an additional polypropylene diaphragm, tightly pressed against the frontal side of the external anode, was used to ensure removal of evolving chlorine to behind the back side of the external perforated anode. The removal of the evolving chlorine from the back side of the gas-permeable anodes made it possible to work with a virtually gas-free anolyte and, therefore, to diminish the interelectrode distance to 6 mm, of which 2.5–3 mm was occupied by an asbestos diaphragm. In this cell, brine is fed into the interdiaphragm space, which ensures a uniform flow across the cathode diaphragm.

The reduced resistance of the additional anode diaphragm was 0.98 $\Omega\,cm^2$ at a current density of 1450 A cm^{-2}. The reduced resistance of the anolyte decreased by 1.67 $\Omega\,cm^2$, compared with BGK-50/25, and by 1.17 $\Omega\,cm^2$, compared with DM-50, at average current densities of 1450 and 1675 A m^{-2}, respectively.

The experimental current density distribution along the height of the laboratory electrolyzer (points) and that calculated using the mathematical model are presented in Fig. 2. For comparison, the current distribution in a BGK-50/25 industrial electrolyzer is shown by a dashed line. These data demonstrate a satisfactory agreement between the experimental and calculated dependences, which gives reason to conclude that the mathematical model we developed is adequate to the processes occurring in real electrolyzers with gas removal from the back side of gas-permeable electrodes. The bends in the current distribution curves can be attributed to nonuniformity of the cross-section of the ORTA current lead along its height for the electrolyzer types mentioned.

The absence of gas-filling in the interelectrode space leads to a more uniform current density distribution along the electrolyzer height. The ratio of the initial to final current density was 1.35 for laboratory electrolyzers assembled with the use of units of BGK-50/25 industrial electrolyzers and 1.28 for DM-50 at average current densities of 1450 and 1675 A m^{-2}, respectively. The remaining nonuniformity of the current density distribution is only associated with the nonuniformity of voltage drop across the anode. The variation of the variable voltage balance components along the height of the laboratory electrolyzers described here is shown in Fig. 3.

The voltage drop across the anolyte, $U_{el} + U_{ad}$, decreased in the experimental electrolyzers, compared with their industrial analogues, from 0.47 to 0.22 V for BGK-50/25 and from 0.29 to 0.23 V for DM-50; the voltage across the electrolyzers at working current densities was 3.28 and 3.33 V, respectively. The more pronounced effect obtained with the additional anode diaphragm for a BGK-50/25-based electrolyzer is due to considerable ohmic voltage loss in the anolyte because of the larger interelectrode distance and greater working height of the anode, compared with those in the electrolyzer based on DM-50.

The ohmic voltage loss in diaphragm electrolysis of aqueous sodium chloride solutions can be decreased to a minimum with a bipolar cell design with gas removal from the back side of gas-permeable electrodes. This cell differs from the previously described monopolar cells in that its anode and cathode have lateral current leads to the external electrodes. An asbestos diaphragm at the cathode and an additional polypropylene diaphragm at the anode ensure removal of the evolving gases from the back side of gas-permeable electrodes. The feed brine is delivered into the interdiaphragm space. The equivalent electrical circuit of the cell described is shown in Fig. 4.

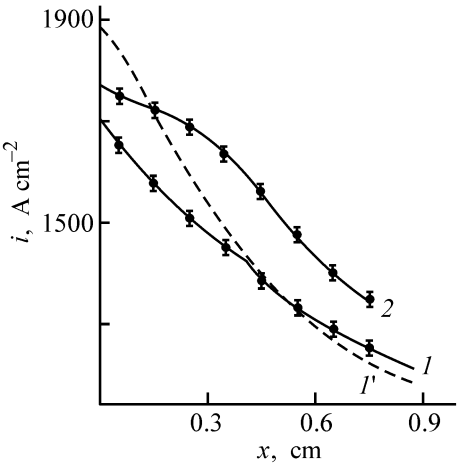

Fig. 2. Distribution of the current density i along the height x of cells of different types with gas removal from the back side of electrodes, obtained on (*1*, *2*) laboratory and (*1'*) industrial electrolyzers. Cell type: (*1*, *1'*) BGK-50/25 and (*2*) DM-50. *Lines*, calculation; *points*, experiment.

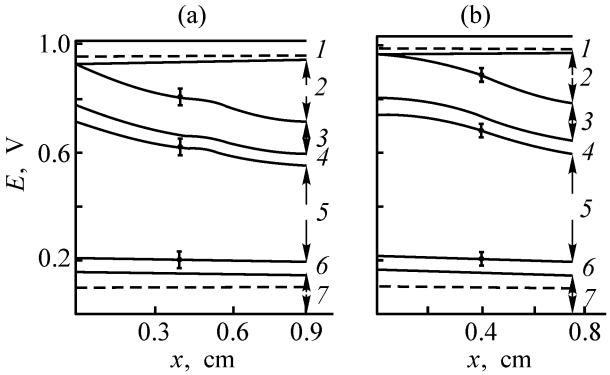

Fig. 3. Variation of the variable voltage balance components along the height of a laboratory electrolyzer with gas removal from the back side of electrodes, fabricated with the use of units of various industrial electrolyzers. (*E*) Sum of variable voltage balance components and (*x*) anode height. (a) BGK-50/25 and (b) DM-50. (*1*) Anode overvoltage; voltage drops across (*2*) anode, (*3*) anode diaphragm, (*4*) anolyte, (*5*) cathode diaphragm, and (*6*) cathode; (*7*) cathode overvoltage.

In accordance with the equivalent electrical circuit, the voltage balance equation for the given bipolar cell has the form

$$E - E_{const} = U_{el} + U_d + U_{ad} + i(p_a + p_c). \quad (22)$$

Substituting Eqs. (8)–(12) into expression (22), we obtain

$$E - E_{const} = -\frac{dI}{dx}(p_a + p_c + R_d + R_{ad} + R_0). \quad (23)$$

Comparative characterization of different types of cells in diaphragm chlorine electrolyzers fabricated with the use of the same units*

Cell type	I, A	H, cm	Current density, A m^{-2}			U_{cell}, V	d, mm
			i_0	i_{av}	i_{fin}		
Monopolar:							
BGK-50/25	1276	88	1883	1450	1185	3.50	12
DM-50	1256	76	1883	1675	1323	3.35	8
with gas removal from the back side	1276	88	1692	1450	1252	3.28	2
of gas-permeable electrodes	1256	76	1772	1675	1355	3.32	2
Bipolar with gas removal from the back	1276	88	1450	1450	1450	3.18	2
side of gas-permeable electrodes	1256	76	1675	1675	1675	3.27	2

* i_0, i_{av}, i_{fin}, the initial, average, and final current density, respectively; U_{cell}, cell voltage; d, interelectrode distance.

From Eq. (23) follows the relation for the current density

$$-\frac{dI}{dx} = \frac{E - E_{const}}{p_a + p_c + R_d + R_{ad} + R_0}. \quad (24)$$

In accordance with Eq. (24), the current density in a bipolar cell of a vertical diaphragm chlorine electrolyzer is independent of the electrode height and remains constant for any point along the electrolyzer height. For example, under the electrolysis conditions used in the preceding calculations (E = 3.5, E_{const} = 2.47 V; p_a = 0.13, p_c = 0.34; R_d = 3, R_{ad} = 0.33, and R_0 = 0.98 Ω cm^2) the current density will be 2150 A cm^{-2}, which exceeds by nearly a factor of 1.5 the average current density in BGK-50/25. In electrolysis with average current density of 1450 A cm^{-2}, the voltage across the bipolar cell we suggested will be 3.18 V. Hence follows that use of a bipolar cell design in a vertical chlorine electrolyzer instead of the monopolar one will make it possible to intensify the process 1.5-fold at the same energy expenditure or to diminish the energy consumption by 235–245 kW h per 1 ton of NaOH (100%) at the same current load on the electrolyzer.

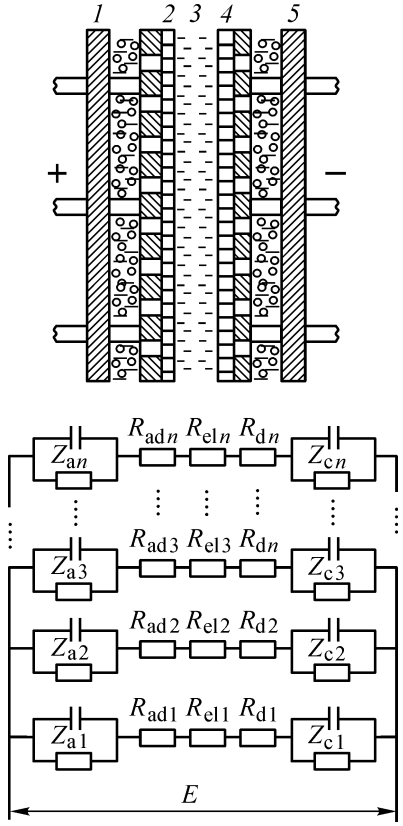

Fig. 4. Equivalent electrical circuit of a bipolar cell.

Comparative characteristics of different types of cells of vertical chlorine electrolyzers fabricated using units of BGK-50/25 and DM-50 industrial electrolyzers are listed in the table.

Use of the monopolar cell design in a chlorine electrolyzer with gas removal from the back side of gas-permeable electrodes makes it possible to decrease considerably the specific power consumption and to improve the current density distribution along the height of a cell of this kind. A more uniform current density distribution offers an opportunity to intensify the process of electrolysis by raising the working current densities. It is possible to further intensify the chlorine diaphragm electrolysis and to diminish the specific electric power consumption if a bipolar cell design with gas removal from the back side of gas-permeable electrodes is used. The requirement of a uniform current density distribution does not restrict the height of such a bipolar cell, which enable a considerable intensification of the diaphragm electrolysis of aqueous sodium chloride solutions.

With the problem of a diaphragm with lower specific electrical resistance under electrolysis conditions resolved, the bipolar design of a chlorine diaphragm electrolyzer becomes the most promising in the development of new chlorine electrolyzers.

CONCLUSIONS

(1) The main reason for nonuniformity in the potential and current distributions along the height of monopolar cells in industrial diaphragm chlorine electrolyzers is the gas-filling of the electrolyte and low electrical conductivity of the titanium ORTA current leads.

(2) Up to 90% of the ohmic voltage loss in electrolysis of an aqueous sodium chloride solution is that in the anode, electrolyte, and diaphragm.

(3) The minimum ohmic voltage loss and the best potential and current distributions are observed in a bipolar cell with gas removal from the back side of the external gas-permeable electrodes.

Abstract—The contact extraction of copper in the form of dispersed powders onto compact zinc from H_2SO_4–$CuSO_4$ and H_2SO_4–$CuSO_4$–$ZnSO_4$ solutions was studied. The influence exerted by acidity and temperature of the solution on the rate and time of cementation, specific consumption of metallic zinc, and morphology of copper deposits was investigated.

The increasing demand for dispersed metal powders [1] stimulates the development of new technologies, especially those using secondary raw materials. This is in the first place topical for copper powders occupying the leading position in volume of production among nonferrous metals [2]. Reprocessing of secondary copper, e.g., of copper–zinc-containing catalysts of KSO and KSO-F brands yields $ZnSO_4$–H_2SO_4–$CuSO_4$ solutions, from which copper and zinc are successively extracted electrochemically. At the same time, complete electrochemical extraction of copper is uneconomical, and, to prevent contamination of zinc with copper, the metal should be only extracted after thorough purification of the solution to remove copper ions by cementation [3]. Taking into account the considerable volumes of this kind of processing, it is reasonable to precipitate copper to obtain cement powders that can be successfully used in powder metallurgy [4].

This study is concerned with contact deposition of dispersed copper powder onto compact zinc in model technological solutions formed in integrated reprocessing of secondary copper raw.

EXPERIMENTAL

The contact precipitation of copper was performed and the kinetic relationships of the process were studied, along with the morphology of dispersed powder, using H_2SO_4–$CuSO_4$ and H_2SO_4–$CuSO_4$–$ZnSO_4$ solutions, which model technological solutions used reprocessing of copper-containing raw materials and spent copper–zinc catalysts. The initial solutions contained (mol dm^{-3}): $CuSO_4$ 0.2, H_2SO_4 0.1–2.0, and $ZnSO_4$ 0–0.8. The cementation was performed on a disc-shaped zinc electrode 30 mm in diameter in a thermostated vessel containing 0.2 dm^3 of the solution, in the temperature range 20–60°C under constant agitation. The disc was situated at the vessel bottom, with its working face upwards. The electrodes were trimmed with a fine emery paper and degreased with alcohol prior to each test. In the course of cementation, the solutions were sampled at regular intervals of time for analysis by the standard iodometric method for the content of copper. After the contact deposition of copper was complete, the dispersed powder was washed with a 0.1 N H_2SO_4 solution, water, and ethanol, and then dried in a vacuum. The morphology of the copper powders obtained was studied with a JEOL T-20 scanning electron microscope.

The results of the study show that, at the initial concentration of 0.2 mol dm^{-3} $CuSO_4$, the morphology of the copper deposits obtained by the contact method depends on the H_2SO_4 concentration. It was established that the dispersity of the copper powder grows with increasing acidity. At the same time, no influence of indifferent ions and, in particular, Zn^{2+} on the dispersity of copper deposits was revealed up to a $ZnSO_4$ concentration of 0.8 mol dm^{-3}.

Under the given cementation conditions, the primary structural units of the cement deposit are globular particles, which form conglomerates with varied spa-

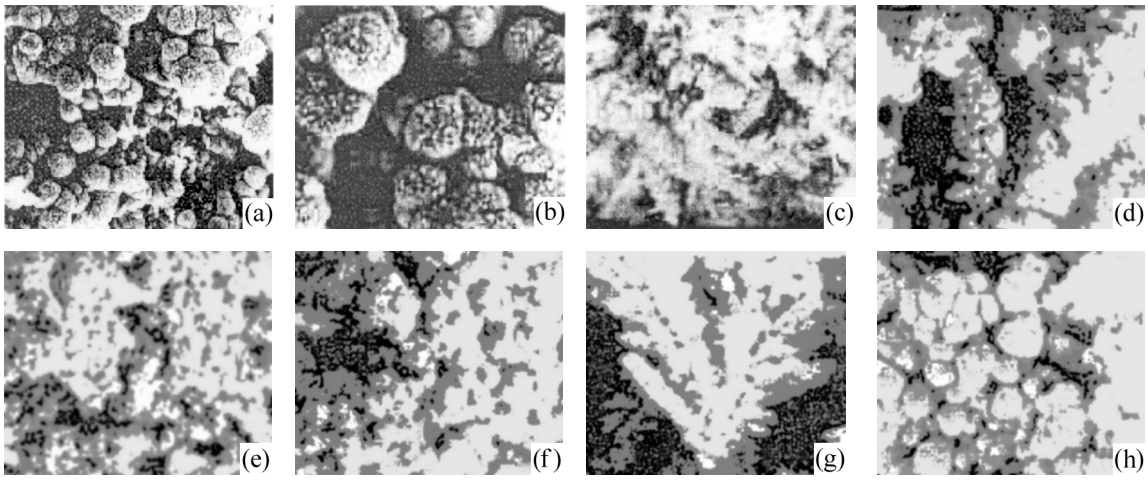

Fig. 1. Electron micrographs of copper powders deposited by the contact method onto zinc in a 0.2 M $CuSO_4$ solution of various compositions. H_2SO_4 concentration (mol dm^{-3}): (a, b) 0.25, (c, d, g, h) 0.5, and (e, f) 2.0. Temperature (°C): (a–f) 2 and (g, h) 50. Magnification: (a, c, e) 1000, (b) 2000, and (d, f–h) 3000.

tial structure (Fig. 1). The size of the primary particles depends on the ratio of rates of nucleation and growth of crystalline copper nuclei, which to a certain extent correlates with the content of H_2SO_4 in solution. With increasing sulfuric acid concentration, the contribution of the conjugate reaction of hydrogen evolution becomes more pronounced. As a result, the degree of surface blocking by hydrogen increases, thus making slower the growth rate of nuclei of the metal being deposited. In addition, the intensified hydrogen evolution facilitates renewal of the surface of zinc owing to a decreased adhesion of the cement deposit to the metal. Hence, with increasing acidity, the rate of nucleation becomes higher, whereas the rate of nucleus growth decreases. For example, at a H_2SO_4 concentration of 2 mol dm^{-3} the particle size does not exceed 10 μm, whereas at the 0.25 mol dm^{-3} concentration, particles up to 40 μm in diameter are formed.

In the second stage, the globular particles, which are structural elements of the copper deposit formed in the first stage, are layered to form conglomerates as the second spatial step of formation of the cement deposit. Starting with the H_2SO_4 concentration of 0.5 mol dm^{-3}, growth of dendrite-like deposits is observed (Figs. 1c, 1d, and 1g), which can be related to the third stage of deposit formation. This can be accounted for by a considerable adsorption of H_3O^+ on the forming copper particles, with the subsequent electroreduction of hydrogen. As a result, the copper deposit, probably, grows as in the case of electrolysis in the mode of deposition of a dispersed copper powder [2]. In deformation, the forming dendrites are easily disintegrated into conglomerates of the second stage.

It is clearly seen that the primary structural elements decrease in size as the cement deposit grows (Figs. 1c, 1d, 1g, and 1h). This is due to a decrease in the concentration of copper ions in the course of cementation.

It was established that the size of the primary structural elements decreases somewhat with increasing temperature, which can be accounted for by the acceleration of hydrogen electroreduction on the copper being deposited. At the same time, no strong effect of temperature on the spatial form of the cement deposits was observed.

The acid concentration also strongly affects the kinetic properties and the process parameters in obtaining a copper powder in purification of zinc sulfate solutions. With the H_2SO_4 concentration increasing to 2 mol dm^{-3}, the cementation rate becomes faster (Fig. 2a), and the process duration, shorter (see table). This is due to the increasing share of the conjugate reaction of hydrogen reduction. This, firstly, facilitates the diffusion of the electrolyte toward the surface of zinc; secondly, makes larger the area of the cementing metal, owing to the appreciable etching of its surface; and, thirdly, prevents formation of an insoluble film of the $xZnSO_4 \cdot Zn(OH)_2$ salt of variable composition on this surface.

The dispersed powder deposited by the contact method in the form of small conglomerates is easily detached from the zinc surface, which also ensures

a large working area of the cementing metal. At the same time, the specific yield of the copper powder considerably decreases with increasing sulfuric acid concentration (table).

With increasing temperature, the cementation rate grows to reach its maximum value at 50°C, with the subsequent deceleration of the process. The time of complete cementation (see table, Fig. 2) decreases to the minimum value at 50°C. This is associated with the increasing rate of the chemical reaction of zinc with H_2SO_4.

The presence of $ZnSO_4$ somewhat hinders cementation at 20°C (Fig. 2a, curve *3*). However, this effect manifests itself to a lesser extent at higher temperatures, and is not virtually observed at 50°C (Fig. 2b, curve *6*). The inhibiting effect of indifferent ions at their high concentrations is due to electrostatic repulsion forces [5]. Analysis of the results obtained shows that the effect of indifferent zinc ions is mainly compensated for by etching of the surface of the cementing metal, i.e., by a sharp increase in the active surface area.

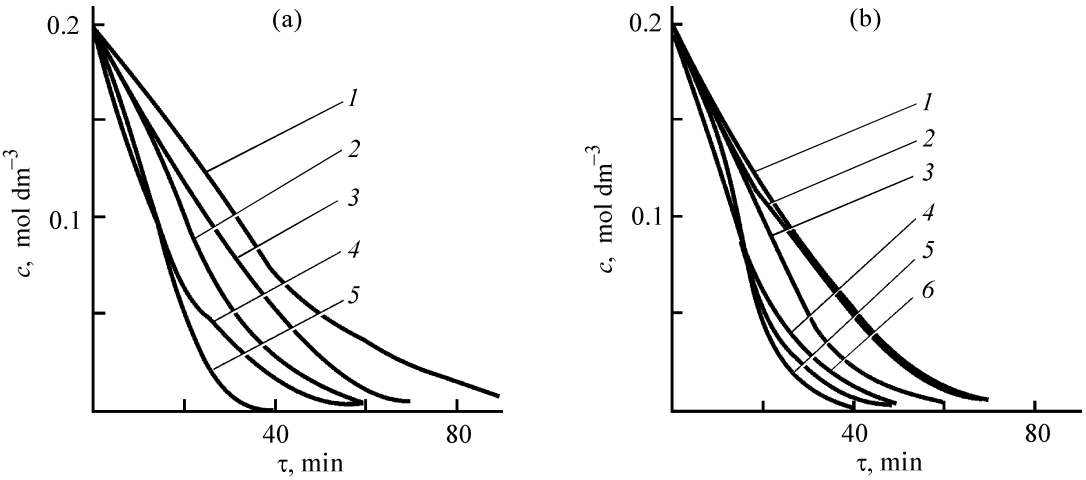

Fig. 2. Influence of (a) H_2SO_4 concentration and (b) temperature on the kinetics of contact deposition of copper onto zinc in a 0.2 M $CuSO_4$ solution of various compositions. (b) H_2SO_4 concentration 0.5 mol dm^{-3}. Temperature (°C): (*1*) 20, (*2*) 30, (*3*) 40, (*4, 6*) 50, and (*5*) 60. $ZnSO_4$ concentration (mol dm^{-3}): (*1–5*) 0 and (*6*) 0.8.

CONCLUSIONS

(1) The cementation of copper on zinc from H_2SO_4–$CuSO_4$ and H_2SO_4–$CuSO_4$–$ZnSO_4$ technological solutions formed in processing of secondary copper- and copper–zinc-containing raw materials is suitable for obtaining finely dispersed copper powders.

(2) The optimal concentration of sulfuric acid is 0.5 mol dm^{-3}, with the $ZnSO_4$ content not limited. The temperature does not affect strongly the morphology of the dispersed copper powder within the range 20–50°C.

CATALYSIS

Use of Cobalt(II) Phthalocyanine Sulfonates in Gas Purification To Remove Hydrogen Sulfide

G. A. Faddeenkova and N. N. Kundo

Boreskov Institute of Catalysis, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

Received August 12, 2002

Abstract—Experiments on liquid-phase oxidation of H_2S with oxygen in the presence of catalysts, cobalt phthalocyanine sulfonates [$CoPc(SO_3Na)_n$], were performed on a laboratory static installation in order to find conditions under which a stationary oxidation mode can be established at pH ≥ 8. The influence exerted by additional introduction of a soluble salt of Mn^{2+} ($MnSO_4$, $MnCl_2$) into the reaction mixture at various pH values was studied.

Cobalt(II) phthalocyanine sulfonates [$CoPc(SO_3Na)_n$] are active catalysts for liquid-phase oxidation of H_2S with oxygen [1–3], which can be successfully used in liquid oxidative processes for purification of various gases to remove hydrogen sulfide. Liquid oxidative methods for gas purification include H_2S absorption with an aqueous solution that contains an alkaline agent and a catalyst and catalytic oxidation of the thus caught H_2S with atmospheric oxygen.

In a weakly alkaline medium (pH 7.3–8.0), the absorbed H_2S, which is in the form of HS^- ions, is oxidized in the presence of $CoPc(SO_3H)_n$ at a high rate by the polysulfide mechanism [1]. The main oxidation products are elementary sulfur and thiosulfates [1]. HS^- ions are oxidized via redox transitions $Co(II)Pc(SO_3H)_n + HS^- \rightleftarrows Co(I)Pc(SO_3H)_n$ The oxidation mechanism is described by the scheme

$$Co(II)Pc(SO_3Na)_n + HS_n^- \rightarrow Co(I)Pc(SO_3Na)_n + HS_n^{\bullet} + H^+, \quad (1)$$

$$2HS_n^{\bullet} \rightarrow S_{2n}^{2-} + 2H^+, \quad (2)$$

$$2Co(I)Pc(SO_3Na)_n + 0.5O_2 + 2H^+ \rightarrow 2Co(II)Pc(SO_3Na)_n + H_2O, \quad (3)$$

$$HS^- + S_{2n}^{2-} \rightarrow HS_n^- + S_{(n+1)}^{2-}. \quad (4)$$

In alkaline solutions (pH > 11), HS^- ions are oxidized through oxygen activation via formation of [$Co(III)Pc(SO_3Na)_n \cdot O^{2-}$] complexes [4], i.e., via the redox transitions [1, 4, 5]

$$Co(II)Pc(SO_3Na)_n \rightleftarrows Co(III)Pc(SO_3Na)_n.$$

In this case, the catalyst activity is more than an order of magnitude lower [1], with sulfites and sulfates formed as a result of oxidation. It should be noted that, in gas purification to remove H_2S, it is important to obtain elementary sulfur, since it is easily separated from the absorbing solution.

At pH 8–11, lower rates of liquid-phase oxidation of H_2S are commonly observed in the presence of $CoPc(SO_3Na)_n$, compared with those at pH 7.3–8.0 and pH > 11. The rate of oxidation and the composition of the oxidation products formed at pH 8–11 are even affected by minor changes in the process parameters {pH value, presence of oxidation (semi)products, such as S^0 and SO_3^{2-} ions [6]}.

In gas purification to remove H_2S, it is necessary to maintain a stationary oxidation mode of oxidation of H_2S being caught. The purification process should be stable in an as wide fluctuation range of the purification process parameters as possible, and, primarily, it should be stable against accumulation of oxidation products and semiproducts.

The aim of this study was to find conditions that make it possible to establish a stationary mode of liquid-phase oxidation of H_2S with oxygen in the presence of catalysts $CoPc(SO_3Na)_n$ at pH 8–11, to select optimal oxidation conditions, and to perform test purification of petroleum gas to remove H_2S on a pilot installation.

EXPERIMENTAL

Experiments on liquid-phase oxidation of H_2S were performed on a static laboratory installation [6].

1070-4272/03/7612-1946 $25.00 © 2003 MAIK "Nauka/Interperiodica"

For the experiments, Na_2S and Na_2SO_3 solutions and solutions of the catalysts $Co(II)Pc(SO_3Na)_2$ and $Co(II)Pc(SO_3Na)_4$ were prepared. The content of Na_2SO_3 and $Na_2S_2O_3$ in the working solutions was determined by iodometry [7], and the concentration of the catalysts, cobalt(II) phthalocyanine sulfonates, by spectrophotometry [6]. The pH value of a solution being oxidized was maintained constant by introducing a phosphate buffer solution.

The rate of NaHS oxidation in the static installation was determined volumetrically from the oxygen absorption, and also from changes in the iodometrically found concentration of NaHS in the reaction mixture [7]. The completion of NaHS oxidation was indicated both by termination of oxygen absorption and by the absence of HS^- ions in the reaction mixture, which was determined using lead indicator paper [8]. The content of oxidation products, Na_2SO_3 and $Na_2S_2O_3$, in the reaction mixture was found iodometrically [7]. The presence of elementary sulfur in the oxidation products in the static installation was determined visually, and the amount of sulfur formed, spectrophotometrically [9]. The overall balance of oxidation products in the static installation correlated with the amounts of oxidized NaHS and oxygen consumed for oxidation.

The concentration of H_2S in an unpurified petroleum gas was found by means of chromatography. The absence of H_2S in a purified gas was established visually, using a lead indicator paper moistened with water and placed in the gas flow [8]. The content of the products formed in oxidation of the H_2S caught, Na_2SO_3 and $Na_2S_2O_3$, was determined iodometrically [7], and the absence of Na_2SO_4 in the absorbing solution was established using $BaCl_2$ [10]. The content of elementary sulfur in the absorbing solution was found spectrophotometrically [9], and the concentration of soda ($NaHCO_3$ + Na_2CO_3), by titration with sulfuric acid [11]. The overall balance of the amount of products formed in oxidation of the H_2S caught in the absorbing solution correlated with the total amount of H_2S caught by the installation for purification of petroleum gas to remove H_2S.

Figures 1a and 1b show the results of experiments on liquid-phase oxidation of H_2S in the presence of catalysts, $CoPc(SO_3Na)_2$ and $CoPc(SO_3Na)_4$, at pH 8.0 and 10.2, performed on the static installation.

As can be seen from Fig. 1a, introduction of already a second portion of the substrate results in that the process becomes steady-state, being characterized by rather high oxidation rate [especially in the presence of $CoPc(SO_3Na)_4$]. In the experiments with

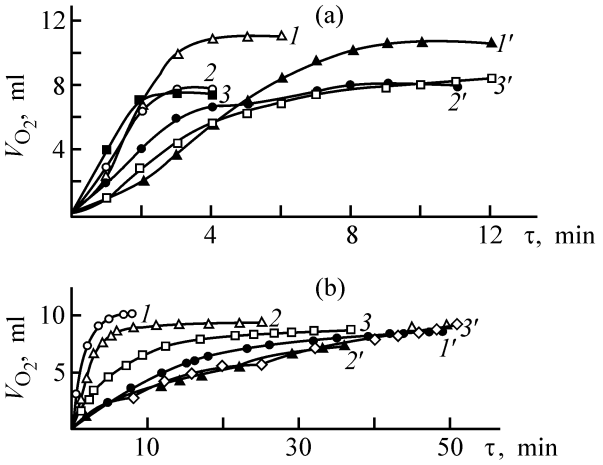

Fig. 1. Kinetics of liquid-phase oxidation of H_2S with oxygen in the presence of a catalyst, (*1–3*) $CoPc(SO_3Na)_4$ or (*1'–3'*) $CoPc(SO_3Na)_2$ at pH value of (a) 8.0 and (b) 10.2. T = 25°C, P_{O_2} = 101 kPa, V_Σ = 20 ml, $[CoPc(SO_3Na)_n]$ = 5 mg l^{-1}. (V_{O_2}) Oxygen volume and (τ) process duration; the same for Figs. 2–4. Concentration $[H_2S]_0$ (M): (*1*, *1'*) 2.4×10^{-2}, (*2*, *2'*) 4.8, and (*3*, *3'*) 7.2.

the initial concentration of H_2S (curves *1* and *1'*), the main oxidation product was $Na_2S_2O_3$ and, in part, elementary sulfur. The increase in the oxidation rate and sulfur yield upon repeated introduction of the substrate being oxidized into the oxidized reaction mixture (curves *2* and *2'*) is due to the fact that the elementary sulfur formed in the initial experiments maintains a high concentration of polysulfide ions in the reaction mixture through the reaction

$$HS^- + (n - 1)S^0 = HS_n^-. \quad (5)$$

The high running concentration of polysulfide ions in the reaction mixture favors the liquid-phase oxidation of H_2S by the polysulfide mechanism. The yield of S^0 in NaHS oxidation is about 60%, and that of $Na_2S_2O_3$, approximately 40% (curves *2* and *2'*). The kinetic curves *2*, *3* and *2'*, *3'*, which describe liquid-phase oxidation of H_2S, are very close. This is accounted for by the fact that the oxidation products S^0 and $Na_2S_2O_3$, which are accumulated in the solution, have no inhibiting effect on the liquid-phase oxidation of H_2S [6]. Thus, a stationary mode of liquid-phase oxidation of H_2S in the presence of catalysts, cobalt(II) phthalocyanine sulfonates $CoPc(SO_3Na)_n$, is ensured at pH 8.0.

The process of liquid-phase oxidation of H_2S at pH 10.2 (Fig. 1b) does not become steady-state upon repeated charging of the substrate: the time of oxida-

Table 1. Calculated equilibrium compositions of an absorbing solution of soda in purification of an H_2S-containing gas ($[H_2S] = 0.3$, $[CO_2] = 2.5$ vol %; $P_{gas} = 101$ kPa)

pH value	Concentration, M			
	$NaHCO_3$	Na_2CO_3	NaHS	Na_2S
8.0	3.17×10^{-2}	1.47×10^{-4}	2.22×10^{-3}	1.6×10^{-7}
8.5	0.100	1.47×10^{-3}	7×10^{-3}	1.6×10^{-6}
9.0	0.317	1.47×10^{-2}	2.22×10^{-2}	1.6×10^{-5}
9.5	1.00	0.147	0.07	1.6×10^{-4}
10.0	3.17	1.47	2.22×10^{-1}	1.6×10^{-3}

tion increases upon introduction of each subsequent portion of the substrate into the reaction mixture. The elementary sulfur formed in the initial experiment (curve *1*) dissolves afterwards (curves *2* and *3*): in runs with the $CoPc(SO_3Na)_2$ catalyst, no sulfur was formed at all. At pH 10.2, an intermediate oxidation mechanism is operative [4], in which a major part of polysulfide ions formed in reactions (1)–(4) is noncatalytically oxidized to SO_3^{2-} ions. Sulfite ions accumulated in the absorbing solution increasingly disrupt the polysulfide oxidation mechanism by decomposing the sulfide ions:

$$(n - 1)SO_3^{2-} + HS_n^- = (n - 1)S_2O_3^{2-} + HS^-. \quad (6)$$

In the experiments performed at pH 10.2, the liquid-phase oxidation of H_2S did not become steady-state. Therefore, absorbing solutions of this composition cannot be recommended for use in gas purification to remove hydrogen sulfide.

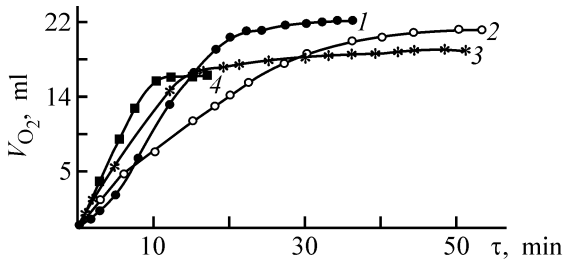

Fig. 2. Kinetics of oxidation with oxygen of alkaline aqueous solutions of NaHS in the presence of catalysts, $CoPc(SO_3Na)_2$, $CoPc(SO_3Na)_4$, and $MnSO_4$. $T = 25°C$, $P_{O_2} = 101$ kPa, pH 11.3, $V_\Sigma = 20$ ml, $[H_2S]_0 = 2.4 \times 10^{-2}$ M. Concentration (M): (*1*) $[MnSO_4] = 0.5 \times 10^{-3}$, (*2*) $[CoPc(SO_3Na)_2] = 10$, (*3*) $[CoPc(SO_3Na)_4] = 10$; (*4*) $[CoPc(SO_3Na)_4] = 10$ mg l^{-1}, $[MnSO_4] = 0.5 \times 10^{-3}$ M.

The disodium salt of disulfonic acid of cobalt phthalocyanine, $CoPc(SO_3Na)_2$, is used in air purification to remove H_2S [12, 13]. In this case, a sufficient capacity of a weakly alkaline absorbing solution for H_2S is ensured both by the alkalinity of the absorbing solution and by the high activity of the catalyst $CoPc(SO_3Na)_2$. In purification of oxygen-free gases, the capacity of the absorbing solution for sulfur depends solely on the alkalinity of the absorbing solution. Table 1 lists calculated equilibrium compositions of a soda solution at various pH values of the solution in purification of a gas containing H_2S.

As follows from the data in Table 1, raising the pH of the absorbing solution from 8.0 to 10.0 leads to an increase in the equilibrium content of H_2S being caught in the absorbing solution by two orders of magnitude (H_2S is present in solutions at pH 8–10 mainly as HS^- and S^{2-} ions). Therefore, it is necessary to use absorbing solutions with the highest possible pH value in purification of oxygen-free gases to remove H_2S with $CoPc(SO_3Na)_n$. Consequently, it is important to select the conditions at which H_2S is oxidized in solutions with the highest possible pH value in the stationary mode by the polysulfide mechanism, to give elementary sulfur as a result of oxidation.

The process of liquid-phase oxidation of H_2S at pH 10.2 (Fig. 1b) does not become steady-state because of the accumulation of the oxidation semiproduct Na_2SO_3 in the absorbing solution. To pass to a stationary oxidation mode, it is necessary to restrict the accumulation of SO_3^{2-} ions in the reaction mixture.

It is known that manganese compounds are active catalysts for liquid-phase oxidation of H_2S and oxidation of sulfite ions to sulfate ions. In this study, it is suggested to introduce soluble Mn^{2+} salts into the reaction mixture in addition to the $CoPc(SO_3Na)_n$ catalyst.

Figure 2 shows data on oxidation of alkaline aqueous solutions of NaHS with oxygen in the presence of the $CoPc(SO_3Na)_2$, $CoPc(SO_3Na)_4$, and $MnSO_4$ catalysts.

Addition of Mn_2^+ salts to the $CoPc(SO_3Na)_4$ catalyst (Fig. 2, curve *4*) makes shorter the time of complete NaHS oxidation, from 48 to 14 min. Also, the composition of the oxidation products is changed: the volume of oxygen consumed for complete oxidation of the reaction mixture decreases from 19.6 to 16.4 ml. In the simultaneous presence of $CoPc(SO_3Na)_4$ and $MnSO_4$, elementary sulfur is formed in NaHS oxidation. In the presence of only one of these catalysts, $MnSO_4$ (Fig. 3, curve *1*) or $CoPc(SO_3Na)_4$ (Fig. 3, curve *3*), no elementary sulfur is formed in NaHS oxidation.

Table 2. 505	2.55	0.64	8.5	8.8	6.89	4.62	108	8.0
960	1.99	0.49	8.7	8.9	6.84	3.68	112	8.4

Figures 3 a 4 show the kinetic curves obtained in experiments on NaHS oxidation in the presence of $MnSO_4$ and $CoPc(SO_3Na)_4$ catalysts at pH 11.0 and 11.85, respectively. In these experiments, the stage of oxidative regeneration of the absorbing solution was simulated by multiple introduction of the substrate into an oxidized solution.

At pH 11.0 and 11.85, the process of liquid-phase oxidation of H_2S becomes steady-state already after a second introduction of the substrate. The main oxidation products are elementary sulfur and thiosulfates. Thus, simultaneous use of two catalysts, $CoPc(SO_3Na)_4$ and Mn^{2+}, must ensure a stationary mode of liquid oxidative purification of oxygen-free gases to remove H_2S.

Petroleum gas was purified to remove H_2S by the liquid oxidative method on the pilot installation. The initial absorbing solution contained $CoPc(SO_3Na)_4$ and $MnCl_2$ catalysts, and also sodium thiosulfate, carbonate, and bicarbonate.[1]

The gas to be purified was fed into the bottom part of an absorber packed with iron chips and was washed there in the counterflow mode with the absorbing solution.

The gas purified to remove H_2S was directed from the upper part of the absorber through a spray catcher to the flare, and the absorbing solution saturated with hydrogen sulfide was delivered to the bottom part of the regenerator, an apparatus with a continuous bubbling bed. In the regenerator, air was bubbled through the solution and the H_2S caught was oxidized. The regenerated solution was delivered from the upper part of the regenerator to the upper part of the absorber. The elementary sulfur formed as a a result of oxidation was floated to the solution surface in the regenerator and was removed therefrom as sulfur foam.

Table 2 presents the results obtained in purification of petroleum gas to remove H_2S with $CoPc(SO_3Na)_4$ and $MnCl_2$ catalysts.

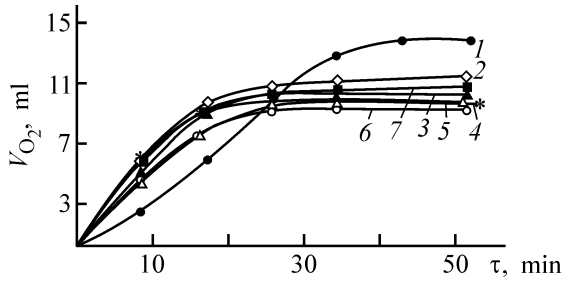

Fig. 3. Kinetics of NaHS oxidation with oxygen in the presence of $CoPc(SO_3Na)_4$ and $MnSO_4$ catalysts. T = 25°C, P_{O_2} = 101 kPa, pH 11.0, V_Σ = 20 ml, $[CoPc(SO_3Na)_4]$ = $10^{-2}\ mg\ l^{-1}$, $[MnSO_4]$ = 0.5×10^{-3} M. (*1*) $[NaHS]_0$ = 2.4×10^{-2} M, (*2–7*) reaction mixture after the preceding experiment, into which NaHS was introduced in amount equal to its initial content in the reaction mixture.

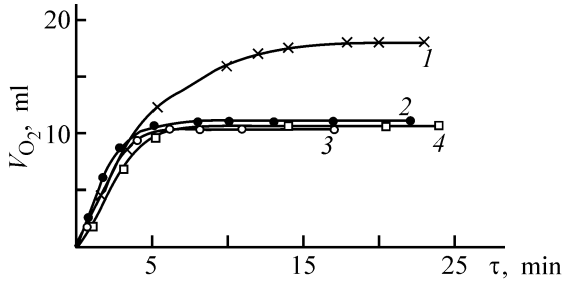

Fig. 4. Kinetics of oxidation of aqueous alkaline solutions of NaHS with oxygen in the presence of $CoPc(SO_3Na)_4$ and $MnSO_4$ catalysts. T = 25°C, P_{O_2} = 101 kPa, pH 11.85, V_Σ = 20 ml, $[CoPc(SO_3Na)_4]$ = $10\ mg\ l^{-1}$, $[MnSO_4]$ = 0.5×10^{-3} M. (*1*) $[NaHS]_0$ = 2.4×10^{-2} M, (*2–4*) reaction mixture after the preceding experiment, into which NaHS was introduced in amount equal to its initial content in the reaction mixture.

[1] The tests were performed by staff members of the VNIPIgazpererabotka Institute (Krasnodar) with participation of one of the authors of this paper.

It follows from the data in Table 2 that complete gas purification was observed at sufficiently high loads in terms of H_2S to be purified (up to 0.6 g H_2S l^{-1}). At solution pH 8.4–9.0, the purification mode was stable. The yield of sulfur was about 90%.

CONCLUSIONS

(1) It was shown that the process of liquid oxidative purification of oxygen-free gases to remove H_2S with cobalt phthalocyanine sulfonates as catalysts is stable if accumulation of SO_3^{2-} ions in the absorbing solution is prevented.

(2) If manganese chloride $MnCl_2$ was used, together with the $CoPc(SO_3Na)_4$ catalyst, on a pilot installation, petroleum gas containing 1.4 to 2.6 vol % H_2S was completely purified to remove H_2S. In this case, the capacity of the absorbing solution for H_2S was up to 0.6 g l^{-1}, with the yield of elementary sulfur obtained in the process of purification equal to about 90%.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Cationic Polymers as Organic Coagulants in Water Treatment at Heat and Electric Power Plants

Abstract—The efficiency of water treatment with organic coagulants (cationic polymers) and calcium hydroxide (alkalizing agent) in combination with iron(II) sulfate (mineral coagulant) was studied as influenced by the nature and concentration of an organic coagulant and concentration of a mineral coagulant.

Coagulation treatment of natural water to remove coarse and colloidal admixtures is an important stage of water pretreatment at heat and electric power plants (HEPPs). Pretreatment is usually performed with various salts of Al(III), Fe(II), and Fe(III) (mineral coagulants); for simultaneous water softening, this process is often combined with liming [$Ca(OH)_2$ is added to the treated water].

To intensify the treatment after liming and coagulation, natural water was treated with Praestol high-molecular-weight polyacrylamide flocculants [1]. The use of flocculants at the water-treatment installation the Kazan HEPP-2 improved the quality of water passed through ion-exchanging filters in further stages of water treatment and was economically efficient.

In the recent decades, organic polymeric coagulants have found increasing application; these water-soluble cationic polymers are mainly used for treatment of wastewater and more complete dehydration of precipitates. Positively charged macromolecules of organic coagulants interact with negatively charged pollutant particles in water, causing their destabilization and rapid flocculation to form coarser aggregates. Mineral coagulants are less expensive, but organic coagulants provide more efficient removal of colloidal and dispersed particles. It should be noted that, in the absence of mineral coagulants, the salt content in purified water would be lower, which, in turn, should decrease the load on the ion-exchange filters and the mineralization of wastewater. Moreover, the concentrations of organic coagulants required for water treatment are significantly smaller than those of mineral compounds; they can be used in a wide pH range and do not affect the acidity of the medium.

Organic coagulants for water treatment are widely used in the Republic of South Africa [2]. The long-time use of organic coagulants (Zetafloc LP526 polyamines) significantly improved the quality of drinking water and decreased its cost. Its has been found [2] that the best results are obtained in a narrow concentration range of organic coagulants, whereas the overcharge of a mineral coagulant does not affect the quality of purified water.

Good results have been obtained with Kemazur 4535 organic coagulant in the stage of water pretreatment at a water-desalinating electrodialysis installation of a cement plant in Tunisia [3]. The water fed into this installation was characterized by wide fluctuations of the content of colloidal and dispersed particles, and the optimal charge of the organic coagulant and flocculant substantially improved the quality of desalinated water and prolonged the service life of the filters. It should be noted that the organic coagulants are most widely used in North America, in contrast to Europe, where various inorganic coagulants are preferred [4].

Previously [5], we studied the water treatment with organic coagulants formed by degradation of high-molecular-weight cationic Praestols [copolymer of

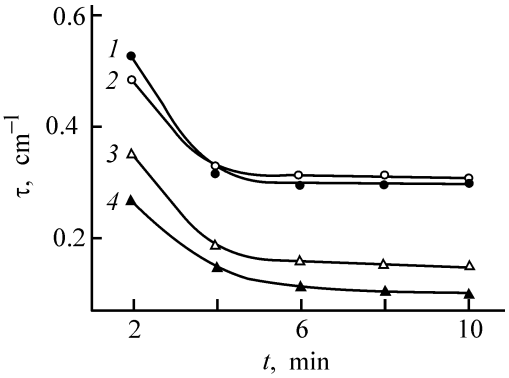

Fig. 1. Turbidity τ vs. the sedimentation time *t* of natural water in the presence of various coagulants. Concentrations: $Ca(OH)_2$ 3.0 mg-equiv l^{-1}, $FeSO_4$ 10 mg l^{-1}, and organic coagulant 1 mg l^{-1}. Coagulants: (*1*) $Ca(OH)_2$ + $FeSO_4$, (*2*) *1* + FL 15, (*3*) *1* + FL 28 P3, and (*4*) *1* + FL 45C.

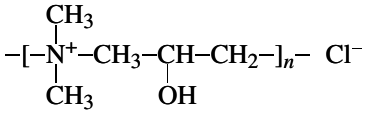
acrylamide (AA) with *N*-acrylamidopropyl-*N*,*N*,*N*-trimethylammonium chloride (APTMAC)]. The resulting low-molecular-weight cationic Praestols improve the efficiency of water treatment, but comparison of their effect with that of water-soluble polymers of other classes, e.g., poly-2-hydroxypropylenedimethylammonium chlorides and polydiallyldimethylammonium chloride, is advisable.

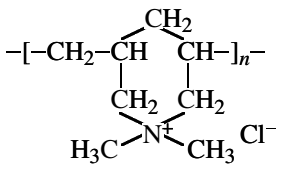
In this study, we analyzed the performance of poly-2-hydroxypropylenedimethylammonium chlorides and polydiallyldimethylammonium chloride (organic coagulants) used in combination with calcium hydroxide in the presence and absence of iron(II) sulfate (mineral coagulant).

EXPERIMENTAL

In the tests, we used cationic poly-2-hydroxypropylenedimethylammonium chlorides FL 15 (M_η = 7×10^4) and FL 28 P3 (M_η = 4×10^5) and polydiallyldimethylammonium chloride FL 45C [M_η = $(1–3) \times 10^5$] purchased from SNF FLOERGER company (France):



(FL 15; FL 28 P3)



(FL 45C)

Iron(II) sulfate $FeSO_4 \cdot 7H_2O$ [technical-grade green vitriol, GOST (State Standard) 6981–75] and a saturated solution of construction lime $Ca(OH)_2$ (GOST 9179–77) were used as coagulants. The initial and purified water was analyzed using chemically pure and analytically pure grade reagents; all solutions were prepared in distilled water. The experiments were performed using river water samples taken at the water scoop of the Kazan HEPP-2 (total hardness 3.8 mg-equiv l^{-1}, alkalinity 2.4 mg-equiv l^{-1}, permanganate oxidizability (PO) 11.0–17.3 mg O l^{-1}, and total content of iron 159–240 mg l^{-1}).

The coagulation tests were carried out by the standard procedure [6] and by sedimentation analysis, using an LAM-1 laboratory turbidity analyzer [7]. The optimal charges of $Ca(OH)_2$ and $FeSO_4$ solutions were calculated in conformity with regulations [6]. The tests were performed as follows. First, natural water samples (150 cm^3) were placed in cylinders with ground-glass stoppers, and then the reagents were added in the following order: $Ca(OH)_2$ solution, mineral coagulant, and, finally, organic coagulant. All the reagents were added successively at 1-min intervals. Then the mixture was agitated by carefully mixed turning-over the cylinder five times (to preserve the sludge structure), poured into a cylindrical optical cell, and the variation of the optical density of the resulting suspension with time was recorded. The measurements were carried out in the same cylinder at a depth of 90 mm from the surface (λ 670 nm, *l* 35.2 mm).

First, we analyzed the effect of organic coagulants on the sedimentation of the disperse phase in natural water after its treatment with calcium hydroxide and mineral coagulant. Figure 1 shows how the water turbidity varies in the absence (curve *1*) and in the presence of various organic coagulants (curves 2–4). The tests were carried out at constant concentrations of $Ca(OH)_2$, $FeSO_4$, and polymers. As seen, the turbidity of water considerably decreases upon addition of organic coagulants owing to intensive sedimentation of the dispersed particles. Comparison of the data of Fig. 1 at τ = const shows that the effect on the suspension clarification increases in the order FL 15 < FL 28 P3 < FL 45C (passing from curve *2* to curve *4*, Fig. 1).

A chemical analysis of the initial and purified water showed that organic polymers do not affect the pH and hardness of water being treated, and only PO values and iron content decrease. Therefore, we evaluated the effect of organic coagulants on the removal of iron compounds and natural organic compounds from natural water. The total content of organic compounds and iron in water was determined from the PO

values (mg O l^{-1}) and by photometry, respectively. The analyses of the initial and clarified water were performed using the known procedures [8]. The effect of the concentration of the organic coagulants on the PO values and content of iron in water is illustrated in Tables 1 and 2, respectively. As seen from these data, the efficiency of water treatment increases with increasing concentration of the organic coagulant. It should be noted that the content of organic and iron compounds decreases even with small additions of organic coagulants.

We also compared the results of water treatment upon substitution of the mineral compound with organic coagulant at optimal and decreased concentrations of iron(II) sulfate. The optimal charge of iron(II) sulfate of 40 mg l^{-1} was determined by analysis of the initial water and confirmed by special coagulation tests. The results obtained are listed in Table 3. It can be seen that lowering the charge of iron(II) sulfate from 40 to 10 mg l^{-1} leads to a decrease in the efficiency of water treatment, i.e., the content of residual iron in the treated water grows. Upon substitution of the mineral coagulant with FL 54C, the efficiency of water treatment improves, this organic coagulant provides more complete removal of organic compounds and iron from water as compared with the effect of the mineral coagulant at its optimal charge of 40 mg l^{-1}.

Figure 2 shows the effect of FL 45C organic flocculant on PO (curve *1*) and content of iron compounds (curve *2*). These parameters of the water treatment efficiency upon addition of the optimal charge (40 mg l^{-1}) of the mineral coagulant are 58 and 69% of the initial values, respectively. As seen from Fig. 2, addition of even insignificant amounts of organic coagulant provides better purification of water as compared with the mineral coagulant.

Our experimental data show that the mineral coagulant $FeSO_4$ can be replaced with with an organic coagulant in pretreatment of water at heat and electric power plants. In this case, use of water-soluble cationic polymers FL 15, FL 28 P3, and FL 45C not only provides more complete removal of impurities but also decreases the salt content in the wastewater. For example, at $FeSO_4$ concentration of 40–50 mg l^{-1}, the content of sulfate ions in water increases by 5–20 g m^{-3}. Moreover, we should remember that, in the flood period, the coagulant is usually taken in a double amount, which increases the pollution of water with sulfate ions. In the subsequent stages of water pretreatment, the ion-exchange filters sorb the sulfate anions, but in the course of filter regeneration they pass into wastewater. Thus, use of organic coagulants significantly decreases the salt content in wastewater and improves the environmental situation at wastewater discharge sites.

Table 1. Oxidizability PO of the clarified water as influenced by the concentration of organic coagulants, c_{oc} ($FeSO_4$ 10 mg l^{-1}, PO of initial water 8.48 mg O l^{-1})

Polymer brand	PO (% of the initial value) at indicated c_{oc}, mg l^{-1}				
	0	0.1	1.0	5.0	10.0

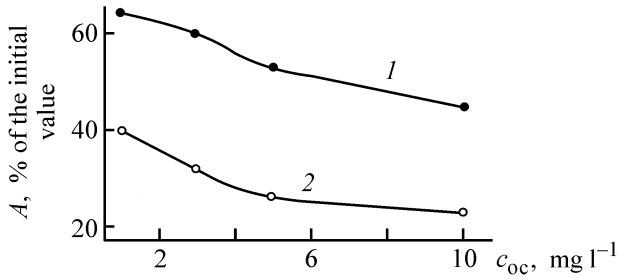

Fig. 2. Quality parameters of clarified water, A: (*1*) permanganate oxidizability and (*2*) total iron content, vs. the concentration of FL 45C organic coagulant, c_{oc}. $Ca(OH)_2$ content 3.0 mg-equiv l^{-1}.

CONCLUSIONS

(1) Poly-2-hydroxypropylenedimethylammonium chlorides FL 15 and FL 28 P3 and polydiallyldimethylammonium chloride FL 45C can be used as effective organic coagulants in the stage of water pretreatment at heat and electric power plants.

(2) The turbidity of water and the content of organic impurities and iron compounds in water decrease upon its treatment with organic coagulants in combination with calcium hydroxide both with and without iron(II) sulfate mineral coagulant.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Base-Catalyzed Autocondensation of Cyclohexanone

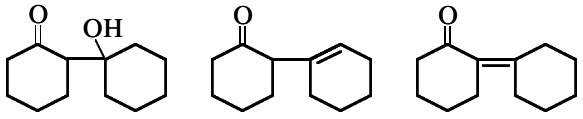
Research Institute of Physicochemical Problems, Belarussian State University, Minsk, Belarus

Received May 6, 2003

Abstract—Autocondensation of cyclohexanone in air at 119–137°C, catalyzed with a solid alkali, was studied.

Cyclohexanone is an intermediate in industrial organic synthesis. Its characteristic feature is tendency to undergo autotransformations yielding a series of products [1]. In synthesis of caprolactam [2] and adipic acid [3], autocondensation is a side reaction, whereas in the first step of industrial synthesis of 2-phenylphenol (a bactericide) [4–6] or 2-cyclohexylcyclohexanol (a fragrance) [7], this is the principal process. To improve the existing processes involving cyclohexanone and develop new ones, it is appropriate to study the kinetic features of its autocondensation, primarily with the aim to obtain input data for simulation of flowsheets and process equipment.

The condensation is nonselective and yields a mixture of isomers; the resulting compounds with double bonds are not quite stable. Therefore, not all of the products of deep autocondensation of cyclohexanone have been identified. Compounds **I**–**III** have been studied in most detail [1, 8–10].



I **II** **III**

Formation of condensation products containing three and more rings was considered in [11–13]. The autocondensation is reversible, and, at elevated temperatures, compounds **II** and **III** are hydrolyzed back to cyclohexanone in the presence of water. The kinetic (in the range 180–290°C) and thermodynamic characteristics of this reaction, which is very important for processing by-products from caprolactam production [14], have been considered previously [15–17].

Data on liquid-phase autooxidation of cyclohexanone under various conditions are summarized in Table 1. It is seen that the major influence on the reaction rate is exerted by the temperature and catalyst. Virtually no data are available for the interval from 80 to 210°C in which the majority of industrial processes are performed. In this study, we examined the kinetics of cyclohexanone autocondensation in air at 119–137°C, catalyzed with a solid alkali.

EXPERIMENTAL

The kinetics of liquid-phase aldol condensation of cyclohexanone was studied in a laboratory installation consisting of a round-bottomed three-necked glass flask fully immersed in a thermostat with silicone oil.

Table 1. Kinetics of liquid-phase autocondensation of cyclohexanone

T, °C	Catalyst/solvent	Other conditions	Analytical method	References
25	Aqueous NaOH	Analysis of aqueous and organic layers	IR	[8]
30–70	Alcoholic or aqueous-alcoholic KOH	Preliminary purging with argon	^{1}H NMR	[9]

The flask was equipped with a reflux condenser with a Dean–Stark trap, a high-speed glass stirrer with a glass hydroseal, and a control thermometer. The temperature in the flask was maintained with an accuracy of ±0.2°C.

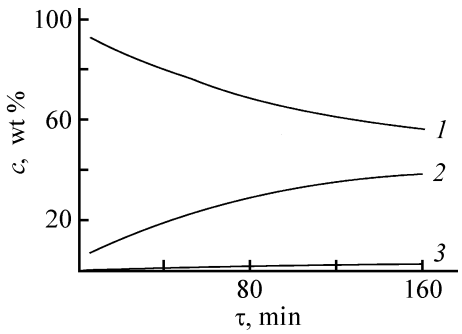

Fig. 1. Variation of the concentrations *c* of (*1*) cyclohexanone and of its condensation products (*2*) **II + III** and (*3*) **IV** with time τ at 137°C.

Five experiments were performed at 119, 125, 129, 133, and 137°C. The flask was charged with 240 ml of purified cyclohexanone (main substance content >99.5%), which was preliminarily kept at the experimental temperature for 40 min. Granulated KOH (chemically pure grade), 2.4 g, was added with vigorous stirring. The time of mixing of the alkali with cyclohexanone was considered to be the start of the process. Samples of the reaction mixture (2–3 ml) were taken with a glass syringe 5, 10, 20, 40, 80, and 160 min after the start of the reaction. The samples were transferred into glass test tubes containing 1-tetradecene (pure grade, distilled). The reaction in a withdrawn sample was stopped by rapid cooling. Preliminary experiments showed that change in the reactant concentrations after rapid cooling to –20°C was negligible.

The amount of water collected in the Dean–Stark trap was insignificant. The maximum amount was about 5 ml at the highest experimental temperature (137°C). Therefore, despite the fact that the distillate was an azeotropic mixture of water and cyclohexanone, changes in the amount of cyclohexanone in the flask were negligible.

Samples were analyzed by gas–liquid chromatography (GLC) on a Tsvet-800 device (flame ionization detector; 2000 × 3-mm steel column packed with Chromaton N-Super + 3% OV-1; column temperature schedule: 140°C, 25 min; heating to 190°C at a rate of 25 deg min^{-1}; 190°C, 35 min; vaporizer and detector temperatures 200°C; carrier gas nitrogen).

According to our results and those of Kim et al. [11], GLC makes it possible to determine the ratios of condensation products differing in the number of cyclohexane rings, but not the ratios of particular isomers, because the products undergo isomerization in the chromatographic column in the course of the analysis. Thus, we determined the total amount of products with two (**II + III**, retention time 10 min), three (**IV**, 35 min), and more (**V**, 52 min) cyclohexane rings. This assignment was based on the retention times of authentic samples of **II** [16], **III** [20], *cis*-2,6-di(1-cyclohexen-1-yl)cyclohexanone (a representative of compounds **IV**) [13], 2,6-dicyclohexylidencyclohexanone [21], and dodecatriphenylene (a representative of compounds **V**) [22]. Compound **I** is thermally unstable [10] and decomposes in the course of the kinetic experiment.

The concentrations of cyclohexanone and its condensation products (Table 2) were calculated from the chromatograms using 1-tetradecene (retention time 5 min) as internal reference [23].

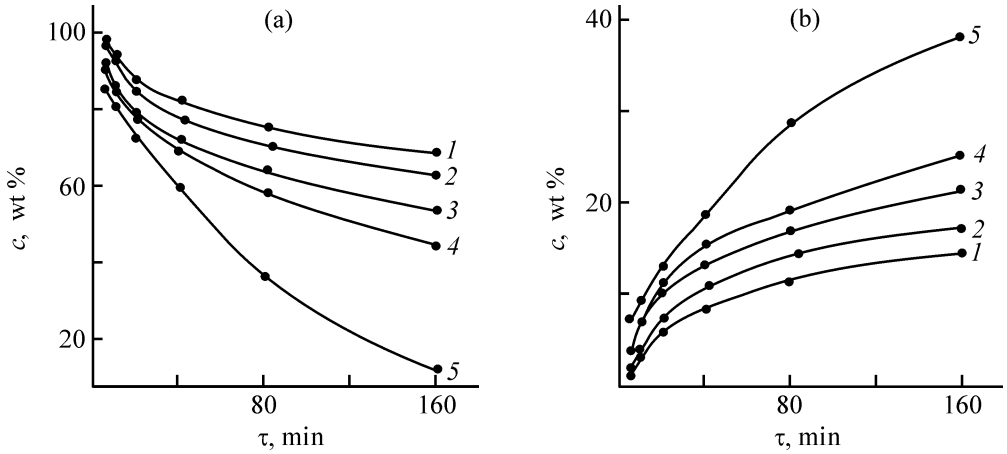

Fig. 2. Variation of the concentrations c of (a) cyclohexanone and (b) **II** + **III** with time τ of autocondensation at (*1*) 119, (*2*) 125, (*3*) 129, (*4*) 133, and (*5*) 137°C.

The kinetic curves of consumption of cyclohexanone and accumulation of condensation products are shown in Figs. 1 and 2. The reaction order evaluated from these curves is abnormally high for all the temperatures except 137°C. We failed to interpret the kinetic curves in terms of formal kinetics and to suggest the condensation mechanism; apparently, several reactions occur simultaneously.

CONCLUSIONS

(1) A procedure was developed for GLC analysis of products of cyclohexanone autocondensation, which differ in the number of cyclohexanone rings.

(2) The temperature dependences of the concentrations of the starting cyclohexanone and reaction products in autocondensation in air were obtained. The reaction is accompanied by formation of "heavy" condensation products in the entire temperature range studied (119–137°C); at 137°C, their amount reaches 4.5% in 2 h.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Chlorophyll and Its Derivatives, Chlorins and Porphyrins, as a Promising Class of Environmentally Friendly Dyes

B. D. Berezin, M. B. Berezin, A. P. Moryganov, S. V. Rumyantseva, and N. S. Dymnikova

Institute of Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

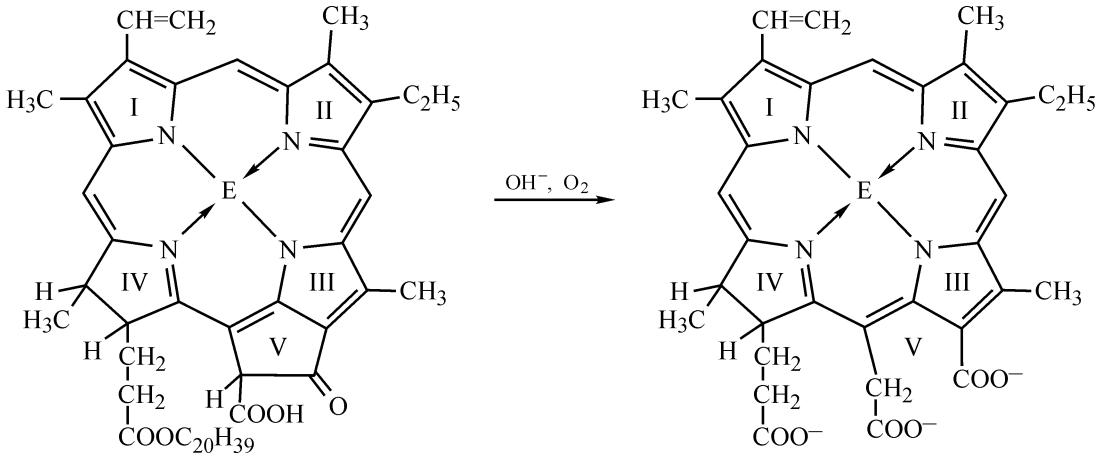
Received October 15, 2002; in final form, September 2003

Abstract—The possibilities of using pheophorbid (*a*), chlorin e_6, its copper complex, 6-*N*-(2-aminoethylamido)chlorin e_6 dimethyl ester, and its complexes with Cu(II), Ni(II), Co(II), and Zn(II) as dyes for cellulose, acetate, and wool fibers were studied.

Chlorophyll is not only one of the most important "life complexes" in photosynthesis, but also the most abundant environmentally clean natural dye. Chlorophyll has been actively studied for several decades, mainly as a compound initiating the photochemical step of photosynthesis [1–7]. Its potential as a source of environmentally clean tetrapyrrole dyes has not received due attention. There are only reports on the use of chlorophyll as a food dye and also as a household dye for imparting color and other useful properties to cleansing agents (toilet soap) and tooth-pastes [8].

Our goal was to search for suitable chlorophyll derivatives and appropriate conditions for dyeing fibrous materials of various origins.

It is known that industrially used synthetic organic dyes are environmentally hazardous not only in production, but also in the use of the dyed textiles. Apparently, tetrapyrrole macrocyclic dyes based on synthetic porphyrins and phthalocyanines are environmentally much more friendly:



E = 2H, chlorophyll ligand;
E = M, metallochlorophyll

E = 2H, chlorin e_6;
E = M, metallochlorin e_6

Porphyrin dyes based on tetra(*p*-chloromethylphenyl)porphine [9], its ammonium, sulfonium [10], and thiosulfo derivatives [11], and also on tetra(*p*-methylpyridinio)octaphenyltetraazaporphine [12] were tested and showed good results as active dyes for polyamide fibers and as cationic dyes for wool, polyamide, polyacrylic, and cellulose fibers. Unfortunately, the study failed to go beyond the stage of lab tests. A particular place among tetrapyrrole compounds was occupied by pigments and water-soluble dyes based on

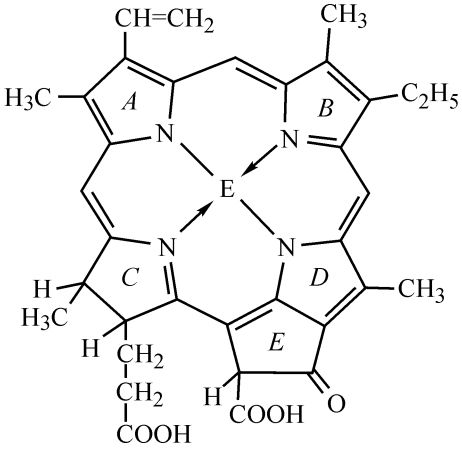
1070-4272/03/7612-1958 $25.00 © 2003 MAIK "Nauka/Interperiodica"

phthalocyanines. Their applications and physicochemical properties are discussed [13–15]. The production of phthalocyanine pigments and dyes is not environmentally friendly. However, ready pigments based on metall-free phthalocyanine and its Cu(II), Co(II), Ni(II), and Al(III) complexes are absolutely resistant to alkalis, moderately concentrated acids, and atmospheric oxygen. Therefore, phthalocyanines are the most harmless in service among synthetic dyes [13].

We performed experiments on dyeing of cotton fabric and of wool and acetate fibers with metal derivatives [Cu(II), Zn(II), Co(II), Ni(II) complexes] of pheophorbid, chlorin e_6, and its aminoethylamide dimethyl ester (at carboxy groups in 6- and γ-positions). The pretreatment of the textiles and dyes and the finishing were performed as recommended in [16–23].

EXPERIMENTAL

Pheophorbid, chlorin e_6, and 6-*N*-(2-aminoethylamido)chlorin e_6 dimethyl ester were prepared from pheophytin recovered from the acetone extract of nettle leaves. Pheophorbid (H_2Pb) was prepared by hydrolyis of the phytol residue of pheophytin with concentrated HCl [6]. The electronic absorption spectrum of the compound are in agreement with published data [4]. Chlorin e_6 (H_2Chln e_6) was prepared from pheophorbid by opening of ring E with a 30% solution of KOH in methanol [6]:



Metallopheophorbids: E = Cu(II), Zn(II), Co(II), Ni(II)

6-*N*-(2-aminoethylamido)chlorin e_6 dimethyl ester was prepared from pheophorbid dimethyl ester in ethylenediamine solution. The electronic absorption spectrum of the product is in agreement with published data [4]. The compounds were tested in dyeing wool and cotton and acetate fibers.

Before dyeing, wool was pretreated with $Na_2Cr_2O_7$ as follows. A wool sample was placed in a solution containing sodium bichromate (4 wt % relative to the fiber) and 5% acetic acid (bath ratio 25). The solution was gradually heated to boiling and boiled for 1 h. Then the bath was cooled, and the wool was washed, dried, and dyed. Since hydrophobic H_2Pb and H_2Chln e_6 are poorly soluble in neutral aqueous solutions, dyeing was performed in 5% aqueous ammonia. With 6-*N*-(2-aminoethylamido)chlorin e_6 dimethyl ester, dyeing was performed in a weakly acidic solution (pH 4). The dyeing solution contained 2.5 g l^{-1} H_2Chln e_6 or its derivatives [CuChln e_6, 6-*N*-(2-aminoethylamido)chlorin e_6 dimethyl ester, or its Cu complex]. In dyeing of wool with 6-*N*-(2-aminoethylamido)chlorin e_6 dimethyl ester, 10 g l^{-1} of $MgSO_4$ was added to improve fixation of the dye. The wool sample was kept in the boiling dyeing bath for 30 min. The dyed samples were washed with hot water (70°C), detergent solution (5 g l^{-1}), and cold water and then dried. Samples dyed with chlorin ligand had intense green-brown color; those dyed with CuChln e_6 were blue-green; with H_2Pb, light green-brown; and with 6-*N*-(2-aminoethylamido)chlorin e_6 dimethyl ester, khaki.

In dyeing of wool with H_2Chln e_6 and 6-*N*-(2-aminoethylamido)chlorin e_6 dimethyl ester, followed by keeping for 1 min in aqueous $Cu(CH_3COO)_2$, the resulting color was intense blue-green in the first case and yellow-green in the second.

6-*N*-(2-Aminoethylamido)chlorin e_6 dimethyl ester was tested as a dye for acetate fiber at a bath ratio of 25. For this purpose, the fiber sample was treated for 30 min in a boiling bath containing 2.5 g l^{-1} of the dye and 10 g l^{-1} of $MgSO_4$. As a result, the fiber acquired the khaki color. Subsequent treatment with aqueous solutions of $Cu(CH_3COO)_2$ and $Ni(CH_3COO)_2$ imparted to the sample intense apple-green color, and upon treatment with $Co(CH_3COO)_2$ and $Zn(CH_3COO)_2$ solutions this color was very weak.

Chlorin H_2Chln e_6 was also tested for dyeing of cotton fabric and printing on it. Dyeing was performed by impregnation with the dye solution, followed by thermal fixation of the dye (bath ratio 25). For dyeing of cotton, 2 g l^{-1} of H_2Chln e_6 was dissolved in water containing 5 g l^{-1} of NaOH and 40 g l^{-1} of NaCl. The sample was padded at room temperature for 1 min. The dye was fixed by two methods. After squeezing, the fabric was either placed for 10 min in an oven heated to 150°C or treated for 10 min with steam in a steaming unit at 103–105°C. The samples became green-yellow. The degree of fixation of the dye on the fabric was determined with a photocolorimeter.

Longer (30 min) steam treatment impaired fixation of the dye. Addition of urea (150 g l^{-1}) to the dyeing bath, followed by steam treatment of the fabric for 30 min, also resulted in worse fixation of the dye. The effect of urea on the uptake and fixation of dyes is ambiguous [24]. It is only obvious that the effect of urea is specific and strongly depends on a particular dye and its concentration in the dyeing bath.

Then, we performed a series of experiments on dyeing a cotton fabric with CuChln e_6 (2 g l^{-1}) by padding with addition of urea (150 g l^{-1}). We found that CuChln e_6 is fixed on fabric worse than H_2Chln e_6 does. To obtain more intense color, padding was performed with H_2Chln e_6. After squeezing, the sample was treated with aqueous $Cu(CH_3COO)_2$, washed with hot water, a detergent solution, and cold water, and dried. The sample had an intense green color. Steaming is not appropriate.

We also tested printing with chlorin e_6. The printing paste consisted of H_2Chln e_6 solution (2.5 g l^{-1}) in 1% aqueous NaOH, mixed with 12% starch thickener. With carboxymethyl cellulose thickener used instead of starch thickener, the fixation of the dye on the fabric was better.

The use of chlorophyll proper (MgChl) as technical dye involves several serious problems. First, chlorophyll and its metal analogs are readily soluble in organic solvents, so that these dyes are easily removed from fibers. Chlorophyll and its metal analogs are unstable to alkaline treatments (laundering): The cyclopentenone ring is opened, and water-soluble metallochlorins are formed. Furthermore, chlorophyll is insufficiently stable in acidic solutions, dissociating with the release of Mg^{2+} [26, 27]:

$$MgChl + 2H_3O^+(2H^+_{solv}) \rightarrow Mg^{2+} + H_2Chl.$$

All these factors prevent straight use of chlorophyll as a dye. However, these difficulties can be overcome [5, 25–31] by modifying chlorophyll molecules. Chlorophyll ligand (H_2Chl) can be readily converted into metal porphyrins difficultly soluble in organic solvents, or into their ionic species. The cyclopentenone ring in H_2Chl and in its phytol-free analog, pheophorbid H_2Pb, transforms in strongly alkaline solutions into other, hydrophobic functional groups [6]. Chlorins and porphyrins obtained from chlorophyll readily form stable complexes with *d* metals. The coordinated metals are not released under conditions of dyeing and use of textiles; furthermore, they can form extra coordination bonds [32] with functional groups of natural and synthetic polymers, thus ensuring their stronger binding with the fiber. Also, *d* metals incorporated in metallochlorins e_6, their functional derivatives, and metalloporphyrins deactivate singlet oxygen $^1O_2$, an agent destroying dyes and fibers, and exert a photostabilizing effect on macrocyclic dyes [32, 33].

Thus, our experiments on dyeing of cellulose, acetate, and wool fibers with chlorophyll dyes gave encouraging results. Bright stable colors were obtained. The tint depends on cation in metal-containing chlorins. Furthermore, metals exert auxochromic and photostabilizing effects on the chlorin chromophore; they enhance the affinity of chlorin for the fiber [33]. The dyes exhibit a weak chemical affinity for cellulose fibers. This is due to low chemical affinity of the π system and functional groups (CO_2R, COOH, C=O, $CH=CH_2$, Alk, CH_2NH_2) of the dyes to functional groups of cellulose (–O–, –OH) and, possibly, also to the low ability of bulky macrocyclic π systems (chlorins, porphyrins, phthalocyanines) to penetrate deep into cotton fiber. However, chemical modification of chlorins, porphyrins, and their metal derivatives [6] may allow preparation of active dyes suitable for high-quality dyeing to obtain green, red, and pink colors.

CONCLUSIONS

(1) Chlorophyll derivatives pheophorbid (*a*), chlorin e_6, 6-*N*-(2-aminoethylamido)chlorin e_6 dimethyl ester, and their Cu(II) and Ni(II) complexes can be considered representatives of a new class of chlorophyll dyes for dyeing of cellulose, wool, and acetate fibers.

(2) In dyeing of wool, chlorin e_6 has advantages over pheophorbid (*a*); to obtain more intense color of cotton fabric and articles from wool fiber, it is appropriate to use chlorin e_6 or 6-*N*-(2-aminoethylamido)chlorin e_6 dimethyl ester, with subsequent treatment with aqueous solutions of Cu(II) or Ni(II) salts.

Received December 19, 2002; in final form, January 2003

Abstract—Binding of Cu(II), Co(II) and Ni(II) cations to humic acids and their sodium salts was studied in aqueous media at pH 3–6 by spectrophotometry and potentiometric titration technique.

Humic acids are the main organic component of soils. They are polyfunctional substances containing carboxy, hydroxy and amino groups. Among these functional groups, the carboxy groups prevail. These functional groups are responsible for binding of metal cations and, in particular, heavy metal cations. The influence of the medium on the complexing of humic acids with heavy metals is an environmentally important problem. It has been found that binding of double-charged metals to humic acids depends on particular metal [1]. For example, the amount of lead and cadmium bound to humic acids varies in direct proportion to the metal concentration in solution, whereas the binding of zinc passes through a maximum. According to [2–4], the carboxy and amino groups of humic acids form chelates with heavy metal cations. The amount of copper(II) bound to humic acids grows with increasing initial copper(II) concentration and pH [5].

In this study, we examined the binding of copper(II), cobalt(II), and nickel(II) to humic acids and their sodium salts.

EXPERIMENTAL

In our experiments, we used $CuSO_4$, $CoCl_2$, and $NiSO_4$ of chemically pure grade and humic acids produced by the Olaine Plant of Chemicals [TU (Technical Specification) 10P 316–69]. The solubility of humic acids grows with pH increasing from 3 to 8. At pH lower than 3, the solubility of humic acids slightly increases owing to protonation of the amino groups. The titration curve of humic acids with aqueous alkali shows that humic acids contain free carboxy groups (titrated approximately at pH 7) and carboxy groups bound to amino groups (titrated at pH 11). In the curve of back titration of aqueous humic acid ammonium salt, there is a bending point at pH 7. The calculated concentration of free and bound carboxy groups in humic acids is 1.9 and 1.7 mmol g^{-1}, respectively.

Our experiments on interaction of humic acids with transition metal cations were carried out as follows. An aqueous suspension of humic acids or an aqueous solution of their sodium salt was mixed with aqueous metal salt being studied and kept for a day with stirring. The resulting suspension was centrifuged for 20 min at 8000 rpm and then the solution of a metal salt with humic acids was separated from the insoluble precipitate. At pH < 5, the concentration of humic acids in the solution after centrifugation was within the limits of the experimental error. After separation of the solid precipitate of the transition metal humates, the concentration of copper(II) and cobalt (II) in the aqueous phase was determined from the absorption of their ammonia complexes at 540 and 490 nm, respectively. The concentration of metal bound to humic acids was determined as the difference between its initial and final concentrations in the liquid phase.

In aqueous suspension, humic acids behave as ion exchangers. Therefore, on adding NaCl or $CaCl_2$ to an aqueous dispersion of humic acids, the pH of the dispersion decreases, and the pH remains unchanged after separation of the suspension by centrifuging. This fact shows that the metal cations are strongly bound to humic acid species by replacing hydrogen ions. Titration of a humic acid suspension with NaCl and $CaCl_2$ solutions shows (Fig. 1) that, at the bending point, the maximum extent of binding of metals to humic acids is attained at the ratio of the metal chloride to humic acids of 7.9 and 25 mmol g^{-1} for NaCl

1070-4272/03/7612-1962 $25.00 © 2003 MAIK "Nauka/Interperiodica"

and $CaCl_2$, respectively. The amount of metal bound to humic acids was calculated from the difference of the pH values of the initial humic acid (HA) suspension and that at the bending point. These values are 1.0 and 1.2 mmol g^{-1} HA for sodium and calcium cations, respectively. We believe that, at suspension pH of approximately 3, mixed calcium humate-chloride salts are formed. Since the total content of carboxy groups in the humic acids, determined by titration with NaOH, is 3.6 mol g^{-1}, our results show that only some portion of the carboxy groups of humic acids interact with sodium and calcium cations.

The titration curve of aqueous $CuSO_4$ with a humic acid suspension (pH 2.8) shows (Fig. 2, curve *2*) that the minimum pH is approximately equal to pH of the initial humic acid suspension. A bend occurs in the titration curve at $\nu[(CuSO_4)/m_{HA}]$ = 1.6 mmol g^{-1}, which exceeds that in titration of aqueous NaCl and $CaCl_2$. Comparison of the titration curves of $CuSO_4$ with humic acid and sodium humate (Fig. 2, curves *2* and *3*) shows that the position of the bending point is independent of the initial pH of these titrating solu tions, although the minimum pH in the titration curves grows with increasing initial pH of titrants. When titrating aqueous sodium humate (pH 7.9) with aqueous $CuSO_4$, the minimum pH in the titration curve is close to the pH value corresponding to $CuSO_4$ hydrolysis (3.8–4.6). Although the titration curves (Fig. 2, curves *2* and *3*) differ in the minimal pH values, the corresponding $\nu[(CuSO_4)/m_{HA}]$ ratios are equal. Under the conditions corresponding to the bending point, insoluble copper humates precipitate.

We found that the amount of copper bound to humic acids in the precipitate grows virtually in direct proportion to the $CuSO_4$ concentration in the solution (Fig. 3). This fact shows that the distribution of Cu(II) cations between the aqueous phase and the solid phase of humic acid suspension [formation of copper(II) humate] is an equilibrium process. With pH increasing from 4.0 to 4.6, the slopes of these straight lines become steeper (Fig. 3, curves *1* and *2*), i.e., this equilibrium is shifted toward copper(II) humate formation. At pH of about 7 and low copper(II) concentration, water-soluble copper(II) humates are formed. With the copper(II) concentration increasing at pH of about 7, a mixture of copper(II) humate and Cu(II) hydroxide precipitates. This precipitate contains up to 40 mmol Cu(II) g^{-1} HA, which considerably exceeds the concentration of carboxy groups in the humic acid suspension (3.6 mmol g^{-1} HA). This fact shows that, under these conditions, poorly soluble basic copper(II) humates are formed.

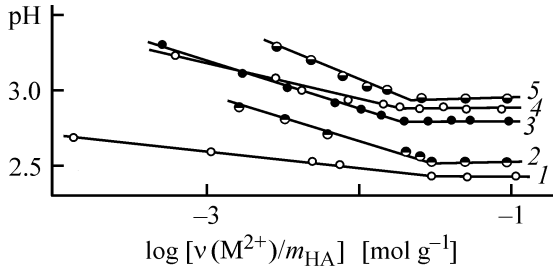

Fig. 1. Curves of potentiometric titration of humic acids with (*1*, *2*, and *5*) $CaCl_2$ and (*3*, *4*) NaCl aqueous solutions $\nu(M^{2+})/m_{HA}$. Metal chloride concentration 10 wt %. Humic acid concentration in suspension (wt %): (*1*) 10, (*2*, *3*) 5, and (*4*, *5*) 2.

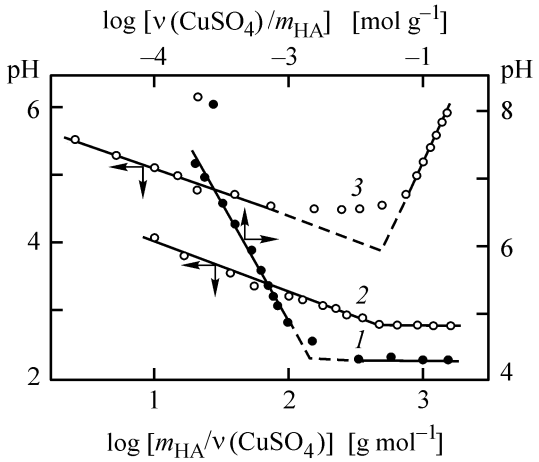

Fig. 2. Curves of potentiometric titration of (*1*) aqueous sodium humates (pH 7.8) with aqueous $CuSO_4$, (*2*) aqueous $CuSO_4$ with humic acid suspension (10 wt %, pH 2.8), and (*3*) aqueous $CuSO_4$ with sodium humate solution (pH 7.6). $\nu(CuSO_4)/m_{HA}$ is the ratio of $CuSO_4$ to humic acids. $CuSO_4$ concentration (wt %): (*1*) 7.9, (*2*) 1.9, and (*3*) 3.95. Sodium humate concentration (wt %): (*1*) 1.2 and (*3*) 5.

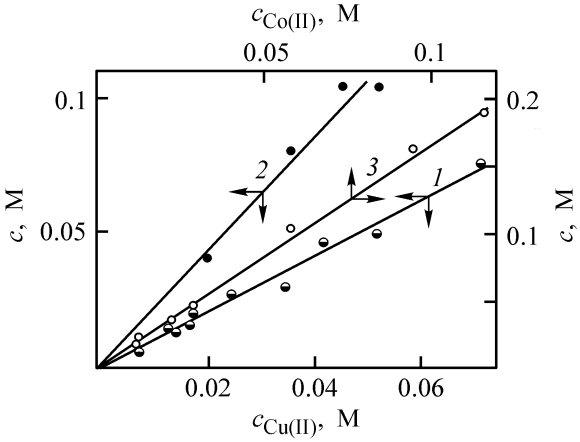

Fig. 3. Plot of the concentration c of (1, 2) copper(II) and (3) cobalt(II) bound to humic acids in suspension vs. the concentration of these metals, $c_{Cu(II)}$, $c_{Co(II)}$, in the solution. Initial concentration of humic acids, g l^{-1}: (*1*, *3*) 2.5 and (*2*) 1.25. pH: (*1*) 4.0 and (*2*, *3*) 4.6.

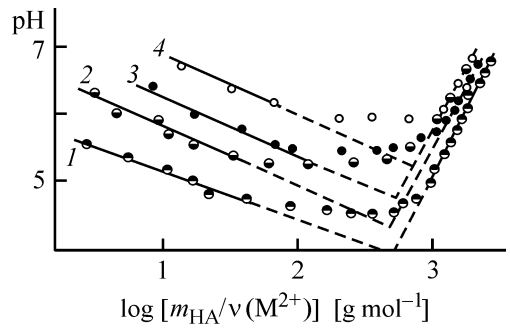

Fig. 4. Curves of potentiometric titration of solution of (*1*) $CuSO_4$, (*2*, *3*) $CoCl_2$, and (*4*) $NiSO_4$ with aqueous sodium humate with the initial pH 7.6. Concentration of titrated salt (wt %): (*1*) $CuSO_4$ 0.395, (*2*) $CoCl_2$ 2.0, and (*3*) $NiSO_4$ 0.25. Sodium humate concentration (wt %): (*1*) 5 and (*2*–*4*) 10.

The curves of potentiometric titration of cobalt(II), nickel(II), and copper(II) with aqueous sodium humate (initial pH 7.6) have a similar shape (Fig. 4). These curves show that, on adding first small portions of sodium humate, pH decreases. We believe that this acidification is caused by displacement of protons of both the free carboxy groups and protonated amino groups of humic acids by the metal cations. On further addition of sodium humate, pH first remains approximately constant and then sharply increases. The minimum pH in these curves increases in the order copper(II) < cobalt(II) < and nickel(II), i.e., in the same order in which grows the pH of conversion of these cations into their hydroxides. At the same time, the bending points in these titration curves occur at approximately equal $\nu(M^{2+})/m_{HA}$ ratios: copper(II) 1.6, cobalt(II) 2.0, and Ni(II) 1.4. We believe that the flat lower portion of the potentiometric titration curves is due to formation of basic metal humates. We found that, like copper(II), the amount of cobalt(II) bound to humic acids at pH 4.6 increases in direct proportion to the equilibrium cobalt(II) concentration in the liquid phase (Fig. 3, curve *3*). The slope of this plot (1.67) is smaller than that for copper(II) (2.42). We believe that this difference is due to the fact that basic Co(II) humates are less stable than basic copper(II) humate at pH 4.6. This difference is also in line with our assumption of formation of basic metal humates and is consistent with the known fact that copper(II) hydroxide, as compared to cobalt(II) hydroxide, is formed at lower pH.

CONCLUSIONS

(1) Humic acids and sodium humates are bound with double-charged transition metal cations in aqueous solutions within the pH range 3–5. The amount of transition metal bound to humic acids grows with the pH increasing from 4.0 to 4.6.

(2) The bending point in the curve of potentiometric titration of double-charged transition metal cations with humic acids and sodium humates occurs at $\nu[(M^{2+})/m_{HA}]$ ratios equal to 1.6, 2.0, and 1.4 mmol g^{-1} for copper(II), cobalt(II), and nickel(II), respectively; its position only slightly depends on the initial pH of the titrants.

Abstract—Kinetics of formation of thermolysis products in heating of thin films of poly-*N*-vinylpyrrolidone and of poly-*N*-vinylpyrrolidone with covalently bound fullerene C_{60} was studied by thermal desorption mass spectrometry.

Since fullerene C_{60} (C_{60}) exhibits biological activity, synthesis of its water-soluble forms and, in particular, polymer–C_{60} systems, is a topical task [1–4]. These are two types of fullerene-containing polymers in which C_{60} is bound to water-soluble macromolecules by covalent or noncovalent bonds. Poly-*N*-vinylpyrrolidone (PVP) is a nonionic water-soluble amphiphilic polymer that can form complexes with molecules of diverse structures and polarities [5]. Poly-*N*-vinylpyrrolidone is produced commercially and is widely used in medicine [6]. Fullerene C_{60} supported by this polymer can be used in biological studies [7]. Some features of the interaction between C_{60} and PVP are known. A radical ion donor–acceptor complex in the PVP–C_{60} system has been detected by ESR spectroscopy [8]. The formation of donor–acceptor bonds between C_{60} and the carbonyl groups of PVP has been confirmed by ^{13}C NMR studies [9].

The structure and properties of solutions of PVP–C_{60} systems are determined by the type of the PVP–C_{60} interaction and the nature of a solvent. As determined by the method of Rayleigh scattering, solutions of PVP–C_{60} complexes contain domains whose size is determined by the balance of the attractive forces between C_{60} molecules and repulsive force between the macromolecules [10]. It should be noted that the degree of heterogeneity of composite and nanocomposite polymer systems is an important parameter affecting their properties. However, there are only a few methods for measuring this parameter. At the same time, this parameter is required to correlate the structure and the properties of these systems and to develop techniques for their synthesis.

The high sensitivity of mass spectrometry and thermal desorption mass spectrometry (TDMS) to a molecule flow in the gas phase allows determination of the weight loss by the polymer–C_{60} system in the course of C_{60} desorption. The sensitivity of other common methods of thermal analysis (e.g., thermogravimetry) is substantially lower, and these methods are unsuitable for this purpose. The type of polymer–fullerene bonding and the structural state of C_{60} (X-ray-amorphous or crystalline) were determined by TDMS from the curves of thermal desorption of C_{60} and the thermolysis products of the polymeric matrix [11–15]. In this study we examined thermal desorption of fullerene C_{60} from PVP–C_{60} systems prepared by different procedures and analyzed the thermolysis products of PVP.

EXPERIMENTAL

Samples of PVP and PVP containing C_{60} bound by covalent bonds (PVP–cov-C_{60}) were prepared by radical polymerization in toluene, using asobis(isobutyronitrile) (AIBN) of pure grade [TU (Technical Specification) 6-09-3840–74]. Trace amount of water were removed from AIBN in a vacuum [16]. *N*-Vinylpyrrolidone (N-VP) was dried over KOH and distilled under reduced pressure. The middle fraction was degassed. A fullerene powder with 98% C_{60} was kept in a vacuum at 100°C. The toluene solutions of C_{60} were prepared by the procedure described in our previous study [17]. Copolymerization of N-VP and C_{60} was performed in toluene at 60°C in the presence of AIBN as an initiator.

Properties of PVP and its complex with C_{60}*

Properties	Sample	
	PVP	PVP–cov-C_{60}
C_{60} content, wt %	–	1.6
MW_{peak} (MEC)	$>90 \times 10^3$	6×10^3
MW_{LS} in water	–	10×10^3
MWD	4.9	2.2
MW_{SD}	–	10^3

* MW_{peak} is the number-average molecular weight corresponding to the maximum content of macromolecules in the molecular-weight distribution (MWD) determined by exclusion chromatography; MW_{LS} is the weight-average molecular weight determined from light scattering; and MW_{SD} is the number-average molecular weight determined by the sedimentation procedure.

Fullerene C_{60} traps free radicals and inhibits copolymerization. This leads to termination of in the early stages in the case of simultaneous component mixing. The monomer conversion is about 20%. To increase the copolymer yield, AIBN was introduced in two steps. Half of the whole amount of AIBN was added at room temperature and the reaction mixture was stirred for 1 h. Then a toluene solution of C_{60} was added, and the reaction mixture was heated at 60°C for 100 h. After that, the remaining portion of AIBN was added, and the copolymerization was continued for the same time. Then PVP–cov-C_{60} was isolated.

The copolymer, formed in 70–90% yield was reprecipitated from diethyl ether, dissolved in distilled water, and lyophilically dried. Polyvinylpyrrolidone prepared by copolymerization in toluene in the presence of AIBN and commercial fractionated PVP with molecular weight (MW) of about $(10–12) \times 10^3$ were used as references. The PVP fraction with MW = 12×10^3 was additionally dried in a vacuum (residual pressure 10^{-6} mm Hg) at 140°C for 10–15 h. The molecular weights of PVP and PVP–cov-C_{60} copolymer were determined by microcolumn exclusion chromatography (MEC) and by the method of Rayleigh scattering (see table).

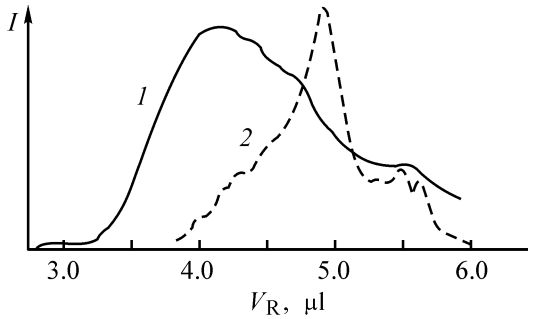

Fig. 1. HPLC pattern of PVP–cov-C_{60} solution in chloroform measured with (*1*) refractometric detection and (*2*) photometric detection (λ = 260 nm, 0.5 × 400-mm Ultrastyrogel 1000 column, chloroform as an eluent, elution rate 3 μl min^{-1}). (*I*) Intensity and (V_R) retention volume.

The glass transition point of PVP $T \sim 180$°C [18].

Complexes of PVP with C_{60}, in which PVP is bound to C_{60} by noncovalent bonds (PVP–C_{60}) were prepared from a benzene solution of these components [19]. The fullerene content in the complex thus obtained may be higher than 1%. In this study, we used the complex containing about 1.7% C_{60}.

Samples of PVP, PVP–cov-C_{60}, and PVP–C_{60} were studied by TDMS. Thin films with a definite thickness were prepared as follows. An aliquot of a dilute solution of PVP–cov-C_{60} or PVP–C_{60} in distilled water or toluene was applied to an oxidized tantalum support-heater equipped with a thermocouple. To minimize the contact of the polymer with water, dried PVP was applied by hatching a support with a sample. The coated support was dried for 5 min at room temperature under a reduced pressure (~700 mm Hg) in a VT6060T vacuum oven (Kendro Laboratory Products) and then placed in a vacuum chamber of MKh-1320 magnetic mass spectrometer (energy of ionizing electrons 75 eV). Thermal desorption experiments were performed in a vacuum with residual pressure of $\sim 10^{-7}$ mm Hg.

The composition of PVP complexes with C_{60} was examined in our previous study by thin-layer chromatography (THC) using toluene as an eluent [16]. The presence of free fullerene was detected only in pure C_{60} and PVP–C_{60}. The absence of free C_{60} in PVP–cov-C_{60} was confirmed by UV spectra of solutions of C_{60} and PVP–cov-C_{60} in chloroform [16]. Naturally, PVP–cov-C_{60} contains large amounts of C_{60} bound to the initiator radicals formed after the second addition of AIBN.

It should be noted that, in these systems, C_{60} is bound to radicals of the initiator and polymer by covalent bonds; their number may range from 1 to 3–4 [16]. We suggest that products are formed with both polymer and initiator radicals, initiator radicals only, and polymer radicals only. A study of PVP–cov-C_{60} solution by two-detector exclusion chromatography confirmed its nonuniformity (Fig. 1). As seen from the chromatogram, the C_{60} content in the low-molecular-weight fractions is high. Apparently, PVP with higher molecular weight is formed after the second addition of the initiator, since the contribution of chain termination reaction decreases owing to the lowering

of the activity of C_{60} that reacted in the first polymerization step. Thus, our chromatographic study demonstrated that the polymerization product is not uniform and contains PVP homopolymer, a series of fullerene-containing PVPs with different numbers of macromolecules with different molecular weights, and structures containing radicals of both the polymer and initiator or only initiator radicals.

The mass spectrum of volatile thermolysis products (VTP) contains signals of vinylpyrrolidone VP (m/z = $56_{100\%}$, $111_{50\%}$, $28_{47\%}$, $27_{25\%}$, $41_{18\%}$), pyrrolidone Pr (m/z = $85_{100\%}$, $42_{42\%}$, $41_{36\%}$, $28_{32\%}$, $30_{29\%}$, $56_{16\%}$) and trace amounts of water (m/z = $18_{100\%}$). The main lines of these compounds and their relative intensities (lower index) are in parentheses. The ratios of VP and Pr formed in thermolysis of PVP and PVP–cov-C_{60} differ in a wide temperature range. A typical mass spectrum of VTP of these samples is shown in Figs. 2a and 2b, respectively. The intensity of the Pr lines in the spectrum of VTP of PVP is the highest, which indicates that elimination of side pyrrolidone groups prevails. On the contrary, PVP–cov-C_{60} is mainly thermolyzed by depolymerization to form VP monomer.

To gain deeper insight into thermolysis of these samples, we recorded the temperature dependences of the rate of formation of the VP monomer $dN_{VP}/d\tau$, pyrrolidone ring $dN_{Pr}/d\tau$, and C_{60} molecules $dN_{C_{60}}/d\tau$ (N_i is the current amount of product liberated from the sample; τ is the time). The kinetics of formation of the thermolysis products was monitored by the line of their molecular ions M^+ 111, 85, and 720, respectively. The samples were heated at a rate of about 7 deg s^{-1}.

The temperature dependences of the rate of liberation of VP $dN_{VP}/d\tau$ from predried PVP and PVP–cov-C_{60} are shown in Fig. 3. It should be noted that, since different radicals are grafted to PVP–cov-C_{60}, only a shift of T_{max} of thermal desorption steps, but not their contribution, can be interpreted. In the case of PVP–cov-C_{60}, the low-temperature peak at T_{max} ~ 290°C is observed along with a high-temperature peak at T_{max} ~ 480°C.

The low-temperature peak is due to rupture of the PVP–C_{60} covalent bond in PVP–cov-C_{60}. This bond is located at the β-position with respect to the double bond of C_{60} and is weak. A similar low-temperature peak has been observed in thermolysis of polystyrene with grafted C_{60} groups [13]. The activation energy of rupture of this bond, calculated from the temperature dependence of the rate of monomer desorption in the low-temperature step (T_{max} ~ 290°C), is about 80 kJ mol^{-1}. The total activation energy of VP formation in thermolysis of dry PVP is ~170 kJ mol^{-1}. It is difficult to calculate the activation energy of PV formation in the high-temperature step of PVP–cov-C_{60} thermolysis, since this step overlaps with the low-temperature step.

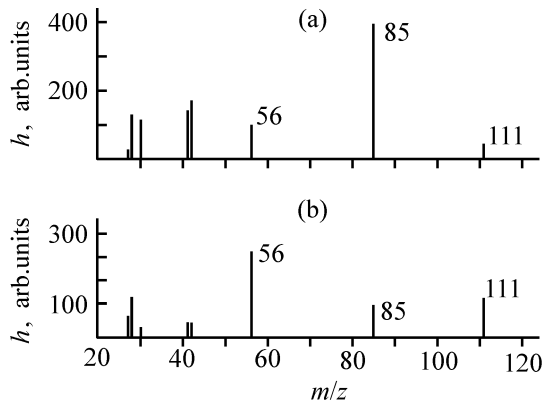

Fig. 2. Fragment of mass-spectrum obtained after thermal treatment of (a) PVP and (b) PVP–cov-C_{60} at ~320°C. (h) Relative peak intensity and (m/z) molecular weight to charge ratio.

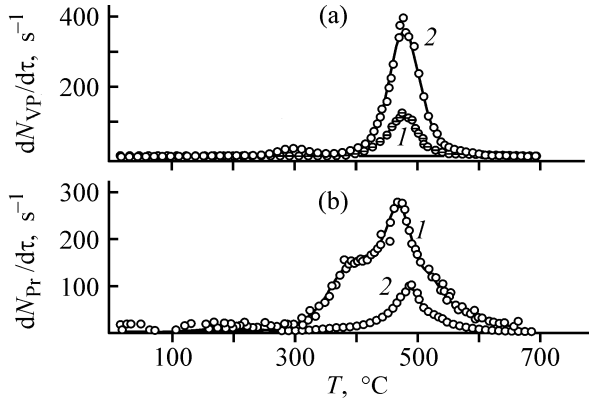

Fig. 3. Rate of formation of (a) VP $dN_{VP}/d\tau$ and (b) Pr $dN_{Pr}/d\tau$ vs. the temperature T of thermal treatment of predried films of (*1*) PVP and (*2*) PVP–cov-C_{60}.

The temperature dependence of the rate of Pr formation, $dN_{Pr}/d\tau$, in the course of thermolysis of PVP–cov-C_{60} films and predried PVP are shown in Fig. 3. As can be seen from Fig. 3, Pr is formed in a wider temperature range (100–700°C) than VP. It should be noted that, at low temperatures, liberation of Pr from PVP predried in a vacuum and applied by the dry procedure is less intense. Poly-*N*-vinylpyrrolidone contains trace amounts of N-VP and 2-pyrrolidone, which are mainly removed by prolonged heating in a vacuum [20]. It is natural to assume that pyrrolidone is released from dry PVP owing to the presence of strongly bound water in the polymer [18]. We suggest that liberated VP undergoes acidic hydrolysis, since the pH of the aqueous PVP solution is ~5.5. The hy-

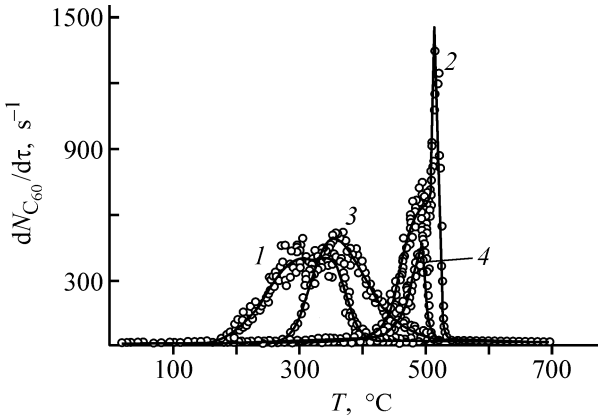

Fig. 4. Rate of C_{60} desorption, $dN_{C_{60}}/d\tau$, vs. the temperature T of thermal treatment of (*1*) 20-nm films of pure C_{60}, applied from a toluene solution to the metal surface, PVP–cov-C_{60} films applied from (*2*) aqueous and (*3*) toluene solutions, and (*4*) PVP–C_{60} film.

drolysis continues until water is present in the system. Water molecules form strong hydrogen bonds with the oxygen atoms of the carbonyl groups and are, apparently, retained in the polymer up to its complete degradation.

The temperature dependences of the rate of C_{60} desorption, $dN_{C_{60}}/d\tau$, from films applied from an aqueous solution of PVP–C_{60}, PVP–cov-C_{60} films applied from aqueous and toluene solutions, and 200-Å films of C_{60} applied from saturated toluene solution of C_{60} to the metal support are shown in Fig. 4. The film of pure C_{60} was studied for comparison, since thermal desorption of C_{60} is not complicated in this case by C_{60} diffusion in the polymeric matrix. The thermogram of thermal desorption of C_{60} from PVP–cov-C_{60} contains a dome-shaped peak at 380–500°C and a sharp peak at 500–530°C. Low-temperature desorption of C_{60} is accompanied by degradation of the macromolecules to form VP and Pr (Figs. 3 and 4). In addition, a comparative kinetic study of C_{60} desorption from a film of pure C_{60} on a metallic support and from PVP–cov-C_{60} film demonstrated that C_{60} molecules are formly retained by the PVP matrix until they diffuse to the polymer–vacuum interface. The total activation energy of low-temperature (380–500°C) desorption of C_{60} (~110 kJ mol^{-1}) is close to that for other polymer–C_{60} complexes bound by covalent bonds [21]. If the low-temperature desorption of C_{60} is caused by rupture of the covalent bonds, the lower activation energy of C_{60} desorption as compared to that of PVP degradation should be due to the fact that the PVP–C_{60} covalent bond is weaker than the C–C bonds in a PVP macromolecule. The high-temperature peak (500–530°C) of C_{60} desorption is absent in the thermogram of PVP–cov-C_{60} films applied from a toluene solution. In this case, C_{60} desorption starts at temperatures lower than those of the onset of PVP depolymerization (Fig. 3a). These data confirm that the mechanisms of high- and low-temperature desorption of C_{60} differ.

The difference in the mechanisms of high- and low-temperature desorption may be due to formation of donor–acceptor bonds of the fullerene both with the macromolecule grafted to it and with free PVP present in the sample. In addition, as we shown previously [19], donor–acceptor bonds and radical ions [8] are formed after exhaustive removal of the solvent (toluene) from the PVP–C_{60} system. Occurrence of these processes in the course of PVP–cov-C_{60} thermolysis cannot be ruled out *a priori*.

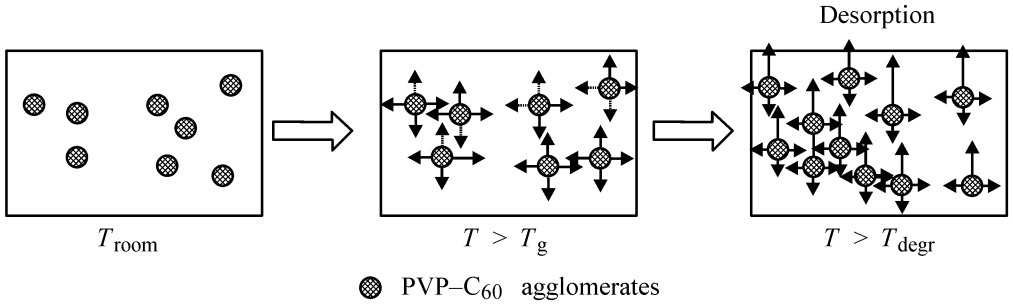
In concentrated aqueous solutions of PVP–C_{60} complexes, aggregation to form fractal structures was revealed by small-angle neutron scattering [22, 23]. At relatively high fullerene content in the complex (more than 1%), phase separation occurs and micellar structures composed of fullerene agglomerates with a polymer shell are formed. At the same time, in toluene, which is bad solvent for PVP, its macromolecules are contracted, which prevents contact between the components. Hence, the probability of formation of PVP–C_{60} donor–acceptor bonds in toluene is very low, and the thermal desorption of C_{60} from a PVP–C_{60} film applied from toluene solutions should be similar to that from other polymers, e.g., poly(methylmethacrylate).

In this stage of the study, we suggest that the difference between the thermal desorption of C_{60} from PVP–cov-C_{60} films prepared from toluene and aqueous solutions is due both to different strengths of interaction of these components and different degrees of fullerene aggregation. The high-temperature peak at 500–530°C can be assigned to desorption of C_{60} molecules bound by donor-acceptor bonds or forming radical ions with appreciable charge transfer from the carbonyl oxygen of PVP to C_{60} (negative charge on C_{60} prevents its desorption from the polymer). The content of these C_{60} molecules, roughly estimated by integration of the desorption rate in the high-temperature step, is about 10% of the total fullerene amount in the sample.

The fact that the temperature dependence of C_{60} formation in the course of thermolysis of PVP–C_{60} film (Fig. 4, curve *4*) shows only the high-temperature peak (T_{max} is slightly lower than that for PVP–cov-C_{60}) and does not contain the dome-shaped peak at 380–500°C, which is present in the thermogram of PVP–cov-C_{60}, confirms our assumption that the high-

temperature step is caused by rupture of donor–acceptor bonds between C_{60} and the polymer. The fullerene content in the complex is about 1.7%, i.e., is higher than the critical concentration (1%) at which, in accordance with the data of small-angle neutron scattering [22, 23], dense micellar structures can be formed. It should be noted that, at the temperatures of desorption of the fullerene from PVP–C_{60} film applied from an aqueous solution [22, 23], the PVP–C_{60} covalent bonds are ruptured and the degree of heterogeneity of the film is determined by the C_{60} content in the system.

Although chemical transformations in solutions that contain PVP and C_{60} and in films applied from these solutions are complex, we suggest the following simplified scheme describing the heterogeneous structure of PVP–cov-C_{60} and PVP–C_{60} films, as well as the temperature transformations of this structure.



Fullerene desorption from PVP–C_{60} agglomerates is difficult, since they are encapsulated in the PVP matrix, which is preserved up to complete thermolysis of the polymer. As a result, the high-temperature peak of C_{60} desorption appears at 500–530°C (Fig. 4). The low-temperature peak (380–500°C) in the thermogram of PVP–cov-C_{60} is caused both by rupture of C_{60}–PVP covalent bonds and desorption of separate nonbonded C_{60} molecules or C_{60} molecules present in loose agglomerates. If the initial system becomes heterogeneous after formation from solution on the support, complex competitive processes determined by the reactivity and interdiffusion of the components will occur on further heating. The diffusion can be accelerated at temperatures higher than the glass transition point $T_{g.}$ The TDMS data discussed above suggest heterogeneous structure of the examined films is caused by agglomeration in the initial solutions is retained up to the temperature of PVP thermal degradation, $T_{degr.}$ The heterogeneous structure of these systems will be studied in more detail in our further works.

CONCLUSIONS

(1) Curves of thermal desorption of fullerene C_{60} from poly-*N*-vinylpyrrolidone bound to C_{60} by covalent bonds were recorded, as well as the curves of formation of thermolysis products of poly-*N*-vinylpyrrolidone films applied from different solvents.

(2) In the sample applied from an aqueous solution, fullerene is firmly retained in the poly-*N*-vinylpyrrolidone matrix up to the decomposition temperature of poly-*N*-vinylpyrrolidone. This interaction is independent of the bonding type in the initial poly-*N*-vinylpyrrolidone–C_{60} system.

(3) The unusual high-temperature peak of C_{60} desorption is due to rupture of the donor-acceptor bonds between the fullerene and the carbonyl oxygen of the pyrrolidone ring in the poly-*N*-vinylpyrrolidone matrix.

(4) The mechanism of thermolysis of the systems examined and the mechanism of thermal desorption of C_{60} from them is determined both by the type of poly-*N*-vinylpyrrolidone-C_{60} bonds and the solvent used for film preparation. The degree of aggregation of C_{60} and its derivatives increases when water is used as the solvent.

Abstract—Radical copolymerization of 1-vinyl-1,2,4-triazole with 2-hydroxyethyl methacrylate in dimethylformamide and ethanol, initiated with azobis(isobutyronitrile), was studied. The copolymerization constants of this pair of monomers at low conversions and the microstructure parameters were determined. New highly hydrophilic thinly cross-linked copolymers were prepared from these monomers in the presence of cross-linking agents.

The interest in polymerization and copolymerization of vinylazoles [1–3] and, in particular, 1-vinyl-1,2,4-triazole (VT) steadily grows. The VT homopolymer, thanks to its unique properties (nontoxicity, high hydrophilicity, chemical stability, complexing power, heat resistance) shows promise for food industry, engineering, and medicine [4, 5]. In turn, polymerization of 2-hydroxyethyl methacrylatye (HEOMA) and its copolymerization with other vinyl comonomers have been fairly well studied. These (co)polymers are widely used for biological purposes and for fabrication of various medical items [6–8].

No data are available on copolymerization of VT with HOEMA, although the possibility of combining the valuable properties of both monomers is very attractive. Synthesis of new copolymers derived from VT and HOEMA would extend the assortment of nontoxic hydrophilic polymeric materials and open up new prospects for using them in medicine.

In this study, we examined the relative reactivities of VT and HOEMA in their binary radical copolymerization in DMF and ethanol, and also some properties of the resulting copolymers.

EXPERIMENTAL

1-Vinyl-1,2,4-triazole was prepared as described previously [9], by the reaction of 1,2,4-triazole with acetylene under pressure in the system KOH–dioxane. The product was distilled in a vacuum; bp 48°C at 3 mm Hg, n_D^{20} 1.5100. HOEMA was purified as described in [10] and distilled in a vacuum; bp 80°C at 3 mm Hg, n_D^{20} 1.4538.

Copolymerization was performed in ethanol and DMF in the presence of azobis(isobutyronitrile) (AIBN) as initiator at 60°C for 5 h. The monomer concentrations were 1 M, and the initiator concentration, 1×10^{-2} M. The molar ratio of the comonomers was varied from 2 : 8 to 9 : 1. The copolymers were isolated, reprecipitated into acetone from DMF solution, filtered off, and vacuum-dried to constant weight. The composition of copolymers was determined by elemental analysis from the nitrogen content. The IR spectra were recorded on a Specord UR-75 spectrometer in the range 400–4000 cm^{-1}; copolymer samples were prepared as KBr pellets. The intrinsic viscosity of copolymers in DMF was measured with an Ubbelohde viscometer at 20°C by the dilution method. A turbidimetric titration was performed on a KFK-2 device. The copolymerization constants were calculated by the Fineman–Ross and Kelen–Tudos methods [11] using the program from [12]. The microstructure parameters of the copolymers were calculated from the copolymerization constants [13]. A thermogravimetric analysis of samples was performed with an MOM derivatograph (Hungary) in air at a heating rate of 5 deg min^{-1}; the maximum temperature was 700°C.

Copolymerization of VT with HOEMA in DMF and alcohol yielded white powdered products soluble in dipolar organic solvents. The formation of true

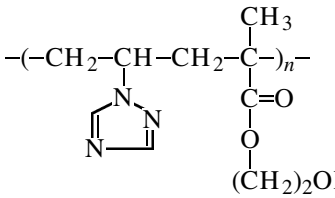
Table 1. Copolymerization of VT with HOEMA in DMF and ethanol (60°C; 5 h; [VT] + [HOEMA] = 1, [AIBN] = 10^{-2} M)

Composition, mole fraction				Yield, %	[η], dl g^{-1}	T_{dec}, °C
starting mixture		copolymer				
VT	HOEMA	VT	HOEMA			
Dimethylformamide						
0.2	0.8	0.09	0.91	84	0.15	140–145
0.5	0.5	0.24	0.76	76	0.69	250–263
0.8	0.2	0.46	0.54	43	1.17	>300
0.9	0.1	0.59	0.41	37	1.35	>300
Ethanol						
0.2	0.8	0.05	0.95	79	0.08	190–195
0.5	0.5	0.17	0.79	61	0.19	218–220
0.8	0.2	0.37	0.60	52	0.53	>300
0.9	0.1	0.57	0.43	50	1.09	>300

copolymers follows from the monotonic run of the turbidimetric titration curve, which has no plateaus characteristics of mechanical blends of homopolymers.

The analytical and IR data prove that the polymeric chain is formed by opening of the double bonds in vinyl groups of both comonomers. New copolymers containing triazole and hydroxyethyl methacrylate units were obtained:



The IR spectra of the synthesized copolymers, contain no absorption bands at 960 and 1650 cm^{-1}, which are characteristic of vinyl groups, are absent. The bands characteristic of the N–H stretching vibrations in triazole at 3300–3400 cm^{-1} are absent, too. At the same time, all the absorption bands of the triazole ring (bending at 670, 1010, 1130, and 1280 cm^{-1}; stretching at 1120, 1430, and 1510 cm^{-1}), as well as the C=O stretching bands in HOEMA (1720 cm^{-1}) are preserved.

Table 1 shows that, as the VT content in the starting monomer mixture is increased, the yield decreases, but the intrinsic viscosity and decomposition point grow, with the latter becoming higher than 300°C.

Analysis of the copolymers shows that, irrespective of the molar ratio of the comonomers, the copolymers are enriched in the HOEMA units, which is consistent with the copolymerization constants (Table 2).

The calculated copolymerization constants of the comonomers show that VT is less active than HOEMA. The decreased reactivity of VT in copolymerization with some unsaturated compounds has been noted previously [1, 14] and was accounted for by polarization of the vinyl group under the influence of the triazolyl substituent.

The higher reactivity of HOEMA [like methyl methacrylate (MMA) and fluorinated methacrylates], compared to VT, may be due to relative stability of the hydroxyethyl methacrylate radical in which the radical center is conjugated with both carboxy and methyl groups. The activity factors are known to grow in going from MMA to higher alkyl acrylates and methacrylates [15]. The quantities $1/r_1$ (Table 2), which characterize the activity of HOEMA to the macroradical with the VT terminal unit confirm that the neutral HOEMA molecules react at a higher rate with the VT radical than with the HOEMA radical. The product of activity constants r_1r_2, equal to 0.22 in DMF and 0.16 in ethanol, shows a tendency toward alternation of VT and HOEMA units in the copolymers. Calculation of the intramolecular distribution of units in the macrochain (see figure) shows that the chains mainly consist of blocks of the more active comonomer, HOEMA, separated by single VT units. As the VT content in the starting monomeric mixture

Table 2. Copolymerization constants of VT (M_1) with HOEMA (M_2)

M_2	Solvent	r_1	r_2	r_1r_2	$1/r_1$	$1/r_2$
HOEMA	DMF	0.09	2.40	0.22	11.11	0.42

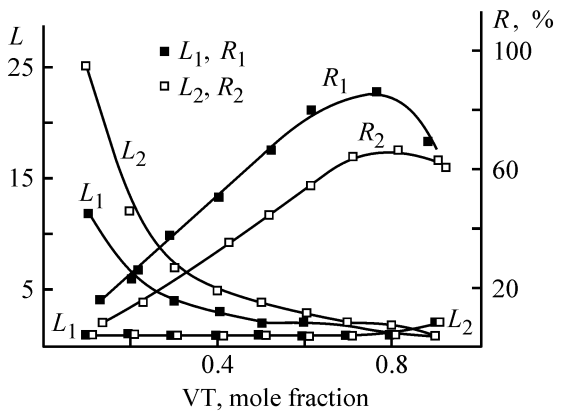
8-FAMA**	DMF	0.25	2.42	0.61	4.00	0.41

* MMA is methyl methacrylate; Q_1 = 0.35, e_1 = 0.08; data of [14].

** 4-FAMA is 2,2,3,3-tetrafluoropropyl methacrylate, and 8-FAMA, 2,2,3,3,4,4,5,5-octafluoropropyl methacrylate [1].



Mean lengths of blocks of similar units L and block structure parameter R vs. the VT mole fraction in the starting monomer mixture. Copolymerization in (*1*) DMF and (*2*) ethanol.

is increased, the length of its blocks grows, and, at the VT mole fraction of 0.75–0.85, the copolymer microstructure becomes close to the alternating structure, which corresponds to the maximum value of the block structure parameter R.

New thinly cross-linked copolymers were prepared by copolymerization of VT with HOEMA in the presence of AIBN and cross-linking agents (0.25 mol %), divinylbenzene and *N*,*N*'-methylenebisacrylamide, at 120°C. The polymerizate is a transparent solid block. The network copolymers are stable up to 240°C according to thermogravimetric analysis. When heated to 260°C, they undergo slow thermal degradation with 10% weight loss. Fast degradation starts at 325°C and is accompanied by 60% weight loss. Above 420°C, the degradation becomes slower, and the residue burns out at 700°C. The thinly cross-linked copolymers prepared have a high refractive index (≥1.5200) and softening point of 110°C; they withstand contact with 0.1 N NaOH and HCl for a week. Hydrated transparent gels with water absorption of 40–75% were obtained.

CONCLUSIONS

(1) Radical copolymerization of 1-vinyl-1,2,4-triazole with 2-hydroxyethyl methacrylate yielded new copolymers containing triazole and hydroxyethyl methacrylate units, soluble in dipolar organic solvents.

(2) 1-Vinyl-1,2,4-triazole is less active in copolymerization.

(3) New thinly cross-linked heat-resistant highly hydrophilic copolymers of 1-vinyl-1,2,4-triazole with 2-hydroxyethyl methacrylate and a cross-linking agent were prepared. These copolymers exhibit high refractive index and are resistant to acid and base hydrolysis; they show promise as raw materials for medicine.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Quantitative Aspects of Competition of Substitution and Addition Pathways in Chlorination of Synthetic Rubbers

V. A. Alferov, V. A. Aver'yanov, and A. A. Goryacheva

Tula State University, Tula, Russia

Received July 1, 2003

Abstract—The competition of substitution and addition pathways in chlorination of SKDN-N, LKN-S, SKDS-N, and NMPB synthetic rubbers in chloroform was studied.

Chlorinated rubbers are of particular importance owing to the unique properties of materials prepared on their basis, such as adhesive composites, paint-and-varnish coatings, heat-insulating materials, and covulcanizates with common rubbers [1–6]. For example, adhesives based on chlorinated rubbers are widely used in various branches of national economy thanks to their high adhesion to various surfaces, elasticity of joints, chemical stability, and low inflammability. Covulcanizates of chlorinated and nonchlorinated rubbers exhibit higher fire, heat, and ozone resistance and enhanced physicomechanical properties [1]. Rubbers and oligobutadienes are widely used as binders that exhibit high strength and heat resistance as compared with the known analogue [2].

The optimal combination of the properties of the resulting materials is ensured by reasonable balance between the amount of chlorine in the rubber and the number of the residual multiple bonds. Fire resistance, chemical stability, and elasticity of the resulting materials grow with increasing chlorine content. However, at a more complete chlorination the amount of the residual double bonds becomes smaller, which adversely affects the strength of a material. At small amount of the residual double bonds, covulcanization between chlorinated and unchlorinated rubbers becomes impossible. Therefore, we examined in this study the competition of the substitution and addition pathways in chlorination as a factor controlling the ratio of the content of chlorine incorporated into the rubber macromolecule to that of the residual double bonds.

EXPERIMENTAL

We used SKDN-N, LKN-S, SKDS-N, and NMPB synthetic rubbers; their chlorination was carried out in chloroform without initiation. In all the cases, the content of rubbers in the chloroform solution was 5 wt %.

The reaction was performed in a glass reactor equipped with a water jacket, a bubbler for chlorine supply, a reflux condenser, and a thermometer. Gaseous chlorine from a cylinder was passed through a Tishchenko bottle with concentrated sulfuric acid and mixed with argon (1 : 1 molar ratio), and the resulting gaseous mixture was passed through the bubbler and fed into the reactor. The constant supply of chlorine was maintained with a manostat, and the rate of chlorine supply was monitored with a rheometer. The temperature of the reaction mixture was maintained by circulating water heated to a required temperature through the water jacket of the reactor. Unreacted chlorine and hydrogen chloride contained in the output gas were trapped with an aqueous solution of potassium iodide at the reactor outlet. At the end of the experiment, the reactor was purged for 40 min to remove chlorine and hydrogen chloride. Then, the solvent was removed from the reaction mixture on a rotary evaporator, and the residue was dried in a vacuum to constant weight. The iodine formed in the reaction between potassium iodide and chlorine in aqueous solution was titrated with a 0.1 N $Na_2S_2O_3$ solution, and the concentration of absorbed HCl was determined by titration with a 0.2 M NaOH solution in

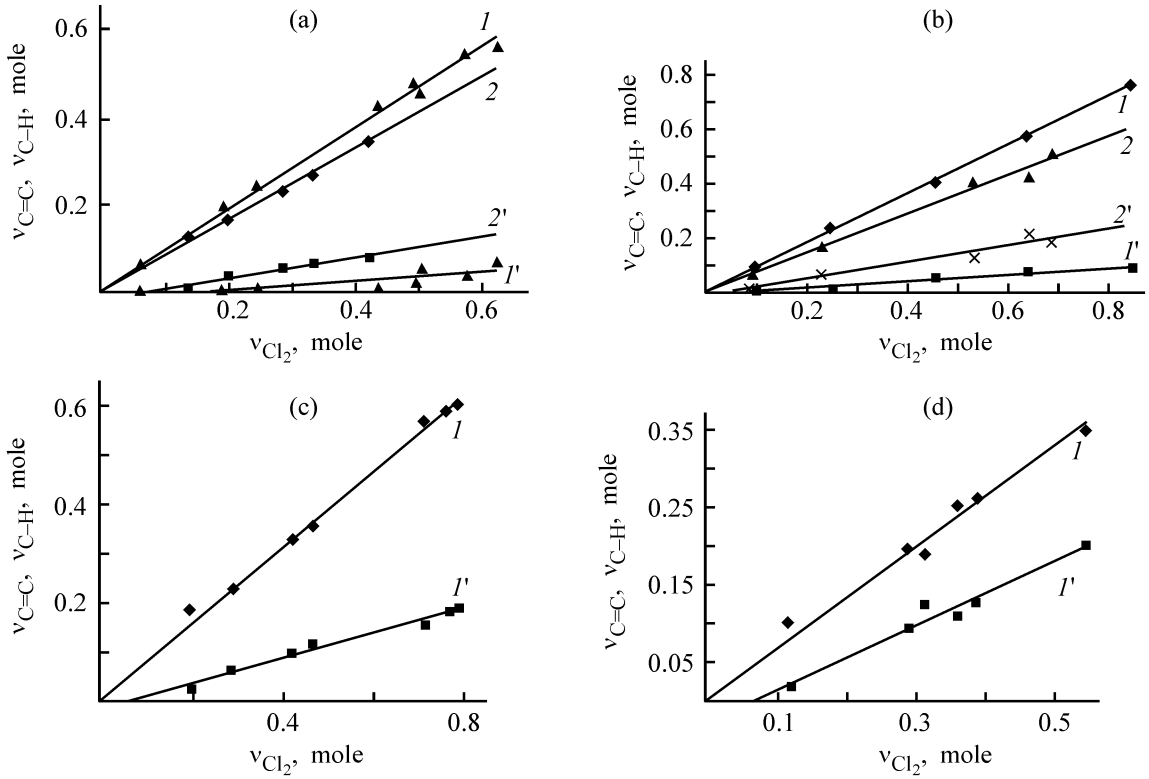

Fig. 1. Dependences of chlorination degree of the C=C and C–H bonds in (a) SKDN-N, (b) SKDS-N, (c) LKN-S, and (d) NMPB rubbers on the overall degree of chlorination. ($\nu_{C=C}$, ν_{C-H}) Content of chlorinated bonds per rubber monomer unit and (ν_{Cl_2}) amount of chlorine taken up per rubber monomer unit; the same for Fig. 2. Chlorination pathway: (*1, 2*) addition and (*1*', *2*') substitution. Temperature, °C: (a) (*1*, *1*') 20 and (*2*, *2*') 58; (b) (*1*, *1*') 15 and (*2*, *2*') 58, and (c, d) 58.

the presence of phenolphthalein. Then, the number of the C–Cl bonds formed in the rubber by substitution chlorination was evaluated. Using these data and the weight of chlorinated rubber, we determined the content of chlorine and the number of chlorinated double bonds in the samples.

The results of chlorination of SKDN-N and SKDS-N rubbers in chloroform are shown in Figs. 1a and 1b as the dependences of the number of moles of the chlorinated C=C and C–H bonds per mole of the monomeric unit ($\nu_{C=C}$, ν_{C-H}) on the number of moles of chlorine taken up per rubber monomer unit (ν_{Cl_2}). As seen, the number of the chlorinated C=C and C–H bonds linearly increases with increasing degree of chlorination. In all the systems studied, the addition pathway in chlorination prevails.

The relative contribution of the addition pathway in chlorination of SKDN-N rubber at 20°C is about 85%. With increasing temperature the contribution of the addition pathway in chlorination decreases, and at 58°C it becomes 71%, which allows preservation of a fairly large amount of the residual double bonds at high degrees of chlorination. At the degree of chlorination, $\nu_{Cl_2} > 0.75$, required to obtain rubber materials with the necessary consumer properties, the content of the residual double bonds is more than 40% of their initial content.

Similar results were obtained for SKDS-N rubber. High-temperature chlorination shows more promise as it ensures the most favorable ratio between the amount of chlorine incorporated in the rubber macromolecule and the content of the residual double bonds. Thus, the chlorination of LKN-S and NMPB rubbers was performed at the maximum temperature of 58°C corresponding to the boiling point of chloroform (Figs. 1c, 1d). The results are similar to those obtained for SKDN-N and SKDS-N rubbers, but in the case of NMPB rubber, the contribution of the substitution pathway in chlorination is greater and, thus, a greater fraction residual double bonds is retained in the rubber (e.g., about 50% at $\nu_{Cl_2} > 0.75$).

Hence, NMPB rubber is of particular importance for modification.

Our analysis of the ν_{C-H}–ν_{Cl_2} dependences showed that their rise begins not from the origin of coordinates, but at some threshold degree of chlorination,

Parameters of Eqs. (1) and (2) for rubber chlorination

Rubber	*T*, °C	α	β	γ	γ/α
SKDN-N	20	0.9 ± 0.03	–0.29 ± 0.02	0.133 ± 0.02	6.767
	58	0.78 ± 0.01	–0.01 ± 0.01	0.23 ± 0.02	3.391
LKN-S	58	0.77 ± 0.02	–0.015 ± 0.02	0.253 ± 0.05	3.043
SKDS-N	15	0.87 ± 0.04	–0.02 ± 0.04	0.159 ± 0.05	5.472
	58	0.71 ± 0.05	–0.01 ± 0.09	0.30 ± 0.14	2.367
NMPB	58	0.66 ± 0.05	–0.03 ± 0.03	0.41 ± 0.09	1.610

which is probably due to the free-radical mechanism of the substitution chlorination of the C–H bonds. It is known that the efficiency of induction of substitution chlorination by chloroalkenes increases with increasing degree of chloroalkene chlorination [7].

This approach can be probably extended to rubber macromolecules. At the beginning of the process, their initiation activity is very low; moreover, the initial stage of the free-radical chlorination (as also that of any free-radical reaction), which involves accumulation of free radicals, is not steady-state. With increasing degree of chlorination, the initiating power of macromolecules increases, but the content of the double bonds decreases owing to the addition of chlorine. The opposite effects of these factors can account for the linearity of the ν_{C-H}–ν_{Cl_2} dependences.

The resulting dependences of $\nu_{C=C}$ and ν_{C-H} on ν_{Cl_2} can be approximated by linear equations

$$\nu_{C=C} = \alpha\nu_{Cl_2}, \quad (1)$$

$$\nu_{C-H} = \beta + \gamma\nu_{Cl_2}. \quad (2)$$

The parameters of the above equations, obtained by the least-squares method [8], are listed in the table.

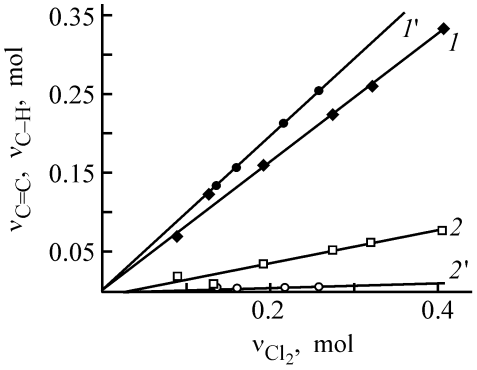

Fig. 2. Degree of chlorination of the (*1*, *1*') C=C and (*2*, *2*') C–H bonds in SKDN-N rubber vs. the overall degree of chlorination in the (*1*', *2*') presence and (*1*, *2*) absence of the inhibitor (5 wt % of the total rubber weight).

The γ/α ratio should obviously correspond to the ratio of the rate constants of the addition and substitution pathways in chlorination.

The difference in the activation energies of these pathways, evaluated from the γ/α ratios at different temperatures, is 14.66 and 15.43 kJ mol^{-1} for SKDN-N and SKDS-N rubbers, respectively. These results are in good agreement with the data on the competitive chlorination of the C=C and C–H bonds under the conditions of free-radical chlorination of tetrachloroethene and 1,2-dichloroethane [9].

The radical-chain mechanism of the reactions studied was confirmed by the data on inhibition of SKDN-N rubber chlorination in the presence of 2,6-di-*tert*-butyl-4-methylphenol. The results are shown in Fig. 2 as dependences of $\nu_{C=C}$ and ν_{C-H} on ν_{Cl_2} in the presence of the inhibitor and without it. It can be seen that, in the presence of the inhibitor, the substitution chlorination, which proceeds exclusively by the free-radical mechanism, is strongly suppressed. At the same time, the increase in the contribution of the addition pathway is due to the fact that this chlorination pathway is not suppressed by the inhibitor.

CONCLUSION

The dependences obtained can be used to determine the content of bound chlorine and the number of residual double bonds in the rubber. The value of these parameters of chlorination, attained in the experiments with the rubbers, make them promising for production of valuable materials and composites.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Allyl Substitution in Chitosan on the Structure of Graft Copolymers

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received July 4, 2003

Abstract—The kinetics of graft polymerization of vinyl acetate on allyl chitosan samples with varied content of allyl groups, initiated with ammonium peroxodisulfate, was studied.

Graft polymerization of vinyl monomers on polysaccharides allows preparation of hybrid copolymers combining the properties of natural and synthetic polymers, e.g., biocompatibility and thermoplasticity. Such copolymers show promise as biomaterials.

Graft polymerization of vinyl acetate (VA) on chitosan in acetic acid solution, initiated with ammonium peroxodisulfate, yielded self-stabilized emulsions. The process kinetics was studied; it was found that the reaction rate only weakly depends on the concentrations of chitosan and initiator and is proportional to the VA concentration. An examination of the thermomechanical properties of the copolymers with different degrees of grafting showed that, at longer grafting time, partially cross-linked structures are obtained. Alkaline treatment of the grafted polyvinyl acetate resulted in transfer of the copolymer into solution or its transformation into a gel (in the case of the cross-linked copolymer) through hydrolysis of acetate groups. The hydrolysis kinetics was studied. The final product was a copolymer of chitosan with polyvinyl alcohol [1]. Despite the 100% conversion of the monomer and high degree of grafting, the grafting efficiency did not exceed 50%, i.e., grafting and homopolymerization of VA occurred at different rates. It has been shown previously that the use of cellulose ethers with a small content of allyl groups sharply enhances the efficiency of grafting of vinyl monomers and the content of grafted chains [2].

In this study we examined the effect of allyl substituents in chitosan on the parameters of graft polymerization of VA and structure of the resulting copolymer.

EXPERIMENTAL

Allyl chitosan (ACAN) with the degrees of allyl substitution, γ_A, of 4, 9, 25, and 38 was prepared as described in [3].

Vinyl acetate was distilled twice; the fraction with bp 72.5–72.8°C was used. Ammonium peroxodisulfate (APS) was recrystallized from water.

Graft polymerization of VA was performed as follows. A calculated amount of water was added to a definite portion of a 4% solution of ACAN in 2% acetic acid to obtain the required ACAN concentration. The mixture had pH 3.6. Then a definite amount of VA was added; the mixture was vigorously stirred to obtain an emulsion and heated to 60°C. The calculated amount of APS was added, with the stirring being continued. This instant of time was considered to be the start of the reaction. Samples of the reaction mixture were taken at regular intervals; the reaction in these samples was stopped by adding acetone. The precipitate was filtered off on a Schott filter placed in a Soxhlet apparatus. The homopolymer was separated from the precipitate by exhaustive extraction with acetone, followed by solvent evaporation in a rotary evaporator. The copolymer yield was determined by weighing the filter with the precipitate after drying in a vacuum at 60°C.

The degree of grafting, C (%), was calculated by the formula

$$C = [(g_1 - g_0)/g_0] \times 100,$$

where g_0 is the ACAN weight in the sample, and g_1, the copolymer weight in the sample.

1070-4272/03/7612-1978 $25.00 © 2003 MAIK "Nauka/Interperiodica"

The grafting efficiency E (%) was calculated as the ratio of the weight of the grafted PVA to the total weight of the polymerized monomer:

$$E = (g_1 - g_0)/(g_1 - g_0 + g_2) \times 100,$$

where g_2 is the weight of VA homopolymer in the sample.

The yields Q_1 and Q_2 of the grafted polymer and homopolymer were calculated as the ratios of the weight of the corresponding polymer to the weight of the monomer taken in the reaction; the conversion K was calculated as $Q_1 + Q_2$.

To isolate the grafted polymer, the purified copolymer was treated for 24 h with a mixture of concentrated acetic acid and 60% sodium nitrite solution at a solid-to-liquid ratio of 1 : 10. Such treatment resulted in deamination and depolymerization of chitosan. The homopolymer was filtered off and heated with 1 N HCl at 100°C for 1 h; the resulting solution was dialyzed against water to negative reaction for chloride ions. The dialyzate was lyophilically dried. The isolated grafted polymer was polyvinyl alcohol (PVAl). Its molecular weight was calculated from the intrinsic viscosity [η] (dl g^{-1}) in water at 25°C by the formula [4]

$$[\eta] = 1.40 \times 10^{-2} M^{0.60}.$$

The number of grafted chains N per 100 monomeric units was calculated by the formula

$$N = g_1(166 + 40x) \times 100/M_i g_0,$$

where $(166 + 40x)$ is the molecular weight of the ACAN monomeric unit with the degree of deacetylation of 0.88 and degree of allyl substitution $x = \gamma_A/100$; M_i is the molecular weight of grafted PVA, which is calculated from the molecular weight of PVAl, determined as described above.

The thermomechanical properties of graft copolymers were studied by the penetration method at a heating rate of 1 deg min^{-1} and a load of 0.1 kg mm^{-2}.

The kinetics of graft polymerization of VA on ACAN was studied in relation to the content of unsaturated groups and concentrations of the monomer, initiator, and ACAN (Fig. 1). The kinetic curves of graft polymerization on ACAN with varied content of allyl groups are similar. Their shape shows that the grafting starts without induction period, occurs fast, and is complete in 15 min. Within this time, all the grafting parameters (degree and efficiency of grafting, monomer conversion) reach their maximum values,

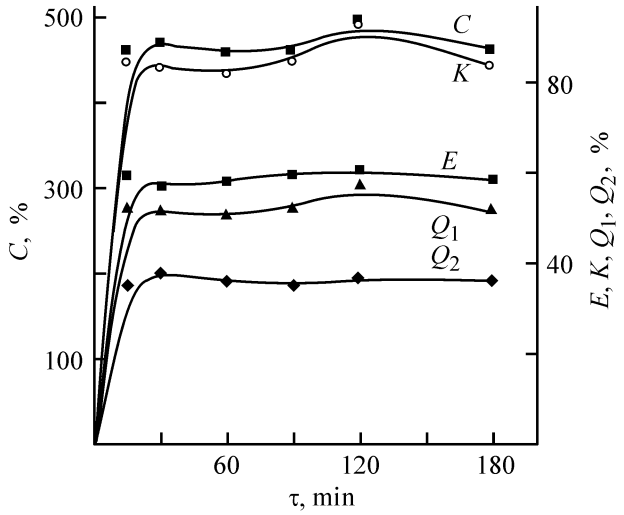

Fig. 1. Kinetic curves of graft polymerization of VA on $ACAN_{\gamma=13}$. [ACAN] = 6 mM; [VA] = 1 M; [APS] = 3 mM; 60°C. (C) Degree of grafting, (E) grafting efficiency, (K) monomer conversion, (Q_1) yield of the grafted polymer, (Q_2) yield of the homopolymer, and (τ) time.

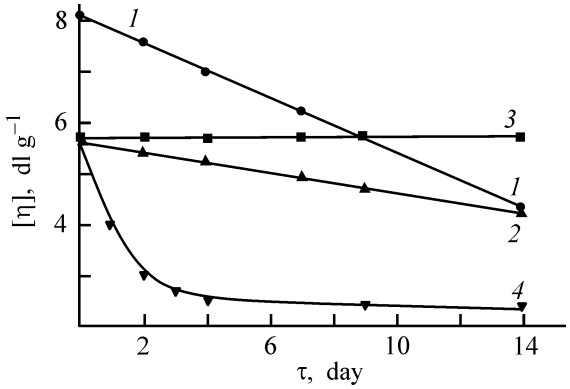

Fig. 2. Variation with time of the intrinsic viscosity [η] of (*1*) chitosan, (*2*) $ACAN_{\gamma=13}$, (*3*) $ACAN_{\gamma=30}$, and (*4*) $ACAN_{\gamma=30}$ in the presence of 3 mM APS. 20°C.

and the secondary processes starting subsequently only weakly affect these parameters.

With ACAN, the absolute degree of grafting increases by a factor of 2, compared to graft polymerization of VA on chitosan, and the grafting efficiency, by a factor of 1.5 even at $\gamma_A = 13$ (480 against 240% and 60 against 40%, respectively), which suggests that the allyl groups are involved in initiation of the graft polymerization. This has been shown previously in studies of graft polymerization of vinyl monomers on allyl hydroxyethyl cellulose (AHOEC) [2]. Initiation can occur via formation of peroxy groups at the allyl α-C atom, with their subsequent decomposition, and(or) via proton abstraction from the allyl α-CH_2 group by the radical ion generated by decomposition of APS.

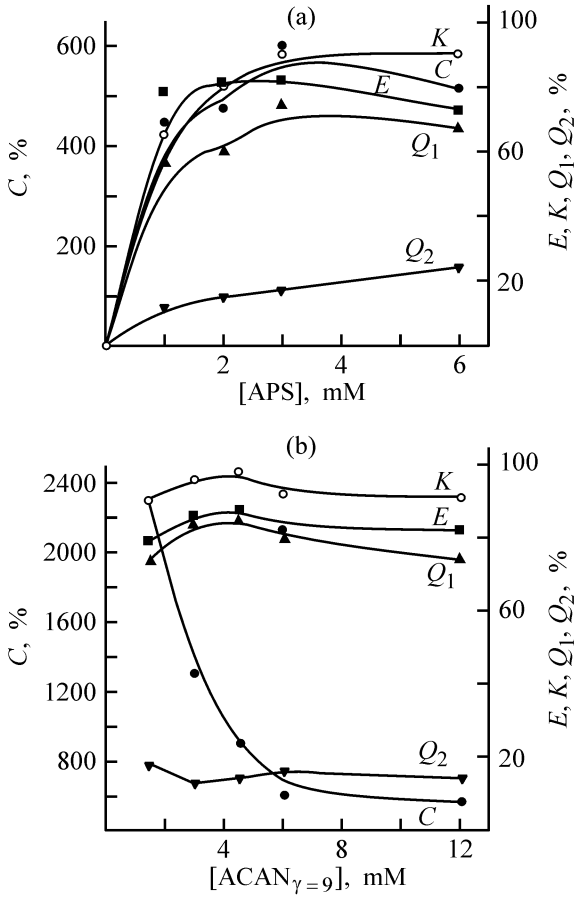

Fig. 3. Degree C and efficiency E of grafting, monomer conversion K, and yields of the grafted polymer Q_1 and homopolymer Q_2 vs. the concentrations of (a) APS and (b) $ACAN_{\gamma=9}$. 60°C; 15 min; [VA] = 1.0 M; (a) $[ACAN_{\gamma=9}]$ = 6 mM; (b) [APS] = 1.0 mM.

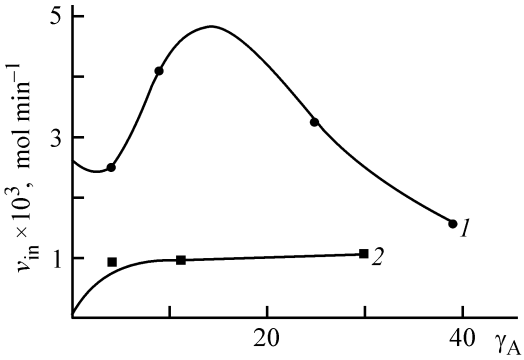

Fig. 4. Initial rate of graft polymerization v_{in} of VA on (*1*) ACAN and (*2*) AHOEC vs. the allyl group content γ_A.

The occurrence of radical oxidation processes in ACAN solutions is indicated by measurements of the intrinsic viscosity of ACAN with various degrees of ally substitution in the course of storage of 3% ACAN solutions in 0.33 M acetic acid at 20°C. The curves of [η] against time (Fig. 2) show that chitosan undergoes hydrolytic and oxidative degradation in the solution, with a decrease in [η] (curve *1*). In the $ACAN_{\gamma=13}$ solution, the degradation is slower (curve *2*), and in the $ACAN_{\gamma=30}$ solution, [η] does not change noticeably with time (curve *3*). Since all the three polymers contain in the backbone glucoside bonds unstable in acid solutions, the constancy of [η] in the $ACAN_{\gamma=30}$ solution suggests a dynamic equilibrium between the degradation and cross-linking of $ACAN_{\gamma=30}$ macromolecules, which occurs as a result of recombination of radicals that arise at the allyl α-CH_2 group. Addition of 3 mM APS to the solution drastically accelerates the degradation (curve *4*) owing to additional generation of peroxy radicals by the reaction of the initiator with the allyl group. In the presence of VA, the additional peroxy radicals act as propagation points of the grafted chain. The combination of the two initiation mechanisms results in that the initial grafting rate grows with increasing γ_A.

The degree and efficiency of grafting considerably grow with the initiator concentration increasing up to [APS] = 3 mM (Fig. 3a). At the same time, an increase in the ACAN concentration results in a sharp decrease in the degree of grafting, without affecting the other parameters (Fig. 3b).

Comparison of the initial rate v_{in} of VA grafting on AHOEC and ACAN (Fig. 4) as a function of γ_A shows that, firstly, v_{in} of grafting on ACAN is higher than that on AHOEC at any γ_A, owing to the activating effect of the chitosan amino groups on the VA double bond. Secondly, the curves differ in shape: With AHOEC, v_{in} tends to weakly grow, whereas with ACAN it passes through a maximum. Inhibition of the reaction on ACAN at $\gamma_A > 15$ may be due to the occurrence of cross-linking within microemulsion particles. Apparently, the presence of a large amount of propagation points results in the occurrence of cross-linking from the very beginning of the reaction, which prevents diffusion of the monomer inside the microemulsion drops. This assumption is confirmed by the fact that the states of the reaction system differ, depending on γ_A, even 15 min after the reaction onset. The copolymerizate is an emulsion at low γ_A (4 or 9), a gel at γ_A = 23 and a two-phase system at γ_A = 38. A similar effect is exerted by an increase in the concentration of allyl groups because of the growing ACAN content, even at small γ_A.

Allylchitosan is a diphilic polymer containing both hydrophilic (hydroxy and amino) and hydrophobic (allyl) groups. At the beginning of the reaction, when VA is dispersed in ACAN solution, a microemulsion is formed. This microemulsion is stabilized by hy-

drophobic interaction of VA molecules with ACAN allyl groups; the ACAN hydrophilic groups are oriented toward the aqueous medium. On adding an initiator, grafting and homopolymerization of VA start within such a microparticle When the amount of propagation points is relatively small (γ_A 4 or 9), the grafted PVA chains do not interact with one another, at least in the first 15 min of the reaction, and the reaction system remains an emulsion. As the content of grafted chains increases (γ_A 13 and 25), the probability of interaction of the propagating chains grows, and a gel is formed in 15 min; at $\gamma_A = 38$, a thick network of cross-linked grafted PVA is formed. At high degrees of grafting, the microemulsion particles get inverted, and the system undergoes segregation. The longer the grafting process, the higher the degree of cross-linking. Therefore, the monomer conversion varies only weakly at reaction times longer than 30 min, and the degree and efficiency of grafting slightly grow because of the incorporation of the homopolymer into the grafted chains by the recombination mechanism.

We were able to determine the number of grafted PVA chains, *N*, only in the range of γ_A from 0 to 9; we revealed a correlation of *N* with γ_A (Table 1). The molecular weight of grafted PVA is independent of the initiator and ACAN concentrations but is determined by the monomer concentration. At high γ_A, the molecular weight could not be determined because of the strong cross-linking.

To calculate the reaction orders with respect to each reactant from the kinetic curves, we determined the initial rates at three concentrations of each reactant (at constant concentrations of the two other reactants) and plotted the concentration dependences of the rates in the logarithmic coordinates. The reaction orders were determined as the slopes of the straight lines obtained. The results are listed in Table 2. We obtained the following equation for the rate of VA grafting to ACAN:

$$v_{in} \sim [VA]^{1.70}[APS]^{0.05}[ACAN]^{-0.10}.$$

Comparison with the corresponding equation for VA grafting to chitosan (CAN) [1],

$$v_{in} \sim [VA]^{1.08}[APS]^{0.04}[CAN]^{-0.02}$$

shows that, with ACAN, the order with respect to the monomer is appreciably higher, which is quite consistent with the presumed participation of ACAN allyl groups in grafting initiation.

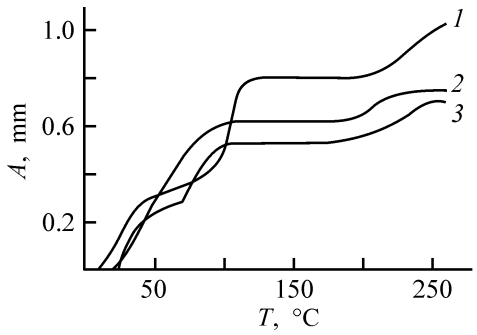

Fig. 5. Thermomechanical curves of graft copolymers: (*A*) strain and (*T*) temperature. (*1*) PVA–$ACAN_{\gamma=9}$ and (*2*, *3*) PVA–$ACAN_{\gamma=30}$. Degree of grafting, %: (*1*) 570 and (*2*, *3*) 450. Grafting time, min: (*1*, *3*) 180 and (*2*) 15.

The presence of cross-linked structures in the copolymers prepared on highly substituted ACAN samples is confirmed by the thermomechanical curves (Fig. 5). Two clearly pronounced thermal transitions are seen: The first one, at about 20°C, corresponds to melting of the grafted PVA chains, and the second, at about 210°C, to softening of the copolymer. The height and length of the plateau in the thermomechanical curves furnish information about the degree of copolymer cross-linking. The copolymer prepared on $ACAN_{\gamma=9}$ shows higher strain than those prepared on $ACAN_{\gamma=30}$; the strain is the lower, the longer the grafting. Hence, the density of cross-linking increases with γ_A and with the grafting time.

Thus, ACAN controls the structure of the graft copolymer: We obtained comb-shaped copolymers at low values of γ_A (4, 9), thinly cross-linked structures at medium γ_A (23), and three-dimensional thickly cross-linked networks at higher γ_A.

CONCLUSIONS

(1) A kinetic study of the graft polymerization of vinyl acetate on allyl chitosan showed that the content of allyl groups in the chitosan samples affects the initial reaction rate, number of grafted polyvinyl acetate chains, and structure of the graft copolymer.

(2) The kinetic orders of graft polymerization with respect to the monomer, initiator, and allyl chitosan were determined. The reaction orders with respect to the initiator and allyl chitosan are zero, and that with respect to the monomer is close to 2.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Simulation of the Kinetics of Plasticizer Extraction with Ethanol

A. V. Dedov

Mosiskozh Open Joint-Stock Company, Moscow, Russia

Received August 12, 2003

Abstract—The main approaches to simulation of the migration kinetics of ingredients from polymers were considered. The mathematical models used for predicting the kinetics of diffusion-controlled migration processes were analyzed.

Extraction of plasticizer from polyvinyl chloride (PVC) deteriorates the polymer characteristics and also has an adverse environmental impact. A decrease in the plasticizer content in PVC makes higher its glass transition point and impairs the consumer properties of articles thereof. A number of plasticizers are toxic, which limits their permissible content in liquids. Reliable prediction of the kinetics of extraction of plasticizers from PVC often allows estimation of the service life of a polymeric article and control over the content of ingredients in the environment.

An analysis of the models used for predicting the kinetics of migration of ingredients from polymers revealed two major approaches to development of such models. One approach consists in processing of the experimental results and derivation of empirical equations [1–5]. The other approach utilizes the mathematical techniques developed to describe processes similar to migration of ingredients from polymers, such as heat loss from solids [6] and diffusion of low-molecular-weight substances in polymers [7].

The validity of empirical models is determined by the large body of experimental data. However, their use is usually limited to specific experimental conditions. This approach requires that the dependences of the coefficients in empirical equations on characteristics of plasticizers should be established [3, 4]. A knowledge of the temperature dependences of the coefficients makes empirical equations suitable for conditions differing from those in accelerated tests of PVC [3].

Equations constituting mathematical models use a parameter characterizing the transfer of plasticizers from the bulk to the surface or escape of an ingredient from the surface of the material to the environment. The kinetics of transfer of a plasticizer in a polymer is governed by the diffusion rate, and the parameter characterizing the escape of the plasticizer from the polymer surface depends on the state of aggregation of the environment. For PVC brought in contact with air, the volatility of the plasticizer serves as such parameter [6]. For PVC brought in contact with liquids or solids capable of absorbing the escaped plasticizer, the coefficient of diffusion of the ingredient in the medium is suitable as such parameter. This approach to simulation of the migration kinetics requires determining the limiting stage of the process, for which purpose there are still no fully adequate calculational procedures [8]. A multitude of models is used now for predicting the migration kinetics of ingredients introduced for various purposes, so that a model suitable for the given specific service conditions of a polymeric article and specific nature of an ingredient.

The aim of this study was to simulate the kinetics of extraction of dioctyl phthalate (DOP) and dibutyl phthalate (DBP) from PVC with ethanol.

The validity of mathematical models was assessed by comparing their predictions with the experimental results reported in [9–12]. These studies were concerned with extraction of DOP and DBP with ethanol at different temperatures and different initial contents of the plasticizer in PVC. The extraction kinetics were shown to depend on the rate of diffusion of an ingredient in PVC, which eliminates the need to determine the limiting stage of the process. Given below are the equations constituting the mathematical models used for predicting the migration kinetics of ingredients introduced for various purposes in the case of a diffusion-controlled process:

$$\frac{M_\tau}{M_0} = 2.26\sqrt{\frac{D\tau}{\delta^2}}, \quad (1)$$

1070-4272/03/7612-1983 $25.00 © 2003 MAIK "Nauka/Interperiodica"

$$\frac{M_\tau}{M_0} = 1 - \frac{8}{\pi}\exp\left(-\frac{4\pi^2 D\tau}{\delta^2}\right), \quad (2)$$

$$\tau_i = \alpha_i \frac{l^2}{D}, \quad (3)$$

$$\frac{M_\tau}{M_0} = 4\left(\frac{D\tau}{\pi}\right)^{0.5}\frac{1}{\delta}. \quad (4)$$

Here, M_τ is the amount of an ingredient, which migrates out of the polymer within a time τ; M_0, the initial content of the ingredient in the polymer; D, the coefficient of diffusion of the ingredient in the polymer; τ_i, the time of migration of ith portion of the ingredient initially contained in the polymer; a_i, a constant coefficient independent of the nature of the ingredient; δ, the thickness of a polymeric article; and l, the parameter relating the conditions of contact between the polymer and the environment to the thickness of the material ($2l = \delta$ and $l = \delta$ in the cases of one- and two-sided contact, respectively).

We give unified designations to the variables in Eqs. (1)–(4), which may differ from those used in the original papers.

Equations (1) and (2) were used for predicting the migration kinetics of the plasticizer for plasticized PVC brought in contact with unplasticized PVC [13] and air [14]. Equation (3) served for predicting the migration kinetics of plasticizers [15, 16] and stabilizers [17–19], and Eq. (4), for describing the kinetics of extraction of stabilizers from polyolefins [7].

It can be seen that it is difficult to analyze Eqs. (1)–(4) in such a form. It is more convenient to have all the equations in the form (3) and use for this purpose the coefficient a_i, which is directly proportional to the time of migration of a certain portion of the plasticizer. The parameter $1/a_i$ can be used for evaluating the migration rate of a certain portion of the plasticizer for a polymer contacting with various media.

Equations (1), (2), and (4), which include the film thickness as a variable, are intended for predicting the kinetics of migration of ingredients in the case of a two-sided contact of the polymer with the environment. In Eq. (3), the type of contact of the polymer with the environment is expressed via parameter l, and after replacing it with δ in accordance with $2l = \delta$, Eq. (3) takes the form

$$\tau_i = \frac{a_i \delta^2}{4D}. \quad (5)$$

The parameters a_i in Eqs. (3) and (5) are governed by the preset M_τ/M_0 ratio, which does not enter into them in the explicit form. In this study, we do not consider the method for calculation of the coefficient a_i; it was described in detail in [6]. For Eqs. (1), (2), and (4), the coefficients a_i are equal to constants appearing in the corresponding equations at preset M_τ/M_0 ratios. The coefficients a_i calculated for Eqs. (1), (2), (4), and (5) are listed in Table 1. Notably, in the case of extraction of a plasticizer with ethanol at one-sided

* Q is the initial content of the plasticizer in PVC, wt parts per 100 wt parts of the polymer.

contact between the liquid and the polymer, the coefficient a_i increases fourfold, compared to the two-sided contact.

In this study, we do not analyze models predicting the kinetics of extraction of plasticizers from PVC with fuels [11, 12] and alcohols [20]. A drawback of these models is that their equations include an additional variable, the equilibrium content of ingredient in the liquid, which depends on the chemical nature and temperature of the liquid [9–12, 20].

The models analyzed in this study were developed under certain assumptions, the most common of which are the constancy of the diffusion coefficient throughout the migration process and immediate and permanent escape of the evolved ingredient from the polymer surface into the environment. However, in extraction of the plasticizer from PVC, the diffusion coefficient D may vary in a certain stage of the process. This is due to glass transition in the polymer [11, 12] or in its surface layer [21] after migration of a certain portion of the plasticizer. When the polymer is in contact with air, these amounts of the plasticizer can be easily calculated [1]; extraction of ingredient may involve a counterflow of the liquid into the polymer, and this may exert varied influence on the glass transition of the material.

As to immediate escape of an ingredient from the polymer surface, this is of less importance for the plasticizer extraction kinetics. This follows from [10, 11], where it was shown that the rates of extraction of the plasticizer with alcohols at vigorous stirring and in a stagnant liquid rapidly approach each other. Along with the aforesaid, the accuracy of prediction of the plasticizer extraction kinetics depends on the PVC brand, composition of the material, and the conditions of manufacturing articles thereof [9].

The diversity of models hinders analysis of their validity by the previously applied method of comparison of the experimental and calculated τ_i values [15–19]. In this study, we solved the inverse problem, namely, calculated the coefficients a_i (Table 1) from the experimental data on the extraction kinetics and compared them with those calculated by Eqs. (1), (2), (4), and (5). In our calculations, we used the experimental data; the τ_i parameters were obtained from the kinetic dependences characteristic of extraction of plasticizers. We calculated the diffusion coefficient of the plasticizer in PVC for the two-sided contact of the polymer with alcohol by the equation [22]

$$D = 0.049\frac{\delta^2}{\tau_{0.5}}, \quad (6)$$

Here, $\tau_{0.5}$ is the time corresponding to extraction of 50% of the initial amount of the plastisizer contained in the polymer, or to $M_\tau/M_0 = 0.5$.

Comparison of the parameters a_i calculated by Eqs. (1), (2), and (4) shows how the plasticizer migration kinetics varies with the state of aggregation of the environment (Table 1). Under identical conditions, the plasticizer migration rate is the lowest when PVC is in contact with air [the coefficient a_i from Eq. (2) is greater than those from Eqs. (1), (2) and (4)]. The revealed dependence of the plasticizer migration kinetics on the state of aggregation of the environment, namely, the greater rate of the process in the case of contact of PVC with liquids and solids, compared to its contact with air, is supported by the experimental data [1].

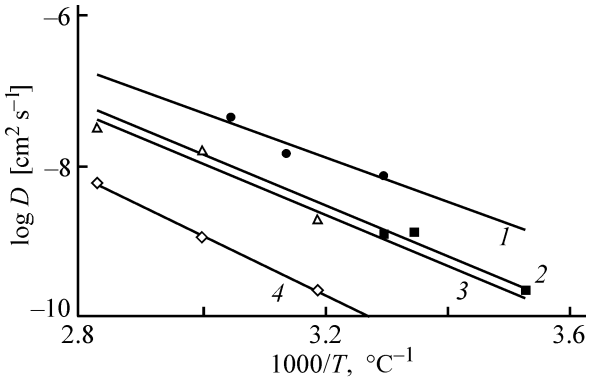
At the same time, the use of Eq. (5) for predicting the plasticizer migration kinetics implies its independence from the state of aggregation of the environment. It should be noted that Eq. (5) was intended specifically for predicting the kinetics of the stabilizer migration from polyolefins. Testing the adequacy of Eq. (5) in predicting the kinetics of the plasticizer migration from PVC suggests that the value of the coefficient a_i is to be corrected (raised) [15].

The dependence of the calculated coefficient a_i on the state of aggregation of the environment is the most pronounced in the initial stage of migration, at $M_\tau/M_0 \le 0.3$. With increasing time of migration, the calculated a_i values get closer, except that calculated using Eq. (5). However, at $M_\tau/M_0 = 0.5$, the coefficients a_i calculated by different equations differ much less significantly.

For $M_\tau/M_0 = 0.5$, the parameters a_i calculated using different equations (Table 1) are equal or close to 0.049 in Eq. (4). At the same time, Table 1 shows that, at $M_\tau/M_0 \ne 0.5$, D varies with the equation chosen for its calculation.

The values of a_i, derived from experimental data, also differ significantly in the initial stage of extraction of the plasticizer and get close at $M_\tau/M_0 \ge 0.3$ (Table 1). The divergence of the coefficients a_i in the initial stage of extraction can be attributed to the experimental inaccuracies in monitoring the migration of relatively small amounts of a plasticizer and in processing the plots constructed on a small scale.

Processing the experimental values of a_i by the Table-Curve program yielded a mathematical expression, which can be substituted into Eq. (5), making it suitable for predicting the kinetics of DOP and DBP extraction with ethanol at various stages of the process.



Temperature dependence of the diffusion coefficient D of (*1, 3*) DOP and (*2, 4*) DBP for (*1, 2*) extraction and (*3, 4*) evaporation.

$$\tau_i = 0.19\left(\frac{M_\tau}{M_0}\right)^2 \frac{\delta^2}{D}, \quad (7)$$

Here, M_τ/M_0 varies from 0 to 1.

The correlation coefficient for Eq. (7) was estimated at 0.92, which is sufficient for tentative calculation of the kinetics of DOP and DBP extraction with ethanol.

The established temperature dependences of the coefficient of the plasticizer diffusion in PVC (see figure) increase the potential of Eq.(7). The figure also presents the temperature dependences of the plasticizer diffusion coefficient in the case of contact of the polymer with air (the corresponding D values are marked with open rhombs and squares). These data were obtained for samples that initially contained 65 wt. parts of ingredient per 100 wt parts of PVC and were subjected to a high vacuum [23]. Table 2 lists the characteristics of the DOP and DBP diffusion under various conditions of use of a polymeric article, which were obtained using the Arrhenius equation. The figure and Table 2 suggest a higher rate of the plasticizer diffusion in extraction from PVC, compared to the case of the polymer contacting air.

Table 2. Characterization of diffusion of plasticizers in PVC for various conditions of use of the polymeric article

Plasticizer	Content in PVC, wt. parts	Extraction		Evaporation*	
		E_a, kJ mol^{-1}	$\log D_0$	E_a, kJ mol^{-1}	$\log D_0$
DOP	60	55.9	1.41	77.3	3.0
DBP	50	55.9	0.74	73.5	3.2

* Initial content of plasticizer 65 wt. parts per 100 wt. parts of PVC.

To conclude, the kinetics of DOP and DBP extraction from PVC with ethanol is most adequately simulated by Eqs. (1) and (4). The precision of simulating the kinetics of migration of an ingredient in the case of a polymer brought in contact with various media is strongly dependent on the conditions under which the coefficient of diffusion of the ingredient in the polymer is determined.

CONCLUSION

Models that most adequately predict the kinetics of extraction of a plasticizer from polyvinyl chloride were identified. The specific features of the plasticizer diffusion in the case of polymer brought in contact with air or ethanol were elucidated.

Abstract—The rheological properties of ethylene–vinyl acetate copolymers of various compositions in blends with pectins of various origins (pectins recovered from apple pulp, watermelon peel, and citrus fruits) were studied. The degrees of swelling of blend films in water were measured.

The interest in studying properties of blends of natural polymers with chemical derivatives of cellulose and with synthetic polymers is dictated by the demand for new compounds suitable for development of biodegradable materials. Such materials become more and more needed in production of polymeric items with short service periods (packaging films and items, package for cosmetics and household chemical products, films for agriculture) [1–3]. The most frequently used natural polymer is starch, a renewable natural polysaccharide consisting of 1,4-α-*D*-glucopyranose units.

Pectins, like starch, are renewable natural raw materials; they are recovered from fruits and vegetables [4, 5]. Pectins are polymers of 1,4-α-*D*-galacturonic acid the contain partially esterified carboxy groups. Blends of pectins with other polymers have been only examined in few studies. In particular, pectin–starch blends have been shown to be similar to synthetic polymers in mechanical properties [6]. The rheological properties of 5% aqueous solutions of citrus pectin isolated from lemon seeds and peel, and also of blends of this pectin with polyvinyl alcohol and polyvinylpyrrolidone were studied in [7]. It was noted that these systems showed non-Newtonian flow behavior; addition of a vinyl polymer to a pectin solution caused its viscosity to increase.

In development of materials for biodegradable packaging films and other consumable items, blends containing hydrophobic polymers are of particular interest, since one of the main functions of packaging is protection from external moisture. In particular, ethylene–vinyl acetate copolymers (EVACs) whose macromolecules contain both hydrophobic methylene groups and hydrophilic vinyl acetate units are rather widely used in production of protective films for foodstuffs. However, EVACs virtually do not degrade in the environment. Addition of natural polysaccharides, pectins, to these copolymers imparts to them biodegradability. The presence of vinyl acetate units (15 to 28–30%) in EVACs should favor formation of stable blends with polar hydrophilic pectin molecules.

In this study, we examined the rheological properties of two EVAC samples containing pectins of various origins as biodegradable additives; we also analyzed how these blends interact with water. Data on the rheological properties of polymer blends allow assessment of the possibility and conditions of preparing from these blends consumable polymeric articles (primarily packaging films) that would rapidly degrade in the nature. In development of biodegradable materials, it is important to study not only the rheological properties of materials, but also their interaction with water, since biodegradation is more intensive in the presence of moisture. Therefore, for a series of EVAC–pectin blends, we studied swelling of films in water, since the equilibrium swelling and swelling rate furnish information on the interaction of blends with water, necessary for the development of materials degrading under the action of environmental factors.

EXPERIMENTAL

Experiments were performed with two EVAC samples containing 15 (EVAC1) and 25% (EVAC2) vinyl acetate units. The content of these units was deter-

Characteristics of polymers studied

Polymer	Content of vinyl acetate groups in EVAC and ester groups in pectins, %	T_m of EVAC and T_{dec} of pectins, °C	[η], dl g^{-1}, at 25°C	MW	Degree of crystallinity, %
EVAC1	15	92.6	0.72 in chloroform	–	27
EVAC2	24	77.0	0.68 in chloroform	–	16
Watermelon pectin	85	175.0	2.36 in water	12.6×10^5	Fully amorphous
Citrus pectin	75	160.0	1.14 in water	5.0×10^5	15
Apple pectin	75	170.0	1.56 in water	7.3×10^5	20

mined by analysis of the products of base hydrolysis of the copolymers in a mixed solvent (hexanol–xylene) [8]. As measure of molecular weights (MWs) of EVACs we used the intrinsic viscosities [η] of the copolymer solutions in chloroform, since calculation by the Mark–Kuhn–Houwink equation is in this case impossible. We used three pectin samples recovered from apple pulp, watermelon peel, and citrus fruits. The intrinsic viscosities of pectins were determined from the viscosities of their aqueous solutions. The resulting values of [η] and molecular weights of the polymers are listed in the table. The composition of pectins was studied by IR spectroscopy. The spectra were recorded on a Perkin–Elmer spectrometer in the 1000–3900 cm^{-1} range using a KBr prism. The spectra contained bands assignable to carbonyl (1750 cm^{-1}) and methoxy (1450 cm^{-1}) groups characteristic of pectins, and also broad bands of hydroxy groups at 3400–3450 cm^{-1}, typical of all polysaccharides [9–11]. All the pectins studied had about the same content of ester groups (see table).

The structure of the polymers was characterized by X-ray diffraction. Measurements were made with a DRON-2.0 diffractometer in the 2θ range 15°–50° with Cu_{K_α} radiation (λ 0.1542 nm). The diffraction patterns of pectins were measured with powdered samples. EVACs were studied as thin (~50 μm) films prepared by heating under a pressure of 15 MPa. The sample structure was characterized by the degree of crystallinity (see table), which was determined as the ratio of the area under the diffraction peak to the total area under the X-ray scattering curve in the angle range under consideration.

To find the conditions for measuring the viscosity of pectin–EVAC blends, we determined by DTA the melting points of the copolymer samples. The thermal behavior of pectins was characterized by thermogravimetric analysis with a Q-1500D derivatograph (MOM, Hungary) in the range 20–240°C. Pectins, like other polysaccharides, do not pass reversibly to the viscous-flow state, since their melting points exceed the decomposition points [12]. The temperatures of the onset of intense degradation of natural pectins are listed in the table.

Samples for rheological studies were prepared by blending a weighed portion of pectin with pulverized EVAC. Blends containing 5–20 wt % pectin were heated for 2 h at 50°C and then compacted at 140°C and a pressure of 15 MPa. Samples had a cylindrical shape; the diameter of their base corresponded to the diameter of the working channel of the viscometer (0.8 cm). Samples of blends were semitransparent, with embedded pectin particles visible with a microscope, i.e., the blends were heterogeneous. The viscosity of EVAC–pectin blends was measured with an MV-2 capillary microviscometer with the capillary length to radius ratio of 25 : 1. Under these conditions, the entrance effect could be disregarded in calculations [13]. The viscosity was measured at stresses of 500–3000 Pa, shear rates of 10^{-1}–10^1 s^{-1}, and temperature of 110°C, which exceeded the melting points of the EVAC samples used and was 50°C lower than the temperature at which the pectins started to degrade.

The interaction of polymer blends with water was evaluated by the extent of equilibrium swelling, which was determined gravimetrically with films prepared by compaction under the same conditions as for rheological tests. To accelerate the swelling, the measurements were performed at 50°C.

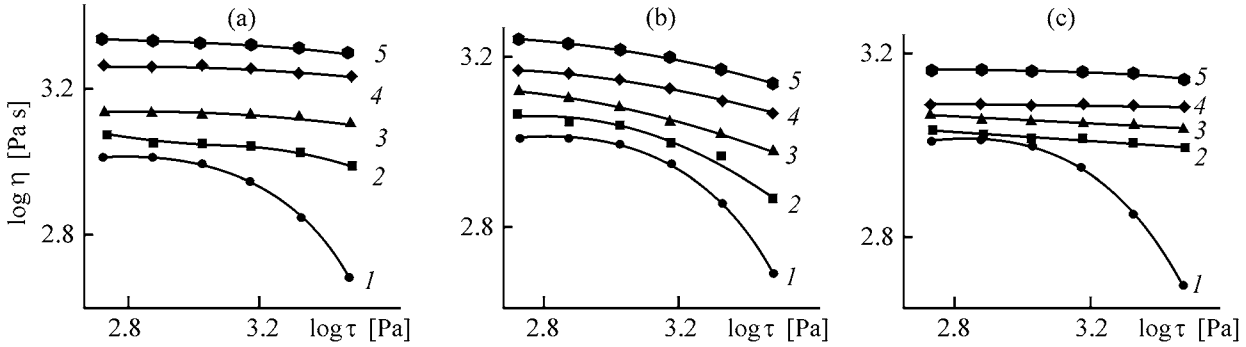

Fig. 1. Flow curves of EVAC2 blends with (a) watermelon, (b) citrus, and (c) apple pectins. (η) Effective viscosity and (τ) shear stress. Pectin content in blends, wt %: (*1*) 0, (*2*) 5, (*3*) 10, (*4*) 15, and (*5*) 20.

Figure 1 shows the flow curves of the blends of EVAC-2 with (a) watermelon, (b) apple, and (c) citrus pectins. The EVAC1 sample was studied only in a blend with watermelon pectin. The dependences obtained for this system are similar to those shown in Fig. 1. It is seen that all the blends behave as non-Newtonian fluids. The dependence of the viscosity on the shear stress was the most pronounced for pure EVAC. As the pectin content is increased, the blends become less flowable, their viscosity grows, and the slope of the curves relative to the abscissa decreases, i.e., the viscosity becomes less dependent on the shear stress. Such trends are known for polymeric systems filled with disperse fillers, in which introduction of a filler results in that, in the flow, the structure of the system is not disturbed by the stress [14].

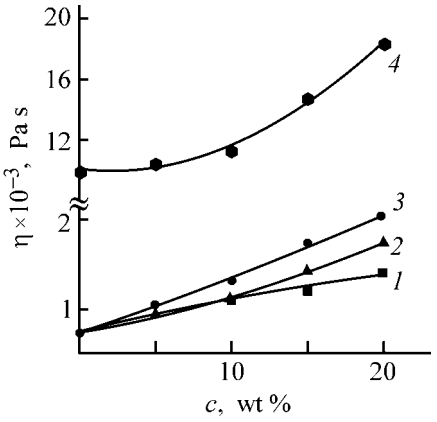

Fig. 2. Effective viscosity η of EVAC2 blends with (*1*) citrus, (*2*) apple, and (*3*) watermelon pectins and (*4*) EVAC-1 blend with watermelon pectin vs. the pectin concentration *c*. Shear stress 2100 Pa.

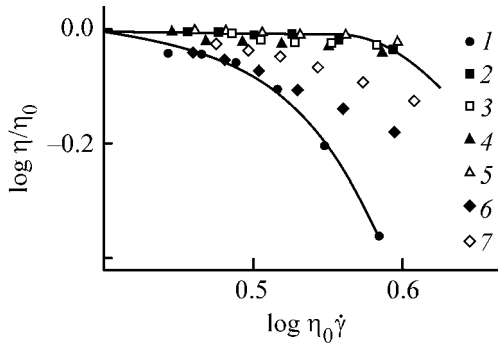

Fig. 3. Flow curves of EVAC2–pectin systems in reduced coordinates: (η/η_0) normalized effective viscosity and ($\eta_0\dot{\gamma}$) shear rate. (*1*) EVAC, (*2*, *3*) EVAC–watermelon pectin, (*4*, *5*) EVAC–citrus pectin, and (*6*, *7*) EVAC–apple pectin. EVAC : pectin ratio: (*2*, *4*, *6*) 90 : 10 and (*3*, *5*, *7*) 80 : 20.

Figure 2 shows the dependence of the effective viscosity of polymer blends on the pectin content. It is seen that, as the pectin concentration is increased, the viscosity of the blends with both EVAC1 and EVAC2 grows. Blends of EVAC2 with different pectins differ in the viscosity only slightly (Figs. 1, 2). The influence of the pectin origin can be revealed by comparing curves *1*–*3* in Fig. 2 and the data in the table. The viscosity of EVAC-2–pectin blends is the higher, the higher the molecular weight of the pectin. The degree of esterification of the natural polymer, similar for apple and citrus pectins (see table), apparently, does not have a decisive effect on the viscosity of blends with EVACs. Comparison of the effective viscosities of blends containing different copolymers (Fig. 2, curves *3*, *4*) with similar molecular weights shows that the viscosity is more sensitive to the content of vinyl acetate units in EVAC than to the pectin origin.

By extrapolating the viscosity coefficients obtained to zero shear stress, using the procedure described in [15], we calculated for the EVAC2–pectin systems the highest Newtonian viscosities η_0 and then, using the concept of invariance of rheological data [13, 15], plotted them in the normalized coordinates. The log–log plots of the normalized effective viscosity η/η_0 vs. shear rate $\dot{\gamma}\eta_0$ for blends of EVAC2 with three pectins are shown in Fig. 3. It is seen that the experimental data on the reduced effective viscosity for all

the three systems containing pectins of different origins form a relatively narrow zone of values at different shear stresses. The existence of such a dependence for normalized effective viscosity of the systems at hand suggests that the relaxation properties of the EVAC2 melt containing pectins of different origins should be described by a common functional dependence characterizing the similarity of the relaxation spectra of these systems [13, 15].

The rheological data show that addition of pectins recovered from various plants results mainly in increased viscosity and hindered flow. The absolute values of viscosity of the blends remain within the limits characteristic of the flow of melts of industrial thermosoftening plastics in the course of molding [16].

Addition of natural polymers to synthetic polymers is aimed to enhance the degradability of utilized polymeric items upon their disposal in soil. An important prerequisite for efficient degradation under the action of a complex of natural agents is the ability of a material to interact with soil moisture. Therefore, we evaluated the swellability of EVAC2–watermelon pectin blends in water. Figure 4 shows the kinetic curves of swelling in water at 50°C of films formed from EVAC2 and its blends. The kinetic curves are typical of systems with limited swelling; the amount of absorbed water grows in proportion to the pectin content. However, as seen from the slopes of the initial portions of the curves, the swelling rates and equilibration time are similar for all the compositions. This is due to the fact that, in the systems studied, the low-polar component, EVAC, prevails, and polar hydrophilic pectin plays the role of a filler enhancing the water-absorption power of the blend films. The dependence of the limiting degree of swelling on the pectin content in the films is shown in Fig. 5.

Thus, addition of pectins as fillers to EVAC results in formation of systems more capable of swelling in water than pure EVAC. This is important from the viewpoint of biodegradation of such systems under natural conditions (disposal of used items in soil).

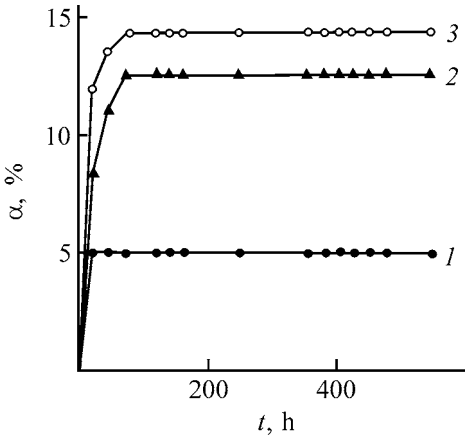

Fig. 4. Kinetic curves of swelling of EVAC2–watermelon pectin blends in water at 50°C. (α) Degree of swelling and (*t*) time. EVAC2 : pectin: (*1*) 100 : 0, (*2*) 90 : 10, and (*3*) 80 : 20.

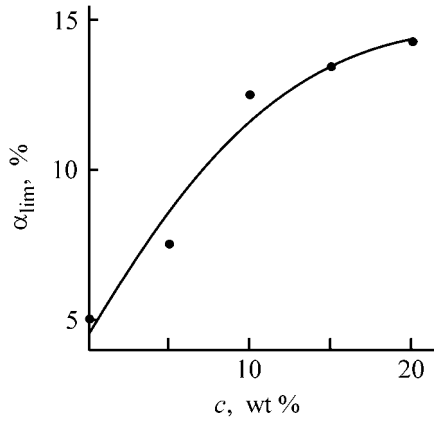

Fig. 5. Limiting degree of swelling α_{lim} of EVAC2–watermelon pectin blends in water at 50°C vs. the pectin concentration *c*.

CONCLUSIONS

(1) Natural polysaccharides, pectins, irrespective of their specific plant origin, when added to ethylene–vinyl acetate copolymers, increase their viscosity to an extent growing with the pectin concentration. The viscosity remains within the limits characteristic of processing of synthetic polymers. The pectin origin (apple pulp, watermelon peel, citrus fruits) affects the rheological properties of pectin blends with ethylene–vinyl acetate copolymers to a lesser extent than does variation of the content of acetate groups in the synthetic component. Pectins enhance the swellability of blends in water, which should positively affect their biodegradability under natural conditions.

(2) Among the systems studied, the optimal rheological characteristics in combination with sufficient water-absorption power are exhibited by blends of the copolymer containing 25% vinyl acetate groups with watermelon pectin. These blends can be used to prepare biodegradable polymeric films and other consumable materials.

Abstract—Treatment of flax cellulose with NaOH was studied.

Because of the limited resources of cotton cellulose, a growing attention has been paid in recent years to production of cellulose from unconventional annually renewable plant raw materials such as flax, jute, hemp, etc. Practical implementation of the corresponding processes requires knowledge of structural changes occurring in cellulose in the course of treatments and in conversion into cellulose ethers and esters.

The interaction of alkali metal hydroxides with regenerated cellulose has been studied quite thoroughly; much less understood are the structural changes in cellulose in cellulose-containing plant raw materials. Therefore, the aim of this study was to analyze structural transformations induced in flax cellulose by alkaline treatment.

EXPERIMENTAL

In the study, we examined intermediate flax fibers after mechanical separation from boon.

Natural flax fibers were beaten in a dry crushing mill with shock-pulse loading (loading velocity 40 m s^{-1}). By virtue of the ventilation effect, the flax is carried away with the air flow, accelerated by spreaders to 40–120 m s^{-1}, and knocked against beaters. In this stage, flax is broken into linen fiber and boon, which are then separated in a cyclone separator.

Fiber samples were treated with NaOH at various temperatures for 1 h at a liquor ratio of 1 : 10. The swelling of the fibers and sorption of water and alkali were determined as in [1]. A weighed portion of air-dry cellulose with a fixed moisture content, taken to with accuracy of 0.0002 g, was placed in a specially designed vessel for swelling runs, poured over with NaOH, and allowed to stand at a fixed temperature for 15 min. Then NaOH-treated cellulose was centrifuged for 10 min at 8000 rpm. It was demonstrated in preliminary experiments that the indicated temperature, swelling, and centrifugal drying conditions are sufficient for equilibration in the cellulose–NaOH–water system. Samples after centrifugation were weighed and analyzed for absorbed NaOH by titration with 0.1 N H_2SO_4 (samples were allowed to stand in distilled water for up to 3 h before titration). For each NaOH concentration, the result was obtained as an average of three replicate runs to within 10%.

Also, we studied structural changes induced in cellulose by alkaline treatment. Samples of NaOH-treated cellulose were washed to neutral reaction and dried to constant weight. Then the thus obtained samples were analyzed for α-cellulose [2], concomitant compounds (lignin [3] and hemicelluloses [2]), degree of polymerization DP [2], water retention [4] and water-absorbing capacity [5]. Structural transformations in cellulose were also monitored by recording IR spectra on an Avatar 360 FT-IR ESP spectrophotometer over the range 400–4000 cm^{-1} in KBr pellets (1 mg per 100 mg KBr).

Interaction of a cellulose-containing material with NaOH involves absorption of NaOH and water (swelling), formation of alkaline cellulose, and dissolution of low-molecular-weight fractions (hemicelluloses) and noncellulose components. Figure 1 shows characteristics of flax cellulose swollen in NaOH solutions with various concentration, including the swelling (swollen cellulose to absolutely dry cellulose weight ratio) and uptakes of NaOH and water (number of absorbed NaOH and H_2O molecules in centrifuged alkaline cellulose per cellulose unit).

The swelling of cellulose and cellulose-containing materials has been long studied. However, the swelling mechanism remains to be conclusively established. One thing is clear: alkaline cellulose is not formed by the reaction with an alkali without swelling, e.g., in an anhydrous alcohol.

The swellability of a cellulose-based material can be characterized by the weight or volume swelling [6], linear expansion of a fiber, etc. Uptake of an alkali and water by cellulose can be determined directly, as in this study, or indirectly [7]. The swellabilities determined by different methods sometimes differ considerably. However, the shapes of the dependences of the swelling and alkali and water uptake on the alkali concentration are independent of the determination procedure. The swelling by weight increases with increasing NaOH concentration, and the corresponding dependence curve shows a peak through a maximum at NaOH concentration of 2–3 M. Figure 1 shows that this behavior correlates with the water uptake. With increase in the NaOH concentration above 3 M, the content of water in the sample decreases (curve *3*), while that of NaOH continues to increase (curve *2*).

The position of the peak depends on the origin of cellulose (flax or wood) and treatment [6, 8]. It is difficult to conclude unambiguously what factors, the degree of purification of the initial material or crystallinity index (CI), are decisive. In our case, the swelling curve of untreated flax fibers (lignin content 16%; cellulose, 72%; hemicelluloses, 6%; DP 4700; and CI 0.6) virtually coincides with that of refined sulfate wood cellulose (lignin content <1%; cellulose, 95%; hemicelluloses, 3–4%; DP 1800; and CI 0.55) [1]. It may be suggested that the swelling curve and the position of the peak are largely determined by parameters of the alkaline solution rather than by structural characteristics of a cellulosic material.

The effect of the alkali concentration in solutions on the swelling of cellulose is usually accounted for by hydration of ions as the main factor [9]. According to the hydrated-ion model, an ion is bound in solution to a fixed number of solvent molecules to form discrete first, second, etc. coordination spheres [10]. The number of bound solvent molecules is determined by the sum of the coordination number (the most probable number of solvent molecules in the first coordination sphere of an ion) and the number of solvent molecules forming the second and more remote coordination spheres. The experimental hydration numbers obtained by different methods differ considerably. The coordination number of ions is a more definite quantitative parameter. The coordination numbers of Li^+, Na^+, and K^+ are 4, 6, and 8, respectively. However, the swellability of cellulose in the corresponding alkalis increases in the reverse order. According to [8], the swellability of cellulose in various alkalis is as follows (%): cotton cellulose: 800 in KOH, 1100 in NaOH, and 1200 in LiOH; and wood cellulose: 1300 in LiOH, 1220 in NaOH, and 850 in KOH. Therefore, the swelling is associated with total hydration of the ions rather than with that of their first hydration sphere.

Based on the X-ray diffraction and spectroscopic data, the authors of [11–13] found that the second hydration sphere around the Li^+ and Na^+ ions consists of 12 water molecules. By the effect on the structure of water, Li^+ and Na^+ are classified with positively hydrated ions (mean residence time of water molecules near an ion is longer than that in the bulk of water). The K^+ ion, demonstrating a weaker capability to form the second hydration sphere in solutions, [14] was classified with the negatively hydrated ions. On the basis of the available data, one may suggest that the hydration shells around the Li^+, Na^+ and K^+ ions include 16 (4 + 12), 18 (6 + 12) and 8 (8 + 0) water molecules, respectively. Accordingly, the alkali metal concentrations at which water in solutions is totally bound to form hydration shells of the ions are as follows (M): LiOH 3.2 (8.28%), NaOH 3.08 (10.99%), and KOH 6.5 (28.7%).

As seen, the hydration number and nature of hydration of the Li^+, Na^+, and K^+ ions are markedly different, which should be reflected in the curves of cellulose swelling and alkali and water uptake. According to [8], the alkali concentration of the maximum cellulose swelling in various alkalis is as follows (M): cotton cellulose: LiOH 4, NaOH 4.5, and KOH 5.8; and wood cellulose: LiOH 2.5, NaOH 2.5, and KOH 6.0. Therefore, the positions of the swelling maxima

are close to the alkali metal concentrations at which water is totally bound to form hydration shells of the ions.

Progressive binding of water with increasing alkali concentration should be accompanied by structural and energy changes in the hydrates. The experimental data suggest that this is a stepwise process. For example, according to the NMR relaxation data [15, 16], the initially octahedral first hydration sphere of Na^+ becomes tetrahedral with increasing NaOH concentration. A similar effect has been observed in X-ray diffraction study of 2–3 M aqueous NaOH and NaCl [13].

Thus, the peaks in the swelling and NaOH and water uptake curves, as well as the appearance of peaks of alkaline cellulose in the X-ray diffraction patterns, i.e., penetration of NaOH into the crystalline regions of the cellulose structure, correspond to an NaOH concentration at which the hydration shell around the Na^+ ion undergoes a structural rearrangement. The initially octahedral first coordination sphere transforms into that of the tetrahedral type, which, presumably, initiates transformation of the second hydration sphere, too.

The structural transformations occurring in the cellulose-containing plant raw material after removal of NaOH and drying was monitored by the optical density ratios in the IR spectra. Levdik *et al*. [17] have demonstrated, using the X-ray diffraction data, that the change in the D_{1375}/D_{1325} ratio in cellulose, observed after alkaline treatment, is associated with the transformation of the cellulose structure from cellulose I to cellulose II. Our results show (Fig. 2a) that the transformation starts at an NaOH concentration of 2.0 M and comes to the end at that of 3.0 M, which corresponds to the maximum swelling range of cellulose (Fig. 1).

Over the range 2–3 M, the degree of structural transformation is virtually a linear function of the NaOH concentration. The transformation into cellulose II occurs only when the initial system of hydrogen bonds in highly ordered regions of the cellulose structure breaks down. Otherwise, the native modification (cellulose I) is restored after removal of NaOH by washing with water. The absorption at 3000–3700 cm^{-1} in the IR spectra of cellulose characterizes the stretching vibrations of the H-bonded hydroxy groups, and the D_{3360}/D_{2920} ratio, the hydrogen bonding strength in cellulose [18]. It follows from the dependence of the D_{3360}/D_{2920} ratio on the NaOH concentration (Fig. 2b) that the strength is at a minimum at 2.0–2.5 M and starts to increase again above 3 M, reflecting the formation of a new system of hydrogen bonds (cellulose II).

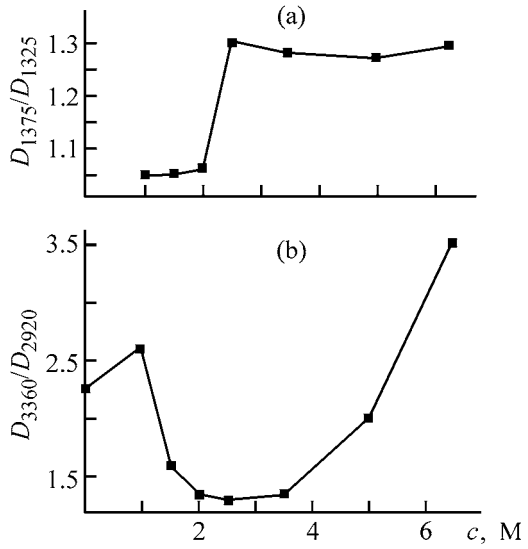

Fig. 2. (a) D_{1375}/D_{1325} as a measure of the cellulose I/cellulose II conversion and (b) D_{3360}/D_{2920} as a measure of the hydrogen bonding strength in flax cellulose vs. the NaOH concentration c.

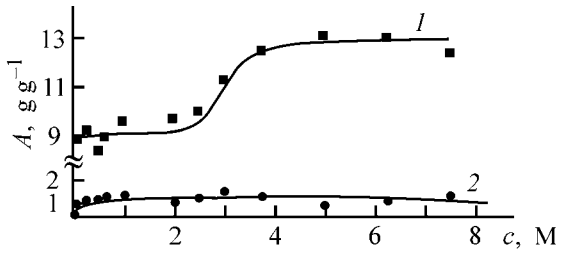

Fig. 3. (*1*) Water absorption and (*2*) retention of flax cellulose after alkaline treatment vs. the NaOH concentration c. (A) Water content.

X-ray diffraction studies of cellulose II [19] revealed that its structure with mixed conformation of the hydroxymethyl groups is characterized by a more developed system of hydrogen bonds as compared to cellulose I in which only one conformation exists. This feature leads to high stability of the system of hydrogen bonds, which, in turn, provides high resistance of cellulose II to dissolution in alkalis and Cadoxene [21]. However, the equilibrium water uptake is higher in cellulose II as compared to cellulose I. As seen from Fig. 3 (curve *1*), the water uptake abruptly changes at NaOH concentration corresponding to the structural transition. The water uptake determined by the procedure described in [4] is independent of the crystal modification (Fig. 3, curve *2*).

It is known that alkaline treatment of cellulose decreases its DP [9]. The dependence of DP of flax

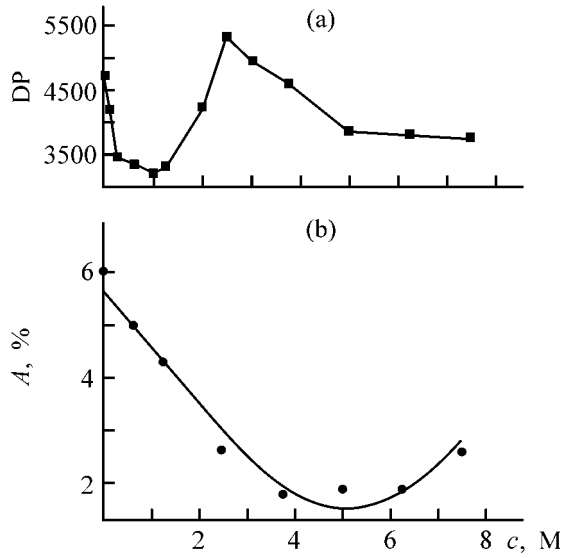

Fig. 4. (a) Degree of polymerization DP and (b) hemicellulose content *A* in flax cellulose samples after alkaline treatment vs. of the NaOH concentration *c*.

cellulose on the NaOH concentration has a maximum within the range 2–3 M (Fig. 4a).

In our opinion, such a dependence is a result of cellulose degradation (breakdown of the glucoside bonds) and transfer of low-molecular-weight fractions to the solution. The DP is at a maximum at NaOH concentrations corresponding to the strongest swelling of cellulose (Fig. 1). In this concentration range, i.e., under conditions favoring the strongest swelling, there is no steric hindrance to dissolution, and the removal of low-molecular-weight fractions and even hemicellulose with higher DP dominates. At NaOH concentrations below 1.5 M, the degree of swelling is still low, and above 4 M, it is no longer sufficiently high, which makes the transfer of hemicelluloses from cellulose fibers into the solution difficult because of the steric hindrance. This decreases the mean DP and increases the hemicellulose content in linen cellulose treated at high NaOH concentration (Fig. 4b).

Thus, the NaOH concentration range 2–3 M provides the minimum energy of hydrogen bonding in cellulose (Fig. 2b) and, as a result, the cellulose I/cellulose II transformation occurs (Fig. 2a) [22]. In this case, the maximum removal of lower-molecular-weight fractions of cellulose makes higher the mean DP in the insoluble fraction.

CONCLUSIONS

(1) The presence of concomitant compounds (lignin, hemicelluloses, etc.) in untreated linen cellulose has no significant effect on the structural transformation occurring in cellulose under the action of NaOH, contrary to, e.g., regenerated wood cellulose (sulfate pulping).

(2) The extrema in the dependences of the parameters characterizing structural changes in cellulose under the action of NaOH (swelling, transformation of cellulose I into cellulose II, hydrogen bonding strength, and degree of polymerization) are found within the NaOH concentration range 2–3 M. It is suggested that, over this range, structural rearrangement in the Na^+ hydration shell facilitates penetration of the alkali into the crystalline regions of the cellulose structure.

Abstract—Single-stage synthesis of carboxymethyl cellulose amides was studied. The influence exerted by introduction of amide groups with bulky alkyl radicals on the thermodynamic affinity of mixed cellulose ethers for a solvent and their solubility in water was evaluated.

There is growing interest in associated polymer systems based on environmentally friendly biodegradable natural polymers. Among derivatives of cellulose, its water-soluble ethers and esters are widely used in manufacture of detergents, oil production (drilling muds), and textile, paint-and-varnish, food, cosmetic, and fragrance industries. These are methyl cellulose (MC), hydroxypropyl cellulose (HPC), hydroxypropyl methyl cellulose (HPMC), methyl ethyl cellulose (MEC), and some others cellulose ethers and esters.

Among ionic derivatives of cellulose, carboxymethyl cellulose sodium salt (NaCMC) is most widely used. Carboxymethyl cellulose is a typical polyelectrolyte [1, 2]. Its application field can be extended by chemical modification.

Two major methods are known to be used for chemical modification of partially substituted cellulose ethers. The first is introduction of new functional groups at the free hydroxy groups in the anhydroglucose units, and the second, selective modification of the already present substituents.

It is of significant scientific and practical interest to synthesize CMC amides (CMCAs) and study the effect of newly introduced substituents on the thermodynamic affinity of the resulting products for water. CMCAs can be synthesized by the reaction of amines with CMC acid chloride [3–5] or CMC in the H form (HCMC) [6]. By varying the molecular weight and degree of substitution in CMC and also the nature of an amine and degree of amidation, new cellulose derivatives soluble in water and organic solvents can be synthesized. New mixed ethers of cellulose can behave as polyacids, weak polybases, nonionic materials, or polyampholytes.

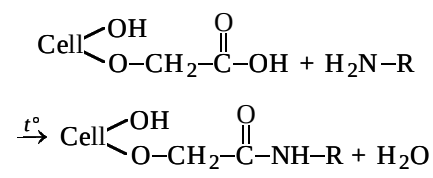
In this study, we examined the synthesis of CMCA by the reaction of amines with the carboxy groups of HCMC.

EXPERIMENTAL

As starting materials we used two NaCMC samples: CMC synthesized in laboratory (degree of polymerization DP_η 360; degree of substitution DS 0.32) and commercial NaCMC (degree of polymerization DP_η 630; degree of substitution DS 0.80). CMC with low DS was chosen with the aim to refine conditions for CMCA synthesis and to study the effect of introduction of small amounts of new functional groups on the thermodynamic affinity of the resulting derivatives for water. With the commercial NaCMC sample, we studied the effect of large amounts of new functional groups on the solubility of CMCA in water. In amidation, we used decylamine.

Samples of NaCMC may contain, as impurities, low-molecular-weight chlorides of the starting reactants used in carboxymethylation of cellulose. To remove foreign compounds, the sample was pretreated in a Soxhlet apparatus with hot 70% aqueous isopropanol for 4 h to negative reaction for chloride ($AgNO_3$) and then vacuum-dried at 50°C for 12 h. The DS_{Na} and DP_η were determined with thus pretreated samples.

CMCA was synthesized by reaction (1).



(1)

1070-4272/03/7612-1998 $25.00 © 2003 MAIK "Nauka/Interperiodica"

The reaction conditions were selected so as to obtain a set of water-soluble mixed cellulose ethers. NaCMC samples were initially converted into the H form by treatment with 20% HCl in 70% ethanol, washed to negative reaction for chloride ($AgNO_3$), and dried to constant weight in a vacuum oven at 60°C for 12 h. The degree of amidation (DA) in the resulting CMCA was estimated by Eq. (2).

$$DA = \frac{179y}{14 \times 100 - 139y}, \quad (2)$$

where y is the nitrogen content (wt %); 179, the molecular weight of the HCMC (DS 0.32) unit; and 139, the increase in the molecular weight of HCMC after introduction of one decylamine group.

Nitrogen was determined by the Kjeldahl method [7].

The solubility of CMCA was determined as follows. A weighed portion of CMCA required for preparation of 1% solution (corrected for the moisture content in CMCA) was stirred in distilled water at room temperature for 6 h. The solution was filtered through a Schott filter no. 2 (pore size 40–90 μm). The precipitate was washed on the filter with water and dried at 105°C to constant weight. The solubility was estimated by Eq. (3).

$$S = \left(1 - \frac{g_2 - g_3}{g_1}\right) \times 100, \quad (3)$$

where g_1, g_2, and g_3 are the weights (g) of the polymer taken for dissolution, filter with the precipitate, and filter, respectively.

The sorption of solvent vapor on CMCA at 293 K was measured at a solvent saturation pressure on a McBain quartz spring balance (sensitivity 1 mg mm^{-1}) with accuracy of about 0.01%.

Infrared spectra of mixed cellulose ethers were recorded on a Bruker FS-88 FTIR spectrometer in KBr pellets.

Table 1 shows the conditions of synthesis of CMCA from HCMC with DS 0.32. The reaction was carried out at 140°C. To decrease the polymer degradation rate, the synthesis was performed in xylene at a liquor ratio of 4 and 13. In carrying out the reaction, we varied the reaction time and amount of decylamine (recalculated to 1 mol of carboxy groups of the polymer). A fixed amount of decylamine was added to HCMC in xylene, and synthesis of CMCA was carried out at elevated temperature with stirring. After the reaction was complete, the samples were washed with 70% aqueous ethanol to remove the amine salt sorbed on the polymer. The washing was repeated five times with fresh portions of the ethanol solution. The completeness of removal of the unchanged amine was controlled by the IR absorption band of the amine salt according to the procedure described in [6].

Table 1. Synthesis of CMCA from CMC (DS 0.32)

Run no.	τ, h	Amount of amine, mol mol^{-1}	Liquor ratio	N, %	DA	Sorption of water vapor, g g^{-1}
1*	–	–	–	–	–	2.203
2	3	1 : 1	4	0.76	0.105	1.517
3	1	1 : 0.5	13	0.15	0.019	1.856
4	2	1 : 0.5	13	0.20	0.026	1.687
5	3	1 : 0.5	13	0.41	0.055	1.680
6	1	1 : 1	13	0.34	0.045	1.785
7	2	1 : 1	13	0.48	0.064	1.776
8	3	1 : 1	13	0.50	0.066	1.764

* Run with NaCMC (DS 0.32).

It should be pointed out that the NaCMC sample with DS 0.32 is highly soluble in water, which is caused by the uniform distribution of substituents [8]. Commercial NaCMC is readily soluble in water at DS 0.40 and higher. The synthesis of the amides is influenced by the liquor ratio and amount of decylamine taken for reaction (recalculated to 1 mol of carboxy groups of the polymer). As seen, DA grows with increasing amount of the amine in the reaction mixture, at the same reaction time (experiment nos. 2, 5, 8). With increasing liquor ratio, DA decreases as a result of a decrease in the amine concentration in the reaction mixture.

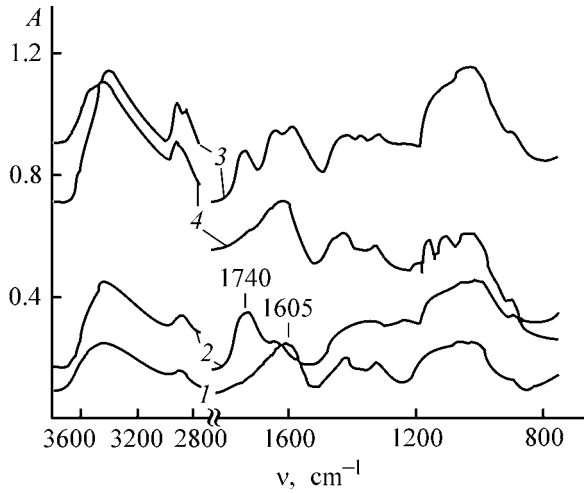


Fig. 1. FTIR spectra: (*1*) NaCMC, (*2*) HCMC, (*3*) amidated HCMC (DA 0.066), and (*4*) amidated NaCMC (DA 0.066). Initial CMC with DS 0.32. (*A*) Absorption and (ν) wave number; the same for Figs. 2 and 4.

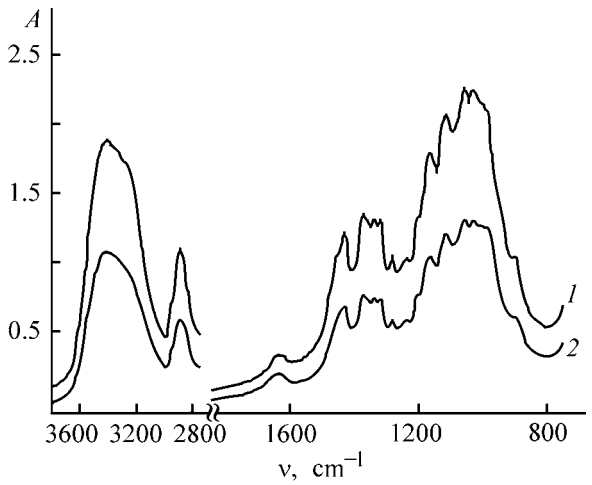

Fig. 2. FTIR spectra of cotton cellulose: (*1*) after amidation and (*2*) that after subsequent saponification. Reaction time 3 h.

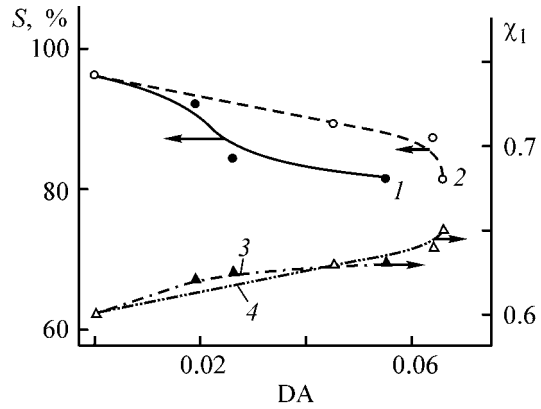

Fig. 3. (*1*, *2*) Solubility *S* of CMCA in water and (*3*, *4*) polymer–solvent interaction parameter χ_1 in the system CMCA–water vs. DA. CMCA samples were prepared from CMC with DS 0.32. Amount of decylamine added (mol mol^{-1} COOH groups of CMC): (*1*, *3*) 0.5 and (*2*, *4*) 1.0.

The chemical analysis data (determination of DA from the nitrogen content) were confirmed by the FTIR spectra of the initial NaCMC, HCMC, and the resulting amides, which contain ionized and free carboxy groups (Fig. 1).

The IR spectrum of regenerated cotton cellulose is characterized by broad adsorption band at 3000–3700 cm^{-1} (free and H-bonded OH groups of the polymer) and a symmetrical band at 2900 cm^{-1} (CH_2 and CH groups of cellulose) [9]. The IR spectrum of NaCMC (Fig. 1) shows a band at 1597–1605 cm^{-1}, assigned to antisymmetrical vibrations of the ionized carboxy groups COO– [6]. On passing to HCMC, an absorption band of COOH at 1740 cm^{-1} and a shoulder at 1647 cm^{-1} are observed [10]. The amide group has absorption bands at 1650 cm^{-1} (amide I) and 1515–1570 cm^{-1} (bending vibrations of the NH group) [11].

As the CO bands of the amide and COOH groups (1647 cm^{-1}) are close, we recorded IR spectra of CMCA, in which unchanged carboxy groups occur in the H form (spectrum no. *3*) and Na form (spectrum no. *4*). As seen, in the case of HCMC amide, characteristic bands of COOH are observed at 1740 cm^{-1}, and amide bands, at 1640–1650 and 1570 cm^{-1}. After conversion of free carboxy groups into the Na form, the CO band of the amide group appears as a shoulder. The band at 1570 cm^{-1} is not observed because of the small amount of the amide groups in CMCA, as demonstrated below. Furthermore, after substitution of even a small amount of the carboxy groups with amide groups, we observed splitting of the band at 2900 cm^{-1}, which should be assigned to additional CH_2 groups of the primary amine used in amidation. The absorption bands at 2875 and 2925 cm^{-1} are assigned to symmetrical and antisymmetrical vibrations of the CH_2 groups of the substituent, respectively [11].

It should be pointed out that, a shoulder at 3180 cm^{-1} is observed in the range of absorption of the OH groups (3000–3700 cm^{-1}), which suggests hydrogen bonding with the NH groups of the amide [11]. Thus, the IR spectra of the CMCA samples confirm the results of chemical analysis.

Under conditions similar to those used in synthesis of CMCA, amines may react with the hydroxy groups of the polymer (such a reaction is used in synthesis of cellulose carbamates [12]). To check the possibility of formation of an amide by the reaction of the amine with the hydroxy groups, cotton linter was treated with the reaction mixture under the same conditions as CMC was. The FTIR spectra of cotton cellulose after amidation and subsequent saponification are shown in Fig. 2. No absorption bands typical of the amide groups are observed in the spectra, which suggests that the amine reacts with the carboxy groups of the polymer essentially by reaction (1).

Since we used decylamine as an amidating agent, it may be expected that introduction of such a bulky radical into the CMC molecule will alter the thermodynamic affinity of the polymer for water. Therefore, we studied the solubility of the resulting products in water and estimated the Flory–Huggins polymer–solvent interaction parameter χ_1, using the water vapor sorption method (Fig. 3). The interaction parameter χ_1 was calculated by Eq. (4).

$$\ln a_1 = \ln(p_1/p_1^0) = \ln(1 - \varphi_2) + \varphi_2 + \chi_1\varphi_2^2, \quad (4)$$

where a_1 is the solvent activity and p_1/p_1^0, relative pressure of the solvent vapor.

The experiments were carried out at a saturated vapor pressure of water, i.e., $a_1 = p_1/p_1^0 = 1$ and $\ln a_1 = 0$.

The volume fraction of the polymer was estimated by Eq. (5).

$$\varphi_2 = \frac{1}{1 + \frac{d_2}{d_1}(\Delta W)}, \quad (5)$$

where ΔW is the sorption of water (g g^{-1}), and d_1 and d_2, the densities of water and the polymer, respectively.

The densities of CMCA samples were calculated theoretically [13].

Figure 3 shows that introduction of a small amount of amide groups containing a long alkyl radical in the CMC macromolecules (DA ≤ 0.06) does not decrease significantly the solubility of CMCA in water. At DA > 0.06, the solubility of mixed cellulose ethers remarkably decreases. The observed steady increase in χ_1 suggests a decrease in the thermodynamic affinity of CMCA for water.

Table 2 summarizes the results of synthesis of CMCA from commercial CMC. At a liquor ratio of 4, the major part of the reaction mixture is absorbed by the sample. As a result, the polymer macrochains suffer a remarkable oxidative degradation at 140°C. To optimize the synthesis conditions, we varied the liquor ratio. The minimum degradation was observed at a liquor ratio of 13, but in this case, the consumption of chemicals is the highest. A liquor ratio of 10 was accepted as the optimum.

As determination of nitrogen in CMCA samples by the Kjeldahl method takes a long time, we studied the possibility of determining DA by the conductometric titration. Determination of the carboxy groups in CMC takes about 1.0–1.5 h. The DS in the initial CMC was determined from the amount of the carboxy groups, using back titration [2]. Then we determined unchanged carboxy groups in the resulting CMCA. The DA was found as the difference

$$DA = DS_{CMC} - DS_{CMCA}.$$

Table 2. Synthesis of CMCA samples from CMC with DS 0.80 (reaction time 3 h; amount of decylamine added 1 mol mol^{-1} COOH groups)

Run no.	Liquor ratio	N, %	DA		Water vapor sorption, g g^{-1}
			Kjeldahl method	conductometric titration	
1*					2.240
2	4	0.58	0.58	0.50	0.687
3	6	0.61	0.61	0.58	0.759
4	10	0.67	0.67	0.63	0.776
5	13	0.65	0.65	0.60	0.825

* Run with NaCMC (DS 0.80).

As seen (Table 2), both methods used for determining DA provide similar results. It should be pointed out that conductometric titration is applicable only to CMCA samples with DA >0.2. For samples with lower DA (Table 1), we obtained considerable discrepancies in the DA values estimated from the nitrogen content and from conductometric titration data.

At high DA, the FTIR spectra shows the characteristic amide band at 1650 cm^{-1} (Fig. 4). The band at 1550 cm^{-1} appears as a shoulder, which becomes more pronounced with increasing DA. Substitution of more than half of the carboxy groups in CMC strongly decreases the CMCA solubility in water and the thermodynamic affinity of the polymer for the solvent (Fig. 5). The resulting CMCA samples demonstrate a limited solubility in aqueous-organic solvents.

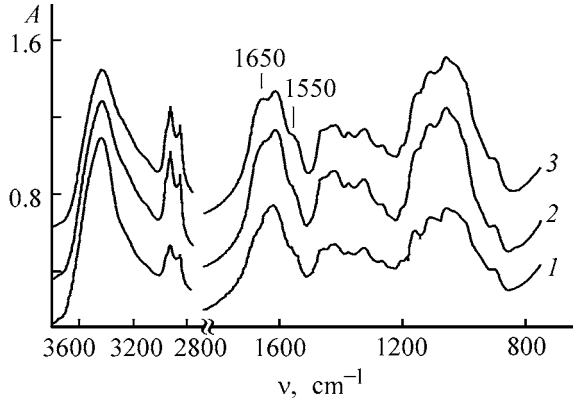

Fig. 4. FTIR spectra of CMCA samples. DA: (*1*) 0.50, (*2*) 0.58, and (*3*) 0.63.

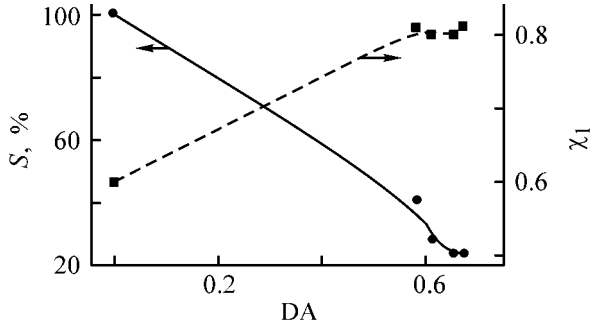

Fig. 5. Solubility S of CMCA in water and polymer–solvent interaction parameter χ_1 in the systems CMCA–water vs. DA. CMCA samples were prepared from CMC with DS 0.80. Amount of decylamine added 1 mol mol^{-1} COOH groups of CMC.

Comparison of Tables 1 and 2 shows that, under similar conditions of CMC amidation (temperature, liquor ratio, amount of the amine added), DA can be controlled by varying DS in the initial CMC.

Finally, the degree of amidation and physicochemical characteristics (solubility in water and aqueous-organic solvents) of CMCA can be controlled by varying the DS in the initial CMC and the structure of an amine.

CONCLUSIONS

(1) Optimal conditions are determined for single-stage synthesis of carboxymethyl cellulose *N*-decylamide (*N*-decylaminocarboxymethyloxycellulose).

(2) Amidation of carboxymethyl cellulose is affected by characteristics of the initial CMC, the amount of the amine added, and liquor ratio.

(3) Small degree of amidation has no considerable effect on the solubility of carboxymethyl cellulose in water. At high DA, the solubility in water is very low, but the products become soluble in aqueous-organic solvents.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Variation of Composition and Submicroscopic Structure of Pine Wood in Potash-Sulfite Cooking

G. A. Pazukhina and O. P. Kovaleva

State Forestry Engineering Academy, St. Petersburg, Russia

Received January 27, 2003

Abstract—Variation of submicroscopic structure and also the behavior of phenolic compounds and polysaccharides of pine wood under conditions of potash-sulfite cooking were studied.

Delignification of pine wood by the traditional sulfite procedure is hampered by the presence of phenolic compounds and their derivatives, such as pinosylvin (3,5-dihydroxystilbene), its monomethyl ether, and flavone compounds of the phenolic type (pinocembrin, pinobanksin, etc.) in the heartwood. Phenolic compounds, entering into the condensation with lignin, inhibit its dissolution to the point of complete termination. Combined alkaline-sulfite procedures of cellulose production allow recovery of various plant raw materials. In so doing, wood is separated into fibers with yield higher by 10% than that in the traditional sulfite cooking, and the yield of cellulose increases by 7–8% due to the stabilization of carbohydrates to acid hydrolysis [1]. This is cased by the differences in the topochemistry of wood delignification processes.

It has been shown previously [2, 3] that, in soda-sulfite cooking of spruce wood, the *P* and S_1 layers of the cell wall of wood are subjected to a directed chemical action. As a result of swelling and subsequent contraction of wood with variation of pH of the cooking liquor at the interface of intercellular substances, microfissures and subcapillaries are formed, which provides early separation of wood residue into fibers and production of cellulose with high morphologic homogeneity. Sodium and potassium compounds can be used as a soluble base for combined alkaline-sulfite delignification [1, 4–6].

The aim of this study was to examine the variation of chemical composition and submicroscopic structure of ordinary pine (*Pinus silvestris*) wood in potassium-sulfite cooking.

EXPERIMENTAL

For chemical analysis of pine wood and wood residue, we used a 0.25–0.50-mm sawdust fraction. The lignin content in wood, wood residue, and cellulose was determined by treatment with sulfuric acid [7]; the cellulose content, by the nitric acid-alcohol method [7]; the content of pentosans, by the bromide-bromate method [7]; and the content of substances extracted with hot water, ethyl ether, and acetone, by the procedure described in [7].

For cooking we used pine wood chips 20–25 mm long, 20–25 mm wide, and 2–5 mm thick. The cooking was carried out in an electrically heated 2.5 dm^3 autoclave. Before cooking, the chips were treated with saturated steam at 100°C for 15 min, after which the chips were impregnated with a 45 g dm^{-3} (in the K_2O units) K_2CO_3 solution at 50°C for 80 min and gage pressure of 0.9 MPa. After completion of impregnation and withdrawal of the draining K_2CO_3 solution, sulfurous acid containing 0.3% (in the K_2O units) potassium base and 8% total SO_2 was introduced into the autoclave. The temperature schedule was as follows: heating to 145°C for 45 min and cooking at this temperature until an intermediate product with a given content of lignin was obtained [8].

The total volume of submicroscopic capillaries (TVSC) was measured by determining the water volume in capillaries inaccessible to polymer macromolecules in moist samples of wood and cellulose. For this purpose, lateral sections of the initial wood and wood residue, 0.2 mm thick, were prepared on a microtome. Polyethylene glycol with the number-

1070-4272/03/7612-2003 $25.00 © 2003 MAIK "Nauka/Interperiodica"

average molecular weight of 40 000 was used as a polymer. The concentration of aqueous solutions of polyethylene glycol was measured with an ITR-1 interferometer. By evaluating the amount of water "inaccessible" to the soluble polymer Q, we determined the point of fiber saturation, which characterizes the total volume of submicroscopic capillaries of cellulose fibers swollen in water ($cm^3\ g^{-1}$) [9].

The amount of water inaccessible to the polymer was evaluated by the formula [9]

$$Q = \frac{W+q}{P}\left[1 - \frac{W}{W+q}\,\frac{c_{in}}{c_{fin}}\right],$$

where W is the weight of the polyethylene glycol solution (g); P, weight of absolutely dry sample (g); q, the weight of water contained in the sample (g); and c_{in} and c_{fin}, the initial and final concentrations of polyethylene glycol solution (%).

The volume of the cell walls (VCW) was evaluated by the formula

$$VCW = (TVSC + 1/1.45)K_y,$$

where K_y is the yield coefficient for wood residue or cellulose determined as the ratio of the weight of the wood residue or cellulose to the weight of the initial absolutely dry wood, and 1.45 is the specific volume of the wood substance ($g\ cm^{-3}$).

The water-retaining power (WRP) of cellulose and wood residue was determined by centrifugation and evaluated from the amount of water retained in fiber shells (% of the weight of absolutely dry wood residue) [10]. The carbohydrate composition of the samples and wood residues was determined by gas–liquid chromatography [7].

The pine wood sample selected for the study had the volume ratio of the heartwood and sapwood parts of wood of 58 and 42%, respectively.

As seen from Table 1, the heartwood and sapwood parts of pine wood differ appreciably in density and chemical composition. The heartwood contains more lignin and extractable substances but less cellulose and pentosans. The presence of significant amounts of extractable substances of the phenolic type (1.8 wt %), extracted with acetone after treatment with ethyl ether, in the heartwood did not allow complete delignification of this sample of pine by the traditional sulfite procedure: as a result of cooking, dark-colored cellulose was obtained in a total yield of 46.4 wt %, with the content of wood residue of 15.4 wt %.

The series of potash-sulfite cookings with sampling of wood residue at certain intervals yielded intermediate products with lignin content from 29.0 to 5.7 wt % in the total yield of 96.7 to 48.1 wt %. As seen from Fig. 1, the TVSC and WRP increase in treatment of pine wood with saturated steam for 15 min. In parallel, the content of extractable substances and acetyl groups decreases by 32 and 12 wt %, respectively (Table 2).

During impregnation, penetration of K_2CO_3 solution into the wood substance is accompanied by its swelling. The layer S_3, which is the layer of secondary cell wall, situated most closely to the lumen, contacts the solution first. To the middle plate, the solution penetrates mainly through the apertures of edged pores. As a result of swelling of cell walls, a developed system of submicroscopic capillaries is formed. The degree of swelling of wood substance can be indirectly judged from the variation of TVSC, VCW, and WRP. At insignificant decrease in the yield of wood residue (by 1.7 wt %) in treatment with solution of potassium carbonate, the TVSC increases by 13 vol %, VCW, by 3.5 vol %, and WRP, by 24 wt %. The rather weak swelling of pine wood substance under the action of K_2CO_3 solution is accounted for by the features of this type of wood, such as the high content of resinous substances, which decrease the permeability

Table 1. Characteristics and chemical composition of pine wood

Characteristic	Heartwood part	Sapwood part	Wood as a whole
Density, $kg\ m^{-3}$	520	470	490
Composition, wt %:			
cellulose	41.9	50.5	45.5
lignin	32.2	26.5	29.8
pentosans	6.9	7.6	7.2
substances extracted with:			
hot water	5.5	4.4	5.0
ethyl ether	7.0	4.8	6.0
acetone after extraction with ethyl ether	1.8	–	1.0

Table 2. Variation of composition of pine wood in treatment with K_2CO_3 solution

Treatment no.	τ, min	Yield, % of the weight of absolutely dry wood	Lignin, wt %		Extractable substances, % of the weight of absolutely dry wood		Acetyl groups, wt %

12	120	51.7	43.3	8.6	14.9	2.6	0.16
13	150	48.1	45.7	5.7	9.2	2.6	0.17

of wood and the state of edged pores of heartwood. It is well known that heartwood differs from sapwood in the predominance of pores closed by toruses, which hampers impregnation.

As the K_2CO_3 solution penetrates into the capillary-porous system, the wood is subjected not only to physical but also to chemical action of this solution. Deacetylation of wood, which started in the stage of steam treatment, is enhanced in treatment with potassium carbonate solution: the content of acetyl groups decreases by additional 25 wt % (Table 2, treatment no. 5). The deacetylation is somewhat accelerated with increasing treatment duration, which is due to improvement of the conditions of wood impregnation through removal of extractable substances.

Treatment of pine wood with K_2CO_3 solution provides dissolution of more than 70 wt % of the substances extracted with ethyl ether and decreases the content of phenolic compounds, which is indirectly suggested by the decrease from 0.83 to 0.22 wt % in the content of substances extracted with acetone after extraction with ethyl ether. After completion of the stage of alkaline treatment of wood, the free-draining solution of K_2CO_3 is fully removed, and only a part of the solution, filling the capillary-porous system of wood, is involved in the sulfite stage. During the first 15 min of the sulfite stage of cooking, i.e., during heating to 70°C, K_2CO_3 reacts with H_2SO_3, which is accompanied by a decrease in the pH of the medium. As can be seen from Table 3 and Fig. 1, during this

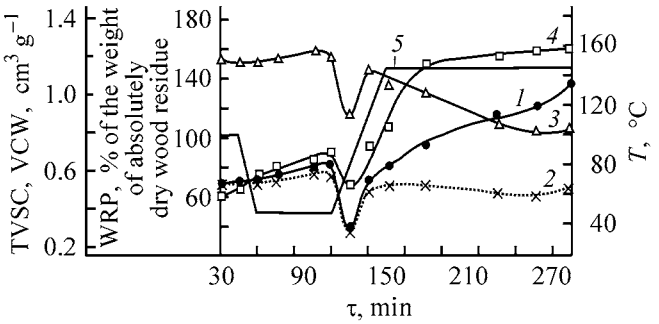

Fig. 1. Variation of TVSC of (*1*) wood residue and (*2*) initial wood, (*3*) WRP, and (*4*) VCW in potash-sulfite cooking. (*T*) Temperature and (τ) time; the same for Figs. 2 and 3; (*5*) temperature regime of cooking.

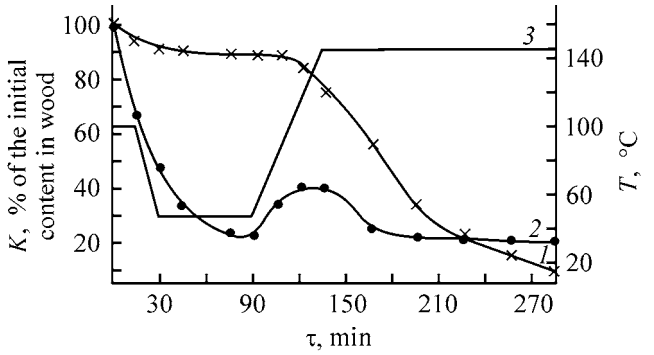

Fig. 2. Variation of content *K* (*1*) lignin and (*2*) resin in potassium-sulfite cooking. (*3*) Cooking temperature.

period the TVSC significantly decreases (by 53%), and the VCW decreases from 87 to 66%. The decrease in TVSC is caused by significant contraction of cell walls of wood (WRP decreases from 1.19 to 0.88 $cm^3 g^{-1}$ of wood residue). The abrupt decrease in the degree of swelling of cell walls is apparently favored by deresinification of tracheids of pine wood in the stage of treatment with K_2CO_3 solution. With further heating, the TVSC, WRP, and VCW of wood residue increase again owing to hydrolysis of polysaccharides and dissolution of their hydrolysis products, and also to formation of solid lignosulfonic acid having hydrophilic properties.

During keeping at the final temperature, sulfonation of lignin is enhanced, its dissolution is accelerated, and carbohydrate components are swollen and partially dissolved. When the final temperature of potash-sulfite cooking is reached, with the development of the system of submicroscopic capillaries continuing, the WRP decreases, which is caused by dissolution of significant amounts of lignin, hemicelluloses, and in part, cellulose.

As can be seen from Table 3, the yield of wood residue somewhat increases within 15 min after supply of sulfurous acid to cooking, presumably owing to uptake of sulfur (sulfonation of lignin) and also to an increase in the content of extractable substances (by 31 wt %) through their precipitation from solution in substitution of the alkaline medium for acidic medium. During heating to 145°C, the yield of wood residue significantly decreases (to 84 wt %) owing dissolution of lignin and readily hydrolyzable carbohydrates. During cooking at the final temperature, the yield of wood residue rapidly decreases, which is caused by dissolution of sulfonated lignin.

After keeping for 30 min at the final temperature, the wood residue is divided into two portions: sorted cellulose (21.2 wt %) and wood residue (50.4%). As can be suggested, the sorted cellulose is formed from sapwood, which contained less lignin and no phenolic compounds among its extractable substances. After longer cooking at the final temperature, the content of sorted cellulose increases and that of wood residue decreases. After the completion of cooking, the total yield of cellulose was 48.1 wt %, with the content of wood residue equal to 2.4 wt %.

It should be noted that, for pine wood delignification by the potash-sulfite procedure, there is no so-called point of desintegration into fibers. The disintegration of wood residue into fibers was extended in time owing to the presence of readily cooked sapwood and difficulty cooked heartwood. The dynamics of lignin dissolution during cooking are complicated. Treatment of wood with saturated steam weakens the bonds between carbohydrate and lignin macromolecules, which favors removal of approximately 6 wt % of lignin from wood with a condensate being formed. During treatment with K_2CO_3 solution, approximately 5 wt % of lignin is dissolved additionally. In the initial stage of sulfite cooking, lignin is not dissolved, since a certain degree of sulfonation is required for lignin to pass into sulfurous acid solution. With increasing temperature, the lignin dissolution accelerates. As a result, when the final temperature is reached, an additional 13 wt % of lignin passes into the solution. The rate of lignin dissolution is the highest during the first hour of keeping at the final temperature, after which the process decelerates. The deceleration of delignification is due to the fact that, by this instant of time, sapwood has got free of the main part of lignin, while delignification of heartwood still continues.

The variation of the content of substances extractable with acetone in the wood residue and cellulose is shown in Fig. 2. After steaming, 34 wt % of resinous substances is removed from wood, and after treatment

with K_2CO_3 solution, 42 wt % of resinous substances passes into the solution. However, after complete withdrawal of draining solution of potassium carbonate and supply of a sulfurous acid, the resin content in the wood residue increases. This is due to the fact that extractable substances dissolved in the alkaline solution, whose certain volume is retained in wood, partially reprecipitate in wood capillaries when pH and temperature change. In the course of subsequent sulfite cooking, the extractable substances slowly pass into the solution. In separation of sorted cellulose and wood residue, it was found that the wood residue contains a large amount of resinous substances. After the cooking is complete, approximately 20% of the initial amount of extractable substances is contained in wood.

Tables 2 and 3 show that the content of phenolic compounds (acetone extract after pretreatment of wood residue and cellulose with ethyl ether) gradually decreases in the course of potash-sulfite cooking. In the first stage of cooking (treatment with saturated steam or and K_2CO_3 solution), up to 80 wt % of the initial amount of phenolic compounds in wood is recovered from pine chips, including 60 wt % in alkaline treatment. In the stage of sulfite cooking, the wood substance continues be feed of phenolic compounds with increasing temperature, but a part of these compounds (0.18% of the weight of absolutely dry cellulose) remains in the fiber. The high content of resinous substances of the phenolic type in the resulting cellulose does not allow its exhaustive delignification. From this sample of highly resinous freshly felled pine wood, cellulose with the lignin weight fraction of 5.7% was produced.

The deacetylation of wood in its treatment with potassium carbonate solution and the swelling and contraction of cell walls of wood, proceeding under conditions of potassium-sulfite cooking, provide favorable conditions for stabilization of carbohydrate components to the action of sulfurous acid. As can be seen from Fig. 3, the first 15-min step of treatment of pine wood with K_2CO_3 solution causes an insignificant loss of readily hydrolyzable polysaccharides as a result of hydrolysis of galactopyranose (25 wt %) and arabinofuranose (22 wt %) side monomeric units of glucomannan and xylan, respectively. After the completion of alkaline treatment, 55 wt % of galactopyranose and 50 wt % of arabinofuranose units are eliminated, and these units are virtually absent in the early stages of sulfite cooking. The increased hydrolytic stability of glucomannan in comparison with other hemicellulose components of wood is retained during most part of the sulfite cooking. After the cooking was complete,

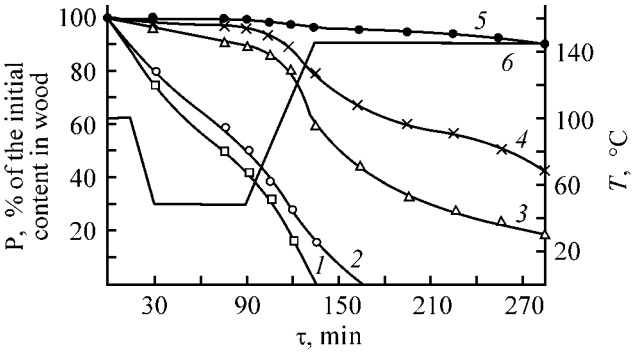

Fig. 3. Variation of the content of polysaccharides P in wood residue in potassh-sulfite cooking: (*1*) galactan, (*2*) arabinane, (*3*) xylan, (*4*) mannan, and (*5*) glucan; and (*6*) cooking temperature.

cellulose contained 41.7 wt % of glucomannan and 19.3 wt % of xylan relative to their initial amount in wood. In the course of sulfite cooking, the content of glucan decreases insignificantly owing to dissolution of glucomannan and, in part, cellulose.

The behavior of hemicelluloses in potassium-sulfite cooking is largely determined by distinctions in delignification of heartwood and sapwood. Decelerated delignification of heartwood results in degradation of a part of polysaccharides of sapwood, more readily liberating the main amount of lignin. Therefore, contrary to spruce wood, the increase in the yield of commercial cellulose in delignification of pine wood by potassium-sulfite cooking is significantly weaker owing to stabilization of carbohydrate components with respect to acidic hydrolysis in the sulfite stage of cooking.

CONCLUSIONS

(1) Under conditions of potash-sulfite cooking, pretreatment of pine wood with saturated steam and K_2CO_3 solution gives rise to a system of submicroscopic capillaries owing to swelling and removal of individual components of wood. This treatment allows recovery of up to 80 wt % of phenolic compounds contained in wood, which significantly facilitates the subsequent sulfite delignification.

(2) On adding sulfurous acid to pine chips impregnated with K_2CO_3, the cell walls of wood undergo contraction. With increasing temperature of cooking, lignin and carbohydrates begin to dissolve.

(3) In delignification of pine wood by the traditional potash-sulfite procedure, degradation of wood residue to fibers is extended in time owing to the difference in rate of delignification between heartwood and sapwood.

(4) Under conditions of potassium-sulfite cooking of pine wood, the stability of glucomannan to acid hydrolysis is increased.

ACKNOWLEDGMENTS

The authors are greateful to A.P. Treiman for the help determining the submicroscopic structure of wood.

Abstract—The kinetics of curing of an epoxy-amine compound by the polymerization mechanism were studied at various temperatures by isothermal calorimetry and rheokinetic procedures. The resulting kinetic data were correlated with the patterns of variation of the adhesion strength of glass–epoxy-amine compound–glass glue joints, of shrinkage stresses, and shrinkage defects, as well as with the nature of the glue joint failure.

In [1–3], we attempted chemical design of high-strength epoxy-amine binders for fiber glass plastics by optimal combination of the structural contributions from polycondensation and polymerization processes to the cohesion strength of the binders proper. Studying the adhesion strength formation in curing of compounds is also essential for designing the chemical structure of the binder for high-strength fiber plastics.

It is important to elucidate how the structural contributions from a combination of different processes of three-dimensional cross-linking of binders (glues) affect the origination, number, and extent of shrinkage and thermal defects, as well as the corresponding stresses and their relaxation processes. This will allow optimization of the molding mode for high-strength composites.

Earlier [4], we have elucidated how the strength properties of model glue joints (MGJs) vary in the course of curing of epoxy-amine compounds by the polycondensation mechanism. Unexpectedly, the time dependence of the glue joint strength σ_{glue} of MGJs proved to be complex. In early curing stages (preceding gelation), σ_{glue} of the GLMs initially grew, then passed through then maximum, and a decreased. Further, σ_{glue} remained unchanged, then grew, and finally approached a constant limiting value.

This complex pattern of variation of the glue joint strength of MGJs in the course of isothermal curing was attributed to two relaxation transitions in the glue interlayer, which are due to physical (glass transition of the binder at the curing and test temperatures) and chemical (gelation) processes, as well as to shrinkage and thermal stresses and the corresponding defects affecting the failure mechanism of adhesion joint.

The aim of this study was to examine the glue joint strength as influenced by the kinetic features of the polymerization curing of the epoxy-amine compound. This process was studied by isothermal calorimetry and rheokinetic procedures, namely, rotation viscometry, tensimetry, and a procedure utilizing a torsion pendulum.

EXPERIMENTAL

As the binder we used a compound based on ED-20 epoxy-4,4'-isopropylidenediphenol resin and benzyldimethylamine (BDMA). The curing kinetics of the individual binder were studied calorimetrically on an EK-2 low-inertia calorimeter with a torsion pendulum (torsion mass 9 g; a 60-mm long VM-1 glass thread containing 25 wt % binder as the working unit) and on a Rheotest-II viscometer [plate-cone design; gelation time at various temperatures was determined by extrapolating the linear portion corresponding to a sharp viscosity growth to the abscissa (time) axis and, additionally, as the time in which a conventional viscosity of 4000 Pa is reached]. The shrinkage stresses were determined tensimetrical-

ly [5]. The glue joint strength of MGJs was determined by the procedure described in detail in [6].

Shrinkage defects were observed directly during isothermal synthesis in long glass tubes [7]. A fairly high adhesion between the system being cured and the glass surface gave rise to initial shrinkage cohesion defects which further, under certain conditions, evolved into adhesion exfoliates.

Figure 1 presents typical kinetic plots for the glue joint strength σ_{glue} at curing temperatures T_{cur} of 50, 70, and 100°C, which are lower than the limiting glass transition point T_{gl}^{∞} of the epoxy-amine compound cured by the polymerization mechanism (T_{gl}^{∞} = 106°C [8]). Figure 1 shows that the time dependences of σ_{glue} for a polymer binder (glue) operating by the polymerization mechanism have two maxima. They tend to shift to smaller times with rising curing temperature; at high T_{cur} the initial maximum finally decays, like in the case of compounds cured by the polycondensation mechanism [4]. Comparison of the results from studies of the glue joint strength in the course of curing of different types of epoxy-amine compounds poses a number of questions as to the reasons for (1) appearance of the initial peak in the glue strength vs. time plots for different types of glue compounds; (2) decrease in σ_{glue} rather than leveling-off (like in the case of polycondensation mechanism) after the secondary growth of the glue joint strength in the case of glue compounds cured by polymerization mechanism; and (3) a much greater strength of a glue joint for compounds cured by polymerization mechanism, despite its lower cohesion strength.

To elucidate the reasons for the appearance of two glue strength peak, let us consider the time dependence of σ_{glue} at 70°C (Fig. 2) together with the analogous dependences for such curing parameters as the current conversion of the functional groups of the glue compound *Q*, the effective torsion elasticity modulus G_{eff}, and the shrinkage stress U_{shr}. Figures 1 and 2 (where the gelation times τ_{gel} for the corresponding T_{cur} are shown with arrows) clearly demonstrate that, in all cases of polymerization curing, the primary glue joint strength maximum precedes the onset of gelation. Notably, this occurs at a time when there is no noticeable growth of shrinkage stress, shrinkage defects are not formed at the curing temperature, and glass transition at T_{cur} is not recorded by the torsion pendulum.

Evidently, like in the case of polycondensation curing, the initial peak in the plot of the glue joint strength against the curing time appear for physical reasons. We have found earlier [4] that the initial growth of the glue joint strength is due to enhancement of the viscous (dissipative) properties of the binder owing to the onset of its transition from the liquid to glassy state at the test (room) temperature. This is indicated by a sharp growth of the viscosity of the compound at room temperature, which is due to the physical process of transition of the binder to the glassy state. Notably, the effective activation energy of this process is much lower than that of the chemical transformations [9]. Therefore, at low curing temperatures, the physical (glass transition) process in the binder may run a head of the chemical (gelation) process, and at higher curing temperatures, on the contrary, it may lag behind. Consequently, the viscosity growth may be due to both physical and chemical processes [8, 9]. In this context, the subsequent decrease in σ_{glue} is, evidently, due to curing and, accordingly, to embrittlement of the binder, which is completely vitrified at room temperature. We emphasize that both the primary glass transition of the glue

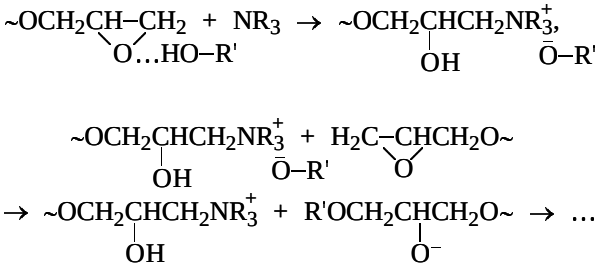
compound cured at room temperature and its secondary glass transition at the curing temperature are treated as prolonged processes [4].

The secondary growth of the glue joint strength is, evidently, due to an increase in the gel fraction content or in the degree of cross-linking, which favors simultaneous enhancement of the elastic and relaxation (dissipative) properties of the glue compound. This is indicated by a sharp rise in the viscosity of the compound owing to the chemical gelation process and also by a noticeable increase in the effective elasticity modulus G_{eff} at T_{cur} (Fig. 2, curve *3*). Notably, the onset of a steep rise in G_{eff} at τ = 150 min is due to the onset of glass transition in the binder. This time corresponds to the beginning of hardening of the binder, as indicated by the penetration method.

Figure 2 shows that the glue joint strength rapidly grows till at 270th–280th min. Diring this same time interval, G_{eff} reaches its limiting values and the conversion curve *2* levels off. This suggests that the stage of intensive chemical and physical (relaxation processes) transformations of the glue composition at the given curing temperature terminates. It could be expected that the glue joint strength should also attain a limiting value, like in the case of the compound cured by the polycondensation mechanism (the more so that the chemical and physical transformations of the binder are not complete even in 600 min). This is indicated by increments, though small, in G_{eff} and Q, seen in Fig. 2. However, despite the increase in these parameters of the curing processes, the glue joint strength clearly tends to decrease after 300 min. Notably, this is typical of all the temperatures studied (Fig. 1).

This is understandable if we take into account that, starting from 150th min, shrinkage defects in long glass tubes tend to noticeably grow and at τ = 280 min they begin to transform into adhesion defects through exfoliation of the binder from the walls of the glass tubes. Also, the shrinkage stress U_{shr} tends to grow steadily throughout the 600-min period (Fig. 2, curve *4*). Evidently, it is the enhancement of internal stresses and increase in the degree of defectiveness of the binder after sharp deceleration of the chemical cross-linking that are responsible for the secondary decrease in the glue joint strength. Along with the above-mentioned factors, the relaxation characteristics of the binder can additionally decrease within 300–600 min due to physical aging [1], i.e., afterpacking of the network structure and the corresponding decrease in the free volume fraction.

Let us discuss why these factors do not exert similar influence in the case of a system cured by the polycondensation mechanism. Above all, the highest attainable strengths of the glue joints in the case of binders operating by the polymerization mechanism substantially (by a factor of 2–2.5) exceed the maximum strength of the glue joint in the case of the system cured by the polycondensation mechanism [4]. This may be due to two major factors. First, it is known [8, 11] that initiation of the polymerization curing typically requires a hydroxyl-containing accelerator acting as a proton donor:



It is seen that, in the first (initiation) stage, a proton is transferred from the hydroxyl-containing HO–R' fragment to the oxygen atom in the epoxy group to form a new hydroxy group and alkoxy anion. In the second stage (polymerization proper), the alkoxy anion (free or as part of an ion pair) attacks the epoxy ring and gets incorporated into the network structure. This scheme suggests that the hydroxy groups contained in the borosilicate glass [12], particularly in its surface layers, can also be involved in the polymerization process to form a chemical bond between the binder and the glass surface. At the same time, it is well known [13–16] that the formation of a chemical bond between the polymer matrix and the substrate surface substantially increases the adhesion strength.

It is known [8, 17] that tertiary amines of the BDMA type are not incorporated into the chemical structure of the network and can act as typical plasticizers, which increase the molecular mobility in the polymer matrix and improve its relaxation ability with respect to internal stresses and excess free volume [3, 17, 18]. To elucidate the possible influence exerted by such a plasticizer as a tertiary amine on the glue joint strength, we carried out the following experiments. Into the glue compound cured by the polycondensation mechanism, which contained ED-20 and *m*-phenylenediamine (*m*-PDA), we introduced 2.5, 5.0, 10, or 15 wt % of a typical plasticizer, dibutyl phthalate (DBP). The glue joint strength was studied for the resulting compounds on keeping the MGJ at

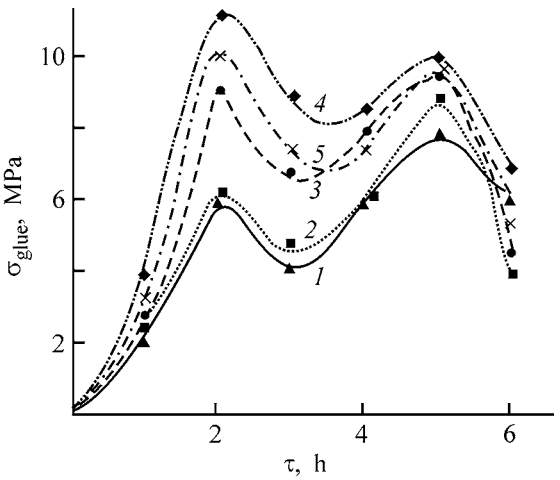


Fig. 3. Variation of the glue joint strength σ_{glue} of the ED-20 + *m*-PDA compound with the curing time τ at 70°C. DBP concentration, wt %: (*1*) 0, (*2*) 2.5, (*3*) 5.0, (*4*) 10, and (*5*) 15.

80°C for 1, 2, 3, 4, 5, and 6 h. Figure 3 shows that the time dependences of σ_{glue} pass through two maxima. With increasing DBP concentration, the glue joint strengths at the maxima tend to increase, with the most significant rise in σ_{glue} observed for the initial maximum. This confirms the assumption that such a plasticizer as tertiary amine exerts physical influence on the glue joint strength for the compound cured by the polymerization mechanism.

A more pronounced influence of the plasticizer on the initial maximum of the glue joint strength is, evidently, due to the specific features of the MGJ failure in the initial stages of curing (cross-linking) of the glue compound transforming to the glassy state at T_{test}. Optical microscopic studies within the time interval corresponding to the appearance of the initial maximum of the glue joint strength showed that, for glue compounds cured by both the polymerization and polycondensation [4] mechanisms, failure at the beginning of curing has a cohesion nature, and the glue interlayer disintegrates like a viscous liquid. Further, a cohesion-plastic failure is observed in the region corresponding to the primary rise in σ_{glue}, and in the region corresponding to the primary decline in σ_{glue}, a cohesion-brittle failure with typical shear bands is observed. Upon introduction of a plasticizer, the range of brittle failure shifts to longer curing times. This is probably due to the fact that the plasticizer increases the molecular mobility of the compound, thus shifting the instant of vitrification to longer times and, thereby, to higher conversion of the functional groups. Evidently, the plasticizer decreases the degree of brittleness of low-molecular-weight glassy binder that has not yet formed a chemically cross-linked three-dimensional structure.

Notably, in the portion of curve *1* between the two glue joint strength peaks, i.e., at minimum values of σ_{glue}, there is another portion corresponding to a cohesion-plastic failure with more pronounced microprofile of the fracture surface. Next, from the beginning of the secondary rise portion to the second σ_{glue} peak, the failure has mixed cohesion–adhesion nature. In all the above-described cases, the nature of failure of the glue compounds cured by the polymerization and polycondensaion mechanisms is about the same. However, upon attainment of the secondary σ_{glue} maximum, the types of failure of these two compounds begin to differ sharply: For the binder operating by the polymerization mechanism, the cohesion failure is observed once again, but this concerns the glass plate rather than the polymer matrix with glass pieces contacting the polymer matrix torn off. This is particularly typical of high curing temperatures, since it follows from Fig. 1 that, with increasing T_{cur}, the σ_{glue}^{max} values tend to increase. These findings clearly illustrate the known enhancement of the strength of adhesion to glass fiber in the case of binders operating by the polymerization mechanism [3, 16, 19, 20]. This validates the idea that the contributions of polymerization and polycondensation to the overall curing process should be optimally combined in order to make high the cohesion and adhesion components of the glass fiber strength [1–3].

CONCLUSIONS

(1) With a binder operating by the polymerization mechanism (ED-20 + benzyldimethylamine), the adhesion strength of a glue joint of glass plates increases by a factor of 2–2.5.

(2) A substantial growth of the glue joint strength is due to combination of two factors: chemical, i.e., formation of a chemical bond between the binder operating by the polymerization mechanism and the glass surface, and physical, i.e., placticizing (relaxation) effect of the tertiary amine acting as initiator.

(3) The major difference in the failure mechanisms for glue joints in the case of systems cured by the polymerization and polycondensation mechanisms is the cohesion failure of the glued plates in the former case.

(4) These findings allow chemical design of high-strength fiber plastics by varying the ratio of the contributions of polycondensation and polymerization to the overall curing process.

Professor Vladimir Avgustovich Kind (To 120th Anniversary of His Birthday)

V.A. Kind, and engineer and pedagogue, made an outstanding contribution to the science of construction materials, the training of specialists in technology of binders, and the development of the cement industry. All his pedagogical and scientific activities were closely associated with higher school institutions of St. Petersburg, Polytechnical and Technological Institutes.

Vladimir Avgustovich Kind was born on October 3 (September 20), 1883, into the family of the manager of Avzyano-Petrovskie ironworks and steel-making plant in the former Verkhe-Ural'skii uyezd (district) of Orenburg Province. The parents of the scientist-to-be, Avgust Kind and his wife Amaliya, were born in Alsace-Lotharingia, a part of Germany in 1871–1918. V.A. Kind was educated at Kazan Nonclassical Secondary School, which he finished with success in 1902. In the same year, he entered, having passed the competition of school-leaving certificates, the electrochemical subdepartment of the metallurgical department at the newly opened St. Petersburg Polytechnical Institute. In those years, N.A. Menshutkin, N.S. Kurnakov, and F.Yu. Levinson-Lessing were among professors; A.A. Baikov, V.A. Kistyakovskii, P.P. Fedot'ev, and a number of other scientists, later widely known, were beginning their pedagogical activities.

In 1908, V.A. Kind graduated from the institute as an engineer metallurgist. Already when being a student, V.A. Kind published his first scientific study "Reactions between Carbamides and Chlorous Salts." Having graduated from the institute, V.A. Kind started teaching at the chair of analytical and organic chemistry at the Polytechnical Institute, headed at that time by B.N. Menshutkin (1874–1938). Till 1916, V.A. Kind's scientific interest were focused on studies and description of oil fields in Southern Russia, oil refining, and technical analysis of oil. Beginning in 1916 and till the end of V.A. Kind's life, his scientific activities were devoted to study of construction materials and binders. The "Society for Promotion of the Development of Portland Cement Industry" was organized in St. Petersburg. Not abandoning his pedagogical activities, V.A. Kind became society manager and editor of the *Portland-Tsement* (Portland Cement) journal (published till 1918).

In 1919, the chemical faculty was organized at Petrograd Polytechnical Institute on the basis of the electrochemical subdepartment of its metallurgical department (faculty). The faculty included chairs (laboratories) of general chemistry, physical chemistry, theoretical electrochemistry, technical electrochemistry, mineral technology, geology, mineralogy, and some others. Professor P.P. Fedot'ev (1864–1934) was appointed the dean of the chemical faculty. On V.A. Kind's initiative, and with his direct participation, a silicate department was organized at the new faculty to train engineers for cement, ceramic, and glass-making industries. A large laboratory of artificial silicates, the first of this kind in St. Petersburg, was created at the silicate department. The laboratory was concerned with the technology of binders and ceramics. Beginning in 1922, V.A. Kind also delivered a course of lectures on construction materials at the construction engineering faculty of the Polytechnical Institute. In 1927, he became professor.

In 1930, the higher school institutions of Leningrad were subjected to a shake-up. The chemical faculty of Leningrad Polytechnical Institute was included in Leningrad Technological Institute. V.A. Kind and his co-workers and colleagues constituted the main part of the staff members of chairs of the silicate profile at the Technological Institute, those of binders, ceramics, glass, and physical chemistry of silicates. V.A. Kind

1070-4272/03/7612-2014 $25.00 © 2003 MAIK "Nauka/Interperiodica"

headed the chair of binders at Leningrad Technological Institute till 1938. Simultaneously, he continued to head the chair of construction materials at the Polytechnical Institute. Under the severe conditions of that time, V.A. Kind managed to create a prominent scientific school and to organize training of specialists in technology of binders , ceramics and glass. Among V.A. Kind's pupils and closest associates were such well-known, in the future, specialists as V.F. Zhuravlev, Ya.V. Klyucharov, S.D. Okorokov, V.V. Yurganov, and V.A. Kind's son, V.V. Kind. V.A. Kind maintained permanent close friendship with academicians A.A. Baikov (1870–1946), D.S. Belyankin (1876–1953) and corresponding members of the Academy of Sciences of the USSR, N.N. Kachalov (1883–1961) and P.P. Budnikov (1885–1968).

V.A. Kind started his active research activities in 1919–1920 at the laboratory of silicates at the chemical faculty of Petrograd Polytechnical Institute and, later, at laboratories of quite a number of institutions, which appeared and disappeared. Nevertheless, V.A. Kind's studies were systematic and interrelated and resolved important problems of manufacture and use of binders. One the first areas of V.A. Kind's research was devoted to use of shale in calcination of portland cement and application of shale ash in manufacture of construction materials. A large series of scientist's studies, which were continued for more than 15 years, were devoted to comprehensive analysis of natural and artificial hydraulic acid additives to various cements. First of all, methods for evaluating the "activity" of additives were developed on the basis of chemical processes that occur in hydration of the most important classes of cements. Particularly important was the fact that V.A. Kind substantiated the possibility of using acid blast-furnace slags as hydraulic additives. This area of V.A. Kind's scien tific activities was analyzed in ample detail by P.P. Budnikov [1].

Of high theoretical and practical importance are V.A. Kind's studies in the field of alumina cements, whose hardening is based on hydration of calcium aluminates. As far back as 1925, V.A. Kind presented at the All-Union Congress on construction materials a report on main prerequisites for manufacture of alumina cements from Tikhvin bauxites. In 1928, V.A. Kind became a member of a special commission for alumina cement. On the basis of the experimental studies carried out by the scientist and his co-workers, a decision was made to manufacture the alumina cement by blast-furnace smelting.

Beginning in 1931, V.A. Kind supervised research at the laboratory of construction materials of the All-Union Research Institute of Hydraulic Engineering and at the laboratory of binders of the Technological Institute. The attention of the first of these two laboratories was focused on problems associated with production of a hydraulic concrete with high water resistance, low shrinkage, weak exothermic effect, high water-impermeability, which would satisfy all the requirements to hydraulic concrete. At the laboratory of the Technological Institute, the chemistry of cements and the influence exerted by their chemical and mineralogical composition on the processes of hardening and the working characteristics of the cements were studied with active participation of students. One of the last V.A. Kind's studies, carried out together with his pupil, V.F. Zhuravlev (1907–1952), was devoted to use of D.I. Mendeleev's Periodic law in classification of chemical compounds with respect to their binding properties (*Zh. Prikl. Khim.*, 1938, no. 5). The authors established that binding properties are observed in chemical compounds that are similar in structure to calcium silicates and aluminates. Later, research in this area was continued by Zhuravlev.

V.A. Kind wrote quite a number of textbooks and monographs, which became widely known and exerted strong influence on the training of specialists and the development of the cement industry in the country. They include: *Instruksii po opredeleniyu aktivnosti gidravlicheskikh dobavok* (Recommendations for determining the Activity of Hydraulic Additives) (together with S.I. Druzhinin and S.D. Okorokov, Moscow, 1931), *Khimicheskaya kharakteristika portlandtsementa* (Chemical Characterization of Portland Cement) (Moscow, 1932), *Spetsial'nye svoistva stroitel'nykh rastvorov* (Special Properties of Mortars) (together with Okorokov *et al*., Moscow, 1933), *Spetsial'nye tsementy* (Special-Purpose Cements) (Moscow, 1932, 1st ed.; 1936, 2nd ed.), *Stroitel'nye materialy (ikh poluchenie, svoistva i primenenie)* (Construction Materials: Manufacture, Properties, and Use) (together with Okorokov, Moscow, 1934), and *Putstsolanovye tsementy* (Puzzolan Cements) (together with Baikov *et al*., Moscow 1936). Among these books, *Stroitel'nye materialy* (Construction Materials) is a textbook of unique information value, largely based on original research of that time, including studies by V.A. Kind and his pupils.

Vladimir Avgustovich Kind suddenly died on February 12, 1938, in Leningrad. Prematurely passed away an excellent person, talented engineer and researcher, pedagogue beloved by his pupils, and organizer and supervisor of research collectives. To his career and pedagogical and scientific activities were

devoted a spacious obituary, written by P.P. Budnikov [1], Okorokov's paper [2], small book by I.L. Znachko-Yavorskii and I.G. Savelov [3], and other publications [4–8]. In [2, 3], a list of the most important V.A. Kind's works was presented.

ANNIVERSARIES

Mikhail Mikhailovich Koton (To His 95th Birthday)

On December 29, 2003, Mikhail Mikhailovich Koton, doctor of chemical science and corresponding member of the Russia Academy of Sciences, is 95.

Mikhail Mikhailovich can be rightfully named "archpastor" of the domestic chemical science, who guided representatives of several generations of scientists working in the filed of chemistry and physics and technologists specializing in polymers.

Mikhail Mikhailovich is still full of creative aspirations, he is honorary director of the Institute of Macromolecular Compounds, Russian Academy of Sciences, whose acting head he had been for nearly thirty years, and leader of a scientific school recognized with a grant from the President of the Russian Federation.

Mikhail Mikhailovich made an invaluable contribution to the research concerned with the problem of thermally stable polymers. The concepts of the ways to synthesize polyimides and the relationship between their structure and properties, developed under his supervision, made it possible to manufacture in our country virtually all types of materials (electrically insulating films, strengthening fibers, membranes for separation of gases and fluids, protective coatings and interlayer insulation for electronic devices, etc.) exhibiting stable operation at temperatures of 300°C and more.

In recent years, members of Mikhail Mikhailovich's scientific school have been developing a new generation of binders for construction composites and new polymeric materials for laser technologies, to be used in optoelectronics and photonics.

Mikhail Mikhailovich was born, and spent his young years at the town of Peterhof, a place that is closely associated with Russia's history and culture.

He spent all days of the Leningrad siege in the besieged city and worked at the laboratory of local air defense. He was elected a deputy of the Leningrad City Council. For many years he had been a member of the Editorial board and Deputy Editor-in-Chief of Zhurnal Prikladnoi Khimii (Russian Journal of Applied Chemistry). Mikhail Mikhailovich is a person of perfect humanity and high moral, which constitute the notion of St. Petersburg culture and way of life.

The Editorial board and the editorial staff of Zhurnal Prikladnoi Khimii heartily congratulate Mikhail Mikhailovich on his jubilee and wish him sound health and success in implementation of his scientific ideas.

Staff members of the Institute of Macromolecular Compounds, Editorial board and editorial staff of Zhurnal Prikladnoi Khimii

BOOK REVIEWS

Pastukhov, E.A., Vatolin, N.A., Lisin, V.L., Denisov, V.M., and Kachin, S.V., *Difraktsionye issledovaniya stroeniya vysokotemperaturnykh splavov* (Diffraction Analysis of the Structure of High-Temperature Melts), Yekaterinburg: Ur. Otd. Ross. Akad. Nauk, 2003, 353 pp.

The monograph by E.A. Pastukhov and co-authors analyzes and summarizes results obtained in diffraction studies of high-temperature metallic, oxide, sulfide, and halide melts. As is known, most of the substances studied in these classes retain, in the liquid state at the melting point and even when overheated to considerably higher temperatures, a certain short-range order that is close to the structure of these same substances in the solid state. However, no rigorous theory that would describe the atomic coordination and properties of various substances in a wide temperature range has been developed for liquid phases as yet. The primary role in studying the structure of liquid high-temperature systems is played by analysis of the short-range order by diffraction techniques and computer simulation.

Previously, N.A. Vatolin, an academician of the Russian Academy of Sciences, and Pastukhov, a corresponding member of the Russian Academy of Sciences, already published a monograph with similar content.[1] During the 20 years that have elapsed since that time, a vast body of new experimental data has been accumulated and new concepts have appeared. The book comprises an introduction, seven chapters, conclusion and bibliographic list with 469 references to domestic and foreign publications.

The introduction (pp. 5–7) emphasizes that the vast body of data on thermodynamic, kinetic, and physical properties of binary metallic and ionic melts, accumulated by now, confirms the theoretical concept of similarity between the nearest coordination of particles in the melt and in the solid state. The advances in the development of the theory of liquid state and the improve accuracy and information value of the diffraction experiment made it possible to calculate the interatomic interaction potential and thermodynamic and transport properties of melts from the structural factor and the radial distribution function. The first chapter (pp. 8–51) gives notion of the basic characteristics of the liquid state, to which belong short-range order, thermal motion of atoms, radial distribution function and structural factor, and potential of pairwise interaction. The second chapter (pp. 52–69) is devoted to X-ray structural analysis as applied to melts. Although X-ray, electron, and neutron diffraction techniques yield close diffraction patterns, the authors restrict the consideration to X-ray diffraction analysis as the more widely used method.

The third chapter (pp. 70–185), which occupies the central place in the monograph, contains information about diffraction studies of metallic melts. Compared with the already mentioned edition of 1980, the number of metals and alloys considered has increased. Unfortunately, the authors did not specify the criteria used in selecting the systems to be discussed; quite a number of liquid alloys with strong interaction between the components, for which the diffraction patterns are known, are not mentioned in the monograph. The fourth chapter (pp. 186–258) is devoted to oxide and some other oxygen-containing melts. In contrast to metallic systems, oxide melts, as a rule, have a considerable fraction of covalent bonding, which leads to certain specific features in radial distribution curves. A small fifth chapter (pp. 259–270) presents the results of studies of sulfide melts. Copper, iron, and thallium sulfides are considered. The sixth chapter (pp. 271–304) discusses the specific features of the structure of molten halides. The seventh chapter (pp. 305–329) is of generalizing nature. It analyzes the fundamental aspects of how the above-mentioned structural parameters change upon melting. In the conclusion (pp. 330–333), the authors emphasize once more, on the basis of the whole body of the material presented, that, as regards the effect of temperature on the structure, the liquid state is a natural extension of the crystalline state. The results obtained

in studying liquid alloys with strong interaction between the components (silicides, germanides, and aluminides of transition metals) point to the existence of regions retaining a short-range order that corresponds to the structures of the most stable high-temperature phases present in the phase diagram. Some semiquantitative estimates are made. For example, it is noted that raising the temperature to 400–700°C above the liquidus line affects the short-range order parameters only slightly. The degree of dissociation in melting is estimated to be 10–20% for the most stable compounds, which show a singular peak in the melting curve, and 40–70% for compounds with broad peaks and relatively moderate melting points.

The structural transformations in the liquid state, associated with a change in the coordination number, are similar to polymorphic transformations, which occur in solids when the number of nearest neighbors decreases or increases and accordingly, the interatomic distance changes.

The monograph by Pastukhov and co-authors is of indubitable interest for a wide audience of specialists in physical chemistry of the disordered state; it can also be of use for postgraduate students, masters, and undergraduate students specialized in this field.
