A single impregnation of supports also gives active alkylation catalysts (SZS-19-1 and SZA-11-1 samples) when the content of applied ZrO_2 lies within the limits of the optimal interval 10–20 wt % we found (Table 4). An HREM analysis of these samples (Fig. 2d) showed their structural identity with the catalysts prepared by multistage application of ZrO_2. Detailed data on acid-base and catalytic properties of these catalysts are listed in Tables 5 and 6. For comparison, data for bulk SZ prepared under the similar conditions are also presented.

According to XPA data, bulk sulfated ZrO_2 is a mixture of monoclinic and tetragonal modifications of zirconium dioxide in approximate ratio of 3 : 1, with ZrO_2 particle size of about 8 nm. Broadening of the peak bases in the diffraction patterns indicates the presence of an X-ray-amorphous phase (up to 10%). This phase may consist of less than 2–3-nm ZrO_2 crystallites and contain strongly disordered ZrO_2 structures.

All the catalysts are characterized by virtually the same strength and concentration of BACs. The content of strong LACs substantially exceeds the content of proton-donor centers. The greatest difference is observed for bulk SZ: the LAC concentration exceeds by approximately a factor of 7 the concentration of BACs. For SZS-19-1 and SZA-11-1 samples, the LAC-to-BAC ratio is 3–4. The total content of LACs on the surface of the bulk catalyst is also two times greater than that on supported catalysts. The 2190–2207 cm^{-1} range corresponds to CO adsorption on coordination-unsaturated Zr^{4+} ions situated at crystal defects and on more ordered surfaces [23, 24]. All the catalysts have close amounts of the strongest LACs (Zr^{4+}), which form complexes with CO with absorption at 2204–2207 cm^{-1}. The concentrations of

medium-strength centers (CO absorption at 2195–2200 cm^{-1}) are also comparable. However, bulk SZ also contains weak LACs (Zr^{4+}) with CO absorption band at 2191 cm^{-1} in approximately the same amounts (283 $\mu mol\ g^{-1}$). On the surface of the SZA-11-1 sample, there are very strong LACs (ν_{CO} = 2223 cm^{-1}) corresponding to Al^{3+} ions, but in very small amounts (8 $\mu mol\ g^{-1}$). Thus, compared with bulk SZ, the supported catalysts exhibit narrower and more uniform distribution of the surface acid centers. In accordance with [24, 25], specifically the surface LACs of the SZ catalysts directly participate in activation of alkanes. In isoparaffin alkylation, LACs can provide the so-called "hydride transfer," which determines stages of initiation and chain transfer in the course of the reaction [26].

All the catalysts are characterized by high activity in alkytation. At feeds of 0.1 to 0.2 g of butenes per gram of catalyst, they ensure complete conversion of butene and a yield of liquid alkylate (C_{5+} product) of no less than 1.7–1.8 g per gram of converted butenes, which amounts to about 80–90% of the calculated value, which is equal to 2.04 $g\ g^{-1}$. However, for the SZA-11-1 sample, the initial concentration of the catalyst is in excess with respect to the alkylation reaction, which is expressed in an overstoichiometric yield of hydrocarbons C_{5+} (up to 2.4 $g\ g^{-1}$), probably due to the so-called autoalkylation of isobutane [27].

During the reaction run, the degree of butene conversion and alkylate yield decrease rapidly on all the catalysts. At feed of 0.4 g of butenes per gram of catalyst, the butene conversion is 80–86%, and the yield C_{5+} hydrocarbons, about 1.4–1.5 $g\ g^{-1}$. The observed changes in the composition of the products are mainly associated with increasing content of heavy hydrocarbons containing more than eight carbon atoms. In accordance with the classical carbenium-ion alkylation mechanism [27], this indicates that, instead of formation of C_8 isoparaffin via abstraction of a hydride ion from the isobutane molecule, the intermediate cation C_{8+} reacts with one more or several butene molecules. This is responsible for the increased content of heavy products, decreased conversion of isobutane, and, correspondingly, lower yield of alkylation products. Thus, during deactivation of catalyst active centers, the alkylation of isobutane with butenes transforms into butene oligomerization.

The SZS-19-1 catalyst is most selective with respect to products and provides virtually the same alkylation parameters as traditional liquid acids [27]: isoparaffins C_8 constitute no less than 75–80 wt % of the liquid alkylate at average ratio of trimethylpentanes (TMP) to dimethylhexanes (DMH) of about 6, whereas the fraction of light paraffins C_5-C_7 is about 11 wt %. The samples of bulk SZ and SZ supported on aluminum oxide are characterized by elevated cracking power, which follows from the high content of the light fraction C_5–C_7. In addition, the SZA11-1 catalyst gives substantial amounts of DMH and other weakly branched octanes (20% and higher), which strongly affects the octane characteristics of the alkylate.

CONCLUSIONS

(1) Application of 10–20% sulfated zirconia (in terms of ZrO_2) on silica gel or aluminum oxide allows preparation of catalysts for isobutane alkylation with butenes. These catalysts are not inferior in activity to bulk zirconium sulfate catalysts. The activity of the supported catalysts is determined by crystalline phases of sulfated ZrO_2. Dispergation of SZ on the support surface provides attainment of the acid properties of the supported catalyst on the level of the bulk catalyst. The more uniform distribution of strong acid centers in the supported catalysts based on silica gel ensures highly selective alkylation.

(2) Despite the relatively short uninterrupted working life of the above catalysts (0.5–1 t of liquid alkylate per 1 t of the catalysts), their effective industrial exploitation in the reactor-regenerator type process with continuous catalyst circulation is possible.

Catalytic Alkylation of 1-Naphthol with Methanol

A. A. Agaev and M. K. Nazarova

Sumgait State University, Sumgait, Azerbaijan

Received January 9, 2003

Abstract—The reaction of 1-naphthol with methanol in the presence of mordenite catalysts was studied. The synthesis conditions ensuring high yields of methylnaphthols, methylnaphthalenes, or methoxynaphthalene were determined.

Catalytic methylation of naphthols with methanol has been poorly studied. Both *C*-alkylation yielding methylnaphthols and *O*-alkylation yielding methoxynaphthalenes are possible. However, it has been reported [1, 2] that the reaction of naphthol with an excess of methanol mainly yields isomeric alkylnaphthalenes. Apparently, the reaction pathway and the composition of the products depend on the reaction conditions and catalysts used.

To examine the effect exerted by zeolite composition and reaction conditions on alkylation of 1-naphthol with methanol, we studied the catalytic properties of synthetic mordenites containing 0.1–5.0 wt % Ni(II).

EXPERIMENTAL

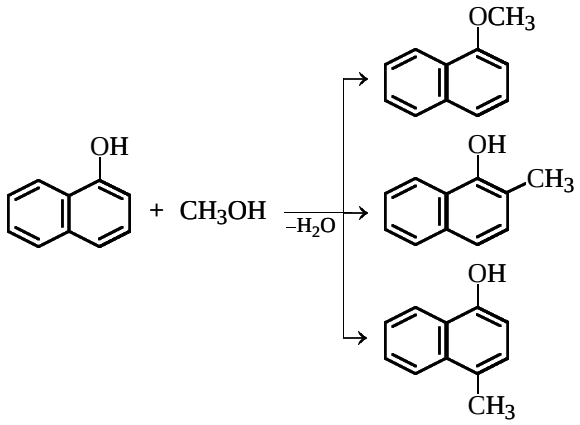
H-Mordenite was prepared by treatment of Na-mordenite ($SiO_2 : Al_2O_3 = 10$) with 1 N NH_4Cl and then with eight portions of 2 N HCl, followed by washing and drying. The nickel-containing zeolite was prepared by impregnation of H-mordenite with a calculated amount of an $Ni(NO_3)_2$ solution. The optimal content of Ni(II) in H-mordenite was 1.5 wt %.

The catalytic activity of zeolites was evaluated on a flow-through installation at atmospheric pressure. A 10-cm^3 portion of the catalyst was charged into reactor and heated for 5 h at 450°C in a flow of dry air and then for 3 h at 450°C in a hydrogen flow. The experiments were performed at 300–425°C, molar ratio 1-naphthol : CH_3OH = 1 : 7, and space velocity of 0.8–1.4 h^{-1}. The reaction products were analyzed on a Chrom-5 chromatograph; 3600 × 4-mm columns were packed with Chromosorb W containing 15 wt % Apiezon M as the stationary phase. The relative error of the analysis did not exceed 3.0%. The IR spectra of individual reaction products were measured on an M-80 spectrometer.

In contrast to the initial Na-mordenite, on which 1-naphthol undergoes virtually no chemical transformations, the naphthol conversion on H-mordenite is significant.

The reaction of 1-naphthol with methanol follows three major pathways: etherification, ring methylation, and self-condensation. In the reaction products, we detected 1-methoxynaphthalene, 2- and 4-methyl-1-naphthols, methylnaphthalenes, and high-carbon compounds.

At low temperatures (320–380°C), the major pathway is electrophilic methylation of the 1-naphthol core at 2- and 4-positions to form the corresponding methylnaphthols. At higher temperatures (380–420°C), the contribution of dehydroxylation accompanying ring methylation increases in the presence of H-mordenite, and methylnaphthalenes become the major products. At moderate temperatures, appreciable amounts of 1-methoxynaphthalene are formed, apparently by the competing *O*-methylation pathway:



The table shows that introduction of Ni(II) into H-mordenite noticeably enhances its catalytic properties in alkylation of 1-naphthol with methanol. In the range 320–360°C, the major reaction products are 1-methoxynaphthalene and 2- and 4-methylnaphthols; the total selectivity of their formation is 91.3–96.4%.

Alkylation of 1-naphthol with methanol in the presence of H- and Ni,H-mordenite (molar ratio 1-naphthol : methanol = 1 : 7)

Parameter	H-Mordenite					Ni,H-Mordenite				
Temperature, °C	320	360	380	420	360	320	360	380	420	360
Space velocity, h^{-1}	1.0	1.0	1.0	1.0	1.4	1.0	1.0	1.0	1.0	1.2
Yield of reaction products based on converted 1-naphthol, %:										
1-methoxynaphthalene	26.8	10.2	4.6	–	10.0	38.5	11.1	5.0	–	12.0
2- and 4-methylnaphthols	40.0	42.1	32.4	11.7	50.3	56.2	80.2	77.7	20.5	84.4
methylnaphthalenes	17.7	44.2	55.1	77.9	36.5	–	4.7	10.0	71.1	2.0
condensation products	2.4	3.0	5.7	7.8	2.1	2.0	3.2	4.1	6.9	1.1
Conversion of 1-naphthol, %	22.2	39.0	46.5	57.7	28.5	15.0	33.8	40.0	51.1	30.0

Despite a certain decrease in the conversion of 1-naphthol, this catalytic system is more selective with respect to formation of 2- and 4-methyl-1-naphthols (56.2–84.4%).

In contrast to H-mordenite, the nickel-containing zeolite ensures highly selective (77.7%) formation of methyl homologs of 1-naphthol at 380°C. It should be noted that, above this temperature, the contribution of methylnaphthalene formation dramatically grows, and at 420°C methylnaphthalenes become the major reaction produts, as in the presence of H-mordenite. The methylnaphthalene fraction formed in the presence of both catalysts has a complex chemical composition. Its major components are 1,2-dimethylnaphthalene, 1,2,4- and 1,2,7-trimethylnaphthalenes, 1,2,4,7-tetramethylnaphthalene, and 1,2,3,4,6-pentamethylnaphthalene. Also detected are 2-methylnaphthalene, 1,2,3-trimethylnaphthalene, 1,2,3,4-tetramethylnaphthalene, and 1,2,3,4,6,7-hexamethylnaphthalene. In addition, the products contain 1-oxo-2,2-dimethyl-1,2-dihydronaphthalene and 1-oxo-4,4-dimethyl-1,4-dihydronaphthalene, which, along with naphthol methyl derivatives, may be intermediates in formation of methylnaphthalenes.

The acid centers present on the H-mordenite surface promote a number of parallel and consecutive reactions, which leads to a decrease in the selectivity with respect to the target products. The increased selectivity of Ni,H-mordenite with respect to methylnaphthols is probably due to favorable changes in the acidity of the H-mordenite surface upon modification with Ni(II). With the Ni-modified catalyst, formation of methylnaphthalenes is fully or largely suppressed. Modification with Ni(II) also makes the catalyst more stable as compared with H-mordenite (the stable working life of the catalyst increases from 5 to 50 h and more) and affects the isomeric composition of methylnaphthols.

Figures 1a and 1b show how the content of 2-methyl-1-naphthol in its mixture with 4-methyl-1-naphthol

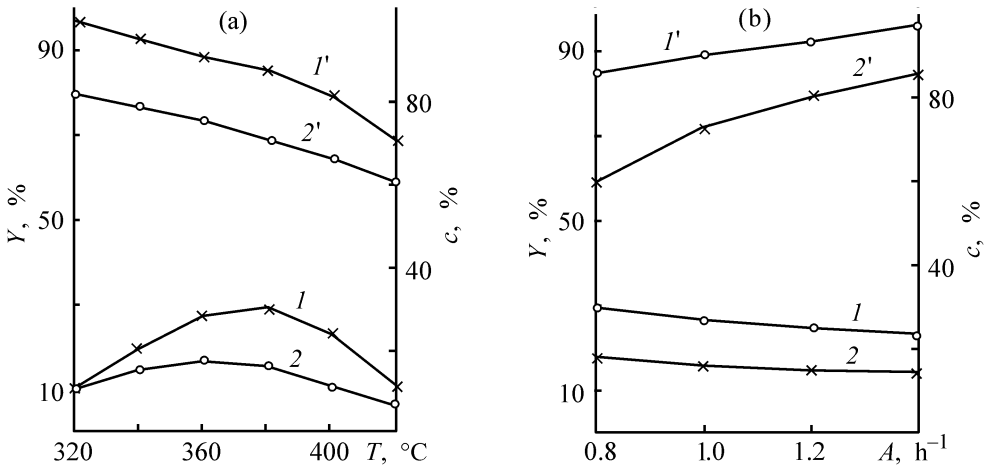

Fig. 1. Influence of (a) temperature *T* and (b) space velocity *A* on the (*1*, *2*) total yield of 2- and 4-methyl-1-naphthols, *Y*, based on the naphthol taken into the reaction and (*1*′, *2*′) content *c* of 2-methyl-1-naphthol in its mixture with 4-methyl-1-naphthol. Catalyst: (*1*, *1*′) N,H-mordenite and (*2*, *2*′) H-mordenite.

and the total yield of methyl homologs of 1-naphthol, based on the naphthol taken into the reaction, depend on the temperature and space velocity, with H- and Ni,H-mordenites as catalysts. It is seen that, as the temperature is increased from 320 to 360 (in the case of H-mordenite) or to 380°C (in the case of Ni,H-mordenite), the yield of methylnaphthols, based on the naphthol taken into the reaction, grows to become 16.4 and 31.1%, respectively. At 420°C, this parameter decreases on both catalysts. Raising the reaction temperature from 320 to 420°C also decreases the content of 2-methyl-1-naphthol in its mixture with the 4-methyl isomer. Raising the space velocity from 0.8 to 1.4 h^{-1} decreases the yield of methylnaphthols based on the 1-naphthol taken into the reaction, with the content of 2-methyl-1-naphthol in its mixture with the 4-methyl isomer growing for both catalysts. Introduction of 1.5 wt % Ni(II) into H-mordenite increases the content of 2-methyl-1-naphthol relative to 4-methyl-1-naphthol (Figs. 1a, 1b). It is seen that, in the presence of Ni,H-mordenite, the *ortho* isomer becomes prevailing in the target methylnaphthol fraction. With increasing space velocity, the content of the *ortho* isomer varies less significantly than in the presence of H-mordenite. Figure 1b shows that, with the space velocity increasing from 0.8 to 1.4 h^{-1}, the content of 2-methyl-1-naphthol in its mixture with the 4-methyl isomer grows by 24.5% on H-mordenite and by only 9.3% on Ni,H-mordenite.

Thus, our resuts suggest that the major pathway of the reaction of 1-naphthol with methanol on mordenite catalysts at 320–380°C is C-alkylation at the 2- and 4-positions. Na,H-Mordenite is more selective with respect to formation of the *ortho* isomer.

CONCLUSIONS

(1) Mordenite catalysts show high activity in reaction of 1-naphthol with methanol.

(2) By varying the reaction conditions and catalyst composition, it is possible to prepare methylnaphthols or methylnaphthalenes, and, if required, also 1-methoxynaphthalene in high yields.

CATALYSIS

Plasma-Enhanced Catalytic Oxidation of Carbon Monoxide

V. I. Grinevich, N. V. Ivanova, and V. V. Kostrov

Ivanov State University of Chemical Engineering, Ivanovo, Russia

Received October 9, 2002

Abstract—Data on the kinetics of plasma-enhanced and plasma-enhanced catalytic oxidation of carbon(II) oxide with IK-1-6 catalyst are presented. The influence exerted by IK-1-6 catalyst on the conversion of carbon-containing components of the $CO–CO_2–CH_4–SO_2$–air gas mixture in barrier-discharge plasma is analyzed.

Methods using fast-electron beams or low-temperature plasma (barrier or corona discharge) to initiate oxidation are presently recognized as promising methods for purification of exhaust gases of thermal power plants and internal-combustion engines, with the plasma activation being, as a rule, more advantageous energetically [1]. Combining the action of nonequilibrium plasma on the gas mixtures with the activating properties of catalysts may lead to a decrease in energy expenditure and increase in the process rate and degree of conversion. However, data on the kinetics of plasma-enhanced catalytic oxidation, and all the more, on their mechanisms, are scarce. Therefore, a study of the conversion of the main components of real exhaust gases or model gas mixtures in barrier-discharge (BD) plasma and in a combined plasma-enhanced catalytic process is a topical task.

The aim of this study was to analyze the processes of plasma-enhanced catalytic oxidation of carbon monoxide in various gas mixtures.

EXPERIMENTAL

As test objects were chosen gas mixtures of composition (vol %): $CO–O_2$–He (CO 6, O_2 24, and He 70), $CO–CO_2–SO_2$–air (CO 5.84, CO_2 0.16, and SO_2 0.10), and $CO–CO_2–CH_4–SO_2$–air (CO 0.74, CO_2 17, SO_2 0.10, and CH_4 0.26). The initial gas mixture was fed at a certain rate into the discharge cell, where a barrier discharge was excited at atmospheric pressure. The reactor was in the form of two coaxial cylinders, one of which (outer) was made of molybdenum glass (dielectric barrier), and the other (inner electrode), of an aluminum alloy [2]. The thicknesses of the dielectric layer (S-49 glass) and air layer between the electrodes were the same in all the experiments (1.5 and 3 mm, respectively). The discharge was excited with a high-voltage transformer (ac frequency 50 Hz,) at a voltage varied within the range 12–16 kV. The discharge current was monitored with an oscilloscope.

Plasma-enhanced catalytic processes were studied with an IK-1-6 ($V_2O_5 \cdot K_2O/SiO_2$) commercial catalyst [3]. The catalyst (grain size 1.0–1.6 mm) was placed in the plasma zone and fixed there with fluoroplastic rings with holes for the gas mixture to flow. The concentration of CO, CO_2, and CH_4 in the initial gas mixture and at the reactor outlet was monitored chromatographically [4] (LKhM–80 chromatograph with heat-conductivity detector, carrier gas helium), and the SO_2 concentration, photometrically, using a standard procedure [5]. The gas flow rate was varied from 0.08 to 0.63 $cm^3\ s^{-1}$, which corresponded to 20 to 120 s of contact of the gas with the plasma. The random error in measuring the CO, CO_2, and CH_4 concentrations in a set of runs was no more than 30% at confidence probability of 0.95.

One of parameters determining the kinetics of processes occurring in BD plasma is the plasma dose D (mA s cm^{-2}), related to the current density j and to the time τ_c of contact between gas and plasma by

$$D = j\tau_c.$$

The plasma dose was varied within 0.1–2.0 mA s cm^{-2}.

It is known that use of BD leads to rather high degrees of carbon(II) oxide conversion in stoichiometric mixtures with an oxidant [6]. Measurements of the

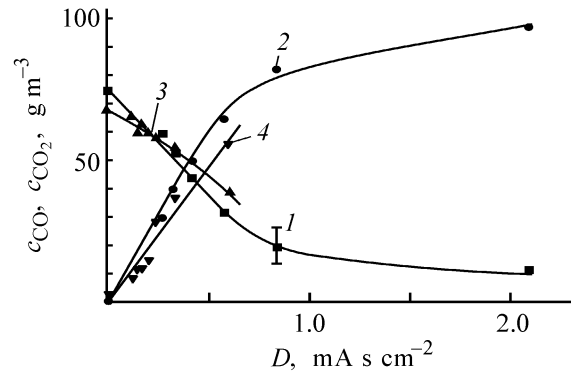

Fig. 1. CO and CO_2 concentrations c_{CO} and c_{CO_2} at the exit from the discharge zone vs. plasma dose *D*. Gas mixture: (*1*) CO (CO–O_2–He), (*2*) CO_2 (CO–O_2–He), (*3*) CO (CO–CO_2–SO_2–air), and (*4*) CO_2 (CO–CO_2–SO_2–air).

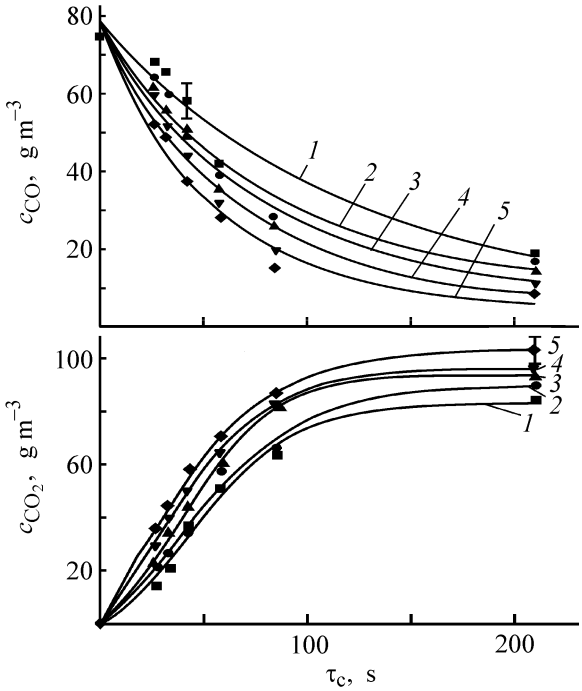

Fig. 2. CO and CO_2 concentrations c_{CO} and c_{CO_2} vs. the time of contact τ_c between gas and plasma at various voltages applied. Voltage (kV): (*1*) 12, (*2*) 13.5, (*3*) 15, (*4*) 16, and (*5*) 17.

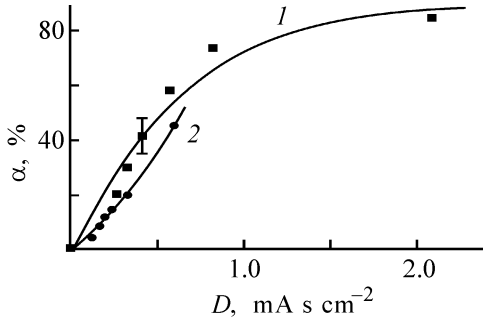

Fig. 3. Degree of CO conversion, α, at various plasma doses *D*. Gas mixture: (*1*) CO–O_2–He, and (*2*) CO–CO_2–SO_2–air.

CO and CO_2 concentrations in the CO–O_2–He mixture at the exit from the discharge zone showed that, with increasing plasma dose, the CO concentration decreases from 74.5 to 11.18 g m^{-3} (i.e., by a factor of 6), and the CO_2 concentration increases (Fig. 1). The CO_2 yield and the decrease in the CO concentration are not affected by the voltage (or power) applied within the experimental error (Fig. 2). The CO concentration in the CO–CO_2–SO_2–air mixture subjected to plasma treatment also decreases from 68 to 38.1 g m^{-3} (i.e., by a factor of 1.8), with a simultaneous increase in the CO_2 concentration (Fig. 1). The carbon monoxide treated with the BD plasma in a mixture with O_2 and He is easily converted into CO_2, with the degree of conversion as high as 80% at the maximum plasma dose (2.0 mA s cm^{-2}) (Fig. 3). In the CO–CO_2–SO_2–air mixture, the maximum degree of conversion of 44% is attained at a plasma dose of 0.63 mA s cm^{-2}. However, the degrees of the CO conversion in the gas mixtures indicated (CO–O_2–He and CO–CO_2–SO_2–air) coincide to within the measurement error at the same plasma doses.

In the CO–O_2–He mixture, the carbon balance (amount of CO converted into CO_2) is observed to within 19% at a short time of contact between gas and plasma and to within 5% at long time of contact. The fact that the carbon balance is observed with rather good accuracy shows that the CO conversion in BD plasma is mainly associated with of CO_2 formation. To a first approximation, formation of other carbon-containing compounds can be neglected. For the CO–CO_2–SO_2–air mixture, the total content of carbon in the system (before and after plasma treatment) remains constant to within 6% at all plasma doses, and the carbon balance is observed to within, on the average, 17%, which does not go beyond the measurement error.

In the general case, the CO oxidation is described satisfactorily by a first-order reaction equation with effective rate constant of 0.005 s^{-1} (for CO–CO_2–SO_2–air) or 0.016 s^{-1} (for CO–O_2–He).

In plasma treatment of CO-containing gas mixtures, the degree of dissociation and the reaction products depend on the composition of a plasma-forming gas and discharge parameters [7]. The action of BD plasma on the CO–CO_2–CH_4–SO_2–air mixture results in that the CO concentration in the mixture grows, compared with the initial concentration, with increasing plasma dose. This is due to the fact that the CO_2 concentration in the mixture exceeds the CO concen-

tration by a factor of 23. Under the action of active species (e.g., free electrons) carbon dioxide dissociates into CO (Fig. 4), and the total content of carbon in the system remains unchanged within the measurement error (no more than 7%) at any plasma dose. If it is assumed that, in the given case, the conversion of the carbon-containing compounds is described by the reactions:

$$CO_2 \rightarrow CO + O,\ CH_4 \rightarrow CO + 2H_2O,$$

then the mass of carbon in the output part of the (CO_2 + CH_4) balance equation will be considerably higher (by a factor of 2–3.5, depending on plasma dose) than the mass in the input part (CO). This means that, alongside with CO_2 conversion into CO (methane contribution to the carbon unbalance is insignificant), there exists at least one more reaction channel. In fact, the set of reactions occurring in plasma is very large. To these belong reverse processes, reactions involving electron-excited species, and those with ozone. Carbon suboxide C_2O_3, carbonyl compounds, compounds with double C=C bond, acetylene, and alcohols can be formed in BD plasma [8]. Among the intermediate products of plasma-enhanced CH_4 oxidation may be aldehydes and alcohols, the possible final products are CO_2 and H_2O. A qualitative reaction for formaldehyde demonstrated its total absence to within the detection sensitivity of the method (less than 0.01 mg m^{-3}). At the same time, appearance of other products of CO_2 and CH_4 conversion, such as carbon suboxide, carbon, and saturated hydrocarbons, cannot be ruled out. Probably, formation of intermediates in the conditions under consideration is not a rate-determining stage. The role of the latter is played by oxidation-initiating reactions, i.e., by the interaction of initial compounds with active species of the plasma.

The reactions of CH_4 oxidation, CO formation, and CO_2 dissociation are satisfactorily described by first-order equations with effective constant of 0.01, 0.004, and 0.0007 s^{-1}, respectively.

To accelerate the CO and SO_2 oxidation in air, the IK-1-6 commercial catalyst was introduced into the plasma zone. The experiments showed that, in a combined plasma-enhanced catalytic process (CO–CO_2–SO_2–air mixture), the degrees of CO conversion are the same as those observed in plasma-enhanced oxidation. This may be due to low efficiency of the given catalyst in CO and CO_2 conversion. Similarly to plasma-enhanced oxidation, combined plasma-enhanced catalytic process is characterized by carbon

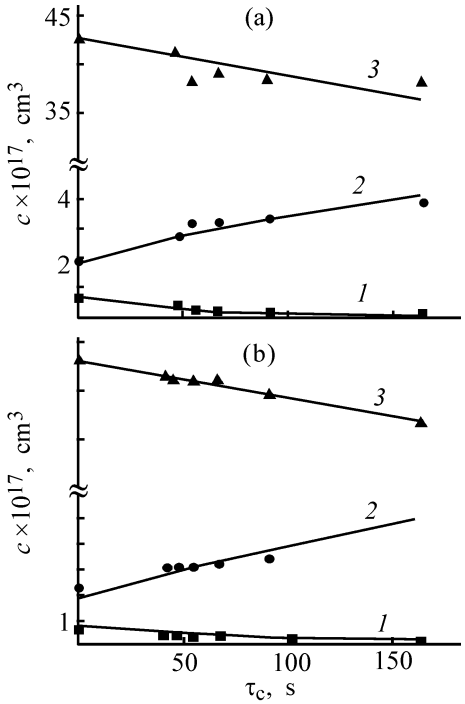

Fig. 4. Kinetics of variation of the concentrations c of carbon-containing components of the CO–CO_2–CH_4–SO_2–air gas mixture in (a) plasma-enhanced oxidation and (b) plasma-enhanced catalytic process. (τ_c) Time of contact. (*1*) CH_4, (*2*) CO, and (*3*) CO_2. Points: experimental data, lines: results of model calculation.

balance observed to within 20% for all plasma doses. The fact that the carbon balance is observed with sufficient accuracy shows that CO_2 formation is the main channel of CO conversion. For the CO–CO_2–CH_4–SO_2–air mixture, the influence of the IK-1-6 catalyst on the efficiency of CO and CH_4 oxidation and CO_2 decomposition is virtually not manifested, either (Fig. 4). The effective rate constant of CH_4 oxidation is approximately twice that of CO formation (Table 1).

Table 1. Effective rate constants of conversion reactions in plasma-enhanced oxidation and plasma-enhanced catalytic process with IK-1-6 catalyst

Mixture composition	K(CO)	K(CO_2)	K(CH_4)	K(SO_2)
	s^{-1}			
CO–CO_2–SO_2–air	0.0050* 0.0045	0.025 0.022	– –	0.039 0.105
CO–CO_2–SO_2–CH_4–air	0.040 0.0055	0.0007 0.001	0.011 0.009	0.018 0.017

* Numerator, without catalyst; denominator, with catalyst.

Table 2. Effective rate constants calculated by parametric identification of the kinetic model for the gas mixture $CO–CO_2–SO_2–CH_4–air$

Process	K_1	K_2	K_3
	c^{-1}		
Plasma-enhanced	0.014	2.6×10^{-4}	6.9×10^{-4}
Plasma-enhanced catalytic (IK-1-6 catalyst)	0.010	4.1×10^{-4}	5.4×10^{-4}

In the plasma-enhanced catalytic process, similarly to plasma-enhanced oxidation, the SO_2 concentration at the reactor outlet decreases with increasing time of contact between the gas mixture and plasma. However, the oxidation of SO_2 is more efficient. The effective rate constant of SO_2 oxidation in the plasma-enhanced catalytic process was 0.105 s^{-1}, i.e., exceeded by approximately a factor of 2.7 that in plasma oxidation (Table 1). The degree of SO_2 conversion in the heterogeneous process grows to 99% with increasing plasma dose. In the $CO–CO_2–CH_4–SO_2–air$ mixture, the rate constant of SO_2 oxidation is independent of the presence of catalyst in the plasma zone and is lower by about a factor of 2 than that in the $CO–CO_2–SO_2–air$ mixture.

The conversion of carbon-containing compounds in a mixture $CO–CO_2–CH_4–SO_2–air$ can be represented by the following simplified scheme

$$CH_4 \xrightarrow{K_1} CO \xrightarrow{K_2} CO_2 \xrightarrow{K_3} \text{products},$$

which is described by a set of differential equations:

$$\begin{cases} \dfrac{dc_{CH_4}}{d\tau} = -K_1 c_{CH_4}, \\ \dfrac{dc_{CO_2}}{d\tau} = -(K_2 + K_3) c_{CO_2}, \\ \dfrac{dc_{CO}}{d\tau} = -K_1 c_{CH_4} + K_2 c_{CO_2}. \end{cases}$$

The rate constants of the elementary processes were estimated by means of parametric identification of kinetic models specified in the form:

$$dX/d\tau = f(X, \theta),\ X_{\tau=0} = X^0,\ Y = GX + \varepsilon,$$

where X is n-dimensional vector of state, Y and ε are m-dimensional vectors of the output and random noise, and θ is p-dimensional vector of the parameters being estimated.

The most plausible estimates of the parameters $\hat{\theta}$ were obtained using the Gauss–Newton method:

$$\hat{\theta}^{k+1} + \hat{\theta}^k + \rho_k P^k,$$

where k is the iteration number, ρ_k and P^k are the step and vector of descent in k-th iteration.

The results of the calculation are in good agreement with the experimental data.

Comparison of the effective rate constants calculated in terms (Table 2) of the given model shows that the rate of plasma-enhanced oxidation of methane without catalyst exceeds by a factor of 1.4 that in the combined plasma-enhanced catalytic process and the total rate of CO_2 dissociation is independent of whether a catalyst is present in the plasma or not. The effective rate constants of methane oxidation and overall dissociation of CO_2 ($K_2 + K_3$), found using the model, coincide with those obtained from kinetic dependences graphically (with the difference not exceeding 22% for methane and 26% for CO_2).

CONCLUSION

The results of the study performed show that the kinetics of CO oxidation is affected, both in plasma-enhanced oxidation and in plasma-enhanced catalytic process, by barrier-discharge parameters and composition of the model gas mixture. The presence in the gas mixture of such carbon-containing compounds as CO_2, CH_4, and SO_2 makes the efficiency of CO oxidation lower at the same parameters of barrier discharge. The obtained data on the kinetics of CO oxidation in the gas mixtures studied confirm the known mechanism of CO oxidation in barrier-discharge plasma.

CATALYSIS

Optimization of Synthesis of 2,4-Dinitrophenylhydrazones under Carbon Dioxide Pressure

A. P. Eremeev

Pod"emtransmash Open Joint-Stock Company, St. Petersburg, Russia

Received July 3, 2002; in final form, January 2003

Abstract—Catalytic synthesis of 2,4-dinitrophenylhydrazones formed in the aqueous reaction mixture of aliphatic and aromatic carbonyl derivatives with 2,4-dinitrophenylhydrazine in the presence of carbonic acid protons under pressure of the CO_2–H_2O a steam–gas mixture was studied for the example of synthesis of *p*-quinone–mono-2,4-dinitrophenylhydrazone.

Hydrazones are brightly colored (yellow to red) chemical products insoluble in water and soluble in polar organic solvents. Also, hydrazones are thermally stable up to their melting points and resistant to direct solar rays and ultraviolet radiation, acids, and oxygen, and act as microbiocides. All this makes hydrazones valuable for various chemical, chemical-engineering, medical, and hygienic applications. When introduced into protective organic-phase or water-dispersible paint-and-varnish and impregnating materials, hydrazones act as biocides and anticorrosives for wood and metals.

Previously, 2,4-dinitrophenylhydrazones have been synthesized in the presence of protons of a strong inorganic acid [1]. A drawback of this process is the need to treat ready-for-use products with an alkali solution to neutralize the residual acid and to additionally wash them with water to completely remove the forming salts, which leads to a loss of up to 10% of the target product.

In this study, we suggested to catalyze the process of interest with carbonic acid formed under carbon dioxide pressure in an aqueous pulp of the reaction mass. We expected that the product to be isolated from the reactor after the condensation of 2,4-dinitrophenylhydrazone with a carbonyl derivative is complete and the carbon dioxide pressure is relieved will not require additional treatment to remove acid, since carbonic acid decomposes and carbon dioxide volatilizes upon completion of the process.

EXPERIMENTAL

In our experiments, we used an RTsG-1.6-10-1k-01 1.6-l autoclave* [TU (Technical Specifications) 26-01-476–85] made of 12Cr18Ni10Ti steel (filling factor 0.7, working pressure up to 100 MPa, temperature up to 300°C) equipped with an impeller-type stirrer (3000 rpm). We used carbon dioxide from cylinders and the following chemicals: 2,4-dinitrophenylhydrazine DNPH (pure grade, TU 6-09-2894–72) and *p*-benzoquinone (PBQ, pure grade, TU 6-09-156–76) in a 1 : 1 molar ratio and also other carbonyl derivatives (RHCO or RR'CO with R or R' = Alk or Ar).

The condensation of DNPH with PBQ to form 2,4-dinitrophenylhydrazone (DNPHN) was studied using the design matrix of full-factorial experiment (FFE-2^3) [2] with varied physical factors: X_1 for the carbon dioxide pressure, MPa (lower level 0.5, upper level 2.5); X_2 for the reaction time, *h* (0.5, 3.5); and X_3 for the reaction mass temperature, °C (50, 80). After isolation from the reaction mass, DNPH was dried at 105°C and weighed, whereupon the yield (% of the theoretical value) was estimated.

The regression equation with the coefficients calculated by the Yates method [2] adequately describes the experimental responses for FFE-2^3 ($Y_i \pm \Delta Y_i = \hat{Y}_i \pm 1.2$ at $p = 0.95$, $f = 2$, $s^2 = 0.5$):

$$\hat{Y}_i = 44.9 + 25.3X_1 + 4.9X_2 + 14.9X_3 + 8.5X_1X_3. \quad (1)$$

In Eq. (1), the pair interaction effect X_1X_3 proved to be significant, in agreement with the local optimum of the DNPH–PBQ condensation, which is determined primarily by the concentration of protons and temperature X_3, and to a lesser extent by the reaction time X_2. This corresponds to the reaction mechanism analogous to that describing the influence of strong acid protons [1, 3] in accordance with the reactions

$$RR'CO + H^+ \rightleftarrows RR'(OH)C^+, \quad (2)$$

* Manufactured by the Staraya Russa Chemical Machine Building Plant.

1070-4272/03/7604-0566 $25.00 © 2003 MAIK "Nauka/Interperiodica"

$$Ph(NO_2)_2NHNH_2 + RR'(OH)C^+ \rightleftarrows [Ph(NO_2)_2NHNH_2C(OH)RR']^+, \quad (3)$$

$$[Ph(NO_2)NHNH_2C(OH)RR'] \rightleftarrows RR'C{=}NNHPh(NO_2) + H^+ + H_2O. \quad (4)$$

The significance of the time factor X_2 is determined by the fact that the reactions are diffusion-controlled and occur at the DNPH | DNPHN | PBQ | water interface in the pulp of the reaction mass, which is saturated with protons, after the necessary degree of hydrolysis of carbon dioxide by the reaction

$$CO_2 + H_2O \rightleftarrows H^+ + HCO_3^- \rightleftarrows 2H^+ + CO_3^{2-} \quad (5)$$

is attained under the optimal conditions as determined by the X_1 and X_3 factors.

The process becomes predominantly kinetically controlled [reactions (2)–(4)] under conditions of vigorous stirring, which continuously renew the DNPH solid particle surface, thereby making it accessible to an attack by protonated molecules of the carbonyl derivative dissolved in water. Thus, DNPHN (a loose product formed on the DNPH particle surface) is removed from the reaction zone owing to constant abrasive collisions of the DNPH particles getting overgrown with a DNPHN layer.

The behavior of the response surface was visualized as the geometric image of the pair interaction [4, 5], using the regression equation

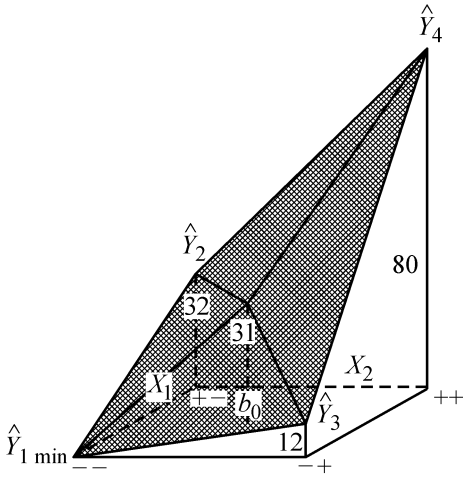
$$\hat{Y}_i = 45 + 25X_1 + 15X_3 + 9X_1X_3, \quad (6)$$

incorporating significant effects of factors entering into the X_1X_3 pair interaction.

The 3D diagram of the response surface of the X_1X_3 pair interaction effect presented in the figure suggests the following.

(1) When the X_1 factor changes from the lower (X_1^- = 5 MPa) to upper (X_1^+ = 20 MPa) level at fixed lower level (X_3^- = 0.5 h) of the X_3 factor, the response changes by $\Delta\hat{Y}_1 = |\hat{Y}_1 - \hat{Y}_2| = 32\%$, i.e., the product yield grows by 32% when the carbon dioxide pressure is raised, owing to an increase in the concentration of protons in the reaction mass via reaction (5).

(2) When the X_1 factor changes from the lower (X_1^- = 5 MPa) to upper (X_1^+ = 20 MPa) level at fixed higher level (X_3^+ = 1 h) of the X_3 factor, the response changes by $\Delta\hat{Y}_3 = |\hat{Y}_3 - \hat{Y}_4| = |12 - 80| =$ 68%, i.e., the product yield increases by 68% (in proportion to the doubled reaction time). This suggests the rates of reactions (2)–(4) are invariable for a given chemical system under the chosen synthesis conditions.



3D diagram of the response surface for X_1X_3 pair interaction. $b_0 = \hat{Y}_0 - \hat{Y}_{\min} = 45 - 14 = 31$. $\hat{Y}_i$ = 12, 32, 80.

(3) When the X_3 factor changes from the lower (X_3^- = 0.5 h) to upper (X_3^+ = 1 h) level at fixed lower level (X_1^- = 5 MPa) of the X_1 factor, the response changes by $\Delta\hat{Y}_2 = |\hat{Y}_1 - \hat{Y}_3| = |0 - 12| =$ 12%, i.e., the product yield increases by 12% only, owing to a low concentration of protons under decreased carbon dioxide pressure and to insufficient shift of equilibrium (5) to the right.

(4) When the X_3 factor changes from the lower (X_3^- = 0.5 h) to upper (X_3^+ = 1 h) level at fixed higher level (X_1^+ = 20 MPa) of the X_1 factor, the response changes by $\Delta\hat{Y}_4 = |\hat{Y}_2 - \hat{Y}_4| = |80 - 32| =$ 48%, i.e., the product yield increases by 48%, which is virtually proportional to the reaction time doubled for chemical reactions (2)–(4).

Thus, the interaction of the upper levels of factors X_1X_3 ensures the optimal influence of these factors on the product synthesis. This can be accounted for by a strong shift to the right of the equilibrium in reaction (2), owing both to an increase in the carbon dioxide pressure and, hence, in the proton concentration [reaction (5)] and to rise in temperature, which favors reactions (3) and (4). This stabilizes the shift of the equilibria of reactions (2), (3), and (5) at a level at which the main reaction (4) proceeds in the optimal regime with high yield of *p*-quinonemono-2,4-dinitrophenylhydrazone (99.95%).

The experimental results for DNPH–PBQ condensation under the optimal conditions we found were extended to some other commercial aliphatic and aromatic carbonyl derivatives. The yields of the corresponding 2,4-dinitrophenylhydrazones (% of the theoretical value) were as follows: anisaldehyde 99.7, acetone 99.2, benzaldehyde 99.5, isobutyraldehyde 99.6, methyl ethyl ketone 99.2, *m*-nitrobenzaldehyde 99.4, salicylicaldehyde 99.3, and cyclohexanone 99.5.

CONCLUSIONS

(1) A full-factorial experiment on condensation of 2,4-dinitrophenylhydrazine with *p*-benzoquinone to *p*-quinone mono-2,4-dinitrophenylhydrazone suggests that synthesis of hydrazones can be catalyzed by protons of carbonic acid formed in the aqueous pulp of the reaction mass via hydrolysis of dissolved carbon dioxide under a pressure of the CO_2–H_2O steam–gas mixture.

(2) The optimal conditions were found for synthesis of *p*-quinone mono-2,4-dinitrophenylhydrazone: pressure $P \geq 2.5$ MPa, temperature $T \geq 80$°C, condensation time $\tau \geq 1$ h.

(3) The 3D diagram of the response surface and the revealed regression effect of the X_1X_3 pair interaction (total pressure of the steam–gas mixture in the autoclave X_1 and the reaction mass temperature X_3) confirms that the proton catalysis mechanism of condensation of 2,4-dinitrophenylhydrazine with *p*-benzoquinone is similar to that revealed previously for strong inorganic and organic acids.

(4) The condensation reaction studied is suitable for synthesizing 2,4-dinitrophenylhydrazones from aliphatic and aromatic carbonyl derivatives in high yield (99.3–99.7%).

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Low-Selective GaAs and GaSb Semiconductor Sensors for Potentiometric Analysis of Liquid Media

Yu. G. Vlasov, V. A. Burakhta, and Yu. E. Ermolenko

St. Petersburg State University, St. Petersburg, Russia

Received February 13, 2003

Abstract—The possibility of using low-selective sensors based on gallium arsenide and gallium antimonide semiconductor compounds as indicators in acid–base, precipitating, and complexometric titration in model multicomponent systems and natural water was studied.

Chemical sensors can be used as a convenient analytical tool in comprehensive ecological monitoring of the environment [1].

At present, the design of chemical sensors is heading in several directions consisting in fabrication of increasingly selective sensors, on the one hand, and development of a multisensor approach employing low-selective sensors, on the other [2]. In analysis of multicomponent systems, to which environmental objects mostly belong, high-selective sensors pose certain difficulties associated with their insufficient selective [2]. Use of a multisensor system of the "electronic tongue" type, which combines an array of various low-selective sensors with high cross sensitivity, enables successful multicomponent quantitative analysis of complex liquids, e.g., technological electrolyte solutions [3]. The created multisensor systems with chalcogenide-glass electrodes characterized by high stability and reproducibility have been tested on model solutions in order to enable their further use in determining heavy-metal cations (Cu^{2+}, Zn^{2+}, Pb^{2+}, and Cd^{2+}) and inorganic anions (Cl^-, F^-, and SO_4^{2-}) in natural and waste water [4, 5]. Use of different sensors in combination with mathematical processing of signals by the image recognition procedure employing, e.g., artificial neural networks makes it possible to overcome the problem of sensor selective, which predominates in analysis of multicomponent solutions in the presence of a great number of interfering ions.

Another promising approach to solving the low selective problem is to use a single semiconductor sensor sensitive to a number of ions for determining several components in complex aqueous systems, with the known methods of potentiometric titration employed.

This study is concerned with the possibility of applying single low-selective semiconductor sensors and methods of potentiometric titration for analyzing such complex solutions as natural water.

EXPERIMENTAL

Potentiometric titration was performed on an EV–74 ion-meter. An EVL–IM3 silver chloride electrode served as reference. As indicator electrodes were studied electrochemical sensors based on semiconductor compounds gallium arsenide (GaAs) and gallium antimonide (GaSb), fabricated in the form of solid contact electrodes. The semiconductor compounds were single crystals grown by the Czochralski technique [6]. When passing in potentiometric titration from one type of ions to another, the electrodes were polished with thin emery paper, washed with distilled water, and wiped dry with filtering paper. Between measurements, the electrodes were stored in air. It has been found previously in preliminary experiments that GaAs and GaSb semiconductor sensors are sensitive in solutions to different ions and, consequently, are low-selective sensors.

For comparison, ion-selective electrodes based on heavy-metal chalcogenides: silver-selective electrode AgSE with Ag_2S membrane, copper-selective electrode CuSE with Ag_2S–CuS membrane, chloride-selective electrode ClSE with Ag_2S–AgCl membrane, and ESL–63–07 glass electrode were also used as indicator electrodes.

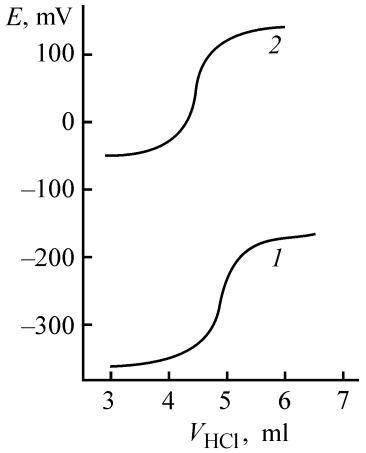

Fig. 1. Curves of potentiometric titration of a $NaHCO_3$ standard solution with a 0.1 N HCl solution (*1*) GaSb sensor and (*2*) glass electrode. (*E*) Potential and (V_{HCl}) titrant volume; the same for Fig. 2.

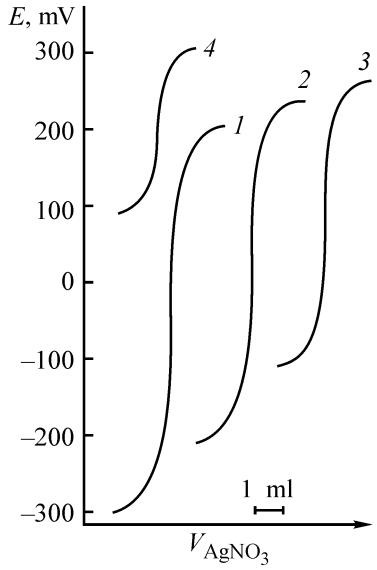

Fig. 2. Curves of potentiometric titration of KCl model solution with a 0.1 N $AgNO_3$ solution, with (*1–3*) GaAs electrode and (*4*) ClSE. Titration: (*1*) first, (*2*) second, and (*3*) third.

As model solution for potentiometric titration served 0.1 N solutions of $NaHCO_3$, KCl, and EDTA, prepared from fixanals. As titrants were used 0.1 N solutions of HCl, $AgNO_3$, and $CuSO_4$.

The possibility of using semiconductor sensors as indicators in acid–base titration was studied with standard solutions of sodium hydrocarbonate. An ESL–63–07 glass electrode served as a standard. The curves of potentiometric titration of a $NaHCO_3$ solution with a 0.1 N HCl solution, shown in Fig. 1, exhibit pronounced potential jump near the final titration point for both glass and GaSb indicator electrodes, with the titration curve measured using a GaSb electrode shifted toward negative potentials. The magnitudes of the potential jumps are the same for both types of electrodes, i.e., semiconductor sensors can be used along with the conventional glass electrodes.

It was established for gallium arsenide and gallium antimonide indicator electrodes used to determine chloride ions by precipitating titration with $AgNO_3$ solution that the end point of titration is clearly recorded with a GaAs electrode. Titration of KCl model solutions can be considered as an example (Fig. 2). As seen, the potential jump corresponding to chloride ions is the most pronounced for sensors with freshly polished surface (curve *1*). When a sensor is used for titration of chloride ions for the second time without preliminary polishing, the titration curve (curve *2*) shifts to more positive potentials, which is a characteristic of a chloride-selective electrode (curve *4*).

After third titration of a KCl solution with $AgNO_3$ solution, using a GaAs electrode having unfreshened surface, the titration curve is shifted to even greater extent to the range of positive potentials, with the magnitude of the potential jump approaching that for ClSE (curve *3*). After three or four successive titrations with GaAs electrode having unpolished surface, the magnitude of the potential jump becomes virtually constant and the titration curve remains in a strictly fixed range of potentials from –150 to +250 mV. When the surface of the semiconductor electrode is freshened with thin emery paper, the first part of the titration curve, which corresponds to the reaction $Cl^- + Ag^+ \rightarrow AgCl\downarrow$, is again markedly shifted to negative potentials to –300 mV. In the course of titration, Ag^+ and Cl^- ions are chemisorbed to give a poorly soluble compound AgCl on the surface. The thus self-modified GaAs sensor ensures a stable potential jump near the end point of titration. The magnitude of this jump exceeds that for the chloride-selective electrode by a factor of 2, which makes it possible to determine the end of titration with high accuracy.

The sensors based on GaAs and GaSb semiconductor compounds were studied in a complexometric titration. The potential jumps obtained for a standard EDTA solution titrated with 0.1 N $CuSO_4$ solution with the semiconductor sensors and the conventional copper-selective electrode do not differ significantly. The potentiometric titration curves measured for an EDTA solution with GaAs and GaSb electrodes are well reproducible, which allows reliable identification of the end point of titration.

The possibility of using GaAs and GaSb semiconductor sensors as indicator electrodes for potentiometric, acid–base, and complexometric titration, which was established on model solutions, made it possible to test them in multicomponent aqueous systems, to which belongs natural water. The determination of HCO_3^-, Cl^-, and SO_4^{2-} in natural water, which is an integral part of ecological analytical monitoring, is commonly performed in laboratory with glass, chloride-selective, and sulfate-selective electrodes, respectively [7]. GaAs and GaSb sensors were tested in determining major anions in river water. Bicarbonates and chlorides were determined by direct titration with 0.1 N solution of HCl and $AgNO_3$, respectively. Sulfate ions were determined by back titration after their precipitation with a barium salt solution and dissolution in an ammonia solution of EDTA [8]. The excess amount of EDTA solution was back-titrated with a 0.1 N solution of $CuSO_4$. The results obtained in determining the main anions in water of the Drakul River (Kazakhstan) are listed in the table. As seen, the determination of HCO_3^-, Cl^-, and SO_4^{2-} ions with sensors based on GaAs and GaSb semiconductor compounds is characterized by sufficient accuracy and good reproducibility. The results obtained with the conventional ion-selective electrodes and semiconductor sensors are in good agreement. However, in the latter case, sensors ensure a more reliable determination of the end point of titration.

Results of determination of anions in water of the Drakul River (n = 5, P = 0.95)

Anion	Titrant	Electrode	Found, mg l^{-1}
HCO_3^-	HCl	GaSb	212 ± 3
		ESL-63-07	214 ± 3
Cl^-	$AgNO_3$	GaAs	223 ± 2
		ClSE	224 ± 3
SO_4^{2-}	$CuSO_4$	GaAs	108 ± 6
		CuSE	104 ± 5

Thus, the properties of low-selective sensors based on semiconductor compounds were used to determine several components in natural water by acid–base, precipitating, and complexometric titration. Unlike direct potentiometry, the given method does not require use of highly selective sensors.

CONCLUSIONS

(1) It is established that low-selective sensors based on gallium arsenide and gallium antimonide semiconductor compounds can be used as indicators for acid–base, precipitating, and complexometric titration.

(2) The possibility of using semiconductor sensors for determining HCO_3^-, Cl^-, and SO_4^{2-} ions in multicomponent systems, including natural water, is demonstrated.

(3) It is proposed to use a single low-selective semiconductor sensor for determining several components in natural water, which is convenient from the standpoint of unification of analytical procedures.

ACKNOWLEDGMENTS

The study was supported in part by the Russian Foundation for Basic Research (project no. 02-03-32 740), Foundation of the Ministry of Education for Basic Research in the Field of Natural and Exact Sciences (project no. E02-5.0–85), and by the Russia's Federal Program "Integratsiya" (project no. B 0028).

Abstract—Physicochemical and explosive properties of cobalt(III) tetrazolate perchlorate complexes were studied. The spectrophotometical properties of these complexes in the solid state and their sensitivity to laser radiation were examined.

Tetramminebis(5-nitrotetrazolato)cobalt(III) perchlorate **I** is used as an explosive in priming charges (PCs) initiated with a laser diode (λ = 800 nm, E_{beam} = 0.5 mJ) [1, 2]. Both **I** and its analogs are promising photosensitive compounds since they are safer than conventional primers used in laser detonators [3]. This study is concerned with a series of tetraminetetrazolato Co(III) perchlorates with the general formula

$$[Co(NH_3)_4(Tz)_n](ClO_4)_m,$$

n = 2, m = 1 (**I**–**IV**); n = 1, m = 1 (**V**); n = 2, m = 3 (**VI, VII**);

Tz =  **(I)**,  **(II)**,  **(III)**,  **(IV)**,  **(V)**,  **(VI)**,  **(VII)**.

Compounds **I**–**VII** were prepared by the reaction

$$\underset{\textbf{VIII}}{[Co(NH_3)_4(H_2O)_2](ClO_4)_3} + n\text{Tz} \xrightarrow[95^\circ C,\ 4\ h]{HClO_4/H_2O,\ pH < 2,} \underset{\textbf{I–VII}}{[Co(NH_3)_4(Tz)_n](ClO_4)_m} + 2H_2O. \quad (1)$$

The complexes are crystalline compounds soluble in water, DMSO, DMF and difficulty soluble in ethanol, isopropanol, and isobutanol. Their physicochemical and explosive characteristics are summarized in the table.

The densities of Co(III) tetramine complexes were calculated as sums of molecular increments of structural fragments with average error of ±0.04 g cm^{-3}. To determine the detonation rate of **I**–**VII**, their molecules were divided into active (perchlorate anion and the ligands) and inert (metal cation) parts. The detonation rate was calculated from these increments with average error of ±140 m s^{-1} [4].

Thermolysis of **I**–**VII** was studied under nonisothermal conditions at a heating rate of 5 deg min^{-1}. These compounds are relatively thermostable since their T_{oid} temperature is higher than 230°C. In the first stage of thermolysis of tetrazolatotetrammine cobalt(III) perchlorates, the inner coordination sphere of this complex degrades with elimination of ammonia. Then tetrazole ligands are thermally decomposed with their stepwise oxidation by outer-sphere perchlorate anions [5]. The thermal analysis curves of **I** and **VII** contain a broad exothermic peak corresponding to simultaneous occurrence of these steps. Clearly, in this case, the energy liberation is at a maximum and the energy loss, at a minimum. As a result, the combustion–detonation transition for **I** and **VII** is the fastest. For **II** and **IV**, the three thermolysis steps are separated in time. The total exothermic effect is lower owing not only to endothermic elimination of ammonia, but also to removal of the fuel from the reaction zone. A nonstoichiometric ratio of the fuel and oxidizing agent may result in

** Load 2 kg, sample weight 20 mg.

additional heat loss and longer combustion–detonation transition, which is actually the case (see table). In thermolysis of **III**, **V**, and **VI**, the pattern is intermediate between those observed with **I**, **VII** and **II**, **IV**.

The kinetic parameters of thermolysis of **I**–**VII** at T_{oid} were calculated from the T–TG, T–DTG, and T–DTA curves. The preexponential factor in the Arrhenius equation, activation energy (kJ mol^{-1}), and reaction order are 18.5, 212.2, 0.5; 18.8, 228.6, 0.5; 16.7, 204.7, 1.0; 26.3, 293.3, 0.5; 17.6, 231.6, 1.0; 17.4, 204.6, 1.0; and 18.6, 218.3, 1.0, respectively. The fact that the reaction order of thermolysis is lower than unity (n = 0.5) is presumably due to occurrence of the reaction at the interface between sample and the reaction product and the influence of the crystal lattice on the diffusion of the reaction products [6]. The reaction order equal to 1.0 indicates that thermolysis is not hindered by diffusion factors.

The IR spectra of **I**–**VII** contain absorption bands associated with coordinated ammonia, substituents in the heterocyclic ring, tetrazole ring, and outer-sphere perchlorate anion.

The electronic absorption spectra of **I**–**VII** in aqueous solutions are typical of this type of compounds [7] and contain the *d*–*d* band of $^1T_{1g} \leftarrow {}^1A_{1g}$ transition. The other strong band ($^1T_{2g} \leftarrow {}^1A_{2g}$) is overlapped by the absorption of the tetrazole ligand. Clearly, these complexes contain the octahedral chromophore CoN_6.

The ^{1}H NMR spectra of all the compounds except **III** contain signals of equatorial (in low field) and ax. (in high field) ammonia ligands in the range 3.4 –4.3 ppm. In the spectrum of **III**, the ammonia ^{1}H signal is not split, probably owing to *trans* configuration of the complex. The different chemical shifts of the equatorial and ax. ammonia molecules are consistent with coordination of the heterocyclic ligands via nitrogen atoms [8]. The splitting of these signals into a doublet is due to nonequivalence of the ammonia protons. This splitting is caused by coordination of the tetrazole ring via different atoms: N^1 and N^2 in **II** and **IV** [9], N^1 and O of one of the nitro groups in **V** (5-nitroaminotetrazole is coordinated in the bidentate manner) [10], and N^3 and N^4 in **VI** and **VII** [11]. The tetrazole ligands of **I** are coordinated only via the N^2 atom [12].

We also studied the sensitivity of pressed powders of the explosives to a single pulse of neodymium solid-state laser (λ = 1.06 μm, τ_q = 2 ms, E = 1.5 J, d_{beam} = 1 mm). The results obtained are listed below.

Compound	Effect
I	Detonation
II	Combustion
III	Failure
IV	Detonation
V	Failure
VI	Detonation
VII	Failure

The modern concept of initiation of explosives with pulsed laser radiation is based on the ignition at centers formed upon hypothesis of radiation absorption by optical microheterogeneities in separate crystals [3]. In this context, a spectral study of the primers in the wavelength range used in industrial lasers (visible and near-IR region, ruby laser operating at 690 nm and neodymium laser operating at 1060 nm) is of not only theoretical, but also practical interest.

We recorded optical spectra of crystalline complexes **I**–**III** and **IV** (in pellets). First we recorded the spectra of **I** and **II**. Since the influence of the material brought in contact with primers in priming charges (PCs) is of practical interest, pellets of the compounds examined were placed on a copper support (Figs. 1, 2).

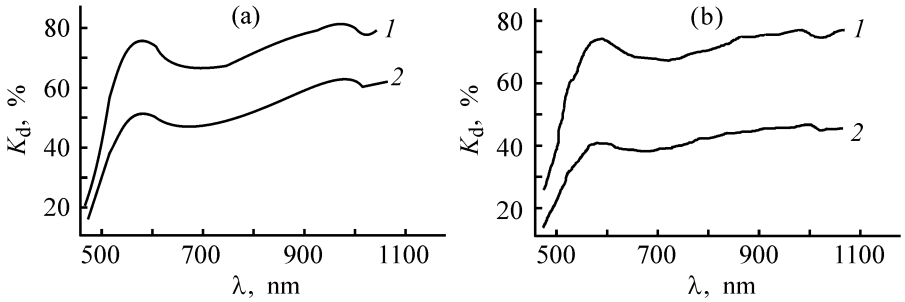

Fig. 1. Diffuse reflectance spectra of (a) **I** and (b) **II**. (K_d) Diffuse reflectance coefficient and (λ) wavelength. (*1*) No support and (*2*) on a support; the same for Fig. 2.

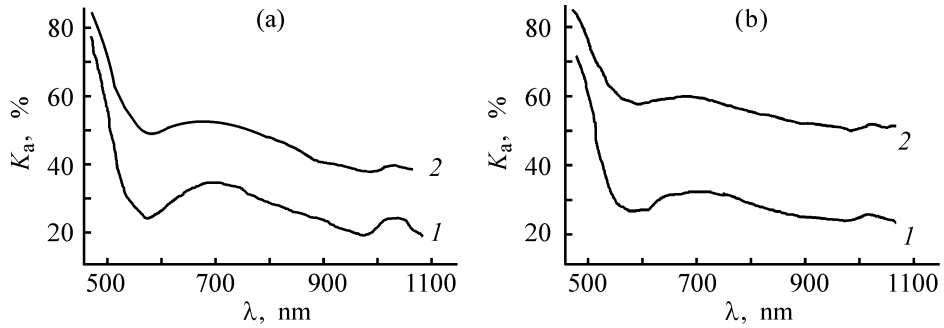

Fig. 2. Electronic absorption spectra of (a) **I** and (b) **II** (K_a) Absorption coefficient and (λ) wavelength.

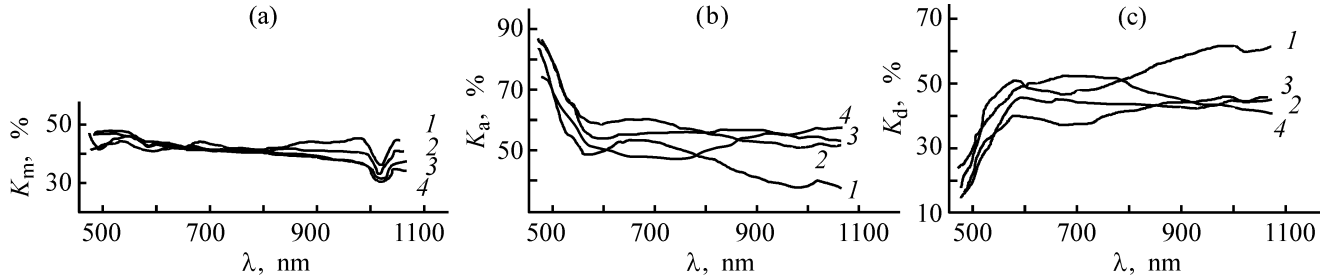

Fig. 3. (a) Mirror reflectance, (b) absorption, and (c) diffuse reflectance spectra of (*1*) **I**, (*2*) **II**, (*3*) **III**, and (*4*) **VI** on a support. (K_m, K_a, K_d) Coefficeints of mirror reflectance, absorption, and diffuse reflectance, respectively; (λ) wavelength.

As seen from Figs. 1 and 2, compounds **I** and **II** behave similarly under exposure to radiation in the whole spectral range, including the wavelength of the neodymium laser (1060 nm). In all cases, the copper support affects the spectral properties. To confirm this result, we also recorded the spectra of **III** and **VI** (Figs. 3a–3c).

As seen from Figs. 3a–3c, the initiation threshold of the crystalline primers is independent of the wavelength of the initiating light. However, it is necessary to study the influence of the particle size distribution and the type of interparticle cohesion on initiation of these explosives. Laser initiation of the complexes was performed with assistance of V.V. Blagoveshchenskii.

Thus, the (tetraminetetrazolato)cobalt(III) perchlorates can be used as primers both in conventional priming charges and in optically initiated priming charges of high safety.

EXPERIMENTAL

The IR spectra of crystalline **I**–**VII** (Nujol or fluorinated oil mulls between KBr windows) were recorded on a Perkin–Elmer M457 spectrometer.

The UV spectra were recorded on a Perkin–Elmer LAMBDA 40 spectrometer in 1-cm quartz cells (analytical concentration 10^{-1}–10^{-2} M).

The ^{1}H NMR spectra were recorded on a Bruker AC (300 MHz) spectrometer using DMSO-d_6 as solvent and hexamethyldisiloxane (HMDS) as internal reference.

Synthesis of **I**–**VII** was monitored by thin-layer chromatography on Silufol UV-254 plates, using 3%

sodium perchlorate as eluent. A thermal gravimetric analysis was performed on an MOM derivatograph (Hungary) in the range 20–500°C at a heating rate of 5 deg min^{-1}. The onset temperature of intense decomposition, T_{oid}, was determined on a thermograph at a heating rate of 5.3 deg min^{-1}. The sensitivity to shock was determined by the pile-driving procedure performed in accordance with GOST (State Standard) 1944–80. The minimal primer charge (MPC) of the complexes was determined with respect to hexogen in the geometry of detonating cap (DC) no. 8 (compaction pressures P_c of the compound and hexogen were 121 and 363 kg cm^{-2}, respectively).

The optical properties of the solid compounds were studied on SPEFOT spectrophotometric unit described in [13].

Diaquatetramminecobalt(III) perchlorate **VIII** prepared by the procedure described in [14] was used in further synthesis without isolation from the solutions.

Tetramminebis(5-nitrotetrazolato)cobalt(III) perchlorate I and **tetramminebis(1-methyl-5-aminotetrazole)cobalt(III) perchlorate VII** were prepared by the procedure described in [15] in 54 and 51% yields, respectively. Compound **I**. IR spectrum, cm^{-1}: 1588 m, 1316 m (NH_3, Tz), 1076 m (ClO_4), 1540 m (NO_2). UV spectrum, λ_{max} = 456 nm, ε = 74 l cm^{-1} mol^{-1}. ^1H NMR spectrum (DMSO-d_6), δ, ppm: 3.79, 4.29 (12H, NH_3).

Found, %: C 4.8, H 2.3, N 42.6.

$C_2H_{12}ClCoN_{14}O_8$.

Calculated, %: C 5.3, H 2.7, N 43.1.

Compound **VII**. IR spectrum, cm^{-1}: 3316 m, 1334 m (NH_3, Tz), 1118 m (ClO_4), 1628 m (C=N), 3236 w, 1616 w (NH_2), 2830 w (CH_3). UV spectrum, λ_{max} = 466 nm, ε = 77 l cm^{-1} mol^{-1}. ^1H NMR spectrum (DMSO-d_6), δ, ppm: 3.85, 3.90 (9H, NH_3 eq.); 3.75, 3.80 (3H, NH_3 ax.); 7.12 (2H, NH_2–Tz, ax.), 7.52 (2H, NH_2–Tz eq.); 4.03 (3H, CH_3–Tz ax.), 4.22 (3H, CH_3–Tz eq.).

Found, %: C 7.8, H 3.3, N 31.9.

$C_4H_{22}Cl_3CoN_{14}O_{12}$.

Calculated, %: C 7.7, H 3.6, N 31.5.

Published procedures were used to prepare tetrazole [16], 5-methyltetrazole [17], 5-nitroaminotetrazole [18], 5-aminotetrazole [19], and 1,5-diaminotetrazole [20]. The physicochemical properties of the compounds agreed with published data.

Tetramminebis(trazolato)cobalt(III) perchlorate II, tetramminebis(5-methyltetrazolato)cobalt(III) perchlorate III, tetramminebis(5-aminotetrazolato)-cobalt(III) perchlorate IV, tetrammine-5-nitroaminotetrazolatocobalt(III) perchlorate V, and **tetramminebis(1,5-diaminotetrazole)cobalt(III) perchlorate VI**. Carbonatotetramminecobalt(III) perchlorate (0.5 g) prepared by the procedure described in [21] was dissolved in 5% perchloric acid (15 ml) until CO_2 evolution stopped. The solution was filtered. An appropriate tetrazole derivative was added in 60% excess to the filtrate. The reaction mixture was heated on a boiling water bath for 4 h, cooled to 15°C, and poured into propan-2-ol (100 ml). The precipitate was filtered off and washed with two portions of ethanol (2 × 5 ml). Yield (60–65 %). Compound **II**. IR spectrum, cm^{-1}: 3320 m, 1329 m (NH_3, Tz), 3050 m (CH), 1094 ws (ClO_4). UV spectrum, λ_{max} = 454 nm, ε = 87 l cm^{-1} mol^{-1}. ^1H NMR spectrum (DMSO-d_6), δ, ppm: 4.00, 4.25 (9H, NH_3 eq.), 3.66, 3.85 (3H, NH_3 ax.), 6.90 (H, C–H, Tz ax.), 8.70 (H, C–H, Tz, eq.).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Thermal Reactions of Fullerene C_{60} with Iron(III) Acetylacetonate

V. G. Isakova, E. A. Petrakovskaya, A. D. Balaev, and T. A. Kolpakova

Kirenskii Institute of Physics, Siberian Division, Russian Academy of Sciences, Krasnoyarsk, Russia

Received June 13, 2002; in final form, February 2003

Abstract—Thermal reaction of solid mixtures of fullerene C_{60} with iron(III) acetylacetonate proceeds in the combustion mode; the composition and characteristics of the reaction products are governed by the Fe : C_{60} ratio in the initial mixture. The magnetization of iron-fullerene complexes was measured.

Iron-fullerene derivatives attract the researchers' attention owing to the possibility of synthesis of new magnetic materials, catalysts, and biologically active compounds based on these derivatives. The characteristics of iron fulleride FeC_{60} and organometallic complexes of fullerene C_{60} with ferrocene and iron carbonyls have been studied most extensively [1–6]. Organometallic iron-fullerene complexes are synthesized by exchange reactions in organic solutions [5, 6]. Iron fulleride can be produced by chemical methods, e.g., by decomposition of ferrocene fullerene complexes [1], reactions in the gas phase [7], or direct synthesis of fullerene in arc discharge with the use of iron-containing graphite electrodes or $Fe(CO)_5$ medium [8]. Crystalline FeC_{60} exhibits superparamagnetic characteristics [1]. In [9], iron-fullerene complexes were produced in a flow of iron-doped carbon-helium plasma formed by a high-frequency ac electric arc. Iron powder or wire was placed in a hole of one of the electrodes. Iron-containing fullerene mixtures extracted from fullerene soot with organic solvents were used in synthesis of water-soluble iron-fullerene products having biological activity [10]. The possibility of synthesis of fullerene derivatives of *d*-transition metals by the reaction of fullerenes with metal acetylacetonates, proceeding in the combustion mode, was shown in [11, 12].

The aim of this study was to make a physicochemical analysis of characteristics of materials and compounds formed by thermal reaction of fullerene C_{60} with iron(III) acetylacetonate.

EXPERIMENTAL

Iron(III) acetylacetonate [$Fe(acac)_3$] used in this study was produced by the procedure described in [13]. Finely ground mixtures of fullerene C_{60}[1] (99.5%) with $Fe(acac)_3$ in stoichiometric ratios C_{60} : Fe 1 : 1, 1 : 2, and 1 : 5 (sample nos. 1, 2, and 3, respectively) were placed in quartz crucibles, which were closed with lids and heated to visual glowing of the substance. The clearance between the crucible and lid allowed removal of volatile products from the reaction area. After completion of the thermal reaction, the combustion products (CPs) were washed with boiling aqueous hydrochloric acid (1 : 5) and organic solvents (benzene and toluene) until colorness solutions were obtained.

Differential thermal analysis (DTA) was performed on an MOM Q-1000 derivatograph (Hungary) with heating of $Fe(acac)_3$ and sample no. 1 in air at a rate of 20 deg min^{-1} in crucibles covered with lids. The weighed portions were 40 mg. The clearance between the crucible and lid was 0.05–0.06 mm. The crucible was fully filled with a sample.

The ESR spectra were recorded on SE/X-2544 and RE-1308 spectrometers in the *X*- and *Q*-ranges at temperatures of 77–500 K. The substances were characterized by the linewidth ΔH and the position of the ESR signal (effective *g*-factor). The spectra of iron-containing products are not typical ESR spectra and differ from the spectra of ferromagnetic resonance in a bulk substance, so we used in this study the term EMR (electronic magnetic resonance). The analysis of magnetic characteristics was based on EMR data, Mössbauer spectroscopy, and measurements of magnetization of some characteristic synthesis products on a vibration magnetometer at 77–300 K. The X-ray

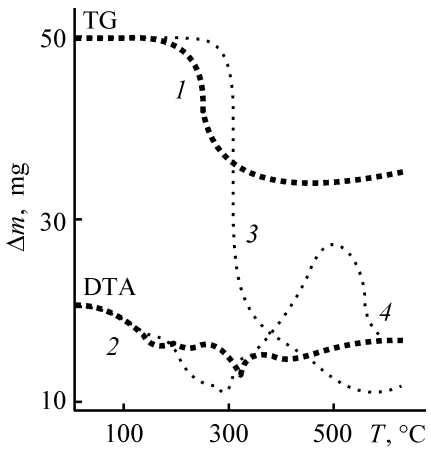

Fig. 1. TG and DTA curves of the initial C_{60}–$Fe(acac)_3$ mixture corresponding to (*1*, *2*) composition no. 1 and (*3*, *4*) $Fe(acac)_3$. (Δm) Weight change, and (T) temperature.

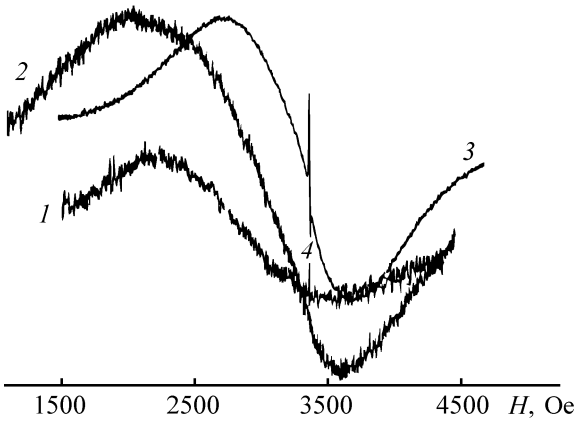

Fig. 2. EMR spectra of the samples of the initial composition 1 : 1. (*H*) Magnetic field strength, the same for Fig. 5. (*1*) C_{60}–$Fe(acac)_3$ mixture after keeping for 24 h at room temperature, (*2*) CP1, (*3*) CP1 treated with HCl, and (*4*) signal from C_{60} radical.

phase analysis was carried out on a DRON-2 equipment.

Heating of solid mixtures $C_{60}/Fe(acac)_3$ in air to 400°C and above, i.e., to temperatures exceeding the thermal decomposition point, results in ignition of reactants and is accompanied by complete loss of fullerene. Under the same conditions, free fullerene does not undergo noticeable transformations, and in the absence of fullerene, $Fe(acac)_3$ sublimes with insignificant decomposition. It is likely that combustion is a catalytic reaction. Fullerene C_{60} is able to chemisorb significant amounts of oxygen [14]; therefore, it can supply active oxygen initiating combustion. At the same time, it is well known that iron acetylacetonate exhibits catalytic ability in oxidation of organic compounds [15].

The DTA curves of sample no. 1 and $Fe(acac)_3$ are compared in Fig. 1. The experiments were carried out under conditions of limited air access. This was done by using crucibles covered with lids and filling the whole crucible volume with the substance. The thermal behavior of $Fe(acac)_3$ is typical of volatile metal acetylacetonates [13]. In the range 190–347°C, the TG and DTA curves correspond to sublimation and evaporation of $Fe(acac)_3$. At higher temperatures, there are two exothermic peaks in the DTA curves, corresponding to pyrolysis of the sample residue. At the same time, the weight loss of the reaction mixture $C_{60}/Fe(acac)_3$ begans at a temperature lower by 30°C than the temperature associated with weight loss of $Fe(acac)_3$ caused by sublimation. The weight loss at 230°C corresponds to the weight of acetylacetone released, apparently, by fullerene-catalyzed homolytic rupture of the bond of acetylacetonate ligand with Fe^{3+} ion and its reduction to Fe^{2+}. The total change in the weight of $C_{60}/Fe(acac)_3$ sample upon heating to 500°C corresponded to conversion of $Fe(acac)_3$ in the initial mixture to Fe_2O_3. With C_{60}, no noticeable weight variation was observed. The final product of heating of free $Fe(acac)_3$ to 500°C is also Fe_2O_3. However, at the temperature corresponding to the onset of thermal decomposition of $Fe(acac)_3$, the product of its pyrolysis is predominantly magnetite.

With account of the DTA data, thermal reactions of C_{60} with $Fe(acac)_3$ were carried out with limited air access. The initial mixtures $C_{60}/Fe(acac)_3$ were heated to a temperature corresponding to the onset of thermal decomposition of $Fe(acac)_3$. In this case, combustion proceeded in the nonequilibrium heterogeneous system $C_{60}/Fe(acac)_3$(solid)–$Fe(acac)_3$(vapor) without ignition, in the glowing mode. The combustion products of the initial mixture nos. 1–3 (CP1–CP3, respectively) were black magnetic powders. According to Mössbauer spectra these powders contain 83–97% magnetic heterogeneous phase similar to magnetite; the rest is paramagnetic. The amount of the paramagnetic phase and deviation of the parameters of the Mössbauer spectra from those of bulk magnetite increase with decreasing content of iron in the initial mixture.

The EMR spectrum of $Fe(acac)_3$ in the initial mixture of reactants is a broad symmetrical line with the parameters g_{eff} = 2.4 and line width 1400 Oe (Fig. 2, *1*). For fullerene C_{60}, the ESR line is characteristic of a radical center (Fig. 3, *1*); its nature was discussed, e.g., in [16]. For the C_{60} samples used in

this study, g = 2.0021 and ΔH = 1 Oe. The EMR spectra of samples CP2 and CP3 at 293 K are broad lines with effective g-factor much exceeding 2 (see table).

The spectra show that, at high content of $Fe(acac)_3$ in the initial sample, the magnetic properties of the products of the thermal reaction are determined predominantly by magnetite formed via thermal decomposition of $Fe(acac)_3$. Lowering the temperature to 77 K results in a considerable broadening of lines and a downfield shift. By contrast, heating to 500 K results in an upfield shift; in this case, the lines became narrower and more symmetrical. The variation of the resonance field and linewidth with temperature correspond to that for amorphous magnetics [17], whose magnetism is caused by the Fe^{3+} ion in octahedral positions with a typical set of nonequivalent distortions of the symmetry. Similar results were obtained for the temperature behavior of the EMR linewidth and resonance field in magnetic polymers [18]. By analogy with these data, and also with account of the results of Mössbauer spectroscopy, the products of thermal synthesis are nonequilibrium ferromagnetics. The ESR line of radical centers of fullerene C_{60} in these products is significantly broadened.

It has been shown previously [19] that the variation of the EMR linewidth with temperature in these systems is governed by fluctuations of magnetization. When the linewidth is determined by anisotropy, these fluctuations result in line narrowing with increasing temperature. The size of magnetic particles can be determined from the relationship

$$\Delta H = \Delta H_0 M_S V H_0 / 2kT,$$

where M_s is saturation magnetization; V, particle volume; k, Boltzmann constant; T, temperature; and ΔH and H_0, the linewidth of EMR signal and its position, respectively.

In the case of magnetite particles, the magnetization is 2400 G; the linewidth ΔH_0 and resonance field H_0 refer to 300 K. For the CP3 sample, the average particle size is 200 nm. Our measurements showed that an increase in the iron concentration results in line narrowing; hence, the particle size decreases and the crystal structure is disrupted. In this context, the absence of reflections characteristic of iron compounds in the X-ray patterns of samples CP1 and CP2 can be accounted for by the amorphous nature of fine particles. An X-ray phase analysis of sample CP3 revealed significantly broadened magnetite reflections.

Parameters of EMR spectra in the X-range for CPs of mixtures $C_{60}/Fe(acac)_3$ before and after treatment with HCl and C_6H_6

Combustion products of mixtures	g_{eff}	ΔH	C_{60} radical, ΔH
		Oe	
CP1	2.16	1000	2
CP2	2.2	1320	
CP3	2.4	1500	
CP1*	2.03	600	1.2
CP2*	2.04	800	2
CP3*	2.06	1300	5
CP2**	2.0337	600	1.5
CP3**	2.1	1300	4.5

* Treated with HCl.

** Treated with HCl and C_6H_6.

The EMR spectrum of sample CP1 is shown in Fig. 2, *2*. For this sample, the ESR signal from the C_{60} radical centers is observed. The transformations of this signal in the course of synthesis are shown in Fig. 3. The appearance of an additional line with g = 1.998 (Fig. 3, *2*), which corresponds to fullerene radical anion [14], suggests the formation of a complex of fullerene with iron acetylacetonate even at room temperature. Then, in the course of combustion, the organic part of the complexes burns out to form $Fe_nO_mC_{60}$.

Magnetic measurements demonstrated that, in the range 300–77 K, this substance is superparamagnetic

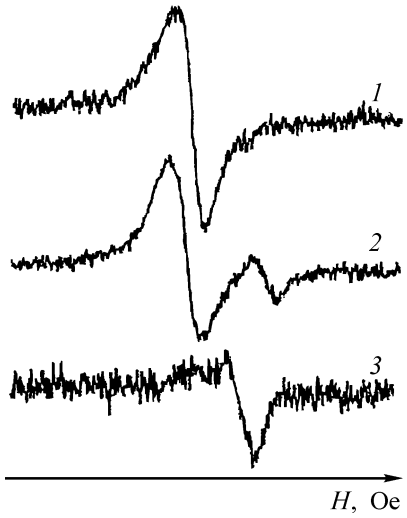

Fig. 3. ESR spectrum of C_{60} radicals in samples of the initial composition 1 : 1. (*H*) Magnetic field strength. (*1*) C_{60} radical of the initial mixture, (*2*) C_{60} radical and C_{60} radical anion after keeping the mixture for 24 h, and (*3*) mixture after thermal reaction.

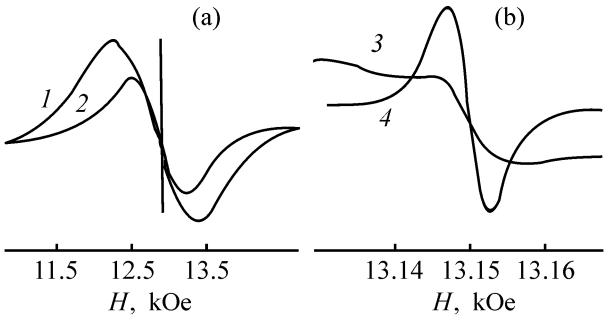

Fig. 4. Spectra of HCl-treated samples recorded in the *Q*-range. (*H*) Magnetic field strength. (a) EMR spectra and (b) single-out ESR lines of C_{60} radical. (*1*) sample CP3, (*2*) sample CP2, (*3*) C_{60} radical of sample CP3, and (*4*) C_{60} radical of sample CP2.

and its temperature and field dependences are similar to those described previously [1]. The magnetization in magnetic field of 5 kOe is 0.25 at 300 K and 0.37 G cm^3 g^{-1} at 77 K. The temperature dependence of magnetization is virtually linear.

Iron-fullerene derivatives were recovered from the combustion products CPs by prolonged (for more than 5 h) boiling of the samples in dilute HCl to dissolve Fe_3O_4 and Fe_2O_3, followed by extraction with organic solvents to remove excess C_{60}.

In treatment of the samples with boiling HCl, the solution color changed from pale green, characteristic of Fe^{2+} chlorohydroxo complexes, to yellow owing to oxidation of Fe^{2+} to Fe^{3+} in air. Iron was not completely recovered from the samples. The parameters of the EMR spectra of insoluble products are listed in the table. The EMR spectrum of sample CP1 treated with HCl is shown in Fig. 2, *3*. The trend toward a decrease in the *g*-factor and linewidth in the spectra of these products is evident.

In the ESR spectra of these samples, there is a signal of C_{60} radical, broadened as compared with that of C_{60} fullerite radical, especially in sample CP3 treated with HCl. This product is ferromagnetic in the range 500–77 K, the coercive force is approximately 250 Oe at 250 K and 50 Oe at 300 K, and the magnetization in the magnetic field of 1000 Oe is 4.5 G cm^3 g^{-1} at 77 K. Extrapolation of the magnetization to high temperatures showed that the Curie point is 427°C, which is much lower than that of bulk Fe_3O_4 (585°C) and suggests the formation of chemical bonds of particles with fullerene. The spectrum in the *Q*-range consists of a symmetrical EMR signal with g_{eff} = 2.002 and ΔH = 1000 Oe (Fig. 4, *1*) and a weak ESR signal of the C_{60} radical (Fig. 4, *3*).

The saturation magnetization of HCl-treated sample CP2 in a magnetic field of 1 kOe was 0.17 G cm^3 g^{-1} and coercive force, 250 Oe at 77 K. In the *Q*-range, there is an EMR signal with g_{eff} = 2.002 and ΔH = 570 Oe (Fig. 4, *2*), and also an ESR signal from the C_{60} radical, ΔH = 4.4 Oe (Fig. 4, *4*). The shift of the EMR line, observed for both samples with increasing frequency (see table), is due to the presence of the energy gap in the magnetic, caused by magnetic anisotropy. Comparison of the spectra of the samples shows that the dependences of the resonance characteristics on the amount of iron in the initial mixture and after treatment of CP2 and CP3 with HCl remain the same. An increase in the intensity of the ESR signal from the C_{60} radical is clearly seen in Fig. 4, *4*.

A set of narrow peaks in a magnetic field of 2000 Oe was observed in the EMR spectrum of CP3 sample treated with HCl. Similar signals were observed in the spectra of insoluble residues when the combustion products were treated with benzene. This effect can be accounted for, e.g., by the spin-wave resonance in thin films of magnetite covering fragments of the C_{60} crystalline phase. It is apparent that a decrease in the amount of iron in the samples "removes" this coating. We obtain a magnetic, which is the product of the reaction of iron(III) oxide with fullerene. The other possible explanation of these peaks is the presence of a phase similar to the Wigner glass [20].

After the reaction with hydrochloric acid, synthesis products CP2 and CP3 were treated with organic solvents (benzene, toluene). Extraction with organic solvents resulted in additional extraction of iron and changes the parameters of the EMR spectra of insoluble residues (see table). Their probable elemental composition, according to chemical analysis and IR spectra, is $Fe_xO_y(OH)_zC_{60}$. Both substances are weak ferromagnetics. The temperature shifts of the EMR lines for these samples are insignificant. In the spectra of fractions soluble in organic solvents and extracted from CPs pretreated with HCl, the ESR signal of the radical anion was observed as an individual line or an unresolved doublet with C_{60} radical. The parameters of EMR spectra were as follows: g_{eff} = 2.02–2.00 and linewidth of approximately 400 Oe. This suggests the presence of iron in the resulting extracts, and the appearance of the radical anion can serve as evidence in favor of chemical bonding between iron and fullerene.

The solid residues formed after treatment of combustion products CP1–CP3 with organic solvents are heterogeneous ferromagnetics. The EMR spectra of the residue after treatment of sample CP2 with toluene were recorded at 300 and 77 K (Fig. 5, *2* and *3*).

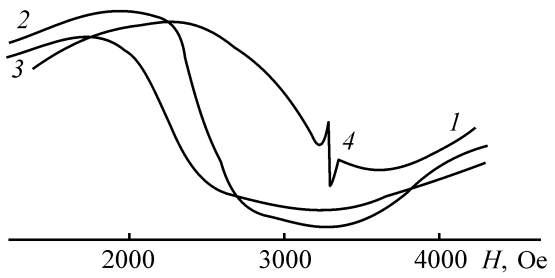

Fig. 5. EMR spectra of CP2 samples after treatment with toluene: (*1*) product soluble in toluene, (*2*, *3*) insoluble product at 300 K and 77 K, respectively, and (*4*) ESR line of C_{60} fullerene radical.

The EMR spectrum of a substance extracted from this sample is shown in Fig. 5, *1*. This substance is not ferromagnetic in the range 77–500 K; however, it differs from ordinary paramagnets. According to the preliminary data, these products are similar to superparamagnets and spin glasses.

CONCLUSION

The products formed by thermal reaction of solid mixtures of fullerene with iron(III) acetylacetonate contain complexes of iron with fullerene and a composite consisting magnetite and fullerite particles. The average size of the magnetite particles decreases with decreasing iron concentration in the initial mixture. Small particles (on the order of nanometers) can be chemically bonded to fullerene. The composition and magnetic characteristics of iron-fullerene complexes vary in purification of the thermal synthesis products to remove Fe_3O_4 and excess C_{60}, but their dependence on the Fe : C_{60} ratio in the initial mixture is retained. A set of products of the synthesis based on thermal reaction of fullerene C_{60} with $Fe(acac)_3$ can be obtained, from heterogeneous ferromagnetics to superparamagnetics and individual ironfullerene complexes.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Absorption and Luminescence Spectra of 1,1,3-Trimethyl-3-Phenylindan

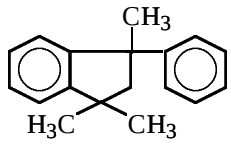
Abstract—Electronic absorption and luminescence spectra of cyclic dimer of α-methylstyrene, 1,1,3-trimethyl-3-phenylindan, were described. The quantum yield and lifetime of fluorescence were determined.

It is well known that certain individual and substituted hydrocarbons, whose molecules contain rings and conjugated double bonds, are capable of light emission, i.e., they luminesce when exposed to high-energy radiation [1]. Such compounds are distinguished by a rigid molecular structure precluding free rotation of molecular segments, thus decreasing the probability of nonradiative transitions.

Among the compounds of interest are aromatic polycyclic hydrocarbons (naphthalene, anthracene, naphthacene, phenanthrene, etc.), aromatic chain compounds (polyphenylenes, stilbene, diphenylpolyenes, aryldivinylbenzenes, etc.) [1–4]. In the molecules of luminescent compounds, the ordinary bond is located between two double bonds or between a multiple bond and an atom having unshared *p*-electron pair. This applies to, e.g., nitrogen- and oxygen-containing heterocyclic compounds (aryloxazoles, aryloxadiazoles, etc.).

Chain aromatic compounds exhibit luminescence in the case when conjugation in the molecule is disturbed by methylene groups inserted between the benzene rings like, e.g., in diphenylmethane or dibenzyl [5]. The absorption and emission spectra of compounds with Ph–X–Ph structure are close to those of the corresponding benzene derivatives.

It was of interest to study the optical properties of an aromatic compound whose molecule contains an X group rigidly linked to one of the benzene rings. An example of such a compound is 1,1,3-trimethyl-3-phenylindan (TMPI) yielded by cyclodimerization of α-methylstyrene [6]. It was termed "crystalline dimer of α-methylstyrene." This is an aromatic hydrocarbon of the following structure



Owing to its π-electron system, TMPI is capable of fluorescence and/or intermolecular energy transfer. Linear oligomers of α-methylstyrene, prepared by its cationic polymerization, exhibit fluorescence at 270–310 nm with emission peak at 285 nm [7]. As far as we know, the luminescence properties of cyclic dimers of α-methylstyrene have not been studied previously.

A great number of luminescent compounds have been proposed recently, but a search for new luminophores with fast luminescence response and high quantum yield for designing scintillators is still a topical task. Candidate scintillators or luminescent additives for liquid or plastic scintillators must exhibit high thermal and chemical resistance and radiation hardness. This is characteristic specifically of TMPI [8, 9].

The electronic structure of the TMPI molecule composed of phenyl and indan rings must be intermediate between the conjugated (biphenyl) and nonconjugated (diphenylmethane) structures. Similarly to diphenylmethane, conjugation in the TMPI molecule is disturbed but, unlike diphenylmethane, the central carbon atom in the TMPI molecule is involved in the five-membered ring of the indan moiety. This must increase to a certain extent the rigidity of its structure, making it more similar to that of biphenyl. Also, the interest in TMPI is due to the possibility of preparing high-purity (up to 99.99%) TMPI in high yield (over 96%), as well as to its good solubility in many organic solvents and polymers (up to 60 wt %).

EXPERIMENTAL

Absorption spectra of TMPI solutions in heptane were recorded on a Specord UV-Vis spectrophotometer.

The luminescence spectra of TMPI in heptane and polymethyl methacrylate (PMMA) were recorded on an MPF-4 Hitachi spectrofluorimeter. Luminescence was excited at λ = 250 nm.

The quantum yield of fluorescence was determined using the procedure from [4] by comparison with the flourescence of toluene whose quantum yield is known.

The fluorescence lifetime was determined using an PRA pulse spectrofluorimeter [4].

1,1,3-Trimethyl-3-phenylindan was synthesized by the procedure from [6] and recrystallized from heptane. The product purity was monitored by gas–liquid chromatography, IR spectroscopy, and ^{1}H NMR spectroscopy (mp 51–52°C, bp 183°C/20 mm Hg).

For studying optical properties, we prepared solutions of the luminophore in heptane and PMMA. TMPI was introduced into PMMA by bulk polymerization of methyl methacrylate in the presence of an initiator, dicyclohexyl peroxodicarbonate, at 40°C. The resulting block was finally polymerized at 110°C, cut into 1-mm high disks, and polished.

The UV spectrum of TMPI contains a well-resolved band at 210–280 nm with peaks at 257, 263, and 270 nm and a stronger band at λ < 240 nm, whose intensity sharply increases with decreasing wavelength, with a peak at 204 nm (Fig. 1). Similarly to other hydrocarbons containing a benzene ring, TMPI is transparent at λ > 300 nm. The emission spectrum of TMPI at room temperature contains bands at 260–320 nm with peaks at 273 and 280 nm and a sholder at 287 nm. The electronic absorption and luminescence spectra of TMPI proved to be close to those of diphenylmethane rather than to biphenyl. Biphenyl absorbs at 220–290 nm and exhibits fluorescence at 290–380 nm [5]. Diphenylmethane absorbs and exhibits luminescence in the same regions as TMPI (240–285 and 260–310 nm, respectively) [5]. Broadening of the bands in the absorption and luminescence spectra of TMPI relative to diphenylmethane is probably due to the alkyl substituent at the central carbon atom. Evidently, TMPI should be treated as a compound with nonconjugated chain structure of the Ph–X–Ph type.

In studies of light absorption by complex molecules, of the greatest interest is the longest-wavelength

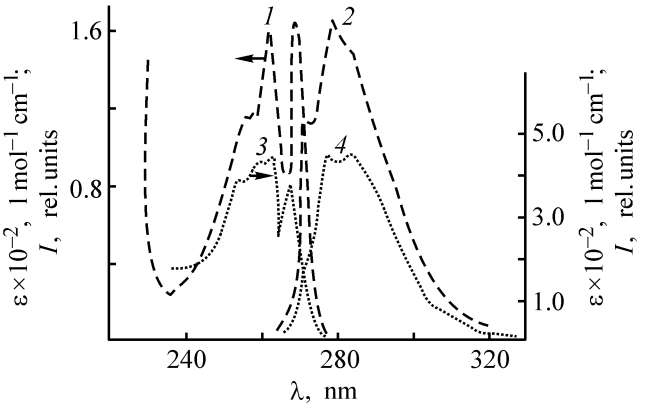

Fig. 1. (*1, 3*) Absorption and (*2, 4*) luminescence spectra of (*1, 2*) TMPI and (*3, 4*) diphenylmethane. (ε) Molar extinction coefficient, (*I*) luminescence intensity, and (λ) wavelength.

absorption band. As known, all lines of this band correspond to transitions between various vibrational sublevels of the ground and lowest-excited electronic states. The molar extinction coefficient ε at the peak of the long-wavelength absorption band of TMPI is 1.69×10^3 l mol^{-1} cm^{-1}, which significantly exceeds that of diphenylmethane (4.6×10^2 l mol^{-1} cm^{-1}). The molar extinction coefficient of TMPI falls within the region characteristic of the bands of π–π transitions [2].

The π–π^* transitions of hydrocarbon molecules are characterized by the predominance of vibrational frequencies of the carbon skeleton, and the frequencies corresponding to C–H vibrations are not very active. The vibronic structure of the TMPI spectra is better resolved than that of diphenylmethane. The increase in the intensity of the absorption and emission bands, as well as the increase in the molar extinction coefficient, in going from diphenylmethane to TMPI may be due to hindered relative rotation of the phenyl groups around the bond linking them to the central carbon atom, because of the increased rigidity of the molecular structure. In diphenylmethane, such rotation is not hindered, which favors dissipation of the electronic excitation energy.

Like the majority of aromatic compounds having Ph–X–Ph structure with conjugated π-electron systems of the benzene rings, TMPI exhibits absorption and emission spectra close to those of the corresponding alkyl-substituted benzenes and, in particular, toluene [5]. Both compounds exhibit absorption and luminescence in the same region; their luminescence can be excited at the same wavelength. The quantum yield of luminescence of TMPI proved to be 0.27, which ex-

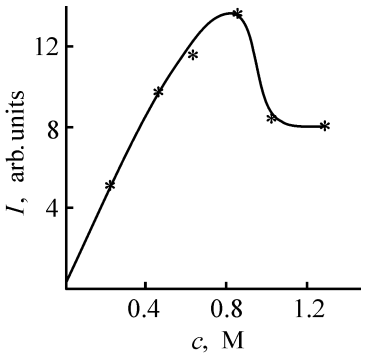

Fig. 2. Intensity I of TMPI fluorescence at λ = 282 nm vs. its concentration c in PMMA.

ceeds significantly those of diphenylmethane and biphenyl (0.16 and 0.18. respectively) [5].

The lifetime of the excited state (luminescence duration) τ for TMPI was estimated at 8 ns, which allows this luminescence to be qualified as fluorescence, for which the light emission spectrum is due to the same electronic states as the long-wave absorption band, i.e., to the transition from the singlet excited state to the ground state ($S_1^* \rightarrow S_0$ transitions). The occurrence of fluorescence suggests that the probability of nonradiative deactivation of the excited S_1^0 state is low.

Polymethyl methacrylate proved to be a good solvent for TMPI; it is characterized by high transparency in the UV and visible regions (including the regions of absorption and luminescence of TMPI). PMMA is used for fabrication of large plastic scintillators [1]. We have shown previously [10] that TMPI does not react with the propagating radical in MMA polymerization and occurs in the polymer as a dissolved substance. Incorporation of the luminophore into the solid solution must impart additional rigidity to its molecule, which will inhibit nonradiative deactivation of the electronically excited states.

Figure 2 presents the concentration dependence of the fluorescence intensity for TMPI in PMMA (Fig. 2). The plot exhibits extrema: With increasing concentration, the fluorescence is initially enhanced, passed through a maximum at 0.85 M, and then decreases owing to the concentration quenching. The electronic energy turns into the energy of vibrational or translational degrees of freedom [11], i.e., an increase in the concentration of molecules similar to the excited molecule makes more probable the nonradiative process. According to Krasovitskii and Bolotin [3], the concentration quenching is due to formation of fluorescent dimers acting as quenchers (deactivators of the excitation energy of the molecules). Concentration quenching may also be due to formation of nonfluorescent excimers yielded by collisions of an excited molecule with unexcited molecules and are stable in the excite states only.

To be suitable as luminophores or scintillator components, luminescent substances must have appropriate electronic absorption spectrum, quantum yield of luminescence, and luminescence duration. TMPI absorbs in the short-wavelength region of the spectrum, which allows more efficient capture of the incident high-energy radiation. TMPI is characterized by high quantum yield of luminescence and short scintillation time. This makes TMPI promising for fabrication of scintillators.

CONCLUSIONS

(1) Fluorescent properties of the cyclic dimer of α-methylstyrene, 1,1,3-trimethyl-3-phenylindan, were revealed.

(2) The lifetime of the excited state was estimated at 8×10^{-9} s, and the fluorescence quantum yield, at 0.27.

CHEMISTRY OF FOSSIL FUEL

Thermolysis of Kansk–Achinsk Coals with Varied Extent of Oxidation and Combustion of Nonvolatile Thermolysis Products: A Study by Complex Thermal Analysis

E. A. Boiko, D. G. Didichin, and P. V. Shishmarev

Received May 27, 2002; in final form, March 2003

Abstract—Thermolysis of Berezovka coals with varied extent of oxidation and combustion of nonvolatile thermolysis products were studied by complex thermal analysis. The dynamics of thermochemical transformation of the fuel in an inert medium was evaluated, with simultaneous determination of the kinetic parameters of evaporation of various kinds of moisture. The burn-out of nonvolatile thermolysis residues obtained from Berezovka coals at various pretreatment temperatures was studied, and a correlation was revealed between the kinetic parameters of combustion of nonvolatile residues and the extent of oxidation of the initial fuel.

Kansk–Achinsk coal fields are important for the development the Russian fuel industry, and proper utilization of coals from these fields is a topical problem. At the same time, the experience of burning of Kansk–Achinsk coals at thermal power plants shows that efficient procedures for pretreatment and combustion of these coals, which could ensure reliable operation of boilers, are still lacking. This is largely due to significant variations in the main thermal characteristics and reactivity of the fuel. The quality of coal supplied to power plants tends to get worse. The coal composition and properties vary across the strata in the horizontal and vertical directions; coals from the upper layers are strongly oxidized and sooty [1].

One of the ways to improve the quality of coals with the minimal power consumption and without major degradation of the organic matter is low-temperature pretreatment of the fuel dust prior to combustion. Theoretical studies [2, 3] have shown that the optimal temperature and time of pretreatment of Kansk–Achinsk coals are, depending on their initial quality, 120–300°C and 0.8–1.2 s. These conditions ensure the required degree of drying and removal of ballast volatiles (in particular, CO_2), with the minimal power and labor consumption. However, since nonvolatile residues from heat treatment of coals with different extents of oxidation are to be utilized for the production of energy, it is of most interest to study these residues from the viewpoint of ensuring their stable ignition and burn-out in a real furnace. This is necessary for understanding the combustion mechanism and for finding the optimal conditions and pretreatment procedures for efficient combustion of Kansk–Achinsk coals of variable quality.

In this study, such experiments were performed with Kansk–Achinsk coals of the Berezovka deposit. The coals differed in the extent of oxidation and had the following characteristics: sooty coal, extent of oxidation 88%, $W_h^{\text{h}} = 18.9\%$, $A^d = 14.5\%$, $V^{\text{daf}} = 53.1\%$, $C_0^{\text{daf}} = 65.8\%$, $H_0^{\text{daf}} = 3.8\%$, $O_d^{\text{daf}} = 28.6\%$, $S_f^{\text{daf}} = 0.7\%$, $N_t^{\text{daf}} = 1.1\%$, $Q_i^r = 11766$ kJ kg^{-1}; oxidized coal lying at a depth of 15–18 m from the stripping level, extent of oxidation 63%, $W_t^h = 16.0\%$, $A^d = 6.4\%$, $V^{\text{daf}} = 48.5\%$, $C_0^{\text{daf}} = 69.3\%$, $H_0^{\text{daf}} = 4.2\%$, $O_d^{\text{daf}} = 25.1\%$, $S_t^{\text{daf}} = 0.7\%$, $N_t^{\text{daf}} = 0.7\%$, $Q_i^r = 13031$ kJ kg^{-1}; run-of-mine coal, extent of oxidation 42%, $W_t^h = 12.1\%$, $A^d = 4.1\%$, $V^{\text{daf}} = 46.0\%$, $C_0^{\text{daf}} = 72.0\%$, $H_0^{\text{daf}} = 4.6\%$, $O_d^{\text{daf}} = 22.5\%$, $S_d^{\text{daf}} = 0.3\%$, $N_t^{\text{daf}} = 0.6\%$, $Q_i^r = 15580$ kJ kg^{-1}. The extent of fuel oxidation was determined petrographically according to GOST (State Standard) 8930. To make the results representative, all samples of Berezovka coal with different extents of oxidation were taken from randomly chosen wells from different points across the coal stratum thickness [2].

Thermolysis of Berezovka coals with varied extent of oxidation and the characteristics and proper-

ties of the nonvolatile residues were studied by complex thermal analysis [4]. Owing to the high resolving power of this method, it is possible to reveal thermal transitions corresponding to changes in the physicochemical state of a coal, evaluate the thermal effects accompanying one or another process, and obtain quantitative data for estimating the process kinetics.

EXPERIMENTAL

Complex thermal analysis of the fossil fuel was performed with an installation consisting of a *Q* derivatograph and a Soyuz-3101 chromatographic gas analyzer. With this installation, data on the dynamics of release of gaseous products (CO, CO_2, H_2, CH_4, etc.) under nonisothermal conditions are obtained along with the integral characteristics of coal thermal behavior (weight loss and its rate, thermal effects). The mode of the *Q* derivatograph operation was chosen so as to single out definite temperature ranges of the heat treatment of the material. In experiments on fuel thermolysis, the conditions were as follows: inert medium (Ar), sample weight 500 mg, and heating rate 5 deg min^{-1}. Experiments on combustion of nonvolatile thermolysis products were performed under different conditions: oxidizing medium (air), coal sample weight 50 mg, and heating rate 10 deg min^{-1}. The following conditions were common to both types of experiments: inert reference Al_2O_3; ceramic crucible; sensitivity levels (mV): TG 500, DTA 250, and DTG 250; gas flow rate 200 cm^3 min^{-1}; polydispersed coal fraction (R_{90} = 45, R_{200} = 30, R_{1000} < 1%).

In experiments on thermolysis of Berezovka coals in the inert medium, we obtained nonvolatile residues corresponding to final temperatures of 120, 150, 200, 250, and 300°C, with TG, DTG, and DTA curves recorded (Fig. 1) and the composition of gaseous products determined (see table).

Data on thermolysis of Berezovka coals in the range 120–300°C (TG curve) allow us to distinguish two steps of the process. In the range 20–160°C, the rate of the weight loss grows, but at approximately 160°C the slope of the TG curve changes and then remains constant in the range 160–280°C.

The curvilinear plot of the weight loss in the range 20–160°C is fully consistent with the pattern corre-

sponding, according to Rebinder's classification, to evaporation of hygroscopic moisture. The change in the fuel mass in this range corresponds to evaporation of capillary moisture and moisture adsorbed in the monomolecular and polymolecular mode owing to hydrogen bonding with the active centers of the fuel surface [5]. Intense evaporation of moisture in this range corresponds to the period of a constant drying rate, accompanied by a pronounced endothermic effect in the DTA curve.

The subsequent weight loss at 160–280°C is associated with two competing processes: evaporation of chemically bound moisture and release of volatiles, mainly CO and CO_2 (see table). It should be noted that the content of chemically bound moisture in Berezovka coals with varied extent of oxidation is rather high, ranging from 4% for run-of-mine coal to 7% for sooty coal. It is known that the hydrophilic components of coal contain active functional groups (OH, COOH, CO, etc.) capable of hydrogen bonding with each other and with molecules of polar liquids, including water; the contribution of the hydrogen bond energy is low: about 24 kJ kg^{-1} [6]. These facts suggest that the chemically bound water, released in the range 160–280°C, is bound to coal macromolecules by secondary valence forces. The rate of evaporation of chemically bound moisture is low (W_{max} = 2.2–2.5 mg g^{-1} deg^{-1}), compared with that of hygroscopic moisture (W_{max} = 4.8–5.3 mg g^{-1} deg^{-1}), owing to the presence of ionic bonds and hydroxy groups in the fuel.

The kinetic parameters of evaporation of various forms of moisture (E_i, k_{0i}) were determined according to [7], using the following kinetic equation [8]:

$$\frac{dU_i}{d\tau} = k_{ei}(U_{0i} - U_i),$$

where $dU_i/d\tau$ is the evaporation rate of ith form of moisture; U_{0i} and U_i are the initial and final contents of the ith form of moisture in coal; k_{ei} is the rate constant of evaporation of ith form of moisture, $k_{ei} = k_0 \exp[-E_i/RT(\tau)]$.

To plot the differential curves for the periods of evaporation of hygroscopic and chemically bound moisture, we subjected the TG and DTG curves for the corresponding temperature ranges to preliminary processing with a 5°C step.

When estimating the rate of evaporation of chemically bound moisture, we took into account the release of volatiles detected with a gas chromatograph (see table). The amount of the released volatiles was subtracted from the total weight loss. The rate of release of individual gaseous components, ω_i (cm^3 g^{-1} min^{-1}), was calculated as a quantity proportional to their concentration c_i (%) [7]:

$$\omega_i = Kc_i/100,$$

where K is the proportionality coefficient taking into account the deviation of the experimental conditions (rate of gas removal, sample weight, etc.) from the standard.

After converting ω_i to the dimension of mg min^{-1}, these quantities were subtracted from the total weight losses at the corresponding temperatures, determined from the TG curves (160–280°C). The initial content U_{0i} of each form of moisture was determined from the area under the $dU_i/d\tau = f(T)$ plots. The running moisture content U_i was determined by planimetric treatment of the portions of the rate curves up to the given temperature.

It is seen that the kinetics of evaporation of hygroscopic moisture is consistent with the mechanism involving competition of the adsorption and desorption of water present in the coal as a common phase and as molecular clusters in pores of the coal structure. The statistically estimated mean binding energy of hygroscopic moisture in Berezovka coals is 12.8 kJ mol^{-1}, and the preexponential factor is 2.3 s^{-1}, which suggests the physical binding [9]. At the same time, we revealed a close correlation between the extent of oxidation of Berezovka coal and the kinetic parameters of evaporation of chemically bound moisture. Despite the high content of chemically bound moisture in sooty coals (6% and more), the binding energy was 18.7 kJ mol^{-1}. In coals oxidized to a lesser extent, the binding energy of moisture is higher: 22.9 kJ mol^{-1} in oxidized coals and 28.3 kJ mol^{-1} in run-of-mine coals. As the extent of coal oxidation grows, the temperature at which the rate of evaporation of chemically bound moisture passes through a maximum increases, which confirms that this moisture is chemically bound to the fuel [10].

The nonvolatile thermolysis residues obtained at various temperatures were subjected to combustion in a derivatograph under oxidative conditions.

The results obtained (Fig. 2) show that the temperatures at which the rate of combustion of the nonvolatile residues passes through a maximum (DTG curve) closely correlate with the extent of oxidation of Berezovka coals. The combustion rate is the highest for nonvolatile residues of the sooty coal, reaching 1.4–1.68 mg g^{-1} deg^{-1}. For nonvolatile residues of the oxidized and run-of-mine coals, the combustion rates

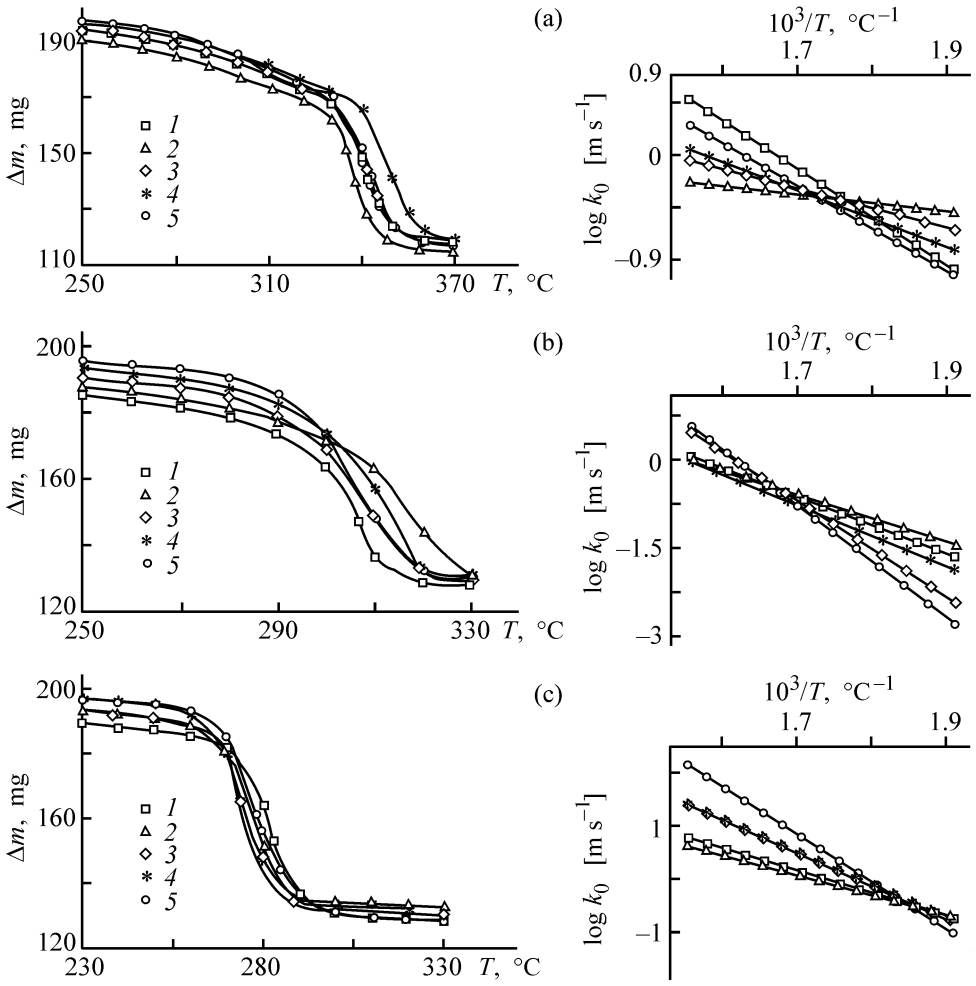

Fig. 2. Kinetics of combustion of nonvolatile residues from thermolysis of Berezovka coals with varied extent of oxidation, monitored under conditions of complex thermal analysis: (Δm) change in the sample weight and ($\log k_0$) logarithm of the rate constant. Coal: (a) run-of-mine, (b) oxidized, and (c) sooty. Final thermolysis temperature, °C: (*1*) 120, (*2*) 150, (*3*) 200, (*4*) 250, and (*5*) 300.

are close, ranging from 0.76 to 0.9 mg g^{-1} deg^{-1}. With increasing thermolysis rate the rate of combustion of the nonvolatile residue decreases by 10–12% for the sooty coal and increases by 5–7% for the oxidized and run-of-mine coals.

We evaluated the kinetic characteristics of combustion of nonvolatile residues from thermolysis of Berezovka coals with varied extent of oxidation. Since the combustion of these materials is a heterogeneous process, its rate W (kg s^{-1}) was determined as a function of the reaction surface area [11]:

$$W = kmS_{sp}\rho_{app},$$

where k is the combustion rate constant, m s^{-1}; m, amount of nonvolatile residue, kg; S_{sp}, specific surface area of the nonvolatile residue, m^2 kg^{-1}; ρ_{app}, apparent density of the nonvolatile residue, kg m^{-3}.

Since the size of nonvolatile residue particles [12], the reaction surface area, and, hence, (under equal other conditions) the combustion rate vary in the course of combustion, we calculated the rate constant k (m s^{-1}) by the equation

$$k = Wd_i/(m_0 - m),$$

where $d_i = d[(m_0 - m)/m]^{1/3}$ is the running size of nonvolatile residue particles [13], m; m_0, initial weight of the nonvolatile residue, kg; and d, mean diameter of nonvolatile residue particles, m.

Using this equation, we calculated the kinetic characteristics of the combustion, assuming that the nonvolatile residue particles are spherical, no reaction occurs within the pores, and the organic matter is fully separated from the mineral matter. After calculating the rate constants at 10°C intervals, we plotted the

Arrhenius dependences $\log k = f(10^3/T)$, which appeared to be straight lines (Fig. 2). From their slopes, we determined the activation energy E, kJ mol^{-1}:

$$E = \frac{2.303R(\log k_2 - \log k_1)}{(1/T_1 - 1/T_2) \times 10^3}.$$

The probability factor was estimated assuming that, if $T_1 \to \infty$, i.e., $k_1 \to k_0$, then

$$\log k_0 = \frac{E}{2.303R}\frac{10^3}{T_2} + \log k_2,$$

where R is the universal gas constant (kJ mol^{-1} deg^{-1}).

The kinetics of combustion of nonvolatile residues from thermolysis of Berezovka coals with varied extent of oxidation (Fig. 3) are described by the following regression equations: for run-of-mine coal, $E = 123.22 - 0.5231T + 0.0022T^2$, $\log k_0 = 10.216 - 0.0467T + 0.0002T^2$; for oxidized coal, $E = 109.56 - 0.4389T + 0.0015T^2$, $\log k_0 = 9.4414 - 0.0375T + 0.0001T^2$; and for sooty coal, $E = 101.31 - 0.3144T + 0.0013T^2$, $\log k_0 = 9.1323 - 0.0285T + 0.0001T^2$, where T is the final temperature of fuel thermolysis (°C).

For all types of the initial Berezovka coal, irrespective of their extent of oxidation, the activation energies E and probability factors k_0 as functions of thermolysis temperature pass through a minimum in the range 120–150°C. For example, for the initial samples of the run-of-mine, oxidized, and sooty coals, the activation energies of combustion are 126.32, 110.79, and 104.14 kJ mol^{-1}, respectively; after heating to 150°C, they decrease to 75.03, 70.55, and 70.2 kJ mol^{-1}; and after heating to 300°C, the activation energies grow again, reaching 154.15, 107.57, and 120.1 kJ mol^{-1}, respectively.

There is good reason to believe that the maximum in the dependence of the reactivity of the nonvolatile residues on the final temperature of thermolysis of Berezovka coals is associated with accumulation of phenolic, carbonyl, and hydroxy groups as a result of cleavage of intermolecular bonds and ether bonds in units linking aromatic rings [14]. For example, on heating the initial fuel to 150°C, the content of carbonyl and hydroxy groups grows from 3.7 to 4.33 and from 3.2 to 4.4 mg-equiv g^{-1}, respectively, which results in a 26% increase in the content of active functional oxygen. The content of carboxy groups slightly decreases (from 0.42 to 0.25 mg-equiv g^{-1}; ≤2% of the total content of functional groups).

Further heating to 300°C leads to a dramatic decrease in the content of oxygen-containing functional groups; as a result, the content of aliphatic compounds changes, and the kinetic parameters grow. Irrespective of the thermolysis temperature, the nonvolatile residues from the sooty coals are the most reactive, then follow the residues from oxidized coals, and those from the run-of-mine coals are the least reactive. This is confirmed by the values of the probability factor, ranging from 2.76×10^{10} to 7.54×10^{13} m s^{-1} for nonvolatile residues from the run-of-mine coal and from 1.09×10^6 to 5.6×10^9 m s^{-1} for those from the sooty and oxidized coals. On the whole, the functional dependence $E = f(\log k_0)$ for the combustion of nonvolatile residues from thermolysis of Berezovka coals is linear, suggesting similar and invariable combustion mechanisms for fuel samples with different extents of oxidation and with different temperatures of preliminary thermolysis.

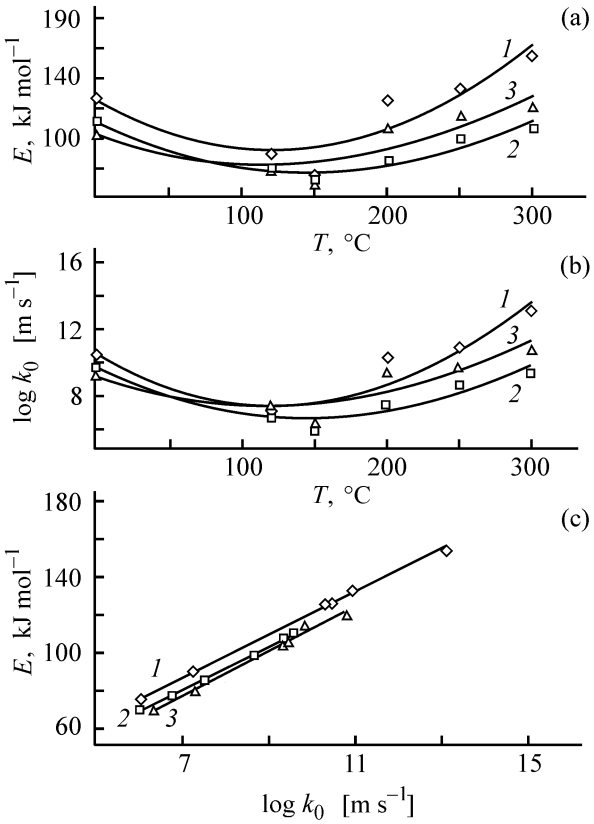

Fig. 3. (a) Activation energy E and (b) logarithm of the preexponential factor, $\log k_0$, for the combustion of nonvolatile residues from thermolysis of Berezovka coals vs. the final temperature T of the preliminary heat treatment; (c) correlation of E with $\log k_0$. Coal: (*1*) run-of-mine, (*2*) oxidized, and (*3*) sooty.

CONCLUSIONS

(1) Thermolysis of Berezovka coals with varied extent of oxidation and combustion of the nonvolatile

residues were studied by complex thermal analysis. It was found that the behavior of these materials largely depends on the extent of oxidation of the initial fuel.

(2) It was shown that the kinetic parameters of evaporation of hygroscopic moisture are independent of the extent of oxidation of the initial Berezovka coal, whereas the parameters of evaporation of chemically bound moisture grow with decreasing extent of oxidation.

(3) Regression equations describing the correlation of the kinetic parameters of combustion of nonvolatile residues from thermolysis of Berezovka coals with the temperature of the preliminary heat treatment of the initial fuel samples with varied extent of oxidation were obtained.

Abstract—The influence exerted by the length exerted by the conjugation chain in 4-hydroxybenzylidenealkanones on the generation of the third harmonic by complexes of these chromophores with aliphatic polyamidine was studied.

At present, growing interest is aroused by materials exhibiting nonlinear optical (NLO) effects [1]. This is primarily due to their promise for optoelectronic applications. Within a large class of compounds with prominent NLO properties, of greatest importance are those with refractive indices widely varying with light intensity. This allows control over the propagation of the optical radiation in a medium in, e.g., designing optical switches, modulators, etc. Special attention is given to preparation of polymeric materials exhibiting NLO effects [2].

Polymers containing NLO-active moieties (chromophores) favorably compare with the conventionally used inorganic substances in a number of properties owing both to the polymeric nature of a substance and to the possibility of directed variation of the structure of the active component.

As known, practically acceptable NLO susceptibilities χ^3 are exhibited by compounds containing a sufficiently long π-conjugation system (e.g., β-carotene, polyacetylene, polythiophene, etc. [3]). Despite much progress achieved in the development of materials with NLO properties, preparation of film-forming macromolecular compounds of the mentioned type or of composite materials of the guest-host type encounters many difficulties because of the poor solubility and complicated synthesis of polyconjugated polymers in the former case and the thermodynamic incompatibility of the polymeric and low-molecular-weight substances, in the latter. Earlier [4], we have proposed an alternative approach to preparing polymer systems exhibiting third-order NLO effects [third harmonic generation (THG)]. It is based on preparing ionic complexes between low-molecular-weight NLO-active chromophores and polymeric carriers [4], in particular, complexes of (4-hydroxyarylidene)alkanones and poly-1,10-decamethyleneacetamidine. It was shown that, owing to formation of quinoid moieties via ionization of chromophores by highly basic poly-1,10-decamethyleneacetamidine, it is possible to prepare filmforming polymer complexes with sufficient thermal resistance, which are stable for prolonged (over 2 years) periods of time and capable of efficient generation of the third harmonic.

The aim of this study was to analuze how the specific chemical structure of chromophores containing the 4-hydroxycinnamoyl moiety, which is capable of quinoidization, affects the THG efficiency of complexes of the above-mentioned compounds with poly-1,10-decamethyleneacetamidine.

EXPERIMENTAL

We synthesized 1-(4-hydroxyphenyl)-5-arylpenta-1,4-dien-3-ones, 1-(4-hydroxyphenyl)-1-arylpropenones, and 1-(4-hydroxyphenyl)-7-phenylhepta-1,4,6-trien-3-one by the known procedures [5, 6]. Consistent analytical data and spectral characteristics were obtained for the synthesized compounds.

Poly-1,10-decamethyleneacetamidine was synthesized by the procedure described in our previous publication [6]. Analysis by gel-permeation chromatog-

raphy showed that the molecular weight of the poly-1,10-decamethyleneacetamidine sample used in the present study was 8000, and the polydispersity coefficient, 2.7.

Solutions of the complexes were prepared by mixing ethanolic solutions of the chromophore and poly-1,10-decamethyleneacetamidine, saturated at room temperature, in a 1 : 0.25 polymer:chromophore ratio (molar ratio of the repeating unit of the polymer to the low-molecular-weight compound). Samples for optical studies were prepared by casting the ethanolic solutions of the complexes onto a rotating glass substrate, followed by solvent vaporization at room temperature under atmospheric pressure. Prior to measurements, the resulting films were dried in a vacuum (0.1 torr) to constant weight.

Calorimetric measurements were carried out with a DSC 7 Perkin–Elmer calorimeter in the range from –50 to 250°C at a heating rate of 10 deg min^{-1}. The UV spectra were recorded on a Varian Cary 100 spectrophotometer suitable for measuring the NLO characteristics of thin films. Thermogravimetric measurements were carried out on a TGA Perkin–Elmer instrument in the range from 30 to 500°C at a heating rate of 10 deg min^{-1}.

The NLO properties of the resulting materials were estimated by the THG method. The samples were excited with a Nd-YAG pulse laser operating at a wavelength of 1.06 μm in the *Q*-switched mode with pulse duration of 15 ns. The radiation energy in the pulse was widely varied (up to 30 mJ). The Gaussian 3D profile of the laser beam was set by selecting the highest transverse modes with an intra-resonator diaphragm. The *p*-polarized radiation was focused onto a sample under study using a convex spherical lens with F = 100 mm. Part (4%) of the radiation was diverted by a beam splitter to a calibrated photodiode. The light from the sample was directed via a lens system to the entrance slit of an MDR-2 grating monochromator and further to an FEU-106 photomultiplier. The electrical signals from both the photodetectors were fed to an integrating analog-digital converter and further, via the CAMAC instrumental interface, to a PC for subsequent processing.

In view of the difficulties encountered in determining the absolute values of the intensity of exciting radiation incident on the sample, the NLO susceptibility of the materials studied was determined against a reference. As the latter served a 0.5-mm-thick fused-silica plate set to the first intensity maximum of the third harmonic (Maker fringe method) [7].

In this case, the χ^3 parameter can be estimated for the materials studied by the relation

$$\chi^{(3)} = \chi_s^{(3)}[I^{1/2}(3\omega)/l_{c,c}]/[I_s^{1/2}(3\omega)/l_{c,s}].$$

Here, $I(3\omega)$ and $I_s(3\omega)$ are the intensities of THG by the samples and reference, respectively; $I_{c,c}$ and $I_{c,s}$ are their respective coherence lengths; $\chi_s^{(3)} = 3.11 \times 10^{-14}$ CGSE units for SiO_2 at λ = 1.06 μm.

To eliminate the influence of the intrinsic absorption of the sample at the THG wavelength (355 nm), the experimental $\chi^{(3)}$ values were normalized using the equation

$$\chi_n^{(3)} = \chi^{(3)}\ln(l/T)/[(l - T)T^{0.5}].$$

Here, $\chi_n^{(3)}$ is the normalized susceptibility, and T is the transmission at the THG wavelength.

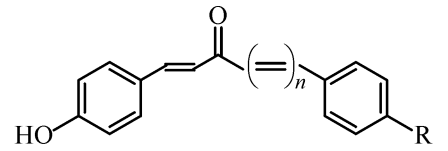
The geometry of the complexes was optimized by the STO-3-21G method (Hyperchem 7.01 software package; RSM energy gradient under 0.01 kcal mol^{-1} $Å^{-1}$). The absorption spectra were calculated by the ZINDO/S semiempirical method, taking into account the configurational interaction for 15 higher occupied and 15 lower unoccupied orbitals. The second-order hyperpolarizabilities were calculated by the AM1 (Austin Model) method (MOPAC 7.0 software package). The averaged hyperpolarizabilities were calculated by the equation

$$\gamma = \frac{\gamma_{xxxx} + \gamma_{yyyy} + \gamma_{zzzz} + 2(\gamma_{xxyy} + \gamma_{xxzz} + \gamma_{yyzz})}{5},$$

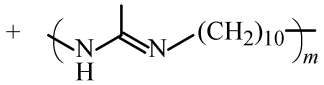
where γ_{ijkl} are the hyperpolarizability tensor components.

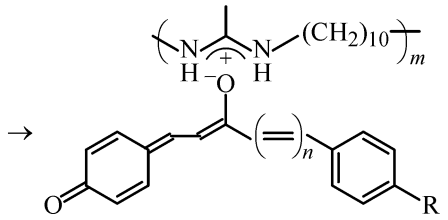
We have shown previously [4] that deprotonation of the chromophores from the series of 1-(4-hydroxyphenyl)-5-arylpenta-1,4-dien-3-ones and formation of quinoid moieties are necessary conditions for their complexes with highly basic polymers to exhibit third-order NLO activity. This effect is evidently due to changes in the conjugation character (transition from a cross-conjugated to a linear π system) and to an increase in the degree of delocalization of π electrons. Tykwinski *et al.* [8] demonstrated that, theoretically, the THG efficiency must be proportional to the conjugation system length raised to fifth power. Thus, it could be assumed that, in going from enol of 1-(4-hydroxyphenyl)-1-arylpropenone (**I**) to that of 1-(4-hydroxyphenyl)-5-arylpenta-1,4-dien-3-one (**II**) and further to that of 1-(4-hydroxyphenyl)-7-phenylhepta-1,4,6-tiren-3-one (**III**), which act as chromo-

phore groups in complexes of their corresponding compounds with 1,10-decamethyleneacetamidine, $\chi^{(3)}$ must obey a power law:



Ia–**Id**, **IIa**–**IId**, **III**





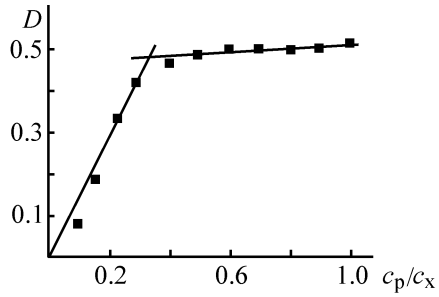
Here, **I**, n = 0, R = H (**Ia**), CH_3 (**Ib**), Cl (**Ic**), $N(CH_3)_2$ (**Id**); (**II**), n = 1, R = H (**IIa**), CH_3 (**IIb**), Cl (**IIc**), $N(CH_3)_2$ (**IId**); (**III**), n = 2, R = H.

It was found that all the chromophores are sufficiently acidic to form ionic structures when reacting with poly-1,10-decamethyleneacetamidine, which is manifested in a bathochromic shift (about 100 nm, depending on the chromophore structure) of the long-wavelength absorption band. According to quantum-chemical calculations, this band can be assigned to the π–π^* transition in the dye molecule.

The polymer reactivity toward a chromophore was found spectrophotometrically [9] (see figure). It was established that, in all cases, the chromophore is completely bound by the polymer molecule up to the polyamideto-chromophore ratio of 3 as calculated for the monomer unit of the polymer. In this context, we chose for studying the NLO properties, complexes containing 0.25 M chromophore per polyamidine unit.

The thermograms suggest that the resulting complexes are individual polymeric compounds, rather than mechanical mixtures of a polymer and a low-molecular-weight substance. The DSC curves of poly-1,10-decamethyleneacetamidine are indicative of a transition at 5°C (T_g), and those of all the complexes, only of a glass transition within 35–55°C, depending on the chemical structure of the chromophore.

As already mentioned, it could be suggested that, in going from enol **Ia** to enol **IIa** and, further, to enol **III** as chromophore groups in complexes with poly-1,10-decamethyleneacetamidene, the parameter



Absorption of the ethanolic solution of the complex (λ = 450 nm) vs. the polyamidine/**Ia** ratio. (D) Optical density, (c_p) concentration of 1,10-decamethyleneacetamidene, mole of unit l^{-1}, and (c_x) the concentration of **Ia**, mole of unit l^{-1}.

$\chi^{(3)}$ must increase. However, Table 1 suggests that the susceptibility is little affected by the conjugation chain length.

At the same time, it is seen that an increase in the number of ethylene units results in a minor bathochromic shift.

Table 2 lists the third-order molecular susceptibilities $\chi^{(3)}$ and the second-order hyperpolarizabilities

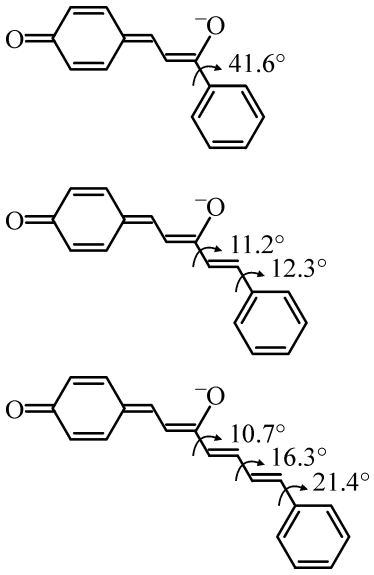
*  R (**Ia**–**Id**),  (**IIa**–**IId**).

γ for complexes containing chromophores **Ia**–**Id** and **IIa**–**IId**. Both the parameters characterize the THG efficiency, with $\chi^{(3)}$ related to the macroscopic effect, and γ, to the susceptibility of an individual molecule. Comparison of the parameters $\chi^{(3)}$ and γ for complexes from the series of substituted 1-(4-hydroxyphenyl)-1-arylpropenones and 1-(4-hydroxyphenyl)-5-arylpenta-1,4-dien-3-ones (Table 2) suggests that the length of the conjugation chain in the chromophore does not markedly affect the susceptibility. Moreover, auxochromes introduced into the molecules of 3-(4-hydroxyphenyl)-1-arylpropenone virtually do not affect $\chi^{(3)}$, whereas in the case of 1-(4-hydroxyphenyl)-5-arylpenta-1,4-dien-3-ones the susceptibilities correlate with the Hammett constants σ [6].

Our data suggest that the main contribution to the NLO effect comes from 3-(4-oxocyclohexa-2,5-dienyl)propene-1-ylate moiety, and the remaining segment of the molecule is less significant. The NLO effect, probably, results from a decrease in the degree of conjugation owing to the noncoplanar arrangement of the π bonds in the chromophore molecule. Quantum-chemical calculations of the molecular geometry of the chromophores in the complexes give the following dihedral angles φ between the "quinoid" and "nonquinoid" moieties of the chromophore molecule:



In view of the proportionality between the degree of conjugation and $\cos^2\varphi$, it can be assumed that the substituents must exert a virtually unnoticeable effect on the susceptibility in the case of 1-(4-hydroxyphenyl)-1-arylpropenones and a rather pronounced effect in the case of 1-(4-hydroxyphenyl)-5-arylpenta-1,4-dien-3-ones. The experimental data agree well with these assumptions.

Thus, the major contribution to the NLO effect manifested by quinoid forms of 4-hydroxybenzylidenalkanones comes from 4-hydroxycinnamoyl moiety, whereas the influence of the lengthening conjugation chain is largely eliminated by the noncoplanarity of the π system as a whole.

CONCLUSION

A study of the nonlinear optical properties of complexes of hydroxyphenyl-substituted unsaturated ketones with poly-1,10-decamethyleneacetamidine as influenced by the chemical structure of the ketones demonstrated that the major contribution to the NLO effect comes from the enol form of 4-hydroxycinnamoyl moiety of the chromophore.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Specific Features of Cellulose Phase Transition via Knecht Additive Compound

Received January 15, 2003

Abstract—The capability of cotton and wood cellulose in the common and microcrystalline forms to transform into cellulose-II under the action of 68–69% HNO_3 was studied. The influence of temperature on the course of the phase transition in cellulose samples differing in origin and morphological structure and the dynamics of concomitant hydrolytic degradation and esterification of these materials were studied.

Mercerization of cellulose (C) based on its intracrystallite swelling in solutions of alkali metal hydroxides is of great applied importance. Intracrystallite swelling of native C is also caused by HNO_3 at its concentrations close to 68.4% (concentration of the azeotropic mixture with water) [1]. As a result of swelling, the crystalline phase of the Knecht additive compound (KC) is formed [2–4]. The action of water regenerates the C-II polymorph from KC, which is similar to the behavior of alkaline C and makes it possible to speak about acid mercerization. Several examples of effective use of this process for preparing structurally and chemically modified forms of powdered C have been reported [4–6]; however, information about specific features of phase transitions of C in nitric acid medium is scarce.

Available data [7, 8] are limited to indications that the extent of the phase transition under the action of 66–69% HNO_3 at room temperature strongly depends on the parameters of the crystal structure of native C. The extent of phase transitions of C, associated with the formation of both KC and alkaline C, is determined by the transverse size $\bar{L}$ of the crystallites of the starting material [8].

Here we discuss the influence of temperature on nitric acid mercerization of C samples differing in origin and morphological structure. The concomitant chemical and physical transformations caused by the nontraditional mercerizing agent are analyzed.

EXPERIMENTAL

The main starting materials were as follows: cotton cellulose (CC) of Hercules brand [98% α-C, degree of polymerization (DP) 2000]; sulfide wood cellulose (WC) of Florenier brand (96% α-C, DP 1200); microcrystalline forms (MCC) of these kinds of cellulose (DP 200 and 160, respectively); and commercial MCC of LT Lachema brand. Preparation of cotton and wood MCC (CMCC and WMCC) involved the following steps: boiling of a fiber in 8% HNO_3 (1 h, liquid-to-solid ratio 20 ml g^{-1}), repeated washing of the slurry with water, and displacement of water with acetone. This was followed by drying at room temperature, grinding in a mortar, and collection of the fraction passing through a 100-μm-mesh sieve. The crystallinity index calculated according to [9] was 0.70 for CC, 0.74 for CMCC, 0.63 for WC, and 0.65 for WMCC. The treatment was preceded by keeping the materials in a desiccator over a saturated $NaNO_2$ solution (66% relative humidity).

Commercial 72% HNO_3 (ultrapure grade) was diluted to 68.5% concentration. The liquid-to-solid ratio in mercerization was 20 ml g^{-1}; the temperature was 20 (thermostat) or 0°C (vessel with thawing ice); the washing and drying procedure was the same as in preparation of MCC.

The degree of polymorphic transition was determined according to [9] from the X-ray diffraction patterns recorded on an HZG-4a diffractometer (Cu_{K_α} radiation, Ni filter). The results from 2–4 replicate measurements were averaged. The measurement error was ±5%.

The degree of polymerization of C was determined from the viscosity of solutions of its nitrate esters [10]. This procedure was successfully tested on samples with known DP. The content of bound nitrogen was determined by the Kjeldahl method. The physical and chemical transformations in C in the

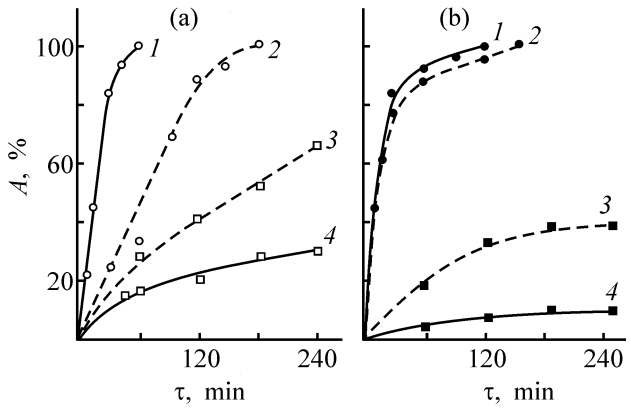

Fig. 1. Degree of conversion into C-II, *A*, of (a) fibrous and (b) microcrystalline forms of (*1*, *2*) WC and (*3*, *4*) CC vs. time τ of treatment with 68.5% HNO_3 at (*1*, *4*) 20 and (*2*, *3*) 0°C.

course of mercerization were monitored by IR spectroscopy (Specord 75-IR, KBr pellets). The water retention capacity (WRC) was determined according to [11], and the sorption power with respect to Congo Red, according to [12].

In contrast to alkali metal hydroxides, nitric acid is, relative to C, a multifunctional agent exerting complexing, estrifying, oxidizing, and hydrolyzing effects. This fact should be taken into account when choosing conditions for nitric acid mercerization. For example, the capability of HNO_3 to form an additive KC with C becomes pronounced at 68% concentration [7, 8]. At higher HNO_3 concentrations, this property is enhanced. At the same time, active accumulation of the pseudo-form of HNO_3 ($HO–NO_2$) causing *O*-nitration of C starts from approximately 69% concentration [10]. Thus, the stimulating effect of HNO_3 on the phase transitions is complicated by the esterifying effect of HNO_3 at its concentrations exceeding 69%. Therefore, we took 68.5% HNO_3.

It is known that traditional mercerization of C is better performed at low temperatures. This is due to the fact that the temperature coefficient of the rate of hydrolysis of alkaline C is higher than that of the rate of its formation. For nitric acid mercerization, such data are lacking.

Our experiments (Fig. 1) show that nitric acid mercerization of C samples of varied origin and morphology is characterized by different temperature dependences. With CC, the temperature dependence is similar to that observed in traditional mercerizartion: As the temperature of HNO_3 treatment is lowered from 20 to 0°C, the polymorphic transition is stimulated (Fig. 1). However, the conversion of the starting material into C-II is incomplete. Compared with the initial CC, the phase transitions in CMCC are considerably slower. The advantage of the common CC form over the microcrystalline form in the capability to form KC has been noted previously [7, 8]. It was presumed that structurally disordered areas of the fibers act as "mediators" facilitating access of HNO_3 to crystallites. However, this viewpoint fails to explain the following facts.

Under the conditions examined, treatment of C with HNO_3 causes complete and relatively fast conversion of sulfite WC into C-II. In contrast to CC, at 20°C the process occurs faster than at 0°C. The abnormal temperature dependence is especially pronounced in samples with common amorphous-crystalline morphology (Fig. 1a). In contrast to CMCC, microcrystalline wood cellulose undergoes mercerization at an unexpectedly high rate, virtually independent of temperature, until approximately 60% conversion is attained (Fig. 1b). The final stage of the polymorphic transition at 0°C is somewhat slower than that at 20°C. According to [8], sulfite WC also shows increased activity in mercerization with NaOH solutions, whereas CC, along with ramie cellulose, is among the least active kinds of cellulose.

Apparently, the true temperature dependence of the rate of the permutoid (according to Mark) reaction of KC can be obtained from experiments with CC, since its chemical purity is higher than that of technical-grade WC, irrespective of its production process. The content of C in the corresponding raw materials is up to 98% in cotton linters and no more than 55% in wood tissues. High concentration of lignin and hemicelluloses (including cellulosans) in wood and severe conditions of cooking, accompanied by degradation, negatively affect the capillary–poroius system and reactivity of the recovered C fibers. It is known that dense deposits of unremoved low-molecular-weight fractions, mainly hemicelluloses, alter the relative contributions of the capillary and diffusion transport of chemical agents in favor of the latter mechanism [10, 13]. Therefore, preactivation procedures are especially necessary in chemical processing of WC. As for CC fibers, concomitant substances affect their capillary-porous system to a lesser extent. The access of chemical agents to CC crystallites is facilitated by the high degree of crystallinity and presence of an internal channel in the fibers.

Thus, there is good reason to believe that, at low temperatures, the transport of HNO_3 to WC crystallites involves larger diffusion hindrance than its transport to CC crystallites. This may be associated with slow transport of the acid through hemicellulose de-

posits, because the hydrolytic activity is lower at low temperatures (Fig. 2). Correspondingly, the transformation of crystallites, detected by X-ray diffraction, is "delayed." This viewpoint is convincingly supported by the fact that WMCC is mercerized at 0°C faster than the initial cellulose. The acceleration is most probably due to weakening of the influence exerted by the diffusion factor on the process kinetics, which occurs when the crystallites get free of the structurally disordered binder. In traditional mercerization, the penetration of the chemical agent is facilitated by the solubility of hemicelluloses in alkalis. Furthermore, the equilibrium swelling of C in 68– 69% HNO_3 is lower than that in NaOH solutions [14].

The incapability of both morphological forms of CC undergoing complete mercerization in conditions at which mercerization of the same forms of WC goes to completion (Fig. 1) is consistent with the concept of Ioelovich and Veveris [8, 9, 15], which concerns the influence of the crystallite dispersity on the extent of phase transitions involving formation of additive compounds. Crystallites of Hercules CC ($\bar{L}$ = 10 nm) are considerably larger than those of Florenier WC ($\bar{L}$ = 6 nm) [15]. As a result of hydrolysis of cellulose fiber to "limiting" DP, $\bar{L}$ inevitably grows owing to recrystallization and hydrolytic breakdown of the smallest crystallites. It follows from [8, 9, 15] that, in preparation of CMCC, the increase in $\bar{L}$ is appreciably more pronounced (~35%) than that in preparation of WMCC (~20%). As the difference between the crystallite sizes of these two kinds of microcrystalline C increases, the difference between the degrees of their mercerization grows also, reaching a factor of 10 (Fig. 1b). Microcrystalline wood cellulose is mercerized at 0°C faster than the initial C, despite the coarsening of crystallites in the partial hydrolysis. However, the coarsening of crystallites is responsible for the appearance of a pronounced slow (final) stage of mercerization of the coarsest crystallites. In all probability, the crystallite size in both morphological forms of WC is smaller than the level limiting the degree of polymorphic transition under the treatment conditions examined. It is quite probable that specifically this fact is responsible for the better suitability of wood C for nitric acid mercerization.

In the course of nitric acid mercerization, common amorphous-crystalline C undergoes significant degradation (Fig. 2). A fast decrease in the DP of the starting C in the initial period of treatment with 68.5% HNO_3 is followed by slow degradation of chain molecules. The rate of hydrolytic cleavage of macromolecules strongly depends on the mercerization temperature. Complete polymorphic transition of Florenier WC at 20°C (1-h treatment with HNO_3) is accompanied by a decrease in the initial DP (1200) by approximately a factor of 3, and at 0°C (3-h treatment with HNO_3), by only a factor of 1.5. In contrast to the initial C, its microcrystalline form remains resistant to hydrolysis under conditions of intracrystallite swelling, too. A factor that possibly prevents development of degradation processes is the high stoichiometry of the interaction of 68.5% HNO_3 with C macromolecules in crystallites [3, 16]. According to [3], the Knecht compound contains one HNO_3 molecule per two anhydroglucopyranose units of C. Within the time of complete mercerization of Florenier WMCC, both at 20 and at 0°C, the initial degree of polymerization remains virtually unchanged (Fig. 2).

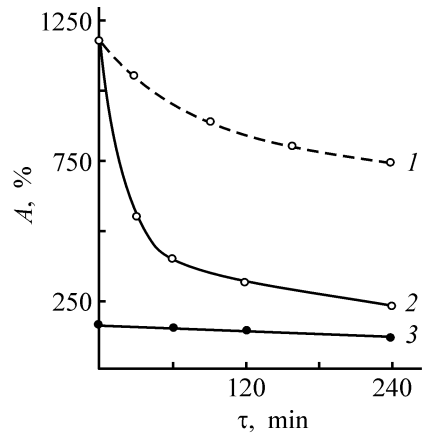

Fig. 2. DP of (*1*, *2*) initial and (*3*) microcrystalline Florenier *C* vs. mercerization time τ at (*2*, *3*) 20 and (*1*) 0°C.

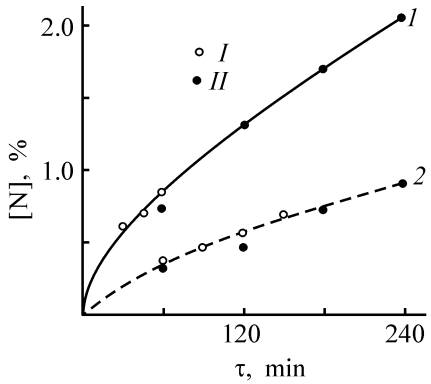

Fig. 3. Content of chemically bound nitrogen [N] in (*I*) initial and (*II*) microcrystalline Florenier C vs. time τ of treatment with 68.5% HNO_3 at (*1*) 20 and (*2*) 0°C.

Specific features distinguishing C-II from C-I [17] are clearly manifested in IR spectra of mercerized C. There is no evidence of oxidative transformations (no carbonyl absorption in the range 1700–1800 cm^{-1}), but the bands belonging to nitric acid esters (1650, 1280, 850, 750 cm^{-1}) are present. The rate of accumulation of bound nitrogen in C strongly depends on the temperature of treatment with HNO_3 (Fig. 3).

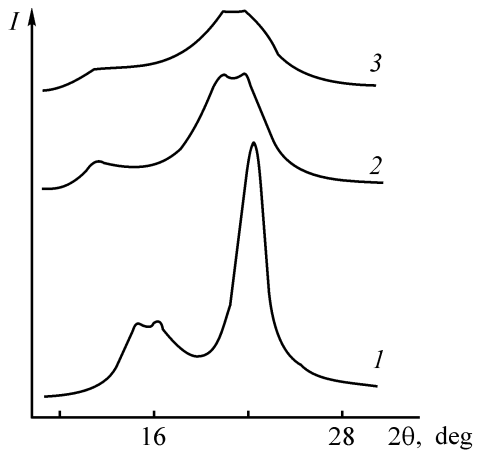

Fig. 4. X-ray diffraction patterns of Florenier MCC: (*1*) initial, (*2*) mercerized for 4 h at 0°C, and (*3*) mercerized for 3 h at 20°C. (*I*) Relative intensity and (θ) Bragg angle.

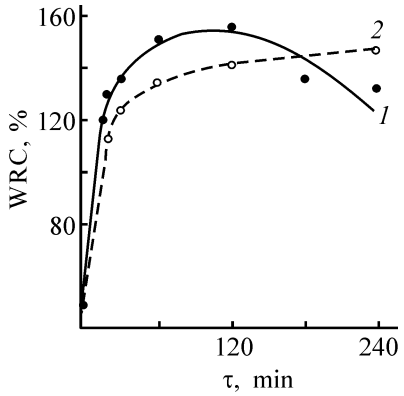

Fig. 5. Water retention capacity WRC of Florenier MCC vs. time τ of mercerization at (*1*) 20 and (*2*) 0°C.

The morphology of the starting material affects esterification with HNO_3 only slightly. Samples of Florenier C accumulate in the course of complete mercerization at 20 (1-h treatment with HNO_3) and 0°C (3-h treatment with HNO_3) approximately equal amounts of nitrogen, 0.7–0.8% (degree of substitution, DS_{ONO_2} 0.8–0.9).

In nitric acid mercerization of WMCC, the effect of esterification on the physical structure of the products is appreciable. Microcrystalline wood cellulose mercerized at 0°C (2.5-h treatment with HNO_3) considerably surpasses in crystallinity the same cellulose mercerized at 20°C (2-h treatment with HNO_3). In the latter sample, the content of bound nitrogen is almost two times higher (~1.3%, DS_{ONO_2} 0.15). Upon longer (4 h) mercerization, the nitrogen content increases to 2% (DS_{ONO_2} 0.25).

In the X-ray diffraction patterns of the products obtained, the crystallite scattering degenerates as the degree of esterification grows, and at DS ≥ 0.25 it virtually disappears. At the same time, in the X-ray diffraction pattern of the MCC sample mercerized for 4 h at 0°C, the crystallite scattering of C-II is rather well pronounced (Fig. 4), since the content of bound nitrogen is as low as 0.9% (DS_{ONO_2} 0.1). There is a clear correlation between the degrees of esterification and decrystallization of mercerized WMCC. We believe that partial esterification is the major factor responsible for the structural disordering of WMCC in the course of its nitric acid mercerization. It should be emphasized that the clearly pronounced decrystallization effect can be observed specifically in mercerization of WMCC. This effect may be favored by relatively low length of WMCC macromolecules, comparable with the segment length in common C.

The different rates of accumulation of bound nitrogen are also responsible for different trends in variation of WRC in the course of WMCC mercerization at 20 and 0°C (Fig. 5). The materials formed by the time when transformation of the native WMCC structure to the hydrated cellulose structure at 20 and 0°C is complete exhibit WRC of 155 and 143%, respectively. Apparently, the observed difference is due to nonequivalent contributions of the decrystallizing effect of *O*-nitration to the increase in WRC. At the same time, accumulation of nitric acid ester groups enhances the sample hydrophilicity owing to decrystallization until the hydrophobizing effect of the ester groups on the forming hydrated cellulose becomes prevailing. In the products of WMCC mercerization at 20°C for 3 and 4 h, the hydrophobizing effect prevails over the effect associated with decrystallization, which results in a noticeable decrease in WRC; however, WRC remains on the level characteristic of WC mercerized by the traditional procedure [13]. In the case of WMCC mercerization at 0°C, esterification is inhibited, and the corresponding effect of the forming hydrated cellulose on WRP is positive (though weakened) in the entire range of mercerization times examined.

To conclude, nitric acid mercerization of specifically WMCC enhances to the greatest extent its sorption activity owing to decrystallization. This can be judged from comparison of the kinetic curves of Congo Red sorption on commercial MCC (LT Lachema) and on the product of its 3-h mercerization at 20°C (Fig. 6). The initial MCC sample is one of the best sorbents of this class, which is used in thin-layer chromatography. As seen from Fig. 6, the limiting sorption of the dye by the mercerized sample increases by approximately 60% as compared with the initial sample, and the sorption–desorption equilibrium is attained approximately four times faster.

CONCLUSIONS

(1) The rate of the polymorphic transition in wood cellulose decreases by about a factor of 3 as the temperature of treatment with 68.5% HNO_3 is lowered from 20 to 0°C, owing to the prevalence of the diffusion transport of the reagent to crystallites over the capillary transport, in contrast to cotton cellulose in which the phase transition occurs faster at lower temperature of HNO_3 treatment. The diffusion hindrance is due to weakening of the hydrolytic activity of HNO_3 at low temperatures, so that it passes more difficultly through hemicellulose deposits in capillaries and pores of wood cellulose fibers. It is quite natural that the microcrystalline form of wood cellulose, free of structurally disordered component, is mercerized under the action of HNO_3 at a rather high rate only slightly depending on temperature.

(2) The complete polymorphic transition of wood cellulose is accompanied by a decrease in the degree of polymerization by approximately a factor of 3 at 20°C and only 1.5 at 0°C. At the same time, the microcrystalline form of this cellulose is mercerized at 20 and 0°C without changes in the degree of polymerization, which is due to the high stoichiometry of interaction of HNO_3 with ordered macromolecules in crystallites (formation of the Knecht compound).

(3) Weak *O*-nitration of cellulose under the conditions of intracrystallite interaction with HNO_3 exerts a decrystallizing influence on the mercerization products, which is the stronger, the higher the temperature and the longer the treatment. This effect, which is the most pronounced in microcrystalline wood cellulose, enhances the hydrophilicity and sorption capacity of the final products.

Abstract—Two previously unknown phenomena were observed in studying the reduction of selenious acid with ascorbic acid in an aqueous hydroxyethyl cellulose solution: (1) formation of nanoparticles of amorphous Se^0 with uniform particle size distribution and mean particle radius of 15 ± 4 nm and (2) adsorption of more than 3000 macromolecules on these nanoparticles with formation of spherical nanostructures.

Thanks to its availability, permanently reproducible natural sources, and wide potentialities for chemical modification, cellulose is of indisputable scientific and practical interest as the basis for development of novel materials for biomedical and health purposes. At the same time, in view of the rapid development of nanotechnology and supramolecular chemistry, particular attention is paid to study of metal–polymer systems containing nanoparticles of metals in zero oxidation state. Such nanoparticles 1–100 nm in size in polymeric matrices demonstrate anomalous physicochemical, catalytic, and biological properties, which is caused by high energy saturation of their surface [1].

For instance, Ag^0 nanoparticles stabilized by polyvinylpyrrolidone demonstrate unique pharmacological properties [2], which are not characteristic of bulk silver. In impregnation of bacterial cellulose (BC) gel films with aqueous solutions of such nanocomposites, Ag nanoparticles are irreversibly adsorbed on the cellulose matrix. As a result, such a bandaging material acquires high antimicrobial activity [3]. Kotel'nikova [4] has succeeded in diffusion-reductive intercalation of silver nanoparticles into fibers and films of microcrystalline cellulose (MCC). In this method, the morphological structure of cellulose is modified, and silver nanoparticles are tightly bound to the cellulose matrix.

It is noteworthy that there are virtually no data on polymer-stabilized nonmetallic nanoparticles. Of particular interest are nanoparticles of amorphous selenium (nano-a-Se^0), which demonstrate not only unique photoelectric, semiconducting, and X-ray-sensing properties, but also exceptionally broad spectrum of biological activity [5].

Since BC and MCC are insoluble in most of solvents, a study of their interaction with nanoparticles in solutions is quite problematic. Here we report on the interaction of the water-soluble polysaccharide hydroxyethyl cellulose (HEC) with nano-a-Se^0.

EXPERIMENTAL

We chose as object of study a-Se^0 nanoparticles prepared by reduction of selenious acid (SA) in an aqueous ascorbic acid solution both in the presence and in the absence of HEC.

We used reagents with the main substance content of no less than 99.99%. The hydroxyethylcellulose used had a degree of substitution of 1.2 and MW 150×10^3.

The reduction kinetics was studied spectrophotometrically (Specord M40, λ = 320 nm, 20°C) at an SA concentration of 1.7 mM and pH 3.1.

Reduction of Se(IV) in its 0.01 wt % solution gives nanocomposites with HEC-to-Se^0 weight ratio of 90 : 10.

The relative viscosity η_r was determined with an Ostwald capillary viscometer (water outflow time 120 ± 0.2 s at 21°C).

Using the flow birefringence (FBR) method [6] we characterized the molecular dispersity of the ad-

1070-4272/03/7604-0600 $25.00 © 2003 MAIK "Nauka/Interperiodica"

sorbates formed. The FBR value Δn was determined as dependent on the rotor speed gradient g and the HEC concentration c at a fixed Se concentration.

In the experiments, we used a titanium dynamo-optimeter with 4-cm-high inner rotor and 0.03-cm gap between the rotor and stator. All the FBR measurements were performed with temperature control (21°C) to eliminate changes in the solution viscosity and also optical distortions induced by the temperature gradient. The measuring system was calibrated against phenylethanol, which is characterized by high FBR ($\Delta n/g = 17 \times 10^{-12}$), and the polystyrene–bromoform system. The intrinsic FBR $[n] = \lim_{g \to 0, c \to 0} (\Delta n/gc\eta_0)$, where η_0 is the solvent viscosity, was determined to within 10%. The measurements were carried out at $g < g_k$, where g_k is the speed gradient at which flow turbulence starts.

The experimental value of $[n]$ ($dn/dc \neq 0$, where dn/dc is the increment in the refractive index of the solution, which is 0.102 and 0.149 for the systems investigated, HEC–H_2O and HEC-Se^0–H_2O, respectively) is, generally, composed of three terms: $[n] = [n]_e + [n]_{fs} + [n]_f$. Here $[n]_e$ is the intrinsic anisotropy; $[n]_{fs}$, microform term; $[n]_f$, macroform term [6]. In this case, the total segment anisotropy ($[n]_e + [n]_{fs}$) is determined by the equilibrium rigidity A of the polymer chain and the polymer unit structure, and $[n]_f$ is related to the asymmetry p of the shape of a macromolecule (particle) as

$$[n]_f = [(n_s^2 + 2)/3)^2 [M_w (dn/dc)^2 f(p)]/(30\pi RTn_s)$$
$$= \text{const}\, M_w (dn/dc)^2 f(p).$$

Here M_w is the molecular weight of the adsorbate macromolecule; n_s, refractive index of the solvent; T, absolute temperature; R, gas constant; $f(p)$, tabulated function for the axis ratio of a rigid (impermeable to the solvent) ellipsoid approximating the particle shape [6].

Therefore, for flexible and moderately rigid-chain high-molecular-weight polymers ($A < 5$ nm) characterized by low optical anisotropy and low molecular weight of the polymer unit, the relationship $[n] \sim [n]_f$ is valid, allowing direct estimation of the parameter p from the experimental data on FBR [6].

The nanostructures investigated were characterized by the molecular weight M_w and size R_g, using the static light scattering method [7], and also by their solvent (water) affinity using data on the second virial coefficient A_2. The amount of adsorbed macromolecules on the surface of Se nanoparticles was determined from the relationship between the M_w values for HEC and its adsorbates. The reduced intensity of light scattering of solutions, R_θ, was determined with a Fica photogoniodiffusometer. The wavelength of vertically polarized incident light was 546.1 nm. The measurements were performed over the scattering angle range $\theta = 30°$–$150°$. The solutions and solvents were clarified by centrifugation at 15 000 rpm for 1–1.5 h. The increment in the refractive index, dn/dc, was estimated from the refractometric data (IRF23 instrument).

The experimental light-scattering data were processed by the Zimm method by double extrapolation (to $c = 0$ and $\theta = 0$) of the Kc/R_θ-vs.-[$\sin^2(\theta/2) + kc$] plot (K is the calibration constant, and k, empirical parameter).

The mean hydrodynamic size R_H of the particles was determined by the quasi-elastic (dynamic) light scattering method [8]. The parameter ρ^*, which characterizes the conformation of nanostructures was estimated from experimental R_g and R_H obtained for the HEC–Se^0 adsorbate [9–12].

The optical part of the setup for measuring the dynamic light scattering was equipped with an ALV-SP goniometer (Germany) and a Spectra-Physics He–Ne laser (λ 632.8 nm, 20 mW) as a source of light. The correlation function for the light-scattering intensity was obtained with a 288-channel Photo Cor-FC correlator (Anteks Private Company, Russia). Experimental data were processed using the cumulant and Tikhonov's regularization methods.

In SA reduction with ascorbic acid, the first-order rate constant with respect to SA was found to be 1.56×10^{-3} s^{-1}, and that in the presence of HEC, 0.42×10^{-3} s^{-1}. In the absence of the polymeric stabilizer, the Se nanoparticles appeared to be aggregatively unstable. In 3–4 days they formed conglomerates and precipitated. In the case of polymer-stabilized nano-Se^0, the aggregative stability of the particles was preserved for at least 6 months.

On passing from the initial HEC to the HEC–nano-Se^0 adsorbate, the intrinsic viscosity $[\eta]$ decreases from 5.3 to 3.6 dl g^{-1}. However, according to the static light-scattering data, the molecular weight M_w of the adsorbate is 480×10^6, which is higher by a factor of 3200 than that of free HEC.

The second virial coefficient A_2 of the HEC–Se^0–H_2O system is zero, suggesting the ideal thermodynamic state of the solution.

The mean hydrodynamic radius R_H of free HEC in aqueous solutions is 182 nm, and that of Se nanoparticles obtained in the absence of the polymeric stabilizer, 170 nm. The size of the HEC–Se^0 adsorbate, estimated by the dynamic and static light-scattering

methods, is smaller (mean-square radius of inertia R_g = 85 nm and mean hydrodynamic radius R_H = 147 nm). In this case, the parameter $\rho^* = R_g/R_H = 0.6$, which suggests an ideal sphericity of the adsorbate formed [9–12].

To determine the radius of Se particles in the adsorbate core, we employed lyophilic drying of the HEC–Se^0 aqueous solution. The resulting dry product was pelletized and studied by the low-angle X-ray scattering method. The radius of Se^0 spherical particles was determined to be 15 ± 4 nm, which is an order of magnitude smaller than that of the Se particles obtained without the polymeric stabilizer (171 nm). Therefore, in the aqueous solution, the depth of the satellite polymeric coating on the Se^0 nanoparticles is about 70 nm, i.e., adsorption results in a considerable compaction of the macromolecules.

On passing from the HEC–H_2O system to HEC–Se^0–H_2O, the optical anisotropy increases substantially from 300 to 3000 $cm^4 s^2 g^{-2}$, which is probably due to the adsorption of a huge number of macromolecules on single nano-Se^0 particles, with the hydrophobic interactions of the nonpolar fragments of the macromolecules with nano-Se^0 being the major driving force of the adsorption.

It should be pointed out that, in the HEC–H_2O and HEC–Se^0–H_2O systems, the molecular dispersion of the solutions remains unchanged over the whole c range, as demonstrated by the features of the $\Delta n = f(g)$ dependences (at $g < g_k$ they are well approximated for any c by straight lines crossing the origin of coordinates).

The parameter p estimated for the HEC–Se^0–H_2O system in the $[n] \sim [n]_f$ approximation revealed that the nanostructure takes a practically ideal spherical conformation (p = 1.4) (it is known that, in water, HEC takes a conformation of Gaussian globule [13]). Taking into account the increased rigidity of HEC (A = 15 nm) [13], one may conclude that the actual p value is even closer to unity. Therefore, the adsorbate is an ordered spherical nanostructure.

Finally, the results obtained cast light on the nature of structural and morphological transformations of cellulose in formation of metallic and nonmetallic nanoparticles in its matrix.

CONCLUSIONS

(1) Spherical nanoparticles of amorphous selenium about 15 nm in size were obtained by reduction of Se(IV) in the selenite–ascorbate redox system.

(2) In the system formed by hydroxyethyl cellulose, Se^0, and water, the viscosity of a solution falls, and the solution properties approach those of an ideal solution, which suggests the formation of compact aggregatively stable adsorbates of the macromolecules on selenium nanoparticles.

(3) The resulting adsorbate is a supramacromolecular close-packed spherical nanostructure consisting of about 3000 macromolecules, as demonstrated for the first time by methods of molecular hydrodynamics and optical methods.

Nesmeyanov Institute of Organoelemental Compounds, Russian Academy of Science, Moscow, Russia

Received August 2, 2002

Abstract—The electrical conductivity of composites produced from thermally expanded graphite, isoprene rubber, and polyvinyl chloride plastisol was studied as influenced by the process conditions.

Preparation of conducting polymers (CPs) is a topical task of modern materials science. Highly conductive polymers are extensively used to ensure reliable operation of radio equipment in, particular, to shield radioelectronic devices [1–7].

Low-resistance composites are known [6] to contain, as a filler, expensive fine silver powders in high amounts.

In this study, we prepared highly conductive polymeric composites containing thermally expanded graphite (TEG) as filler and analyzed their properties as influenced by the conditions of mixing of the filler with a binder.

EXPERIMENTAL

Thermally expanded graphite was prepared by the hydrosulfate procedure [8–10] involving the following three main steps: (1) stirring of low-ash GSM-1 graphite for 30 min in a mixture of concentrated nitric and sulfuric acids to form an intercalation compound (graphite hydrosulfate), (2) hydrolysis of the graphite intercalation compound with water and drying of oxidized graphite to a friable state, and (3) thermal expansion of oxidized graphite by rapid heating to 800–900°C to form TEG. The bulk density of the TEG was ρ_{bulk} = 16 g l^{-1}. Elemental analysis showed the presence of up to 0.5 wt% sulfur in the TEG. As determined by scanning electron microscopy with 100-nm resolution, graphite had pronounced layered structure [11].

Since TEG has the layered structure, it can be rolled to give highly conductive sheets. A porous flat 1–2-cm-thick TEG sample prepared by compacting a TEG powder was rolled on bench rolls with variable gap to thickness of 0.7–0.3 mm. The rollers were 10 cm in diameter (*D*), and their rotation rate was ν = 5–15 rpm. Dense sheets of TEG are formed by compaction of the initial porous sample; in the process, the gap between the rollers and the shearing stress arising in the course of rolling were varied.

We used SKI-3 rubber and polyvinyl chloride (PVC) plastisol as binders for prepating conducting TEG composites.

The conducting composites of TEG (50%) and SKI-3 rubber were prepared by the following procedure. A rubber solution in benzine (1 l, 15 g l^{-1} concentration) was mixed with dicumyl peroxide (1 g) and TEG (15 g). The solvent was removed on a rotary evaporator at 50°C to give a loose powder. To obtain samples for resistance measurements, the resulting formulation was pressed in a mold at 143°C and a pressure of 20 MPa for 30 min.

The plastisol technology is frequently used to produce highly filled polymeric composites [12]. This is due to low viscosity of the plastisol, simple production of the composite, and satisfactory physicomechanical properties of the plastigel.

The procedure for preparing PVC–TEG composites included the following steps. An EP-66 PVC powder was thoroughly mixed with dioctyl phthalate in the weight ratio of 2 : 1 or 1 : 1. The mixture was plasticized on a water bath at 90°C for 45 min. To inhibit dehydrochlorination, 3wt % of calcium stearate was added with vigorous stirring. Then, the conducting filler, TEG, was added. The mixture was stirred until a uniform composition was formed. The composites was prepared by pressing in a mold at 0.2–0.5 MPa. The resulting samples were rolled at 120–140°C with the gap between the rollers slowly varied.

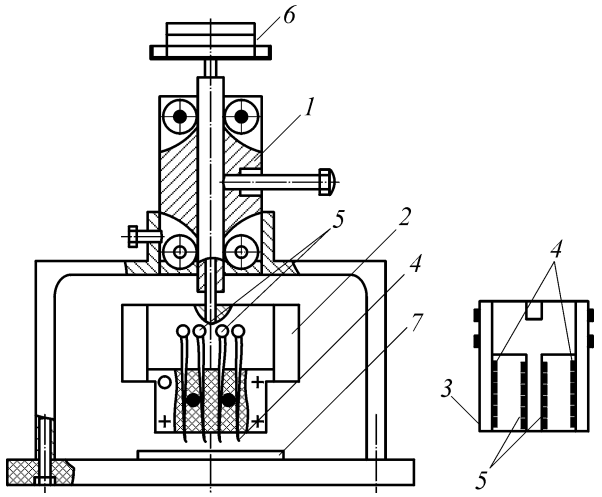

Fig. 1. Unit for measuring the electrical conductivity of the composites by the four-probe method. (*1*) pressure pad, (*2*) removable contacts with needle electrodes, (*3*) removable contacts with plate electrodes, (*4*) current electrodes, (*5*) potential electrodes, (*6*) load on the pressure pad, and (*7*) sample.

The bulk resistivity ρ_v of the composites was measured by the four-probe method [13]. To provide fast fixing of the sample, a pressure pad with removable contacts was used (Fig. 1).

The resistivity of the samples with thickness of 0.3 to 3 mm was measured with a contact unit made from Plexiglas, in which plates of current and potential electrodes were fixed (Fig. 1). The resistivity ρ_v was calculated by the common equation for the plane-parallel geometry of conducting samples

$$\rho_v = R_{av}\frac{S}{l},$$

where R_{av} is the electrical resistance of a sample (Ω), calculated by the least-squares procedure from the $I(U)$ dependence; S, the area of a cross section of the sample with the plane normal to the current direction; l, the distance between the potential electrodes.

We measured the bulk resistivity of a sample 0.3 to 3 mm thick, 25 mm wide, and 40 mm long. The distance between the potential electrodes was 5 mm.

The shielding coefficient K_{sc} (dB) of the samples was determined as the logarithm of the ratio of the power of incident microwave radiation I_{inc} to that of the radiation passed through the sample I_{pas}:

$$K_{sc} = 10\log\frac{I_{inc}}{I_{pas}},$$

This coefficient depends on the radiophysical properties (complex permittivity and magnetic permeability) and thickness of a sample. As the conductivity of a sample increases, both the reflection of the electromagnetic energy from the conductive surface and the energy dissipation in the bulk of the sample increase. Hence, the shielding coefficient K_{sc} increases. The general equation taking the interference into account is rather cumbersome [14, 15]. However, for thin conducting nonmagnetic samples it reduces to the equation

$$K_{sc} \simeq 20\log(1 + 188\sigma d),$$

where 188 (Ω) is the wave resistance of free space, σ is the electrical conductivity of the material (S cm^{-1}), and d is the sample thickness (mm).

The shielding coefficients were determined on a unit for measuring coefficients of transmission and reflection of microwave radiation in rectangular 23 × 10 mm waveguide (H_{01} mode). The unit was constructed on the basis of P2-61 panoramic standing wave-ratio meter and was modified to allow automated measurements. The measurements on this unit involve the following steps. A sample in the form of rectangular plates 0.3 to 10 mm thick was placed in a rectangular waveguide at a right angle to the direction of propagation of the electromagnetic energy. The internal cross-section (23 × 10 mm) of the waveguide was completely covered. Identical directed couplers with built-in microwave diode detectors were fixed in front of, and behind the sample. A sweep oscillator was connected to one end of the waveguide, and a matched load, which substantially decreases the reflection from the end of the line, to the other end. Both microwave detectors were connected via an amplifier-demodulator to an analog receiver-divider of the signal. The sweep oscillator and receiver were controlled by a computer. The signal from both detectors is proportional to the electromagnetic power propagating from the generator to the load. Hence, the ratio of the detector signals is proportional to the ratio of the microwave power of the incident radiation and that of the radiation passed through the sample. Analog-digital processing of this ratio gave the shielding coefficient.

It is known [16, 17] that binder-free TEG is molded owing to mechanical adhesion of the carbon layers. The folded and deformed structure of the carbon layers favors compression of the material and formation of graphite foil in the course of rolling on rollers with variable gap.

The electricalal conductivity of a material strongly depends on its production process. For example, pressed 3-mm-thick TEG sample with bulk density

ρ_{bulk} = 140 g l^{-1} has volume conductivity Σ_v = 1.5×10^2 S cm^{-1}, tensile strength γ_t = 0.05 MPa and relative elongation at rupture ε = 2%. After rolling of this sample to a thickness of 0.4 mm, these parameters changed as follows: ρ_{bulk} = 1100 g l^{-1}, σ_v = 1.5×10^3 S cm^{-1}, γ_t = 0.5 MPa, and ε = 5%.

The conductivity of graphite foil is close to the limiting value permissible for preparing TEG composites, since the conductivity of a composite composed of a conducting filler and dielectric binder must be lower than that of graphite foil because of the formation of nonconducting layers between graphite particles.

The dependence of the conductivity of TEG–SKI-3 rubber composites on the concentration of the conducting filler is shown in Fig. 2. As seen from Fig. 2, the conductivity reaches 60–80 S cm^{-1} at filler concentration of 50–60 wt %. This value is lower by a factor of 20–30 than the conductivity of a TEG foil but is sufficient for preparing antistatic materials or materials shielding high-frequency electromagnetic radiation.

After rolling of the samples at 40°C at different rotation rates of the rollers (the procedure typically used with rubber stocks), which provides more uniform distribution of the filler in the rubber, the elasticity and strength increases and the conductivity decreases. The conductivity of a sample containing 60 wt % TEG decreases by a factor of 10 (σ_v = 7.7 S cm^{-1}) and the tensile strength and relative elongation increase by a factor of 2 (γ_t = 1.2 MPa and ε = 10%) after rolling of the sample for 7 min. Probably, the conductivity decreases owing to degradation of conducting TEG aggregates in the SKI-3 polymeric matrix under high dynamic stresses arising in the course of the rolling.

We studied the conductivity of the composites based on PVC plastisol as influenced by the procedure for rolling the samples on rollers with variable gap. The conductivity of PVC composites containing initial GSM-1 low-ash graphite and TEG is higher at low TEG content.

When the content of GSM-1 graphite in the PVC composites ranges from 33 to 55 wt %, the conductivity of the samples σ_v (ρ_{bulk} = 800–870 g l^{-1} for unrolled samples) increases from 2.5×10^{-5} to 0.1 S cm^{-1}. At the filler content of 3.6 to 13 wt %, the conductivity of unrolled samples filled with TEG (ρ_{bulk} = 450–500 g l^{-1}) increases from 2.0×10^{-4} to 1.0 S cm^{-1}. The conductivity of the samples filled with TEG and rolled on rollers with variable gap grows from 3.3×10^{-3} to 25.0 S cm^{-1} as the concentration of the conducting filler is increased from 2.4 to 26 wt %.

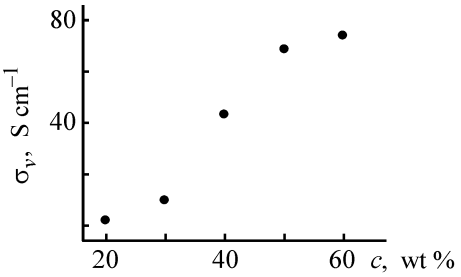

Fig. 2. Electrical conductivity σ_v of composites based on SKI-3 rubber vs. the concentration c of TEG conducting filler.

The physicochemical parameters of PVC composites with 9.1 wt % TEG rolled at 120–140°C and different gaps between the rollers, are listed in Table 1.

The rise in the conductivity of the samples after rolling is obviously due to an increase in the number of conducting chains in a unit volume owing to a change in the bulk density of the composite from 400 to 1000 g l^{-1}. The rise in the tensile strength and relative elongation of the samples may be due to strengthening of the interaction between TEG and the binder during rolling.

The volume conductivities σ_v, tensile strengths γ_t, and elongations at rupture, ε, of the composites with varied TEG content are listed in Table 2. These

Table 1. Physicomechanical parameters of PVC plastisol–TEG composites rolled at different gaps between rollers h (PVC : DOP = 1 : 1)

h, mm	σ_v, S cm^{-1}	γ_t, MPa	ε, %

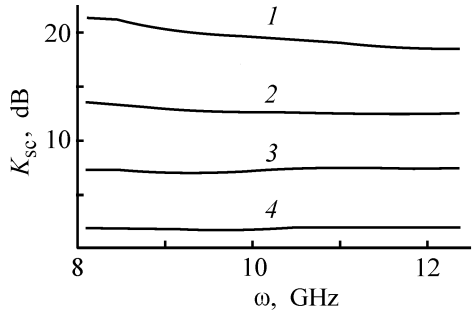

Fig. 3. Shielding coefficient K_{sc} of TEG–PVC composites vs. frequency ω. TEG content (wt %): (*1*) 25, (*2*) 26, (*3*) 14, and (*4*) 6.3. Sample thickness (mm): (*1*) 0.70, (*2*) 0.25, and (*3*, *4*) 0.30.

data confirm the advantages of composites with TEG filler, rolled at a variable gap between rollers. As seen from Table 2, the electrical conductivity σ_v of composites increases by four orders of magnitude when the filler content is raised by an order of magnitude. The tensile strength increases owing to strong interaction of TEG with the binder.

As noted above, the composites can be used for various radio engineering purposes. Experimental dependences of the shielding coefficients of radio-frequency radiation for PVC–TEG composites are shown in Fig. 3.

Having all properties of graphite, TEG exhibits new properties, such as easy molding, low bulk weight, and strong interaction with a polymeric matrix, which makes TEG promising for preparing conducting composites.

CONCLUSIONS

(1) Low-resistance composites with thermally expanded graphite as filler of the polymeric binder were prepared at lower filler content as compared with that of other graphites.

(2) The conditions for preparing polyvinyl chloride-thermally expanded graphite composites with the conductivity from 10 to 25 S cm^{-1} were determined.

(3) The mechanical and electrical properties of composites formed by polyvinyl chloride and thermally expanded graphite were determined as influenced by the rolling conditions.

(4) The possibility of using TEG composites for radio engineering purposes was demonstrated.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Specific Features of Suspension Copolymerization of Vinyl Chloride with Methyl Methacrylate

Abstract—Suspension copolymerization of vinyl chloride with methyl methacrylate was studied. The process is characterized by a pseudo-gel effect manifested as a sharp increase in the reaction rate after exhaustion of methyl methacrylate. The influence exerted by the monomer addition procedure on how the copolymer composition varies in the course of polymerization was examined.

Recently there has been a great deal of interest in modification of polymers by blending of macromolecular compounds of varied chemical nature. Naturally, these studies mainly concern combinations of various comprehensively studied and commercially available polymers. In particular, much attention is given to binary systems based on polyvinyl chloride (PVC) and polymethyl methacrylate (PMMA); however, most of these studies are purely scientific rather than applied. It has been shown that, in a wide range of compositions, this system exhibits two glass transition points and tends to form multiphase structures [1].

To improve the compatibility of PVC with PMMA, it seemed promising to add a third component, a copolymer of vinyl chloride (VC) and methyl methacrylate (MMA). Since the copolymerization constants of these monomers differ dramatically [2, 3], it can be expected that the resulting copolymer will be strongly nonuniform in composition and that the solubility parameters of its fractions will vary widely. This factor may be of decisive importance for improving the compatibility of PVC with PMMA. Furthermore, VC–MMA copolymers themselves may be of interest, since introduction of MMA units may improve the physicomechanical and optical properties of PVC, with the incombustibility of the material preserved. Therefore, we studied the suspension copolymerization of these monomers.

EXPERIMENTAL

Suspension copolymerization of VC with MMA was performed in a 3.5-l autoclave equipped with an impeller stirrer (180–200 rpm), a dosing unit, and a sampler. Methyl oxypropyl cellulose (F-50 brand) was used as protective colloid. The initiating system was a mixture of di-2-ethylhexyl peroxodicarbonate and lauryl peroxide. The ratio of the monomeric and aqueous phases was 1 : 2. The copolymerization was performed at 66°C until the pressure in the autoclave started to decrease. In some cases, with the aim to monitor variation of the composition and molecular weight of the copolymer, samples were taken in the course of the process. To obtain a copolymer with more uniform composition, the more active monomer, MMA, was introduced into the autoclave in small portions during the whole polymerization process. The polymer was separated from the mother liquor on a Büchner funnel, washed with distilled water, and dried in an oven at 55–60°C. The composition of the copolymers was evaluated from the chlorine content [GOST (State Standard) 25303–92], and the molecular weight (MW), from the Fickentscher constant K_F (GOST 14040–82), which varies in parallel with MW. In some cases, for PVC (control sample) and copolymers containing more than 50 wt % vinyl chloride, MW was determined from the Mark–Kuhn–Houwink equation [4] (cyclohexane, 25°C):

$$[\eta] = KM^{\alpha}, \text{ where } K = 1.37 \times 10^{-4}, \ \alpha = 0.78.$$

In synthesis of suspension copolymers VC–MMA of different compositions and approximately equal degrees of conversion, the process decelerates with increasing content of the more active component, MMA. It should be noted that approximately 80 wt % conver-

* K_p values for homopolymerization of the monomers [6].

sion is attained in 7.5 h in copolymerization of VC (95 wt %) with MMA (5 wt %) and in 2.5 h in homopolymerization of VC and MMA, i.e., the copolymerization rate is slower than the rate of homopolymerization of both monomers. This trend is characteristic of copolymerization of active monomers and inactive monomers in which the double bond is not conjugated with an unsaturated group of the substituent. The copolymerization constants for VC and MMA ($r_{VC,1}$ = 0.02, $r_{MMA,2}$ = 15) [5] and the rate constants of chain propagation in homopolymerization of VC and MMA allow calculation of the propagation rate constants for elementary stages of copolymerization. The table shows that the fastest elementary propagation reaction is the reaction of the VC propagation radical with MMA, and the slowest, the reaction of the MMA propagation radical with VC. This result is fully consistent with the well-known rule according to which inactive propagation radicals are formed from active monomers with π–π conjugation of the double bond and vice versa. The fastest stage involves the active VC radical and active MMA monomer, and the slowest stage, the inactive MMA radical and inactive VC monomer. The latter stage decreases the overall copolymerization rate as compared with the rates of VC and MMA homopolymerization, because the rate of a chain reaction is limited by the rate of the slowest stage.

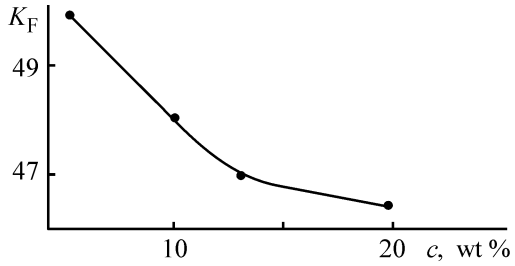

Fig. 1. Fickentscher constant K_F vs. MMA content *c* in copolymer with VC.

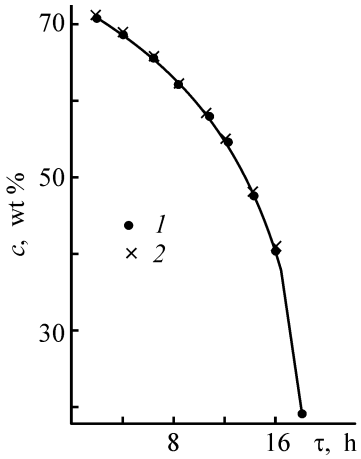

Fig. 2. Variation of the copolymer composition in the course of polymerization. MMA content in the monomer mixture 17 wt %. (*c*) Content of MMA units and (τ) reaction time; the same for Fig. 4. Copolymer samples taken (*1*) after termination of polymerization after a certain time and (*2*) directly in the course of polymerization.

Simultaneously, MW decreases, as judged from the variation of K_F (Fig. 1). The observed effects are due to a considerable difference in the copolymerization constants of VC and MMA. More active MMA monomer acts as a chain-terminating agent for the copolymer: As the MMA content in the macromolecule grows, K_F clealrly tends to decrease. Analysis of samples taken in the course of copolymerization shows that, in the initial stages, the polymer is strongly enriched in MMA, whereas in later stages, as MMA is exhausted, the composition of the copolymer becomes similar to that of the initial monomer mixture. The reliability of conclusions concerning the variation of the composition of the VC–MMA copolymer was confirmed by the consistence of composition data obtained by sampling in the course of polymerization and by stopping the polymerization at various stages by rapid cooling (Fig. 2). The dramatic changes in the copolymer composition in the course of conversion indicate that the copolymer is strongly nonuniform in composition.

A characteristic feature of copolymerization of VC with MMA is a pronounced pseudo-gel effect, specifically, sharp acceleration of copolymerization upon exhaustion of MMA. Therefore, in all the cases under consideration, the conversion in the initial stages is low, which is confirmed by kinetic curves in Fig. 3. In contrast to the true gel effect, which is due to a decrease in the rate of bimolecular termination with increasing viscosity of the reaction medium, the reaction acceleration in our case is due to a change in the apparent rate constant. It was already noted that MMA inhibits the copolymerization (addition of ~17 wt %

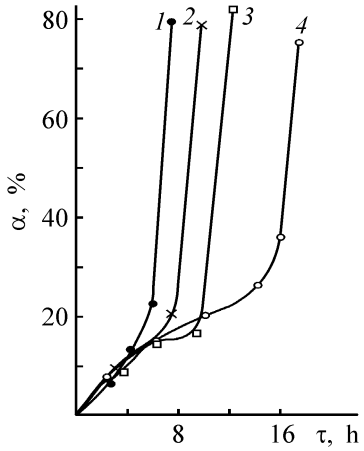

Fig. 3. Variation of the conversion α in the course of copolymerization at the MMA content in the monomeric mixture of (*1*) 5, (*2*) 9, (*3*) 13, and (*4*) 17 wt %. (τ) Reaction time.

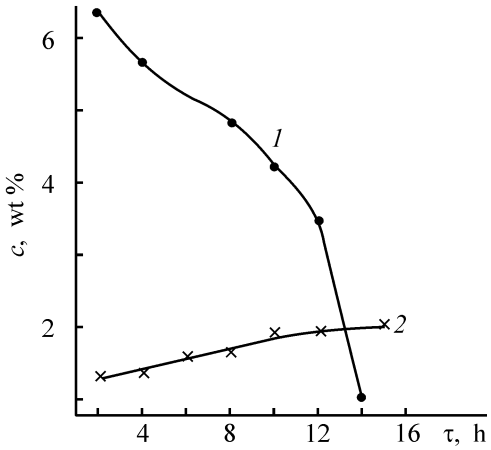

Fig. 4. Composition of copolymer vs. time for different ways of MMA introduction. MMA content in the monomer mixture 13 wt %. (*1*) Both monomers loaded simultaneously and (*2*) more active MMA added in portions.

MMA decelerates the process by more than an order of magnitude as compared with homopolymerization of VC). With increasing conversion, MMA is rapidly exhausted, the relative amount of low-active propagation radicals decreases, and, as a result, the chain propagation accelerates.

It was interesting to compare the trends in variation of the composition (monitored directly in the course of copolymerization) synthesized of VC–MMA copolymers with simultaneous addition of both monomers and with addition of more active MMA in portions (three portions at 3.5-h intervals). Figure 4 shows that, when both monomers are loaded simultaneously (curve *1*), the MMA content in the copolymer varies in a wide range (within more than 50%), whereas with addition of MMA in portions (curve *2*), this range is much narrower (about 6%), which means that the copolymer becomes much more uniform in composition, which favorably affects its solubility. It should be noted that, in the latter case, the MMA content in the copolymer is higher and its MW is somewhat lower (30 000 against 43 000) at the same composition of the monomer mixture.

CONCLUSIONS

(1) Suspension copolymerization of vinyl chloride with methyl methacrylate is characterized by the inhibiting effect of the second comonomer and significant variation of the copolymer composition with increasing conversion.

(2) Addition of more reactive methyl methacrylate in portions in the course of suspension copolymerization with vinyl chloride results in the formation of a product that is considerably more uniform in composition.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Sedimentation Kinetics of Bentonitic Clay Suspension as Influenced by pH of the Medium, Chemical Nature and Concentration of Surfactants, and Molecular Properties of Cationic Acrylamide Copolymer Flocculants

V. E. Proskurina, L. A. Akhmetova, and V. A. Myagchenkov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received December 6, 2002

Abstract—The kinetics of flocculation of bentonitic clay suspensions and thickening of the sediments was studied in the modes of free and hindered sedimentation as influenced by pH of the medium, chemical nature and concentration of surfactants, and molecular properties of cationic flocculants, random copolymers of acrylamide with dimethylaminoethyl methacrylate hydrochloride.

The kinetic dependences of flocculation and thickening of sediments of model disperse systems (MDs) in the presence of ionic and nonionic polyacrylamide flocculants (PAAFs) and their mixtures have been studied extensively, and the results are partially summarized in reviews [1–3]. At the same time, the effect of PAAFs on the kinetic aspects of flocculation and sedimentation stability of real DSs has been poorly studied.

Since real disperse systems are multicomponent compositions and frequently comprise involve a poorly characterized ensemble of dispersed phase (DP) particles [3, 4], a study of flocculation and thickening of real DS sediments in the presence of polymeric additives is obviously rather difficult. Thus, data on the effect of active components on the flocculation kinetics of real DSs (in particular, bentonitic clay suspensions) in the modes of their free and hindered sedimentation are of scientific and practical importance. This DS finds wide application in oil production as effective regulator of the bed permeability to aqueous and organic components of the dispersion medium, as sorbent of a wide assortment of pollutants present in wastewaters from motor-car factories, and as agent increasing the flake weight [2].

It should be particularly noted that a search for new active additives and study of sedimentation conditions both decreasing and increasing the sedimentation stability of the Bentokam clay powder are of practical importance. In oil production, a bentonitic clay suspension is added to multicomponent aqueous solutions with varied pH and containing various salt additives, wide assortment of surfactants, etc. The effect of the solution ionic strength on the kinetics of flocculation of bentonitic clay suspensions and thickening of sediments was studied in [5].

In this paper, we report on our continued studies in this direction and examination of the kinetics of flocculation of a bentonitic clay suspension in the modes of free and hindered sedimentation as influenced by the concentration and molecular weight of cationic acrylamide copolymers, solution pH, and surfactants. The cationic acrylamide copolymers in question are of particular interest owing to their high flocculating properties, which are probably related, to a certain extent, to the difference in the charge of the bentonitic clay particles and macromolecular cations. It should be noted that the pH of a dispersion medium strongly affects the macromolecule conformation and flocculation properties.

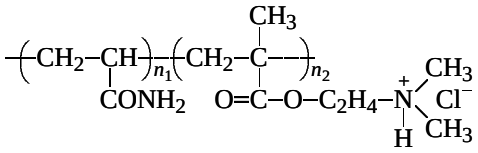
EXPERIMENTAL

In our study, we used a Bentokam bentonitic clay suspension from the Berezovo deposit (Tatarstan) [TU (Technical Specifications) 39-0147001-105–93] with average particle radius $R = 7.28 \times 10^{-6}$ m. The integral curve of the DP particle size distribution, found from data of sedimentometric analysis performed in the mode of free (unhindered) sedimentation, is shown

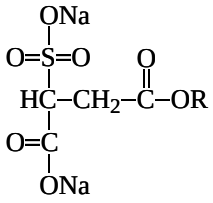
1070-4272/03/7604-0610 $25.00 © 2003 MAIK "Nauka/Interperiodica"

in Fig. 1. As seen, the minimal and maximal sizes of DP particles differ by nearly an order of magnitude ($\bar{R}_{min} = 0.24 \times 10^{-5}$ and $\bar{R}_{max} = 2.38 \times 10^{-5}$ m). As cationic PAAFs we used samples of a random copolymer of acrylamide and dimethylaminoethyl methacrylate hydrochloride with varied molecular weight and similar compositions of the copolymer macromolecules (weight content of ionic units β 16.3%).

Similarly to [6], the polymer samples were prepared by radical degradation of the initial macromolecular copolymer $\mathbf{K}_1$ under mild conditions. The initial copolymer $\mathbf{K}_1$ with $\bar{M} = 2.3 \times 10^6$ was prepared from acrylamide and dimethylaminoethyl methacrylate hydrochloride in an aqueous solution in the presence of potassium persulfate as initiating agent. The molecular weight of the copolymer samples studied, $\mathbf{K}_9$–$\mathbf{K}_1$, was varied in a wide range from 2.5×10^4 to 2.3×10^6. The structure of these copolymers can be represented as

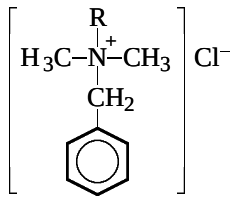


In this study, we used the following surfactants: (1) anionic surfactant (AS): disodium alkylsulfosuccinate (Surfagen S-30 brand, Vopelius Chemie GmbH, Germany)



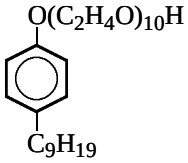
R = C_{16}–C_{18}

(2) cationic surfactant (CS): alkyldimethylbenzylammonium chloride [Katamin AB brand, Bursintez-M Joint-Stock Company, Moscow, Russia, TU (Technical Specifications) 9392-003-48 482 528–99]



R = C_{16}–C_{18}

(3) Nonionic surfactant (NS): oxyethylated isononylphenol (Neonol AF_9-10 brand, Nizhnekamskneftekhim Joint-Stock Company, Nizhnekamsk, Russia, TU (Technical Specifications) 2483-077-05 766 801–98)



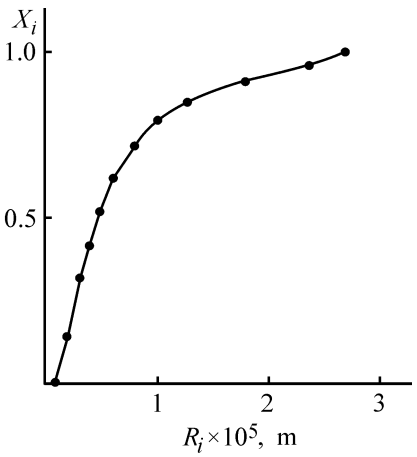


Fig. 1. Integral curve of the particle size distribution of the dispersed phase (bentonitic clay). (X_i) Integral weight fraction of the *i*th fraction and (R_i) particle radius in *i*th DP fraction.

The sedimentation kinetics of the bentonitic clay suspension was studied by sedimentometric analysis performed in the mode of free sedimentation (DP concentration c_d = 0.8%), using a VT-500 torsion balance in a 400-ml cylinder at different pH adjusted by adding required amounts of 0.1 M HCl or KOH solution to the disperse systems. Before tests, the clay suspensions were clarified for 1 day at each given pH. Then, a 200-ml portion of the flocculant solutions with concentration 2*c*, prepared by preaddition of the required volume of 0.1% solutions of copolymers $\mathbf{K}_1$–$\mathbf{K}_9$, was poured into a cylinder containing 200 ml of a bentonitic clay suspension. The resulting solution was mixed with a perforated disk stirrer, which was slowly shifted within the cylinder 10 times in the vertical direction, and then the sedimentation kinetics of the bentonite suspension was studied on a torsion balance.

The sedimentation kinetics of the bentonitic clay suspension in the mode of hindered sedimentation (DP concentration c_d = 7%) and sediment thickening was studied in a 100-ml cylinder by monitoring the shift of the boundary between the clarified and unclarified fractions of the suspension after mixing by overturning the cylinder ten times. Before tests, the clay

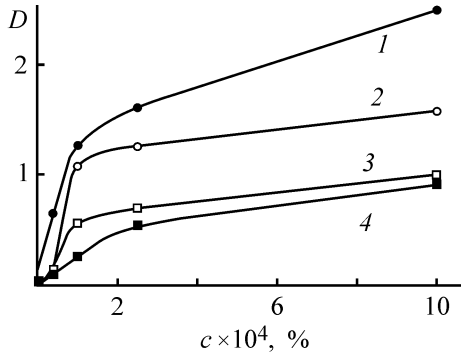

Fig. 2. Flocculation parameter D vs. concentration c of the cationic acrylamide copolymers at pH (*1*, *4*) 3.3 and (*2*, *3*) 7.0. PAAF: (*1*, *2*) $\mathbf{K}_2$ ($\overline{M} = 1.44 \times 10^6$) and (*3*, *4*) $\mathbf{K}_8$ ($\overline{M} = 0.093 \times 10^6$).

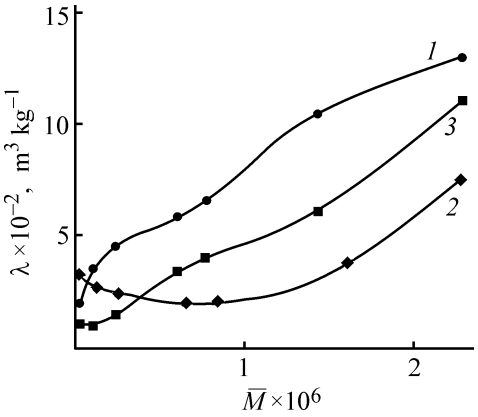

Fig. 3. Flocculation activity λ vs. the molecular weight $\overline{M}$ of cationic acrylamide copolymers at pH (*1*) 2.2, (*2*) 7.0, and (*3*) 13.2.

suspensions were clarified for 1 day at each given pH. Immediately before the tests, a required amount of 0.1% PAAF solutions (0.4–4.0 ml) was diluted with distilled water to 50 ml and then mixed with the bentonitic clay suspension (50 ml). The resulting solution was mixed by tenfold overturning of the cylinder.

Let us consider sedimentation of the bentonitic clay suspension in acidic and weakly alkaline solutions as influenced by the cationic PAAFs. Although several experiments were performed in strongly alkaline solutions, their results were ambiguous and did not allow correct conclusions on the features of sedimentation of bentonitic clay suspensions under such conditions. Therefore, only acidic and weakly alkaline mixtures were studied.

To obtain quantitative characteristics of the flocculation kinetics, we calculated the flocculation effect D and flocculation activity λ [3]:

$$D = \frac{v}{v_0} - 1, \quad (1)$$

$$\lambda = \left(\frac{v}{v_0} - 1\right)\frac{1}{c} = \frac{D}{c}, \quad (2)$$

where v and v_0 are the average rates of sedimentation of the bentonitic clay suspension in the presence of flocculant or surfactants and without them, respectively; c is the concentration of the polymeric additive or surfactant.

The positive values of D and λ indicate the flocculating effect of the additive, whereas at $D < 0$ and $\lambda < 0$ a stabilization effect is observed.

The concentration dependences of the flocculation effect D for two PAAF samples with different molecular weights are shown in Fig. 2. First of all, we should note the dependence of the parameter D on the average molecular weight $\overline{M}$: At pH 3.3 and 7.0, summarized flocculation effect was observed with the cationic PAAF $\mathbf{K}_2$ ($\overline{M} = 1.44 \times 10^6$) than that with the low-molecular-weight copolymer $\mathbf{K}_8$ ($\overline{M} = 0.093 \times 10^6$). Obviously, the comparison was performed at $[\mathbf{K}_2] = [\mathbf{K}_8] = 10 \times 10^{-4}$%. To account for the experimental dependences $D = f(\overline{M})$, we should note that the rms macromolecule size $(\overline{R}^2)^{0.5}$ varies in parallel with $\overline{M}$ [7]. Greater $(\overline{R}^2)^{0.5}$ values increase the probability of interaction of a single macromolecule with two and more DP particles (formation of bridges), and thus D values for copolymer $\mathbf{K}_2$ are greater than those for $\mathbf{K}_8$.

The quantitative data on the flocculation of the bentonitic clay suspension in the presence of cationic acrylamide copolymers with various $\overline{M}$ at various pH are summarized in Fig. 3. To determine the dependence $\lambda = f(\overline{M})$ adequately, we performed the experiments so that, except the main factor, the effect of all other factors on the sedimentation of DP particles could be neglected. In the case of a copolymer with strongly different physicochemical properties of the components (e.g., copolymers $\mathbf{K}_1$–$\mathbf{K}_9$), the effect of the copolymer composition on the flocculation parameters D and λ is probably more essential than that of $\overline{M}$ [6]. The samples with various molecular weights $\overline{M}$ were prepared by radical degradation, which allowed us to exclude *a priori* significant differences in the composition of copolymer macromolecules [8]. As seen from Fig. 3, the flocculation activity grows with increasing molecular weight of cationic PAAFs in the entire pH range studied. However, the shapes of the $\lambda = f(\overline{M})$ dependences at each pH are fundamentally different. The greatest λ values are typical of acidic media (Fig. 3, curve *1*). Naturally, we compared samples with equal molecular weights. In ac-

* Q_{max} is maximal clarification degree of the suspension in the cylinder, and ρ_s is the sediment density.

cordance with [9], chages in λ on varying the pH of the medium may be due not only to changes in the structure of the electrical double layer around the DP particles, but also to those in the mechanism of copolymer macromolecule adsorption on the DP particles.

Now we consider the effect of pH on the flocculation in the mode of hindered sedimentation of a bentonitic clay suspension in the presence of polymeric flocculants. The optimal concentration of the polymeric additives ($c = 4 \times 10^{-3}$%) was determined experimentally. Previously [3], we have made a general conclusion that the flocculation parameters of flexible-chain weak polyelectrolytes of the PAAF type strongly depend on pH of the medium. Therefore, this parameter must affect the conformation of the cationic copolymer macromolecules, structure of the electrical double layer (especially its electrokinetic potential ζ), and nature and concentration of the adsorption centers localized on the DP particle surface. In analyzing of the effect of pH on the flocculation, we should also take into account, that, with the DP concentration increasing by an order of magnitude (on passing from free to hindered sedimentation), the influence of pH on the balance of the attraction and repulsion forces between the bentonitic clay particles must obviously increase [10].

The kinetic curves of sedimentation and thickening of bentonitic clay suspensions at pH 1.85 in the presence of copolymers $\mathbf{K}_1$ and $\mathbf{K}_9$ with maximal and minimal molecular weights (2.3×10^6 and 0.025×10^6, respectively) are shown as example in Fig. 4. The data on the flocculation and thickening of the bentonite suspensions at three pH values studied are listed in Table 1. The resulting data were plotted in the $\ln[Q_{max} - Q(t)] = f(t)$ coordinates, which allowed us to calculate the constants of sediment thickening, γ, from the slopes of the experimental straight lines (Fig. 4b) [11].

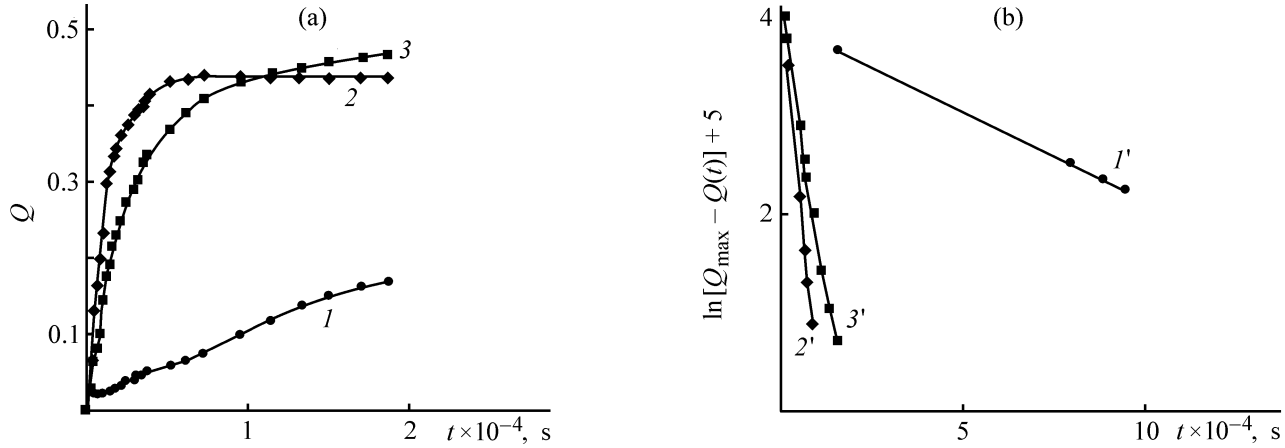

Fig. 4. Kinetic curves of sedimentation and thickening of a bentonitic clay suspension at pH 1.85 in the coordinates (a) $Q = f(t)$ and (b) $\log[Q_{max} - Q(t)] = f(t)$. $[\mathbf{K}_1] = [\mathbf{K}_9] = 4 \times 10^{-3}$%. 		9.6	–0.354

Along with Q_{max} and γ, the density ρ_s is also an important sediment characteristic, which gives information on the sediment structure and degree of its thickening and dehydration. The sediment density ρ_s depends on the weight concentration and density of the DP particles in the sediment [12]:

$$\rho_s = [m + (V_s - m/\rho)\rho_0]/V_s, \quad (3)$$

where ρ and ρ_0 are the densities of clay (2.63×10^3 kg m^{-3}) and water (1.0×10^3 kg m^{-3}), and m is the clay weight.

The sediment volume

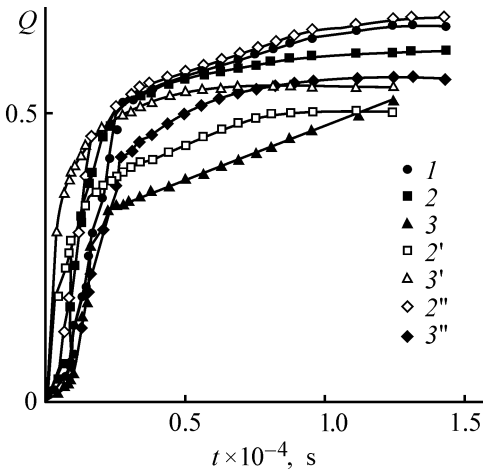

Fig. 5. Kinetic curves of sedimentation of the bentonitic clay suspension at pH 3.3 containing (*1*) no surfactant, (*2*, *3*) AS, (*2*', *3*') CS, and (*2*", *3*") NS. [SAS], %: (*1*) 0, (*2*, *2*', *2*") 0.38, and (*3*, *3*', *3*") 1.07.

$$V_s = (1 - Q_{max})V_0, \quad (4)$$

where V_0 is the volume of bentonitic clay suspension in the cylinder (V_0 = 100 ml).

Our experimental data on the kinetics of the sediment thickening, given in Table 1 and Fig. 4b, show that the sediment density ρ_s and the constant of sediment thickening, γ, decrease upon addition with polymeric flocculants $\mathbf{K}_1$ and $\mathbf{K}_2$ as compared with similar parameters of the bentonitic clay suspension in the absence of PAAF. These differences suggest changes in the structure of the resulting sediments; more friable structure of the bentonitic clay sediment is typical of systems containing PAAF additives whose macromolecules participate in the aggregation in the initial stage of sedimentation.

As a continuation of our systematic study of the effect of various active parameters of the dispersion medium on the sedimentation stability of a bentonitic clay suspension, we analyzed along with ionic strength [5] and pH, also the effect of surfactants of various types. Surfactants, depending on their type, can accelerate or decelerate sedimentation of a model kaolin disperse system [13]; certain variations in the sedimentation stability with surfactant concentration were also revealed. At low degrees of coating of the DP particle surface, hydrophobization of the particle surface was observed, which destroys the boundary water layers on the particle surface and thus promotes coagulation. With increasing surfactant concentration, the disperse system tends to stabilize owing to the secondary hydrophobization of the particle surface and appearance of the steric repulsion barrier [14].

The data on the flocculation of a bentonitic clay suspension in the presence of anionic (AS), cationic (CS), and nonionic (NS) surfactants at various solution pH are listed in Table 2.

The negative values of λ indicate that the anionic and nonionic surfactants act as stabilizers of the DP particles ($v < v_0$). Only upon addition of CS, the parameter λ slightly increases, and thus this additive accelerates sedimentation ($v > v_0$). As seen from the data on the sedimentation stability of the real DS studied in the presence of AS and CS in various concentrations, the surfactant concentration affects the sedimentation rate v only slightly. We should note that, in these experiments, the working concentrations of surfactants were several orders of magnitude higher than the concentrations of the polymeric additives.

In the mode of hindered sedimentation (c_d = 7%), a series of tests were performed with addition of various surfactants to the bentonitic clay suspension at constant pH 3.3. The kinetic curves of flocculation shown in Fig. 5 illustrate the effect of the concentra-

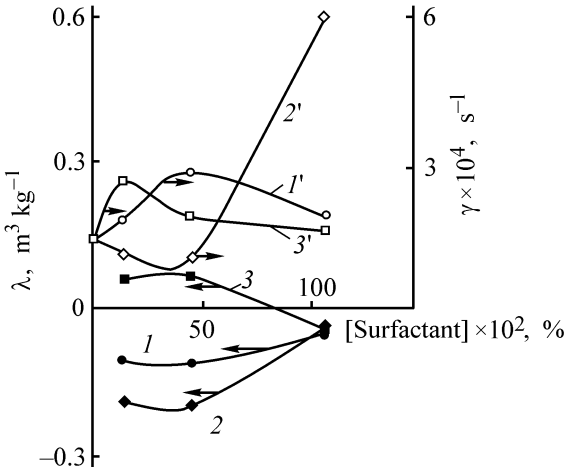

Fig. 6. Flocculation activity λ and thickening constant γ vs. the surfactant concentration at pH 3.3. (*1*, *1*') AS, (*2*, *2*') CS, and (*3*, *3*') NS.

tion and chemical nature of surfactants on the sedimentation rate of the bentonitic clay suspension. As seen, the sedimentation rate decreases with increasing content of the anionic or nonionic surfactants. This is primarily due to the excess of a surfactant in the system, which promotes stabilization of the DP particles by surfactant molecules.

The data on sedimentation and thickening of the sediments of the bentonitic clay suspension in solutions with varied pH are shown in Fig. 6. The relatively low λ parameters recorded for the samples in question may be due to the their low effect on the sedimentation rate *v*. This occurs for two reasons: (1) "deficiency" of surfactant due to the high concentration of the dispersed phase (c_d = 7%) and (2) considerably weaker effect of surfactant on the average rate of the DP sedimentation, compared with the effect of PAAFs.

Thus, our preliminarily data allow only schematic assessment of the influence exerted by the concentration and chemical nature of the surfactants on the sedimentation rate of bentonitic clay suspension.

CONCLUSIONS

(1) As found with a real disperse system (bentonitic clay suspension) as an example, the concentration and molecular parameters of the cationic acrylamide copolymer and pH of the medium strongly affect the kinetics of flocculation and thickening of the sediments in the modes of free and hindered sedimentation.

(2) The effect of pH on the flocculation parameters of the multicomponent disperse system and on the structural parameters of the resulting sediments was evaluated.

(3) The effect of the chemical nature and concentration of surfactants on the sedimentation stability, thickening constants, and density of the Bentokam clay sediments in aqueous solutions was determined.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Small Additions of Stabilizer and Pigments on the Degree of Bulk Curing of a Filled Photopolymer

D. L. Starokadomskii and T. N. Solov'eva

Institute of Surface Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received June 25, 2002; in final form, February 2003

Abstract—The effect exerted by additions of stabilizer and pigments to oligoether acrylate compounds filled with finely dispersed silica on the degree of curing and its variation with depth was examined.

Photocurable compounds based on oligoether acrylates have found numerous applications in the past 15 years [1–7]. The use of filled photopolymeric materials in stomatology [6–11], microelectronics [12], and other fields tends to grow. Most of the compounds used in practice contain stabilizing additives preventing spontaneous polymerization [6–8, 9, 13, 14]. However, the effect of stabilizers on the polymerization capacity of filled photocurable compounds has been studied insufficiently. Stomatological photopolymers contain pigments as essential components [6, 7, 9]. Polymerization in the presence of pigments [15–17] has also been studied insufficiently, especially the photopolymerization of filled systems.

EXPERIMENTAL

Studies were performed by multiple attenuated total internal reflection [4] (MATIR) IR spectroscopy with a UR-20 double-beam IR spectrophotometer. A trapeziform total-internal-reflection element made of KRS-5, providing 10–20 reflections, was brought in optical contact with a millimeter-thick layer of a formulation. The degree of curing was evaluated by a decrease in the intensity of the absorption band at 1635 ± 5 cm^{-1}, associated with the vinyl bonds in the oligomers.

We used the following chemicals: OKM-2 oligomer [α,ω-bis(methacryloyloxyethyleneoxycarbonyloxy)ethyleneoxyethylene], TU (Technical Specifications) 113-03-22-65–79, fresh (subject to gradual turns yellowing in storage); UDMA oligomer (bisphenol A glycidyl methacrylate); benzoin isobutyl ether (photoinitiator), chemically pure grade; dimethylaminoethyl methacrylate, chemically pure grade; methacrylic acid, MRTU (Interrepublican Technical Specifications) 6-09-1768–64, chemically pure grade; Aerosil A-100 silica, GOST (State Standard) 14922–77, specific surface area 100 ± 7.5 m^2 g^{-1}, additionally calcined for 1 h at 400°C; pigments (yellow burnt sienna, cadmium lemon, burnt umber, TU 6-10-1320–77); and Ionol stabilizer (2,5-di-*tert*-butyl-*p*-cresol), chemically pure grade.

The formulations studied consisted of 65 wt % polymeric matrix (compound A) and 35% A-100. The composition of the polymeric matrix (wt %) was as follows: urethane dimethacrylate 35, oligocarbonate methacrylate 53, photoinitiator 1.0, dimethylaminoethyl methacrylate 0.1, and methacrylic acid 10.9. In experiments with addition of Ionol stabilizer (0.4, 1.0 wt %), the content of the major component, OKM-2, was correspondingly decreased (to 53.6 and 53.0 wt %, respectively). The degree of conversion, α, was studied in relation to the Ionol concentration *c*, irradiation time *t*, and mixture layer thickness *h*.

To examine the effect exerted by pigments, we added to the filled formulation the following pigments (with the corresponding decrease in the OKM-2 content), wt %: formulation P1, yellow sienna 0.025 and cadmium lemon 0.025; formulation P2, umber 0.05; and formulation P3, umber 0.02, cadmium lemon 0.01, yellow sienna 0.01, and black iron oxide pigment 0.01.

Figure 1A shows that, in curing the formulation without stabilizer (c = 0 wt %) at $h \le 1.5$ mm, the degree of curing, α, decreases gradually (the α–t curves slightly shift down); in the range $1.5 \le h < 2$ mm, α abruptly decreases. Addition of the stabilizer causes the degree of curing to decrease: The α–t curves in Fig. 1A for c = 0.4 and 1.0 wt % lie below the curve for c = 0 wt %). Figure 1A shows that the effect of the stabilizer depends on the layer depth h. Indeed, at $h \le 1$ mm α decreases only slightly after adding

1070-4272/03/7604-0616 $25.00 © 2003 MAIK "Nauka/Interperiodica"

the stabilizer, whereas at h = 1.5 mm the decrease is abrupt; with the thickness increasing further, to 2 mm, the effect of the stabilizer does not become appreciably stronger (Fig. 1A).

Thus, the effect of the stabilizer is manifested in a decreased α. The effect becomes stronger in going to deeper layers of the formulation. The shielding effect of the surface layers on the deeper layers is also enhanced in the presence of a stabilizer. This may be due to the ability of the stabilizer to deactivate radicals generated by UV irradiation.

It is interesting that the dependence of α on the stabilizer concentration c is nonmonotonic. For example, there is a clear minimum in curves 1–3 at c = 0.4 wt %, especially pronounced at h = 1.5 and 2 mm (Fig. 1B). At the stabilizer concentrations exceeding 0.4 wt %, its effect weakens. From the kinetic viewpoint, this trend suggests that the deactivating effect may be even stronger at lower stabilizer content. As a rule (Fig. 1B), the minimum in the α–c curves is the more pronounced, the shorter the irradiation time t and the deeper the mixture layer under examination.

Figure 2 shows that addition of even small amounts of the pigments noticeably decreases the reactivity of the formulation in polymerization and enhances the deactivating role of the upper layers relative to the lower layers. Indeed, after adding the pigments, the conversion falls by 25–30%, and the decrease in α with the depth becomes more pronounced (Figs. 2, 3). At 1 < h < 1.5 mm, the nonuniformity in curing of different layers can be leveled out by raising (e.g., doubling) the curing time; however, at h > 1.5 mm longer curing fails to produce the desired effect.

The conversion α is also influenced by the type of pigment. Comparison of the curves in Fig. 2 shows that addition of dark pigments causes a stronger decrease in α than addition of light pigments. On addition of dark and light pigments simultaneously (Fig. 2d), the effect on α is intermediate between the effects exerted by the dark and light pigments.

Let us consider the α–h dependence for the pigment-free formulations and those with pigments added. In the absence of pigments (Fig. 3a), α varies with h only slightly at 0 < h < 1.5 mm, but decreases appreciably at h > 1.5 mm. This means that, for the pigment-free formulation, photocuring is virtually complete in 7 min, and at h < 1.5 mm longer irradiation (15 min) only slightly affects α. With the dark pigment added (formulation P2), the degree of conversion is not appreciably affected by the irradiation time and layer depth at h < 1 mm. However, the dependence of α on t becomes more pronounced at h > 1 mm, and at h ≈ 1.5 mm the conversions attained in 7, 10, and 15 min differ considerably. With the light pigments added (formulation P1), the dependence of α on the irradation time (Fig. 3b) is noticeable even at h ≈ 1 mm. The α–h curves for P1 and P2 (Figs. 3b, 3c) somewhat differ in shape, which may

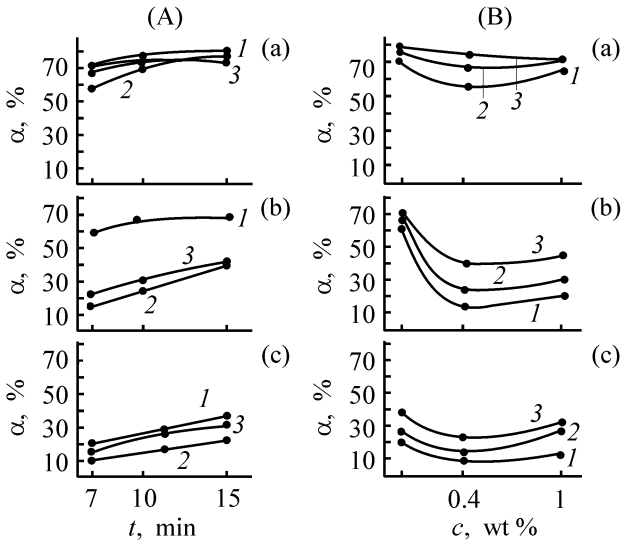

Fig. 1. Degree of conversion, α, vs. (A) irradiation time t and (B) stabilizer concentration c. (A) c, wt %: (*1*) 0, (*2*) 0.4, and (*3*) 1.0. (B) t, min: (*1*) 7, (*2*) 10, and (*3*) 15. h, mm: (a) 1.0, (b) 1.5, and (c) 2.0.

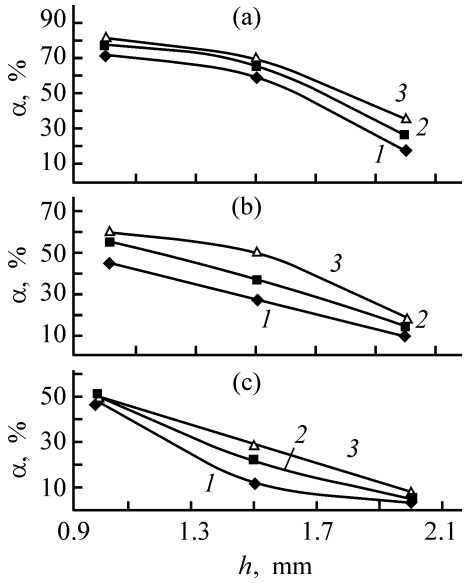

Fig. 3. Degree of conversion, α, vs. thickness *h* of the mixture layer. Irradiation time *t*, min: (*1*) 7, (*2*) 10, and (*3*) 15. Pigments added: (a) none, (b) yellow (P1), and (c) dark (P2).

be due to a faster decrease in α with increasing *h* for the formulation with the dark pigment.

CONCLUSIONS

(1) The effect exerted by small additions of a stabilizer (Ionol) and pigments (umber, cadmium lemon, black iron oxide, yellow sienna) on the photopolymerization of oligoether acrylate formulations filled with silica was studied. The stabilizer and pigments impair the quality of curing and increase the nonuniformity of curing throughout the depth. This fact should be taken into account when performing polymerization of thick layers.

(2) The dependence of the inhibiting effect of Ionol on its concentration is nonmonotonic: The curve of the degree of conversion vs. stabilizer concentration passes through a minimum.

(3) The conversion α is largely influenced by the type of the pigment added. Additions of dark pigments decrease α more significantly, compared with light pigments, and, on adding dark and light pigments simultaneously, the effect is intermediate.

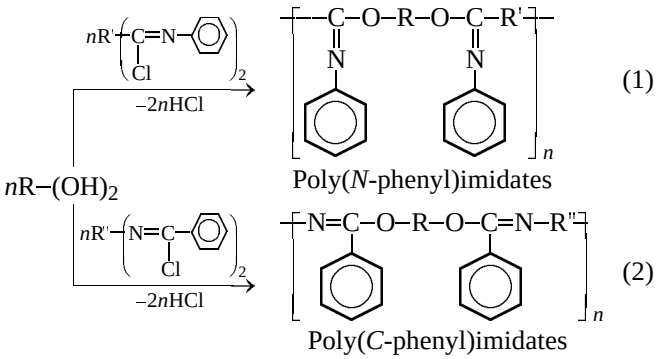
Received January 15, 2002

Abstract—New polyimidates were prepared from bisphenols and mono- and dicarboxylic acid imidoyl chlorides. The structures of the polymers were determined, and their physicochemical, chemical, and thermal properties were studied. The possibility of preparing film and compression materials with good mechanical characteristics from these polymers was examined.

Among the known polyheteroarylenes, nitrogen-containing aromatic polymers are of particular interest owing to their high heat resistance and high softening point in combination with good electrophysical and physicomechanical properties. However, data on aromatic polyimidates (PIDs) as a particular class of heat-resistant nitrogen-containing polymers [1, 2] are lacking. Synthesis of new polyheteroarylenes and materials thereof, combining good thermal, chemical, and physicomechanical properties, is still a topical problem.

The goal of this study was to develop synthesis procedures and analyze new PIDs derived from bisphenols and mono- and dicarboxylic acid imidoyl chlorides.

The polymers were prepared similarly to polycondensation of aromatic diamines with mono- and dicarboxylic acid imidoyl chlorides (MDAICs) [3], using bisphenols as nucleophilic agents:



(1)

(2)

where R =  ; R' and R'' =  ,  ; X = $-C(CH_3)_2-$, $-CH_2-$, –O–, σ bond; Y = $-CH_2-$, –O–, σ bond.

With the reaction of diphenylolpropane with *N*,*N*'-diphenylisophthalimidoyl chloride taken as example, we studied in detail how the reaction temperature and time, and also the concentration and ratio of monomers, affect the reduced viscosity and yield of PID. The main trends are similar to those obserbed in polycondensation with aromatic diamines, despite that the structures of MDAICs are different. Figure 1 shows that the highest yield (90%) and viscosity (η_r = 0.88–0.93 dl g^{-1}) of the polymers are attained at 140–160°C,

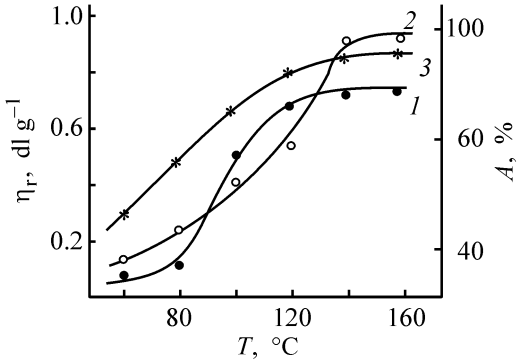


Fig. 1. Influence of temperature *T* on the (*1*, *2*) reduced viscosity η_r and (*3*) yield *A* of the polymer. Solvent: (*1*) dimethylacetamide and (*2*) *N*-methylpyrrolidone; the same for Figs. 2 and 3.

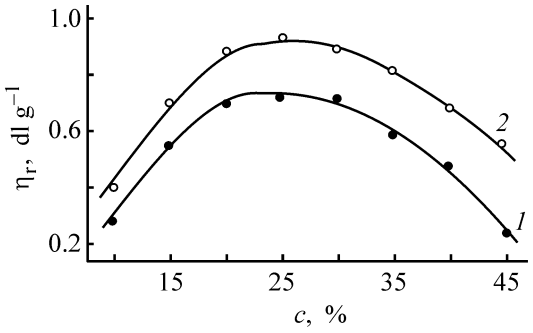

Fig. 2. Influence of the concentration *c* of the monomers on the reduced viscosity η_r of the polymer.

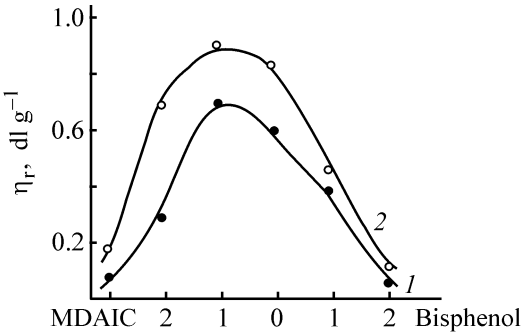

Fig. 3. Influence of the monomer ratio on the reduced viscosity η_r of the polymer. Reaction time 12 h, 160°C. *Abscissa*: relative molar excess (×10) of monomers.

reaction time of 12–14 h, and excess of imidoyl chloride (solvent *N*-methylpyrrolidone, *N*-MP).

The PID viscosity is affected by the concentration of the initial monomers (Fig. 2). At the optimal concentration (20–30%), the reaction is fast and yields polymers with better viscosity characteristics. A decrease in the η_r of the solutions of the polymers prepared at monomer concentrations exceeding the optimum value is due to slow diffusion of molecules in highly viscous reaction solutions.

* In dimethylacetamide.

The viscosity characteristics of the polymers are also largely affected by the monomer ratio (Fig. 3). Polymers with the highest η_r are obtained at a relative molar excess of MDAIC of 0.1 mol. Such a ratio may be due to interaction of MDAIC with solvent molecules (Vilsmeier adduct, iminium complex) [4].

With respect to the capability to form high-molecular-weight polymers, MDAICs can be ranked in the following order: *p*-C_6H_4 < *m*-C_6H_4 < (1,4-C_6H_4)$_2$O < (1,4-C_6H_4)$_2$$CH_2$ (Table 1).

The PIDs were identified by elemental analysis and IR spectroscopy. The following absorption bands were detected (cm^{-1}): 3060–3010 (C–H arom.); 2950, 2870 (C–H aliph.); 2000–1790 (C_6H_5); 1665–1635 (C=N acycl.); 1600 (C–C atom.); 1420 (C–N); 1390, 1280–1260 (C–O ether), and also the bands of stretching and bending vibrations of atoms of disubstituted benzene and diphenyl ether. The characteristic bands are those of C=N acycl. and C–O, indicative of the formation of the imidate group, the unit of the macromolecules.

The polymers are readily soluble in highly polar organic solvents: DMF, dimethylacetamide, *N*-MP, DMSO, and *m*-cresol. The chemical resistance of the polymers was evaluated by the reduced viscosity before and after treatment with solutions of mineral acids and alkalis at 25–100°C for 48 h. Polyimidates are more resistant to concentrated acid solutions; their viscosity decreases only slightly. At the same time, tratment with alkali solutions decreases the reduced viscosity of PIDs [especially poly(*C*-phenyl)imidates] considerably. This fact suggests the occurrence of base hydrolysis of the polymers with cleavage of the macromolecular chain, primarily across the C–O and C=N bonds of the imidate group (Table 1).

The results of thermomechanical and thermogravimetric studies are listed in Table 2. The temperature of the plastic deformation of the polymers lies within 225–390°C. Polymers consisting of only aromatic fragments are the most resistant to thermal oxidative degradation: they decompose at 490°C. For polymers containing bridging groups in the hydrocarbon radical, the heat resistance decreases in the following order: σ bond > –O– > –CH_2– > –$C(CH_3)_2$–.

The relatively large margin between the softening and decomposition points offers good opportunities for PID processing into finished items. For example, compression materials (without filler) obtained by direct pressing at 245–400°C and 75 MPa exhibit good physicomechanical properties (Table 2).

Table 2. Thermal and physicomechanical properties of PIDs derived from bisphenols and MDAICs*

PID no.	T_s, °C	$T_{5\%}$, °C	σ_t, MPa	ε, %	*a*, kJ m^{-2}
1	230	385	43	3–4	7.5–8.0
2	315	460	40	–	–
3	365	490	35	2–3	7.5–8.5
4	225	365	44	3–4	7.5–8.5
5	390	465	42	2–4	6.5–7.0
6	325	405	43	2–3	6.5–7.5

* (T_s) Softening point corresponding to 5% deformation of PID, ($T_{5\%}$) temperature of 5% weight loss in air, (σ_t) tensile strength, and (ε) relative elongation.

EXPERIMENTAL

Dicarboxylic acid imidoyl chlorides were prepared according to [5].

Polyimidates were prepared in a three-necked flask equipped with a stirrer, and argon inlet tube, and a dropping funnel, with vigorous stirring. A solution of 0.011 mol of imidoyl chloride in *N*-MP was added in small portions from a dropping funnel to a solution of 0.01 mol of bisphenol in *N*-MP containing 0.022 mol of triethylamine. The mixture was gradually heated to 140–160°C and kept at this temperature for 13–15 h. The polymer was isolated by precipitation into water. The precipitate was filtered off, washed successively with 0.5% solutions of Na_2CO_3, HCl, and H_2O to pH 7, and dried in a vacuum oven at 80°C to constant weight.

The reduced viscosity of PIDs was determined according to GOST (State Standard) 18249–79. The IR spectra were recorded on a Specord IR-75 spectrophotometer.

A thermomechanical analysis of PIDs was performed on a modified Tsetlin device at a load of 0.33 or 1.0 MPa and heating rate of 100 deg h^{-1}. The thermal characteristics were obtained with a Q-1000 derivatograph at a heating rate of 5 deg min^{-1}. Mechanical tests were performed according to GOSTs 17036–71 and 14235–69.

CONCLUSIONS

(1) A number of new poly(*N*-phenyl)- and poly(*C*-phenyl)imidates were prepared by nonequilibrium

polycondensation of mono- and dicarboxylic acid imidoyl chlorides with bisphenols. The products were identified by elemental analysis and IR spectroscopy, and their properties were studied.

(2) Examination of the physicomechanical, thermal, and chemical properties of the polymers synthesized revealed their high heat resistance and a large margin between the softening and decomposition points.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis and Properties of Epoxy–Acrylate Polymers Prepared in the Presence of Sulfoxides and Their Complexes

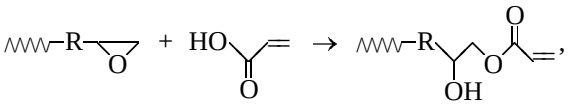
G. V. Gatiyatullina, Yu. A. Prochukhan, E. M. Battalov, N. G. Afzaletdinova, and Yu. I. Murinov

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received July 19, 2002; in final form, December 2002

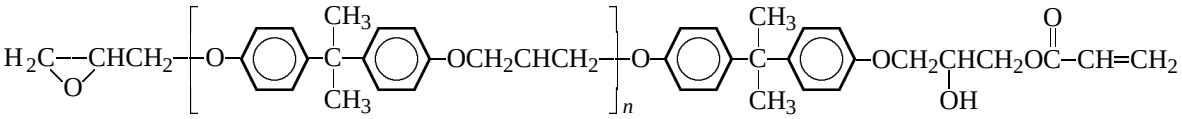
Abstract—The initiating activity of some sulfoxides and their complexes in photopolymerization of epoxy–acrylate oligomer obtained by the reaction of ED-16 epoxy oligomer with acrylic acid was studied, and the degree of cross-linking of the resulting polymers was evaluated by analyzing their swelling kinetics.

The epoxy–acrylate oligomer was prepared by esterification of an epoxy oligomer with an equimolar amount of acrylic acid (AA) at 120°C in the presence of a polymerization inhibitor (hydroquinone) and a catalyst of epoxy ring opening (triethylamine), by the following scheme:



where R is the oligomeric block of the epoxy oligomer.

We used ED-16 epoxy oligomer. Acrylic acid was purified by distillation. The oligomers synthesized chiefly contain diacrylates and certain amount of epoxy acrylates (in the course of synthesis of the epoxy–acrylate oligomer, the content of epoxy groups decreases from 24 to 9 mol %). Such an oligomer was used in this work. Its structural formula



ED-16–AA

It was confirmed by the ^{13}C and ^{1}H NMR spectra. The NMR spectra were recorded on a Bruker AM-300 spectrometer (working frequency 76.46 and 300 MHz, respectively; solvent $CDCl_3$, internal reference TMS). The signals were assigned using the two-dimensional correlation technique (COSY H–H, C–H).

The degree of swelling was studied with films of ED-16–AA polymers prepared in the presence of sulfoxides and their complexes. The film thickness was about 50 μm.

Sulfoxide complexes were prepared at the Laboratory of Physical Chemistry, Institute of Organic Chemistry, Ural Scientific Center, Russian Academy of Sciences, and recrystallized from hexane; the purity was checked by IR spectroscopy and potentiometric determination of sulfoxide sulfur (98.5–99%). Petroleum sulfoxides (PSOs) were prepared from petroleum sulfide concentrates or straight-run fractions of high-sulfur oils boiling in the range 260–360°C. Petroleum sulfides were oxidized with hydrogen peroxide. In the process, the substituents at sulfur remained intact. The physicochemical constants of purified individual sulfoxides were in agreement with published data. Sulfoxide complexes have the general structure

$$R{-}S{=}O{\cdots}X{\cdots}O{=}S{-}R,$$

where R is an aliphatic or cyclic substituent; X = HCl, H_3PO_4, $VOCl_3$, $HCl \cdot FeCl_3$, etc.

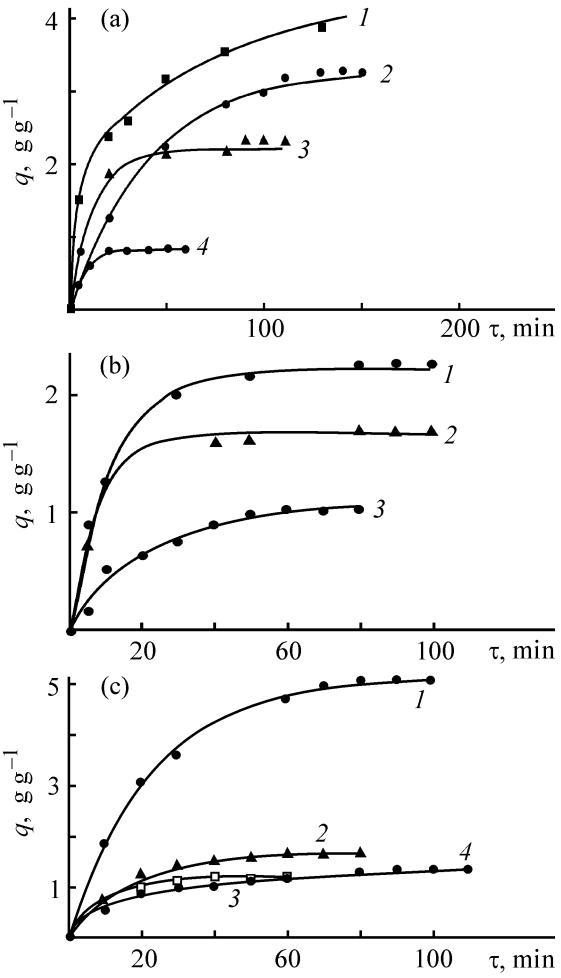

Fig. 1. Kinetic curves of swelling of polymers prepared in the presence of (a) aliphatic sulfoxides, (b) mixed sulfoxides, and (c) sulfoxide complexes. Photopolymerization time 60 min, concentration of sulfoxides and sulfoxide complexes 2.0 wt %. (*q*) Degree of swelling and (τ) time. (a) (*1*) Didodecyl sulfoxide, (*2*) dioctyl sulfoxide, (*3*) dihexyl sulfoxide, and (*4*) dimethyl sulfoxide; (b) (*1*) benzyl octyl sulfoxide, (*2*) dibenzyl sulfoxide, and (*3*) PSOs; (c) (*1*) $HCl \cdot FeCl_3 \cdot 4DHSO$, (*2*) $VOCl_3 \cdot 3DHSO$, (*3*) $HCl \cdot 2DHSO$, and (*4*) $H_3PO_4 \cdot 2DHSO$.

Photopolymerization was induced with a PRK-400 medium-pressure mercury lamp placed at a distance of 14 cm from the oligomer.

It is known that free sulfoxides affect the photopolymerization kinetics of vinyl monomers only slightly. However, sulfoxide complexes of metal chlorides and oxychlorides, HCl, and uranyl are effective photoinitiators of methyl methacrylate polymerization [1]. The sensitizing activity of sulfoxides in photochemical cross-linking of polyvinylbutyral and polyethylene was reported in [2]. In an ESR study of low-temperature radiolysis and photolysis of DMSO [3], methyl radicals were detected in photolysis of polycrystalline DMSO; further annealing resulted in the formation of sulfinyl radicals $CH_3SO^{\cdot}$. The relative concentration of methyl radicals in γ-radiolysis was considerably lower than in photolysis. It has been found previously by ESR spectroscopy that thiyl $RS^{\cdot}$, formyl $HCO^{\cdot}$, and methyl radicals are generated in prolonged photolysis of DMSO (naphthalene sensitizer, λ = 313 nm). The radicals accumulate without induction period. The mechanism of radical generation in photolysis of DMSO assumes initial generation of the $^{\cdot}CH_2SOCH_3$ radical, but the mechanism of this process is not fully understood [4]. An ESR study of thermolysis and photolysis of other sulfoxides was made in [5].

The above-cited demonstrated [1–5] show that photolysis of DMSO involves generation of free radicals. These species must be reactive in polymerization of monomers (or oligomers) and cross-linking of polymers. Without dwelling upon the mechanism of radical generation and concentration of radicals in photolysis of various sulfoxides, we can judge the efficiency of sulfoxides as photoinitiators of polymerization or cross-linking from the degree of cross-linking of the polymers formed in the presence of sulfoxides. In this context, it is of interest to study photopolymerization of an epoxy–acrylate oligomer in the presence of sulfoxides.

Below is given the time τ in which polymeric films are formed in photopolymerization of ED-16–AA epoxy–acrylate oligomer in the presence of certain sulfoxides (2.0 wt %):

Sulfoxide	τ, min
Benzophenone	10
Didodecyl sulfoxide	20
Dibenzyl sulfoxide	30
Dioctyl sulfoxide	35
Dihexyl sulfoxide (DHSO)	40
Petroleum sulfoxides	50
Dimethyl sulfoxide	60

The rate of oligomer photopolymerization in thin films on a glass support was evaluated by the time of formation of a nonsticking polymeric film.

It is seen that the initiating activity of sulfoxides is lower than that of the known photopolymerization initiator, benzophenone, but sufficient for the synthesis of epoxy–acrylate polymers.

The kinetic curves of swelling in trichloroethylene of the polymers prepared in the presence of aliphatic and mixed sulfoxides in the same reaction time are shown in Figs. 1a and 1b, and similar plots for the polymers prepared in the presence of certain sulfoxide complexes, in Fig. 1c.

The values of the limiting swelling of the polymers (Figs. 1a, 1b) show that the degree of cross-linking depends on the sulfoxide used. As the length of the alkyl substituent in an aliphatic sulfoxide is increased, the degree of cross-linking decreases (Fig. 1a). Mixed sulfoxides and PSOs favor formation of relatively more cross-linked polymer as compared with aliphatic sulfoxides. The degree of swelling (or cross-linking) of the polymeric material correlates with the rate of formation of a nonsticking polymeric film: The higher the curing rate, the lower the degree of the polymer cross-linking (Figs. 1a, 1b). The above data on the degree of cross-linking of the epoxy–acrylate polymer show that aliphatic and mixed sulfoxides effectively initiate photopolymerization of this oligomer. To compare, with benzophenone as initiator, the degree of swelling is 2–5 g g^{-1}.

The structure of the sulfoxide affects both the rate of radical generation and the intensity of their decay under the action of UV light. Figures 1a and 1b show that the most cross-linked polymers are formed in the presence of DMSO and petroleum sulfoxides. It seems probable that the common feature of DMSO photolysis, both in polycrystalline DMSO at low temperatures and in a viscous medium of the oligomer, is the low probability of the radical decay. This assumption is supported by the fact that, apparently, DMSO does not initiate photopolymerization of methyl methacrylate [1].

Sulfoxide complexes of metal chlorides, uranyl, or inorganic acids, e.g., $VOCl_3$, HCl, and H_3PO_4, also show promise as initiators of photochemical curing of epoxy–acrylate oligomers. Firstly, as shown above, the sulfoxides themselves initate photopolymerization; secondly, some metal salts and inorganic acids exhibit a photoinitiating activity [5].

Figure 1c shows the kinetic curves of swelling of polymers prepared in the presence of sulfoxide complexes. It is seen that, in almost all the cases, the resulting polymers are more cross-linked than those obtained in the presence of free sulfoxides. For example, UV-induced polymerization of the oligomer in the presence of DHSO and $H_3PO_4 \cdot 2$DHSO yields a polymer with the limiting swelling of 2.2 and 1.24 g g^{-1}, respectively. With the other sulfoxides and their complexes, the pattern is similar, i.e., the sulfoxide complexes are, on the whole, more active in photopolymerization than the free sulfoxides. The photoinitiation mechanism may be specific for each sulfoxide complex. There may be a synergism in the effect of sulfoxide and metal halide (or inorganic acid) in the complex. Similarly to the case of UV-induced polymerization of methyl methacrylate in the presence of sulfoxide complexes of metal halides and oxychlorides, the initiating radicals are probably halogen atoms.

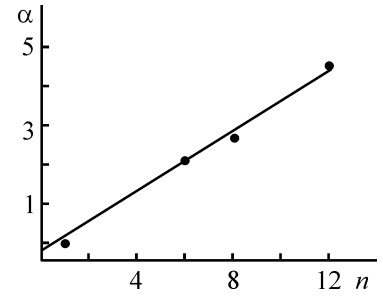

Fig. 2. Limiting swelling α of the polymers vs. the number *n* of carbon atoms in aliphatic substituent R in sulfoxides R_nSOR_n.

An interesting fact is observed in photopolymerization of the epoxy–acrylate oligomer, initiated by aliphatic sulfoxides: As the number of carbon atoms *n* in alkyl substituent R in sulfoxide R_nSOR_n is increased, the limiting swelling grows (Fig. 2). This is apparently due to a decrease in the mole fraction of SO groups with increasing *n*.

CONCLUSIONS

(1) Sulfoxides and their complexes are fairly effective and available initiators of photopolymerization of ED-16–acrylic acid oligomer.

(2) Sulfoxide complexes surpass free sulfoxides in the capability to initiate photochemical cross-linking of epoxy–acrylate oligomers and show promise for synthesis of epoxy–acrylate polymers with a prescribed degree of cross-linking.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Evaluation of the Degree of Cross-Linking of Epoxy–Acrylate Polymers with a Luminescence Probe

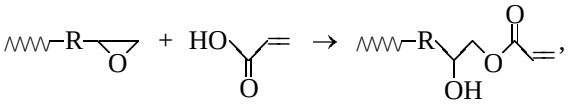
G. V. Gatiyatullina, E. M. Battalov, A. I. Voloshin, and Yu. A. Prochukhan

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received July 19, 2002; in final form, December 2002

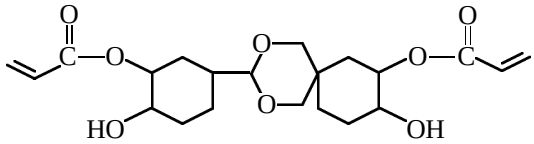
Abstract—Luminophores, 4,4'-diaminodiphenylmethane and Oxazine-17, were introduced into a photopolymerizable formulation based on an epoxy–acrylate oligomer, and their behavior in thin-film polymerization was studied.

Experiments were performed with an epoxy–acrylate oligomer derived from UP-612 cycloaliphatic epoxy resin. Epoxy–acrylate resins were prepared by esterification of epoxy oligomers with acrylic acid (AA) in the presence of a polymerization inhibitor at 120°C by the following scheme [1]:



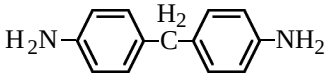
where R is the oligomeric block of the epoxy oligomer.

The oligomers were identified by ^{13}C and ^{1}H NMR spectroscopy. The NMR spectra were recorded on a Bruker AM-300 spectrometer (working frequency 76.46 and 300 MHz, respectively; solvent $CDCl_3$, internal reference TMS). The signals were assigned using the two-dimensional (2D) correlation technique (COSY H–H, C–H).

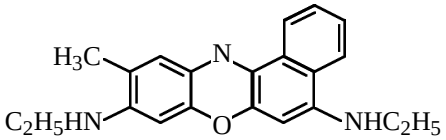


The reaction course was monitored by variation of the iodine number [1]. Acrylic acid was purified by distillation.

Epoxy–acrylate films were prepared from acetone solutions of the initial oligomer, containing 5 wt % benzophenone (BP) as photoinitiator. The film thickness was 75 μm. A 0.5-cm^2 square piece of a film was irradiated with two SVD-120 lamps (VIO-2 illuminator); the line with λ = 313 nm was picked out with ZhS-3 and UFS-2 color filters. The incident light intensity was determined with a ferrioxalate actinometer [2]. The following luminophores were chosen:



4,4'-Diaminodiphenylmethane (DAM)



Oxazine-17

The concentration of the luminophores in the initial oligomer was 1×10^{-4} M.

The luminescence spectra were recorded with an MPF-4 device (Hitachi). The photomicrographs in polarized light were obtained with Amplival-pol and Axiolab-pol microscopes (Carl Zeiss, Germany).

It is known that the luminescence spectra of luminophores in polyethylene terephthalate, polycaproamide, and polyvinyl chloride appreciably change upon orientation extension of the polymer [3–5], which allows monitoring of changes in the polymer microstructure. Changes occurring in a polymer under mechanical action affect the state of the luminophore introduced, which allows interpretation of its spectral characteristics. It is also known that, with a luminescence probe introduced into a polymerizing system, it is possible to monitor the polymerization of monomers and curing of epoxy compounds by variation of the luminophore spectrum [6, 7]. However, studies in which various probes were used in synthesis

1070-4272/03/7604-0626 $25.00 © 2003 MAIK "Nauka/Interperiodica"

of 3D polymers are very few, and changes in the luminescence spectra were different in each particular case, irrespective of the nature of a probe used.

In this study, we monitored the photochemical curing of UP-612–AA epoxy–acrylate oligomer by introducing Oxazine-17 and DAM as luminescence probes into a photocurable system and by measuring the luminescence spectra during the process.

Figure 1 shows how the photoluminescence spectra of luminophores introduced into the epoxy–acrylate oligomer change upon curing. It is seen that the intensity of Oxazine-17 luminescence in the long-wave region (650 nm) grows upon photocuring, and that of DAM luminescence decreases. Such a behavior of the luminescence spectra of Oxazine-17 may be due to changes in the state of the luminophore molecules with increasing degree of cross-linking. The decomposition of luminophore associates (polymeric species) and formation of dimers in the course of the polymer cross-linking, as also in the course of extension of polyvinyl chloride films containing the same luminophore [5], results in a redistribution of the luminescence bands and a long-wave shift of the luminescence spectrum. The photomicrographs of UP-612–AA films, taken in polarized light after photocuring for different times (Fig. 2), illustrate changes occurring in the polymer upon UV irradiation.

Figures 2a and 2b show that, in the initial stage of photopolymerization, when the polymer is not fully cross-linked, the sample is anisotropic. After the cross-linking under the given conditions is complete, the sample becomes isotropic (Fig. 2c). As the polymer microstructure gets stabilized, the luminescence spectra of Oxazine-17 no longer change. Apparently, in cross-linked polymeric films in which there is no anisotropy of the polymer properties, the conditions are favorable for the existence of dimeric Oxazine-17 species. A decrease in the intensity of DAM luminescence in the course of the oligomer cross-linking may be due to the luminophore consumption in side reactions and to significant changes in the probe configuration in the rigid polymeric matrix.

Our results, ultimately characterizing the degree of cross-linking of the polymer being synthesized, are well consistent with the results obtained in determining the degree of cross-linking by other methods. For example, the degree of cross-linking of 3D polymers is usually determined from their swelling in a solvent [8]. The degree of swelling of the polymer derived from UP-612–AA in trichloroethylene is plotted in Figs. 3 and 4 together with the shift of the luminescence peak of Oxazine-17 and with the decay of

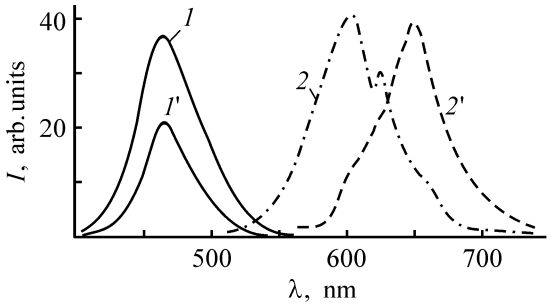


Fig. 1. Photoluminescence spectra of (*1*, *1*') DAM and (*2*, *2*') Oxazine-17 (*1*, *2*) before and (*1*', *2*') after photocuring of UP-612–AA oligomer. Excitation wavelength 365 nm. (I) Emission intensity and (λ) wavelength.

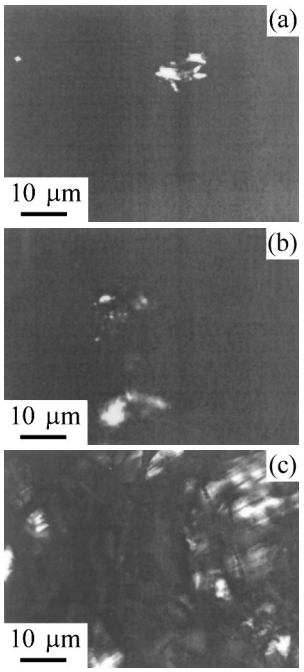

Fig. 2. Photomicrographs (polarized light) of epoxy–acrylate oligomer subjected to UV curing for different times. Exposure time, min: (a) 20 and (b) 30; (c) polymer washed to remove the sol fraction.

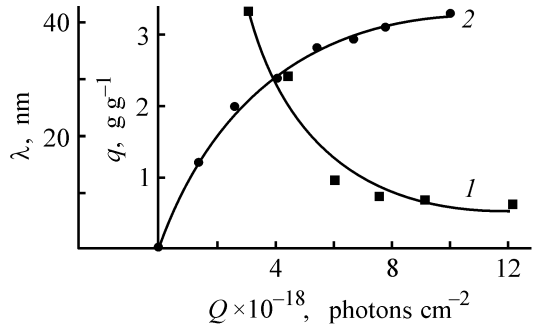

Fig. 3. (*1*) Shift λ of the luminescence peak of Oxazine-17 in the oligomer and (*2*) degree of swelling *q* of the polymer in TCE, vs. the irradiation dose *Q*. Photopolymerization of UP-612–AA with 313-nm light;the same for Fig. 4.

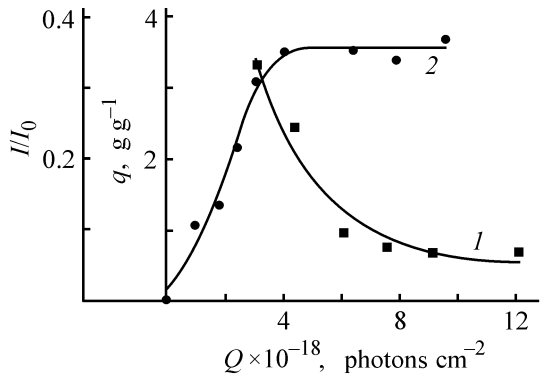

Fig. 4. (*1*) Decay of the intensity I/I_0 of DAM luminescence in the oligomer and (*2*) degree of swelling q of the polymer in TCE vs. the irradiation dose Q.

DAM luminescence in the polymeric matrix against the exposure of the oligomer to UV light. It is seen that the curves for these parameters level off at similar irradiation doses. In turn, the luminescence spectra of the polymer with these luminophores allow estimation of the degree of cross-linking. Such an approach to evaluation of the degree of cross-linking is especially important for industrial processes, as a way of prompt and nondestructive process monitoring.

CONCLUSION

Luminescence probes introduced into a photocurable oligomer show different trends in variation of the luminescence spectra in the course of polymerization. The photopolymerization of epoxy–acrylate oligomer can be to a certain extent monitored by variation of the luminescence spectra of the probe.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

ESR Study of Photopolymerization of Epoxy-Acrylate Oligomers

R. A. Sadykov, G. V. Gatiyatullina, E. M. Battalov, and Yu. A. Prochukhan

Institute of Petroleum Chemistry and Catalysis, Academy of Sciences of the Republic of Bashkortostan, Ufa, Bashkortostan, Russia

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received July 22, 2002; in final form, January 2003

Abstract—Photopolymerization and thermal polymerization of epoxy-acrylate oligomers were studied by ESR at room temperature.

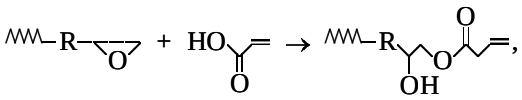
Epoxy-acrylate oligomers are extremely attractive materials for use as, e.g., protective and reinforcing coatings in production of waveguide fibers, adhesives, etc.

For the most of polymerizable systems based on vinyl monomers, the nature of radicals responsible for polymerization has been studied in sufficient detail [1]. At the same time, any studies of the nature of active centers for epoxy-acrylate oligomers are lacking.

This is concerned with the paramagnetic centers arising in polymerization of epoxy-acrylate oligomers.

EXPERIMENTAL

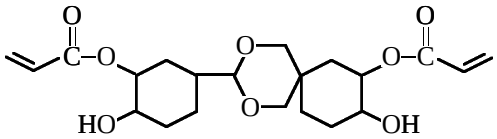
Epoxy-acrylate oligomers were synthesized by esterification of epoxy oligomers with acrylic acid at equimolar ratio of reactants in the presence of a polymerization inhibitor (hydroquinone) and a catalyst [2-(diethylamino)-1-ethanol] for opening of epoxy rings at 120°C by the scheme



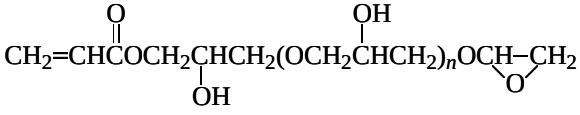
where R is the oligomer block of an epoxy oligomer.

We used epoxy oligomers UP-612 and Oksilin (ON), which is the product of reaction of glycerol with epichlorohydrin and ED-16. Acrylic acid (AA) was purified by distillation. The oligomers synthesized (UP-612–AA, ON–AA, and ED-16–AA, respectively) contain mainly diacrylates and a certain amount of epoxy acrylates (less than 5%; from here on, wt %).

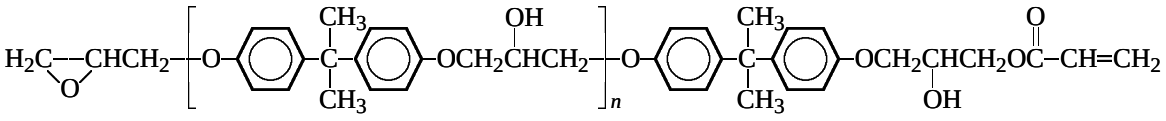
The structure of the oligomers synthesized



UP-612–AA



ON–AA



ED-16–AA

1070-4272/03/7604-0629 $25.00 © 2003 MAIK "Nauka/Interperiodica"

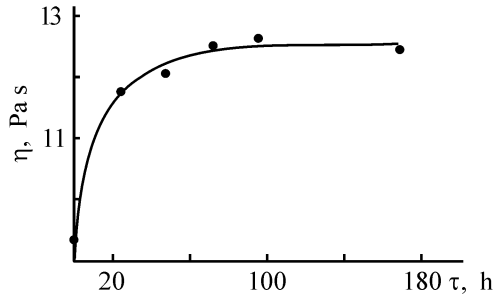


Fig. 1. Variation of dynamic viscosity η of UP-612–AA oligomer with time τ after UV irradiation for 15 s.

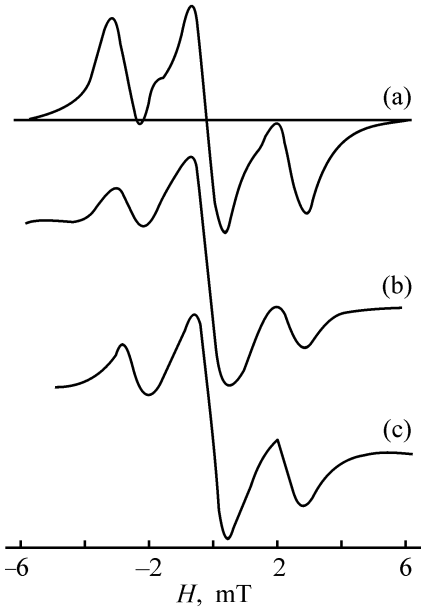

Fig. 2. ESR spectra of solid polymers at 20°C. (*H*) Magnetic field strength; the same for Figs. 3 and 4. (a) Polyacrylic acid after gamma irradiation [5], (b) oligomer UP-612–AA + 10% BP after UV irradiation for 110 min, and (c) oligomer ED-16 + 1% BP after UV irradiation for 2 h (irradiation at 20°C).

was determined by ^{13}C and ^{1}H NMR spectroscopy. The NMR spectra were recorded on a Bruker AM-300 spectrometer operating at 300 (^{1}H) and 76.46 MHz (^{13}C). $CDCl_3$ was used as a solvent, and TMS, as internal reference. The spectra were analyzed and the signals were assigned using two-dimensional H–H and C–H COSY NMR techniques.

The dynamic viscosity of epoxy acrylates was measured on a Rheotest rotary viscometer. Benzophenone (BP) was purified by the common procedure.

To detect radicals generated in thermal polymerization and photopolymerization, we used as spin trap 2-methyl-2-nitrosopropane (MNP) synthesized by the procedure described in [2]. MNP was added to the oligomer in a concentration of $(1–5) \times 10^{-2}$ M.

The ESR spectra were recorded on an SE/X 2543 spectrometer operating at 9 GHz (wavelength $\lambda = 3$ cm). The samples were placed in quartz ampules 4–5 mm in diameter. In the experiments on photopolymerization, BP (1 and 10%) was used as photoinitiator.

The experiments on thermal polymerization in the presence of a spin trap were carried out directly in the resonator of the ESR spectrometer equipped with a temperature-control unit.

Photopolymerization of oligomers was carried out by irradiation with light from high-pressure mercury lamp. To suppress the visible radiation, especially the band with $\lambda = 650$ nm, which readily causes photolysis of MNP to give di-*tert*-butylnitroxyl radical interfering with the study, we used a UFS-2 filter. The field sweep range was determined from the field marks generated by a special unit.

To determine the *g*-factors of radical centers, we used 1-1-diphenyl-2-picrylhydrazyl (DPPH) with $g = 2.0037$ [3]. The *g*-factor of the sample under study was determined by the formula

$$g_X - g_S = \frac{-\Delta H}{H_S} g_S,$$

where g_S is the *g*-factor of the reference, g_X is *g*-factor of the sample being studied; H_S, magnetic induction corresponding to the center of the reference signal; and ΔH, the distance between the centers of ESR signals from the reference and a sample studied.

Of some interest is the prolonged post-effect in studying the polymerization of epoxy oligomers. For example, after UV irradiation of an oligomer based on UP-612–AA (initiator 5% BP) for 15 s, its dynamic viscosity increases (Fig. 1), which suggests postpolymerization after cutting off the light source. A similar pattern is observed in thermal initiation. Long-lived radicals of chain propagation, which are responsible for postpolymerization and whose decay is limited owing to relatively high viscosity of the oligomer medium, must be detectable by direct methods.

It is well known that radical centers similar to the centers expected have been observed directly. For example, upon gamma irradiation of a solid polymer of acrylic acid at room temperature, a triplet signal was observed in the ESR spectrum (Fig. 2a) [4]. This signal was assigned to a terminal radical of the $–CH_2\dot{C}HCO_2H$ type; the *g*-factor of this signal is 2.0031. Upon heating of the sample irradiated at 77 K or upon irradiation at 300 K, macroradicals $–CH_2\dot{C}(COOH)CH_2–$ (quintet, $\Delta H_r = 2.4$ mT) initially predominate. At 300 K and higher temperatures, these macroradicals are irre-

versibly converted to terminal radicals $-CH_2(CO_2H)\dot{C}H$. The signal from this radical is characterized by the constants $a_{\alpha}^{H} = 2$, $a_{\alpha}^{H_1} = 2.5$, and $a_{\beta}^{H_2} = 3$ mT. It can be suggested that the terminal radicals in polyacrylic acid are formed by the reaction of macroradicals with AA. In the above examples, the radical centers became stable as a result of their fixing in the solid polymer matrix. In the liquid phase, these radicals rapidly decay. In the case in question, the propagation radical differs only in the presence of the methyl substituent, instead of the hydrogen atom, in the acid group, which does not noticeably alter the spectrum shape. We hope that, at high degrees of conversion in polymerization of oligomers, the propagation radical stabilized in the solid phase will be detected.

To verify this assumption, we carried out photopolymerization of two samples, oligomer UP-612–AA with 10% BP and ED-16–AA with 1% BP, to high degrees of conversion. The ESR spectra recorded after this procedure are shown in Figs. 2b and 2c, respectively. The ESR spectrum is similar to that reported in [5] ($g = 2.0031$). The shift of the side components of the triplet from the triplet center is 2.57 mT. The shift found previously [5] is 2.55 mT. Thus, it can be concluded that, in both cases, the observed triplet can be assigned to the same radical center, specifically, to the terminal radical or the propagation radical.

Comparison of Figs. 2a and 2b shows that the intensity of the central component of the ESR signal of gamma irradiated polyacrylic acid is lower than that in the samples of UV-irradiated oligomers. This is apparently caused by the existence of another signal coinciding with the central component of the triplet and corresponding to another radical center. With the aim to resolve this signal, we carried out photolysis of the gel fraction of the polymers produced from epoxyacrylate polymers (ED-16–AA and UP-612–AA) after removal of the residual oligomer (sol fraction). As a result, we obtained the ESR spectra shown in Figs. 3a and 3b. These spectra are superpositions of the ESR signals from several radical centers. The first is well-known propagation radical, to which two weak side lines are assigned. The triplet with components of equal intensity, separated by 0.8 mT, can be assigned to the second radical center. The singlet obscured by the triplet of the latter radical center can be assigned to an unknown third radical center. The unknown paramagnetic centers cannot be identified under these experimental conditions. The presence of other radical centers governing the cross-linking in the polymer at high degrees of conversion is indirectly confirmed by the recombination chemiluminescence in photopolymerization of these oligomers [6].

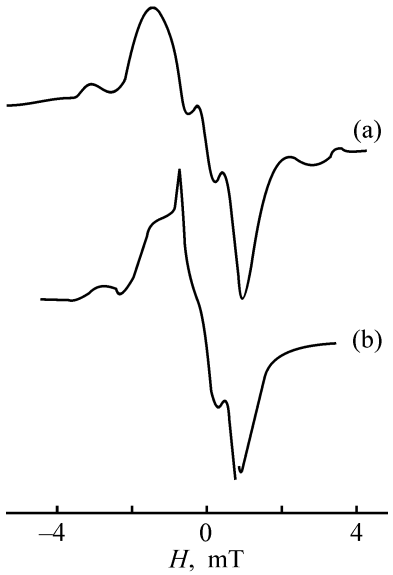

Fig. 3. ESR spectra of the gel fraction of polymers subjected to UV irradiation at 20°C: (a) ED-16–AA + 5% BP, irradiation time 40 min and (b) UP-612–AA + 5% BP, irradiation time 1 h.

With the aim to confirm the conclusion about the nature of the propagation radical, we carried out experiments on detection and identification of radical centers formed in the course of polymerization, using the well-known method of spin traps [7]. This method involves the reaction of a spin trap (MNP) with a short-lived radical to form nitroxyl radical, adduct of unstable radical with the trap, which is sufficiently stable for recording the ESR spectra:

$$(CH_3)_3CN{=}O + R^{\bullet} \rightarrow (CH_3)_3CNR,\ \ |\ O^{\bullet}$$

The presence of ESR signals not only proves the formation of paramagnetic centers in the system at hand, but also allows, in many cases, their simple identification from the hyperfine structure of the spectra. As a result of UV irradiation of UP-612–AA oligomer with 1% BP in the presence of MNP (c = 0.05 M), we obtained the ESR spectrum shown in Fig. 4a. It is believed that the spectrum is a superposition of a broadened triplet of doublets and a triplet. The triplet with characteristic coupling constant with nitrogen nucleus $a_N = 1.573$ mT is assigned to the side di-*tert*-butylnitroxyl radical formed under the action of UV irradiation [7] and has no relation to the reaction in question:

$$(CH_3)_3CN{=}O \xrightarrow{h\nu} (CH_3)C^{\bullet} + NO^{\bullet},$$

$$(CH_3)_3CN{=}O + (CH_3)_3C^{\bullet} \rightarrow (CH_3)_3C{-}N{-}C(CH_3)_3.\ \ |\ O^{\bullet}$$

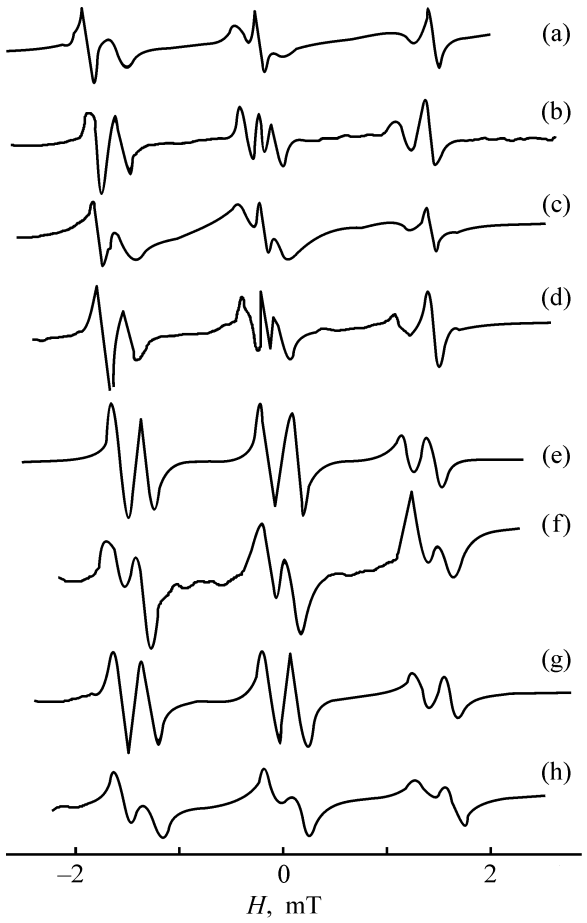

Fig. 4. ESR spectra obtained in the course of polymerization of oligomers (UV irradiation) in the presence of MNP (5×10^{-2} M): (a) UP-612–AA + 1% BP, irradiation for 10 s; (b) UP-612–AA with 1% BP (diluted with CH_2Cl_2, 1 : 1), irradiation for 2 min; (c) ON–AA + 1% BP (diluted with CH_2Cl_2, 1 : 1), irradiation for 160 s; (d) ED-16–AA + 1% BP (diluted with CH_2Cl_2, 1 : 1), irradiation for 20 s; (e) ED-16–AA + 1% BP (diluted with CH_2Cl_2, 1 : 1), irradiated for 35 s with subsequent heating of the sample for 5 min at 70°C; (f) butyl acrylate + 1% BP, irradiated for 2 min; (g) ED-16–AA after thermal polymerization, heating at 70°C for 40 min; and (h) ON–AA after thermal polymerization, heating at 60°C for 22 min.

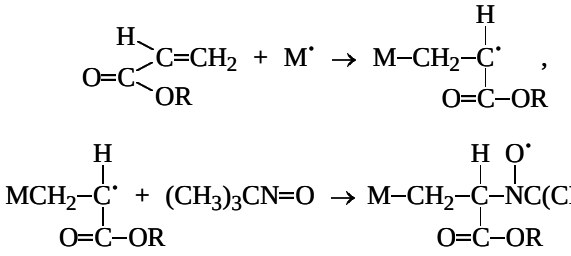
Broadening of the lines in the triplet of doublets assigned to the adduct of the propagation radical of oligomer with MNP is caused by high viscosity of UP-612–AA. Under these conditions, the triplet lines are broadened to a significantly lesser extent, since, despite the high viscosity of the medium, di-*tert*-butylnitroxyl radicals, having significantly smaller size as compared with the oligomer radical, are more mobile. With the aim to decrease the linewidth and improve the spectrum resolution, the sample was diluted with methylene chloride. As a result of dilution and, correspondingly, more prolonged irradiation, the spectrum became better resolved (Fig. 4b).

The measured hyperfine coupling constants of unpaired electron with nitrogen and hydrogen nuclei were a_N = 1.43 and a_H = 0.27 mT.

The ESR spectra of irradiated samples of oligomers ON–AA and ED-16–AA diluted with CH_2Cl_2 are shown in Figs. 4b and 4c. Similarly, the spectra contain a triplet and a triplet of doublets. In the case of ED-16–AA, the triplet of doublets has the following parameters: a_N = 1.52 and a_H = 0.30 mT, and in the case of ON–AA, a_N = 1.45 and a_H = 0.28 mT. It is of interest that the adduct of the propagation radical of ON–AA oligomer gives a strongly broadened signal even at high dilution of the sample with CH_2Cl_2. To obtain a better resolved ESR spectrum of the adduct of the propagation radical of the oligomers with the spin trap, the sample of UV-irradiated ED-16–AA oligomer having the spectrum presented in Fig. 4b was heated at 70°C for several minutes. As a result, the interfering triplet of di-*tert*-butylnitroxyl radical disappeared and practically pure signal of the propagation radical adduct remained in the spectrum. The decay of di-*tert*-butylnitroxyl radicals can be explained as follows. Upon heating of the sample, thermal polymerization of the oligomer starts, in the course of which the forming propagation radicals of the oligomer recombine with di-*tert*-butylnitroxyl radicals as the most mobile species.

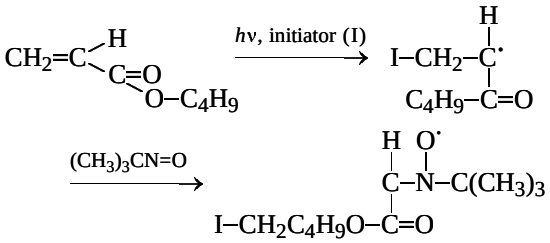
The hyperfine splitting in the form of a triplet of doublets in the ESR spectra of propagation radicals is caused by the interaction of the unpaired electron spin with the nitrogen nuclear spin and with the spin of one hydrogen nucleus at the α-carbon atom. It is believed that the adduct is formed by the scheme



where M$^{\cdot}$ is the propagation radical or initiator.

To confirm additionally the suggested structure of the propagation radical, we performed an independent experiment on recording the propagation radical of the well-known acrylic monomer, butyl acrylate (BA). As a result of UV irradiation in the presence of MNP of the BA sample containing 1% BP for 2 min,

the ESR spectrum containing a triplet of doublets was recorded (Fig. 4f). Undoubtedly, this spectrum can be assigned to the adducts of the propagation radical of BA with MNP; it has the same parameters as the above spectra (a_N = 1.43 and a_H = 0.28 mT):



It is well known that acrylic monomers undergo thermal polymerization at elevated temperature. To identify the propagation radicals in the course of thermal polymerization of the oligomers at hand, we heated oligomers ED-16–AA and ON–AA in the presence of MNP to 60–70°C directly in the spectrometer resonator. In both cases, after heating the samples for 40 min at 70°C, we observed in the ESR spectra a triplet of doublets with parameters corresponding to the signals from the adduct of the propagation radical with MNP, recorded in photopolymerization (Figs. 4g, 4h). The triplet of di-*tert*-butylnitroxyl radical was not recorded. The ESR signals observed in thermal polymerization and photopolymerization of the adducts studied have virtually the same parameters, which suggests the similar structure of the adducts.

Unknown radicals found at high degrees of conversion suggest complex character of polymerization of epoxy-acrylate oligomers.

CONCLUSION

Thermal polymerization and photopolymerization of epoxy-acrylate oligomers based on epoxy oligomers ED-16, UP-612, and Oksilin were studied by ESR at room temperature. The ESR spectra of propagation radicals stabilized in the solid polymer matrix were recorded at high degrees of conversion and in the initial stages of polymerization. The propagation radicals have the same structure and correspond to typical propagation radicals of acrylic monomers, irrespective of the procedure of polymerization initiation.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis, Structure, Composition, and Properties of Rolivsans

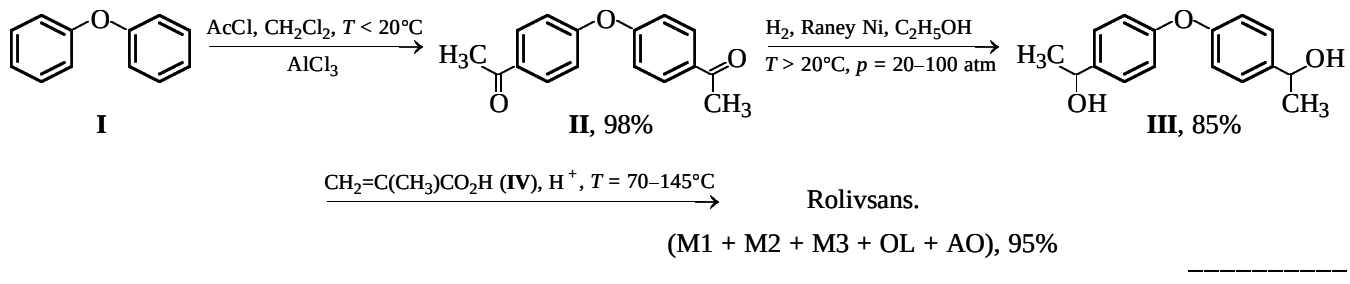
Received February 17, 2002; in final form, January 2003

Abstract—Novel thermosetting resins Rolivsans were prepared, and their structure, composition, and properties were studied. The structural parameters of Rolivsans as influenced by the synthesis conditions were determined.

Novel thermosetting liquid (solvent-free) resins named Rolivsans are used for preparing polymeric and composite materials with enhanced resistance to heat and to the most aggressive agents [1–12]. They are used in various branches of engineering. Rolivsans have been prepared by acid-catalyzed reactions of bis[4-(1-hydroxyethyl)phenyl] ether with methacrylic acid [13–15].

The goals of this study were to analyze in detail the synthesis conditions, elucidate the composition and structure of Rolivsans, and reveal correlations between their structural characteristics and properties. The starting compound in the synthesis is diphenyl ether **I**, which is quantitatively converted to di(4-acetylphenyl) ether **II** by the Friedel–Crafts acylation. Compound **II** is subsequently hydrogenated in the presence of Raney nickel to obtain bis[4-(1-hydroxyethyl)phenyl] ether **III**, which is then refluxed with methacrylic acid **IV** in an aromatic solvent in the presence of an acid catalyst (e.g., *p*-toluenesulfonic acid) and a polymerization inhibitor (e.g., hydroquinone):



where M1–M3 are monomers, OL is an oligomer, and AO denotes antioxidants (products of alkylation of phenolic compounds with monomers M1 and M2 and with oligomer OL).

Comprehensive studies have shown that a one-pot process resembling the synthesis of oligoether acrylates and performed in the course of one or several hours at 70–110°C involves the following successive-parallel reactions: polycondensation of diol **III** [15, 16]; esterification with methacrylic acid of this diol and oligoethers containing terminal hydroxy groups and formed by polycondensation (formation of monomeric and oligomeric methacrylates [13–15]); dehydration of diol **III** and oligoethers [15, 17, 18]; cleavage of (di)methacrylates to (di)vinyl-substituted aromatic compound and methacrylic acid [13–15, 19, 20]; stepwise (co)polymerization of (di)vinyl-substituted aromatic compounds by the polyaddition mechanism with proton transfer (oligomerization) [13–15, 18, 21–23]; and alkylation of dihydric phenols (e.g., hydroquinone) with unsaturated aromatic compounds [24].

Each of these reactions was studied separately with model compounds and Rolivsan components; also, separate stages of the synthesis of Rolivsan as a system of monomers and oligomers were examined. The composition and structure of Rolivsans were studied by exclusion liquid chromatography (ELC) (Figs. 1, 2), IR and ^{1}H NMR spectroscopy, elemental analysis, and analysis for functional groups (ester and bromine numbers, ozonolysis). The IR and ^{1}H NMR

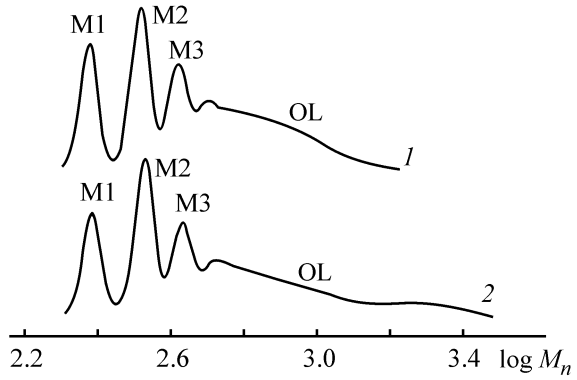

Fig. 1. Gel chromatograms of sample K (Table 2), obtained at 20°C with (*1*) one column and (*2*) six series-connected columns. Eluent tetrahydrofuran. ($\overline{M}_n$) Number-average molecular weight; the same for Fig. 3.

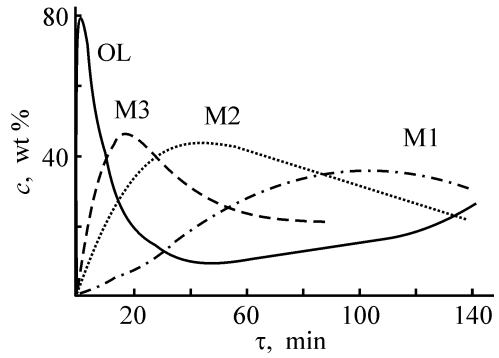

Fig. 2. Composition of Rolivsan vs. synthesis time τ (benzene, 13.5 mM sulfo acid **V**, 80°C). (*c*) Content of components.

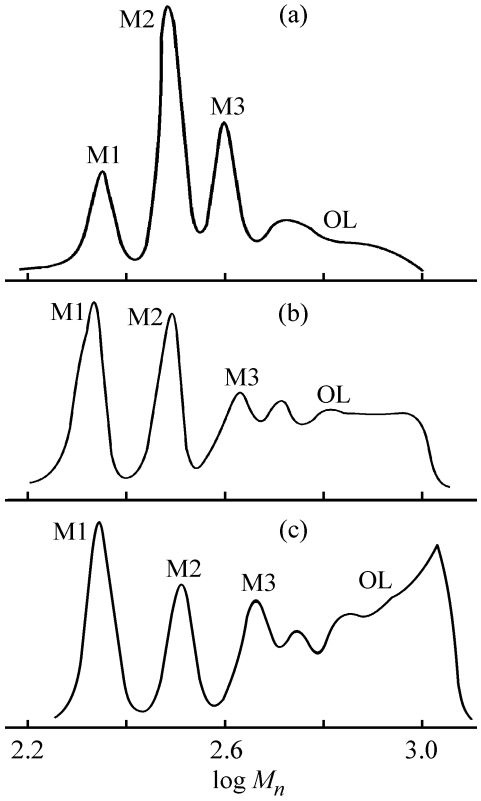

Fig. 3. Gel chromatograms of Rolivsans prepared in benzene at the ratio diol **III** : acid **IV** = 1 : 2.5. Initial concentration of sulfo acid **V** 13.5 mM. Samples were taken (a) 45, (b) 90, and (c) 120 min after the beginning of the synthesis.

spectra of model compounds and separate Rolivsan components M1, M2, M3, and OL have been discussed previously [15, 22–25]. Naturally, the spectra of Rolivsan as a system of monomers and oligomers contain a much greater number of absorption bands associated with various functional groups than the spectra of the components taken separately.

A typical IR spectrum of Rolivsan contains absorption bands of unsaturated and aromatic groups at 3080, 3060, 3030, 2975, 1630, 1600, 1500, 985, 965, 940, and 905 cm^{-1}, and also bands of methyl and methylene groups at 2960, 2925, 2870, and 2850 cm^{-1} and methine groups at 2900 cm^{-1}. The IR spectrum also contains strong absorption bands related to carbonyl groups in methacrylates (1715 cm^{-1}) and to aromatic ether groups (1240 cm^{-1}), and to other absorption bands (1170, 1100, 1060 cm^{-1}, etc.) assignable to stretching vibrations of ester and ether groups.

The ^{1}H NMR spectrum of Rolivsan contains signals typical of such related compounds as styrene, its unsaturated dimer *trans*-1,3-diphenyl-1-butene [24], and methacrylates. Protons of the substituted phenylene group give an *AA*'*BB*' pattern centered at δ = 7.25 ppm. Protons of the unsaturated groups appear as a set of signals (ppm) at δ = 6.7–5.2, namely, at 6.66 (CH= in CH_2=CH), 6.21 and 5.75 [CH_2= in CH_2=C(CH_3)], doublets at 5.63 (5.60 and 5.66; CH_2= in CH_2=CH) abd 5.23 (5.20 and 5.26; CH_2= in CH_2=CH), and a doublet of doublets at 6.45. The signal at 6.21 ppm also belongs to the *trans*-CH=CH protons, since similar signals of the internal double bond (δ 6.19, 6.24 ppm) are observed in the ^{1}H NMR spectrum of the related compound, unsaturated styrene dimer [PhCH=CHCH(CH_3)Ph]. The *tert*-H proton in the >CHPh group appears as a broad ill-resolved multiplet at 3.67 ppm and a multiplet at 4.32 ppm (PhCHPh). The methyl and methylene groups give signals at 2.01 and 1.45 (MeC=CH_2), 1.61 and 1.64 (MeCHAr), and 2.59 ppm (CH_2Ar). The ^{1}H NMR spectrum contains no signals at 2.3 ppm, which are characteristic of toluene methyl protons. This fact suggests that, under the conditions of Rolivsan synthesis, acid-catalyzed aralkylation of the solvent (toluene) with M1, M2, and OL does not occur.

Table 1. Influence of the synthesis time τ on the composition and properties of Rolivsans

τ, min	Resin composition, wt %					Unsaturation, mol >C=C</100 g product	Ester number, mg KOH/g product	n_D (T, °C)
	M1	M2	M3	OL	AO

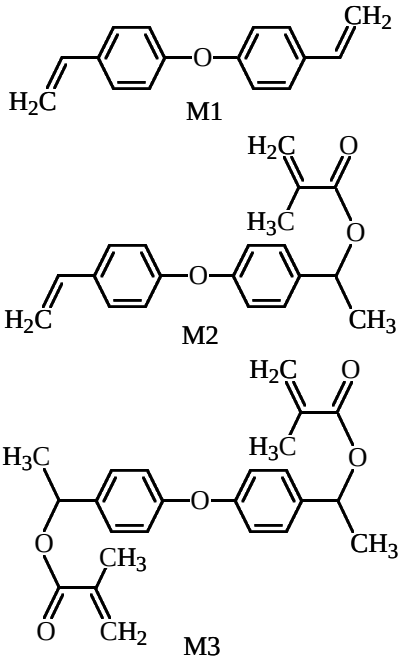
90	20	24	21	34	1	0.592	160	1.597 (40)
120	16	20	15	48	1	0.610	135	1.609 (40)

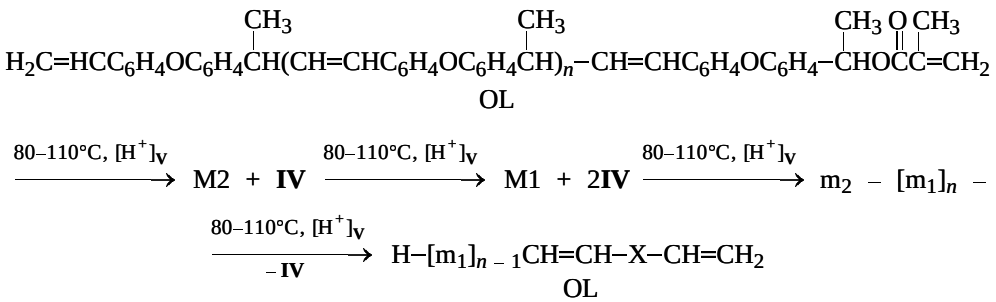
Table 2. Characteristics of Rolivsan M1

Grade	Component content, wt %					Unsaturation, mol >C=C</100 g product	$\overline{M}_n$	n_D^{20}	η^{25}, cP	d^{20}, g cm^{-3}
	M1	M2	M3	OL	Ar(OH)$_n$					
K	14	27	25	32	2	0.58	420	1.590	1620	1.09
S	12	22	18	46	2	0.55	480	1.600	3500	1.10

Figures 2 and 3 show how the composition and molecular-weight distribution (MWD, found by ELC) depend on the synthesis conditions. Initially, refluxing in benzene or toluene results in fast polycondensation of diol **III**, which results in the formation of an oligoether with terminal hydroxy groups [15, 16]. The competing reactions are esterification of the oligoether of diol **III** with methacrylic acid [15, 16] and dehydration; these reactions yield oligomeric methacrylates (OL), monomer M1 [15, 18], and water removed by azeotropic distillation. Acidolysis of the oligoether and oligomeric methacrylates yields monomeric methacrylates M2 and M3 [13–15].

It is known that the components of Rolivsans are M1, M2, M3, OL, and AO. The composition and properties of Rolivsans can be varied widely by ensuring a greater extent of oligomerization of M1 and M2 in the presence of *p*-toluenesulfonic acid **V** by the step (dimerization) addition mechanism with proton transfer to the monomer and formation of, first, dimers, then trimers [13–15, 21–23], etc. Methacrylates M2 and M3 are gradually cleaved to form acid **IV** and, respectively, monomers M1 and M2 (Table 1):





m_1 = CH=CH–X–CH(CH$_3$), m_2 = H$_2$C=CMeCO$_2$MeHC–X–CHMe, X = C$_6$H$_4$OC$_6$H$_4$.

Tables 1 and 2 show that, at relatively low conversions, when the concentrations of methacrylates M2 and M3 are relatively high and the content of oligomers (mainly dimers) is low, the refractive index n_D^{20} and viscosity η^{25} of the resin are comparatively low (1.56 and 450 cP, respectively).

Oligomerization leads to lower content of M2 and M3 and higher content of linear unsaturated oligomers with increased molecular weights (mainly dimers to pentamers); as a result, the refractive index and viscosity grow substantially (to n_D^{20} = 1.60–1.62 and η^{25} = 2500–4000 cP).

Thus, the composition and properties of Rolivsans, molecular-weight distribution of oligomeric components, and distribution of functional groups can be varied within prescribed limits by changing the synthesis conditions.

EXPERIMENTAL

The IR spectra were measured on a Specord 75-IR spectrophotometer (thin films), and the ^{1}H NMR spectra, on a JEOL C-60 HL spectrometer (60 MHz, $CDCl_3$, internal reference TMS). The ELC analysis of Rolivsans and their components was performed using a Waters gel-permeation chromatograph with columns packed with Ultrastyrogel (500 Å) at 20°C; eluent THF, $CHCl_3$, or toluene. The number-average molecular weight $\bar{M}_n$ was determined with a Hitachi–Perkin–Elmer 115 vapor osmometer. The content of unsaturated bonds was found by ozonation (ADS-3 ozonizer, 0°C, solvent CCl_4) and by the bromide–bromate method (determination of the bromine number, followed by recalculation to the iodine number). The ester number was found by dissolving the resin sample in dioxane purified by distillation from KOH and Na, adding 0.1 N solution of KOH in ethanol–dioxane, refluxing for 7 h (the reflux condenser was equipped with a tube packed with soda lime), and titrating with 0.1 N HCl.

CONCLUSIONS

(1) The mechanism of formation of Rolivsans, novel thermosetting resins whose curing yields heat-resistant network polymers, was elucidated.

(2) The composition and structure of Rolivsans were determined by IR and ^{1}H NMR spectroscopy, vapor osmometry, elemental and functional analysis, and exclusion liquid chromatography.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Destruction and Hydrolysis of Proteins in Their Electrochemical Extraction

E. E. Kuprina, S. V. Vodolazhskaya, and G. G. Nyanikova

Gyprorybflot State Research and Design Institute for Fishing Fleet, St. Petersburg, Russia

Received February 26, 2002

Abstract—An electrochemical method was used to extract proteins from a dispersed protein-containing raw material. Cleavage of disulfide and peptide bonds in protein solutions in the course of electrochemical extraction and dissolution of proteins was studied.

Extraction of proteins from dispersed biological raw materials is based on successive separation of water-, salt-, and alkali-soluble proteins from various tissues. The acid and enzymic extraction and dissolution of proteins from different protein-containing raw materials are the most widely used methods for production of protein hydrolyzates for various purposes. However, in shellfish processing to separate proteins from the shell with the purpose of chitin production, base treatment is more effective as compared with the acid and enzymic methods, since, in this case, hydrolysis of β-*D*-glycoside bonds of chitin occurs to a lesser extent [1].

In the electrochemical technology[1], an aqueous salt dispersion of a raw material is processed in dc membrane electrolyzers. In this case, protein extraction and hydrolysis occur in the alkaline medium forming in the cathode cells. This technology allows virtually complete decomposition of the raw material into constituents, such as protein in the form of a protein solution, lipids, and insoluble bone tissue (in the case of a fish raw material) or cover shell tissue (for a shell-fish raw material) [2].

In the electrochemical processes, when a weakly alkaline medium (NaOH concentration 0.025 M) and reducing potential (appearing as a result of discharge of water molecules and dissolved oxygen at the cathode) act on a protein-containing raw material simultaneously, the degree of protein extraction approaches 98–99%. At the same time, with NaOH of the same concentration used alone, proteins are only partially dissolved (degree of extraction ≤40%). Deep extraction of proteins, with tissue decomposition into components, can only be achieved by raising the NaOH concentration to 1.0–2.0 M [3].

[1] Developed at Giprorybflot.

By no means all the protein transformations occurring under the action of the alkali [4] are desirable: proteins after alkaline treatment more difficultly undergo enzymic proteolysis; their nutritive value decreases; finally, they may become toxic.

It is well known that the solubility of proteins in alkaline solutions is caused by cleavage of the intermolecular disulfide bonds responsible for the stability of the protein tertiary structure [5]. In protein molecules, the S–S bonds are weak and labile, especially in reducing media, and also upon heating and in alkaline solutions [6]. At high OH^- concentrations, the cleavage of the S–S bonds proceeds mostly as β-elimination with partial racemization of amino acids [7].

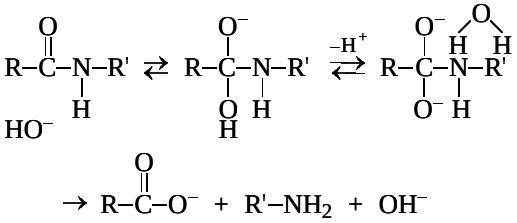
A-0.1	500	125	75
C-5	550	100	80
EC	500	125	75

The forming dehydroalanine demonstrates high reactivity toward a number of nucleophilic groups of proteins, yielding a spectrum of new toxic products, thus decreasing the quality of the hydrolyzates [4].

Hydrolysis of the peptide bonds in alkaline solutions is also possible [4].



However, this process can have only insignificant effect on the dissolution of proteins. To gain better insight into the electrochemical extraction of proteins, we studied variations in the amounts of the disulfide and thiol groups and amine nitrogen in protein solutions for different methods of processing of protein-containing raw materials.

EXPERIMENTAL

In this study, we a used protein-containing muscular tissue of fish, which was dispersed to particle size of 5×10^{-3} m, and bovine serum albumin (BSA) with standard content of the S−S and SH bonds in the molecule (17 and 1, respectively) and molecular weight of 67 000.

Electrochemical treatment of aqueous salt suspensions of the protein-containing raw material was carried out in a cathode cell of a membrane electrolyzer. The cathode material was Cr18Ni9Ti stainless steel, and the anode material, platinized titanium. As membrane served MF4SK-100 ion-selective sulfonic cation-exchange fabric. The raw material was mixed with an aqueous salt solution (NaCl concentration <10%) at fixed weight ratio.

To study the effect of the treatment procedure on the content of the S−S and SH group and amine nitrogen in the course of electrochemical extraction and hydrolysis of proteins, we prepared variously processed samples referred to as EC, C-5, A-0.1, A-4, and W.

Sample EC was prepared by electrochemical treatment of a suspension of the raw material in a cathode cell of the electrolyzer. Electrolysis was carried out until reaching pH ≥ 12.0 ± 0.1 and $Eh \le -600 \pm 10$ mV. The pH and *Eh* were measured against an Ag/AgCl reference electrode with a pH-metric glass and redoxmetric Pt electrodes, respectively, on an I-120.2 ion meter [8].

Sample C-5 was prepared in a stirred reactor by treating the raw material with a catholyte solution obtained in the cathode cell of the electrolyzer. Electrolysis was performed until reaching pH ≥ 12.2 ± 0.1 and $Eh \le -850$ mV.

To elucidate the effect of electrochemical treatment, we studied protein solutions prepared by treating the raw material in water and aqueous NaOH (c_{NaOH} 0.025 and 1.0 M). The respective samples are designated as W, A-0.1, and A-4.

The content of SH and S−S group in protein solutions was determined by direct and back amperometric titration [5] to within 5%. Amine nitrogen was determined using the Formalin test according to GOST (State Standard) 7636–85, and the protein content, by the Lowry method [10] to within 0.6%. The experimental results were statistically processed at a 0.95 confidence level.

The BSA concentration in all the samples was 5 mg ml^{-1}, which is close to the protein content in the commercial hydrolyzates produced from hydrobionts. Experimental data on the content of S−S and SH group contents are listed in Table 1.

The results show the lack of cysteine SH groups in the aqueous BSA solution (sample W) in the absence of electrochemical and base treatment, which is consistent with published data [5] (native BSA contains only cystine responsible for the formation of its tertiary structure through S−S bonding).

In the case of treatment with 1.0 M NaOH (sample A-4), virtually all the S−S bonds were cleaved (their content decreased by a factor of 10). This process favors denaturation of the protein (protein molecules lose the crosslinks and the tertiary structure). However, only 40% of S−S groups of cystine are converted into SH groups of cysteine. The remaining

S–S groups, evidently, enter side reactions involving cleavage of the C–S bonds by the β-elimination mechanism and yielding rather toxic products (β-elimination is followed by nucleophilic addition) [4].

In samples A-0.1, C-5, and EC, the amount of S–S groups decreases by a factor of 4–5, i.e., the degrading effect on the protein molecule appears to be lower by a factor of 1.6–1.8, suggesting, on the one hand, weaker degradation processes and preservation of the protein native structure, and, on the other, suppression of undesired side reactions in cleavage of the S–S bonds.

Thus, the low NaOH concentration (0.025 M) in the extractant provides better quality of the extracted protein, so that it is not advisable to raise the NaOH concentration to 1.0 M. Unfortunately, the measured SH content can be underestimated because of the masking of these groups in the protein, which results from their steric inaccessibility to the $AgNO_3$ reagent and also from specific features of their ionic environment and hydrophobic interactions [5]. However, we have no information about more precise methods.

Finally, electrochemical dissolution of BSA proteins in the catholyte or directly in the cathode cell of the electrolyzer has 2 times weaker degrading effect on the S–S bonds as compared with samples treated with NaOH, promotes the favorable degradation mechanism to give SH groups of cysteine.

To confirm the observed trends, we studied the content of SH and S–S groups in protein extracts obtained from protein-containing muscular tissue of fish under conditions similar to those used for BSA, except for A-0.1 sample, since tissue proteins cannot be dissolved at such a low NaOH concentration. In the samples studied, the protein content determined by the Lowry method was 29.0 ± 0.1 mg ml^{-1}. The data obtained are listed in Table 2.

The results show that, in fish proteins extracted and dissolved electrochemically (EC and C-5 samples), the degree of protein denaturation caused by cleavage of S–S bonds is lower than that in A-4 sample prepared with 1.0 M NaOH. At the same time, in EC and C-5 samples, the SH content is higher by a factor of 2.2–2.4 as compared with A-4, which suggests lower content of by-products formed by the β-elimination mechanism through cleavage of C–S bonds [4].

Protein extraction by treating the aqueous salt suspension of the raw material in the cathode cell leads to stronger degradation with cleavage of the S–S bonds than that with the catholyte (C-5), which is probably due to the effect of reducing agents, such as

Table 2. Effect of extraction procedure on the content of S–S, SH, and NH_2 groups in protein solutions obtained from protein-containing raw material

Sample	pH	c_{SH}	c_{S-S}	c_{NH_2}
		μM		
A-0.1	12.31	1000	300	1.02
EC	11.25	2200	550	1.14
C-5	11.25	2400	700	1.09

$H^{\cdot}_{ads}$, H_2, etc., reacting with the protein just *in statu nascendi*. Cleavage of the S–S bonds in proteins under the action of reducing agents and, in particular, hydrogen was studied in [5].

$$R_1{-}S{-}S{-}R_2 \xrightarrow{\text{Reducing agent}} R_1{-}SH + HS{-}R_2.$$

It is known that dissolution of alkali-soluble proteins necessarily involves the stages of degradation of their tertiary structure and unrolling of their molecule [5]. Ashikari *et al*. have demonstrated for model immunoglobulins that degradation with cleavage of the S–S bonds and the subsequent unrolling of a protein molecule in the presence of reducing agents occur at pH 8.5. In the absence of reducing agents, unrolling of protein molecules in the solution starts only at pH > 11.6 [11]. It was demonstrated by the same authors that, at the indicated pH, no functional groups other than SH are involved in the unrolling of protein molecules.

It may be concluded that the effect of electrochemical dissolution of tissue proteins at such a low NaOH concentration as 0.025 M, observed for EC and C-5 samples (Table 2), is caused by reducing agents, whose presence is demonstrated by strongly negative redox potentials of the extractant (*Eh* = –600 to –850 mV). The dissolution is also promoted by hydrolysis of the peptide bonds increased by 10%, as estimated from the NH_2 content.

CONCLUSION

The electrochemical extraction and hydrolysis of proteins is based on the ability of extractants to reduce proteins with cleavage of mainly disulfide bonds and formation of thiol groups under the action of reducing agents formed in the course of water electrolysis. Suppression of protein destruction at the –C–S– bonds, which are responsible for formation of hazardous by-products in the course of extraction, provides high quality of the resulting hydrolyzates.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Dynamics of Propyl Chitosan Solutions in Longitudinal and Shear Modes

Z. F. Zoolshoev, I. A. Strelina, V. A. Petrova, and L. A. Nud'ga

Institute of Macromolecular Compounds, Russian Academy of Sciences, St.Petersburg, Russia

Received October 18, 2002; in final form, January 2003

Abstract—Low-substituted chitosan was synthesized from shrimp chitin. The effect of the ionic strength on the dynamics of acetic acid solutions of propyl chitosan in longitudinal and shear modes was studied. The dynamic characteristics of these solutions under the action of hydrodynamic fields were estimated.

Steadily increasing requirements to the environmental safety of the use and utilization of polymeric materials stimulate interest in natural polymers. Among them a particular attention is paid to chitosan (Ch) and its derivatives, whose molecules contain ionic amino groups. Thanks to electrostatic interactions between these groups, the chitosan molecules can change their conformation and size. Processing into films and fibers is one of the advanced practical applications of these polymers. Films prepared from chitosan–cellulose composites demonstrate high sorption capacity and low toxicity and show promise as materials for wound and burn cure [1–3]. In production of fibers, chitosan solutions are exposed to strong longitudinal fields. This is the case in both the predrawplate region and orientation drawing. As a result, the molecules pass into a highly oriented state, which does provide high strength of the final product.

By now, the dynamics of uncharged macromolecules in the longitudinal mode has been rather thoroughly studied both theoretically and experimentally [4–6]. However, the dynamics of polyelectrolytes in the longitudinal mode remains to be understood yet [7].

Previously, in studying chitosan solutions, Brestkin *et al*. [8] have demonstrated that deformation effect of a longitudinal flow is stronger than that of a shear flow.

This study is concerned with a new chitosan derivative, low-substituted propyl chitosan (PrCh) containing the hydrophobic propyl substituent in addition to the hydrophilic amino and hydroxy groups. Synthesis of organo-soluble propyl cellulose was reported in [9, 10] and that of the water-soluble mixed cellulose ether, propyl methyl cellulose, in [11]. Introduction of the propyl substituent into methyl cellulose considerably shifts the hydrophilic-hydrophobic balance of the macromolecule, and, at a degree of substitution (DS) exceeding 0.3, the mixed ether no longer dissolves in water. In this context, we developed in the course of the study conditions under which the resulting propyl chitosan preserves its solubility in 0.33 M acetic acid.

The goal of this study was to analyze the effect of the ionic strength on the dynamics of weakly charged propyl chitosan chains in the longitudinal and shear modes.

EXPERIMENTAL

We studied PrCh solutions containing 0.33 M CH_3COOH and 0.01 or 0.3 M NaCl. Concentrations of the polymer, c_p, and salt, c_s, in solutions are listed in Table 1. Because of the low degrees of dissociation of acetic acid and PrCh as a polybase, the ionic strength I of the solution is controlled in the experimental c_s range mostly by the NaCl concentration ($I \approx c_{NaCl}$). In the case of acetic acid solutions of PrCh, containing low-molecular-weight chitosan, the contribution of the polymer to the ionic strength should be taken into account.

In synthesis of PrCh, we used Ch extracted from shrimp chitin (MW 1.88×10^5, degree of deacetylation 0.88). The alkylating agent, propyl bromide was distilled and the 71°C fraction was taken. The diluent, isopropanol (chemically pure grade) was used without further purification. The reaction was performed

3	1 : 3 : 2	30	0.2	7.06	6.94

as follows. A weighed portion of air-dry Ch was dispersed in 2-propanol (solid-to-liquid ratio 1 : 20). Then a calculated amount of 47% aqueous NaOH was added, the mixture was stirred for 20 min at room temperature with bubbling of N_2, and the required amount of propyl bromide was added. The reaction was performed at 70°C (glycerol bath) with stirring. After the completion of the reaction, PrCh was filtered off, washed with 80% methanol to remove NaOH, and dried at 60°C in a vacuum. The degree of substitution was estimated from data on the amine nitrogen content, obtained by conductometric titration. The synthetic procedure conditions are listed in Table 2.

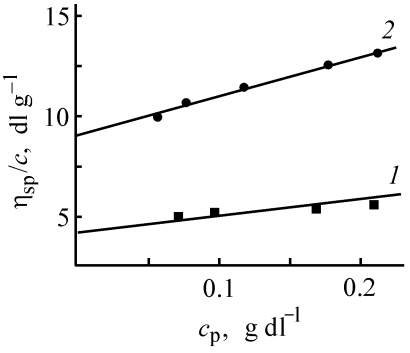

Fig. 1. Reduced viscosity η_{sp}/c of PrCh in 0.33 M CH_3COOH vs. the polymer concentration c_p. Ionic strength (M): (*1*) 0.3 and (*2*) 0.01.

To evaluate the effect of the ionic strength of the solution on the dynamics of PrCh macromolecules, we selected sample no. 2, which appeared to be quite sufficient, since the samples studied only slightly differed from one another in the degree of substitution, and the difference in the birefringence for them was within the experimental error at all.

The solution viscosity was measured at 21°C on a modified Ostwald viscometer with a spiral-shaped capillary (length 100 cm, diameter 0.06 cm). Measurements were carried out at velocity gradients of 20 to 1000 s^{-1}. The viscosity data reported here were obtained by extrapolation of the viscosity to zero velocity gradient.

The reduced viscosity of the PrCh solutions (η_{sp}/c) is given in Fig. 1 as a function of the polymer concentration c_p at various ionic strengths. As seen, the reduced viscosity is a linear function of the polymer concentration, suggesting that the size and shape of the polyions, as well as the ionic strength, remain unchanged upon dilution, so that there is no need to use the isoionic dilution method. Lowering the ionic strengh of the solution results in an increase in η_{sp}/c (Fig. 1) and intrinsic viscosity [η] (Table 1). For example, lowering I from 0.3 to 0.01 M leads to an increase in [η] by a factor of 2, suggesting increase in the size of macromolecular coils as a result of polyelectrolyte swelling.

The birefringence (BR) Δn was measured, as influenced by the velocity gradient g' and polymer concentration, using the procedure described in [12]. The shear flow velocity gradient is written as

$$g' = (\omega r)/2\Delta r, \quad (1)$$

where ω is the angular velocity of a rotor with the radius $r = r_1$; r_2, the stator radius; and $\Delta r = r_1 - r_2$. We used a titanium dynamo-optimeter with rotor height of 8.95 cm, Δr = 0.075 cm, and $2r_1$ = 7.5 cm.

Similarly to other polysaccharide solutions, PrCh solutions demonstrate positive birefringence in a flow. The dependence of Δn–g' for a shear flow was obtained at velocity gradients ranging from 200 to 2000 s^{-1}, in which the flow laminarity condition is met. Over the indicated range, this dependence is linear and passes through the origin (Fig. 2), indicating a molecular dispersity of the PrCh solutions. We also determined

the optical shear coefficient $\Delta n/g'(\eta - \eta_0)$ (Table 1). With changing polymer concentration, the optical shear coefficient remains unchanged, suggesting an insignificant contribution of the macroform anisotropy.

The longitudinal flow dynamics of the solutions was studied on the experimental setup described in [13]. The principle of its operation is similar to that of Frank–Keller's method proposed for generation of a longitudinal hydrodynamic field in a gap between coaxial capillaries. Upon suction of a solution into the capillaries along their axes, an optically anisotropic region appears as a thin luminous filament at some critical velocity gradient g_{cr}. The Δn was determined by measuring the phase difference σ of the ordinary and extraordinary waves passing along the diameter of the optically anisotropic region of the solution and the diameter d of this region:

$$\Delta n = (\delta\lambda)/(2\pi d), \quad (2)$$

where λ is wavelength. The velocity gradient is written as

$$g = Q/\pi r^2(l/2), \quad (3)$$

where Q is the volumetric flow rate of the solution through a capillary; r, radius of the capillaries; and l, distance between their end faces. The degree of uncoiling in the longitudinal flow was characterized by reduced birefringence $\Delta n/\Delta n_\infty$. Here the limiting birefringence Δn_∞ for a given solution concentration is writen as

$$\Delta n_\infty = [2\pi(n^2 + 2)^2/9n](\alpha_1 - \alpha_2)N, \quad (4)$$

where n is the refractive index of the solution; $(\alpha_1 - \alpha_2)$, optical anisotropy of the chain segment, associated with its intrinsic optical anisotropy and macroform effect; N, number of segments in the unit volume of the solution.

The results obtained in studying the effect of longitudinal hydrodynamic field on PrCh solutions of various polymer concentrations and ionic strengths are shown in Fig. 3 as the dependences of $\Delta n/\Delta n_\infty$ on the velocity gradient g in the solution flow direction. With increasing c_p, $\Delta n/\Delta n_\infty$ decreases, which is due to strengthening of intermolecular interactions and to the effect of partial uncoiling of the chains on the structure of the hydrodynamic field itself. In the velocity field, rotation components appear; the deformation effect on the molecule becomes alternating, and the

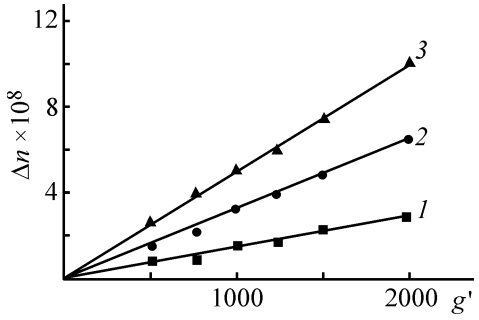

Fig. 2. Birefringence Δn of PrCh in 0.33 M CH_3COOH vs. shear flow velocity gradient g'. I = 0.3 M. c_p (g dl^{-1}): (*1*) 0.06, (*2*) 0.12, and (*3*) 0.24.

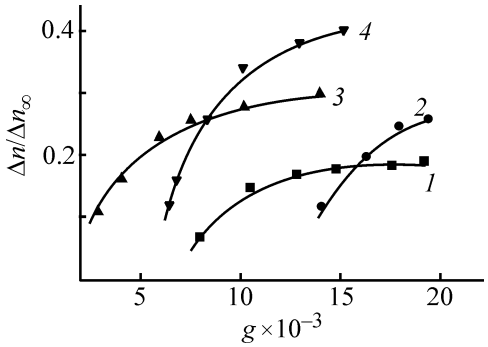

Fig. 3. Reduced birefringence $\Delta n/\Delta n_\infty$ vs. longitudinal flow velocity gradient g in PrCh solutions in 0.33 M CH_3COOH. I (M): (*1*, *2*) 0.03 and (*3*, *4*) 0.01. c_p (g dl^{-1}): (*1*, *3*) 0.24 and (*2*, *4*) 0.12.

degree of uncoiling decreases [14]. These effects become more pronounced with increasing polymer concentration. It should be pointed out that, lowering the ionic strength of the solution from 0.3 to 0.01 M at the same polymer concentration leads to an increase in $\Delta n/\Delta n_\infty$ (Fig. 3, curves *1*, *3*). This is associated with increasing length of the Kuhn segment as a result of electrostatic repulsion of the charge-bearing groups of the macromolecule. The maximal $\Delta n/\Delta n_\infty$ obtained did not exceed 0.4. It may also be noted that transition of the macromolecules to the uncoiled state takes place over a rather wide range of velocity gradients, and the $\Delta n/\Delta n_\infty$–g curves are concave down, suggesting that the orientation of molecular coils contributes significantly to the observed birefringence of the PrCh solutions [15].

It was demonstrated in [16–18] that, under the action of a longitudinal hydrodynamic field, uncharged macromolecular coils of rigid-chain polymers pass virtually completely into the uncoiled state, and $\Delta n/\Delta n_\infty$ approaches 0.95. The $\Delta n/\Delta n_\infty$–g curves are markedly concave up (toward the ordinate axis). All these cir-

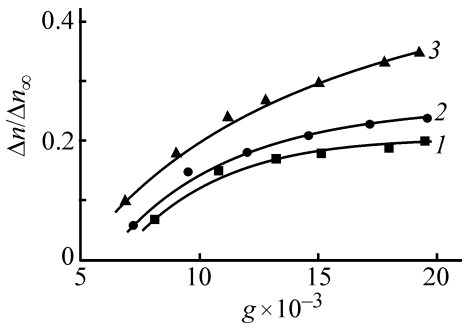

Fig. 4. Reduced birefringence $\Delta n/\Delta n_\infty$ vs. longitudinal flow velocity gradient g in PrCh solutions in 0.33 M CH_3COOH with addition of low-molecular-weight chitosan (LCh). c_p = 0.24 g dl^{-1}. I (M), c_{NCh} (g dl^{-1}): (*1*) 0.3, 0; (*2*) 0.3, 0.5; and (*3*) 0.15, 0.5.

cumstances suggest that, in the case of flexible-chain polymers, the effect of a longitudinal hydrodynamic field is of essentially the deformation nature.

Lyubina *et al*. [19] have demonstrated that, in acetic acid solutions, the chitosan macromolecules take the swollen coil conformation. The macromolecular coil loses its conformational stability in a longitudinal hydrodynamic field, and the polymer solution passes into the forced anisotropic state at a velocity gradient meeting the condition given by Eq. (5) [20, 21]:

$$g_{cr}\tau = 1/2, \quad (5)$$

where $\tau = M[\eta]\eta_0/RT$ is the time of orientation-deformation relaxation of the whole chain; η_0, solvent viscosity; R, gas constant; T, temperature (at $g < g_{cr}$, the flowing polymer solution is virtually isotropic).

The g_{cr} and τ values determined for the longitudinal flow are listed in Table 2. At a constant ionic strength of the solution, raising the c_p results in a decrease in g_{cr} and increase in τ. This effect strengthens with decreasing I. Lowering the ionic strength of the solution increases the electrostatic repulsion between the charged groups of the macromolecules. In this case, the number of monomeric units in the segment and the relaxation time τ increase, which also shifts g_{cr} to lower values.

We also studied the effect of addition of low-molecular-weight chitosan on transition of PrCh solutions to the anisotropic state. Our results showed that raising the solution viscosity by addition of the low-molecular-weight component has no significant effect on the anisotropic transition. For example, after adding low-molecular-weight Ch (c_{NCh} = 0.5%, $[\eta]$ = 1.2 dl g^{-1}) to an acetic acid solution of PrCh (c_p = 0.24 g dl^{-1}, I = 0.3 M) g_{cr} decreased from 6200 to 6000 s^{-1}. In a similar experiment, but with I = 0.1, g_{cr} decreased to 5500 s^{-1}.

In isoionic solutions, the lower the ionic strength, the higher the maximum achieved $\Delta n/\Delta n_\infty$ (Fig. 4), suggesting that the ionic strength is the crucial factor in anisotropic transition in the PrCh solutions.

CONCLUSIONS

(1) A new chitosan derivative, low-substituted propyl chitosan (DS 0.05–0.20) soluble in 0.33 M acetic acid was synthesized.

(2) It was shown that the forced optical anisotropy of the propyl chitosan solutions is caused by essentially orientational, rather than deformational effect of the hydrodynamic field. Lowering the ionic strength shifts the anisotropic transition range in propyl chitosan solutions to lower velocity gradients.

Abstract—The effect of arylamines containing a sterically hindered phenolic fragment on the resistance of polypropylene, synthetic isoprene rubber, and thermoelastoplastics derived from them to oxidative and thermomechanical degradation was studied in relation to the structure of the additives.

One of promising lines in extension of the range of raw materials for rubber items is utilization of thermoelastoplastic (TEP) materials based on mixtures of rubbers with thermoplastics. Such polymeric materials exhibit a wide spectrum of service properties which can be controlled by varying the type and ratio of the polymeric components. One of promising TEPs is a blend of synthetic isoprene rubber with polypropylene (SIR–PP).

Previously we have prepared a number of arylamines containing a sterically hindered phenolic (SHP) fragment. In their molecules, there are at least two functional groups (SHP and secondary amino group) potentially capable of inhibiting oxidative processes [1]. The capability of these compounds to prevent oxidation of organic substrates by scavenging peroxide radicals responsible for the aging was evaluated in model reactions of initiated oxidation of styrene and PP, and their antioxidative performance was found to be high [2].

In this study we examined the possibility of using these additives to preserve in the course of aging the physicomechanical properties of PP, SIR, and TEPs derived from them.

EXPERIMENTAL

The stabilizers, *N*,*N*'-bis(3,5-di-*tert*-butyl-4-hydroxybenzyl)-*p*-phenylenediamine **I**, mp 197–199°C; *N*,*N*'-bis(3,5-di-*tert*-butyl-4-hydroxybenzyl)ethylenediamine **II**, mp 189°C; (3,5-di-*tert*-butyl-4-hydroxybenzyl)phenylamine **III**, mp 105°C; and *N*,*N*,*N*',*N*'-tetra-(3,5-di-*tert*-butyl-4-hydroxybenzyl)-*p*-diphenylenediamine **IV**, mp 192–194°C, were prepared according to [1].

Autooxidation of polymers was performed in an installation described in [3], in an oxygen atmosphere (p_{O_2} = 250 mm Hg) at 165°C (polymer sample weight 0.1 g). The dissolved stabilizing components were added to the PP powder and thoroughly mixed at room temperature; the mixture was vacuum-dried to constant weight. SIR-3 was reprecipitated three times with acetone from toluene solution according to [4]. The stabilizer was added to a 5% (here and hereinafter, wt %) solution of SIR-3 in toluene and stirred to complete dissolution, after which the solvent was vacuum-evaporated.

The torque M_t was determined in a Brabender plasticorder [5]. The choice of the time for recording M_t was governed by the residence time of the polymer in the mixing chamber in TEP preparation.

The TEP based on SIR and PP was prepared using the formulation from [6]; the resulting TEP exhibits high physicomechanical parameters. The vulcanizate composition and the time of successive addition of ingredients are given in Table 1.

After adding all the ingredients, they were stirred for 6–7 min, with simultaneous melting of PP and vulcanization. The vulcanization was performed in the dynamic mode. The vulcanization time was determined from the maximal value of M_t in the kinetic curve. Af-

III	150	9.65	6.45	1	1
IV	100	2.84	2.84	4	–
V	130	13.32	10.20	–	2

ter reaching the maximal M_t, the stirring was continued for additional 3 min. Then the TEP was subjected to sheeting with microrolls (2-mm slit). The cooled material was extruded through a slit die head (1.5-mm slit).

The TEP samples were tested according to GOST (State Standard) 270–85 [7] to determine the tensile strength σ, relative elongation L_{rel}, and residual elongation L_{res}.

The antioxidative effects of amines **I**–**IV** on PP and SIR-3 were evaluated by the induction period of oxidation, determined in the autooxidation mode on a static oxidation unit. Such tests allow evaluation of the performance of an additive under the conditions of polymer processing [3]. Also, we examined the capability of stabilizers **I**–**IV** to prevent thermomechanical degradation of PP and SIR-3. This parameter is particularly important for dynamic TEPs whose vulcanization is combined with mixing at the temperature of the thermoplastic melt, which results in that the polymers undergo significant degradation. The degradation is manifested in a decrease of the torque in mechanical treatment of the polymer.

We evaluated the effect of **I**–**IV** on the stability of physicomechanical parameters of TEPs in the course of aging. The polymeric material is a multicomponent system whose properties depend not only on the initial mixture composition and mixing procedure, but also on possible interactions between the mixture components in the course of mixing. Therefore, the stabilizing performance of antioxidants (AOs) depends on the mixture ingredients.

The results of testing of amines **I**–**IV** as AOs for SIR-3 are listed in Table 2. The reference stabilizer was *N*-phenyl-*N*'-isopropylphenylenediamine **V** (stabilizer 4010 NA) used in industry for stabilization of dark SIR brands and their vulcanizates. When autooxidation of a polymer is performed at elevated temperature (130°C), stabilizer **V** starts to sublime; this significant drawback was noted in a number of papers [8–10]. No noticeable sublimation of **I**–**IV** was observed under the testing conditions.

As seen from Table 2, the longest induction period in oxidation of SIR-3 was observed with **I** and **III**. Comparison of **I**–**V** shows that the best stabilizing effect is achieved with the molecules that combine SHP and NH_{Ar} groups. Amine **II** combining the SHP and NH_{Alk} groups, is a poor inhibitor, probably because of the high rate of oxidation chain transfer from the $\dot{N}_{alk}$ radical generated in the course of stabilization [11]. The advantages of **I** and **II** become particularly obvious when using the molar scale (mol kg^{-1}), which reflects the molecular activity of the compounds, instead of the weight percentage scale accepted in industry (Table 2).

Table 2 shows that, with **I** and **III**, the 100-min induction period of SIR-3 oxidation is attained at a lower inhibitor concentration than with **V**.

Amine **I** also ensures the longest induction period in oxidation of PP:

V	143.2	158.4	136.8	90.4

Compound **I** is comparable in its antioxidative power with the commercial PP stabilizer Irganox (**VI**), ester of pentaerythritol and 2,6-di-*tert*-butyl-4-hydroxyphenylpropionic acid.

In treatment of SKI-3 in a Brabender plasticorder for 10 min at 130°C, addition of **I**–**IV** in amounts of less than 0.3% had no effect on the torque variation. In all the cases, M_t decreased by approximatelyl 50%. In the presence of **I** and **III** in a concentration exceeding 0.3%, M_t decreased to a considerably lesser extent (Table 3), i.e., these stabilizers efficiently prevent the thermomechanical degradation of the polymer.

Similar data on the performance of **I**–**IV** were obtained in experiments on thermomechanical treatment of PP (Table 3).

Amines **I** and **III**, which showed the best stabilizing performance were tested as stabilizers for TEP derived from a mixture of SIR-3 and PP (weight ratio SIR-3 : PP from 75 : 25 to 50 : 50).

Data on the influence of the stabilizer structure on the physicomechanical properties of TEPs (Table 4) show that the strength σ of the material is virtually independent of the rubber : plastic ratio in the range

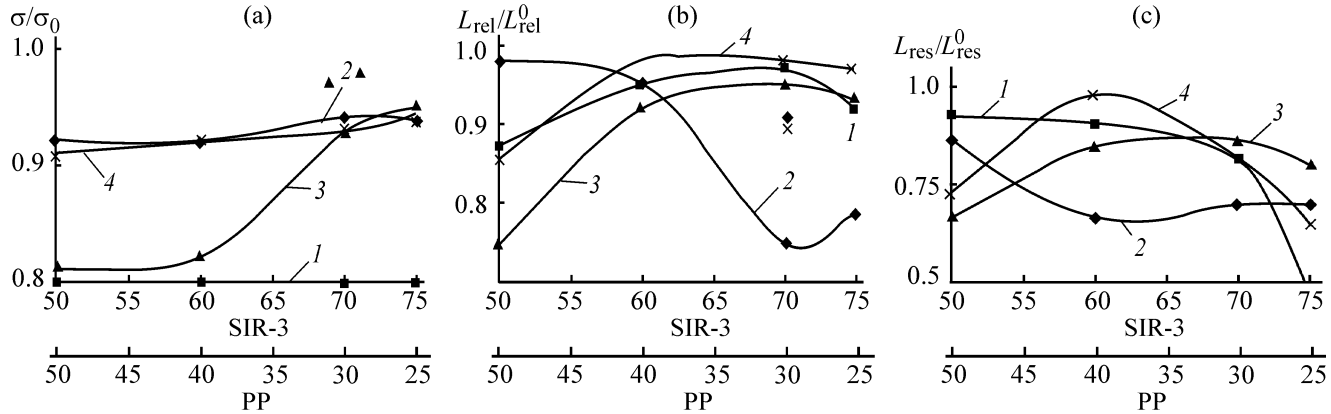

Fig. 1. Variation of TEP properties in the course of thermal aging at various ratios (mol %) of SIR-3 and PP. c_{AO} = 1%, 100°C, 72 h. (a) (σ/σ_0) tensile strength, (b) (L_{rel}/L_{rel}^0) relative elongation, and (c) (L_{res}/L_{res}^0) relative residual elongation (relative to the initial values). Stabilizer added: (*1*) none, (*2*) **V**, (*3*) **I**, and (*4*) **III**.

from 50 : 50 to 70 : 30 and of the presence and type of a stabilizer, except for amine **III** with which the strength decreases at rubber content in TEP exceeding 60%. The relative elongation L_{rel} depends on the polymer ratio only weakly in the presence of **I** and **III**, but with **V**, the relative elongation sharply increases at rubber content exceeding 60%. The relative residual elongation L_{res} of TEPs stabilized with **I** and **III** decreases approximately linearly with increasing content of SIR-3, whereas with **V**, the residual elongation as a function of the SIR-3 content passes through a maximum.

The AO effect of stabilizers in TEP was evaluated by the coefficient of resistance to thermal aging, equal to the ratio of a parameter determined after aging to that before aging. These coefficients are plotted in Fig. 1 against the ratio of the polymeric components.

Figure 1 shows that stabilizers **I** and **III** are level with V or even surpass it in the capability to preserve the properties of TEPs at the SIR-3 : PP ratio varied from 55 : 45 to 70 : 30.

CONCLUSION

Arylamines combining sterically hindered phenolic and HNAr fragments show promise as agents enhancing the resistance of isoprene rubber and polypropylene, and also of thermoelastoplastics derived from them (rubber : polypropylene ratio from 50 : 50 to 70 : 30), to oxidative and thermomechanical degradation.

Abstract—The influence of the charge of a metal cation and the nature of a coagulant on the recovery of butadiene–styrene rubber and properties of rubber stocks and vulcanizates was examined.

Rubbers produced by emulsion copolymerization are widely used in industry for production of tires and other rubber items [1–5]. An advantage of the emulsion copolymerization is the absence of dangerously explosive, inflammable, and harmful organic solvents. A wide variety of butadiene–styrene rubbers are produced commercially; the starting monomers for their synthesis are readily available, and the polymers are uniform in properties and have high quality.

One of the key stages in production of emulsion rubbers is their recovery from latexes with an aqueous NaCl solution acidified with H_2SO_4 [3]. The high consumption of the coagulant (180–250 kg t^{-1} rubber) results in strong contamination of the forming wastewater with NaCl, which cannot be removed at water treatment facilities. Therefore, active efforts are made to develop new processes for recovery of rubbers from latexes, including a search for new coagulants [6].

Numerous inorganic and organic coagulants have been suggested [7–10]. However, their commercial application involves serious problems. For example, aqueous solutions of protein coagulants exhibit low stability, especially at elevated temperatures. Proteins degrade with evolution of noxious substances with unpleasant odor, which results in air pollution in the working rooms. Other coagulants are expensive and are in short supply. Therefore, up to now, the main coagulant used in production of emulsion rubbers has been NaCl; recovery is performed at 50–65°C [3].

Published data and industrial experience show that multicharged metal salts are the most promising coagulants; they can be taken in considerably smaller amounts than NaCl [3]. However, the relationship between the consumption of coagulants based on multicharged metal salts and the composition of emulsifying systems is poorly understood.

The emulsifying agents that are widely used today in commercial production of emulsion butadiene–styrene rubbers are soaps based on tall oil, disproportionated rosin, and fatty acid salts, taken in various ratios.

In this study, we analyzed coagulation of SKS-30 ARK butadiene–styrene latex at low temperature, with NaCl, $CaCl_2$, $AlCl_3 \cdot 6H_2O$, and $SnCl_4 \cdot 5H_2O$ as coagulating agents.

Experiments on rubber recovery from the latex were performed in a stirred vessel placed in a thermostat. The vessel was charged with 20 ml of the latex and kept for 15–20 min to attain the required temperature, after which aqueous solutions of the coagulants acidified with H_2SO_4 were added. Coagulation was performed at pH 2.0–2.5.

Coagulants were taken as aqueous solutions containing (wt %) 24 NaCl or 10 $CaCl_2$, $AlCl_3$, or $SnCl_4$.

Data on the completeness of rubber recovery from the latex as influenced by temperature, nature of coagulant, and its consumption are given in Figs. 1 and 2.

The experimental dependences show that, in going from single- to triple-charged metal ion, the required coagulant consumption considerably decreases, which is consistent with the results of [3].

At 2–4°C, the consumption of $SnCl_4$ required for complete recovery of the rubber is lower than the con-

1070-4272/03/7604-0652 $25.00 © 2003 MAIK "Nauka/Interperiodica"

sumption of $AlCl_3$, the most active coagulant among those tested previously. At 20°C, however, the consumptions of $SnCl_4$ and $AlCl_3$, required for 100% coagulation, become approximately equal, and at 40°C $AlCl_3$ becomes even more effective. Thus, the Sn(IV) cation exhibits high coagulating power only at low temperatures. With $SnCl_4$, no acidification with H_2SO_4 is required. In aqueous solution, $SnCl_4$ undergoes hydrolysis to form HCl, stannic acid, and hexachlorostannic acid [11]:

$$SnCl_4 + 6H_2O \rightleftarrows H_2[Sn(OH)_6] + 4HCl,$$

$$3SnCl_4 + 4H_2O \rightleftarrows 2H_2[Sn(Cl)_6] + Sn(OH)_4,$$

$$SnCl_4 + 2HCl \rightleftarrows H_2[Sn(Cl)_6].$$

Hexachlorostannic acid is strong; its stable salts give a neutral reaction in aqueous solution and are not hydrolyzed even on boiling. Therefore, the surfactants present in the emulsifying system can react with hexachlorostannic acid:

$$H_2[Sn(Cl)_6] + R\text{–}COONa(K)$$

$$\rightarrow Na_2(K_2)[Sn(Cl)_6] + R\text{–}COOH.$$

Hydrolysis of $SnCl_4$ makes the content of the salt in the system lower, especially at elevated temperature [12], and may be responsible for the increase (relative to $AlCl_3$) in the consumption of $SnCl_4$ required for 100% recovery of rubber from the latex with the temperature increasing from 2–4 to 20 and then to 40°C.

A specific feature of coagulation with $SnCl_4$ is the formation of a fine rubber crumb, which results in major loss of rubber with washwater.

By computer processing of the experimental data, we obtained the following regression equations for the dependence of the coagulant consumption on the cation charge at various temperatures of rubber recovery:

$$Y_{2-4°C} = 318 - 307.33x + 100x^2 - 10.667x^3,$$

$$Y_{20°C} = 877 - 892.33x + 297.5x^2 - 32.167x^3,$$

$$Y_{40°C} = 845 - 841.17x + 275.5x^2 - 29.333x^3.$$

From the dried samples of SKS-30 ARK rubber, we prepared standard rubber stocks, which were vulcanized at 143°C.

Tests of rubber stocks and vulcanizates based on SKS-30 ARK rubber recovered from latex with salts of single- to quadruple-charged metal ions showed that the properties of these materials are not influenced appreciably by the nature of the coagulant.

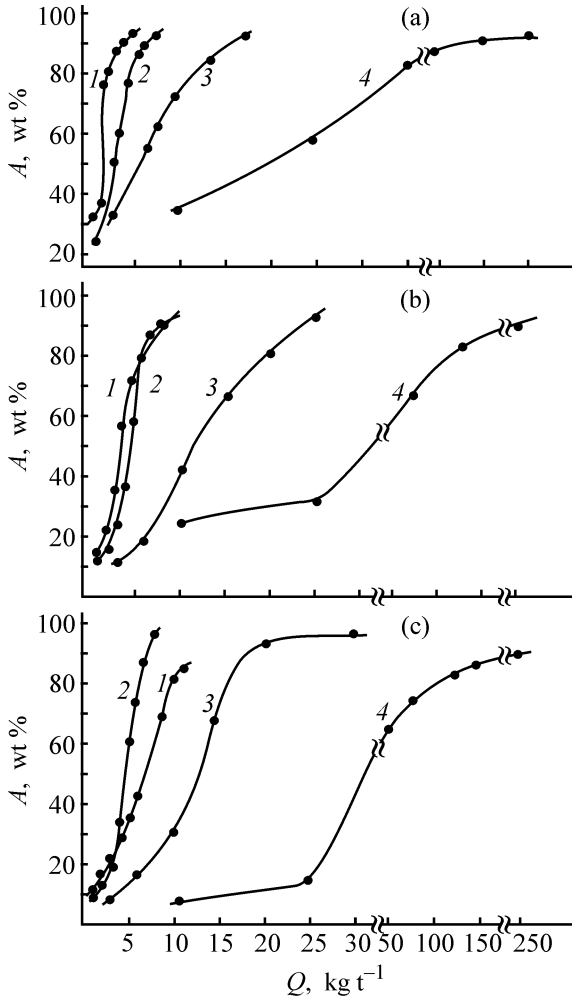

Fig. 1. Degree of recovery *A* of rubber from SKS-30 ARK lattice, as influenced by the nature and consumption *Q* of the coagulant. Temperature, °C: (a) 2–4, (b) 20, and (c) 40. (*1*) $SnCl_4$, (*2*) $AlCl_3$, (*3*) $CaCl_2$, and (*4*) NaCl.

Note. Vulcanization at 143°C for 60 (numerator) or 80 (denominator) min.

Table 2. Characteristics of vulcanization of rubber stocks based on SKS-30 ARK rubber at 160°C

Parameter	Coagulant			
	NaCl	$CaCl_2$	$AlCl_3$	$SnCl_4$
Minimal torque M_L, N m	4.8	4.6	5.1	5.1
Maximal torque M_H, N m	36.5	33.0	33.5	36.2
Time of vulcanization onset t_S, min	3.5	4.0	4.0	4.0
Time of 50% vulcanization $t_{S(50)}$, min	10.2	10.7	11.5	9.9
Optimal vulcanization time $t_{S(90)}$, min	27.5	18.5	26.0	23.0
Vulcanization rate R_v, min^{-1}	4.17	6.90	4.54	5.26

However, it should be noted that the rubber stocks based on SKS-30 ARK rubber coagulated with $SnCl_4$ show higher plasticity and lower recovery (Table 1).

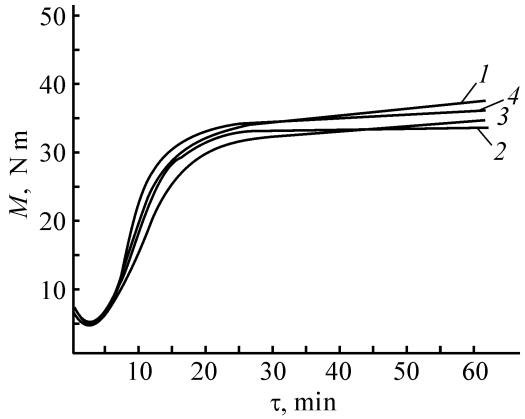

Fig. 3. Kinetics of vulcanization of rubber stocks based on SKS-30 ARK rubber recovered using (*1*) $SnCl_4$, (*2*) $AlCl_3$, (*3*) $CaCl_2$, and (*4*) NaCl. (*M*) Torque and (τ) time.

The kinetic curves of vulcanization (Fig. 3) show that the rubber stocks prepared from SKS-30 ARK rubber coagulated with $CaCl_2$ are characterized by faster vulcanization, and in the case of NaCl and $AlCl_3$ coagulants, the vulcanization is the slowest (Table 2).

CONCLUSIONS

(1) The maximal decrease in the salt consumption was observed on passing from single- to triple-charged metal ions.

(2) With $SnCl_4$ as coagulant, acidification is unnecessary.

(3) With $SnCl_4$, coagulation is more efficient at lower temperatures.

(4) The nature of the coagulant has no appreciable effect on the properties of the resulting rubbers, rubber stocks, and vulcanizates.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Higher Fatty Acids and Their Mixtures on Interfacial and Physicomechanical Properties of Vulcanized Rubbers

Abstract—The interfacial characteristics of stearic and oleic acids and their mixtures were studied. The surface free energies of isoprene and butadiene–styrene rubbers and vulcanizates thereof, obtained using fatty acids and their synergistic mixture as vulcanization activators, were evaluated from the contact angles.

Surfactants play an important role in preparation and processing of rubber stocks. They are used as vulcanization activators and process additives improving the dispersion and ensuring uniform distribution of all the rubber stock components; they improve the compatibility of fillers with the polymeric matrix and control interphase interactions at phase boundaries [1, 2]. Higher fatty acids and their salts are traditional ingredients of rubber stocks exhibiting, along with the capability to affect the colloidal-chemical characteristics of the system, also the properties of structural plasticizers [2]. Active search for new, more effective surfactants and for optimal conditions of their introduction is being continued, together with studies concerned with the mechanism of the effect of surfactants on the rheological characteristics of rubber stocks, vulcanization rate, and physicomechanical parameters of the vulcanizates. Published data on the effect of unsaturated fatty acids on the density of the structural network and vulcanization characteristics show that surfactants exert a polyfunctional effect and can affect selectively and directionally the properties of elastomers [3, 4].

It is known that combinations of different surfactants can exhibit enhanced performance in complex multicomponent systems [4, 5]. For example, the synergistic effect has been revealed in studies of crystallization of isoprene rubber in the presence of a mixture of saturated and unsaturated fatty acids [6]. This opens up wide opportunities for formulating rubber stocks. In this context, the use of surfactant mixtures as process additives with a wide spectrum of activity is of scientific and applied interest.

In this study, we analyzed how mixtures of saturated and unsaturated fatty acids affect the interphase properties, vulcanization parameters, and physicomechanical parameters of vulcanized rubbers. We chose saturated stearic (St) and unsaturated oleic (Ol) acids, which are widely used in rubber and tire industry as activators of vulcanization of rubber stocks.

EXPERIMENTAL

Experiments were performed with isoprene (SKI-3) and butadiene–styrene (SKMS-30, ARKM-15) rubbers. The rubber stocks contained the following additives (wt parts per 100 wt parts rubber): vulcanizing system, technical-grade sulfur 2.1 and sulfenamide Ts 1.5; vulcanization activators, zinc oxide 3.0 and fatty acid 2.0. Samples with surfaces to be studied were obtained by compacting rubbers and rubber stocks were pressed at 100°C for 10 min. Rubber stocks with laboratory rollers and vulcanized in an electric press at 143°C for 50 min. The vulcanization kinetics was studied with a Monsanto vibrorheometer at 143°C. The vulcanometric curves were processed according to GOST (State Standard) 12535–84, and the physicomechanical properties of rubber stocks and their vulcanizates were evaluated according to GOST 270–75.

The surface tension γ of higher fatty acids and their mixtures was determined by the Wilhelmi plate method in a temperature-controlled cell. The temperature was varied from 25 to 80°C; the accuracy of the method was 0.3%. The contact angles θ were determined by the sedentary drop method with a KM-8 cathetometer modified with an ocular micrometer. The surface

1070-4272/03/7604-0656 $25.00 © 2003 MAIK "Nauka/Interperiodica"

free energy (SFE) γ_s of rubber and vulcanizate samples and its polar, γ_s^p, and dispersion, γ_s^d, constituents were determined using the Fowkes plots [7], from the contact angles with the surface wetted with test liquids at $25 \pm 1°C$. As test liquids we used water, dimethylformamide, dimethyl sulfoxide, glycerol, and α-bromonaphthalene, which were freshly distilled and purified by appropriate procedures.

The ability of surfactants to be involved in interphase interaction can be quantitatively characterized by the surface free energy; for equilibrium liquids, it is equal to the surface tension. We measured the surface tension of Ol, St, and their mixtures of definite compositions at 60, 70, and 80°C.

At any of the examined temperatures, the composition dependences of the surface tension pass through a minimum at 40 wt % St and 60 wt % Ol (Fig. 1). As the temperature is raised, the minimum shifts toward lower surface tensions, with the deepest minimum being observed at 80°C. These data reveal a synergistic effect: At definite acid ratios, the surface tension of a mixture of acids is appreciably lower than that of the acids taken separately. The temperature dependence of γ is linear for both individual acids and their mixtures, which is, on the whole, consistent with published data [8].

According to Fainerman *et al.* [9], there is a correlation between γ of a substance and its surface activity at interfaces. Therefore, it can be expected that a mixture of Ol and St in a weight ratio of 60 : 40 will affect the interfacial characteristics of rubber stocks more efficiently. The fact that the minimum of γ becomes deeper with increasing temperature suggests the hydrophobic nature of intermolecular interactions in the system Ol–St, since it is well known that hydrophobic interactions become stronger with increasing temperature [10]. Apparently, at certain ratio of the acids, St molecules form surface-active associates in the medium of Ol. We examined the effect of St additions (up to 1 wt %) on γ of Ol. Experimental data (Fig. 2) show that γ of Ol decreases in the presence of St, suggesting participation of St molecules in formation of boundary layers.

Wetting, as the most important surface phenomenon occurring at the boundary of three phases, plays an important role in preparation of polymeric composites. In this study, we examined the wetting power of Ol relative to various surfaces and the effect of St additions on the contact angle. As models we chose glass for hydrophilic surface and Teflon for hydrophobic surface. Addition of St to Ol (up to 1 wt %) results in virtually complete spill on the polar surface

crease $\cos\theta$ to a greater extent; the wetting power of the liquid grows owing to adsorption of St on the Ol–solid interface. Thus, studies of wetting give an estimate of the intensity of adhesion interaction of fatty acids with surfaces of various polarities.

One of our goals was to study the specific features of interaction of Ol, St, and their mixtures with rubbers and ingredients of rubber stocks. We studied wetting of the surface of the rubbers tested with Ol containing additions of St.

Figure 3b shows that isoprene rubber is wetted with Ol better than does butadiene–styrene rubber. Addition of 0.125 to 0.5 wt % St sharply decreases the wetting. Probably, the effect of St adsorption at the rubber–Ol interface prevails in this concentration range; intense interactions of the molecules with the surface make the surface oleophilic. Further increase in the concentration of stearic acid results in stronger spill owing to prevailing adsorption of St at the Ol–air interface. Furthermore, chemisorption of St on the rubber surface cannot be ruled out.

With rubber containing vulcanizing agents, the results were, on the whole, similar to those obtained with pure rubber. The minimum in the curve of γ vs. c_{St} shifted somewhat (Fig. 3b). In the presence of vulcanizing agents, the amount of active centers on the surface increases, which results in the growth of the polar constituent of SFE. This, apparently, complicates adsorption of St at the interface, and $\cos\theta$ decreases to a lesser extent.

The surface and interfacial phenomena in polymeric composites largely determine their performance. The structural features of polymer macromolecules affect the formation of boundary layers and the intermolecular interactions leading to conformational transformations at phase boundaries [11]. One of the main parameters of polymer surfaces, attracting researchers' attention, is the surface free energy, often considered a response function of interactions in the system.

We determined SFE and its constituents for isoprene and butadiene–styrene rubbers and various vulcanizates based on them (Table 1).

Experiments showed that, as expected, the surface of rubbers is characterized by low energy with small polar constituent, which is somewhat higher for butadiene–styrene rubber. This is associated with the structural features of its macromolecule, apparently exhibiting an appreciable dipole moment and asymmetry. The susceptibility of the rubbers to surface oxidation may also vary. Addition of vulcanizing agents increases the polar constituent owing to the appearance of surface polar groups. These may be sulfur-containing groups or fragments of sulfur particles insufficiently well dispersed in the rubber. On the whole, however, SFE somewhat decreases, which may be due to disordering of the boundary layer.

Addition of vulcanization activators considerably increases SFE. Comparative analysis shows that, in the presence of stearic acid, the major contribution to the growth of SFE is made by the dispersion constituent, and in the presence of Ol, by the polar constituent. This fact points to specific participation of surfactants in the formation of the boundary layer. On the whole, the increase in SFE indicates that the arrangement of macromolecules in the boundary layers becomes more ordered, which may be due to significant role of surfactants in homogenization of the system and more uniform distribution of the ingredients. The highest values of SFE were obtained for the rubber stock containing a synergistic mixture of surfactants; in this case, the contribution of the polar constituent of SFE is high, suggesting increased role of polar interactions in the surface layer of the elastomers. The mechanism responsible for the increase in SFE and its polar constituent requires further study; apparently, energy barriers at boundaries of phases with different polarities become lower, strong adhesion couples are formed, and formation of a three-dimensional structure is facilitated. Vulcanization of rubbers increases SFE owing to restriction of the macromolecule mobility upon formation of a cross-linked structure and to partial oxidation of the surface. In vulcanized rubbers, the trends in the dependence of SFE on the kind of surfactant are preserved. The highest SFE is observed in the sample containing a mixture of Ol and St; in this sample, γ_s^p is also high. Our results show that the synergistic mixture of surfactants exhibiting the minimal surface tension shows the highest activity at phase boundaries.

The interfacial surface energy affects the deformation and failure of solids. The correlation between the mechanical strength of polymeric materials and SFE was repeatedly noted by Lipatov [11].

In this study, we also revealed a correlation between SFE and strength characteristics of crude unfilled rubber stocks. The nominal tensile strength of butadiene–styrene rubber decreases somewhat upon introduction of sulfur and sulfenamide Ts, which correlates with SFE of the same systems (Table 1). When vulcanization activators are added along with the vulcanizing system, the strength of crude rubber stocks grows; this trend is the most pronounced when Ol and St are taken simultaneously in the optimal ratio. The strength characteristics of vulcanized rubbers are independent of a fatty acid used; their parameters are virtually similar. However, the mixture of surfactants appreciably affects the relative elongation of both crude stocks and vulcanized rubbers.

Table 2. Vulcanization characteristics of unfilled vulcanized rubbers based on butadiene–styrene rubber*

Acid	M_L	M_{max}	t_s	$t_{s(90)}$	R_v, min^{-1}
	N m		min		
St	5.8	31.6	20.0	36.5	6.1
Ol	4.6	33.4	17.5	37.8	4.9
Ol + St	4.6	33.9	13.5	30.1	6.0

* (M_L, M_{max}) Minimal and maximal torque, respectively; (t_s, $t_{s(90)}$) time of vulcanization onset and optimal vulcanization time; (R_v) vulcanization rate.

For unfilled stocks based on butadiene–styrene rubber, the time of vulcanization onset and the optimal vulcanization time are shorter with a synergistic mixture of Ol and St than with each of these acids taken separately (Table 2), i.e., this mixture of surfactants accelerates vulcanization. This allows the power consumption for preparation of rubber stocks to be reduced. Similar results have been obtained previously for filled rubbers [12].

It has also been found previously that a mixture of Ol and St exerts a synergistic effect on the rheological and dynamic properties of filled rubbers based on SKMS-30 ARKM-15 rubber. It was found that the viscosity of the rubbers and endurance of the vulcanizates as functions of the composition of the fatty acid mixture pass through a minimum and a maximum, respectively [12]; their position corresponds to the composition at which the surface tension of the acid mixture passes through a minimum: 60 wt % Ol and 40 wt % St.

Our studies confirm that the synergistic effect of mixtures of saturated and unsaturated fatty acids, mainfested in vulcanization and physicomechanical properties of rubbers, is due to interfacial properties of these acids and specific features of intermolecular interaction.

CONCLUSIONS

(1) Measurements of the surface tension of mixtures of oleic and stearic acids as a function of their ratio revealed a minimum at a weight ratio of 60 : 40, which becomes deeper with increasing temperature.

(2) Experiments on wetting of the surfaces of glass, Teflon, isoprene rubber, and butadiene–styrene rubber with oleic acid containing additions of stearic acid showed that stearic acid is involved in formation of the boundary layer at the rubber–oleic acid interface.

(3) The surface free energy and its constituents were calculated for rubbers, unfilled rubber stocks, and vulcanizates prepared using oleic acid, stearic acid, or their synergistic mixture. An increase in the surface free energy is due to the predominant contribution of the polar constituent, which is the most pronounced for rubbers prepared with the synergistic acid mixture.

(4) The correlation revealed between the vulcanization and physicomechanical properties of unfilled rubber stocks and vulcanized rubbers, on the one hand, and the interfacial properties, on the other, opens up prospects for improving the efficiency of various processes in production and use of rubber items.

BRIEF COMMUNICATIONS

Synthesis of NaA Zeolite by Mechanochemical Methods

N. E. Gordina, V. Yu. Prokof'ev, and A. P. Il'in

Ivanovo State University of Chemical Technology, Ivanovo, Russia

Received September 13, 2002

Abstract—A method for obtaining NaA zeolite by mechanochemical activation of a raw material is proposed. The method produces no wastewater in the course of zeolite synthesis.

It is known that synthesis of zeolites by their precipitation from solutions leads to formation of a considerable amount of wastewater [1]. Therefore, development of new methods for production of zeolites is a promising direction of research in the field of synthesis of these compounds.

In the present study, it is proposed to synthesize a NaA zeolite by mechanochemical treatment of raw materials, which yields the product without any liquid-phase products.

EXPERIMENTAL

To carry out mechanochemical synthesis under "mild" conditions [2, 3], it is preferable to use compounds containing constitution water. This is the reason why aluminum hydroxide $Al(OH)_3$ (hydrargillite), sodium silicate $Na_2SiO_3 \cdot 6H_2O$ and silica gel $SiO_2 \cdot nH_2O$ with $n = 0.875$ were chosen as raw material. The component ratio corresponds to the stoichiometry of the reaction producing NaA zeolite:

$$6(Na_2SiO_3 \cdot 6H_2O) + 12Al(OH)_3 + 6(SiO_2 \cdot 0.875H_2O) = 6Na_2O \cdot 6Al_2O_3 \cdot 12SiO_2 \cdot 59.25H_2O.$$

The synthesis was performed in a VM-4 roller vibrating mill with impact-shear loading, vibration frequency of 930 min^{-1}, and energy load of 5.4 kW kg^{-1}, in the course of 30 min. Then a sample obtained was calcined at 450°C for 4 h. The resulting zeolite was identified by comparing its characteristics with published data [1] and parameters of a commercial NaA zeolite [TU (Technical Specifications) 38-83-047–88]. An X-ray phase analysis was made on a DRON-3M diffractometer with Cu_{K_α} radiation, and a differential-thermal analysis, on a Q-1500D derivatograph (Hungary) in air at sample heating rate of 5 deg min^{-1}. IR spectra of samples compacted with KBr in 5% dilution were measured on a Nicolet AVATAR 360 FT-IR IR spectrometer in the 400–1250 cm^{-1} spectral range.

As shown by the experimental data obtained (Fig. 1), the X-ray diffraction pattern of the starting mixture used to synthesize the A zeolite contains diffraction peaks of hydrargillite and sodium silicate. After dispergation of the mixture for 30 min the reflections associated with sodium silicate disappear, and the intensity of reflections corresponding to hydrargillite decreases substantially (by approximately a factor of 3). New peaks appear at diffraction angles 2θ 14.0°, 24.3°, 34.4°, 42.7°, and 52.0°. Comparison of the X-ray diffraction pattern with published data suggests

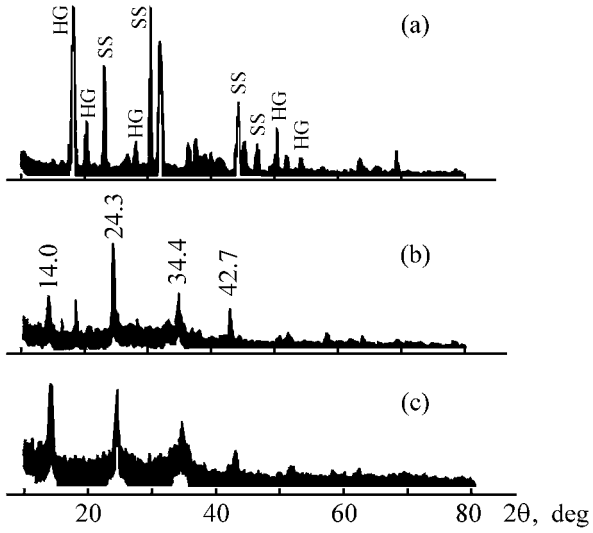

Fig. 1. X-ray diffraction patterns (Cu_{K_α} radiation) of mixtures used to synthesize NaA zeolite. (2θ) Bragg angle. HG stands for hydrargillite, and SS, for sodium silicate. Time of dispergation (min): (a) 0 and (b) 30; (c) calcined sample.

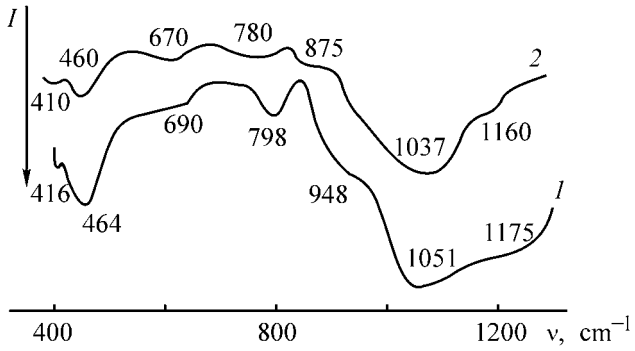

Fig. 2. IR absorption spectra of (*1*) NaA zeolite produced by mechanochemical synthesis and (*2*) commercial NaA sample. (*I*) Absorption intensity and (ν) frequency.

that the NaA zeolite is formed already in the course of mechanochemical synthesis, and calcination completes the formation of its crystal lattice.

X-ray diffraction data are confirmed by the results obtained from IR spectra. The spectrum of a sample synthesized in this study is similar to that of the commercial zeolite (Fig. 2), with only minor differences observed. For example, the bands in the spectrum of the synthesized zeolite are shifted to lower frequency, with their intensity decreasing, relative to the bands in the spectrum of the commercial sample. These differences are accounted for by the fact that the sample synthesized in this study contains a greater number of crystal structure defects. This is also confirmed by X-ray diffraction data, the diffraction peaks of the synthesized sample have relatively low intensity and large width (Fig. 1c), which is characteristic of poorly crystallized samples [4, 5].

The use of mechanochemical synthesis makes it possible to eliminate the stage of activation of zeolites to improve their reactivity [5], since their crystal structure changes already in the course of synthesis.

The presence of structural defects in the NaA zeolite synthesized in this study is also indicated by the fact that this sample is less thermally stable than commercial zeolite. The first exothermic peak (590°C) corresponds to disintegration of crystalline zeolite to the amorphous state, and the second peak at around 700°C indicates recrystallization to yield a new phase, which is of the β-crystobalite type in the given case [1]. For commercial zeolite, these temperatures are higher: 700 and 800°C, respectively.

CONCLUSION

The possibility of mechanochemical synthesis of NaA zeolite from hydrated aluminum and silicon oxides and sodium silicate is established. The sample synthesized by this method has defective crystal structure. Use of this synthesis technique eliminates formation of a liquid phase.

Determination of the Surface Area of Minerals by Sorption of Methylene Blue and Thermal Desorption of Argon

D. E. Chirkst, I. S. Krasotkin, O. V. Cheremisina, M. I. Streletskaya, and M. V. Ivanov

St. Petersburg State Mining Institute (Technical University), St. Petersburg, Russia

Received May 30, 2002

Abstract—The specific surface area of a number of natural aluminosilicates was determined by the methods of thermal desorption of argon and limiting sorption of Methylene Blue. The correlation between the results obtained using these two techniques was discussed.

In view of the undertaken studies of the sorption properties of mineral components of soils, the specific surface area and exchange capacity of a number of minerals were analyzed. It was necessary to consider the correlation between the results obtained in determining the specific surface area by the commonly accepted methods of thermal desorption of argon [1–3] and limiting sorption of Methylene Blue (MB) [4]. Natural aluminosilicates commonly occurring in northwestern Russia: kaolinite $Al_4(OH)_8[Si_4O_{10}]$, Cambrian blue clay $K_2Al_4[Al_2Si_6O_{20}](OH,F)_4$, albite $Na[AlSi_3O_8]$, oligoclase $(Na_{0.9}Ca_{0.1})[Al_{1.1}Si_{2.9}O_8]$, and microcline $K[AlSi_3O_8]$, were chosen for the study.

Mineral samples were ground and sieved into fractions with different particle sizes. The specific surface area of the minerals was determined by gas chromatography by the method of thermal desorption of argon [1–3] and from MB sorption from solution [4]. According to the latter technique, a 0.5–2-g portion of air-dried mineral powder passed through a sieve with 0.1–0.4-mm mesh was placed in a 100-cm^3 conical vessel. A 20–50-ml portion of a 10^{-2}–10^{-3} N solution of MB was introduced with a pipette. Then the contents of the vessel were shaken and the resulting suspension was allowed to stay for 12–14 h.

The dyed suspension was twice filtered through "blue ribbon" filter. First portions of the filtrate (~10 ml) were discarded because of the sorption of MB on the filter. Pipette was used to take 1-ml samples of the filtrate and the initial MB solution. The aliquots were diluted with water to 100 ml. An SF-46 spectrophotometer was used to measure the optical density of an MB solution under study and of the initial MB solution at a wavelength of 665 nm. The MB concentration in the filtrate was calculated using the formula

$$c_f = c_{in}(D_f/D_{in}).$$

The exchange capacity E was calculated (with accuracy of 0.1 mg-equiv kg^{-1}) by the formula

$$E = \frac{\Delta cV \times 10^3}{m}, \quad (1)$$

where Δc is the difference of the concentrations of the initial MB solution and that under study (equiv l^{-1}), V is the amount of the initial solution (cm^3), and m is the mass of a mineral sample (g).

The exchange capacity of the minerals studied was used to calculate the specific surface area. The landing area of a single MB cation is 95.6 $Å^2$ according to X-ray diffraction analysis [4]. If it is assumed that the limiting sorbed amount of MB corresponds to a monomolecular layer of the dye on faces of layered minerals, then the specific surface of these minerals, S_{sp} ($m^2 g^{-1}$) can be calculated using the formula

$$S_{sp} = 10^{-6} E N_A W_0, \quad (2)$$

where E is the exchange capacity of a mineral for MB (mg-equiv kg^{-1}), N_A is the Avogadro number, and W_0 is the area occupied by an MB cation.

The results of determinations are listed in the table. As determination error is given the reproducibility of the values obtained.

The measurement results suggest the following. With the average particle diameter decreasing by

	0.4 ± 0.16	0.36 ± 0.02	0.21 ± 0.01	0.21 ± 0.01

an order of magnitude (from –0.4-mm to –0.04-mm fraction), the specific surface area increases by a factor of 2–4. In this case, the least pronounced rise in the surface area (by approximately a factor of 2) is observed for kaolinite containing no cations of alkali and alkaline-earth metals. In feldspars (oligoclase, albite, and microcline), the rise in the surface area is by a factor of 3–4, being the most pronounced for oligoclase containing calcium cations in the outer sphere. The varying rise in the surface area of the minerals upon grinding can be understood in terms of the hydration energies of the outer-sphere cations. The enthalpies of hydration were calculated from the data of [5] to be (kJ mol^{-1}) –767 for K^+, –851 for Na^+, and –2455 for Ca^{2+}. The stronger the exothermic effect of hydration of cations, the more pronounced their leaching from the surface layer of the crystals into solution, which favors the development of porosity. It should be noted that kaolinite and feldspars also have different surface microprofiles. The surface microprofile is determined by cleavage microcracks in kaolinite and by step-like cleavages in spars [6].

In spars, the S_{sp} values obtained by thermal desorption of argon, as a rule, exceed those found from MB sorption (except in the case of microcline), with this difference correlated with the magnitude of the exothermic effect of hydration of outer-sphere cations in the order microcline < albite < oligoclase. Correspondingly, in albite and, especially, oligoclase, separate fragments of the surface microprofile become inaccessible to large MB molecules. The landing areas for argon and MB are, respectively, 15.7 [7] and 95.6 $Å^2$ [4]. This can account for the difference between two S_{sp} values obtained by two independent techniques.

However, the S_{sp} value obtained for kaolinite with MB exceeds by nearly a factor of 3 that determined from thermal adsorption of argon. The reason is that the adsorption of the dye from an aqueous solution was studied after agitation of phases for many hours. As a result, kaolinite particles and clays were additionally dispersed to form a fine difficultly filterable suspension. In the given case, the S_{sp} values found from MB adsorption correspond to a finely dispersed aqueous suspension of the mineral, rather than to its sieve fraction taken for the experiment.

It may be concluded that, to evaluate the sorption capacity of minerals for metal cations, it is advisable to use the method of thermal desorption of argon, since the landing areas for argon and metal cations are close. Previously, the results obtained in studying the isotherms of sorption of Sr(II) cations on clay have been reported [8]. The limiting sorption of Sr(II) from an aqueous solution, i.e., the sorption capacity of the clay for Sr(II) cations, was found to be 68 mg-equiv kg^{-1}. The sorption of Sr(II) was studied under the conditions identical to those for MB sorption on the same clay sample. Consequently, the S_{sp} of the clay can be taken to be 5.86 $m^2\ g^{-1}$ (see table). Hence the landing area for Sr(II) cations, calculated by the formula

$$S_m = \frac{S_{sp}}{\Gamma_\infty N_A},$$

where Γ_∞ is the limiting sorption (mol kg^{-1}), equal to 28.6×10^{-20} m^2. This value corresponds to a cross-section of a hydrated cation, $Sr_{aq}^{2+} = 30.0 \times 10^{-20}$ m^2, calculated from the Stokes radius of 309 pm. Thus, in studying the sorption from aqueous solutions, it is better to characterize minerals dispersed in the course of phase convection by the sorption of MB.

The capacity of the clay for strontium cations is 6.6 times that for MB. The presumable reason is that not all exchange groups are involved in sorption of large molecules of the dye. The landing area for Sr(II) cations is smaller by a factor of 3.2, with the capacity being correspondingly higher. However, to account for the observed capacity of the clay for Sr(II),

an assumption should also be made that the capacity is proportional to the cation charge, which leads, in the case in question, to an additional increase in capacity by a factor of 2. Thus, the exchange capacity of the minerals is proportional to the ratio of the charge of a cation being sorbed to its landing area, which can be calculated from the Stokes radius. In accordance with the aforesaid, the capacity of the clay for Sr(II) cations must higher by a factor of $3.2 \times 2 = 6.4$ than that for MB, with the corresponding experimental value equal to 6.6.

CONCLUSIONS

(1) It is advisable to use for determining the specific surface area of minerals the method of thermal desorption of argon. However, in studying sorption of cations from solution on minerals dispersed in convection, the surface areas obtained from the limiting sorption of Methylene Blue under the identical conditions should be used.

(2) The exchange capacity of the minerals is proportional to the ratio between the charge of a cation being sorbed and its landing area corresponding to the Stokes radius.

BRIEF COMMUNICATIONS

Use of Mother Liquor from Fluorplastic Production for Preparing Composite Coatings

S. V. Devyaterikova, S. V. Khitrin, and S. L. Fuks

Vyatka State University, Kirov, Russia

Received November 27, 2002

Abstract—The composition and properties of mother liquor from production of F4D fluoroplastic were studied. Nickel–fluoroplastic cathodic and aluminum oxide-fluoroplastic anodic composite coatings were prepared. Aluminum oxide–fluoroplastic composite coatings were obtained by thermal treatment of aluminum oxide coatings impregnated with the mother liquor.

The mother liquor (ML) from production of emulsion fluoroplastic is presently discharged into industrial wastewater. In order to improve the environmental situation, decrease the load on sewage plants, and reduce the price of the target product, we studied the possibility of utilizing mother liquors in production of composite coatings.

EXPERIMENTAL

In our experiments, we used mother liquors from production of F4D fluoroplastic. These mother liquors containing valuable components are discharged in large amounts into industrial wastewater.

The mother liquor is a suspension of polytetrafluoroethylene (PTFE) particles with density of 1.21 g cm^{-3}, viscosity of 1.034–1.069 cSt and pH 0.45–3.9. The nephelometrically determined size of polytetrafluoroethylene particles [1] is 116–124 nm. Upon neutralization of this suspension with alkali to pH 8, the fraction of the coarsest particles decreases by more than 30% and their anionic electrophoretic activity decreases. This fact shows that neutralized ML suspensions can be used for preparation of cathodic composite coatings (CCPs).

The curve of potentiometric titration of the mother liquor with aqueous alkali has four inflection points presumably corresponding to successive neutralization of perfluoropelargonic, perfluoroenanthic, and dibasic succinic acids [2].

A chromatographic-mass spectrometric analysis showed [3] that the mother liquor contains paraffins, used as a latex stabilizer in production of PTFE, and amino and fluoro derivatives, used as PTFE emulsifiers.

The surface-active properties of PTFE particles suspended in the ML were characterized by electrocapillary curves obtained with a mercury dropping electrode. Plots of the surface tension on the mercury dropping electrode in the Na_2SO_4 + ML (F4D) mixture against the polarization voltage are given in Fig. 1 [4]. These curves show that nonionic fluoroplastic particles contained in the mother liquor are specifically sorbed on mercury at both the anodic and cathodic polarization. With increasing ML content in the Na_2SO_4 (0.1 M) + ML (F4D) mixture, the electrocapillary maximum is not shifted. These results show

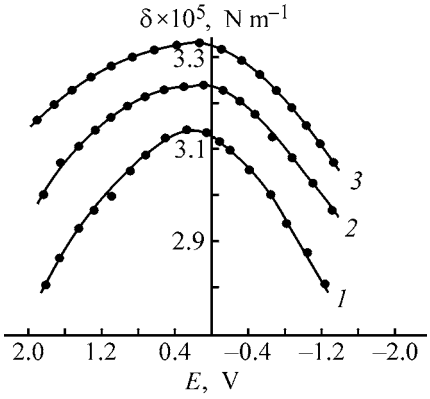

Fig. 1. Electrocapillary curves for PTFE particles in a 0.1 M Na_2SO_4 + ML (F4D) suspension. (δ) Surface tension and (*E*) voltage. ML (F4D), ml^{-1}: (*1*) 4.04, (*2*) 8.72, and (*3*) 18.52.

that PTFE particles can be sorbed on both positively and negatively charged surfaces.

To elucidate whether the PTFE particles can be sorbed on both anodically and cathodically polarized electrodes, we determined their electrophoretic mobility and the electrokinetic potential ξ. Figure 2 shows that PTFE particles have positive ξ potential and its value is somewhat larger at anodic polarization than at cathodic polarization. This means that the anionic contribution to the electrophoretic activity of the PTFE particles predominates. This may be due to the fact that PTFE macromolecules, owing to their helical conformation, form a cylindrical structure with an external shell containing electronegative fluorine atoms. Owing to high electrophoretic mobility of the PTFE particles, their electrodeposition must be rather fast. Thus, the mother liquors can be used for preparation of anodic composite coatings.

In order to obtain cathodic composite coatings, the negatively charged PTFE particles should be recharged to impart to them a fractional positive charge. Such recharging was performed by introducing a surfactant (SURF) [ammonium perfluoroenanthate (4 g l^{-1})] into the MLF4D) suspension [5].

Figure 2 shows that the negative ξ-potential and the corresponding electrophoretic mobility are at a maximum within the first 10 min of electromigration. In further electromigration, these parameters gradually decrease, and, after 1 h, the electrophoretic mobility decreases by a factor of 4 as compared with its maximal value. Therefore, the optimal time for preparation of the cathodic composite coatings is 15–20 min. Upon longer exposure, the initially formed composite coating is covered with a metallic film.

In the first experiments, composite cathodic coatings were obtained on a 08 kp nickel-plated steel electrode with surface area of 1 dm^2. The nickel-plating was carried out from a standard nickel-plating electrolyte-PTFE suspension. In these experiments, semilustrous and dull light gray coatings uniformly incrusted with fluoroplastic particles were obtained. We found that, irrespective of the nature and concentration of surfactant and the PTFE content, the current efficiency by nickel, evaluated by the method reported in [6], first reaches a maximum (70–99%) within the current density range 2–3 A dm^{-2} and then decreases.

The amount of PTFE incorporated into a composite coating grows with increasing PTFE content in the suspension and exhibits a complicated dependence on the surfactant concentration [5].

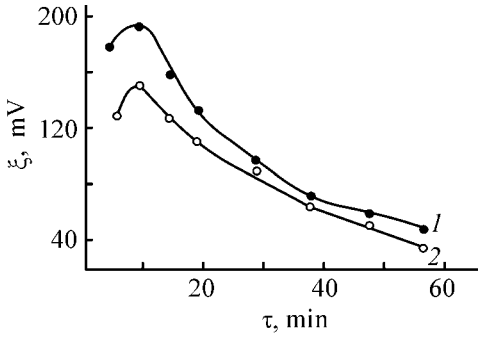

Fig. 2. ξ-potential of ML (F4D) suspension (1 : 300) vs. the electrophoresis time τ at E = 95 V.

In further experiments, the cathodic nickel-plating was performed from a standard nickel-plating electrolyte modified by adding a mother liquor containing PTFE particles with sorbed surfactant molecules. The optimal current densities were determined in a Hull cell on the basis of such coating characteristics as luster, peeling, and presence of uncoated areas.

Composite nickel–PTFE coatings were prepared in a Moler cell at current density of 0.5–7.7 A dm^{-2} and plating time of 20 min from various nickel-plating solutions whose compositions are listed in the table.

With electrolyte no.1, the current efficiency increases from 55.8 to 97.8% within the current density range 0.5–2 A dm^{-2} and gradually decreases to 90.5% at higher current densities. With nickel electrolyte no. 2 and no. 1 + ML (10 vol %) and no. 2 + ML (10 vol %), the current efficiency is lower than that with electrolyte no. 1 by 14.6–36.4%, and a sharp decrease in the current efficiency occurs already at a current density of 4 A dm^{-2}.

With electrolyte no. 3, the current efficiency is 98.5–99.0 within the current density range 1–6 A dm^{-2}. Introduction of ML (100 ml l^{-1}) into this electrolyte expands the current density range in which the highest current efficiency (79.4%) is observed to higher cur-

Compositions of nickel-plating electrolytes

Electrolyte component	Component concentration, g l^{-1}		
	no. 1	no. 2	no. 3
$NiCl_2 \cdot 6H_2O$	–	50	250
$NiSO_4 \cdot 7H_2O$	200	300	–
H_3BO_3	30	30	30
NH_4Cl	–	–	50
$C_6H_4–SO_2–CO–NH$	1	1	1

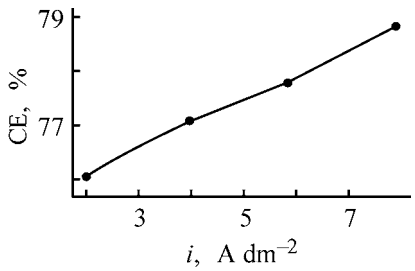

Fig. 3. Nickel + PTFE current efficiency CE vs. current density *i* in plating composite Ni–PTFE coatings from electrolyte no. 5 + 100 ml l^{-1} ML (F4D) at pH 2.8.

rent densities. As in the above experiments, the coatings formed under these conditions have uniform light gray semilustrous surface.

Figure 3 shows that, on addition of ML to nickel electrolyte no. 3 in amount of 100 ml l^{-1}, the current efficiency grows from 76.1 to 78.9% with the current density increasing from 2 to 7.7 A dm^{-2}.

The sign and value of the stretching stress in the composite coatings were determined [7]. We found that the internal stress in the coatings obtained from the nickel electrolyte is compressive and grows on adding ML. Therefore, crack formation in these coatings is unlikely.

The mother liquor was also added to electrolyte in aluminum anodic oxidation to obtain an aluminum oxide film on the surface of metallic aluminum. Anodic oxidation was performed in concentrated ML containing citric and oxalic acids. Within the current density range 10–50 A dm^{-2}, uniform gray coatings including visible incorporated PTFE particles were obtained on the surface of AD 32 aluminum.

Composite coatings with similar characteristics were obtained by thermal treatment of an aluminum oxide coating preliminarily impregnated with the mother liquor. In these experiments, uniform gray coatings with PTFE particles incorporated into aluminum oxide pores were obtained.

CONCLUSIONS

(1) The composition and properties of the mother liquor from F4D fluoroplastic production were studied; it was found that polytetrafluoroethylene particles contained in the mother liquor are adsorbed under both anodic and cathodic polarization.

(2) Polytetrafluoroethylene particles exhibit high electrophoretic mobility.

(3) Cathodic nickel–polytetrafluoroethylene coatings were obtained after recharging the surface of initial polytetrafluoroethylene particles with a surfactant. Aluminum oxide–polytetrafluoroethylene coatings were obtained on the surface of metallic aluminum both by anodic oxidation of aluminum in the mother liquor without recharging of polytetrafluoroethylene particles and by thermal treatment of the aluminum oxide coatings preliminarily impregnated with the mother liquor.

ANNIVERSARIES

Boris Veniaminovich Gidaspov (To 70th Anniversary of His Birthday)

On April 16, 2003, Boris Veniaminovich Gidaspov, a corresponding member of the Russian Academy of Sciences and an outstanding scientist in the field of chemistry and technology of nitrogen-containing organic compounds, will be 70.

In 1955, B.V. Gidaspov graduated from Kuibyshev Industrial Institute and was left there as an assistant at the chair of explosives.

In 1954, he developed, when being a 5th-year student, an original technology for obtaining trinitrobenzene (industrial manufacture started in 1970), and later, in 1956, a technology for production of sodium azide from hydrazine.

In 1959, Gidaspov became a postgraduate student at Lensovet Technological Institute in Leningrad and, having successfully backed hid dissertation, worked at this institute from 1961 till 1977 to make a career from junior research worker to head of chair, dean of the special department of chemical engineering, and chief designer of Tekhnolog Special Designing Office. Gidaspov's outstanding organizational talent, initiative, and persistence favored the intensive development of research carried out by the Special Designing Office in the field of new technology.

The basic principle constituting the foundation of Tekhnolog Special Designing Office is the opportunity, for creative groups, to work freely beyond the limits of the administrative-command system, and, therefore, the Designing Office conforms to all requirements of the market economy and successfully operates at the present time.

Gidaspov is a leading scientist in the field of energy-intensive compounds.

He has carried out extensive studies aimed at developing new methods for synthesis of nitro- and polynitrocompounds of the aliphatic, aromatic, and heterocyclic series and polynitrous compounds of the aliphatic and heterocyclic series, and analyzed their structure, physicochemical properties, and reactivity.

He has established the mechanism of highly important chemical reactions of nitroaminoalkylation, transaminomethylation, N-nitration, and alkylation of triazoles and tetrazoles.

Foundations of a quantitative theory have been developed for these and some other reactions, and a general approach allowing prognostication of the chemical structure of reaction products and also rates and constants of equilibrium of reversible processes in relation to the properties of the starting reagents and characteristics of the reaction medium.

Based on the results of these studies, groups of researchers, headed by Gidaspov, developed technologies and created several large-tonnage continuous highly automated plants satisfying the needs of the country for special-purpose chemical materials.

For his participation in the development of a new class of organic compounds and an industrial technology for their manufacture, Gidaspov was awarded the 1976 Lenin Prize in science and technology.

From March 1977 till August 1989, Gidaspov was general director of the Gosudarstvennyi institut prikladnoi khimii (State Institute of Applied Chemistry) research-and-production association (NPO GIPKh).

1070-4272/03/7604-0669 $25.00 © 2003 MAIK "Nauka/Interperiodica"

NPO GIPKh has developed under Gidaspov's supervision new homogeneous fuels for promising power stations, energy-intensive hydrocarbon fuels, and oxidizing agents ensuring the development of new technology exceeding in basic parameters the world's best level. High-output-capacity processes for their manufacture and exploitation have been developed and put into industrial practice. For these works, Gidaspov was awarded a 1981 State Prize of the USSR in science and technology.

From 1977 till 1989, Gidaspov was the scientific supervisor of most important fields of technical chemistry in the national economy and special-purpose technology.

In 1988–1989, Gidaspov was the chairman of the board of directors of the Tekhnokhim Interbranch association, a versatile research-and-production organization comprising plants and research institutes of Leningrad and other cities of northwestern Russia, which was the first country's organizational structure that existed beyond the limits of industrial ministries and integrated plants from various industries (machinebuilding, instrument-building, petrochemical, fertilizer-producing, etc.) to solve the problem of chemicalization of the region.

From 1989 till 1991, Gidaspov was the first secretary of the Leningrad committee of the communist party of the USSR, secretary of the Central committee of this party, chairman of the Council for economical cooperation of provinces belonging to the Northwestern Region; he became the chairman of the board of directors of Aviatsionnoe vooruzhenie (Airforce Armaments) corporation in 1996, president of Interkhimprom financial-and-industrial group in 1998, and chairman of the Coordination council of Azot AKhK (Nitrogen-Chemical Combine) in 2001.

Gidaspov, a corresponding member of the Russian Academy of Sciences, developed new forms and methods for supervision and control of leading research institutes and plants of chemical industry. In the fundamentally changed conditions of management, he organized the reforming of the scientific and technological institutions of the country in order to preserve the scientific potential for development of chemical industry.

As the chairman of the board of directors of Aviatsionnoe vooruzhenie corporation he implements innovative technologies of new materials and components to develop new types of warfare.

Gidaspov made a major contribution to the coordination of the work of plants in territorially remote regions and to the development of scientifically substantiated, efficient programs for modernization and renewal of facilities for manufacture of mineral fertilizers to satisfy the needs of Russia's agriculture and to export part of the fertilizers produced.

Gidaspov's activities in the Interkhimprom Joint-Stock Company, which are concerned with the development of chemical industry and creation of scientific and technological prerequisites for its successful operation, planning and coordination of joint research of scientific institutions, industrial plants, and designing offices, and wide cooperation with foreign companies in manufacture of chemical products, make an important contribution to strengthening of the national economy.

Gidaspov's scientific activities have resulted in more than 200 publications (including two monographs) and 250 inventor's certificates, with many of his inventions implemented in industry and design developments.

At present, Gidaspov is Editor-in-chief of *Khimicheskaya promyshlennost'* (Chemical Industry) journal, deputy Editor-in-chief of *Zhurnal organicheskoi khimii* (Russian Journal of Organic Chemistry), and member of Editorial boards of *Zhurnal obshchei khimii* (Russian Journal of General Chemistry) and *Zhurnal prikladnoi khimii* (Russian Journal of Applied Chemistry).

Gidaspov has founded a highly productive scientific school: 55 candidate and 12 doctoral dissertations have been backed under his supervision, new courses of lectures have been created, and a number of textbooks and manuals have been written.

Gidaspov was awarded Lenin Order (1983) and Order of October Revolution (1969) for successful scientific and technological, organizational, and pedagogical work; Order of Labor Red Banner for his part in eliminating the consequences of the Chernobyl disaster (1987); medals; Honored Tester of Space Technology badge (2003).

Staff members of Prikladnaya Khimiya Russian Scientific Center, St. Petersburg Publishing House Nauka of the Russian Academy of Sciences, and editorial office of Zhurnal prikladnoi khimii heartily congratulate Boris Veniaminovich Gidaspov on the jubilee and wish him sound health and further creative success.

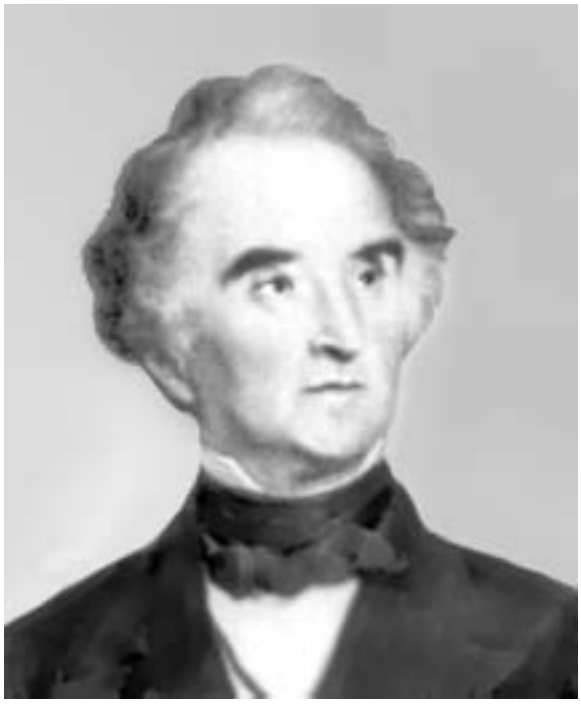
Justus von Liebig (To 200th Anniversary of His Birthday)

German scientist Justus von Liebig is among the most outstanding chemists of the XIX century. He made a major contribution to the development of organic, analytic, agronomic, and physiological chemistry and created an extensive international scientific school. At different times, such known Russian chemists as A.A. Voskresenskii (1809–1880), N.N. Zinin (1812–1880), A.I. Khodnev (1818–1883), P.A. Il'enkov (1821–1877), N.N. Sokolov (1826–1877), and F.F. Bel'shtein (1838–1906) worked at Liebig's laboratory in Gissen. Already in 1830, Liebig was elected a foreign corresponding member of the St. Petersburg Academy of Sciences.

Justus Liebig was born on May 12, 1803, in Darmstadt (Duchy of Gessen). His father manufactured and sold paints and chemical preparations. Already at early age, the youth became interested in chemistry, carried out experiments at home laboratory, gained necessary experimental skills, and read all the available chemical literature. At the age of 15, Liebig left gymnasium and worked as apprentice pharmacist in 1818. In 1819, Liebig entered Bonn University and came there under strong influence of professor of chemistry, Karl Kastner (1783–1857). Following Kastner, Liebig moved to the University of Erlangen in 1821. In 1822, he published his first scientific study concerned with the action of alkalis on fulminating silver. In October 1822, a stipend granted by the government of the Duchy of Gessen enabled Liebig to continue his education in Paris, where, in contrast to Germany, natural sciences flourished at that time. Liebig worked at laboratories and attended lectures delivered by L.J. Thenard (1777–1857) and L.J. Gay-Lussac (1778–1850), prominent French chemists members of the Paris Academy of Sciences, and honorary foreign members of the St. Petersburg Academy of Sciences (since 1826). Liebig made friends with P.L. Dulong (1785–1838), a known French chemist and physicist. Particular mention should be made of the support and help provided to the young scientist by Alexander Humboldt (1769–1858), an outstanding German natural scientist, traveler, and public figure.

In 1823, in Paris, Liebig continued, together with Gay-Lussac, an experimental study of fulminates,



started in Bonn. A comparison of the results of this study with the data obtained by another young German chemist, Friedrich Wöhler (1800–1882), demonstrated that the scientists observed for the first time the phenomenon later named isomerism. The friendship of Liebig and Wöhler, these two prominent German chemists, continued for 45 years, till the end of Liebig's life. In 1823, the University of Erlangen conferred to Liebig, by correspondence, the degree of a doctor of philosophy for his theoretical work "On the Relationship between Mineral Chemistry and Vegetation Chemistry." In May 1824, by Humboldt's recommendation, Liebig was appointed an extraordinary professor of Gissen University. Soon, a vacancy appeared at the university and he became an ordinary professor (1826). In addition to Wöhler, Liebig was on intimate terms with another known German chemist, Karl Mohr (1806–1879).

In a short time, Liebig managed to equip a chemical laboratory at Gissen University and introduced into the curriculum laboratory works by students. The exceptional talent and diligence of the young scientist, and pupils' help allowed Liebig to perform a large

1070-4272/03/7604-0671 $25.00 © 2003 MAIK "Nauka/Interperiodica"

number of various investigations in a short time. Already by the 1830s, the small town of Gissen became one the most prominent international centers of chemical education and research. In contrast to France, where most of scientists were concentrated in Paris at that time, there was no centralization of this kind in Germany.

The main direction of the scientist's research during the first period of his activities concerned the elemental analysis of organic compounds. The methods developed by him allowed whole sets of analyses to be made during a rather short time. These methods were described in a book published by Liebig in 1831 *On a New Apparatus for Analysis of Some Organic Substances*. A Russian translation of the second German edition of this book (1853) was published in Germany under the title *Rukovodstvo k analizu organicheskikh veshchestv* (A Manual of Analysis of Organic Substances) (1858).

Experimental studies led Liebig to develop a theory of complex radicals and that of polybasic acids. When studying the composition of compounds of benzoic acid and chemical reactions involving these compounds, Liebig and Wöhler came to a conclusion (in 1832) that there exists a complex radical, named by them benzoyl. The concept of the radical was accepted by a number of leading chemists; however, there also were those opposing such an approach. In particular, the existence of complex radicals, including oxygen in addition other elements, contradicted the concept of the structure of organic acids, developed by the known Swedish scientist, Jöns Jacob Berzelius (1779–1848). Liebig became acquainted with Berzelius at a congress of natural scientists in Hamburg.

Based on a study of quite a number of organic acids, Liebig was the first to give their clear classification in basicity. The fundamentals of the theory developed by him were described in detail in his work *On the Structure of Organic Acids*, published by him in 1838. Liebig defined organic acids as compounds that contain hydrogen which can be substituted by metals. As mentioned in the monograph [1], Liebig's theory of polybasic organic acids was highly appreciated in all fundamental works on history of chemistry.

Beginning in 1839, the central place in Liebig's works was occupied by problems of feeding of plants and animals. In 1840, he completed his book *Chemistry as Applied to Agriculture and Physiology*. The book aroused strong interest and was repeatedly republished, with already its ninth edition published by 1876. This Liebig's book was published in Russia in full in the Klassiki estestvoznaniya (Classics of Natural Science) series [2]. Based on numerous analyses of plants and soils, the scientist came to a conclusion that growing plants extract mineral substances from soil, and these substances are not returned into the fields. This was, in Liebig's opinion, the reason for falling productivity. Liebig's contribution to foundations of agricultural science is of great importance. The use of artificial fertilizers in agriculture in accordance with Liebig's concepts of plant feeding made it possible not only to preserve, but also to improve the fertility of soil. Beginning in 1847, Germany did not suffer for decades any significant crop failure. Liebig's theory of rational agriculture and development of plants for manufacture of artificial fertilizers brought excellent results. In 1844 and 1845, Liebig visited Britain to organize manufacture of fertilizers recommended by him.

Of particular interest are Liebig's articles on the state of agriculture, published in Russian in 1861 [3].

In parallel, the scientist carried out studies in the field of biological chemistry. Liebig considered very important the problem of providing the mankind with food. The transition from studies of plant feeding to investigations of how animals and humans feed seems to be logical. Among the first Liebig's works in the field of biochemistry belongs *A Study of the Nature of Uric Acid*, carried out together with Wöhler (1838). In this and following studies, precise chemical investigation techniques were used. In 1842, in Germany and then in Britain, a fundamental work of the scientist was published, namely, *Organic Chemistry as Applied to Physiology and Pathology*. This study was analyzed in detail in the monograph [1].

The scientific merits of Liebig are rather diverse and great. The scientist was invited more than once to head a chair or a laboratory of universities in Germany and in other countries, including Russia. Only in 1852, Liebig considered his 28-year services to Gissen University complete and accepted an invitation to get a chair at the University of Munich, the capital of Bavaria, having made a provision that his pedagogic activities are to be limited. Nevertheless, he delivered public lectures on various parts of chemistry for all comers.

A prominent place in Liebig's scientific-organizational activities was occupied by publication of a journal, which was named *Annalen der Pharmacie* originally (beginning in 1832), *Annalen der Chemie und Pharmacie* in 1840–1873, and *Liebigs Annalen der Chemie* in memory of Liebig since 1873. The journal published papers by leading chemists of Germany, France, Britain, Russia, and other countries. The scientific authority of the journal was very high.

In 1855, Liebig was elected a member of the Berlin Academy of Sciences; in 1860, he became president of the Bavarian Academy of Sciences. In subsequent years, he was elected an honorary member or foreign corresponding member of most of the academies and scientific societies of the world, awarded various kinds of orders, and two Russian orders among these. Justus von Liebig passed away on April 18, 1873, shortly before his 70th birthday. The International committee for immortalizing the memory of the scientist included leading scientists from many countries all over the world. Russian scientists, academician Zinin and professor Beil'shtein (academician since 1886), were among these. Monuments to Liebig were erected in the tree cities in which he had lived: Darmstadt (1887), Gissen (1890), and Munich (1883). By Humboldt's words "scientific interests were above any other human interests" for Liebig.

A vast literature is devoted to the life and activities of the outstanding German scientist. Much was done by the known historian of chemistry Yu.S. Musabekov (1910–1970), professor of the Yaroslavl Technological Institute. He wrote a popular-science biography of Liebig and described in detail the life and scientific, pedagogical, and public activities of the scientist [1]. The book also presents a list of Liebig's works in chronological order, and also a list of publications about Liebig. In separate publications, Musabekov considered methodological problems in the creative work of Liebig as a chemist-thinker and philosopher [4] and scientific relationships between Russian scientists and Liebig [5].

A major contribution to making the Russian audience familiar with Liebig's works was made by Il'enkov, a known chemist-technologist and agricultural chemist, professor of Peter the Great Academy of Agriculture and Forestry in Moscow. After graduating from St. Petersburg University in 1843, Il'enkov improved his education in universities of Germany and France for about two years and worked with Liebig. Il'enkov not only popularized Liebig's ideas, but also developed them on his own. To the importance of Liebig's works for agriculture was devoted Il'enkov's report at the Annual meeting of Moscow Society for Agriculture in April 1874 [6].

The evidence concerning Liebig's life and activities can be found in books by Sharvin [7], Krasnogorov [8], article by Debu [9], etc. [10–12]. Spacious articles about Liebig can be found in known foreign reference books [13, 14].

A. G. Morachevskii

Russian Journal of Applied Chemistry, Vol. 76, No. 4, 2003, p. 674. Translated from Zhurnal Prikladnoi Khimii, Vol. 76, No. 4, 2003, p. 698.

Paderin, S.N. and Filippov, V.V., *Teoriya i raschety metallurgicheskikh sistem i protsessov* (Theory and Calculation of Metallurgical Systems and Processes), Moscow: Mosk. Inst. Stali i Splavov, 2002, 334 pp.

The book is devoted to a topical problem and is recommended by the educational-methodological association for education in metallurgy as a textbook for students of higher school institutions training bachelors and engineers specialized in metallurgy. This purpose of the book, aimed at a wide audience of specialists in metallurgy, imposes special requirements on its structure, content, manner of presentation, graphical illustrations, and choice of examples for calculations.

The textbook comprises a foreword, nine chapters, and list of recommended literature. The very brief foreword (pp. 7, 8) describes the level of cast iron and steel production and modern tendencies in the development of ferrous metallurgy. The first chapter (pp. 9–30) is devoted to the state and nearest prospects for the development of ferrous metallurgy in the world. Unfortunately, virtually no attention is given to the industry of Russia, its state and prospects.

The second chapter (pp. 31–54) contains general evidence about thermodynamic description of metallic solutions. The third chapter (pp. 55–77) considers very briefly some thermodynamic models, which are mainly based on complicated versions of the consept of regular solutions. The fourth chapter (pp. 78–114) is devoted to specific features of the thermodynamic behavior of dilute solutions. The problems associated with the choice of the standard state and the interaction parameters are discussed in detail. The objects of thermodynamic analysis in the fifth chapter (pp. 115–209) are metallurgical slags, mattes, and fluxes. The small sixth chapter (pp. 210–233) contains evidence about the solubility of oxygen in liquid iron, oxidative refining of the liquid metal, and thermodynamics of steel deoxidation. The seventh chapter (pp. 234–293) considers in detail the use of solid electrolytes with anionic conduction for determining the activity of oxygen in liquid iron and steels and discusses the electrochemical properties of solid electrolytes and the limits of electrochemical stability of transducers. The eighth chapter (pp. 294–316) analyzes the problem of steel decarbonization with gaseous oxygen, considers kinetic features of the process, and presents results of pilot meltings under industrial conditions. The ninth chapter (pp. 317–329) contains evidence about oxidation processes accompanying the decarbonization of steels. The bibliographic list gives the recommended literature for each chapter of the book separately. Unfortunately, the absence of titles of journal articles impairs its information value, the more so as no references are given in the text.

Each chapter, including the first one, which drops out of the general structure of the textbook, pays much attention to problems, some of which are worked and others are intended for independent solution. On the whole, both kinds of problems and control questions account for about 30% of the book's volume.

Analysis of the textbook by S.N. Paderin and V.V. Filippov shows that, in describing the concentration and temperature dependences of thermodynamic functions in metallic and slag melts, the authors obviously prefer "complicated" versions of the regular solution model, using such not quite clear terms as "pseudoregular" and "subregular" solutions. The terminology of this kind and the associated mathematical apparatus were first applied to metallurgical systems more than 40 years ago in publications of mostly domestic authors and are used now only by few researchers. It is hardly advisable to use models of this kind in a textbook intended for introduction of students into the thermodynamics of variable-composition phases for the example of metallurgical systems. Unfortunately, the presentation of the basic thermodynamic relationships is impaired by a number of annoying errors.

In our opinion, the book can be used in training of engineers and masters specializing in ferrous metallurgy, but there is no sufficient reason to recommend it for bachelors specializing in metallurgy or engineers of wide metallurgical profile.

A. G. Morachevskii

Russian Journal of Applied Chemistry, Vol. 76, No. 4, 2003, pp. 675–676. Translated from Zhurnal Prikladnoi Khimii, Vol. 76, No. 4, 2003, pp. 699–700.

BOOK REVIEWS

Denisov, V.M., Istomin, S.A., Podkopaev, O.I., Belousova, N.V., Pastukhov, E.A., Serebryakova, L.I., and Kvasova, T.O., *Germanii, ego soedineniya i splavy* (Germanium, Its Compounds and Alloys), Yekaterinburg: Ur. Otd. Ross. Akad. Nauk, 2002, 600 pp.

A group of authors from the Institute of Metallurgy, Ural Division, Russian Academy of Sciences, wrote a capital monograph devoted to analysis of experimental data on compounds and alloys of germanium, their structure and physicochemical properties. Much attention is given to the liquid state. The electrical properties of germanium-based materials are discussed.

The book comprises an introduction, ten chapters, and a bibliographic list. The very brief introduction (p. 7) notes the role of germanium and its compounds in modern technology. The first chapter (pp. 8–42) contains evidence about physical properties of germanium in solid and liquid states. Specific features of the liquid state are considered in detail with account of the fact that transition from covalent to metallic bonding occurs in melting of germanium. Special mention is made of the results obtained in studying liquid germanium by diffraction techniques.

The second chapter (pp. 43–123) is devoted to interaction of germanium with Group-I elements. Alloys with alkali metals are described very briefly, the main attention is given to interaction of germanium with copper, silver, and gold. The third chapter (pp.124–164) contains evidence about alloys of germanium with Group-II elements. Alloys of magnesium not only with germanium, but also, for comparison, with other Group-IV elements: silicon, tin, and lead, are considered in detail. Their electrical conductivity and magnetic properties in liquid and solid states, thermodynamic properties of liquid phases and methods for their assessment and description in terms of various model concepts are discussed. Less attention is given to alloys of germanium with calcium, strontium, and barium. Evince concerning the thermodynamic properties of liquid alloys of germanium with zinc and some data on solid alloys of germanium with cadmium or mercury are given.

The fourth chapter (pp. 165–247) includes a vast body of data on interaction of germanium with scandium, lanthanoids, and boron-subgroup elements. Having mentioned investigations of V.N. Eremenko and co-workers into phase diagrams of germanium alloys with rare-earth metals, the authors pay no attention to the concluding publication of this group, the book by Yu.I. Buyanov *et al*. *Fazovye ravnovesiya i termodinamika obrazovaniya faz v dvoinykh sistemakh redkozemel'nykh metallov s germaniem* (Phase Equilibria and Thermodynamics of Phase Formation in Binary Systems Formed by Rare-Earth Metals with Germanium), Kiev: Inst. Probl. Materialoved. Nats. Akad. Nauk. Ukrainy, 1998. The fifth chapter (pp. 248–304) is concerned with analysis of systems formed by germanium with Group-IV elements. There is only limited evidence about the interaction of germanium with titanium, zirconium, and hafnium and virtually no data on the system germanium–carbon. The central position in the chapter is occupied by alloys of germanium with silicon.

The sixth chapter (pp. 305–355) presents a relatively small amount of data on alloys with germanium with vanadium-subgroup metals. Most attention is given to the interaction of components in the system germanium–arsenic. The seventh chapter (pp. 356–457) contains evidence about alloys of germanium with Group-VI elements. For the chromium subgroup, the body of data on the interaction of germanium with molybdenum and tungsten is at a minimum. In most detail are discussed germanium oxides, glassy formulations with GeO_2, and various compounds and systems, including germanium dioxide. Much attention is given to the system germanium–tellurium and ternary compounds on its base.

The eighth chapter (pp. 458–471) is concerned with the interaction of germanium with Group-VII elements, manganese and halogens. Among the latter, most attention is given to bromine interacting with germanium. The ninth chapter (pp. 472–528) mainly considers alloys of germanium with iron-subgroup

1070-4272/03/7604-0675 $25.00 © 2003 MAIK "Nauka/Interperiodica"

metals. Of platinum-subgroup metals, some evidence is only given for alloys of the system germanium–palladium. The very small tenth chapter (pp. 529–530) notes that alloys of germanium with actinoids are the least studied, with phase diagrams only given for the systems germanium–thorium and germanium–uranium.

The bibliographic list (pp. 531–597) contains 1204 references to studies of predominantly domestic authors, with references to foreign investigations not exceeding 20%. The inclusion of article titles makes the list more informative.

On the whole, the book is a reference publication including various kinds of evidence concerning one or another system under consideration: phase diagram, thermodynamic characteristics and structure of predominantly liquid phases, data on electrical conductivity, magnetic susceptibility, density, surface properties, and electrical properties associated with impurity doping. In this situation, a particular attention of the authors to data sources, formulas presented, terminology, and dimension of the quantities mentioned is required. Unfortunately, this is not always the case. Let us give a characteristic example: "Heat of lithium dissolution in solid germanium, ΔH = 54.43 kJ mol^{-1}" (p. 45), with the authors referring to a low-authority publication. The phrase poses quite a number of questions. Many equations cannot be used, since the necessary dimensions of the quantities involved are not given. In a number of cases, complex equations have purely "decorative" importance, being not commented at all. The books gives in ample detail the results of thermodynamic investigations of numerous systems in liquid state, but they are not, as a rule, discussed by the authors. Not always there is the necessary unity in designations and terminology throughout the monograph.

The authors have done an extensive amount of work on collecting and systematizing a wide variety of experimental data. The monograph may be of interest for a wide audience of specialists in inorganic materials science and semiconducting materials. The book is very well printed in all respects.

A. G. Morachevskii

Russian Journal of Applied Chemistry, Vol. 76, No. 5, 2003, pp. 677–688. Translated from Zhurnal Prikladnoi Khimii, Vol. 76, No. 5, 2003, pp. 705–715.

300th ANNIVERSARY OF ST. PETERSBURG

Studying chemistry has two goals: progress of natural science and improvement of the well-being.

M. V. Lomonosov

Chemists of St. Petersburg and Development of Science and Technology in Russia

A. G. Morachevskii and V. S. Shpak

St. Petersburg was founded by Peter the Great on May 16(27), 1703, in the marshy delta of the Neva River on a small island Ennisaari (Zayachii). Having chosen this place close to an exit to open sea, for which he strove so much, Peter the Great laid there foundation of a fortress. The victory over Swedes in the Poltava battle (1709) strengthened the positions of Russia near the exit into the Baltic Sea and made it possible to begin, together with creating a defense system, the construction of the city. In 1712, St. Petersburg was finally recognized as the capital of the Russian Empire. Administrative buildings, sea-port, and shipyards were under construction. Already in 1715, the first state plant for manufacture of powder was founded near St. Petersburg, on the Okhta River. In 1720, the first chemical laboratory, in which ores were analyzed, was created at the Berg-Kollegiya (the governing body for Russia's mining and metals industry).

To the most important decisions made by Peter the Great belongs foundation on February 8, 1724, of the Academy of Sciences and Arts, and also of the university and gymnasium affiliated with the Academy. Thus, during the initial period of its existence, the Academy of Sciences (AS) was simultaneously a research and educational institution.

Chemical research in Russia was initiated by M.V. Lomonosov (1711–1765), who was elected an academician in 1745. His scientific activities were rather diverse, but his main attention was focused on the development of chemistry and physics. By the scientist's initiative, the first Russia's chemical research laboratory was created in St. Petersburg in 1748. This laboratory existed till 1793. In 1748 to 1757, Lomonosov carried out at this laboratory, nearly without any assistants, a great number of various studies. The scientist's achievements in the design of colored glasses, which served as a basis for the famous mosaics, and glasses with different refractive indices are outstanding. A glass factory was built by his design near St. Petersburg (1752). In 1752–1754, Lomonosov delivered the first world's course of lectures on physical chemistry to students of the Academy University. After Lomonosov's death, the Academy University started to die away and was abolished in 1767, having served to training of first domestic scientists.

Lomonosov made an invaluable contribution to the development of chemistry and chemical technology, which were the same science at that time. After Lomonosov, studies of Russian chemists of the second half of the XVIII century were mainly aimed to solve practical problems with relatively narrow scope. Academician I.G. Leman (1719–1767) was mainly engaged in analyses of ores and minerals, and wrote the first manual of assaying. E.G. Laksman (1737–1796) was known for the development of a new technique for manufacture of glass with the use of dehydrated sodium sulfate instead of potash. T.E. Lovits (1757–1804, academician since 1793) discovered the phenomenon of impurity adsorption from various solutions by charcoal. He also was the first to obtain glacial acetic acid, suggested a number of cooling mixtures, improved methods for chemical analysis, and was a many-sided chemist. V.M. Severgin (1765–1826) was elected an academician in mineralogy, but was also known for his studies in chemistry and technology of mineral salts and in assaying.

At the turn of the XIX century, the nature of activities of the AS changed, it ceased to execute educational functions; simultaneously increased the number of corresponding members and honorary members of the AS, who not necessarily lived in St. Petersburg. Many scientists, when elected to the AS, continued working at higher-school institutions. Thus, St. Petersburg, remaining the largest scientific center of Russia,

1070-4272/03/7605-0677$25.00

D. I. Mendeleev

took an opportunity to coordinate research in other cities of the country. This part had been played by St. Petersburg at least till the mid 1930s.

Honorary member of the AS (since 1796) A.A. Musin-Pushkin (1760–1809), vice president of the Berg-Kollegiya, carried out the first Russia's investigations in the field of chemistry and technology of platinum-group metals and suggested a method for purification of raw platinum to remove iron and iridium impurities. After the discovery of extremely rich platinum deposits in the Urals (1824–1825), the Joint laboratory of the Department of Mining and Salt Affairs, Gornyi Kadetskii Korpus (Military Mining College; later, Mining Institute), and Gornaya Apteka (Mining Repository) commenced industrial refining of platinum, which was then converted into a forgeable form. The latter procedure laid foundation of a new technology, powder metallurgy. From 1841 till 1867, platinum was refined by St. Petersburg mint. To the most important events related to studies and manufacture of platinum metals in Russia belongs the discovery of ruthenium in insoluble residues of the Ural platinum ore by C.E. Claus (1796–1864), professor of Kazan university and corresponding member of the St. Petersburg AS since 1861. Claus is one of founders of the chemistry of platinum and associated metals in Russia.

In 1808, Academician A.I. Sherer (1772–1824), professor at a number of higher-school institutions of St. Petersburg, wrote the first original textbook on chemistry in Russian, *Rukovodstvo k prepodavaniyu khimii* (Chemistry Teacher's Manual), in which the oxygen theory of H. Lavoisier (1743–1794) was popularized and much attention was given to development of the Russian chemical nomenclature. Later achievements in the field of chemistry were reflected in a textbook *Osnovaniya chistoi khimii* (Foundations of Pure Chemistry, 1831), by Academician G.H. Hess (1802–1850). The book was approved by the AS and ran through seven editions in 18 years. In the 1830s–1840s, the book served as the main textbook on chemistry and much affected the scientific concepts of the following generations of Russian chemists, among whom were N.N. Zinin (1812–1880), N.N. Beketov (1827–1911), A.M. Butlerov (1826–1886), and D.I. Mendeleev (1834–1907).

In 1831, the St. Petersburg Applied Technological Institute was opened in order to "train people who would possess theoretical and practical knowledge sufficient for managing factories or parts of these" [1]. This was the first educational institution of this kind in Russia. The training course covered three years. Hess accepted an invitation to take the position of inspector of classes (deputy director) at this institute. He composed the curricula and invited the best specialists from other civilian and military educational institutions of St. Petersburg for teaching the basic disciplines. In accordance with Hess's recommendations, a chemical laboratory was organized at the Technological Institute.

In 1832, Hess was elected professor of chemistry and technology at the Chief Pedagogical Institute, he also taught at the Military Institute of Means of Communication and Mikhail Artillery College. Particular intensive were his activities at the Mining Institute (1832–1849). He created there a chemical laboratory, introduced practical studies in chemistry for students, and paid much attention to training students in experimental work. Mainly owing to Hess's efforts, the chemical laboratory of the Mining Institute became a prominent research and pedagogical center in Russia. Such outstanding scientists as K.I. Lisenko (1836–1903), V.F. Alekseev (1852–1919), D.P. Konovalov (1856–1929), I.F. Shreder (1858–1918) and N.S. Kurnakov (1860–1941) received education and started scientific activities at this laboratory. A many-

sided scientist, one of creators of modern thermochemistry, Hess made a major contribution to training of highly skilled chemists in Russia in the first half of the XIX century.

Much was done in teaching chemistry at the University and other higher-school institutions of St. Petersburg and creating scientific schools in the field of chemistry by A.A. Voskresenkii (1809–1880, Corresponding Member of the AS since 1864). He graduated from the Chief Pedagogical Institute, where he attended Hess's lectures, in 1836. In his turn, Voskresenskii taught chemistry to Mendeleev, who entered this institute in 1850.

A prominent role was played in the development of applied electrochemistry in Russia by a St. Petersburg scientist, academician in physics, B.S. Jacobi (1801–1874). A broadly educated scientist, he made a major contribution to the development of electrical engineering and science of electromagnetic phenomena. Simultaneously, he was inventor of electroforming and did much for improvement of chemical power sources of that time. As noted by A.N. Frumkin [2], the discovery of electroforming, studies of chemical power sources, and development of techniques for measuring electrochemical parameters place Jacobi in one of the first places in the electrochemical science of the XIX century.

In the second half of the XIX century, chemistry in St. Petersburg flourished. The Academy of Sciences, St. Petersburg University, Mining Institute, Mikhail Artillery Academy, Technological Institute, and Agricultural (Forestry) Institute constituted the St. Petersburg scientific center, which exerted profound influence on the development of not only domestic, but also world science [3]. A school of chemists, characterized by one or another direction of research, formed at each of the above institutions. The scientific force accumulated in St. Petersburg constituted the basis of the scientific potential of the country. Among those who worked in St. Petersburg were Zinin, founder of the domestic school of organic chemists; Butlerov, creator of the theory of chemical structure of substances; Mendeleev, discoverer of the periodic law of chemical elements; Beketov, the first Russian physical chemist.

In the initial period of his scientific activities, Zinin worked at Kazan University. However, already in 1847, he was elected a professor at the chair of chemistry and physics of St. Petersburg Military Medical-Surgical Academy (Military Medical Academy since 1881); in 1865, he was elected ordinary academician

N. S. Kurnakov

of the St. Petersburg AS. A prominent place among Zinin's works is occupied by synthesis of primary aromatic amines (aniline, aminonaphthalene, benzidine, etc.), which are exceedingly important for synthesis of organic dyes, by reduction of nitro compounds. The reaction for synthesis of amines, which is of general character, became history as the Zinin reaction. The new method, its simplicity, and low cost of raw materials ensured manufacture of aniline in enormous quantities. Already several years after Zinin's works, a new large branch of chemical industry, manufacture of dyes, was created. In 1871, Butlerov wrote in an article "On Practical Importance of Scientific Studies in Chemistry": "Manufacture of aniline paints grew monthly, rather than yearly, and managed to occupy a prominent place in very few years. At present, this is a matter of extensive factory industry..." [3]. Zinin was among those who initiated the organization of Russian Chemical Society and was elected its first president at the organizational meeting held on December 5, 1868.

Butlerov, a graduate from Kazan University, was a professor there and became a professor of St. Peters-

St. Petersburg State Technological Institute.

burg University in 1869, and an academician in 1874. Together with creating the theory of chemical structure of organic compounds and writing a classical work "Introduction to Comprehensive Studies of Organic Chemistry" (1864–1866), Butlerov carried out a great number of experimental investigations, including synthesis of tertiary alcohols and studies of polymerization involving unsaturated compounds. The school of organic chemists founded by Butlerov and his scientific ideas exerted a profound influence on the development of organic chemistry in various cities of Russia. For example, Butlerov's disciples and followers include known chemists, founders of chemical directions of research in their own regions: V.V. Markovnikov (1837–1904), professor of Moscow University; A.M. Zaitsev (1841–1910), professor of Kazan University and corresponding member of the AS; F.M. Flavinskii (1848–1917), professor of the same university; S.N. Reformatskii (1860–1932), Professor of Kiev University, corresponding member of the AS since 1928, and founder of the Kiev school of organic chemists.

In 1869, Mendeleev discovered the periodic law of chemical elements and substantiated it experimentally and theoretically in the nearest two or three years. This greatest discovery was based on the entire body of evidence concerning the properties of elements, obtained by the middle of the XIX century, and established relationships between elements. Already in 1870, the structure of the periodic system acquired the most perfect form. The fundamental Mendeleev's work *Osnovy khimii* (Foundations of Chemistry) ran through eight editions during his life (1st in 1868–1871, 8th in 1906). The periodic law exerted profound influence on the development of research in the field of structure of substance both by physicists and by chemists. In addition to the periodic law, Mendeleev was interested during his entire scientific life in the problem of solutions. In the late 1880s, he put forward and substantiated the concept of existence of "singular points" in the curves describing the composition dependence of the solution density. In its final form, this concept was formulated by the scientist in the monograph *Issledovanie vodnykh rastvorov po udel'nomu vesu* (Study of Aqueous Solutions by Analysis of Their Density) (1887). Mendeleev's ideas in the field of variable-composition phases were further developed by two scientific schools founded in St. Petersburg by Kurnakov (physicochemical analysis) and Konovalov (thermodynamic theory of solutions). Mendeleev was engaged in pedagogical activities at St. Petersburg University (1857–1890) and, simultaneously, for several years, at the Technological Institute (1864–1872). A rather comprehensive characteristic was given to Mendeleev by L.A. Tschugaeff (1873–1922), a known chemist: "Genius chemist; first-rate physicist; fruitful researcher in the field of hydrodynamics, meteorology, geology, various branches of chemical engineering (explosives, oil, theory of fuels, etc.), and other disciplines adjacent to chemistry and physics; expert in chemical industry in general, and Russian chemical industry, in particular; original thinker in the field of domestic economy..." [4].

Mendeleev was more than once elected president of the Russian Chemical Society.

A.A. Fadeev (1810–1898), head of the chair of chemistry of Mikhail Academy, was founder of the school of chemists concerned with explosives. His disciple L.N. Shishkov (1830–1908) created there in 1860 one of the best Russia's chemical laboratories of that time. Among graduates from this educational institution were A.N. Engel'gardt (1832–1893), a professor of the St. Petersburg Agricultural Institute (1866–1870) and publisher, together with N.N. Sokolov (1826–1877), of the first Russian chemical journal (1859–1877); V.N. Ipat'ev (1867–1952, academician since 1916), one of the most outstanding chemists of the first half of the XX century.

A.A. Letnii (1848–1883), a lecture at the Technological Institute, was the first to discover decomposition of heavy oil residues at above 300°C, which served as a basis for the development of the cracking process and for production of divinyl from oil. Benzene, toluene, xylene, anthracene (1877), and butadiene (1878) were isolated by pyrolytic decomposition of Caucasus oils, and fundamental aspects of oil pyrolysis were established.

Of great importance for the development of physical chemistry, theory of solutions, and resolution of applied problems were investigations of D.P. Konovalov, a disciple and closest Mendeleev's associate and academician since 1923. As far back as 1884, he established in his classical work "On Vapor Pressure of Solutions" important relationships named Konovalov's laws. Further scientist's investigations were devoted to the development of Mendeleev's concepts of interaction between solute and solvent. In 1907–1915, Konovalov held important positions in the Russian government. To Konovalov's disciples belong, in particular, A.A. Baikov (1870–1946, academician since 1932) and M.S. Vrevskii (1871–1929, corresponding member of the AS since 1929).

In February 1899, Emperor Nicholas II approved the report by the minister of finance S.Yu. Witte on organization of the Polytechnic Institute in St. Petersburg. Mentioning the deficiency of specialists with higher technical education in a number of industries in Russia, Witte, in particular, wrote: "...with the development of those branches of industry in which chemical technology occupies the most important place, a necessity for specialization of applied science is increasingly manifested, which is exemplified by electrochemistry and metallurgy." Studies began already on October 2, 1902. The central place in the curricula of the metallurgical department, which also included

V. N. Ipat'ev

an electrochemical subdepartment, was occupied by chemical disciplines. The curricula were composed with participation of such known chemists as Mendeleev, P.I. Walden (1863–1957, academician since 1910), and D.K. Chernov (1839–1921), a prominent metallurgist. A spacious chemical building housed excellently equipped laboratories of general chemistry, analytical and organic chemistry, physical chemistry and theoretical electrochemistry, technical electrochemistry and mineral technology, mineralogy and geology, and also laboratories and cabinets of metallurgical profile [5]. As the first dean of the metallurgical department was appointed, and then elected, N.A. Menshutkin (1842–1907), a prominent scientist in the field of organic and analytical chemistry, who had been a lecturer at St. Petersburg University (1865–1901, professor since 1869). His major success was invitation to the Polytechnic Institute, for teaching the basic disciplines, of quite a number of the already well-known specialists. Later, the leading professors of the department, Baikov, F.Yu. Levinson-Lessing, V.A. Kistyakovskii, N.S. Kurnakov, and M.A. Pavlov became academicians, and V.E. Grum-

V. I. Vernadsky.

Grzhimailo and P.P. Fedot'ev, corresponding member of the AS. Among young lecturers, who later became known scientists, were S.P. Gvozdev, S.F. Zhemchuzhnyi, B.N. Menshutkin, D.N. Monastyrskii, and L.A. Rotinyants.

The opening of the Polytechnic Institute with its modern laboratories allowed training of highest-skill specialists. By Kurnakov's initiative, students of the metallurgical department were entitled, for the first time in the practice of Russia's higher-school technical institutions, to defend their experimental studies to be qualified as engineer-metallurgists. From the very first years of existence, the Polytechnic Institute became one of the best higher-school institutions of not only Russia, but also Europe.

In the early XX century, training of specialists in applied electrochemistry was commenced by the initiative of professor A.A. Krakau (1855–1909) and N.A. Pushin (1875–1947) at the St. Petersburg Electrotechnical Institute.

The chemical laboratories of the Mining, Polytechnic, and Electrotechnical institutes served as experimental base for creation by Kurnakov (academician since 1913) of the Russian school of inorganic chemists. His closest associates at these institutes were N.I. Stepanov (1879–1938, corresponding member of the AS since 1929), Zhemchuzhnyi (1873–1929), and Pushin. A great number of investigations of metallic and other systems served as a basis for formulation of general principles of physicochemical analysis (1913), a branch of general chemistry that studies by physical and geometric methods various equilibrium systems formed by two or more components. The physicochemical analysis is very important, in scientific and applied regard, for the development of chemical technology, halurgy, and metallurgy.

At the turn of the XX century, work in the field of organic chemistry were successfully developing in St. Petersburg. Of outstanding importance were investigations by representatives of Butlerov's school, A.E. Favorskii (1860–1945, academician since 1929) and V.N. Ipat'ev. Butlerov's own disciple, Favorskii (a professor of St. Petersburg University since 1896) was among those who created the chemistry of acetylene compounds, discovered and studied a great number of isomerization processes in series of unsaturated hydrocarbons, and founded his scientific school of organic chemists. V.N. Ipat'ev commenced studies of isomerization of unsaturated hydrocarbons on Favorskii's advice. In 1896–1897, when working in Munich at the laboratory of A. Bayer (1835–1917), V.N. Ipat'ev concluded studies of the isoprene structure and synthesized this monomer unit of natural caoutchouc. In autumn of 1900, the scientist started experimental studies of catalytic organic synthesis. Rather fruitful was the period of time from 1900 till 1914, which yielded original results [6, 7]. V.N. Ipat'ev was the first to apply high pressure (up to 1000 atm) and temperature (up to 700°C) in performing heterogeneous catalytic processes and to introduce into laboratory and technological practice a great number of previously unused catalysts. In 1909, the scientist made a major discovery: He demonstrated that use of mixed catalysts increases dramatically the possibilities of heterogeneous catalysis and allows directed variation of the properties of solid catalysts. V.N. Ipat'ev's studies served as a basis for a great number of industrial process, many of which are used now.

The discovery of the phenomenon of radioactivity (H. Becquerel, 1896) and radioactive elements (Pierre and Marie Curie, 1898) gave birth to a new chemical discipline, radiochemistry. Prominent Russian scientists, including V.I. Vernadsky (1863–1945, academician since 1912), a geochemist and mineralogist,

understood the importance of these discoveries. Already in 1910, the Radium committee was created in the AS. Making a report at the annual meeting of the AS in 1910, Vernadsky said: "The radioactivity phenomena open up new sources of atomic energy, which are millions of times more powerful than any sources of energy that could be imagined by the mankind... We cannot be indifferent toward how the radium ores will be studied. They should be studied by us, Russian scientists" [8]. Vernadsky organized and supervised prospecting for radioactive minerals and headed this important field of research till the end of his life.

Despite the successes of chemical science and foundation of scientific schools, World War I revealed the technological and economic backwardness of Russia and weakness of its chemical industry. Russia possessed abundant mineral wealth, but mining and processing of mineral resources were undeveloped. In 1907–1914, Russia's material production increased rapidly, but, on the whole, it remained low and the country was unready for a long war. Already in the first months of war, it was found that nitric and sulfuric acids were in short supply for satisfying the dramatically increased demand for powders and explosives, and neither benzene nor toluene were available in sufficient amounts. When the Germans started to use chemical warfare, it was found that means of protection were totally lacking and adequate means of attack were in acute deficiency. Also in short supply were pharmaceutical preparations, fuels, and lubricants. During this difficult period of time, general-lieutenant V.N. Ipat'ev, professor of the Artillery Academy, manifested his superior qualities as organizer, scientist, and technologist who supervised reforms, in the shortest time, and organization of the military chemical industry in Russia [6, 7]. V.N. Ipat'ev was appointed chairman of the committee for provision of explosives in February 1915, and head of the Chemical committee at the Main Artillery Commission, in April 1916. The committee, which comprised five departments and had numerous regional bureaus, included leading chemists of Petrograd: Academician Kurnakov, professors Favorskii, Tschugaeff, Tishchenko, G.V. Khlopin, and A.A. Yakovkin, and a number of scientists from other regions of the country. In [6, 9] were reported data characterizing the fast rise in manufacture of explosives and war gases and other important chemical products already by the end of 1916.

G.V. Khlopin (1863–1929), professor of the Clinical Institute in Petrograd, headed a special commission for problems associated with manufacture of a gas mask. Petrograd scientists headed by professor N.D. Zelinsky (1861–1953, academician since 1929) developed the schematic of a gas mask and methods for manufacture of activated carbon. A major contribution to studies of adsorption of war gases by carbon and analysis of the protective action of the gas mask was made by Professor N.A. Shilov (1872–1930), a physical chemist from Moscow. During V.N. Ipat'ev's work at the Chemical committee of the Main Artillery Commission, more than 15 million gas masks were delivered to the front lines [6]. The activities of the Chemical committee were described by V.N. Ipat'ev in 1921 [10].

Vernadsky, a prominent public figure and member of the State Council, initiated, with the support of a number of other leading scientists, organization by the AS in 1915 of the Permanent commission for investigation of natural productive forces of Russia (CNPF). Vernadsky was elected its chairman, and A.E. Fersman (1883–1945, academician since 1919), its secretary. The principal goals of the commission were to study the natural wealth and its industrial use. In the first place, it was necessary to organize throughout the country a precise and, to the maximum possible extent, comprehensive and systematic accounting of the natural resources of Russia. Already in 1916, CNPF organized 14 special expeditions to various regions of the country [11]. Relationships were established with a number of important State institutions whose activities satisfied the needs of the military industry. In addition, the Military-Chemical committee was organized in Petrograd at the Russian Physicochemical Society to "unite efforts of Russian chemists for joint and systematic work on problems associated with the needs of State defense" [12]. Kurnakov was elected the chairman, Tishchenko (1861–1941, academician since 1935), the deputy chairman, and Professor Tschugaeff, the secretary of the committee.

In 1918–1920, CNPF initiated organization in Petrograd, despite the general devastation in the country, a number of scientific institutions, which later served as a basis for prominent research centers. Kurnakov supervised organization of the Institute of Physicochemical Analysis, in which studies concerned with the theory of physicochemical analysis, salt-containing and organic systems, natural salts, and metallic alloys were carried out. It was necessary to resolve urgent problems associated with manufacture of new metals and alloys in the country and use of the mineral wealth of our salt lakes.

Prikladnaya Khimiya Russian Scientific Center

Simultaneously, in 1918, the Institute of Platinum and Other Noble Metals was organized. The institute was headed by Tschugaeff (1873–1922), a professor of Petrograd University and author of fundamental studies in the field of chemistry of coordination compounds. One of the main tasks of the institute was to improve methods for refining of platinum-group metals. Such known scientists as A.A. Grinberg (1898–1966, academician since 1958), I.I. Chernyaev (1893–1966, academician since 1943), and V.V. Lebedinskii (1888–1956, corresponding member of the AS since 1946) started their scientific careers under Tschugaeff's supervision. After the untimely death of Tschugaeff in September 1922, Kurnakov was elected director of the institute. The level of investigations of platinum-group metals, achieved in scientific institutions of Petrograd, enabled industrial-scale refining of the Ural platinum at a plant in Yekaterinburg. This involved direct participation of a Kurnakov's disciple, N.N. Baraboshkin (1880–1935), subsequently a professor of the Ural Polytechnic Institute. Later, scientists from Leningrad took part in the development of a technology for obtaining platinum-group metals from sulfide ores of the Norilsk deposit.

In 1918, a decision was made to organize a pilot plant for recovery of radium from the ore mined at the Tyuya-Muyun deposit in Central Asia. Owing to efforts of Petrograd chemists I.Ya. Bashilov (1892–1953) and V.G. Khlopin (1890–1950, academician since 1939) already in December 1921, the first Russia's high-activity radium preparations were obtained from domestic raw materials [6, 13]. In January 1922, the State Radium Institute was created in Petrograd, with a pilot plant included. Vernadsky was approved as director of the institute and held this position till 1938.

To solve the most important tasks of the national economy in the field of chemistry and chemical technology, the State Optical Institute (1918), Russian Institute of Applied Chemistry (1919; later, GIPKh, State Institute of Applied Chemistry; now, Prikladnaya Khimiya Russian Scientific Center), and other industrial institutes were founded in Petrograd [14].

The necessity for producing aluminum from domestic ores was stated by Vernadsky and Kurnakov as far back as 1915. By that time, Pushin at the Electrotechnical Institute and Fedot'ev (1864–1934, corresponding member of the AS since 1933) performed, together with V.P. Il'inskii (1885–1964), investigations into production of aluminum by electrolysis of melts. In 1916, a bauxite deposit was discovered near Tikhvin (now, Leningrad oblast). A geological survey carried out by 1923 demonstrated that the deposit can satisfy the nearest demand of the country for aluminum; also, mention was made of the low cost of bauxite mining. However, the bauxites are low-grade because of the high content of silica (up to 18%) and required development of a new technology for their processing. Several scientific institutions of

Leningrad started a search for the most feasible flowsheet. The industrial procedure for recovery of alumina from high-silica bauxites was developed at GIPKh under supervision of Yakovkin (1860–1936, corresponding member of the AS since 1925). Raw materials were processed by the pilot plant, and first aluminum was obtained in June 1929. Already a year later, construction of the first Russia's aluminum plant was commenced on banks of the Volkhov river, and the plant was put into service on May 14, 1932.

In June 1933, production of aluminum was commenced by the Dnieper aluminum plant. Alumina raw materials for this plant were manufactured from Tikhvin bauxites by a procedure developed by staff members of the Mining institute in Leningrad, A.N. Kuznetsov (1877–1946) and E.I. Zhukovskii (1892–1965). Further, major contribution to studies in the field of production of alumina, aluminum, magnesium, and titanium and to plant designing was made by staff members of the All-Union Research Institute of Aluminum, Magnesium, and Electrode Industry (VAMI), founded in Leningrad in September 1931 [15, 16]. In particular, an efficient technology for integrated processing of nepheline concentrates to produce alumina, soda, potash, and portland cement was developed for the first time in the world practice. Of particular importance for extension of the raw material resources of the aluminum industry were works of VAMI on development and implementation of a technology for processing of alunites into alumina, sulfuric acid, and potassium sulfate. In 1998, the output of the metal by the Russian aluminum industry exceeded three million tons. Russia is second only to the United States in production of primary aluminum and occupies the first place in the export of this metal.

As far back as 1917, analysis of preliminary samples of brine led Kurnakov to a conclusion that the Verkhnekamskoe deposit of potassium salts is of industrial interest and detailed geological and chemical studies are necessary for determining the limits and conditions of occurrence of salts. In 1925, an expedition headed by Leningrad geologist, Professor P.I. Preobrazhenskii (1874–1944) discovered the world's largest deposit of potassium and magnesium salts. In November 1927, in Solikamsk of Perm oblast was laid foundation of a potassium mine, and utilization of the natural wealth of upper flows of the Kama River commenced. At the beginning of 1934, construction of the potassium combine was complete, and fields started to receive a valuable fertilizer, potassium chloride [17]. In the following years, processing of carnallite and manufacture of a number of other chemical products were organized with active participation of Leningrad chemists. The problem of integrated use of potassium salts, sylvinite and carnallite, from the Verkhnekanskoe deposit was resolved during a rather short time.

The process of magnesium manufacture from carnallite was developed at GIPKh under supervision of P.F. Antipin (1860–1960, corresponding member of the AS since 1939). The magnesium plant constructed in Solikamsk produced first batches of metal in March 1936. One of the oldest cities of the Urals became a prominent center of chemical industry.

In 1931, the All-Union Research and Design Institute of Halurgy (VNIIG) was created in Leningrad. The results obtained by the institute served as a basis for organization of the industry of potassium salts in the Soviet Union and also plants for mining and processing of rock salt, sodium sulfate, phosphorites, and other halurgic and mining-and-chemical raw materials.

Kurnakov and co-workers also paid uninterrupted attention to the unique salt field, Kara-Bogaz-Gol, containing vast resources of sea-type salts in its brines and deposits. After quite a number of expeditions, industrial mining of the Karabogaz sodium sulfate, a highly important raw material for chemical industry, commenced in 1924.

Geological surveys of the Kola Peninsula had been carried out under supervision of Fersman, one of the closest Vernadsky's associates, beginning in 1920 [18]. In the 1930s, quite a number of scientific institutions from Leningrad took part in the development of apatite–nepheline deposits of the Khibiny massif, deposits of copper–nickel ores in Monche-tundra, and ores of rare metals in Lovozero tundras.

An event of worldwide importance was the development in the Soviet Union of an industrial technology for manufacture of synthetic rubber. S.V. Lebedev (1874–1934, academician since 1932), Favorskii's disciple, came, as far back as 1913, to a conclusion that the ability to polymerize is a general property of hydrocarbons possessing a conjugated system of double bonds. He also formulated general concepts concerning the nature, rate, and mechanism of polymerization processes. At the beginning of 1926, the Supreme Council of the National Economy of the USSR announced an international competition for the best process for industrial manufacture of synthetic rubber. By the end of 1927, Lebedev's group comprising seven chemists developed procedures for obtaining divinyl directly from ethanol and for polymeriza-

Institute of Macromolecular Compounds, Russian Academy of Sciences.

tion of divinyl, having chosen appropriate catalysts and process modes. The Lebedev method for production of synthetic rubber was recognized as the best. A Pilot plant was constructed in Leningrad, together with some laboratories. On February 15, 1931, the plant produced by the Lebedev technique a first block of synthetic rubber, weighing 260 kg. In basic parameters, the rubber obtained compared well with the natural product. In 1932–1933, plants for manufacture of sodium-butadiene rubber were constructed in Voronezh, Yaroslavl, and Efremov (Tula oblast). The Pilot plant in Leningrad was transformed into the Academician Lebedev All-Union Research Institute of Synthetic Rubber (VNIISK). In subsequent years, a major contribution to the development of various methods for manufacture of synthetic rubber was made by Leningrad scientists, Academician B.A. Dolgoplosk (1905–1994) and Corresponding Member of the Academy of Sciences A.A. Korotkov (1910–1967).

The achievements in the field of chemical kinetics are associated with activities of Academician N.N. Semenov and co-workers, first at the Physicotechnical Institute of the AS, and then at the Institute of Chemical Physics, organized in Leningrad in 1931. They developed a rigorous theory of branched chain reactions, which was one of the most outstanding achievements of theoretical chemistry in the first half of the XX century. For his works in the field of chain reactions, Semenov was awarded, together with a British physical chemist C. Hinshelwood (1897–1967), the 1956 Nobel Prize in chemistry.

In 1902–1904, V.A. Kistyakovskii (1865–1952, academician since 1929) created at the Polytechnic Institute the first Russia's laboratory of physical chemistry and electrochemistry, which was excellently equipped by the standards of that time. Among numerous directions of research conducted by Kistyakovskii, the central position was held by studies of the electrochemical behavior of metals in aqueous media [19]. By 1925, the concepts concerning the film theory of passivity and its relationship with corrosion processes had formed conclusively. The scientist regarded as the reason for the onset of the passive state the formation of an amorphous or glassy oxide film densely coating the metal surface. In 1930, Kistyakovskii organized in Leningrad the Colloid-Electrochemical laboratory, affiliated with the AS (now, Institute of Physical Chemistry, Russian Academy of Sciences, in Moscow). A major contribution to the understanding of corrosion and passivation phenomena was made by Leningrad scientists A.I. Shultin (1898–1978), Ya.V. Durdin (1900–1980), V.V. Skorchelletti (1902–1982), and A.M. Sukhotin (1928–2002).

In 1926, by V.N. Ipat'ev's initiative, the Laboratory of high pressures was created at the Institute of Applied Chemistry. The laboratory soon became an independent scientific institution. It served as a basis

for the organization, in 1927, of the Institute of High Pressures, at which organic catalysis, ammonia synthesis, and displacement of metals from salts were studied. Of young V.N. Ipat'ev's co-workers, B.N. Dolgov, V.V. Ipat'ev, B.L. Moldavskii, M.S. Nemtsov, A.D. Petrov, G.A. Razuvaev, A.V. Frost, and others became known scientists.

An exceedingly strong influence on the development of chemistry after World War II was exerted by the necessity for studying the chemical aspects of nuclear power engineering and creating structural materials for new technology. Somewhat later, it also became necessary to develop techniques for obtaining substances in high-purity state, synthesize materials with various valuable physical and chemical properties for radioelectronics and other purposes. The staff of research institutes and educational institutions of Leningrad made a major contribution to the solution of these problems.

Under the general supervision of Academician V.G. Khlopin, a technology for recovery of plutonium from irradiated uranium was under development at the Radium Institute of the AS. The following Leningrad scientists took part in the industrial implementation of the process at the first Russia's radiochemical plant: B.P. Nikol'skii (1900–1990, academician since 1968) and Corresponding Members of the Academy of Sciences B.A. Nikitin (1906–1952), I.E. Starik (1902–1964), and V.M. Vdovenko (1907–1978) [20]. B.P. Nikol'skii, a professor of the Leningrad University, was a representative of M.S. Vrevskii's school and an outstanding physical chemist and radiochemist.

In the late 1940s, investigations in the field of macromolecular compounds became much more extensive. In 1948, the Institute of Macromolecular Compounds, Academy of Sciences of the USSR, was organized by the initiative of Corresponding Member of the Academy of Sciences S.N. Ushakov (1893–1964) and other scientists. At this institute worked, in particular, such known scientists as P.P. Kobeko (1897–1954), a corresponding member of the AS and a specialist in the physics of amorphous substances; S.N. Danilov (1889–1978), a corresponding member of the AS, who studied both natural and synthetic macromolecular compounds, cellulose ethers and esters, and viscose; N.I. Nikitin (1890–1975), a corresponding member of the AS, specialist in chemistry of wood. The fundamental and applied studies carried out at the institute enabled synthesis a large number of polymeric products.

A major contribution to the organization of industrial manufacture of polyethylene, polystyrene, and other important materials was made by the Plastpolimer Research and Production Association.

In 1948, the Institute of Silicate Chemistry was founded in Leningrad with active participation of Academician I.V. Grebenshchikov (1887–1953). The institute's scientists carried out extensive studies in the field of structure, chemistry, and thermodynamics of glass-forming melts and glasses and created new multipurpose corrosion-protective materials. In 1953–1968, the institute was headed by N.A. Toropov (1908–1968), a corresponding member of the AS and a prominent scientist in the field of inorganic materials science and technology of silicate systems. During 1948–1961, N.N. Kachalov (1883–1961), one of those who organized the domestic manufacture of optical glass, the author of fundamental works in the field of glass-making and grinding and polishing of glasses, worked at the institute. In 1930, the scientist founded at the Technological Institute the chair of glass technology and headed this chair till the end of his life.

In the postwar period, quite a number of tasks of primary importance, mainly associated with defense, were assigned to staff members of GIPKh. To accomplish them successfully, it was, in fact, necessary to create a scientific institution of a new type, including a research complex, a designing unit, and pilot plants. In this way, GIPKh became the largest chemical institute of the country, with a number of branches and unique technological base. Mention can be made here of only some of the most important developments. Based on the institute research and designs, an industry for manufacture of fluorine and fluorine-containing compounds was created in the country. Wide application was enjoyed by organofluorine polymers, Freons, and surfactants. GIPKh took active part in the development of propellants and structural materials for rocket engines. In creating the propellants, facilities for large-scale manufacture of hydrogen peroxide, hydrazine and its derivatives, ammonium perchlorate, various oxidizing agents, corrosion inhibitors, catalysts, and other products were set up, and conditions were determined under which these substances can be stored and safely used. The results obtained were important not only for defense purposes but also for the national economy.

To the important scientific and technological achievements of GIPKh belong industrial synthesis of a great number of chemical compounds with molecules containing radioactive or certain stable isotopes and manufacture of a wide variety of luminophores for various purposes.

In all periods of its development, chemistry always

has been solving the main problem of how to obtain substances and materials with valuable properties. Decades and centuries passed by, systems of state organization and generations of scientists changed, research techniques were improved, requirements to the final product became increasingly stringent, but the basic concept remained as before. We made an attempt to reflect in a brief essay the contribution made by St. Petersburg scientists to the solution of problems encountered by chemistry and chemical technology in the XVIII–XX centuries, to demonstrate the succession of scientific schools, and to make the reader recall some most important scientific events.

Fullerene-Containing Chalcogenide Glassy Materials

L. N. Blinov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received July 15, 2002

Abstract—Possibilities of simulation and subsequent synthesis of fullerene-containing chalcogenide glasses are considered, and some characteristics of this class of semiconducting disordered materials are analyzed.

Fullerenes and fullerene-containing materials have been extensively studied recently [1–15]. The 1991 discovery of nanotubes (or tubelenes) composed of two halves of a fullerene molecule and a cylinder of hexagons in the form of a rolled-up graphite layer aroused to even greater extent the interest in carbon materials with varied hierarchy of structures [16–21]. A powerful stimulus to studies of fullerenes was the discovery of the ability of their compounds with some metals (fullerenides) to undergo, on being cooled to a certain threshold temperature T_c, a superconducting transition characteristic of other substances of varied chemical nature [22–29].

However, despite the great, and increasing, number of publications concerned with fullerenes and their derivatives, studies devoted to development of a fundamental general theoretical approach to creation of fullerene-based materials and, in particular, to determining their place (niche) among other materials exhibiting high-temperature superconductivity (HTSC) are virtually lacking. It is known that the efficiency of application of various materials and, in particular, those possessing HTSC is determined both by what, and to what extent, is known about particular substances and by the existence of a general conceptual approach, unified theory, and general criteria for a broad class of materials [30]. Development of such an approach will make it possible not only to consider and analyze from a common standpoint single-type or closely similar classes of known materials with different compositions, but also to determine the strategy of a search for new materials. However, most of studies and reviews on fullerenes and their derivatives and also materials exhibiting HTSC are, as a rule, devoted to investigation of separate properties or groups of objects and generalization of the results obtained. In this case, a "physical" or "chemical" trend in analysis and presentation of data can be clearly observed.

In the chemical part of investigations concerned with fullerenes and their derivatives, the following sections can be distinguished [1–22, 29–38]: endohedral complexes of fullerenes, chemical properties of fullerenes and their derivatives, reactions of fullerenes with metals, oxidation of fullerenes, their reactions with Lewis acids, reactions of fullerenes with free radicals, behavior of fullerenes as ligands, nanotubes (or tubelenes), etc.

Separate publications have been devoted to reaction of radical cations of the type C_{60}^{+}, C_{60}^{2+}, and C_{60}^{3+} with water, alcohols, ethers, and esters; dissolution of fullerenes in organic solvents; adsorption properties of fullerene-containing materials; host–guest complexes with fullerenes; etc. [39–45].

A large group of studies have been concerned with synthesis of fullerenes and fullerene-containing materials [20, 21, 31, 46–52].

On the whole, analysis of papers reporting on physicochemical studies of fullerenes and their derivatives shows that they are mainly concerned with reactions of fullerenes with a limited set of metals or with organic substances of varied composition. No general approach to fullerene-containing materials, including those exhibiting HTSC, has been developed; although noticeable success has been achieved in separate directions [20, 21].

At present, investigations in the field of noncrystalline materials occupy one of central positions in physics and chemistry of solids. The interest in these materials is due to their inherent specific properties (variable composition, efficient production and processing, stability in various media, etc.), which favor their wide practical application, and to importance of studying these materials for the development of fundamental science. The progress in this field is promoted, in particular, by physicochemical studies of glasses, which belong to noncrystalline materials.

1070-4272/03/7605-0689$25.00

To elucidate the nature of the glassy state, it is necessary to determine the extent to which the concept that any substance except helium can be, in principle, obtained in glassy state is correct [53]. Of particular importance for experimental verification of this hypothesis are data on synthesis of glasses containing some unconventional components. To these belong, in particular, fullerenes.

Chalcogen- and chalcogenide-based glassy materials have been known for a rather long time [54–59]. Data on existence of a glassy material based on fullerene C_{60} are also available [60]. Since new materials based on chalcogenide glasses and fullerenes show promise for diverse applications, in particular, as matrices for creation of high-temperature superconducting materials, it was of scientific and practical interest to study the possibility of obtaining fullerene-containing chalcogenide materials and to establish a correlation between the superconductivity and composition of substances [61].

Any basic property of a substance is ultimately determined by the electronic structure of its constituent atoms and nature of their chemical interaction. On determining how these characteristics, which are related to the composition of a compound, vary with the charge of the nucleus of an averaged atom ($\bar{Z}$) or with some other reliably established numerical value, e.g., number of electrons in a substance (N_e), the above question can be resolved.

In [62–65], it was established that an expression of the type

$$G_T = \bar{n}\bar{K}/\bar{Z} \quad (1)$$

can characterize the glass-forming ability of a molten substance in its spontaneous cooling.

In Eq. (1), G_T is the glass-forming ability of a melt; $\bar{n}$ and $\bar{Z}$ are, respectively, the contributions of the principal quantum numbers of valence electrons and charge numbers of nuclei of melt components; $\bar{K}$, the mean rigidity of the electronic skeleton of chemical bonds (ESCB). In the general case, the overall $\bar{K}$ value is constituted by several components [66]. Further investigations demonstrated that this qualitative approach is promising for assessing the possibility of obtaining a number of new compositions of glassy materials after performing preliminary calculations of their glass-forming ability [64–67].

A relation similar to Eq. (1):

$$S = \bar{n}_s\bar{K}_s/\bar{Z}_s, \quad (2)$$

where the parameters $\bar{n}_s$, $\bar{K}_s$, and $\bar{Z}_s$ refer to substances capable of a superconducting transition above a certain temperature T_c, and S is the ability of a substance to undergo a superconducting transition, was used to analyze the main materials under study, with widely differing compositions (metals, intermetallic compounds, oxides, chalcogenides, fullerenides), which can pass into the superconducting state at temperatures close to 0 K or at higher temperatures (Table 1).

In calculating the numerical values, account was only taken of the main contributions to the ESCB rigidity, since all other contributions in these superconductors are zero [61, 68].

Further, it was necessary to determine the dependence of the S-function on the total number of electrons (N_e) in atoms of a substance $A_xB_yC_z$..., where A, B, C are symbols denoting chemical elements and x, y, z are their indices in a substance. With this dependence established, it becomes possible to perform a purposeful search for new substances that can undergo a superconducting transition both at low and at high temperatures. Figure 1 plots such a dependence, whence it can be seen that virtually all substances considered in this paper fall, as regards their glass-forming ability, on a single smooth curve. Comparison of this curve with a similar plot describing the glass-forming ability of melts [62, 64] shows that the latter lies lower than the curve for substances capable of a superconducting transition. This leads to the following suggestions.

(1) Most of substances that can pass into the glassy state in spontaneous cooling (cooling rate <100 K s^{-1}) cannot be superconductors. A possible exception are simple bodies and chemical compounds of constant and variable composition for which the charge number of an "averaged" atom (calculated from mole fraction) is within the range $Z = 20–30$. It should be noted that the possibility of superconduction in chalcogenide glasses was mentioned in [69].

(2) Most of substances capable of a superconducting transition cannot solidify as a glass on cooling their melts at cooling rate <100 K s^{-1}. The only exception are superconductors with averaged-atom charge $\bar{Z} = 20–30$.

(3) Analysis of the data in Table 1 and Fig. 1 shows that the most appropriate chalcogenide glassy matrices for introduction of fullerenes are selenium, systems on its base, and also ternary and more complex systems based on Se, S, P, As, and some metals, in which the charge number of averaged atom is close to the range 20–30.

(4) Evaluation calculations of S also demonstrated that, to obtain glassy compositions, the amount of fullerenes in chalcogenide matrices cannot be high. In this case, the rate of melt cooling should exceed 100 K s^{-1}. The available, by that time, experimental data on introduction of preliminarily treated shungites into chalcogenide glasses confirmed to a certain extent the suggestions made [29, 70, 71].

On the basis of the aforesaid, selenium [72] and glassy compounds of the systems P–Se, As–P–Se, and Ag–As–Se were chosen for studying the possibility of fullerene introduction into chalcogenide glasses serving as reference substrate (matrix). The choice of a procedure and mode of synthesis was determined by

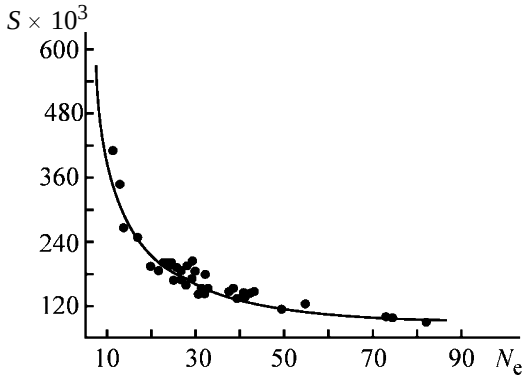

Fig. 1. Capacity S of a substance for a superconducting transition in relation to the total number of electrons in an "averaged" atom (N_e).

several factors specified below. It is known that the classical procedure for preparing a glass consists in nonequilibrium cooling of a melt preliminarily brought into thermodynamic equilibrium at a sufficiently high synthesis temperature T_s. Determining the temperature T_s and the minimum time of keeping the melt at a given temperature is an important experimental task [57]. However, there exist glasses which cannot, in principle, be obtained by the classical method, and these are not only glassy crystals for which the glass phase is obtained by cooling of the corresponding crystal [60]. It is the necessity for bringing a melt into the state of thermodynamic equilibrium that precludes synthesis of some glassy materials. In particular, such a situation is characteristic of fullerene-containing glassy materials, first synthesized in 1993 [29].

Fullerenes are big spherical molecules composed of carbon atoms. The most stable of these is the C_{60} molecule, a spherical molecular formation in the form of a truncated icosahedron. The C_{60} molecule, which resembles in its shape the surface of a soccer ball, is composed of edge-linked pentagons and hexagons, with each pentagon surrounded by hexagons only. The diameter of the C_{60} molecule is 7.2 Å. Fullerenes can be, in particular, obtained in evaporation of graphite by a special procedure [3, 73]. Naturally, such exotic molecules as C_{60} and C_{70} constitute only a minor fraction in graphite vapor mainly composed of small

clusters, mostly C_2. This is not surprising, since spontaneous formation of rather complex C_{60} and C_{70} molecules is unlikely, and their decomposition is, as a rule, irreversible. In view of this circumstance, melts containing a noticeable fraction of fullerenes are commonly thermodynamically unstable.

Since fullerenes can survive in thermodynamically unstable melts only at relatively low temperatures, it is hoped that fullerene-containing glassy materials can be obtained by relatively rapid cooling of such melts. Compared with glasses prepared by the classical technique of fast cooling of an equilibrium melt [56, 57], the given materials are characterized by lower configuration entropy [74]. Since the mutual position of atomic nuclei ultimately determines most of properties of any condensed system, the following questions are of primary importance. How are the structure R and parameters of a transition to the superconducting state related? Is it possible to increase the critical temperature T_c (R) of a superconducting phase transition by varying the structure R of a system at its invariable chemical composition? What is the structure R^{max} to which corresponds the absolute maximum

$$T_c^{max} \equiv T_c R^{(max)} = \max_{\{R\}} T_c(R) \quad (3)$$

of the function $T_c(R)$? These issues were considered in detail in [74–77].

It was shown in these publications that specific ensembles of structures with decreased configuration entropy can be distinguished in condensed systems. Systems with structures composed of these ensembles can be named systems with decreased configuration entropy. Here is meant the *a priori* (before obtaining any of the systems under consideration) configuration entropy, determined by probabilities of occurrence of the structure, which characterize a certain statistical ensemble of structures.

To systems with decreased configuration entropy belong, in particular, disordered microscopically heterogeneous materials with relatively large heterogeneity lengths λ [74]. For example, the λ value for glasses containing shungites with additions of fullerenes and fullerenides exceeds 100 Å [29, 74]. As established in [72, 74], the structurally inhomogeneous materials considered contain superconducting fragments for which T_c lies within the range 70–100 K (depending on composition).

Within the approach being developed, it becomes clear why the high-temperature superconductivity has been discovered just in structurally inhomogeneous materials, specifically, metal oxide ceramics. In all probability, the following hypothesis is valid. Most of high-temperature superconductors are structurally inhomogeneous materials with decreased configuration entropy and relatively large heterogeneity length λ(R) (Fig. 2).

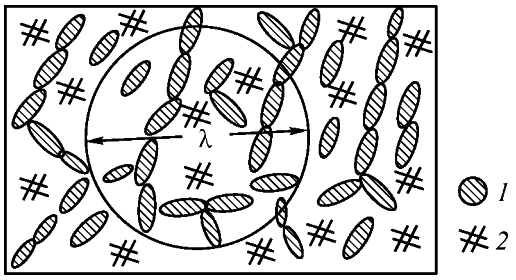

Fig. 2. A variant of the structure of a structurally inhomogeneous superconductor: (*1*) superconducting fragments and (*2*) fragments of the atomic network.

It is due to the existence of heterogeneities that the critical temperature T_c can be raised. The microscopic mechanisms responsible for this increase vary. For example, if heterogeneities are created (Fig. 2), the frequencies of atomic vibrations within them become higher. This leads [78] to an increase in the T_c values corresponding to these heterogeneities. In addition, it has been shown that, when the concentration of a certain kind of heterogeneities is raised, it may be hoped that the T_c values will increase [29, 72, 74].

It follows from the aforesaid that fullerenes of the types C_{60}, C_{70}, etc. must lead to a decrease in the structural disorder in the whole fullerene-containing system, i.e., to lowering of the configuration entropy. Naturally, preserving fullerenes in a melt in the course of synthesis requires that not only temperatures should be comparatively low, but also the chemical interaction with other components should be nondestructive. Unfortunately, the chemistry of fullerenes has not been studied sufficiently completely. Most of the presently known chemical reactions involve only chemical bonds separating two neighboring hexagons [1–15]. As a rule, mixtures of products are obtained, since multiple additions are possible. The last fact indicates that fullerene fragments are incorporated in condensed matrices by alternative mechanisms.

According to quantum-mechanical calculations, the energy of the whole system is lowered upon addition of one or two electrons to a C_{60} molecule by, respectively, 0.92 and 3.6 eV [3], and, therefore, many metals and their salts can serve as electron donors for fullerenes. For example, electron transfer from alkali

metal atoms to C_{60} occurs easily. Rubidium, potassium, and cesium fullerenides M_3C_{60} have metallic conductivity and exhibit superconductivity at low temperatures. The conductivity decreases when the composition deviates from M_3C_{60} to both higher and lower content of the alkali metal [79].

Being acceptors, C_{60} molecules form with electron donors, depending on their strength, either charge-transfer complexes or radical ion salts. Some of these show ferromagnetism or superconductivity [80]. A specific feature of the C_{60} molecule as an acceptor is its spherical shape and comparatively high negative reduction potentials. This circumstance predetermines the relatively low stability of fullerenes in air.

The criteria to be used in choosing donors for the C_{60} molecule have not been determined conclusively. It is believed [80] that the configuration flexibility is an important structural characteristic of a donor molecule as a component of a charge-transfer complex. Donors capable of changing their configuration, adjusting it to the rather rigid spherical shape of the C_{60} molecule, seem to be preferable for formation of sufficiently stable charge-transfer complexes. To such donors, in particular, belong molecules of chalcogens, e.g., sulfur molecule S_8. A complex $C_{60} \cdot 2S_8$ has been prepared [80]. It may be stated that sulfur is a sufficiently versatile donor for fullerenes.

It seems reasonable to assume that not only sulfur, but also other chalcogens (selenium, tellurium) can form charge-transfer complexes with C_{60}, and, therefore, fullerenes can, up to their certain concentrations, be incorporated in the network (structure) of some chalcogenide glasses. This is indicated by the data in Fig. 1.

Glassy fullerene-containing materials were synthesized using as a basis the temperature mode of synthesis developed for obtaining glasses containing Karelian shungites [29, 81]. The synthesis was carried out in preliminarily washed and dried (at 150°C) quartz ampules evacuated to a residual pressure of 10^{-5} torr. Ampules containing 2 g of the starting materials were kept in a furnace at 800°C for 2–3 h. For better homogenization of the melts in synthesis, they were agitated by rotating the ampules. Several parallel meltings were carried out for each composition. All measurements were done on no less than two samples from parallel meltings. As criteria of the glassy state served the shell-like fracture, absence of lines in powder X-ray diffraction patterns, and lack of heterogeneities on samples inspected using an MIK-1 IR microscope.

Fullerene-containing glassy materials were synthesized on the basis of the systems Se–C_{60}, P–Se–C_{60}, As–P–S–C_{60}, and Ag–As–S–C_{60}. It should be noted that as one of the main criteria for selecting chalcogenide matrices for introduction of fullerenes served the ability of the matrices to be donors for fullerenes, and also the configuration flexibility and diversity of structural formations. For example, glassy selenium has a rather labile polymeric skeleton based on covalently bonded structural units $SeSe_{2/2}$, which can adjust to the rigid structure of fullerenes. Matrices based on P–S and P–Se not only can be donors for fullerenes, but are also characterized by a wide diversity of structural groups, which facilitates incorporation of fullerenes in the structural network (matrix) of the glassy alloy. The choice of metals contained in glassy matrices was governed by the ability of such systems to form structurally inhomogeneous glasses.

As starting fullerenes served a mixture of 96 wt % C_{60} and 4 wt % C_{70}. In all of the systems studied, introduction of up to 2 wt % fullerenes preserved the glassy state of the initial matrices, and introduction of more than 2 wt % yielded glassy crystals.

To confirm the survival of fullerenes after synthesis, the mass spectra of the glassy samples obtained were measured. The mass-spectrometric studies were carried out with a time-of-flight mass spectrometer of the mass-reflectron type with resolution of 5000 at half-maximum of a peak at mass number of 500 amu [82]. Typical results of a mass-spectrometric study of fullerene-containing chalcogenide glassy materials are presented in Fig. 3. The presence of lines corresponding to fullerenes in the mass spectra clearly indicates that the fullerene structure is preserved in the synthesis mode used.

Some physicochemical parameters of the glassy materials obtained are listed in Table 2. The density ρ of the samples was measured by hydrostatic weighing in toluene, and their microhardness was determined on a PMT-3 device. The electrical conductivity of the samples was measured by the two-probe method at temperatures in the range 20–100°C, with the error in determining $\log\sigma$ not exceeding 0.1 order of magnitude. The glass transition temperature T_g was found from the bend in the temperature dependence of the electrical conductivity under condition of constant sample compression between the electrodes.

Analysis of the results obtained shows that the most pronounced changes in the structure and properties of a glass after introduction of fullerenes are observed for selenium-based samples. This is also indicated by the data listed in Table 3.

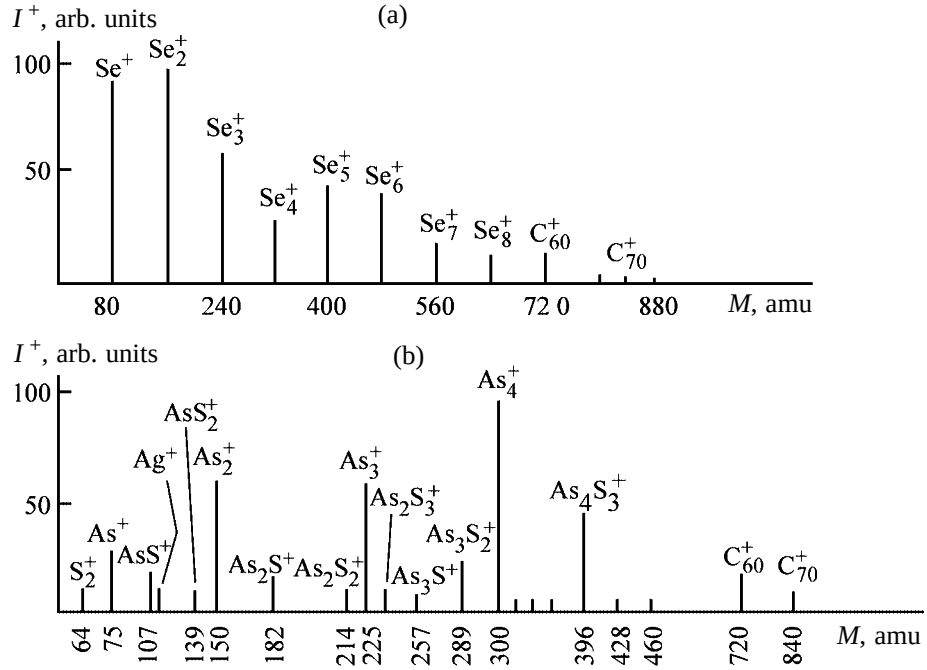

Fig. 3. Mass spectra of fullerene-containing glassy compositions: (a) Se + 2% C_{60}, T_{ev} = 200°C, U_{el} = 50 eV; (b) Ag_3AsS_3 + 2% C_{60}, T_{ev} = 350°C, U_{el} = 30 eV.

The results of examining with a metallographic microscope the polished surfaces of the alloys synthesized show that selenium-based samples are the most homogeneous. They also exhibit an increase in microhardness and a pronounced rise in glass-transition temperature. Probably, chemical interaction of carbon clusters with selenium, which leads to strengthening of the alloy structure, is manifested to the greatest extent. The temperature dependence of electrical conductivity shows clearly pronounced exponential behavior both at $T < T_g$ and in the glass-forming region (Fig. 4). The observed differences in the activation energy before and after T_g indicate that structural transformations occur in the glass network.

Table 2. Physicochemical characteristics of fullerene-containing glassy materials

System	Composition of the initial matrix	C_{60} content, wt %	ρ, g cm^{-3}	H, kg mm^{-2}	$-\log\sigma_0$, [Ω^{-1} cm^{-1}]	Type of conduction
Se–C_{60}	Se	0.9	4.27	42	12.7	Electronic
	Se	2.0	4.21	45	10.8	〃
P–Se–C_{60}	P_2Se_5	2.0	3.80	56	>12	〃
	P_2Se_5 + 0.1Fe	2.0	3.63	51	>12	〃
As–P–Se–C_{60}	AsP_3S_{10}	2.0	4.09	76	>12	〃
Ag–As–S–C_{60}	Ag_3AsS_3	2.0	5.75	62	6–7	Hole

Table 3. Parameters of selenium-based glassy materials

Composition	T_g, K	$-\log\sigma_{20}$	$-\log\sigma_{T_g}$	E_0, eV	$\log\sigma_0$	Notes
Se	314	13.8	11.0	0.90	4.0	Data of [15]
Se + 0.9 wt % C_{60}	333	12.7	10.4	0.95	3.7	$T < T_g$
				0.50	3.2	$T > T_g$
Se + 2.0 wt % C_{60}	338	10.8	10.7	1.15	6.8	$T < T_g$

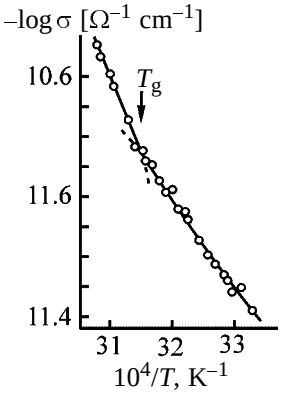

Fig. 4. Electrical conductivity of glassy selenium containing 2 wt % C_{60} vs. temperature T.

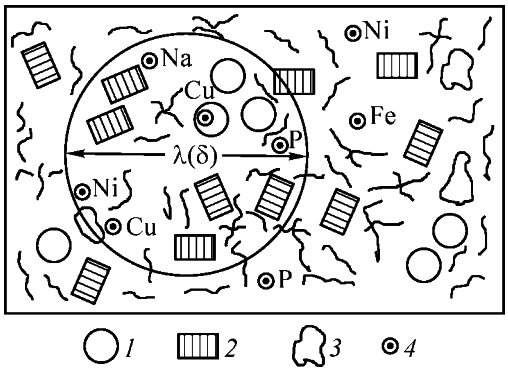

Fig. 5. Fullerene-containing selenium–carbon matrices: (*1*) fullerene molecule, (*2*) graphite fragment, (*3*) chain of selenium atoms, and (*4*) impurity atoms.

It should be noted that two characteristic regions with different activation energies of conductivity have also been observed in C_{60}-based films [83].

As already noted, the problem of glass formation in the system Se–C_{60} and other chalcogenide systems with fullerenes is far from being trivial. On the one hand, glassy selenium is a classical glass obtained by rapid cooling of an equilibrium melt [57], and on the other, the glassy phase of C_{60} is an example of a nonclassical glass obtained by nonequilibrium cooling of a C_{60} crystal from 300 to 15 K [60], with the corresponding glass transition temperature T_g equal to 90 K.

Thus, the preparation procedure is not the only factor governing the nature of the glassy state. Therefore, it is of prime importance to understand on the microscopic level the common features of all the above-considered cases (in particular, formation of Se and C_{60} glasses). This consideration can be based, to certain extent, on data in [76, 84–86]. Let us briefly discuss some conclusions following from these works.

Depending on the thermal history of a glass synthesized, the system "falls" into different potential wells. In other words, virtually infinite number of different glasses can be, in principle, obtained at fixed chemical composition. Being close in structure, most of these glasses have close properties.

The properties of the classical glasses are determined by potential wells which coincide with, or are close to those characteristic of a melt. However, there also exist an exponentially large number of potential wells grouped around the potential well of the ideal crystal. A rather great number of stationary quantum states are localized within these wells. A quantity ε_{cr}, which is similar to ε_g, can be introduced for the ensemble of these states [87]. For a C_{60} crystal, a temperature of about 90 K corresponds to the energy ε_{cr}. In other words, if the energy of a crystal exceeds ε_{cr}, then transitions between different states of the ensemble under consideration occur rather rapidly, with the result that an equilibrium is attained. If the energy is lower than ε_{cr}, such transitions are frozen.

Thus, the microscopic mechanisms of glass formation in Se and C_{60} are similar. The only difference consists in that these mechanisms operate in dissimilar ensembles of stationary quantum states, which differ fundamentally from one another.

Naturally, the exponentially large number of potential wells includes those to which correspond heterogeneous structures. In all probability, fullerenes are arranged within matrices of chalcogenide glasses statistically nonuniformly. Fullerene molecules form a kind of clusters (Fig. 5). This is confirmed by the presence of the above-mentioned superconducting fragments and absence of through superconductivity (Fig. 2). Surely, the clusters are much smaller in size (on the order of 10^{-3} cm) than the initial particles in a weighed portion. If these latter were preserved in the alloys synthesized, they would be observable under an IR microscope.

Quantitatively, the degree of heterogeneity of a system can be characterized by the value of $\lambda(\sigma)$ [88]. The length $\lambda(\sigma)$ is equal to the diameter of a sphere with minimum dimensions (Fig. 5), which isolates, irrespective of its position within a macroscopic sample, similar (to within relative fluctuation σ) regions. The similarity not necessarily means identity, it suffices that a number of integral characteristics of the regions, such as dipole moment, polarizability, overall chemical composition, etc., are close. In other words, even though regions of diameter $\lambda(\sigma)$ differ, as a rule, from one another in how the constituent fragments are linked, they are, nevertheless, closely similar.

The order of magnitude of $\lambda(\sigma)$ can be evaluated using a simple formula [88]:

$$\lambda(\delta) \approx D/(\delta^{2/3} \min_i n_i^{1/3}), \quad (4)$$

where D is the diameter of a sphere whose volume is equal to the average volume per atom in the system, and n_i is the relative concentration of atoms of ith kind.

According to Eq. (4), the values of $\lambda(0.01)$ for the alloys synthesized are on the order of 100 Å. It is fragments of this diameter that contain information about most of the properties of the materials considered. This, apparently, cannot be said about fragments with dimensions not exceeding 10 Å, since the diameter of a fullerene molecule is on the order of 10 Å.

Studies concerned with fullerene-containing glasses and with fullerenes themselves are still in the initial stage. In view of this circumstance, it is difficult to make any prognoses, but, in the author's opinion, these studies are of not only scientific, but also practical importance. In this context, it suffices to recall that the already investigated compositions of disordered materials with fullerenes possess a number of nontrivial properties, including high-temperature superconductivity [29, 72, 89]. Rather promising for studying this phenomenon in such materials is the method of microwave absorption in zero magnetic field [90]. This technique was used by the author in a study of selenium with addition of shungite (Fig. 6). A certain information about specific structural-chemical features of these materials can also be furnished by ESR spectroscopy (Fig. 7).

The main result obtained is that the possibility in principle of preparing fullerene-containing glasses by cooling the corresponding melts is established. In this case, the extent to which fullerenes interact with matrices of different compositions varies, which is, in particular, indicated by the dissimilar degrees of microheterogeneity of the compositions obtained. This is also favored by cluster formation. The fragments containing information about most of the properties of the materials under consideration have the size on the order of 100 Å and more.

It follows from the presented data on the chemical properties of fullerenes and glasses of the systems Se–C_{60}, P–Se–C_{60}, As–P–S–C_{60}, and Ag–As–S–C_{60} that the class of fullerene-containing chalcogenide glasses may be rather broad.

The microscopic mechanism by which widely diverse glasses, including glassy crystals, are obtained

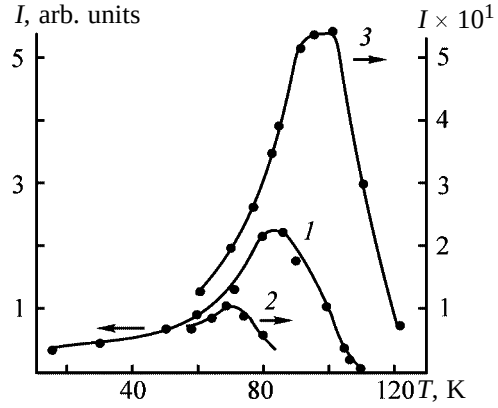

Fig. 6. Intensity of microwave absorption vs. temperature T: (*1*) glassy shungite in paraffin, (*2*) glassy selenium with 0.9 wt % shungite, and (*3*) glassy-crystalline selenium with 9 wt % shungite.

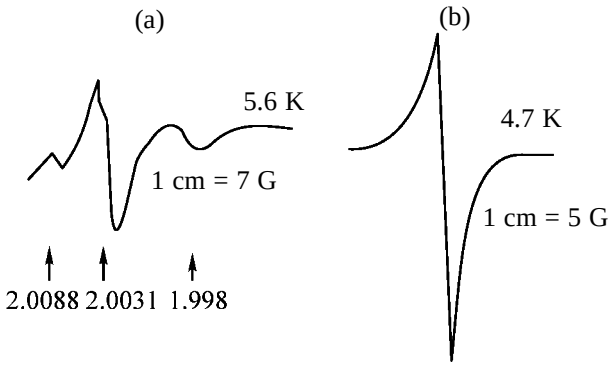

Fig. 7. ESR spectra of (a) amorphous shungite and (b) glassy selenium with 0.9 wt % shungite.

is the same. It consists in transitions between quasi-stationary quantum states with markedly different lifetimes.

The preservation of the fullerene structure in chalcogenide glass matrices also opens up new opportunities for preparation on their base of new disordered materials exhibiting high-temperature superconductivity.

ACKNOWLEDGMENTS

The author thanks M.D. Bal'makov, who participated in some parts of the study, for help in discussion of many of the results obtained.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Nonhydrothermal Synthesis and Properties of Saponite-Like Materials

Abstract—Main features of nonhydrothermal synthesis of saponite-like materials containing Zn(II) and Mg(II) cations in octahedral networks were studied. Optimal conditions for the synthesis were determined. The influence exerted by the double-charged structure-forming cation on the rate of structure formation in the synthesized materials and also on their pore structure and thermal stability was studied.

Unique catalytic and adsorption properties of natural clay minerals are known and are a subject of numerous papers [1]. However, nonuniformity of the chemical composition and pore structure and a considerable content of impurities considerably limit their application in catalysis [2]. At the same time, synthetic clays have homogenous composition and structure, and their physicochemical properties can be controlled already in the stage of their preparation [2–4]. This fact, and also the possibility for the directional synthesis of materials having no natural analogs open new prospects for catalytic applications [5–8].

Synthetic clays are usually prepared under hydrothermal conditions (5–17 MPa, 423–773 K) [9] using special expensive autoclaves, which considerably limits applications of these materials. Therefore, it is urgent to develop alternative procedures for their preparation, among which the nonhydrothermal synthesis (synthesis under normal pressure) is the most promising [5]. The applicability of this procedure to obtaining saponite-like materials was shown in [5–8]. The key moment in the process is the use of urea as a hydrolyzing agent; its thermally initiated decomposition makes it possible to smoothly vary pH of the reaction medium [10] and thus to control the hydrolysis rate and hence the formation of the target material [5–7]. However, detailed information on the features of the nonhydrothermal preparation of synthetic clays is lacking.

Clay minerals included in the group of natural layered aluminosilicates are formed mainly from two structural fragments, namely, the networks of silicon–oxygen tetrahedra SiO_4 (*T*-network) and of aluminum–oxygen octahedra $Al(O, OH)_6$ (*O*-network) [11]. These networks are joined through O^{2-} ions into layers, which form the basis of the unit cell of the minerals. The structure of smectites, including saponite, is formed by layers separated by interlayer intervals, in which two *T*-networks are joined with an *O*-network lying between them (*T*–*O*–*T* minerals). The isomorphous substitutions, e.g., Al(III)→Si(IV), in the *T*-networks give rise to an excessive negative charge which is compensated by either positive charges localized in the *O*-networks or charges of cations arranged in interlayer spaces [1, 2, 11]. The idealized formula of saponite is $M^{z+}_{x/z}[Mg_6](Si_{8-x}Al_x)\cdot O_{20}(OH)_4\cdot nH_2O$, where M are exchange (interlayer) cations; cations in the composition of the *O*-network are given in brackets; ions in tetrahedral networks are given in parentheses; $x = 1.2$ [11]. This mineral is of considerable interest for heterogeneous acid catalysis [2, 5, 6], because its surface has enhanced acidity owing to the isomorphism Al(III) → Si(IV) in the *T*-networks.

The aim of this work was to reveal the main features of the synthesis of Zn- and Mg-containing synthetic analogs of natural saponite under nonhydrothermal conditions and to study their physicochemical properties.

EXPERIMENTAL

The objects of this study were synthesized by a procedure close to that described in [5–8]. We used

1070-4272/03/7605-0700$25.00

$Na_2SiO_3 \cdot 9H_2O$ (27 wt % SiO_2), $Al(NO_3)_3 \cdot 9H_2O$, $Mg(NO_3)_2 \cdot 6H_2O$, or $Zn(NO_3)_2 \cdot 6H_2O$ as sources of Si(IV), Al(III), and double-charged cations.

The synthesis procedure is described for a sample with the atomic ratio Si(IV)/Al(III) = 12 as example. An $Al(OH)_4^-$ sol was prepared by dissolution of 4.22 g (11.25 mmol) of $Al(NO_3)_3 \cdot 9H_2O$ in 2 M NaOH (28 cm^3). Then this sol was added in portions with vigorous stirring to a solution of $Na_2SiO_3 \cdot 9H_2O$ (30.0 g, 0.135 mol) in 75 cm^3 of demineralized water. The resulting gel was kept at room temperature for 1 h without stirring, suspended with stirring in 600 cm^3 of H_2O, and heated to 363 K. Then 500 cm^3 of a separately prepared aqueous solution containing 32.60 g (0.109 mol) of $Zn(NO_3)_2 \cdot 6H_2O$ [or 28.1 g of $Mg(NO_3)_2 \cdot 6H_2O$ (0.109 mol)] and $CO(NH_2)_2$ (0.15–0.80 mol) was added to the heated gel suspension. The addition rate was selected so that the temperature of the reaction mixture did not decrease by more than 10 K. This mixture was heated at 363 K for 3–72 h with continuous stirring. The resulting solid phase was separated by filtration, washed with five portions of distilled water, and dried for 12 h at 383 K. The samples containing Zn(II) and Mg(II) cations in octahedral networks are denoted as Zn-SP and Mg-SP, respectively.

The pH of the reaction medium was monitored with a CG804 (Schott–Gerade) pH-meter with automatic data recording. The ^{27}Al NMR spectra were obtained in the magic angle spinning mode on a Bruker AMX 300 WB spectrometer (standard ZrO_2 rotor, magnetic field frequency 78.20 MHz). The ^{27}Al chemical shift was determined relative to $[Al(H_2O)_6]^{3+}$. The X-ray diffraction (XRD) patterns of the synthesized materials were taken on DRON-3 and Philips 1170 diffractometers (CuK_α radiation, λ = 0.154178 nm, Ni filter). The adsorption–desorption isotherms of nitrogen (77 K) were obtained on an ASAP 2010 (Micromeritics) adsorption installation using samples preliminarily evacuated for 5 h at 473 K and a pressure of 10^{-2} Pa. The IR spectra of samples prepared as pellets in thoroughly dried KBr (1 : 60) were recorded on Specord-M80 and FTIR Perkin–Elmer 2000 spectrophotometers.

The content of Mg(II), Zn(II), and Al(III) cations was determined by atomic absorption spectroscopy (Perkin–Elmer PE 3030 spectrophotometer). The cation-exchange capacity (CEC) of the synthesized materials was determined according to [12] by adsorption of a copper(II) ethylenediamine complex at pH 7.

The experimental dependences of pH of the medium on the synthesis time (Fig. 1) have no pronounced

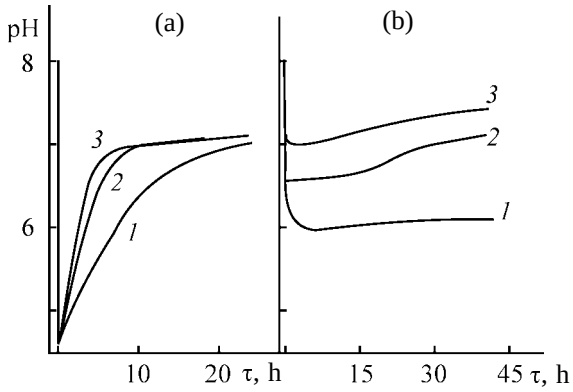

Fig. 1. Variation with synthesis time τ of pH of the reaction medium at various urea concentrations. Sample: (a) Zn-SP and (b) Mg-SP; the same for Fig. 3. $CO(NH_2)_2$ concentration, M: (*1*) 0.15, (*2*) 0.45, and (*3*) 0.80.

extrema, which suggests smooth nucleation and growth of particles of the synthesized materials. It is most probable that the decrease in pH observed in the initial moment of the reaction is due to the formation of $Zn(OH)_2$ and $Mg(OH)_2$ phases. A considerable difference in the initial pH values during the syntheses of Zn-SP and Mg-SP may be due to different solubility of these hydroxides, which is much higher in the case of $Mg(OH)_2$.

The ^{27}Al NMR spectra of the starting gels used for the synthesis of Zn-SP and Mg-SP contain a resonance of tetrahedrally coordinated Al(III) cations [Al(III)(tetr.)] with a chemical shift δ about 54 ppm (Fig. 2). At the reaction time of 3 h, a signal of octahedrally coordinated Al(III) (δ = 10 ppm) and a shoulder with δ = 64 ppm assignable to Al(III)(tetr.) are observed in the spectrum of Zn-SP. The latter signal is characteristic of Al(III) cations localized in tetrahedral networks of smectites (Al–O–Si bonds) [13]. When the syntheses time increases to 12, and especially to 24 h, the intensity of this resonance considerably increases, which is accompanied by the disappearance of the signal with δ = 24 ppm (Fig. 2a). In this case, the change in the urea concentration within these limits affects the parameters of the ^{27}Al NMR spectra only slightly. Nevertheless, the strongest signal of Al(III)(tetr.) was observed for a sample prepared in the presence of 0.45 mol of $CO(NH_2)_2$. The data obtained suggest that the incorporation of Al(III) cations into the crystal lattice of Zn-SP is practically complete within approximately 24 h. In the case of Mg-SP, this process is much slower, and a weak signal of Al(III)(tetr.) with δ about 64 ppm was detected only at the reaction time of 30 h. Its intensity considerably increases as the synthesis time is increased

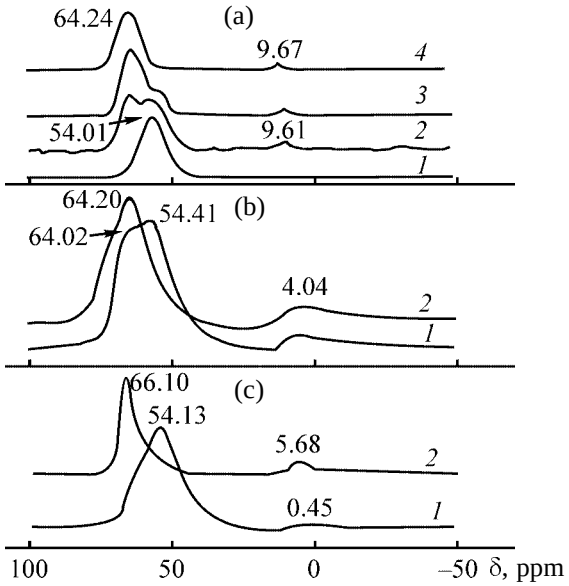

Fig. 2. ^{27}Al NMR spectra of synthesized materials. (δ) Chemical shift. Sample: (a) Zn-SP and (b, c) Mg-SP; the same for Fig. 4. to 36 h (Fig. 2b). In this case, the amount of urea and hence the pH value crucially affect the course of Al(III) incorporation into the tetrahedral network of the synthesized material (Fig. 2c).

The increase in the Si(IV)/Al(III) atomic ratio in the reaction gel from 5 to 12 results in an appreciable decrease in the content of octahedrally coordinated Al(III)., with the content of Al(III)(tetr.) remaining virtually unchanged. Therefore, we can conclude that saponite-like materials with preferential Al(III) localization in the tetrahedral networks (a characteristic feature of this smectite [3, 5]) can be obtained under non-hydrothermal conditions only at Si(IV)/Al(III) ≥ 12. Therefore, further experiments were performed using samples with the Si(IV)/Al(III) atomic ratio of 12 and Mg-containing materials synthesized in the presence of 0.80 mol of urea.

The X-ray diffraction analysis has shown that, in the case of Zn-SP, a certain amount of a saponite-like phase is formed within 3.0–3.5 h. As the synthesis time is increased to 12 h, its amount and the crystallinity of the resulting material increase (Fig. 3a), as indicated by the growth of the intensity of the long-range order basal reflections (020/110) and (113) [4, 6]. At the reaction time increased to 24 h, the X-ray peaks become narrower, and the intensity of the first basal reflection [*d*(001)] considerably increases. At the synthesis time of 36 hm the shape of X-ray diffraction patterns undergoes no significant changes, suggesting that the crystallization of Zn-SP is complete within 24 h. The macrostructure of this material is formed by crystallites with fairly large particles connected to each other predominantly by a plane–plane motif, as indicated by considerable intensity and symmetry of basal reflections [4, 5, 14, 15].

The X-ray diffraction patterns of Mg-saponite obtained at various synthesis times are given in Fig. 3b. They show that the structure of this material is formed much more slowly than that of Zn-SP. At a reaction time of 5 h only weakly pronounced reflections (060) and (201) are detected. The diffraction pattern of Mg-SP synthesized in 36 h contains all the basal reflections characteristic of saponite [4, 14]. However, the corresponding peaks remain fairly broad, with the value of *d*(001) being greater than for Zn-SP (Fig. 3b). Further prolongation of the synthesis (to 72 h) only slightly affects the intensity and width of the X-ray peaks. It should be noted that it is almost impossible to obtain X-ray patterns for Mg-SP using nonoriented samples. This fact suggests that the macrostructure of this material is formed by small particles, the majority of which are connected to each other by a plane–facet or facet–facet motif [4]. Such a structure is called "house of cards" or delaminated [2, 16]; its formation was noted earlier in the case of low-temperature syntheses of others trioctahedral Mg-containing clays [15].

The capability to swell in polar media, in particular, in ethylene glycol vapor, is a characteristic feature

Pore structure parameters, elemental composition, and exchange capacity of synthetic saponite-like materials

* (τ) Synthesis time.

of smectites [1]. We found that Zn-SP samples synthesized in 3 or 24 h have this property, as seen from an increase in the size of their interlayer space Δd; in the sample prepared in 24 h, this effect is more pronounced. Among the Mg-SP materials, the swelling was detected only for samples synthesized in more than 30 h. These observations agree with the assumption that the crystallization of Zn-containing saponite is practically complete in 24 h, whereas the formation of the Mg-SP structure requires a longer time. Furthermore, the nature of the structure-forming double-charged cation appreciably affects the value of Δd. In the case of Mg-SP samples, it is greater by 0.3–0.4 nm than that in their Zn-containing analogs. This may be due to the effect of a smaller size of Mg-SP crystallites and also to weaker electrostatic interaction of its silicate layers [14]. In view of these facts, we further studied the Zn-SP samples synthesized in 12 and 24 h and the Mg-SP samples synthesized in 24, 36, and 72 h.

The isotherms of N_2 adsorption–desorption for the Zn-containing materials (Fig. 4a) can be assigned to type IV according to the IUPAC classification [17]. This is indicative of the predominantly mesoporous structure [18]. The observed shape of the hysteresis loop (mixed type H4 + H2 [17–19]) is indicative of the presence of slit- and bottle-like pores [19]. The increase in the synthesis time from 12 to 24 h only slightly affects the shape of the isotherms and the parameters of the pore structure of Zn-SP samples (see table; Fig. 4a). In the case of Mg-containing materials, these parameters, as well as the shape of the isotherms of nitrogen adsorption, strongly depend on the synthesis time (see table; Fig. 4b). The sample obtained in 24 h is mainly mesoporous (type IIb isotherm [15]). Taking into consideration the NMR and XRD data, we can explain this fact by the presence of an amorphous phase. For materials prepared in a longer time (36–72 h), the adsorption isotherms differ insignificantly, and they can be assigned to distorted type I [20], which is characteristic of microporous substances [18–20]. A narrow hysteresis loop (Fig. 4b) close to the H4 type [18] points to the presence of slit-like pores. Similar isotherms were obtained for synthetic laponite, a mineral with a delaminated structure [20]. Therefore, we can suggest that the macrostructures of Mg-SP and laponite are similar to each other, which also agrees with the above-given XRD data. Thus, we can conclude that the formation of the pore structure of Mg-containing saponite is complete in 36 h.

The nature of double-charged cations strongly affects the size and volume of pores and the specific surface area of the synthesized clays (see table). Sam-

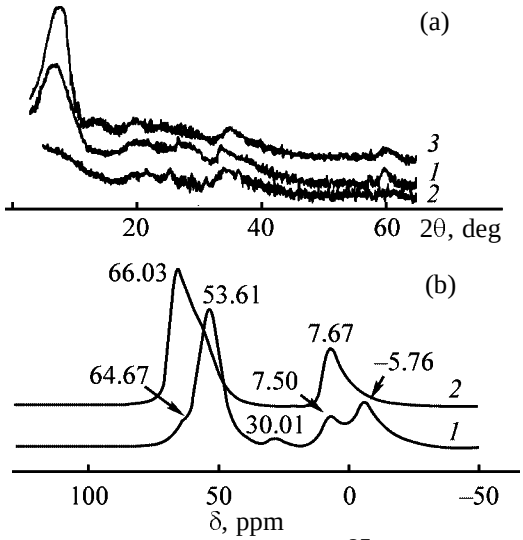

Fig. 6. (a) Diffraction patterns and (b) ^{27}Al NMR spectra of calcined samples. (2θ) Bragg's angle and (δ) chemical shift. Sample: (a) (*1, 2*) Zn-SP and (*3*) Mg-SP; (b) (*1*) Zn-SP and (*2*) Mg-SP. *T*, K: (a) (*1*) 673, (*2*) 773, and (*3*) 873; (b) (*1*) 773 and (*2*) 873.

ples of Zn-SP are mainly mesoporous, whereas Mg-containing saponite-like materials are microporous.

The IR spectra of Zn-SP and Mg-SP samples in the region of lattice vibrations are given in Fig. 5. It is seen that the nature of the structure-forming double-charged cation affects the position of the maximum of the strong band near 1020 cm^{-1} (Si–O–Al bending vibrations [13, 21]). Less intensive absorption bands at 915–920, 800–780, and 660–620 cm^{-1} are assignable to the Si(Al)–O, Si–O–Al, Al–OH–Mg, and Si–O–Mg vibrations, respectively [11, 18]. The bands of the Mg(Zn)–OH, Si–O–Mg, or Si–O–Zn vibrations (550–527 and 460–440 cm^{-1}) are also present in the IR spectra [13, 22]. All these absorption bands are characteristic of lattice vibrations of trioctahedral smectites [21, 22], including natural saponite (see spectrum of the reference sample). The chemical compositions of the synthesized materials and their cation–exchange capacities (see table) also agree with the corresponding published data for this clay mineral [14, 22].

Summarizing the data obtained, we can conclude that the optimal parameters of the Zn-SP synthesis are the time of 24 h and the urea concentration in the reaction mixture of 0.45 M, whereas for the synthesis of its Mg-containing analog these are 36 h and 0.80 M, respectively.

The thermal stability is one of the major characteristics of heterogeneous catalysts [23]. As the substances studied in this work can be potentially used in high-temperature catalytic reactions [4–8], it seemed important to study the stability of their structure at elevated temperatures. We heated the samples stepwise in an air flow in the range 298–1073 K at a rate of 5 deg min^{-1}, with keeping at selected temperatures for 18 h. The structural transformations were monitored by XRD and ^{27}Al NMR.

The results obtained are shown in Fig. 6. It is seen from the X-ray patterns (Fig. 6a) that the calcination of Zn-SP at 623 K makes its structure amorphous to a considerable extent, and at 773 K its crystallinity is virtually fully lost. The NMR spectrum appreciably changes in the process (Fig. 6b). The signal at δ = 64 ppm [Al(III)(tetr.)] becomes considerably less symmetric. The computer resolution of this signal has shown that it is a superposition of two signals with δ 62 and 56 ppm. The latter signal is assignable to the Al(III)(tetr.) resonance in an amorphous phase. Simultaneously, a weak signal appears in the NMR spectrum near 30 ppm, which is assignable to the resonance of five-coordinate Al(III) [24]. In the case of Mg-SP, the calcination at temperatures of up to 873 K does not make its structure amorphous to a noticeable extent (Fig. 6a), and the shape of the ^{27}Al NMR spectra does not change appreciably (Fig. 6b). As the temperature is increased further to 973 K, the Al(III)(tetr.) signal becomes less symmetric, suggesting partial degradation of the crystal structure. Thus, Mg-SP is more thermally stable than its Zn-containing analog. This may be due to the effect of the size of the double-charged cation forming the octahedral networks of synthetic saponite. It was

shown in the case of trioctahedral micas that the minerals containing structure-forming cations with large ionic radii have a lower thermal stability [25].

It should be specially noted that the temperatures at which the structures of the synthesized materials degrade are higher than those known for natural saponites. This fact once again demonstrates prospects for using synthetic clays as heterogeneous catalysts.

CONCLUSIONS

(1) Experiments on optimization of the conditions for preparing of Zn- and Mg-containing synthetic analogs of natural trioctahedral smectite (saponite) under conditions of nonhydrothermal synthesis showed that the preferential localization of Al(III) cations in the tetrahedral networks of these materials is possible only at the atomic ratios Si(IV)/Al(III) ≥12.

(2) The rate of formation of the structure of M(II)-containing synthetic saponites [the process is complete in 24 h for Zn(II) and 36 h for Mg(II)], the parameters of their pore structure, and the macrostructure and thermal stability depend on the nature of the structure-forming cation [Zn(II) or Mg(II)]. Synthetic Mg-saponite has a large specific surface area (650 $m^2 g^{-1}$) and a high thermal stability (up to 973 K).

ACKNOWLEDGMENTS

The authors are grateful to M. Mittelmayer-Haseleger (University of Amsterdam, Netherlands) for adsorption measurements. The work was financially supported by the Ministry of Education and Science of the Ukraine (grant 0102 U 002 191), Committee for Scientific Research of Poland (KBN), and also NWO, the Netherlands (Spinoza grant).

Abstract—The burning velocity of sodium chlorate based formulations with polyethylene and kerogen under atmospheric conditions was studied in relation to composition, i.e., oxygen excess factor.

The increasing prospects for use of high-energy explosive formulations (blends) in various branches of the national economy: mining, building, metal working, and manufacture of construction materials, required enhanced safety measures (including environmental safety) in use of these formulations. A necessity has arisen for development of a procedure for calculating charges of these formulations with account of specific properties of a medium to be destroyed.

This study was devoted to development and analysis of formulations based on some widely used oxidizing agents and low-cost and readily available combustibles whose burning occurs in the deflagration mode.

In the first stage, we chose a formulation based on sodium chlorate (SC) and hydrocarbons. The kinetics of burning of SC-based formulations with polyethylene (PE) or kerogene (KE) was analyzed on a laboratory setup. Our goal was to search for and develop new materials for mining of block stone (for building industry), with sparing approach to natural and artificial objects. The studies in this direction, e.g., those concerned with pastelike hydrogen peroxide [1, 2], have been limited to separate tests and are hindered now by difficulties encountered in the development of a formulation that would be stable in prolonged storage. As for blended explosives based on liquid oxygen and formulations with liquid hydrogen peroxide, their use is problematic, except in special cases, because handling them in field conditions is complicated and dangerous. Use of standard explosives based on chlorates and perchlorates [3] is undesirable because of the detonation mode of their physicochemical conversion [4]. Detonation leads to cracking and microcracking both in a block being separated and in the solid rock, which makes the yield of the finished product lower, and the time during which a deposit can be in service, shorter [4]. According to preliminary data, the necessary requirements can be satisfied by a formulation based on SC and hydrocarbons, placed in a special gas generator [5, 6]. In energy-related parameters, the formulations proposed are somewhat inferior (by $5 \pm 15\%$) to those based on hydrogen peroxide. The environmental impact of formulations of this kind exceeds that of peroxide formulations only slightly.

The aim of this study was to determine the burning rate of formulations based on SC (which is the most accessible and cheap among chlorates and perchlorates) and hydrocarbons under atmospheric conditions as a preliminary stage of works necessary for their industrial implementation.

EXPERIMENTAL

In an experimental study of the burning of an SC formulation with combustibles, the rates of burning and weight change were determined in order to analyze the manner in which the solid residue of burning products moves away from the flame zone. The combustion time of a formulation was measured on a setup similar to that described previously in [1], between two reference points spaced by $l = 55$ mm (determined when mounting the contacts). In this case, the measuring system included two electric circuits with a single dc power source ($V = 5$ V) connected to an electrically conducting casing. Each circuit had an electric contact introduced through an insulating ceramic channel to within the casing. The instants of time at which the combustion surface passed through the reference points were recorded as successive closures of contacts in two electric circuits connected to an S9-8 digital storage oscilloscope. Another setup was used to determine qualitatively how the formulation weight

1070-4272/03/7605-0706$25.00

changes in the course of burning: whether the burning rate varies with time and, if so, whether it decreases or increases as the formulation burns out. The setup was constituted by VLK-500 g electromechanical balance with an inductive displacement sensor attached to the balance beam. The tests were performed under atmospheric pressure at ambient temperature. The combustible formulation included SC oxidant of 50–150-μm fraction (50% 25–65-μm fraction) and PE of 10–180-μm fraction (71% 15–65-μ fraction) or KE of 20–150-μm fraction. Several experiments were performed with addition of Al powder of 10–25-μm fraction to make higher the energy released in the process. In each run, the SC weight was varied within the range 57–82 g. A preliminarily interspersed mixture of SC and PE (KE) of required (as regards the oxidant excess factor) composition was charged to a height of 80 mm into the experimental vessel (l = 30 mm) made of Cr18Ni9Ti steel, and the weights of the vessel and charge were measured. The scatter in bulk density did not exceed 7% for the oxidant excess factor equal to unity, and 4% otherwise. The fuel formulation was ignited in both setups with a 1-g weighed portion of the PTT paste, using a Nichrome coil (V = 12 V, R = 1 Ω). To obtain more reliable results, all the tests were replicated at least twice. The linear burning velocity (mm s^{-1}) was determined as

$$U = l/t_b,$$

where l is the distance between the reference points (mm), and t_b is the time of burning of a formulation between the reference points (s).

The overall relative error in measuring the linear velocity did not exceed ±10%.

The specific mass velocity of burning, U_m (g cm^{-2} s^{-1}), was calculated by the formula

$$U_m = mh_r/(hft_b),$$

where m is the total charge of a formulation in the casing (g); h_r, the distance between the reference points, 55 mm; h, the total height (m) to which the casing is charged with a weighed portion m of a formulation; $f = 0.785d^2$, the area of the internal cross section of the casing (mm^2).

The main results obtained in studying the influence exerted by the excess of the oxidant on the linear velocity U (mm s^{-1}) of burning of a formulation are shown in Fig. 1a. The lines represent regression equations derived by polynomial processing of experimental data by the least-squares method. For formulation no. 1 (SC + PE), the following regression equation is obtained with a correlation factor R^2 = 0.950:

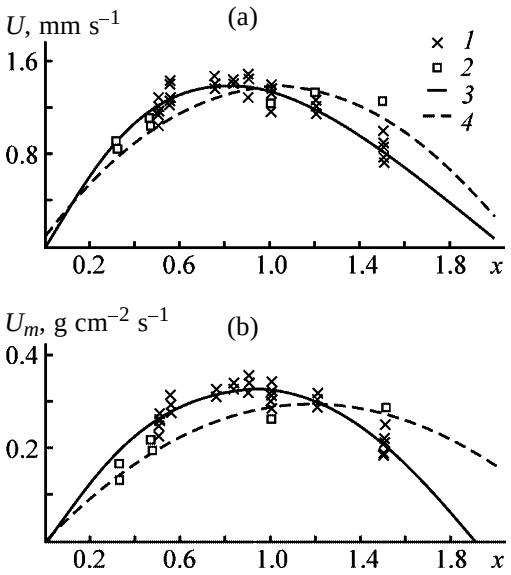

Fig. 1. (a) Linear burning velocity U and (b) U_m in relation to composition (oxidant excess factor x). Formulation: (*1*) no. 1 (SC + PE) and (*2*) no. 2 (SC + KE); (*3*, *4*) approximations for formulation nos. 1 and 2, respectively.

$$U = 0.554x^3 - 2.983x^2 + 3.797x - 0.004.$$

Consequently, the maximum linear burning velocity of the given formulation is 1.41 ± 0.01 mm s^{-1} at the oxidant excess factor x = 0.827.

For formulation no. 2 (SC + KE), the regression equation has the following form (R^2 = 0.939):

$$U = -1.206x^2 + 2.506x + 0.095.$$

The maximum linear burning velocity is 1.43 ± 0.01 mm s^{-1} at the oxidant excess factor x = 1.039.

Analysis of the data obtained shows that the maximum linear burning velocity of formulation no. 2 virtually coincides with the velocity for the stoichiometric composition, whereas for formulation no. 2 the maximum in velocity is shifted toward an excess of the combustible. Introduction into the formulations of 3 g of powdered aluminum (oxidant excess factor x = 0.93) leads to an increase in the linear burning velocity to (3.77–4.09) ± 0.01 mm s^{-1} for formulation no. 1 and to 2.17 ± 0.01 mm s^{-1} for formulation no. 2. The effect of aluminum on the burning velocity is particularly pronounced for formulation no. 1. Figure 1b shows the main results obtained in studying how the formulation composition (oxidant excess) affects the

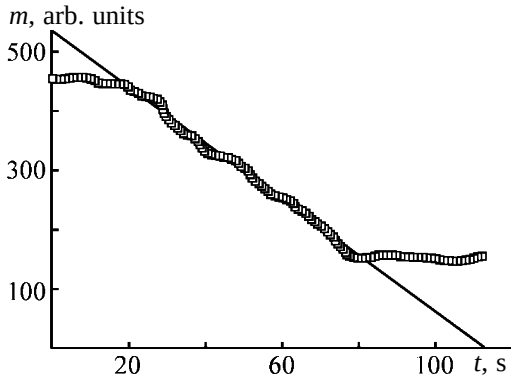

Fig. 2. Variation of the weight m of a formulation in the course of its burning-out. (t) Time. Points, experimental data; straight line, approximation.

specific mass velocity of burning, U_m (g cm^{-2} s^{-1}). The interest in this parameter can be accounted for by the fact that the rate of pressure build-up in the volume is determined just by the mass of substance burnt-out in unit time, whereas the linear burning velocity is only necessary for assessment of the mode of conversion, by deflagration or detonation. Similar processing yields the following results. For formulation no. 1 (R^2 = 0.956)

$$U_m = 0.036x^3 - 0.466x^2 + 0.761x - 0.001.$$

The maximum specific mass burning velocity, which is achieved at oxidant excess factor x = 0.913, is 0.33 ± 0.01 g cm^{-2} s^{-1}. For formulation no. 2 (R^2 = 0.821), the following dependence was obtained:

$$U_m = -0.203x^2 + 0.485x + 0.009.$$

In this case, the maximum specific burning velocity, equal to 0.30 ± 0.01 g cm^{-2} s^{-1}, is achieved at oxidant excess factor x = 1.195. Addition of aluminum to the formulations also increased the specific mass burning velocities: to (0.59–0.64) ± 0.01 g cm^{-2} s^{-1} for formulation no. 1 and to 0.34 ± 0.01 g cm^{-2} s^{-1} for formulation no. 2. Analysis of the dependences obtained shows that the maxima of specific mass burning velocities are shifted to higher oxidant excess factors, compared to the maxima of linear burning velocities.

Among the experimental results not represented in the plots, the following are worth mentioning. According to preliminary thermodynamic calculations, the burning products of the formulations under consideration contain a substantial amount of NaCl with the melting point of 1073 K and boiling point of 1713 K. For the oxidant excess factors in the interval of interest, the process temperature falls within the range 2370–3470 K. Thus, NaCl is in the gaseous state at the combustion front. Away from the front, the salt condenses, because of heat losses, either at a large distance from the front, within the flow, or at casing walls. This is manifested both in the manner in which the burning products outflow from the cylinder and in salt deposits on the inner surface of the cylinder. For example, at oxidant excess factor less than unity ($0.4 < x < 0.75$) the salt was carried by flame away from the reaction zone, the casing was heated to bright red, and no salt deposits were found on the inner surface of the cylinder after burning terminated. With the oxidant concentration increasing further, up to unity, the casing color changed, despite that the process temperature reached a maximum (3470 K), to dull cherry, instead of the expected bright white, and a 0.5–1.5-mm-thick salt deposit appeared on the inner surface of the cylinder. Larger, than before, drops of molten salt were observed in the flame trail. At oxidant excess factor of 1.5, the casing ceased to glow during burning, the salt layer became as thick as 2–8 mm, and molten salt was ejected from the cylinder as lava from a volcanic pipe (in the form of large conglomerates). In view of these specific features of the burning process under study, we studied the manner in which the weight of a formulation charged into the cylinder changes during burning. Figure 2 shows how the formulation weight (in arbitrary units) varies with time. Analysis of this dependence shows that the formulation burns out at a virtually constant rate, with the exception of transient processes at the beginning and end of burning. Only slight fluctuations of the burning rate are observed near the mean value which can be determined from the process equation (correlation factor R^2 = 0.989):

$$Y = -4.734t + 536,$$

where Y is weight (arb. units), and t is time (s).

Seemingly, when using the given technique, account should be taken of the influence exerted by the reactive force created by gases outflowing from the reaction zone. This force is proportional to the dynamic pressure created by the outflowing gases and to the flow cross-section area. However, since the dynamic pressure does not exceed 90 mm Hg even for mercury fulminate $Hg(CNO)_2 \cdot 1/2H_2O$ (mass burning velocity 5.9 g cm^{-2} s^{-1} according to data obtained by A.F. Belyaev), the influence of the reactive force can be neglected for the formulations studied.

Full-scale tests of the formulations under study (SC + PE) under the standard conditions demonstrated

complete absence of detonation and improvement of the quality of stone blocks.

CONCLUSIONS

(1) The dependence of the burning velocity of formulations based on sodium chlorate and polyethylene or kerogen under atmospheric conditions was analyzed in the preliminary stage of the study in relation to the oxidant-to-combustible ratio at oxidant excess factor varying from 0.37 to 1.5.

(2) The burning velocity depends on the composition of the formulations studied and reaches a maximum at nearly stoichiometric compositions at an excess of the combustible for sodium chlorate with polyethylene, and at an excess of oxidant for sodium chlorate with kerogen.

(3) The maximum burning velocities (linear and mass), which are virtually the same for the formulations studied, do not exceed 1.5 mm s^{-1} and 0.4 g cm^{-2} s^{-1}, respectively.

(4) In the composition range studied, the formulations burn out at a constant rate.

(5) Introduction of 3–5% aluminum into a combustible formulation raises the burning velocity by approximately a factor of 2 for the formulation composed of sodium chlorate and polyethylene and by about 12–20% for the formulation with sodium chlorate and kerogen.

(6) Full-scale tests carried out in block stone mining show that the formulations proposed are efficient and promising.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Activity of Components in Surface Layer of Chloride–Fluoride Mutual Melts

B. V. Patrov

St. Petersburg State Technical University, St. Petersburg, Russia

Received February 5, 2002; in final form, February 2003

Abstract—The activities of components in the bulk and surface layer of melts of chloride–fluoride ternary mutual systems were calculated in the framework of the regular solution model using surface tension values and considering the surface layer is a separate phase.

Study of the surface tension of chloride–fluoride melts is of theoretical and practical significance, because they can be used in electroslag remelting as flux and for welding of nonferrous metals. Determination of the activity of melt components is of great importance for thermodynamic calculations of salt systems [1]. The most widely used method in studying the metallurgical systems is the model of regular solutions.

A calculation of the component activity for mutual melts from experimental surface tension values has been described previously [2]. For the exchange reaction MA + NB = NA + MB, the diagonal MA–NB is stable at $\Delta G_T^0 > 0$. The mole fractions x and $(1 - x)$ of substances MA and NB in the initial mixture become $(x - y)$ and $(1 - x - y)$ in the equilibrium mixture, i.e., become lower by the value of y equal to the mole fraction of the reaction products. Within the framework of the regular solution model [3, 4], we can write

$$\ln\gamma_1 = A(1 - x - y)^2/RT, \quad (1)$$

$$\ln\gamma_2 = A(x - y)^2/RT, \quad (2)$$

where γ_1 and γ_2 are the activity coefficients of components MA and NB belonging to the stable diagonal; A is the interaction parameter determined from comparison of the experimental and calculated phase diagrams [4].

Because the concentration of the components belonging to the unstable diagonal did not exceed 6 mol %, their activities a_{NA} and a_{MB} were assumed equal to the mole fraction y. The latter was derived from the equation for the equilibrium constant of exchange reaction:

$$K_a = y^2\{(x - y)\exp[A(1 - x - y)^2/RT](1 - x - y) \times \exp[A(x - y)^2/RT]\}^{-1}. \quad (3)$$

The interaction parameter A was determined from experimental data on the surface tension described by the Burylev equation [5] for regular solutions

$$\sigma = \sigma_1 x_1 + \sigma_2 x_2 + Cx_1x_2, \quad (4)$$

where x_1 and x_2 are the mole fractions of components MA and NB ($x_1 = x$, $x_2 = 1 - x$), and σ_1 and σ_2 are the surface tensions of these components comprising a mixture, the calculated surface tension of which σ was compared with the experimental value for the mutual system.

The constant C includes the mutual exchange energy [5] and is related to the interaction parameter A from Eqs. (1) and (2). To find A, it is sufficient to multiply C by the molar surface area:

$$A = C\omega, \quad (5)$$

where $\omega = V_m^{2/3}N^{1/3}$, and N is the Avogadro number.

To a first approximation, the molar volume of the mixture is calculated by the additivity equation $V_m = xV_{MA} + (1 - x)V_{NB}$, and more exactly it is calculated from the equation

$$V_m = (x - y)V_{MA} + (1 - x - y)V_{NB} + yV_{NA} + yV_{MB}.$$

The necessary data on the density of components involved in the exchange were taken from [6].

Comparison of the component activities in LiF–NaCl and LiF–KCl systems, calculated by the Fellner

1070-4272/03/7605-0710$25.00

procedure [4] and by the method proposed, showed that the maximal difference is 0.008 at the mole fraction $x = 0.5$ and does not exceed 2%, i.e., both methods yield the similar values. Consequently, the proposed calculation method using surface tension gives reliable data on the component activity in ternary mutual systems.

From the condition [7] for equilibrium of a component in solution surface layer and bulk,

$$\mu_i^\omega - \mu_i = \sigma\omega_i, \quad (6)$$

we obtain the expression for the binary solution at the equal molar surface areas:

$$\sigma = \sigma_1 + \frac{RT}{\omega}\ln(a_1^\omega/a_1) = \sigma_2 + \frac{RT}{\omega}\ln(a_2^\omega/a_2). \quad (7)$$

This equation yields the component activities in the surface layer of mutual melts:

$$\ln a_1^\omega = \frac{\sigma - \sigma_1}{RT}\omega + \ln a_1, \quad (8)$$

$$\ln a_2^\omega = \frac{\sigma - \sigma_2}{RT}\omega + \ln a_2. \quad (9)$$

The component activities a_1 and a_2 of the systems studied have been reported elsewhere [2, 8, 9]. Assumption is made that the melt surface layer, like bulk, is a regular solution. For regular solutions, the activity coefficients of components belonging to the stable diagonal in the surface layer are as follows:

$$\ln\gamma_1^\omega = A(a_2^\omega)^2/[RT(\gamma_2^\omega)^2], \quad (10)$$

$$\gamma_2^\omega = \exp\{A(a_1^\omega)^2/[RT(\gamma_1^\omega)^2]\}, \quad (11)$$

where A is the interaction parameter determined from the experimental data on the surface tension described by the Burylev equation [5].

Substitution in Eq. (10) of the expression for the activity coefficient of the second component in the surface layer gives

$$\ln\gamma_1^\omega = \frac{A}{RT}\frac{(a_2^\omega)^2}{\{\exp[A(a_1^\omega)^2] - \exp[RT(\gamma_1^\omega)^2]\}^2}. \quad (12)$$

Thus, the activity coefficients in the surface layer of the components belonging to the stable diagonal are calculated by Eqs. (10) and (12), and the mole fractions, by the equations

$$x_1^\omega = a_1^\omega/\gamma_1^\omega, \; x_2^\omega = a_2^\omega/\gamma_2^\omega. \quad (13)$$

The data obtained on the component activity should be discussed taking into account the Gibbs energy of the exchange reactions. In the series of the KF–CsCl, NaF–CsCl, and LiF–CsCl systems, with increasing Gibbs energy, a eutectic phase diagram of the stable diagonal changes to a singular phase diagram with separation [8, 9]. In this series of systems comprising different fluorides and the same chloride, the cesium chloride surface activity increased simultaneously. It is noteworthy that the cesium chloride activity in the surface layer of the systems studied appeared to be equal to the mole fraction: $a_2^{\omega} \sim x_2^{\omega}$. This is clearly illustrated by the $a_2^{\omega} = f(x_2)$ and $x_2^{\omega} = f(x_2)$ plots for the KF–CsCl system in which the difference between the activities and mole fractions was the largest (Fig. 1). The activity of lithium, sodium, and potassium fluorides was also equal to the mole fraction, but at a high mole fraction of fluorides (higher than 0.5). At a lower content of fluorides, the difference between the activity and mole fraction in the surface layer ranged from 0.02 to 0.04.

The second group of chloride–fluoride mutual systems included the LiF–NaCl, LiF–KCl, and NaF–KCl systems characterized by the following values of the Gibbs energy, constant of the Burylev equation, molar surface area, and interaction parameter:

System	T, K	ΔG_T^0, J	$-C$, mJ m^{-2}	ω, m^2 mol^{-1}	$-A$, J mol^{-1}
LiF–NaCl	1123	52 109	95	72 189	6858
LiF–KCl	1123	65 392	212	86 877	18 418
NaF–KCl	1173	24 933	113	86 896	9819

With respect to the Gibbs energy, the systems of this group can be presented as a series LiF–NaCl, LiF–KCl, LiF–CsCl, with the same fluoride (LiF) and different chlorides. However, the LiF–CsCl system was considered within the first group. Replacement of this system by the system NaF–KCl should not affect the eutectic phase diagrams of the stable diagonal [10]. The calculated component activities in the surface layer of the melts are presented in Table 2.

As seen, the general conclusions made for the systems of the first group are also true for the systems of the second group. For example, the activity of chlorides in the surface layer is virtually equal to the mole fraction. The activity of fluorides is equal to the mole fraction when their content x_1^{ω} is higher than 0.6, with the activity coefficient γ_1^{ω} of fluorides exceeding 0.9.

Consequently, Eq. (7) for the surface-active com-

ponents, i.e., chlorides, takes the form

$$\sigma = \sigma_2 + \frac{RT}{\omega}\ln(x_2^{\omega}/a_2). \quad (14)$$

For the surface-inactive components, i.e., fluorides, in the concentration range x_1 = 0.5–1, this equation becomes

$$\sigma = \sigma_1 + \frac{RT}{\omega}\ln(x_1^{\omega}/a_1). \quad (15)$$

CONCLUSION

The equations were obtained for calculating the surface tension of mutual chloride–fluoride systems as a function of the concentration of fluorides and chlorides in the surface layer.

Abstract—The temperature dependences of the saturated vapor pressure, the enthalpies of vaporization, standard boiling points, enthalpies, entropies, Gibbs energies, and component activities were calculated for liquid alloys of the copper–zinc system from the measured boiling points at various pressures. The calculation results were compared with the previous data obtained for this system by other methods.

Data on the copper–zinc system are important for production of copper–nickel alloys. It was of interest to compare the thermodynamic characteristics obtained by different methods. Data on thermodynamic properties of solutions can be obtained directly from the generalized Raoult equation if data on the vapor phase composition are available. One of versions of this method is the method of boiling points, which allows all thermodynamic functions of binary systems to be obtained for a wide range of temperatures and concentrations [1].

Based on reference data [2] and on the enthalpies and entropies of vaporization, we obtained the dependences of the saturated vapor pressure P_i^0 (Pa) of a pure liquid component i (i = Zn or Cu) on temperature T (K):

$$\log P_{Zn}^0 = -(6024/T) + 10.114, \quad (1)$$

$$\log P_{Cu}^0 = -(15\,760/T) + 10.601. \quad (2)$$

The similar dependences can be obtained from experimental data of [3, 4]:

$$\log P_{Zn}^0 = -(5962/T) + 10.074, \quad (3)$$

$$\log P_{Cu}^0 = -(15\,870/T) + 10.445. \quad (4)$$

The results of calculation of the saturated vapor pressure P_i^0 (kPa) for a pure component i (i = Zn, Cu) by Eqs. (1)–(4) at various temperatures T (K) are given in Table 1.

The saturated vapor pressure of zinc calculated by Eqs. (1) and (3) are virtually the same, whereas those for copper differ appreciably. However, this is of no importance, because, according to [2], the ideal separation coefficient

$$\alpha = P_{Zn}^0/P_{Cu}^0 \quad (5)$$

in the temperature range 1323–1523 K varies from 7.5×10^6 to 0.8×10^6, i.e., zinc vaporizes from copper–zinc alloys predominantly.

The saturated vapor pressures of copper calculated from data of [4–13] for a wider temperature range (up to 1973 K) are presented in Table 2.

It is seen that the vapor pressures calculated from data in [6] and, to a lesser extent, from data in [5, 7] exceed the values calculated from data in the other works. At the same time, all data unambiguously show that the saturated vapor pressure of zinc exceeds that of copper by several orders of magnitude.

The boiling points in the Cu–Zn system at different

pressures, as calculated from data of [14], are presented in Table 3.

The experimental data were treated by the least-square method at the confidence level $p = 0.95$ using the equation

$$\log P = -\frac{a \pm \Delta a}{T} + b \pm \Delta b, \quad (6)$$

where P is the saturated vapor pressure (Pa), T is temperature (K), a and b are the constants determined from experimental data, and Δa, Δb, the confidence intervals.

The experimental data of [14] and the results of calculation by Eq. (6) are plotted in Fig. 1. The calculated values of the constants are given in Table 4.

According to [2], the standard boiling point of zinc is 1179.35 K. The value from Table 4 is 1178 K. The enthalpy of vaporization of 115.31 ± 0.42 kJ mol^{-1} [2] is higher by 1.4% than that in Table 4.

Using data of Table 4 and in accordance with the generalized Raoult equation, we determined the zinc activities:

$$a_{Zn} = P_{Zn}/P^0_{Zn} \quad (7)$$

or

$$\log a_{Zn} = \log P_{Zn} - \log P^0_{Zn}. \quad (8)$$

For different compositions we obtained the equation

$$\log a_{Zn} = -A/T + B, \quad (9)$$

The enthalpy of vaporization ΔH_{vap} calculated by the equation from [15], and also the entropy of vaporization ΔS_{vap} and the standard boiling point T_{sb} determined from relations (10)–(12) are given in Table 4.

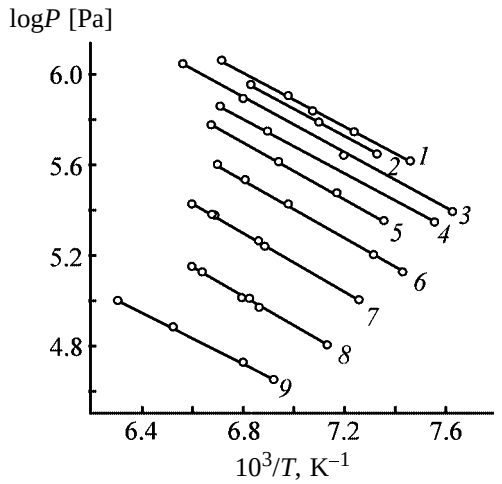

Fig. 1. Logarithm of the saturated vapor pressure P vs. reciprocal temperature $1/T$ for various compositions of the Cu–Zn system. (*1–9*) Calculation by Eq. (6) (line nos. are system nos. in Table 3); (points) experimental data [14].

$$\Delta H_{vap} = 19.14a, \quad (10)$$

$$\Delta S_{vap} = 19.14(b - 5.006), \quad (11)$$

$$T_{sb} = a/(b - 5.006). \quad (12)$$

The partial molar enthalpy of mixing of zinc $\Delta\bar{H}_{Zn}$ was determined from the expression

$$\Delta\bar{H}_{Zn} = \Delta H^0_{Zn} - \Delta H^s_{Zn}, \quad (13)$$

where ΔH^0_{Zn} is the enthalpy of vaporization of pure zinc and ΔH^s_{Zn}, the enthalpy of zinc vaporization from a solution of a given composition.

The values of $\Delta\bar{H}_{Zn}$ (J mol^{-1}) at 1450 K, obtained using data of Table 4, are as follows:

x_{Zn}, mol %	$-\Delta\bar{H}_{Zn}$	x_{Zn}, mol %	$-\Delta\bar{H}_{Zn}$
0.900	190	0.502	5610
0.7955	140	0.384	10 990
0.681	860	0.278	18 140
0.589	2930	0.1825	22 320

By integrating the Gibbs–Duhem equation, we can determine the partial molar enthalpy of mixing of copper $\Delta\bar{H}_{Cu}$ and then the enthalpy of mixing

$$\Delta H_m = \Delta\bar{H}_{Zn}x_{Zn} + \Delta\bar{H}_{Cu}x_{Cu}. \quad (14)$$

At the same time, the concentration dependence of $\Delta\bar{H}_{Zn}$ can be fitted by an interpolating polynomial [15]

$$-\frac{\Delta\bar{H}_{Zn}}{(1 - x_{Zn})^2} = a + b(1 - x_{Zn}) + c(1 - x_{Zn})^2, \quad (15)$$

in which $a = 15.117$, $b = -14.105$, and $c = 56.523$.

The results of the comparison are shown in Fig. 2.

Since an increase in the number of terms in interpolating polynomial (15) does not improve fitting to experimental data, we use the binomial equations given in [16] and taking into account the energy nonadditivity in a binary solution:

$$\Delta\bar{H}_1 = (Q_1 - Q_2)(1 - x_1)^2 + 2Q_2(1 - x_1)^3, \quad (16)$$

$$\Delta\bar{H}_2 = (Q_1 + 2Q_2)(1 - x_2)^2 + 2Q_2(1 - x_2)^3. \quad (17)$$

It follows from the dependence of $\Delta\bar{H}_{Zn}/(1 - x_{Zn})^2$ on $(1 - x_{Zn})$ (Fig. 3) that

$$\Delta\bar{H}_{Zn} = 5000(1 - x_{Zn})^2 - 55\,000(1 - x_{Zn}), \quad (18)$$

$$Q_1 = -50\,000 \text{ and } Q_2 = 27\,500 \text{ J mol}^{-1}.$$

The results of the calculations by formulas (15) and (18) are plotted in Fig. 2.

For the enthalpy of mixing, we obtain the expression

$$\Delta H_m = Q_1x_1x_2 + Q_2x_1x_2^2 = -50\,000x_{Cu}x_{Zn} + 27\,500\,x_{Cu}x_{Zn}^2. \quad (19)$$

Below we present the concentration dependence of the enthalpy of mixing ΔH_m (J mol^{-1}):

x_{Zn}	$-\Delta H_m$	x_{Zn}	$-\Delta H_m$
0.1	4252	0.6	8040
0.2	7120	0.7	6458
0.3	8768	0.8	4920
0.4	9360	0.9	2273
0.5	9062		

The data presented show the dependence to be asymmetrical, with the extremum at $x_{Zn} = 0.435$. The negative asymmetric deviations in this system were also observed in [17].

From data of Table 4 and the equation

$$\Delta\bar{S}_{Zn} = \Delta S^0_{Zn} - \Delta S^s_{Zn}, \quad (20)$$

the partial molar entropy of mixing of zinc $\Delta\bar{S}_{Zn}$ (J mol^{-1} K^{-1}) at 1450 K was found for various compositions as the difference between the entropies of vaporization of pure zinc, ΔS^0_{Zn}, and of zinc from a solution, ΔS^s_{Zn}:

x_{Zn}	$\Delta\bar{S}_{Zn}$	x_{Zn}	$\Delta\bar{S}_{Zn}$
0.90	0.037	0.502	0.2702
0.7955	0.1086	0.384	0.3123
0.681	0.1739	0.278	0.3525
0.589	0.2043	0.1825	0.5066

The results obtained can be approximated at 1450 K by the equation

$$\frac{\Delta\bar{S}_{Zn}}{(1 - x_{Zn})^2} = 4.7071 - 11.8240(1 - x_{Zn}) + 8.6535(1 - x_{Zn})^2. \quad (21)$$

The results are compared in Fig. 4.

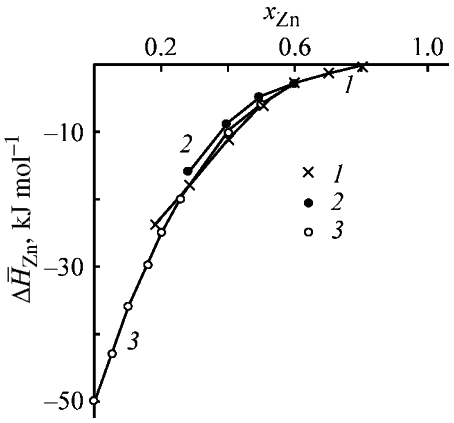

Fig. 2. Partial molar enthalpy of mixing of zinc $\bar{H}_{Zn}$ vs. zinc mole fraction x_{Zn}: (*1*) experimental data and (*2*, *3*) calculations by Eqs. (15) and (18), respectively.

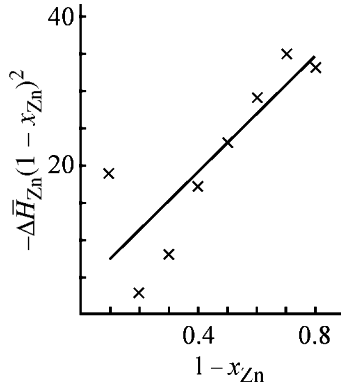

Fig. 3. Plot of $\Delta\bar{H}_{Zn}/(1 - x_{Zn})^2$ vs. $(1 - x_{Zn})$ at 1450 K. (Points) experimental data.

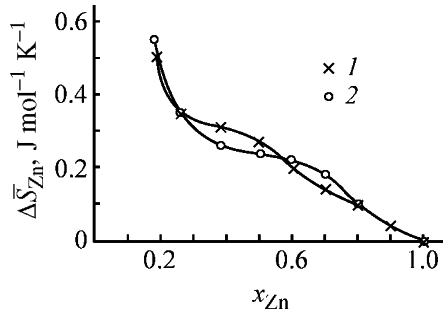

Fig. 4. Partial molar entropy of mixing of zinc $\Delta\bar{S}_{Zn}$ vs. zinc mole fraction x_{Zn}: (*1*) experimental data and (*2*) calculation by Eq. (21).

The Gibbs energy can be determined from the relationship

$$\Delta G^{ex} = \Delta H_m - T\Delta S^{ex}. \quad (22)$$

From the experimental data of [18], an expression for the activity coefficient of zinc f_{Zn} at 1200 K can be derived:

$$\frac{\ln f_{Zn}}{(1 - x_{Zn})^2} = (5.25 \pm 0.57)(1 - x_{Zn}) + (1.33 \pm 0.28). \quad (23)$$

It is recommended in a review [19] to determine f_{Zn} from the equation

$$RT \ln f_{Zn} = Q(1 - x_{Zn})^2, \quad (24)$$

where $Q = -27\,000$ J mol^{-1}, in good agreement with the results of [3].

The negative deviations from ideality were shown in [20, 21]. In [22, 23], the Krupkowski equation was used to describe the concentration dependence of the activity, and negative deviations from ideal solutions in the given system were observed.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Chlorobenzene on γ-Al_2O_3 Obtained by Calcination of Boehmite at Various Temperatures

L. D. Asnin and A. A. Fedorov

Institute of Technical Chemistry, Ural Division, Russian Academy of Sciences, Perm, Russia

Received July 22, 2002

Abstract—The influence exerted by the temperature of boehmite calcination in air within the range 450–600°C on the adsorption properties of the resulting γ-Al_2O_3 with respect to chlorobenzene was studied.

γ-Al_2O_3 is frequently used as support for catalysts for deep oxidation of chlorobenzene [1–4]. The concentration of surface OH groups, which largely determines the sorption properties of a support, may vary widely with synthesis and working temperatures of these catalysts (these temperatures are limited to the existence range of the γ phase, up to 900°C [5, 6]). The influence exerted by the concentration of surface OH groups on the sorption characteristics of oxide supports has been studied extensively [7–12]. For example, it is known that step-by-step removal of chemisorbed water from the Al_2O_3 surface leads to an increase in its hydrophilicity [11]. By contrast, it has been established for the example of ZnO that the heat of adsorption of benzene, toluene, and chlorobenzene decreases with decreasing number of surface OH groups [12]. A similar pattern has been observed for silica gel [13]. Presumably, such a behavior will be observed for aromatic compounds on oxides of other elements (Al, Ti). Kiselev and Lygin [3] attributed this to a decrease in the number of surface OH groups interacting with the aromatic ring. Nagao *et al*. [10, 12] pointed to a decreasing probability of two-center adsorption of chlorobenzene on the dehydroxylated surface of oxides.

Less unambiguous is the influence exerted on the sorption capacity of oxide supports by dehydration. This is so because the calcination conditions affect not only the content of structural water, but also the support texture. However, a general pattern can be revealed in this case also. For example, it was shown in [9, 10] that the fraction of aromatic compounds irreversibly sorbed on TiO_2 and ZnO is the lowest for hydrated oxides and increases for dehydrated oxides. A detailed study of the influence exerted by conditions of thermal treatment of aluminum hydroxides on the texture characteristics of the oxides obtained was reported in [14].

Thus, some aspects of the influence of calcination temperature T_{cal} on the adsorption properties of aluminum oxide can be predicted qualitatively. It is of interest to evaluate the extent of this influence on the chlorobenzene adsorption. The present study is concerned with chlorobenzene adsorption on γ-Al_2O_3 samples obtained by calcination of boehmite at 450 (OA1) and 600°C (OA2) in air for 5 h.

EXPERIMENTAL

The boehmite used to obtain aluminum oxide was synthesized by a procedure described in [15]. The phase composition of the samples was determined by X-ray phase analysis on a DRON-2 diffractometer. Adsorption isotherms were measured chromatographically [13] in the temperature range 190–300°C; the apparatus used and experimental conditions were described in [15]. The same equipment was used to determine by the method of frontal chromatography the sorption capacity of the samples for chlorobenzene at 50 and 100°C. The working gas-and-vapor mixture was prepared by saturating the carrier gas (nitrogen, flow rate 25 $cm^3\ min^{-1}$) with chlorobenzene vapor in a glass saturator with constant evaporation area at room temperature (vapor concentration 43–46 $\mu g\ cm^{-3}$). The dead time was determined for methane. The specific surface area S_{sp} of the samples was found by the method of thermal desorption of nitrogen, and the content of structural water, by calcination at 1000°C of samples preliminarily dried at 300°C. The pore volume V_p was found from the weight gain of samples after their saturation with benzene vapor in a desiccator at room temperature. The characteristics of the samples are listed in Table 1.

1070-4272/03/7605-0719$25.00

Table 1. Characteristics of γ-Al_2O_3 samples

Sample	T_{cal}, °C	S_{sp}, $m^2\ g^{-1}$	V_p, $cm^3\ g^{-1}$	n
OA1	450	160	1.07	0.18
OA2	600	150	0.86	0.10

* (n) Number of water molecules per Al_2O_3 formula unit.

Table 2. Sorption capacity of γ-Al_2O_3 samples

Sample	T = 50°C			T = 100°C		
	SC, $g\ g^{-1}$	SC', $g\ m^{-2}$	θ	SC, $g\ g^{-1}$	SC', $g\ m^{-2}$	θ
OA1	0.086	0.00054	1.3	0.028	0.00018	0.45
OA2	0.079	0.00053	1.3	0.022	0.00015	0.36

Both samples studied give similar X-ray diffraction patterns, which are characteristic of γ-Al_2O_3. The specific surface areas of the samples are about the same, in agreement with the data of [14]; a more pronounced difference is observed in the pore volumes. The samples differ strongly in the content of structural water. If it is assumed that the whole amount of water is present on the surface as OH groups (as demonstrated by recent measurements by Simonova *et al.* [16], no more than 5% of OH groups in γ-Al_2O_3 calcined at 600°C belong to intraglobular water), then the density of surface OH groups is 13.2 and 7.8 OH groups per 1 nm^2 for samples OA1 and OA2, respectively.

Table 2 lists the values of static sorption capacity per unit weight (SC) and unit surface area (SC') of the samples. The isotherms of chlorobenzene adsorption on sample OA1 were presented in [15], and those for sample OA2 are shown in Fig. 1. In all cases, the experimental data are described satisfactorily by Freundlich's adsorption isotherm equation (correlation coefficient ≥0.998).

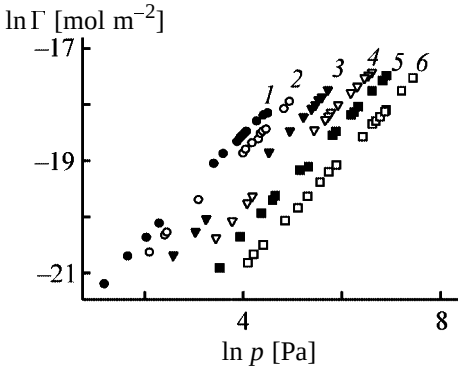

Fig. 1. Isotherms of chlorobenzene adsorption on OA2 sample. (Γ) Adsorption and (p) partial pressure of adsorbate. Adsorption temperature (°C): (*1*) 190, (*2*) 200, (*3*) 220, (*4*) 240, (*5*) 260, and (*6*) 300. Error in determining Γ and p does not exceed 7%.

The isotherms of chlorobenzene adsorption on sample OA1 lie above those for sample OA2, with the curves converging with increasing temperature. The difference in specific sorption activity between the samples at low surface fillings ($\theta \approx 10^{-4}$–10^{-3}) results from the difference in the concentration and, possibly, features of the surface OH groups. In the saturation region, these differences become insignificant, since the entire surface is involved in the adsorption process in this case. This is also confirmed by the fact that the specific surface sorption capacities are close for both samples at 50°C ($\theta > 1$). At 100°C the fraction of "working" surface area is lower ($\theta < 0.5$), and SC' is somewhat higher for sample OA1.

The isosteric heats of chlorobenzene adsorption, q_{st} (Fig. 2), were calculated from the equilibrium adsorption data obtained by the known method (by plotting adsorption isosteres) [13].

The isosteric heats of adsorption of both benzene and chlorobenzene on OA2 are somewhat lower than the respective values for OA1. Apparently, this is due to lower degree of hydration of sample OA2; a similar effect was observed on Si and Zn oxides. Commonly, it is attributed to lower probability of formation of a hydrogen bond between protons of OH groups and the aromatic molecule on a dehydrated oxide. Estimation of the upper limit of the number of OH groups per molecular area of chlorobenzene (0.465 nm^2 [10]) gives 6 and 3–4 OH groups for samples OA1 and OA2, respectively. Thus, multicenter adsorption is possible on the hydrated oxide. The involvement of several OH groups in benzene adsorption on silica gel was reported by Kiselev and Lygin [8]. A strong two-center interaction of chlorobenzene with the surface of hydrated Ti and Zn oxides through formation of hydrogen bonds OH···π electrons of the aromatic ring and OH···Cl was observed in [9, 10, 12]. The lower concentration of surface OH groups on OA2 decreases the probability of two-center adsorption and makes unlikely fixation of a chlorobenzene molecule on more than two surface centers. It is also known for the example of silica gel that, in the first place, calcination removes closely arranged OH groups, i.e., potential centers of multicenter adsorption are destroyed.

The centers present on the surface of aluminum

oxide include, in addition to OH groups (Brønsted centers), also Lewis acid and base centers, Al^{3+} cations and O^{2-} anions of varied coordination, which belong to the crystal lattice of the oxide [5, 17]. These centers will also take part in the formation of the common electrostatic field of the surface; however, their contribution to nonspecific adsorption interaction will be insignificant, since they are shielded by surface OH groups and the energy of nonspecific interaction falls rapidly with increasing distance. Moreover, it may be assumed by analogy with silica gel [8] that the contribution of nonspecific interactions to the heat of adsorption will be the same on samples with different degrees of hydroxylation.

As for specific interactions of chlorobenzene with surface Lewis centers, the contribution of these interactions to the heat of adsorption must also be not too great because of the shielding effect of surface OH groups [18]. Thus, the difference between the heats of chlorobenzene adsorption on samples OA1 and OA2 is mainly associated with the difference in the degrees of surface hydroxylation.

With a knowledge of q_{st}, the differential entropy change in adsorption can be readily calculated:

$$\Delta\bar{S}^s = -q_{st}/T_{am},$$

where T_{am} is the arithmetic mean temperature of the interval studied (T_{am} = 235°C).

The model of ideal two-dimensional gas can be used to calculate the theoretical decrease in entropy in adsorption, $\Delta\bar{S}^s_{theor}$. The procedure for calculating $\Delta\bar{S}^s_{theor}$ in the case of adsorption described by Freundlich's isotherm equation was presented in [15]. Comparison of $\Delta\bar{S}^s$ and $\Delta\bar{S}^s_{theor}$ with the use of the function $D = |\Delta\bar{S}^s| - |\Delta\bar{S}^s_{theor}|$ gives certain information about the mobility of molecules in the adsorption layer [19]. The D–Γ dependences are plotted in Fig. 3, whence it can be seen that the curves describing the D–Γ functions for the samples run virtually in parallel and are similar to the corresponding q_{st}–Γ dependences. As expected, the D–Γ function is a descending function, since molecules adsorbed in the initial stage are less mobile than those adsorbed from the subsequent portions of the adsorbate. At the same time, there is no strict localization of chlorobenzene molecules on the sample surface. Indeed, a calculation of the decrease in entropy in adsorption on the assumption of three translational degrees of freedom and absence of vibrations perpendicular to the surface [20] gives for both samples a value of about 180 J mol^{-1} K^{-1}, which is independent of Γ within the experimental error.

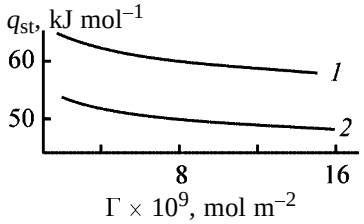

Fig. 2. Isosteric heat of chlorobenzene adsorption, q_{st}, vs. adsorption Γ for samples (*1*) OA1 and (*2*) OA2. The error in determining q_{st} does not exceed 3 kJ mol^{-1}.

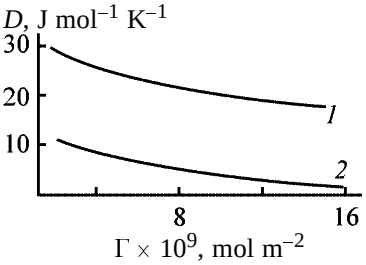

Fig. 3. Function D vs. adsorption Γ for samples (*1*) OA1 and (*2*) OA2. The error in calculating D is 7 J mol^{-1} K^{-1}.

With increasing Γ, the observed $|\Delta\bar{S}^s|$ steadily decreases within the range of partial adsorbate pressures studied from 127 to 114 J mol^{-1} K^{-1} for sample OA1 and from 106 to 95 J mol^{-1} K^{-1} for sample OA2, which is much lower than the above value.

Chlorobenzene molecules are more mobile on sample OA2. With increasing Γ, the adsorption layer on this sample becomes virtually similar to the ideal two-dimensional gas, which is not surprising in view of the high adsorption temperature.

CONCLUSION

The calcination temperature affects the adsorption properties of γ-Al_2O_3 with respect to chlorobenzene primarily by changing the concentration of surface OH groups. Under the adsorbent preparation conditions considered, oxides are formed with a hydroxide coating largely shielding Lewis acid centers on the surface. In this case, an increase in the calcination temperature, lowering the degree of surface hydroxylation, leads to a decrease in the isosteric heat of chlorobenzene adsorption and to an increase in its mobility in the adsorption layer.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Carbon Monoxide on Oxidized Activated Lignin Carbon

L. N. Grigor'ev, T. I. Burenina, and A. M. Sukhenko

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received December 9, 2002; in final form, April 2003

Abstract—Experimental data on the dynamics of carbon monoxide adsorption on oxidized activated lignin carbon are presented.

Flue gases of industrial installations and exhaust gases of vehicles are mostly rendered harmless by catalytic afterburning [1]. The adsorption-catalytic method is commonly regarded in recent years as an alternative means for rendering harmless low-temperature discharges [2]. In [3, 4], the possibility of using this technique for purification of wastes to remove carbon monoxide CO was demonstrated, and the direction of its modification, a search for new catalytically active materials with increased adsorption and chemical activity, was determined. As a material of this kind was proposed mordenite modified with manganese or cobalt oxide. It should, however, be noted that the results of [4] are best applicable to the case of detoxication of relatively highly concentrated wastes (CO concentration 1.25–7.50 g m^{-3}) taken in small amounts. This can be judged from the low linear velocity of the gas flow in the free cross section of the adsorption-catalytic reactor (0.03 m s^{-1}), which is lower than that in adsorbers (0.15–0.25 m s^{-1}) or catalytic reactors (0.5–1.0 m s^{-1}).

Considerable amounts of gases discharged into the atmosphere have relatively low CO concentrations (20–100 mg m^{-3}) and large flow rates [$>(10-60)\times 10^3$ m^3 h^{-1}]. These mainly include ventilation gases discharged by installations for plasma cutting of metals, oxygen bleaching of cellulose, and electric smelt furnaces, air from compressors, etc.

Deeper understanding of the adsorption-catalytic conversion of CO in detoxication of such gases could enable wider use of the method as regards the contamination sources and a search for new adsorbents-catalysts. Of interest as adsorbents-catalysts are oxidized activated lignin carbons prepared from wastes of pulp-and-paper and hydrolysis plants.

It has been shown previously [5, 6] that additional oxidation of the activated lignin carbon (ALC) enhances its chemisorption activity toward nitrogen monoxide NO. It was shown in [7] that is possible, in principle, to oxidize CO on ALC containing manganese and copper oxides. To determine the feasibility of practical application of oxidized ALC for treatment of gases contaminated with CO, it is necessary to have information about their properties in dynamic adsorption conditions.

Our goal was to analyze the equilibrium and dynamics of CO adsorption on oxidized ALC, with the aim to obtain data necessary for calculating an adsorption-catalytic reactor.

Isotherms of CO adsorption were calculated on the basis of the results of dynamic studies from full output curves.

The dynamics of adsorption was studied on a flow-through installation. As adsorber served a molybdenum glass column with inner diameter of 1.4×10^{-2} m, sealed in a column of diameter 2.6×10^{-2} m, within which water from a thermostat was circulated. Carbon monoxide was obtained in nitrogen [grade 1, GOST (State Standard) 9293–74] as described in [8]. A model gas mixture was prepared by evacuating a cylinder to residual pressure of 3.5 Pa, introducing CO with a calibrated syringe, and filling the cylinder with nitrogen to a pressure of 4.5 kPa. Metered amounts of the mixture of nitrogen and CO were introduced in an air flow delivered to the adsorber. The CO concentration c_0 in the air was 35.0–105.0 mg m^{-3}. The CO concentration was determined by gas chromatography [8] with a Chrom-5 chromatograph (heat conductivity detector) and AgNaγ zeolite as concentrator.

An ALC sample on which the best kinetic parameters were obtained in studying CO chemisorption [7]

was chosen as object of the study. Sample parameters: content of manganese 4.11%, that of copper 6.97%, specific surface area of mesopores 37.3 $m^2 g^{-1}$, and extent of sample oxidation 0.498 mg-equiv g^{-1}. It should be noted that, before treating an ALC sample with manganese and copper compounds, an air flow was passed through it at 423 K.

The overall mass-transfer coefficient β was calculated from the output curves of adsorption, using the expression [9]

$$\beta = -(\ln c_b/c_0)\omega/L,$$

where ω is the linear air flow velocity in the free section of the adsorber (m s^{-1}); L, sample bed height (m); and c_b, breakthrough concentration of CO (mg m^{-3}).

The isotherms of CO adsorption on oxidized ALC samples are shown in Fig. 1. The rise in the equilibrium CO adsorption a with increasing temperature indicates the chemisorption nature of the process. Figure 1 shows that the shape of the output curves depends on the adsorption temperature, i.e., in all probability, the type and strength of CO binding to active centers on the ALC surface change with temperature; stronger chemisorption complexes are formed at higher temperature. Figure 1 also shows that increasing humidity of the gas flow does not exert any noticeable influence on the adsorption activity of ALC.

Adsorption of CO on an ALC sample proceeds in accordance with the commonly accepted concepts: At low initial CO concentrations in the gas, the output curves in Fig. 2 are straight lines over virtually the entire range of relative breakthrough concentrations. These lines can be considered parallel at different sample bed heights, i.e., CO moves along the ALC bed at the same velocity. It could be expected that, with increasing temperature and with accumulation of intermediates and carbon dioxide CO_2 on the sorbent surface, the process would pass to the non-steady-state mode, previously observed in NO adsorption on oxidized ALC [5]. However, in the case of CO adsorption on oxidized activated carbon, the process starts to become non-steady-state only at high relative breakthrough concentrations ($c/c_0 \geq 0.95$). This is presumably due to the fact that the chemical reaction of adsorbed CO with the surface functional groups of the active centers of carbon is not accompanied by CO_2 accumulation at these centers, with CO_2 adsorption proceeding, in all probability, at other centers.

To assess the role of mass transfer in CO adsorption on a sample, the mass-transfer coefficients were calculated (Table 1). Table 1 shows that raising the temperature leads to an increase in the mass-transfer coefficient, which decreases when the CO concentration becomes lower.

In CO adsorption on ALC containing manganese and copper oxides, the coefficient β remains constant in a wide range of relative breakthrough concentrations. This fact suggests that, within the concentration range studied (straight portions of the output curves), the kinetics of adsorption is mainly determined by the external mass-exchange, and to much lesser extent by the longitudinal transfer.

The data presented in Table 1 and Fig. 1 were used

* (ν) Relative error of calculation.

to calculate the duration of adsorption, τ_b, by the equation derived by Dubinin and co-authors [9]:

$$\tau_b = [1 - \omega \ln(c_0/c_b)/\beta]\alpha a/(c_0\omega),$$

where α is a coefficient found from the output curve, and a is the equilibrium adsorption (mg m^{-3}).

Table 1 shows that the relative error ν of calculation by the equation does not exceed 18.1%, which allows it to be recommended for determining the duration of the stage of CO adsorption on oxidized ALC in calculating the process of treatment of gases discharged into the atmosphere.

Of primary importance for practical application of oxidized ALC is the possibility of its regeneration, which assumes removal of adsorbed CO from the surface and restoration of the activity of the functional groups. The regeneration was carried out by passing an air flow through the ALC layer at 453 K, with the linear flow velocity gradually raised from 0.10 to 0.30 m s^{-1}. The regeneration efficiency was evaluated by comparing the initial CO concentration c_0 at the adsorber inlet and the breakthrough CO concentration c_b in the purified gas at the adsorber outlet at constant duration of the adsorption stage. The maximum efficiency (95%) is achieved after the first stage of adsorption (before regeneration of the adsorbent). The regeneration conditions and the change in the ALC activity (at adsorption stage duration of 20 min), evaluated by the efficiency of purification of the gas flow, in the cyclic operation mode (adsorption–regeneration–cooling) are listed in Table 2.

Table 2 shows that, under the experimental conditions, stable and efficient operation of ALC is achieved by the 3rd cycle at regeneration stage duration of 20 min. Under any particular conditions, efficient operation of ALC can be ensured by controlling the air flow rate and the temperature of ALC treatment.

In analyzing the prospects for practical use of oxidized ALC, the following can be noted. Comparison of the above data with the results of [4] shows that, under comparable conditions of CO adsorption (c_0 = 1250 mg m^{-3}, $\omega = 0.03$ m s^{-1}, $L = 0.026$ m, relative humidity of gas flow 5.0%), ALC is a material less active toward CO: at 293 K the equilibrium adsorption a of CO on ALC is 2.98 mg ml^{-1}; the amount

of CO adsorbed on mordenite containing 16% MnO_2 is 6.7 mg ml^{-1}. However, at 323 K the sorption activities of the materials become comparable (a = 5.88 mg ml^{-1} for ALC). It should be noted that the sorption activity of ALC can be raised not only by carrying out the purification process at higher temperatures, but also by making higher the concentration of active centers and using other oxidizing agents (mixture of oxidants) that would be more active than those contained in the ALC studied. Under real conditions of application of oxidized ALC, its advantages are lower energy expenditure for the regeneration stage, which is carried out at lower temperatures (no higher than 473 K) as compared to, e.g., mordenite modified with MnO_2 (623 K) [4], and also a weak dependence of the ALC activity on the gas flow humidity.

CONCLUSIONS

(1) Oxidized activated lignin carbon can be used as adsorbent-catalyst in treatment of low-concentration discharges of various industries to remove carbon monoxide at moderate temperatures (293–353 K).

(2) The main resistance to mass transfer in CO adsorption on oxidized activated lignin carbon is concentrated in the gas phase.

(3) The duration of CO adsorption on oxidized activated lignin carbon can be calculated using the Dubinin equation.

(4) Effective regeneration of activated lignin carbon is ensured by passing through it an air flow with a linear velocity of 0.15–0.30 m s^{-1} at 453–473 K.

SORPTION AND ION-EXCHANGE PROCESSES

Isotherm of Strontium Sorption on Clay

D. E. Chirkst, T. E. Litvinova, O. V. Cheremisina, M. V. Ivanov, and N. A. Mironenkova

St. Petersburg State Mining Institute, St. Petersburg, Russia

Abstract—Sorption of strontium(II) with soil components from model solutions was studied. Limiting sorption of strontium ions, their landing site area, and Langmuir constants were determined.

Previously, we studied the strontium(II) sorption with soil components to substantiate, develop, and optimize a process for decontamination of soils from ^{90}Sr [1, 2]. To calculate the process parameters, the thermodynamic characteristics of strontium desorption from the surface of soil components into the washing solution are required. At the equilibrium, they are equal to the thermodynamic functions of sorption with the opposite sign; therefore, we studied sorption of Sr^{2+}.

The strontium(II) sorption with soil was determined under static conditions from model strontium chloride solutions. The solution was mixed with a sample of an air-dry soil for 5–6 h to attain the equilibrium [constant Sr(II) concentration in the solution], as judged from the constancy of Sr(II) concentration in time. The liquid volume to sample weight ratio was 10 $cm^3\ g^{-1}$ at a sample weight of 3 g.

After sorption completion, the liquid was filtered through a blue tape paper filter, the filtrate (2–10 ml depending on Sr^{2+} content) was transferred into a 50-ml flask, and required pH 2.8–3.0 was adjusted with acetate buffer (10 ml). Then, 25 ml of 60% acetone in water and 1 ml of 0.1% nitroorthanil C (nitrochromazo) were added. The strontium(II) content in the solution was determined by measuring the intensity of the absorption band of the Sr(II) complex with nitrochromazo at 650 nm. This method allows determination of 2 to 20 μg of Sr(II) in 25 ml of the solution [3]. Under these conditions, 100-fold excess of Na^+ and NH_4^+, 30-fold excess of K^+, 1.5-fold excess of Ca^{2+}, and 5-fold excess of Mg^{2+} do not interfere with determination of the target cation. The Sr(II) distribution coefficient between the solid and liquid phases was calculated by the formula

$$D_{s/l} = \frac{(c_0 - c_\infty)Vd}{c_\infty m \gamma_{Sr^{2+}}}, \quad (1)$$

where C_0 and C_∞ are the initial and equilibrium strontium concentrations in the aqueous phase (M), respectively; V, solution volume (m^3); d, solution density ($kg\ m^3$); m, sample weight (kg); and $\gamma_{Sr^{2+}}$, Sr(II) activity coefficient in the initial solution calculated by the Davies equation [4].

The composition and specific surface area S_{sp} of the soil components studied are as follows [5]:

Sample	S_{sp}, $m^2\ g^{-1}$
Kaolinite $Al_4(OH)_8[Si_4O_{10}]$	5.2
Cambrian blue clay $K_2Al_4[Al_2Si_6O_{20}](OH, F)_4$	5.86
Oligoclase $(Na_{0.9}Ca_{0.1})[Al_{1.1}Si_{2.9}O_8]$	0.17
Albite $Na[AlSi_3O_8]$	0.20
Potassium feldspar $K[AlSi_3O_8]$	0.21
Dolomite $Ca(Mg, Fe)[CO_3]_2$	–

The distribution coefficients obtained are listed in Table 1.

As seen, in accordance with a decrease in $D_{s/l}$ and S_{sp}, the minerals can be ranked in the following order: Cambrian blue clay ~ kaolinite > potassium feldspar >

Table 1. Distribution coefficients of strontium ions between $SrCl_2$ solution and soil components

Mineral	pH_{init}	pH_{fin}	$c_\infty \times 10^4$, mol kg^{-1}	$D_{s/l}$

albite > oligoclase. Hence, we can conclude that in contaminated soils ^{90}Sr is fixed mainly on the surface of clay minerals, which is in agreement with reference data [6, 7]. Therefore, we studied the Sr(II) sorption with clay more thoroughly.

The thermal analysis showed that Cambrian blue clay belongs to hydromicaceous type. The sorption isotherm was studied at the initial pH 3.0. The average equilibrium pH was 3.4 ± 0.2. A small increase in pH can be explained by substitution of anions of weak acids with the anion of a strong acid, Cl^-, on the mineral surface. The choice of pH value is governed by two factors. First, the soil is decontaminated from ^{90}Sr by washing with an iron(III) salt solution [1, 2]. Weakly acidic medium is required to avoid hydrolysis of Fe^{3+} ions. Second, conversion of clay into the H form allows stabilization of the mechanism of strontium ion sorption. Therefore, clay was preliminarily treated with 1 M HCl, washed with water to pH 3, and dried to air-dry state. The $SrCl_2$ solutions were also acidified to pH 3. The clay sample weight was 3 g, and the l/s ratio was 10 $cm^3\ g^{-1}$. The equilibrium was attained in 5–6 h, but actually the contact time was no less than 1 day. The data on Sr^{2+} distribution between the model $SrCl_2$ solution and clay are presented in Table 2. The sorption isotherm constructed from these data is shown in Fig. 1. The sorption Γ (mol kg^{-1}) was calculated by the formula

$$\Gamma = (c_0 - c_\infty)V/m.$$

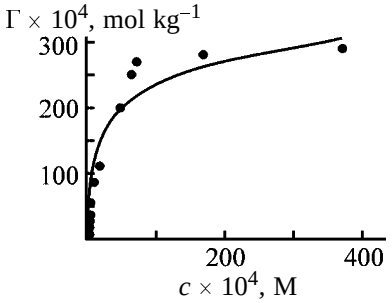

Fig. 1. Isotherm of Sr^{2+} sorption on clay: (Γ) sorption and (c) strontium(II) concentration; the same for Fig. 2.

At equilibrium pH 3.4 ± 0.2, the distribution coefficient of strontium(II) between the solid and liquid phases is 10 ± 1.8 (Table 2). A decrease in $D_{s/l}$ at high Sr^{2+} concentrations in the aqueous phase is caused by saturation of the surface. When pH is increased to 7.0–7.5, the degree of dissociation of silanol groups, negative charge of the surface, and $D_{s/l}$ increase (Table 1). A similar increase in the ^{137}Cs distribution coefficient between the model solution and kaolinite was observed in [8].

The ^{90}Sr distribution coefficients obtained in this work are lower than those obtained in [7] for certain minerals (1710 for montmorillonite and 180 for kaolinite at pH ~7). One of the probable reasons of this disagreement is the presence in the samples studied in [7] of the soil organic substance, which increases D. Another reason is the dependence of D on the degree of surface filling. In [8], the distribution coefficient of ^{137}Cs between montmorillonite and the solution decreased from 7200 to 23 as the surface was filled, since sorption primarily proceeds on crystal faces, and, as they are filled, D decreases. In [7], sorption was studied with trace amounts of ^{90}Sr; this explains high distribution coefficients. The D values obtained in our study are related to conditions of thermodynamic equilibrium with weighable amounts of Sr and agree with the concept of high strontium(II) mobility in grounds [6, 9, 10].

Sorption isotherms can be described by the Langmuir equation, as indicated by the linear dependence of reciprocal sorption on reciprocal concentration:

$$\frac{1}{\Gamma} = \frac{1}{\Gamma_\infty} + \frac{1}{\Gamma_\infty K}\frac{1}{c_\infty}, \qquad (2)$$

where Γ and Γ_∞ are equilibrium and limiting sorption values (mol kg^{-1}), K is the Langmuir constant, and c_∞ is the equilibrium concentration of strontium cations in the aqueous phase (M).

The absolute term of Eq. (2) is equal to the reciprocal value of the limiting sorption, which amounts to

0.034 mol kg^{-1} for Sr^{2+} and is consistent with the Γ_∞ value in the sorption isotherm. Since the substituting ability of strontium cations with respect to hydroxonium ions is high and clay initially was in the H form, the exchange capacity of clay can be estimated as 68 mg-equiv kg^{-1}. From data on sorption of methylene blue on this clay sample we obtain 10.3 mg-equiv kg^{-1} [5] The underestimated value of the sorption capacity can be explained by a large landing site area of methylene blue.

The landing site area of Sr^{2+} ions found by the formula

$$S_M = \frac{S_{sp}}{\Gamma_\infty N_A}, \quad (3)$$

where N_A is Avogadro number, is equal to 28.6×10^{-20} m^2. Hence, the radius of sorbed Sr^{2+}_{aq} cation is 302 pm. This value is close to the Stokes radius of Sr^{2+}_{aq}, 309 pm. This shows that strontium ions are sorbed in the hydrated state in the Stern layer on the clay surface. The constant K, determined from the slope, is 294.

In this work, we studied the thermodynamic phase equilibrium under conditions of sorption of macrocomponent ions from dilute solutions. Let us consider the correlation between the Langmuir constant and the equilibrium constant of sorption:

$$Sr^{2+}_{aq} \rightarrow Sr^{2+}_{ads}. \quad (4)$$

In contrast to the distribution coefficient, both Langmuir and equilibrium constants should not depend on the degree of filling of the mineral surface. We obtain the following correlation between them:

$$\Gamma = c_\infty \gamma_{Sr^{2+}} D_{s/l} = \Gamma_\infty \frac{Kc_\infty}{1 + Kc_\infty}, \quad (5)$$

and find the distribution coefficient:

$$D_{s/l} = \frac{\Gamma_\infty K}{\gamma_{Sr^{2+}}(1 + Kc_\infty)}. \quad (6)$$

It follows from Eq. (6) that the distribution coefficient depends on the Sr(II) concentration in the equilibrium solution and hence on the degree of surface filling (Table 2). However, at infinite dilution $D_{s/l} = \Gamma_\infty K = 10.0$, which coincides with the experimental value (Table 2). For equilibrium (4), which characterizes the sorption ability of strontium ions, we obtain

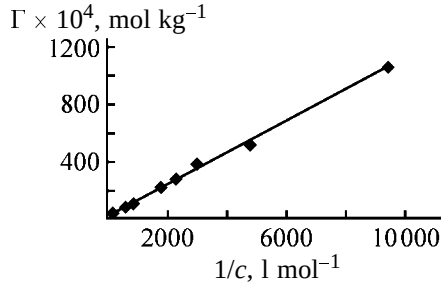

Fig. 2. Linearized form of the isotherm of Sr^{2+} adsorption on clay.

the Gibbs energy $\Delta G^0_{298} = RT \ln D_{s/l} = -5.7$ kJ mol^{-1}. Taking $\Delta_f \Delta G^0_{298}(Sr^{2+}_{aq}) = -563.9$ kJ mol^{-1} [11], we obtain the following Gibbs energy of formation of the sorbed cation: $\Delta_f G^0_{298} = -569.6$ kJ mol^{-1}.

CONCLUSION

Sorption of Sr^{2+} ions with Cambrian blue clay is described by Langmuir isotherm with the constant of 294 and limiting sorption of 0.034 mol kg^{-1}. The landing site area of Sr^{2+} is 28.6 Å^2. The radius of the hydrated cation is 302 pm, which coincides with the Stokes radius of 309 pm. The Sr^{2+} distribution coefficient between the solid and liquid phases at pH 3.4 ± 0.2 is 10, and the Gibbs energy of sorption is –5.7 kJ mol^{-1}.

SORPTION AND ION-EXCHANGE PROCESSES

Preparation and Ion-Exchange Properties of Mixed Zirconium(IV) Phosphate–Phosphonate Sorbents

I. V. Romanova, I. A. Farbun, V. S. Aleksandrova, and S. A. Khainakov

Institute of Sorption and Endoecological Problems, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received December 19, 2002

Abstract—Composite sorbents based on Zr(IV) phosphate–hydroxyethylidenediphosphonate with different phosphate–phosphonate ratio were prepared. These sorbents were characterized by elemental analysis, X-ray diffraction, and IR spectroscopy, and their ion-exchange sorption capacity for several transition metals and strontium was studied. The sorption capacity of these sorbents increases with increasing pH.

Sorbents based on hydrated oxides and phosphates of Group III and IV metals are widely used for sorption decontamination of various liquids from heavy metals and radionuclides. These sorbents are characterized by chemical, thermal, radiation, and microbiological stability; furthermore, they exhibit high selectivity for several toxic metals. The selectivity of such sorbents, in particular, those based on titanium and zirconium phosphates, is governed by the structure of their matrix and the nature of the functional groups located on the sorbent surface [1].

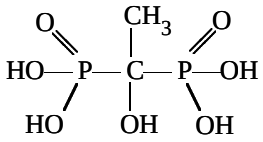
Different approaches were developed to improve the sorbents under consideration. With this aim, additional agents are introduced into reaction mixture in preparing these sorbents to form pores of a certain size and shape in the sorbent matrix [2]. According to another technique [3], the initially prepared sorbent is treated with an appropriate chemical agent [3] to modify the sorbent surface with the additional complexing functional groups.

In this work, the initial sorbent (zirconium phosphate) was prepared by a gel–sol technique [4] based on the reaction between a zirconium salt and phosphoric acid in an aqueous solution. It was found that thermal treatment of the initial zirconium phosphate increases its sorption capacity with respect to Sr^{2+} [2]. The reason is that the strontium cations are sorbed on zirconium phosphate mainly by their exchange for the protons of the hydrogen and dihydrogen phosphate groups of the sorbent. The thermal treatment results in condensation of the mono- and dihydrogen phosphate groups to form polymeric phosphate anions which are stronger complexing agents for alkaline-earth cations.

In order to increase the contribution of complex formation to the total sorption capacity of zirconium phosphate, the sorbent was modified with hydroxyethylidenediphosphonic acid (HEDP). This acid was chosen as a modifying agent because of its structural similarity with phosphoric acid and its strong complexation with various metal cations [6].

The synthesis of tin phosphate modified with nitrilotris(methylenetriphosphonic acid) was reported in [7]. As compared to titanium and zirconium phosphates, this sorbent shows higher selectivity for alkali, alkaline-earth, and some transition metals and exhibits higher stability to hydrolysis in both strongly alkaline and strongly acidic solutions. These features considerably widen the areas of the sorbent application.

The complexation of zirconium with hydroxyethylidenediphosphonic acid (HEDP)



was studied in [8, 9].

It is known [6] that HEDP forms very stable complexes with alkali, alkaline-earth, and some transition metals. Long-term application of HEDP in agriculture (as a fertilizer component) and medicine (as a drug component) showed that this compound is nontoxic [6], which is important for future application of HEDP for water treatment.

The aim of this work was to prepare ion exchangers based on mixed Zr(IV) phosphate–phosphonate. The procedures used in synthesis of these sorbents and

1070-4272/03/7605-0731$25.00

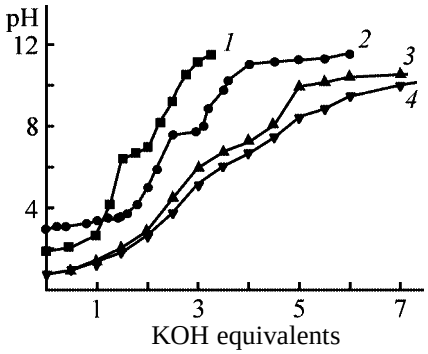


Fig. 1. Curves of potentiometric titration of (*1*) H_3PO_4, (*2*) HEDP, (*3, 4*) H_3PO_4–HEDP mixtures at (*3*) 1 : 1, and (*4*) 1 : 0.1 H_3PO_4 : HEDP ratio. For these mixtures, the KOH equivalent was recalculated to H_3PO_4.

their main physicochemical and sorption characteristics are given below.

EXPERIMENTAL

All the chemicals used in our experiments were of chemically pure or analytically pure grade. Aqueous solutions of alkaline-earth and transition metal chlorides and acetates and of potassium hydroxide were prepared by dissolution of their weighed portions in water.

Zirconium(IV) phosphate–phosphonates were prepared by adding an aqueous solution containing a mixture of phosphoric (3 M) and hydroxyethylidenediphosphonic (1.5 M) acids into an aqueous zirconium oxychloride solution (2 M) with vigorous stirring. This synthesis was carried out with varied ratios of phosphoric and hydroxyethylidenediphosphonic acids. In order to prolong the gelation process so as to obtain the uniform product, an appropriate complexing agent was added. The H_3PO_4 : HEDP ratio in the initial solution, the gel time, and some characteristics of the final sorbents are listed in the table. The Zr : P molar ratio in all the prepared sorbents was 1.5. After mixing, the reaction mixture gradually transformed into a gel. As the gel time we took the time τ after which the reaction mixture loses fluidity on inclining the reaction vessel (for 6–15 s). The gel was kept for 1 day, broken-down to small particles, washed with distilled water, and air-dried at room temperature to the moisture content of 20%. The resulting dried gel is a mechanically strong, glass-like colorless material.

The X-ray diffraction phase analysis of the sorbents was carried out on a DRON-3M diffractometer. The IR spectra (KBr pellets or mulls in Vaseline oil) were recorded in the range 400–4000 cm^{-1} on an M-80 (Carl Zeiss, Jena) IR spectrometer. The changes in the sorbent structure result in appearence of broad bands in the IR spectra in the range of the OH vibrations. In order to improve the analysis of these spectroscopic effects, the baseline was built and the absorption intensity was measured relative to the H_2O bending vibration band at ~1635 cm^{-1}, insensitive to structural changes in the sorbent matrix.

The carbon content in the sorbents was determined after their dissolution in HF-containing solution. The moisture content and the pore sorption volume W_s (with respect to water and benzene) were determined by the desiccator technique [10]. The pH was measured on an I-130.2M.1 ionometer. The initial and equilibrium copper and cobalt content in the initial solutions was determined photocolorimetrically. The strontium content in the solutions was determined on a C-115M-1 atomic-absorption spectrometer by a standard procedure.

The sorption recovery of transition metals from aqueous solutions with the sorbents prepared was studied as follows. An MCl_2 aqueous solution (M = Cu^{2+}, Co^{2+}, or Sr^{2+}) with the concentration of 1×10^{-3}–6×10^{-2} M was stirred, using a magnetic stirrer, with the sorbent sample at the solid to liquid phase ratio s : l = 1 : 100 at room temperature for 1 day. The sorption capacity of the sorbent with respect to the individual ion A (mmol g^{-1}) is expressed by the equation

$$A = (c_i - c_e)V/m,$$

where c_i and c_e are the initial and equilibrium metal concentrations in the solution (mM), m is the sorbent sample weight, and V is the solution volume.

The Zr(IV) complexation with both phosphoric acid and HEDP in aqueous solutions was studied in [8, 9] by potentiometric titration. In these works, curves of potentiometric titration of zirconium(IV) chloride, phosphoric and hydroxyethylidenediphosphonic acids, and complexes formed at various reactant ratios were also obtained. Proceeding with these studies, we prepared two series of metal-free solutions with the H_3PO_4 : HEDP ratio of 1 : 1 and 1 : 0.1 and varied their pH from 1 to 11 by adding aqueous KOH. We found that, on standing for 3 days, pH first decreased and then remained constant. Figure 1 shows the equilibrium curves of potentiometric titration of aqueous phosphoric acid, hydroxyethylidenediphosphonic acid, and their mixtures. These curves show that, in going from individual acid solutions to their mixtures, pH decreases and the inflection point shifts toward

higher pH. These results suggest that a common system of hydrogen bonds between different acids is formed in H_3PO_4–HEDP mixtures. The difference between the titration curves of the individual acids and their mixtures is stronger at lower HEDP content (Fig. 2). Presumably, the common system of hydrogen bonds is preferably formed at lower HEDP content.

We prepared ten samples of Zr(IV) phosphate–phosphonate sorbents at different H_3PO_4 : HEDP ratios in the reaction mixture (see table). The table shows that, with increasing HEDP content in the reaction mixture, the gelation significantly decelerates. This fact shows that in our systems the gelation is inhibited not only by zirconium(IV) complexation with the standard complexing agent added to the reaction mixture, but also by additional compexation with HEDP. Large amounts of HEDP deteriorate the gel structure. We found that both the appearance and mechanical properties of the sorbents prepared with the HEDP content in the reaction mixture less than 10% (sample nos. 2–6) are identical to those of the initial zirconium phosphate (sample no. 1). With HEDP content exceeding 10% (sample nos. 7–9), less uniform sorbents containing separate aggregates are formed. Elemental analysis showed that these sorbents incorporated HEDP.

The carbon content in the modified sorbent linearly increases with increasing HDEP content in the reaction mixture (correlation coefficient $R = 0.977$). We found that the carbon amount in the modified sorbents does not exceed 40% of that introduced into the reaction mixture with HEDP. The sorption pore volume of the sorbent determined with respect to water and benzene decreases with increasing HEDP content in the reaction mixture, which suggests condensation of phosphate and phosphonate groups in the course of formation of zirconium(IV) phosphate–phosphonate sorbents. The prepared sorbents have microporous structure. Variations of the appearance and structural characteristics of the sorbents with the HEDP content and the results of potentiometric titration show that the HEDP content in the reaction mixture must not be higher than 10%.

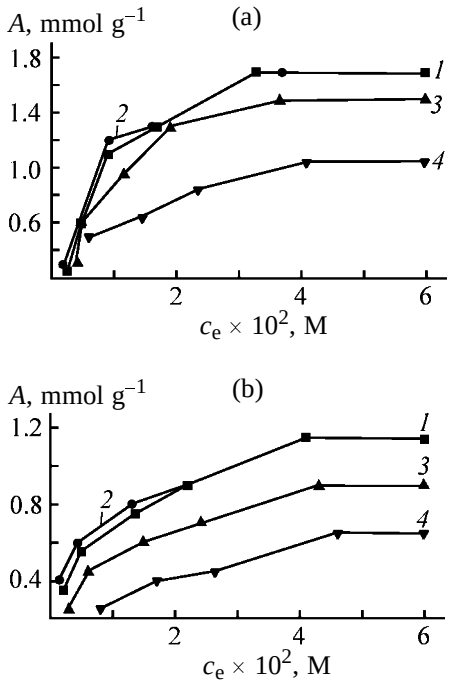

Fig. 2. Sorption isotherms of (a) cobalt and (b) copper on (*1*) unmodified zirconium phosphate and (*2–4*) zirconium phosphate modified with HEDP. (*A*) Sorption capacity and (c_e) Me^{2+} equilibrium concentration in the aqueous phase. HEDP content in the reaction mixture (%): (*2*) 5, (*3*) 50, and (*4*) 100.

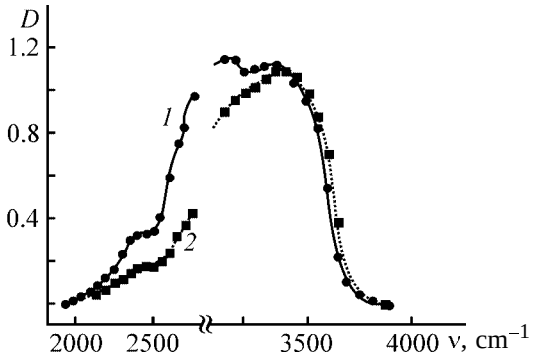

Fig. 3. IR spectrum of Zr phosphate–phosphonate (5% HEDP, sample no.4) in the range 1500–4000 cm^{-1} (*1*) before and (*2*) after strontium sorption. (*D*) Optical density and (ν) wave number.

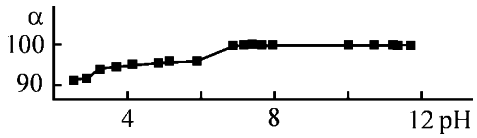

Fig. 4. Decontamination factor of solution from strontium after treatment with Zr(IV) phosphate–phosphonate sorbent (sample no. 4) as a function of pH. Initial Sr concentration $c_{Sr} = 7 \times 10^{-3}$ M.

The X-ray diffraction patterns of the prepared sorbents are indicative of their amorphous structure. With increasing HEDP content in the sorbent, the absorption bands of the ν(CO) groups (~1120 cm^{-1}) [11] becomes sharper, and absorption of the (C)–OH groups is manifested as broadening of the absorption band of the surface hydroxy groups and water molecules from its high-frequency side.

Owing to the surface (P)–OH groups, among them those belonging to HEDP, the sorbents in hand are cation exchangers. The ion-exchange properties of these sorbents were characterized by their sorption capacity with respect to copper and cobalt. Figures 2a and 2b show the sorption isotherms of copper and cobalt on both the initial zirconium phosphate and that modified with HEDP. The static exchange capacity of the tested sorbents for heavy metals varies from 1.2 to 1.75 mmol g^{-1} depending on the kind of metal and sorbent composition. On the whole, the sorption capacity of the sorbents containing 50% and more HEDP is substantially lower than that of the unmodified zirconium phosphate (sample no. 1). The sorption capacity of the sorbents containing less than 5% HEDP is considerably higher and close to that of the initial zirconium phosphate. The sorption capacity of zirconium phosphate modified with a small amount of HEDP (5×10^{-3}–2×10^{-2} M) exceeds that of the initial sorbent.

We also studied strontium sorption on modified sorbents. The following exchange capacities for strontium were obtained (mmol g^{-1}): 0.3–0.4 (sample nos. 6–10; HEDP content in the reaction mixture exceeds 10%), 0.6–0.7 [initial zirconium(IV) phosphate], 0.7–0.9 (sample nos. 3 and 4; HEDP content 3 and 5%, respectively). These results show that the relationships in sorption of transition metals and strontium are similar. It was reported [5] that Zr(IV) phosphate sorbents subjected to high-temperature treatment have sorption capacity for strontium of 0.3–0.4 mmol g^{-1}. Our sorbents, prepared without thermal treatment, exhibit higher sorption capacity for strontium.

Figure 3 demonstrates the effect of Sr sorption on the IR spectrum of the Zr(IV) phosphate–phosphonate sorbent (sample no. 4). The Sr sorption results in significant decrease in the intensity of the OH stretching band from the low-frequency side. This suggests that strontium is sorbed by the mechanism of exchange for protons of the (P)–OH groups.

The best Zr phosphate–phosphonate sorbent (5% HEDP, sample no. 4) was tested for decontamination of aqueous solutions from strontium ($c_{Sr} = 7 \times 10^{-3}$ M) within a wide pH range (1–12). The decontamination factor from strontium as a function of pH is given in Fig. 4. This plot shows that, with increasing pH from 1 to 12, the decontamination factor increases from 90 to 99.8%. The stepwise shape of this plot suggests that the zirconium phosphate–phosphonate sorbents have several kinds of sorbing sites of different acidities.

The results obtained in this work show that zirconium phosphates modified with HEDP are promising sorbents. We believe that the use of phosphonic acids with a branched bulky hydrocarbon radical as modifying agents may improve the structural and sorption characteristics of the sorbents.

CONCLUSIONS

(1) New sorbents based on zirconium phosphate modified with hydroxyethylidenediphosphonic acid (HEDP) were prepared. The elemental analysis and IR data showed that the sorbent matrix includes HEDP.

(2) With HEDP content in the reaction mixture about 5% relative to H_3PO_4, the conditions for condensation of the phosphate and phosphonate groups in the sorbent matrix are optimal. Modification of zirconium phosphate sorbents with HEDP improves

their sorption characteristics and extends the pH range of the efficient sorption. This improvement is due to both the favorable structural changes (increase in the size of channels and pores) and appearance of additional complexing groups on the sorbent surface.

SORPTION AND ION-EXCHANGE PROCESSES

Application of a Matrix of Piezosorption Sensors to Analysis of Ethanol-Containing Gas Mixtures

Abstract—General relationships were established for operation of piezosorption sensors when exposed to an ethanol-based multicomponent gas mixture. The operation conditions were optimized for the sensors; a matrix comprising six piezosorption elements was designed for analyzing gas mixtures containing low-boiling C_1–C_5 alcohols and ethyl acetate. The sensor matrix is suitable for foodstuff analysis.

The demand for sensors characterized by high selectivity and low detection limits, as well as by compactness, reliability, and easy exploitation, steadily grows. Development of express and test analytical methods and their wide application in analytical practice allow solution of not only certain environmental but also social problems such as deriving information on the air and water condition and foodstuff quality [1].

Ever growing importance is assigned to foodstuff identification by a number of procedures aimed at elucidating whether a foodstuff corresponds to the reference or its description.

This makes it important to design sensors suitable for identifying rude falsifications or low-quality foodstuffs at acceptable economic costs. In this case, the analytical information "carriers" are not only the foodstuffs themselves but also the equilibrium gas phases [2–4]. The presence/absence of low-boiling microimpurities (alcohols, alkyl acetates, acids) and their levels (if present) allow judging the quality and safety of certain types of the foodstuffs tested.

The aim of this work is to develop a procedure for analyzing alcohol-containing solutions by piezoelectric-quartz microweighing of the equilibrium gas phase.

EXPERIMENTAL

Gas mixtures of low-boiling compounds were analyzed with a specially designed matrix detector based on six piezoelectric quartz resonators (PQRs) of volume-acoustic waves with the intrinsic vibration frequency $F_v = 9 \pm 1$ MHz [5]. The piezoresonator electrodes were coated with receptor sorbent films by the method of static evaporation of a drop within 30 min at 40–45°C. We analyzed solutions of polyethylene glycol-2000 (PEG-2000), polyethylene glycol succinate (PEGS), polyethylene glycol sebacate (PEGSb), polyethylene glycol adipate (PEGA), Triton X-100, dinonyl phthalate (DNP) in ethanol, bees glue (propolis) in ethanol, beeswax (BW), dicyclohexano-18-crown-6 crown ether (DCH-18-C-6) in chloroform, and polystyrene (PS) in toluene. The complete removal of the solvent was ascertained by the stability of the vibration frequency of the resonator coated with a modifier film, F^f, Hz (drift $\Delta F^f \leq 3$ Hz min^{-1}).

An aqueous solution containing (ω, wt %) ethanol 40–42, ethyl acetate 0.02–0.05, C_1–C_4 alcohols 0.09–0.15, and isopentyl alcohol 0.07–0.10 was injected into the detector, and the vibration frequency was determined for each sensor (film-coated resonator) of the matrix by the appropriate algorithm. The analytical signal of the detector is the total response composed of the changes in the vibration frequency of all the sensors, Hz: $\Delta F^s_{i(i \to 1-6)} = F^f_i - F^s_i$. As the responses of each individual matrix element we took the individual kinetic and quantitative parameters of interaction between the receptor film and the mixture components. The "visual imprint" of the equilibrium gas phase of the solution was represented as a circular diagram ("aromatogram"). The final decision on the composition of the tested samples containing the components of the mixture analyzed (whether the sample corresponds to the standard and, if corresponds, to what extent) was taken using the sample identification algorithm.

1070-4272/03/7605-0736$25.00

The accuracy of determining low-boiling alcohols and ethyl acetate in the matrix of piezosorption sensors was controlled by gas chromatography (3 m × 3 mm column packed with Inerton modified with polyethylene glycol PEG-1500; helium carrier gas, flow rate 40 $cm^3\ min^{-1}$; injector, column, and flame-ionization detector temperatures 150, 80, and 200°C, respectively). The results were compared with those obtained at the accredited laboratory for foodstuff analysis and certification, Voronezh State Technological Academy.

The piezosorption matrix detector was regenerated by blowing with dry air for 15–20 min. The detector is suitable for conducting no less than 20 sorption–desorption runs in analysis of ethanol-based solutions without application of fresh receptor films.

The theoretical basis for controlling the sensitivity level of the piezoelectric sensor (resonator coated with a modifier film) in the gas phase was the Sauerbrey's microgravimetric concept of operation of a PQR [6]. The corresponding model is used for interpreting the experimental results obtained with a piezoresonator in the gas phase more frequently than the more recently developed theoretical models. This model is, essentially, represented by Eq. (1).

$$\Delta F = -2.3 \times 10^{-6} \frac{F_v^2 M_f}{A}. \quad (1)$$

Here, ΔF is the sensor response, i.e., the change in the vibration frequency of the PQR due to sorption of low-boiling compounds on the receptor films, which is calculated as the difference between the initial frequency of vibrations of the film-coated sensor F_f^0 and the equilibrium frequency of vibration of the sensor during sorption F^s, Hz; 2.3×10^{-6}, calibration constant; F_v, intrinsic frequency of vibrations of the PQR, MHz; M_f, mass of film coating on the electrodes, μg; and A, PQR electrode area, cm^2.

The change in the resonance frequency of vibrations of the PQR quantitatively correlates with the parameters of the surface wear or with the inequality of the masses of the coatings applied to both sides of the electrode. Viscous and liquid film coatings with a low kinematic viscosity are characterized by significant damping powers. Therefore, when applied to a piezoelectric quartz resonator, they cause a frequency instability of the sensor response. At the same time, the Sauerbrey model can be applied in the case of small mass increments (film thickness up to 3 μm) on electrodes without taking into account the details of the film structure and its changes on sorption [7, 8]. Upon application of film coatings thicker than 3 μm (60–80 μg), the energy losses in the film and piezoresonator tend to significantly increase and become comparable. Further thickening of the film coating tends to increase the contribution to the total response of the sensor from the component due to the wave propagation through the film rather than to the change in its mass upon sorption. Heavy coatings cause the piezoresonator vibrations to fail. The general relationships in sorption of low-boiling compounds of various classes on thin films of modifiers of the PQR electrodes with masses of up to 40 μg were described by the Sauerbrey model. The energy losses in such films can be neglected, and Eq. (1) can be taken as adequately describing the experiment.

Available data from the existing databank of kinetic and quantitative sorption parameters for the major classes of organic compounds, treated using the cluster analysis, suggest the possibility of designing a PQR-based sensor matrix for analyzing ethanol-containing gas mixtures with impurities such as C_1–C_5 alcohols and ethyl acetate [9–11].

We estimated the sorption affinities of individual sensors for low-boiling alcohols and alkyl acetates whose levels are regulated by appropriate norms and which are indicative of falsifications of certain foodstuffs (Table 1). As selectivity criteria we chose the kinetic (the time of the maximal response of the sensor τ_{max}, s) and quantitative (analytical signal ΔF_c, Hz, and sensitivity S, Hz $mol^{-1}\ dm^3$) parameters of the sensors when exposed to vapors of these compounds. Also, we took into account the stability of the operation of the modified sensor when exposed to a low-boiling compound vapor (characterized by S_r, relative rms deviation, %).

We found that the sorption efficiency tends to increase with increasing mass of the sorbent film in the range from 5 to 20 μg. With films heavier than 30 μg, the zero signal appreciably drifts and the results become poorly reproducible. Also, with PEG-2000 and DNP films the overcharges are responsible for "failures" of the resonator autovibrations. The optimal mass of the films for sorbents studied in this work is 10–20 μg.

The complementarity of the receptor films to low-boiling alcohol and alkyl acetate microimpurities is high, but the selectivity is low. The response of one sensor based on the receptor films studied does not allow identification of the microimpurities and determination of their ratio in the gas phase. This problem can be solved by using several sensors with cross sensitivities (like in "electronic nose" systems) and by

subsequent mathematical processing of the overall response [12–14].

To improve the efficiency and selectivity of analysis, we applied, for the first time, a sensor based on DCH-18-C-6 crown ether which is an efficient extracting agent for oxygen-containing substances. Preliminary assessment of the selectivity and sensitivity of the receptor films and the stability of the position of the zero signal suggest that it is appropriate to use the following set of substances in the sensor matrix intended for testing alcohol mixtures: PEG-2000, PEGA, Triton X-100, propolis, DNP, and crown ether. We established the relationships in variation of the sensor response under successive introduction of microamounts of ethanol homologs and ethyl acetate into aqueous solution with high ethanol content (Table 2). With introducing ethyl acetate and pentyl alcohols, the analytical signal from PEG-2000-, DNP-, and DCH-18-C-6-based sensors significantly changes. The same effect in the case of PEGA-, propolis-, Triton X-100-, and beeswax-based sensors is due to all the impurities occurring in aqueous ethanol (Table 2). The PS films are weakly sensitive to volatile components of the ethanol-based mixture but exhibit a minor drift of the zero signal (film instability) (Fig. 1).

* Confidence interval for ΔF^s at the confidence level of 0.95.

Sensitive DNP and DCH-18-C-6 films exhibit a significant drift of the zero signal. It is recommended that ΔF^f be decreased by preliminarily exposing the sensors to the "analyte" vapor (film "training").

Valuable information about the operation of the sensor when exposed to single- and multicomponent gas mixtures can be derived from the frequency vs. time plots (Figs. 2, 3). Taking the sensor with a DCH-18-C-6 crown ether film as an example, we studied the geometry parameters of the frequency vs. time plot as influenced by the microimpurities (Fig. 2). To elucidate the relationships in variation of the sensor sensitivity with the compositions of the solution and the equilibrium gas phase, we successively introduced the components into the mixture analyzed. The time vs. frequency plot is strongly influenced by introduction into an aqueous ethanolic solution of microimpurities such as ethyl acetate (Fig. 2, curve *2*) and isopentanol (Fig. 2, curve *5*).

We analyzed the trends in variation of the sensor response within 5, 60, 120, and 180 s as measured from the moment of injecting the sample containing ethanol solely (curve *1*), ethanol + methanol, isopropanol, and *n*-butanol microimpurities (curve *3*), the alcohols + ethyl acetate (curve *4*), and all the above-listed components + isopentanol (curve *5*). The sensor response reaches a maximum in 5-s sorption of the

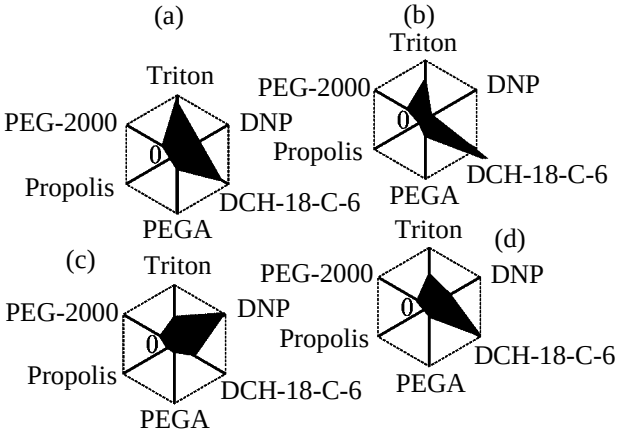

Fig. 4. Sorption diagrams for (a, c) C_1–C_4 alcohol mixture and (b, d) C_1–C_5 alcohol + ethyl acetate mixture on Triton X-100, DCH-18-C-6, propolis, PEGA, PS, and PEG-200 films. Response recorded in (a, b) 5 and (c, d) 30 s. Sensor response magnitude: (a, b) 1200 and (c, d) 4000 Hz.

equilibrium gas phase of aqueous ethanol. With introducing microamounts of more volatile methyl and isopropyl alcohols into an aqueous solution, ΔF tends to decrease (>5 s). Butyl and pentyl alcohols and their isomers affect similarly (decrease) the sensor response at the initial moment of sorption. The response from the crown-ether-based sensor was at a minimum at the moment of introducing ethyl acetate into the alcohol mixture.

Thus, by analyzing the responses of the sensor after 5-s sorption, it is possible to estimate the content of the microimpurities (isopropanol, iso- and *n*-butanol, and ethyl acetate) in aqueous ethanolic solutions with a high concentration of ethanol. Similar changes were observed in the frequency vs. time plots for 14–45-s sorption. The sensor responses recorded after 60–180-s sorption differ less significantly when microimpurities are introduced. The weakest response was observed with pentanol and butanol impurities. The responses from the crown-ether-based sensor in sorption runs longer than 15–30 s bear no information.

Prompt response was obtained from the DNP film sensor when exposed to a vapor of a solution based on ethanol with microimpurities of other alcohols and ethyl acetate (τ_{max} = 5–15 s, see curves *1*, *2* in Fig. 3). Microamounts of C_1–C_5 alcohols and ethyl acetate introduced into an aqueous ethanol affect the frequency vs. time plot (Fig. 3, curve *2*). A sharp increase in the DNP sensor response in a 15-s sorption run is due to the presence of C_4–C_5 alcohols and ethyl acetate microimpurities in the solution with a high ethanol content. The parabolic shape of the frequency vs. time plots (τ up to 15 s) suggests desorption of the components from the film surface. Sensors based on propolis, Triton X-100, and PEGA films characterized by longer desorption (over 180 s) operate similarly.

The PEG-2000 film is the site of absorption; the frequency vs. time plot is clearly indicative of the main stages of interaction between the mixture components with the receptor film (Fig. 3, curves *1*', *2*'). The first maximum (τ^1_{max} = 15 s) corresponds to adsorption of low-boiling alcohols (C_1–C_4) and ethyl acetate, and when these are partially desorbed, the sensor begins to respond to isopentanol. Accumulation of ethyl acetate by the receptor film takes much time, as the entire film is involved in sorption (absorption). The second maximum in the frequency vs. time plot is observed at τ^2_{max} = 150–180 s. Thus, prolonged sorption on the PEG-2000 receptor film and a drastic change in the signal of the DNP film sensor after 5–10-s sorption suggests the presence of isopentanol microimpurities in the equilibrium gas phase.

The mutual location of the maxima in the frequency vs. time plots for various sensors governed the order of their arrangement in the matrix, as well as the algorithms of receiving individual and forming the overall signals from the detector. The maximal response time $\tau_{max(i)}$ determines the inertia of the entire detector. Figure 4 demonstrates the overall signal from the matrix comprised of six sensors based on various films when exposed to a vapor of model mixtures containing C_1–C_4 alcohols, as well as C_1–C_5 alcohols + ethyl acetate. The overall signal is represented by a circular diagram with the sensor responses corresponding to various sorption times ($\tau_{max(i)}$ = 5 and 30 s) plotted on the axes. The changes in the geometry of the overall signal upon introducing isopentanol and ethyl acetate confirm our suggestions concerning the influence exerted by these microim-

purities on the frequency vs. time plots for sensors based on PEG-2000, DCH-18-C-6, and DNP films.

Our results were applied to analyzing solutions with a high content of ethanol, containing microamounts of other alcohols and alkyl acetates. This method was tested with foodstuffs containing such compounds. All the samples were simultaneously tested using standard techniques, gas chromatography, and the suggested method based on the use of a piezosorption matrix detector. Microamounts of acetaldehyde and ethyl formate do not affect the results of analysis by the method proposed; determination of their amounts in specimens has no priority in estimating the foodstuff quality. Based on the results of analysis by standard techniques and gas chromatography, we selected samples for compilation of the database using standard aromatograms.

Thus, we demonstrated the possibility of reliably analyzing the equilibrium gas phase of ethanol-containing solutions with a matrix detector. This method does not require sample preparation; a small sample volume (1 ml) is sufficient; the detector is simple and cheap.

CONCLUSION

Ethanol-based multicomponent gas mixtures can be analyzed using a sensor matrix. Polyethylene glycol PEG-2000, dinonyl phthalate, dicyclohexano-18-crown-6 ether, polyethylene glycol adipate, propolis, and Triton X-100 are suggested as selective coatings for the electrodes of piezoelectric quartz resonators. The optimal mass of the film applied is 10–20 μg. A specific algorithm of receiving the signals from individual sensors improves the selectivity of detecting complex mixtures of vapors of organic compounds from various classes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Features of Spark Dispersion of Some Metals

Abstract—The influence exerted by the frequency of current pulses applied to the electrodes on spark erosion of some metals was studied.

Spark dispersion of metals results in formation of essentially different products depending on the process conditions [1–3]. Conventionally, metals subjected to spark dispersion can be subdivided into two groups. The first group includes metals forming surface oxide films having high contact resistance and undergoing spark erosion, and the second group includes metals that to not form such films [4]. In spark erosion of the latter metals, the probability of spark discharges is lower, and that of shorts between the electrodes and metal granules is higher, which ultimately results in cessation of the spark erosion. The spark dispersion of such metals is performed using a metal of the first group, e.g., aluminum, a certain amount of which in the form of electrodes or granules is introduced into the reactor together with the metal studied [4].

In this work we studied the influence exerted by current pulses applied to the electrodes on spark erosion of some metals. The installation and experimental procedure are described in [12]. The electrodes made of the metal studied were fixed to the edges of the reactor, and granules of the same metal were charged inside. The working solution was distilled water. The current pulses of varied frequency F (Hz) were applied to the electrodes in the course of spark erosion, and the optimal frequency was determined. The spark-erosion efficiency of the metals N (kg h^{-1}) was determined as the ratio of the weight loss of the electrodes and granules after erosion to the erosion time. The efficiency largely depends on the electrode surface area [5]. In our experiments, the total surface area of the electrodes was about 16 cm^2. The specific energy consumption W (kW h kg^{-1}) was calculated as the ratio of the consumed energy to the weight of the dispersed metal obtained from electrodes and granules.

The results obtained in studying the effect exerted by the frequency of the current pulses applied to the electrodes on the spark-erosion efficiency of the metals are plotted in Fig. 1. As known, the oxide film covers the metal surface nonuniformly and has variable thickness. Figure 1 shows that, with increasing frequency of current pulses, the spark-dispersion efficiency by zinc, which belongs to the first group, first grows sharply and then gradually approaches the limiting value (curve *1*). Such a trend in the erosion efficiency suggests that, in sites where the surface oxide film is thinner, a part of the supplied energy goes into the metal bulk [6]. At higher frequencies, the supplied energy is redistributed, with the main part accumulated on the surface. As a result, the efficiency by zinc grows sharply. When the accumulated energy attains the limiting value, the spark erosion efficiency virtually stops to vary.

In spark erosion of tungsten (curve *2*) and nickel (curve *3*), which belong to the second group, the pattern is different. As the frequency of current pulses is increased, the dispersion efficiency of both metals first grows sharply. Then, in the ranges F = 300–500 (Ni) and 600–800 Hz (W), the spark-erosion efficiency varies insignificantly. At higher F (up to 2500 Hz), the efficiency decreases (first sharply and then slowly for Ni; gradually for W).

Such a shape of the N–F curves in spark dispersion of the second-group metals is due to the different distribution of the supplied energy at the metal surface and in bulk, which affects the spark-erosion efficiency. The different positions of the maxima of the spark-erosion efficiency for Ni and W may be due to specific features of these metals and formation of the surface oxide film.

The influence exerted by the frequency of current

1070-4272/03/7605-0742$25.00

pulses applied to the electrodes on the specific energy consumption upon spark erosion of the metals is illustrated in Fig. 2. As seen, the specific consumption of the electrical energy in spark dispersion of zinc, which belongs to the first group, varies in parallel with the process efficiency. In spark erosion of the second-group metals, e.g., tungsten (curve *2*) and nickel (curve *3*), the specific energy consumption varies in opposite direction with the process efficiency. As noted above, the second-group metals undergo spark dispersion in the presence of electrodes or granules of a first-group metal. This is presumably due to the fact that a natural oxide film on their surface increases the electrical resistance of the chain.

In spark dispersion of the metals studied, in the points denoted by asterisks in Figs. 1 and 2, the spark erosion was performed using aluminum electrodes and granules of the metals studied. In spark dispersion of zinc, the use of aluminum electrodes does not noticeably affect spark erosion. It is quite natural, because both aluminum and zinc are first-group metals. For tungsten and nickel, which are second-group metals, a different pattern was observed. In this case, the spark-erosion efficiency decreased, and the specific energy consumption increased. In all probability, the fact that, without aluminum electrodes or granules, the metals of the second group do not undergo spark dispersion [4] can be due to the high frequency of the current pulses applied to the electrodes and to the low contact resistance of surface oxide films.

The influence exerted by the frequency of current pulses on the composition of the products obtained in spark erosion of aluminum is illustrated in Fig. 3. As seen, with increasing frequency the content of the metal powder increases (curves *1*, *2*) and the content of aluminum hydroxide in the erosion product decreases (curves *3*, *4*). When the frequency of current pulses applied to the electrodes is low, a part of the supplied energy goes into the metal bulk. As a result, the number of spark discharges decreases. In the process, the portion of the energy spent for the thermal decomposition of the working solution components decreases. As a result, the amount of atomic oxygen and, consequently, the fraction of the dispersed metal coated with a protective oxide film decrease. The content of the metal powder in the erosion product also decreases. The increase in the current pulse frequency results in the formation of atomic oxygen in a greater amount and, as a consequence, in the growth of dispersed metal particles coated with the protective oxide film. Ultimately, the content of the metal powder in the erosion product increases.

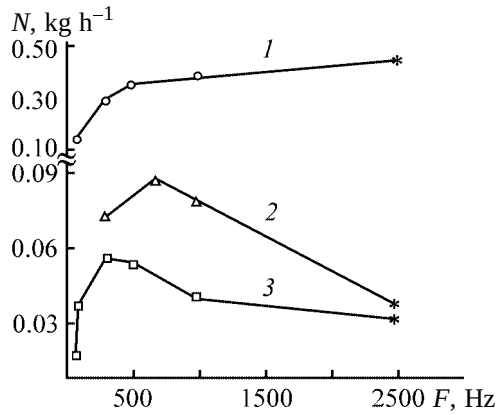

Fig. 1. Spark-erosion efficiency *N* for (*1*) zinc, (*2*) tungsten, and (*3*) nickel as a function of the frequency *F* (Hz) of the current pulses applied to the electrodes. Distilled water working medium, slurry treatment temperature 25°C, time 4 h; the same for Fig. 2.

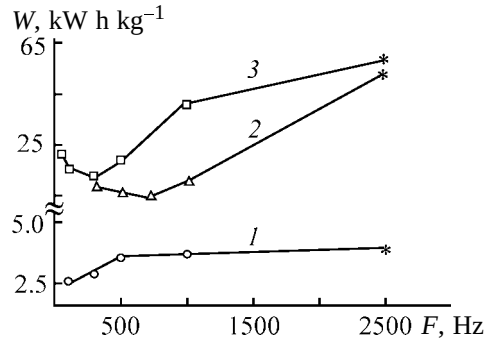

Fig. 2. Specific consumption of electrical energy *W* in the course of spark erosion of (*1*) zinc, (*2*) tungsten, and (*3*) nickel vs. the frequency *F* (Hz) of current pulses applied to the electrodes.

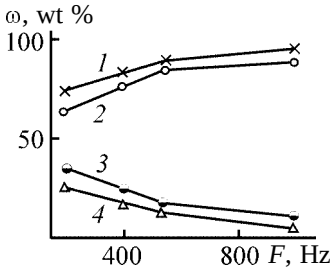

Fig. 3. (*1, 2*) Concentration ω of aluminum powder and (*3, 4*) total content of aluminum hydroxides vs. frequency *F* of current pulses applied to the electrodes. Slurry treatment temperature 25°C and time 4 h. Working medium, M: (*1, 4*) 0.19 acetic acid and (*2, 3*) 0.14 oxalic acid.

Thus, our results show that spark dispersion of second-group metals can be performed using electrodes and granules of the metal studied and current pulses of the optimal frequency.

CONCLUSION

The spark erosion of the metals studied is strongly affected by the frequency of the current pulses applied to the electrodes. The metals forming surface oxide films with low contact resistance undergo spark dispersion at the optimal frequency of the current pulses. It was shown that the amount of the metal powder in spark dispersion of aluminum increases with increasing frequency of the current pulses.

Abstract—The temperature and concentration dependences of the electrical conductivity was studied in Li_2S–$LiPO_3$ glasses. The effect of lithium sulfide additions (22.5–25 mol %) to $LiPO_3$ on the electrical conductivity was studied. The nature of the conductivity was studied over the whole range of Li_2S concentrations using Tubandt's procedure, and the contribution of electronic component to the total electrical conductivity was examined by Liang–Wagner's polarization method.

Ion-conducting substances used as solid electrolytes (SELs) for chemical current sources and in producing electrochemical transducers and ion-selective sensors attract intent researchers' attention. Crystalline compounds are most commonly used as SELs; however, glassy compounds are also given a considerable attention. These latter have a number of advantages over crystalline SELs: they are weakly sensitive to impurities and convenient in processing; they allow vacuum-tight connections to be ensured. Electrical parameters of glassy compositions are highly stable and reproducible. Moreover, the electrical conductivity of glassy compositions is one or two orders of magnitude higher than the conductivity of crystalline compounds of the same composition.

In SEL, the electronic component of electrical conductivity is absent, and the total conductivity is determined by the migration of ions in an electric field. The expression for the total conductivity of SEL taking into account the contribution of both positive and negative current carriers has the form

$$\sigma = \sigma_+ + \sigma_- = qn(\mu_+ x_+ + \mu_- x_-), \quad (1)$$

where σ is the total electrical conductivity; σ_+ and σ_-, electrical conductivities determined by the migration of positive and negative current carriers, respectively; n, number of molecules per unit volume; $q = ez$, electrical charge of a carrier; x_+ and x_-, mole fractions of cations and anions; and μ_+ and μ_-, ionic mobilities.

Often one kind of the current carriers dominates in the electrical conductivity. In this case, the conductivity of glassy systems can be described by the equation [1]

$$\sigma = n\alpha(ez)\mu, \quad (2)$$

where α is the degree of dissociation.

It follows from relationship (2) that an increase in the conductivity can be achieved by increasing both the number of current carriers and their mobility.

The electrical conductivity of binary alkali oxide glasses increases as the content of an alkali metal oxide increases. Therefore, seemingly, glassy SELs should be searched for among the systems into which a maximal amount of current carriers could be introduced. However, this line is limited by the fact that glasses with a high M_2O content (M = Li, Na, K, etc.) have a low chemical stability and readily crystallize. At the same time, the number of ions participating in current transfer can be increased at the expense of decreasing the energy of their bonding with the glass matrix. This can be achieved by introducing inorganic salts with large anions (SO_4^{2-}, SO_3^{2-}, and halide ions) into the glass composition. In this case, the structure of the starting glass becomes loosened, and the electrical conductivity increases [2–4].

As believed in [5–8], the substitution of sulfur(II) ions for oxygen ions in the glass structure should also be accompanied by an increase in the ionic conductivity. In fact, sulfur(II) ions are larger than oxygen ions ($r_{S^{2-}}$ = 1.84 and $r_{O^{2-}}$ = 1.40 Å) and have a more pronounced tendency to form covalent bonds. Therefore, the energy of interaction between sulfur-containing glass fragments and alkali metal ions is lower than in oxide glasses. Consequently, the energy of dissociation of polar structural chemical units containing

25.0	75.0	10.55	11.52	30.61	9.93	11.26	30.68

sulfur(II) will be lower, and the electrical conductivity itself must increase at the expense of an increase in the number of current carriers. Thus, the substitution of sulfur for oxygen in Na_2O–GeO_2 glasses (to give the Na_2S–GeS_2 system) was shown [6–9] to result in increased conductivity. This can be accounted for by the fact that sulfur(II) compounds have a higher ionic conductivity than their oxide analogs. Indeed, the electrical conductivity of sulfide glasses considerably exceeds that of oxide glasses. At room temperature, the specific electrical conductivity of glasses, e.g., in the Na_2O–P_2O_5 system attains 7×10^{-9} S cm^{-1} at E_σ = 1.36 eV [10], and in the Na_2S–P_2S_5 system, $\sigma = 3.9 \times 10^{-6}$ S cm^{-1}, E_σ = 1.08 eV [11].

To further increase the electrical conductivity, halide salts are introduced into sulfide glasses. For example, a glass of the composition $0.477(GeS_2 \cdot Ag_2S) \cdot 0.523AgI$ with the conductivity of 4.7×10^{-3} S cm^{-1} (25°C) and E_σ = 0.50 eV was described in [12]. The study of the conductivity nature showed that glasses of these systems are ionic conductors, and the electronic component of the conductivity in silver-containing sulfide glasses is 3–4 orders of magnitude lower than the ionic component [13]. Among essential drawbacks of such glasses are their high hygroscopicity and difficult synthesis [11, 14]. We emphasize that the published data on the properties of glassy compositions mainly concern silicates and borates. The electrical properties of sulfur-containing oxide–phosphate glasses are known only for Na_2O–Na_2S–P_2O_5 glasses [15] and for silver-containing systems [16]. In this work we studied the temperature and concentration dependences of the electrical conductivity and the nature of current carriers in the Li_2S–$LiPO_3$ glasses.

EXPERIMENTAL

We synthesized the glasses in glassy carbon crucibles in a dry argon atmosphere in a laboratory electric furnace at 1100–1150°C for about 25 min. This time was sufficient for complete melting and homogenization of the melt. The charge was prepared from chemically pure grade $LiPO_3$ and lithium sulfide obtained by direct synthesis in liquid ammonia [17]. The purity of the resulting Li_2S was no worse than 99.5%, with polysulfides as impurities.

To decrease sulfur volatilization, we placed the crucible with the charge into a crucible of a larger volume; the space between the crucibles was filled with lithium sulfide, and the external crucible was covered by a lid [8]. We sampled the glasses by pouring off the melt into preheated metallic molds with the subsequent annealing for 1 h in a muffle furnace at a temperature approximately 15°C lower than T_g and cooling together with the muffle to room temperature. The glass transition point T_g was determined by the plot of the relative elongation of the sample (a glass cylinder 50.0 ± 0.5 mm long) vs. temperature. The measurements were performed on a DKV-5 vertical quartz dilatometer. The annealing quality was monitored by the polarization optical method.

The chemical analysis of the synthesized glasses showed that their compositions are close to the calculated compositions (Table 1). The phosphorus content was determined by the standard procedure involving the formation of phosphomolybdic acid [18]. Since sulfur can be in various forms in the glass structure (free, sulfide, and polysulfide), we determined the total content of sulfur by the decomposition of a glass sample and subsequent sulfur oxidation to sulfate ion [15]. The lithium content was determined by flame photometry.

We determined the density of glasses by hydrostatic weighing in carbon tetrachloride. The reproducibility of the results for glasses obtained in replicate meltings is $(3–5) \times 10^{-3}$ g cm^{-3}.

The electrical conductivity was measured with parallel-plate finely polished samples 1.50 ± 0.01 mm

thick and 20 mm in diameter [19]. To exclude the possible surface conductivity, we carried out the measurements using safety electrodes [according to GOST (State Standard) 6433.2.71] in the direct current mode with active (lithium amalgam) electrodes in the range from room temperature to 270°C under heating and cooling conditions. No hysteresis phenomena were observed. We used ED-05M and ITN-7 electrodynamic electrometers as measuring devices. The obtained experimental data lied along a straight line in the $\log\sigma = f(1/T)$ coordinates. The data were processed using the equation

$$\sigma = \sigma_0 \exp(-E_\sigma/2kT).$$

Lithium metaphosphate has an electrolytic conductivity, the transport numbers of lithium ions being 0.97–1.00 depending on the conditions of its synthesis [19]. Along with lithium ions, protons formed upon dissociation of impurity water can take part in current transport. To estimate the content of water in the glasses under study, we recorded the IR transmission spectra of parallel-plate polished samples (l = 1.50 mm) in the range 2000–5000 cm^{-1}. The intensity of absorption at 2300, 2900, and 3400 cm^{-1} in the spectra of $Li_2S–LiPO_3$ glasses is substantially lower than in the spectra of $Li_2O–P_2O_5$ and $Li_2O–LiPO_3$ glasses, which indicates that the content of impurity water in the first case is small [$\sim(2–5) \times 10^{-2}$ wt %]. The introduction of lithium sulfide, which is a cationic conductor, into $LiPO_3$ should not be accompanied by a change of the nature of current carriers. The conductivity of $Li_2S–LiPO_3$ glasses will be determined by the migration of lithium ions only. To check this assumption, we determined the transport numbers of lithium ions using Tubandt's method. The amount of electricity passing through the samples during electrolysis was measured by a silver–thallium coulometer and a Kh-603 electrolytic quantity meter connected in series. We let 4–6 C of electricity pass through a stack of glasses. If more than 10 C of electricity passed, the growth of dendrites and breakdown of the samples were observed. We estimated the changes in the composition of the near-electrode and middle samples after the electrolysis by the changes in their weight. We weighed the samples on a VLAO-100/1 semimicroanalytical balance. An experiment was considered to be correct if the weight of a middle sample before and after electrolysis remained the same within the error of weighing. The contribution of the electronic component (10^{-3}%) to the total conductivity was determined using the Liang–Wagner polarization method.

It follows from Table 1 that the analytical content of lithium and phosphorus virtually corresponds to their calculated content, whereas the sulfur loss reaches 6–7%. This is due to the fact that water present in the charge as an impurity reacts with sulfide ions to give hydrogen sulfide.

It is interesting that, in the $Li_2O–P_2O_5$ system, it is possible to synthesize a glass containing 58 mol % Li_2O (Table 2) [19]. The concentration of lithium ions in this glass is 3.08×10^{-2} mol cm^{-3}, and in $LiPO_3$ it is 2.74×10^{-2} mol cm^{-3}. The activation energy at such an increase in the content of lithium ions decreases from 1.36 to 1.12 eV, and the electrical conductivity (at 200°C) increases by almost an order of magnitude (see figure; Table 2).

The addition of lithium sulfide to lithium metaphosphate is accompanied by an increase in the concentration of lithium ions by a factor of almost 1.5 (Table 3). This concentration is 3.84×10^{-2} mol cm^{-3} in the glass containing 25 mol % Li_2S. In this case, the activation energy of the electrical conductivity

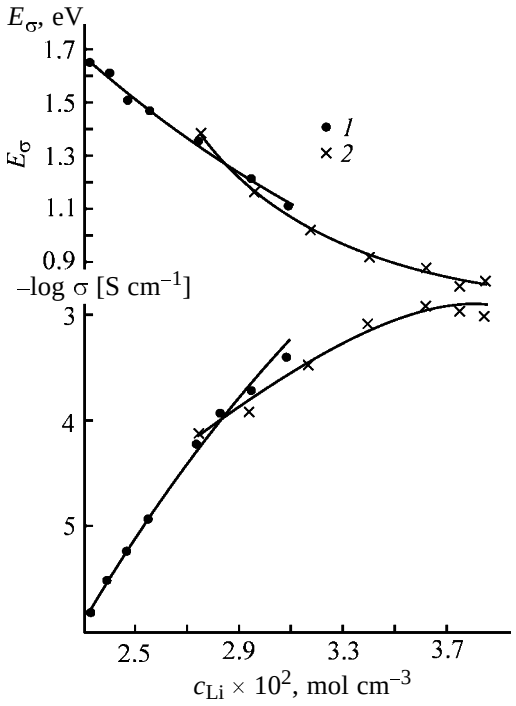
* $V_{mol} = M/d$, where M is the molar weight of the glass.

decreases from 1.38 to 0.84 eV, and $-\log\sigma$ at 200°C changes from 4.15 to 3.0 (see figure; Table 3).

When the concentration of lithium ions increases within the limits of $(2.74–3.08) \times 10^{-2}$ mol cm^{-3}, the activation energy of electrical conductivity and the electrical conductivity itself for the Li_2O–P_2O_5 and Li_2S–$LiPO_3$ glasses almost coincide (see figure). This may be due to the fact that sulfur-containing polar structural chemical units appear to be blocked (in this concentration range of Li_2S) by the $Li^+[O^-PO_{3/2}]$ units.



Plots of the logarithm of specific electrical conductivity $\log\sigma$ and of the activation energy of electrical conductivity E_σ of (*1*) Li_2O–P_2O_5 [19] and (*2*) Li_2S–$LiPO_3$ glasses vs. concentration of lithium ions c_{Li^+} at 200°C.

The introduction of lithium into P_2O_5 is actually accompanied by the break of bridging P–O–P bonds and by the depolymerization of polyphosphate chains to give di-, tri-, and tetraphosphate anions. Myuller [1] believes that the structure of such glasses consists of polar and nonpolar structural chemical units [1]. When [Li]/[P] < 1, the structure will be determined by a combination of polar $Li^+[O^-PO_{3/2}]$ and nonpolar $[PO_{4/2}]$ structural chemical units. As the concentration of lithium ions increases, the content of polar structural chemical units increases, and at [Li]/[P] = 1 the structure of the glass of the metaphosphate composition will consist mainly of polar $Li^+[O^-PO_{3/2}]$ structural chemical units only. In the glasses with [Li]/[P] > 1, along with polar $Li^+[O^-PO_{3/2}]$ structural chemical units, new polar $Li_2^+[O_2^-PO_{2/2}]$ units are formed. The interaction between polar $Li^+[O^-PO_{3/2}]$ structural chemical units is accompanied by the appearance of the quadrupoles

$$\begin{array}{l} O_{3/2}P–O^-Li^+ \\ \quad\vdots\quad\vdots \\ Li^+O^-–PO_{3/2}. \end{array}$$

The energy of lithium dissociation from these quadrupoles is lower than that from the polar $Li^+ \cdot [O^-PO_{3/2}]$ structural chemical units. The number of current carriers increases at this expense. The energy of activation shift, E_a, of dissociated ions in the medium of polar structural chemical units is lower than that in the medium of the nonpolar $[PO_{4/2}]$ structural chemical units. As already noted, the structure of lithium metaphosphate is formed by polar structural chemical units; hence, lithium ions migrate in a polar medium, and $E_a \approx$ const, as the migration mechanism remains unchanged. The increase in the electrical conductivity can be accounted for by a decrease in the dissociation energy of quadrupoles E_g, which results

Table 4. Transport numbers of lithium ions in the Li_2S–$LiPO_3$ glasses*

* $Q' = Q/F$, where F is the Faraday number; $\nu_{Li^+} = Q''/Q'$.

in increased number of dissociated lithium ions, which are the current carriers. As a result, the activation energy of electrical conductivity, E_σ, decreases (see figure; Table 2).

In experiments with $AgPO_3$–Ag_2S glasses, it was suggested that sulfur(II) is able to replace oxygen in the glass structure [15]. In line with this concept, introduction of lithium sulfide into lithium metaphosphate will be accompanied both by incorporation of sulfide ions in the anionic component of the structure ($O_{3/2}P$–S–$PO_{3/2}$) and by the formation of various sulfur-containing polar structural chemical units. Therefore, we assume that, along with polar oxide $Li^+[O^-PO_{3/2}]$ and $Li_2^+[O_2^-PO_{2/2}]$ structural chemical units, the $Li^+[S^-PO_{3/2}]$ units

$$\begin{array}{ccc} Li^+S^-PO_{3/2}, & & Li^+O^-PO_{3/2} \\ \vdots\ \vdots & & \vdots\ \vdots \\ O_{3/2}PS^-Li^+ & & O_{3/2}PS^-Li^+ \end{array}$$

are formed in the structure of Li_2S–$LiPO_3$ glasses.

The ionic conductivity depends on the energy of lithium binding with the glass framework. A decrease in the binding energy is accompanied by an increase in the number of current carriers at the expense of increased degree of dissociation of polar structural chemical units and, consequently, by an increase in the electrical conductivity (Tables 3, 4).

Therefore, the increase in the electrical conductivity of the Li_2S–$LiPO_3$ glasses is attributable to the fact that the replacement of oxygen in the glass structure by a more polarizable sulfur(II) ion results in the weakening of bonds between lithium ions and the glass framework. This is responsible for a decrease in the dissociation energy of polar structural chemical units and an increase in the number of current carriers and in the electrical conductivity itself.

CONCLUSION

The formation of sulfur-containing oxide polar structural chemical units in the structure of Li_2S–$LiPO_3$ glasses is accompanied by an increase in the electrical conductivity and a decrease in the activation energy of electrical conductivity. Such structural chemical units have a lower (compared to pure oxide) dissociation energy, which results in an increase in the number of current-carrying ions.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Nickel–Zinc Battery with Nickel Oxide Electrode Made of Spherical Nickel Hydroxide on Foamed Nickel Support

M. M. Loginova, T. B. Kas'yan, Z. P. Arkhangel'skaya, and L. B. Raikhel'son

Abstract—Electrochemical and working characteristics of a nickel–zinc battery with nickel oxide electrode made of spherical nickel hydroxide on foamed nickel support were determined.

Nickel–zinc (NZ) battery yielding high output power is known as a power supply for means of transportation, such as underwater vehicles, motor scooters, motorcycles, and hybrid automobiles. Its specific energy is as high as 75–80 W h kg^{-1}, and specific power, 250 W kg^{-1}. However, application of NZ batteries for these purposes has been limited until recently by their short service life and high cost of the positive electrode with metal–ceramic (MC) support.

New methods for fabrication of nickel oxide electrodes (NOE) of nickel–cadmium and nickel–metal hydride batteries have been developed and successfully implemented. These methods employ highly dispersed materials, which are deposited onto a foamed nickel (FN), rather than metal–ceramic, support. To materials of this kind belong spherical nickel hydroxide with addition of hydroxide compounds of cobalt and zinc [1]. Fabricated by pasting and subsequent compaction, NOE have 1.2–1.5 times better specific characteristics because of the use of a lighter support and a compact arrangement of particles of the active paste [2].

Use of spherical nickel hydroxide modified with activating additives in an NZ battery in the form of a compacted electrode with FN support may affect substantially the processes occurring in the battery. In particular, addition of cobalt hydroxide can prevent the commonly occurring in NZ batteries "poisoning" of a compacted NOE by zinc ions [3]. In addition, the dynamics of intraelectrode ("loss of shape") and interelectrode zinc transfer may change because of the densified structure of NOE with spherical nickel hydroxide, and this can affect the working capacity of the zinc electrode. The loss of shape has been attributed to various factors: phase segregation in the electrolyte upon a change in the concentrations of KOH and $Zn(OH)_4^{2-}$ [4], convection in the electrolyte [5], and nonuniform distribution of the current over the electrode surface [6]. Solution of this problem, which is of high theoretical and practical importance, cannot be considered conclusive up to now.

EXPERIMENTAL

In this study, we determined the electrical characteristics of an NTs-25 battery with compacted NOE fabricated by pasting spherical nickel hydroxide onto an FN support. Nickel hydroxide contained 5.6% cobalt and 3.2% zinc. In other respects, the design and technology of fabrication of the battery were the same as those for a battery with MC NOE. The cobalt-to-nickel ratio in the material used was close to the optimal value [Co/(Co + Ni) = 0.07] [7].

The basic parameters of batteries of several types differing in the amount of active paste in unit volume of the positive electrode and in the ratio of active paste masses in the positive and negative electrodes are given in Table 1.

The calculated capacities of positive electrodes, listed in Table 1, correspond to the transformation of Ni^{2+} to Ni^{3+}. The ratio of capacities of the negative and positive electrodes in the batteries under study is smaller than that in batteries with MC NOE, since a greater amount of the active paste is contained in the same NOE volume.

This makes it possible to obtain a higher capacity from the battery in the initial cycles, but, at the same time, creates conditions for fast accumulation of excess charged phase in the zinc electrode, especially so in view of the fact that an excess, with respect to the calculated value, capacity should be imparted to the positive electrode in battery forming.

1070-4272/03/7605-0751$25.00

Table 1. Characteristics of NTs-25 batteries. Thicknesses of positive and negative electrodes 0.95 and 1.25 mm, respectively

Battery	Calculated electrode capacity, A h		Density of active paste, g cm^{-3}		(+)-to-(–) capacity ratio	Battery weight, g
	(+)	(–)	(+)	(–)		
NTs-25:						
with MC NOE	30.8	95	–	1.7	3.0	780
with FN NOE I	46.8	95	2.5	1.7	2.0	735
with FN NOE II	54.0	95	2.7	1.7	1.74	760

The batteries were studied in cycling in the ventilated mode (with low-pressure valves). At regular intervals of time, one battery of each batch was disassembled to determine its state and make analyses; in addition, discharge was performed in separate cycles by different currents to determine the working capacity of a battery in the range from 0.1 to 2*C*.

In order to determine the extent of self-discharge, part of batteries were stored in the charged state for 1 month with the subsequent discharge.

It was found that, in contrast to the MC electrode, the active paste of the positive electrode made of spherical $Ni(OH)_2$ acquires capacity in forming cycles gradually, in 2–3 cycles (Table 2). In the first cycle, the discharge capacity of batteries of type I was only 50–55% of the capacity imparted in charging, and that in the second cycle, 83%, which corresponds to 60% of the theoretical capacity corresponding to conversion of Ni^{2+} into Ni^{3+}. Batteries of type II, with NOE possessing increased capacity, were subjected to three forming cycles, with the positive electrodes yielding in discharge 80% of the calculated capacity.

Charging was done in each stage to a final voltage of 1.98–2.0 V, and discharge, to 1.2 V.

In subsequent cycling, the initial discharge capacity of batteries with FN NOE I (25–27 A h) approximately corresponded to the capacity of batteries with the MC electrode, which allowed their comparison under comparable conditions (Fig. 1).

Table 2. Forming modes and results obtained for different types of NTs-25 batteries

Cycle no.	Charging/discharge capacity, A h		
	with FN NOE I	with FN NOE II	with MC NOE
1st	33/18	42/32	33/27
2nd	33/27.5	45/37.5	33/27
3rd	–/–	55/43	–/–

One of basic characteristics of NZ batteries, which determines the possibility of their use in means of transportation, is their working capacity in intensive discharge modes. Tests demonstrated that the voltage of batteries with FN NOE in charging was markedly lower than that in batteries with the MC electrode, and, in discharge with currents of 0.1–1*C*, their capacity and voltage are virtually identical. And only in the 2*C* mode, the batteries under study, with spherical nickel hydroxide on FN support, have somewhat lower capacity at the same electrode thickness (~1 mm). Therefore, it is advisable to use thinner compacted NOE in batteries intended for short discharge modes.

Comparison of characteristics of the batteries under study (types I and II) with different active paste densities shows that the voltage of a battery with increased amount of electrode material is higher in charging and lower in discharge, with the difference becoming more pronounced with increasing discharge current (Fig. 2). With increasing number of cycles, the achieved degree of NOE charging decreases to a greater extent for batteries of type II, although the discharge capacity of this type of batteries retains higher values up to 100 cycles (Fig. 3).

A decrease in the ratio of capacities of the negative and positive electrodes affects adversely the states of the zinc electrode. As shown by chemical analysis of the active paste from negative electrodes of disassembled batteries, the content of the reduced phase increased, and that of the oxidized phase, decreased.

Content of reduced phase in discharged negative electrode of NTs-25 battery with FM NOE

Cycle	(Zn/Zn + ZnO), %
Initial	7.4
After forming	31
63rd	78
110th	80
200th	85

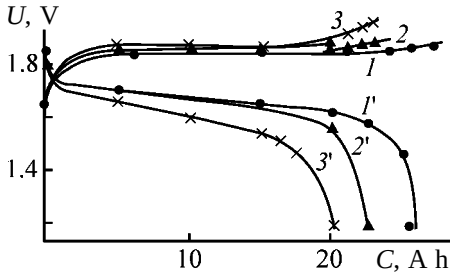

Fig. 4. Effect of service time on (*1–3*) charging and (*1'–3'*) discharge characteristics of NTs-25 battery with NOE on foamed nickel support. (*C*) Discharge capacity and (*U*) voltage; the same for Fig. 5. Cycle: (*1, 1'*) 10th, (*2, 2'*) 100th, and (*3, 3'*) 200th.

In batteries of type I, the whole amount of the oxidized phase was exhausted by the 125th cycle, and in batteries of type II, already by 70th cycle, which required deep discharge to convert the accumulated metallic zinc into the oxidized state (Fig. 3). Changes in the active paste of the negative electrode in the course of cycling lead to a decrease in discharge capacity and increase in charging voltage of the batteries (Figs. 3 and 4).

Apparently, to prevent accumulation of the charged phase in the electrode and to stabilize the discharge capacity of a battery for a longer time, it is necessary to pass to a sealed battery design. This will also ensure deeper deforming of the NOE under study without overcharging of the zinc electrode, since its active paste will be oxidized by evolving oxygen [8].

An analysis of the state of batteries disassembled after cycling demonstrated that changes in the shape of the negative electrode, which only become noticeable by 200th cycle, are manifested in a decrease in the thickness of the active paste layer in a narrow upper part of the electrode. At the same time, in a battery with metal–ceramic NOE the active paste is absent, under the same conditions, on 20% of the electrode area [6]. This is a favorable indication of longer service life of the battery under study, compared with that of the already existing battery.

A study of the influence exerted by storage of a charged battery with NOE made of nickel hydroxide on foamed nickel support demonstrated a 9% self-discharge in 30 days (Fig. 5), which virtually coincides with the degree of self-discharge of batteries with MC support [9].

Our results show that, on replacing the positive electrode with MC support by a compacted electrode with spherical nickel hydroxide, the NZ battery has similar electrical and service characteristics. In addition, the electrode under study is simpler in fabrication.

However, the practically accepted ratio of capacities of the negative and positive electrodes is violated in view of the fact that the capacity of the compacted electrode exceeds that of MC in the same volume. Raising the ratio to the optimal value will enable an increase in the discharge capacity of the NZ battery by 20–30%. Making larger the reserve of the active

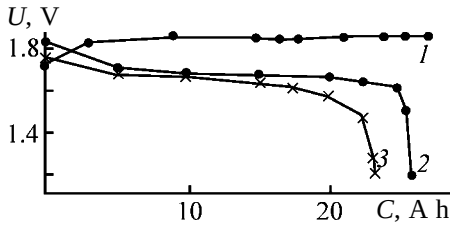

Fig. 5. Effect of storage on discharge capacity of NTs-25 battery with NOE on foamed nickel support. (*1*) Charging; discharge: (*1*) 1 h after charging and (*2*) 30 days after charging.

paste in the negative electrode is also necessary in view of the overcharging of the zinc electrode in forming and subsequent cycling of a battery and the resulting necessity for periodic "deep" discharges.

CONCLUSIONS

(1) The nickel oxide electrode made of spherical nickel hydroxide on a foamed nickel support ensures, in operation in a previously developed nickel–zinc battery, electrochemical characteristics similar to those of the metal–ceramic electrode in a wide range of current loads.

(2) To improve the characteristics of batteries with nickel oxide electrode on foamed nickel support, it is necessary to optimize the active paste ratio in the negative and positive electrodes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Determination of Ascorbic Acid by Electrocatalytic Response of an Electrode Coated with Polyvinylpyridine Film and Palladium-Plated

L. G. Shaidarova, A. V. Gedmina, and G. K. Budnikov

Kazan State University, Kazan, Tatarstan, Russia

Received January 10, 2003

Abstract—A procedure was developed for analysis of ascorbic acid with a carbon glass electrode coated with a palladium-modified poly(2-vinylpyridine) film.

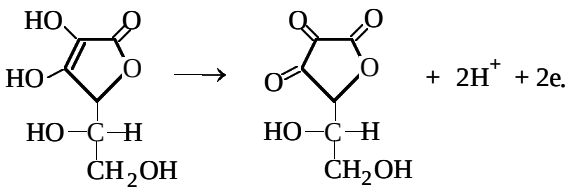
Ascorbic acid is a water-soluble vitamin which is involved in a number of biochemical processes including electron transfer, oxidative catabolism of aromatic amino acids, synthesis of precollagen and collagen, etc. Owing to reducing properties, ascorbic acid is widely used in food industry as a preservative or food additive. Pharmaceuticals containing ascorbic acid are used to prevent and treat various diseases. Therefore, determination of ascorbic acid in biological objects is an important analytical task. Ascorbic acid can be quantitatively determined by titrimetric [1, 2], spectrophotometric [1–4], and chromatographic [5, 6] procedures. Most of them are labor-consuming or have limited application. Highly sensitive electrochemical methods are also used to determine ascorbic acid. Ascorbic acid is reversibly oxidized on a mercury dropping electrode [7]. However, on solid electrodes it is irreversibly oxidized with a high overvoltage [8]. Polarographic methods were widely used to determine ascorbic acid. However, mercury toxicity prevents application of these methods in laboratory practice. Analytical potentialities of voltammetry with chemically modified electrodes (CMEs) are substantially wider. Various CMEs were proposed to increase the sensitivity and selectivity of ascorbic acid determination [9]. Advantages of CMEs in flow-injection analysis of ascorbic acid are reviewed in [10].

Chemically modified electrodes based on electron carrier materials are of special interest [9]. Wring *et al.* [11] used an epoxy–graphite composite electrode modified with cobalt phthalocyanine for determining ascorbic acid. The detection limit of amperometric determination of ascorbic acid in multivitamin preparations is 0.65 ng ml^{-1}. Disadvantages of this method are complex preparation of the electrode and limited application in flow-injection systems. Electrodes coated with a polymeric film are used in [12–14]. Electrooxidation of ascorbic acid on CMEs coated with polypyrrole [12], poly(3-methylthiophene) [13], and polyaniline [14] films was studied. Preparation of film electrodes is simple, and their catalytic activity is high. However, although the analytical signal of film electrodes has better shape and higher intensity, the detection limit of ascorbic acid does not noticeably decrease. Determination of ascorbic acid with CMEs plated with platinum group metals was studied in [15, 16]. These electrodes are highly sensitive to ascorbic acid but their analytic signal is poorly reproduced.

Inclusion of platinum metals in polymeric films is one of the pathways to improve electrocatalytic properties of platinum metals and the stability of chemical sensors on their base. Ruthenium, Rh, Pd, and Pt are electroplated on polyvinylpyridine film in the form of finely divided deposits having high catalytic activity [17–21]. The influence of the polymeric matrix on the deposit properties is provided by adsorption interaction of its fragments, in particular, pyridine rings, with the surface of metal particles.

In this work we studied electrocatalytic acidity of palladium particles plated on the surface of carbon glass (CG) and a poly(2-vinylpyridine) (PVP) film in electrooxidation of ascorbic acid.

Electrooxidation of ascorbic acid on carbon glass. Ascorbic acid is irreversibly oxidized on solid electrodes to form dehydroascorbic acid. This two-electron process is usually describe by the equation [15]



1070-4272/03/7605-0755$25.00

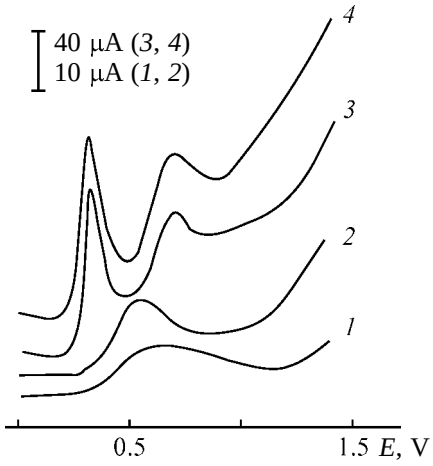


Fig. 1. Voltammogram of ascorbic acid oxidation in 0.1 M H_2SO_4 on (*1*) CG, (*2*) PVP-CG, (*3*) Pd-CG, and (*4*) Pd-PVP-CG electrodes. Ascorbic acid concentration 5×10^{-3} M; the same for Fig. 2. (*E*) Potential; the same for Fig. 2.

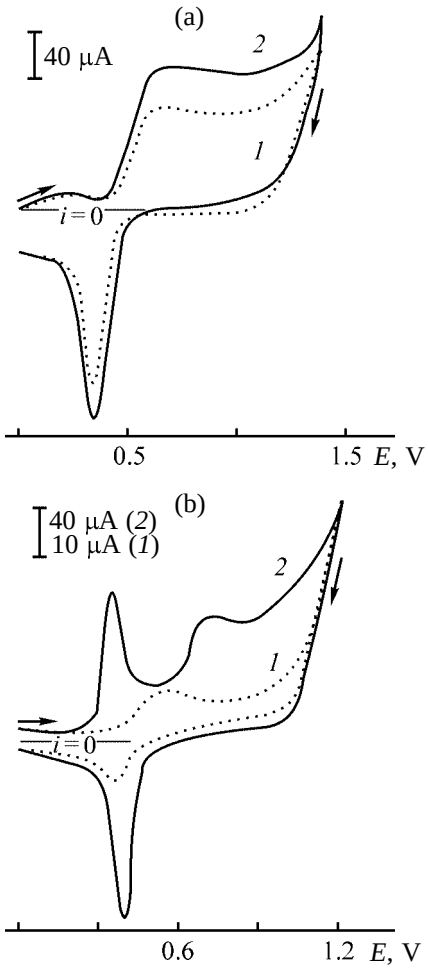

Fig. 2. Cyclovoltammogram of (a) Pd plating and (b) ascorbic acid oxidation in 0.1 M H_2SO_4 on (*1*) Pd-CG and (*2*) Pd-PVP-CG electrodes. (a) (*1*) Pd-CG and (*2*) Pd-PVP-CG; (b) (*1*) PVP-CG and (*2*) Pd-PVP-CG.

Voltammogram of ascorbic acid oxidation on CG electrode (Fig. 1, curve *1*) contains a broad irreversible peak at E_p = 0.60 V, whereas a reversible wave with $E_{1/2}$ = –0.4 V (vs. SCE) is registered on a mercury dropping electrode (m.d.e.) [7]. The overvoltage on CG electrode is more than 500 mV as compared to m.d.e. In addition, the electrochemical signal of the solid electrode is poorly reproducible owing to adsorption of products of the electrochemical reaction. All these factors affect the metrological parameters of ascorbic acid determination. The dependence of peak current on the ascorbic acid concentration is linear in a narrow concentration range from 5×10^{-4} to 1×10^{-2} M.

When electrocatalytic CMEs are used, the overvoltage decreases, the shape of the electrochemical signal is improved, and the sensitivity of determination of ascorbic acid increases.

We compared electrochemical behavior of ascorbic acid on CG, CG with electrodeposited PVP film (PVP-CG), palladium-plated CG (Pd-CG), and on GC electrode coated with PVP film and then palladium-plated (Pd-PVP-CG). Preliminarily we determined conditions for preparing these chemically modified electrodes.

Palladium electroplating of CG. Palladium electrochemistry is relatively complex and involves formation of oxo and hydroxo derivatives with various oxidation states of palladium, such as PdO, PdOH, $Pd(OH)_2$, PdO_2, and PdO_3 [22]. The cyclovoltammogram recorded on a Pd-CG electrode in 0.1 M H_2SO_4 is shown in Fig. 2. When the anodic potential is swept to the positive region, a wave with $E_{1/2}$ = 0.65 V appears due to Pd^{2+} formation:

$$Pd^0 \rightleftarrows Pd^{2+} + 2e.$$

At more positive potentials, palladium(II) oxide particles inhibiting this reaction are formed. Higher palladium oxides are formed simultaneously with oxygen liberation at E > 1.2 V [22]. A sharp peak with E_p = 0.34 V assigned to reduction of PdO to Pd^0 is observed at the reverse potential sweeping [22]. The standard potential of the Pd^{2+}/Pd^0 redox system (E^0 = 0.951 V [23]) differs from the potential of palladium electroplating on CG (E_p = 0.34 V) owing to the overvoltage of palladium electroplating of graphite support [24].

Palladium was electroplated on the surface of CG electrode by two methods: cyclic potential sweeping in a definite potential range and potentiostatic electroplating (Table 1). In both cases, palladium was plated

Table 1. Conditions for palladium plating on the CG and PVP-CG surface

Matrix	Cyclic sweeping		Electroplating			
	E_p, V	i, μA	E_e, V	i, μA	t_e, min	i, μA
CG	–0.3 to +0.3	40	+0.3	17	1	14
	–0.3 to +0.2	50	+0.1	21	3	22
	–0.3 to +0.1	53	+0.0	23	5	30
	–0.3 to +0.0	58	–0.2	26	7	32
	–0.4 to +0.0	58	–0.4	30	9	31
PVP-CG	–0.3 to +0.3	55	+0.3	30	1	32
	–0.3 to +0.2	65	+0.1	39	3	46
	–0.3 to +0.1	76	+0.0	48	5	60
	–0.3 to +0.0	87	–0.2	54	7	59
	–0.4 to +0.0	87	–0.4	60	9	60

in a stirred electrolyte. When the first method was used, the potential was swept from –0.3 to +0.3 V. At lower potential, the palladium layer was loosened by the hydrogen evolved. A shift of the polarization potentials to the positive region appreciably decreased the intensity of the palladium oxidation wave at $E_{1/2}$ = 0.65 V (Table 1).

Potentiostatic palladium electroplating was performed at E < 0.3 V, since Pd(II) is reduced to Pd(0) at E_p = 0.34 V. The working electrolysis potential was E_e = –0.3 V, and the electrolysis time was t_e = 5 min (Table 1). However, when E_e was decreased even to –0.3 V, the current of palladium oxidation was substantially lower than that in the first procedure. In the subsequent experiment, palladium was plated by potential sweeping from –0.3 to +0.3 V over five cycles. Voltammograms were recorded after keeping the electrode at the initial potential E_i = 0.0 V for 50 s.

Palladium plating on PVP film on CG support. Palladium-modified PVP film was also prepared by potential sweeping and electrolysis at a constant potential. Previously we determined conditions for depositing PVP film of CG [25]. We prepared composite electrodes under different conditions. The currents registered on the electrodes prepared by successive application of PVP film on CG and palladium plating were maximal. The preparation conditions of CMEs are summarized in Table 1. The maximal current of palladium oxidation was observed on the Pd-PVP-CG (as well as Pd-CG) electrode prepared by cyclic potential sweeping from –0.3 to +0.0 V.

The composite film was prepared as follows. First, PVP film was deposited on CG surface by electrolysis of an acetonitrile solution containing 1 mg ml^{-1} PVP and 0.1 M $LiClO_4$ at E_e = –1.5 V. Then palladium was plated on the PVP film from a 5×10^{-3} M solution of $PdCl_2$ in 0.01 M H_2SO_4 by potential sweeping from –0.3 to +0.0 V over five cycles. The voltammogram recorded on the CME contains two sharp anodic–cathodic peaks (Fig. 2, curve *2*) whose intensity is reproduced for several days. We studied the shape of the anodic–cathodic peaks registered on the CME as influenced by the pH of the supporting electrolyte. The palladium oxidation wave decreases with increasing pH and disappears at all at pH > 5.

The shapes of voltammograms recorded on Pd-CG (Fig. 2, curve *1*) and Pd-PVP-CG (Fig. 2, curve *2*) electrodes are similar. However, the peaks registered on the composite electrode are more intense and better reproducible (S_r < 1%). The peak intensity increases owing to an increase in the dispersity of the palladium deposit. Smolin *et al*. found [17] that the size of crystallites formed in the Pd-PVP-CG system was more than an order of magnitude smaller than that of Pd crystallites plated on CG. This fact was explained by the influence of porosity of the PVP film. In the first electrocrystallization steps, nucleation and initial growth of palladium crystallites occurs on the CG surface. Then crystallites grow along the pores and reach the PVP–electrolyte interface. The degree of dispersion of the deposit affects not only the size of the effective electrode surface but also the palladium electrocatalytic properties.

Electrooxidation of ascorbic acid on CME. Voltammograms of oxidation of ascorbic acid in 0.1 M H_2SO_4 on CG coated with PVP film (curve *2*), palladium-plated CG (curve *3*), and composite electrode coated with PVP film and plated with Pd particles (curve *4*) are shown in Fig. 1.

Ascorbic acid is oxidized on PVP-CG electrode at

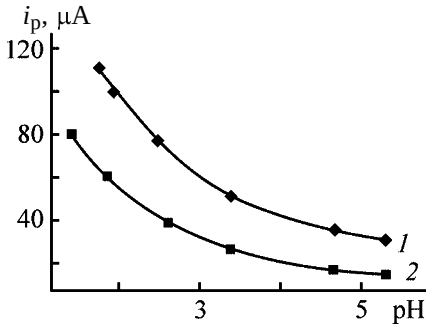

Fig. 3. Peak current i_p of ascorbic acid oxidation on Pd-PVP-CG electrode as a function of pH of the electrolyte. Peak potential E_p, V: (*1*) 0.32 and (*2*) 0.65.

E_p = 0.54 V. The anodic peak is close to that registered on the nonmodified CG (E_p = 0.06 V), i.e., the overvoltage on the CME decreases negligibly. The reaction on the film electrode is reversible, unlike the CG electrode on which irreversible peak of ascorbic acid oxidation is registered. The cyclovoltammogram on the PVP-CG electrode (Fig. 3, curve *1*) contains a couple of anodic–cathodic peaks (E_a = 0.54, E_c = 0.35 V) whose intensities are higher than those on the nonmodified electrode. Appearance of the reversible peak and an increase in the current of ascorbic acid oxidation can be due to mediator properties of the polymeric film.

The overvoltage of electrooxidation of ascorbic acid on the palladium-plated CG electrode is substantially lower than that on the PVP-CG electrode. In this case, the anodic branch of the cyclovoltammogram contains two peaks at E_p = 0.32 and 0.70 V. The peak potential of ascorbic acid oxidation on the Pd-modified electrode is lower by 300 mV than that on the nonmodified electrode. The electrochemical signals on the modified electrode have the peak shape, with the first peak being sharper. The intensity of second peak is higher by several orders of magnitude than that of the peak of ascorbic acid oxidation on CG and increases with increasing substrate concentration. The second peak appears at the palladium oxidation potentials, and its intensity decreases with increasing ascorbic acid concentration.

The logarithm of the peak current of the first and second waves is directly proportional to the logarithm of the sweeping rate of the potential with the slope of 0.40 and 0.80, respectively. This indicates that the oxidation at the potentials of the first and second peaks is complicated by chemical reaction and adsorption, respectively. The voltammograms were recorded at different initial potentials E_i and times of electrolysis at this potential t_d. We found that, as E_i decreased and t_d increased, the intensity of the first peak did not change and the limiting current of the second peak increased. This also suggests the adsorption mechanism of ascorbic acid oxidation at the second peak potential.

Probably, at the first peak potentials ascorbic acid molecules diffusing to the electrode are oxidized. The second peak appearing in the range of PdO formation is due to oxidation of ascorbic acid molecules adsorbed on the electrode surface. Weakening of the second peak with increasing ascorbic acid concentration can be explained by adsorption of the products of its electrochemical oxidation, shielding the electrode surface. However, it should be noted that adsorption of these products has no effect on the voltammogram reproducibility, which is likely due to reversibility of the electron transfer on the modified electrode.

The voltammograms of ascorbic acid oxidation, recorded on Pd-CG and Pd-PVP-CG electrodes, are similar (Fig. 1): The peak potentials are the same and the currents of the first peak are close, i.e., the palladium dispersity has virtually no effect of the electrode process. On the contrary, the current of the second peak increases in going from Pd-CG to Pd-PVP-CG, i.e., it depends on the support nature and hence on the palladium dispersity.

It should be noted that, unlike a graphite electrode, the products of the electrochemical reaction are sorbed, as in the case of Pd-CG electrode, on the surface of the modified electrode. However, the sorption products have no effect on the voltammogram reproducibility, since they are reduced in the course of the reverse potential sweeping at the reduction potentials of palladium(II) oxide and palladium(II) hydroxide.

The catalytic effect of palladium electroplated both on CG and PVP-CG can be due the modification of the support properties in the presence of the palladium catalyst. Hydrogen adsorption on the palladium surface is also possible. As also observed in [24], carbon glass is activated in the course of palladium electroplating, which favors electrooxidation of ascorbic acid. Protons formed during this process are probably sorbed on palladium particles, thus catalyzing the reaction and increasing the yield of the oxidation products. Probably, at the second peak potentials Pd is electrooxidized to Pd(II) species which oxidize ascorbic acid.

We studied electrocatalytic oxidation of ascorbic acid on the Pd-PVP-CG electrode at different pH. As pH is increased from 1.0 to 5.3, the currents of the first and second peaks decrease (Fig. 4), probably

owing to a decrease in the catalytic activity of CME and a change in the acid–base properties of the substrate. In alkali solutions, the peak potential is shifted to zero, broadened, and weakened. In the subsequent experiments, voltammetric determination of ascorbic acid on Pd-PVP-CG electrode was performed in 0.1 M H_2SO_4.

Thus, as compared to nonmodified CG electrode, the overvoltage on the Pd-modified electrode is lower by about 300 mV and the peak current is many times higher. The current of the first peak of both Pd-CG and Pd-PVP-CG electrodes is directly proportional to the ascorbic acid concentration in the range from 1×10^{-6} to 1×10^{-2} M. However, the catalytic current of the composite film electrode is better reproducible (Table 2). We used Pd-PVP-CG electrode for analytical purposes.

Ascorbic acid determination on CG electrode coated with polyvinylpyridine film and palladium-plated. To a 10-ml volumetric flask, a definite volume of standardized ascorbic acid solution or a solution of a weighed portion of a pharmaceutical in 5 ml of 0.2 M H_2SO_4 was introduced. The volume was brought to the mark with distilled water. The resulting solution was placed in an electrochemical cell. CME and auxiliary and Ag/AgCl electrodes were immersed in the solution. The voltammogram was recorded in the potential range from 0.0 to 1.2 V. The current of the oxidation peak at E_p = 0.32 V was measured.

The ascorbic acid concentration was determined by the calibration curve fitted by the regression equation $i_p = a + bc$ (I_p, μA; c, M), where $a = 5.7 \pm 0.3$, $b = (1.9 \pm 0.1) \times 10^{-4}$ and $r = 0.9999$. To illustrate the advantages of the CME, the $\log i_p$ vs. $\log C$ dependence is shown in Fig. 4. As seen from Fig. 4, the dependence of the analytical signal of CG and Pd-PVP-CG electrodes on the ascorbic acid concentration is linear in the range 5×10^{-4}–1×10^{-2} and 1×10^{-6}–1×10^{-2} M, respectively, i.e., the use of CME with electrocatalytic properties broadens the range of analytical concentrations and decreases the detection limit of ascorbic acid by two orders of magnitude.

The accuracy of the procedure was determined by the introduced–found method (Table 2). The relative standard deviation in the whole concentratin range is no more than 5%.

We used a Pd-PVP-CG electrode for voltammetric determination of ascorbic acid in some pharmaceuticals. In preliminary experiments, we studied the influence of various components of these preparations on the analysis results. The compounds exhibiting

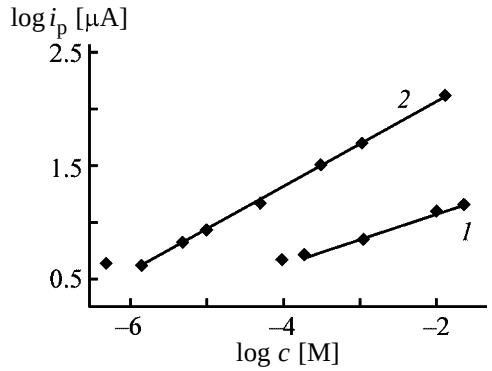

Fig. 4. Logarithm of peak current i_p of ascorbic acid oxidation on (*1*) CG and (*2*) Pd-PVP-CG electrodes as a function of the logarithm of its concentration c.

electrochemical or electrocatalytic activity at the potentials of ascorbic acid oxidation interfere with the determination. For example, the presence of iron species interferes with ascorbic acid determination, since their oxidation potentials are close. In this case, the analysis should be performed after appropriate pretreatment. The results of determination of ascorbic acid in the presence of glucose, nicotinamide, vitamins A, B_1, B_2, B_6, P, and E, as well as calcium and magnesium cations, which do not interfere with the determination, are given in Table 3. The results converge well ($S_r < 5\%$).

The results of determination of ascorbic acid in some pharmaceuticals are presented in Table 4. The content of ascorbic acid indicated in the direction for each pharmaceutical was used as the reference. Statistical treatment of these results with the use of t criterion showed the absence of significant fixed error: $t_{calc} < t_{tabl}$.

EXPERIMENTAL

The dc voltammograms were recorded with a PU-1 polarograph, and cyclovoltammograms, with a PI-50-

1.1 potentiostat in a three-electrode cell. Carbon glass electrode with the working surface area of 0.1 cm^2, palladium-plated CG electrode, and CG electrode coated with PVP film or palladium-plated PVP film were used as the working electrodes. A silver chloride electrode and platinum wire were used as the reference and auxiliary electrodes, respectively. The potential was swept at a constant rate of 20 mV s^{-1}, or the sweeping rate was varied from 10 to 50 mV s^{-1}.

The film electrode was prepared from PVP of pure grade (Ferak). Palladium was plated from a $PdCl_2$ solution (Aldrich). Prior to the modification of a CG electrode, its surface was pretreated by the following procedure: the electrode was polished on filter paper and tracing paper, washed with double-distilled water, and activated by repeated potential sweeping in 0.5 M H_2SO_4. PVP films were applied from acetonitrile solutions of PVP and $LiClO_4$, which, in turn, were prepared by dissolution of weighed portions of these substances in magnetically stirred acetonitrile. Acetonitrile was purified by the known procedure [26]. The polymeric film was removed from the XME surface by immersion in acetonitrile.

Table 4. Concentration of ascorbic acid in pharmaceuticals determined by voltammetry on a CG electrode coated with PVP film and palladium-plated (n = 6, P = 0.95, t_{tab} = 2.57)

Pharmaceutical	Reference value	Found	S_r	t_{calc}
	g			
Ascorbic acid with glucose	0.100	0.096 ± 0.005	0.005	2.0
Hexavit	0.030	0.026 ± 0.004	0.004	2.4

Karinat	0.010	0.014 ± 0.006	0.006	1.6
Dolmatin S	0.050	0.054 ± 0.008	0.008	1.2
Mumivit	0.030	0.027 ± 0.003	0.003	2.4

Solutions of ascorbic acid were prepared by dissolution of its weighed portions in water. Solutions with lower concentrations were prepared by dilution of the initial solution prior to the experiment. The supporting electrolyte was 1 M H_2SO_4. Required pH was adjusted by adding NaOH to this solution. pH was measured with a pH-150 pH-meter. Solutions of pharmaceuticals were prepared by dissolution of their weighed portions in 0.1 M H_2SO_4. When a pharmaceutical contained fillers insoluble in water, the precipitate was filtered off and the filtrate was studied.

CONCLUSIONS

(1) Palladium particles plated on carbon glass or polyvinylpyridine film catalyze oxidation of ascorbic acid.

(2) Conditions for preparing composite film on carbon glass surface and for obtaining the maximal catalytic effect of this electrode were determined. Palladium plated on poly(2-vinylpyridine) film increase the catalytic activity of the electrode and improve the

metrological parameters of voltammometric determination of ascorbic acid.

(3) A carbon glass electrode coated with poly(2-vinylpyridine) film and palladium-plated was used for voltammetric determination of ascorbic acid in some pharmaceuticals. The components of pharmaceuticals that do not interfere with ascorbic acid determination were found.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Exhaustive Purification of Aqueous Solutions with Schungite Rock To Remove Phenols

I. G. Lugovskaya, S. I. Anufrieva, N. D. Gertseva, and A. V. Krylova

Fedorovskii Russian Institute of Mineral Raw Materials, Moscow, Russia

Received July 26, 2002; in final form, March 2003

Abstract—The possibility of exhaustive purification of aqueous solutions with schungite to remove phenol to the MPC level and effects of the initial phenol concentration, sorption time, and other factors on the efficiency of phenol recovery are studied.

In wastewater treatment by sorption, diverse synthetic and natural materials are used, including activated and oxidized coals and active anthracites. Theoretical and practical aspects of the use of carbonaceous adsorbents in wastewater treatment to remove organic substances are thoroughly examined in [1, 2].

Apart from the known advantages, activated carbons have a series of drawbacks such as low abrasion resistance, thermal regeneration loss, and, finally, high cost. Furthermore, one of the significant drawbacks of activated carbons is their low selectivity with respect to many readily soluble organic compounds [3].

Recently good results were obtained with various natural sorbents and also with some combinations of sorbents, particularly, of activated carbon and mineral sorbents (silica gels etc.) [3].

Among materials showing considerable promise are Karelian schungite materials, which, thanks to their complex mineral composition (quartz, aluminosilicates, carbon, etc.) are of interest as potential integrated sorbents simultaneously having properties of carbonaceous and silicate materials. Schungite rocks are characterized by high mechanical strength and thermal and chemical resistance, and lower cost (compared to activated carbons).

Gorshtein and Baron [4} reported on sorption of phenol from aqueous solutions with modified schungite obtained by alkaline, autoclave alkaline, or basic aluminum nitrate treatment, etc. Note that most of the works on phenol sorption with various sorbents, including schungite, were performed for an initial phenol concentration of 100–500 mg l^{-1}, not covering the concentration range practically important from the exhaustive purification standpoint, i.e., with phenol concentrations lower by 2–3 orders of magnitude.

Because of extremely low maximal permissible concentration (MPC) accepted for phenol (0.001 mg l^{-1} for fishponds), finishing treatment of weakly polluted water is of particular importance. As follows from published data, exhaustive water purification to remove phenol remains till now one of the most difficult problems, since none of the existing methods provides a desired efficiency at reasonable performance characteristics [5]. Here we report data on phenol sorption from aqueous solutions (initial phenol concentration 0.1–2 mg l^{-1}) with schungite.

According to [6], Karelian schungite rocks are subdivided into five types by the free carbon content in them (wt %): I 98, II 35–75, III 20–35, IV 10–20, and V 5–10. In sorption experiments we used schungite sorbent (SchS) samples obtained by crushing type III schungite rock from the Zazhogino deposit to the 2.5–0.5 mm size grade and also that modified with aqueous NaOH. The contents of basic chemical components in SchS, obtained by the photometric ($SiO_2 \cdot Al_2O_3$, and Fe_2O_3), gasometric (C), atomic absorption (CaO and MgO), and flame photometric methods (K_2O and Na_2O), were as follows (wt %): SiO_2 56.46, C 26.26, Al_2O_3 4.05, Fe_2O_3 1.01, CaO 0.12, MgO 0.56, K_2O 1.23, and Na_2O 0.36.[1]

According to quantitative X-ray diffraction analysis data, the major rock-forming minerals of schungite rock are quartz (52%), hydromica (15%), schungite matter (20%), feldspar (10%), and pyrite (2%).

[1] Analyses were made at the Analytical Center for Certification Testing, Russian Institute of Mineral Raw Materials.

* Initial phenol concentration c_0 was 1.89 and 1.90 mg l^{-1} for SchS and MSchS, respectively.
** Residual phenol concentration.

Among secondary minerals are carbonates (calcite and dolomite) and gypsum.

The BET specific surface area of the samples was determined by the nitrogen thermal desorption method [7]. To increase the specific surface area and sorption capacity, schungite sorbents were modified by alkaline treatment [8] (NaOH concentration 250 mg l^{-1}, liquid to solid phase ratio l : s = 10, treatment time 2 h, and temperature 80–85°C). Modification increased the specific surface area from 6.8 to 17.0 $m^2 g^{-1}$. Also the micropore structure became more developed, as judged from an increase in the sorption capacity for iodine from 2.4 to 24.1 mg g^{-1}.

The sorption of phenol was studied in both the static and dynamic modes. The phenol concentration in solutions was monitored by the fluorescence spectra. In the kinetic experiments, 15-g SchS and MSchS samples were contacted with solutions of fixed phenol concentrations in flasks with ground-glass stoppers. The flasks were shaken at 135 rpm for 5–90 min. Then the sorbent was filtered off, and the filtrate was taken for analysis.

The kinetic curves of phenol recovery with SchS and MSchS at an initial phenol concentration of 1.9 mg l^{-1} are presented in Fig. 1.

Figure 1 shows that, at such a low phenol concentration, sorption proceeded quite rapidly, especially on MSchS. In the first 5 min, the degree of phenol recovery was 50 and 40% on MSchS and SchS, respectively. Then phenol recovery decelerated with both sorbents, and practically stopped 30 min after for SchS and 60 min after for MSchS. Finally, the degree of phenol recovery was above 60 and about 80% with SchS and MSchS, respectively.

The static sorption capacity of SchS and MSchS was determined at various solution to sorbent volume ratios (V_l/V_s). The initial phenol concentration (c_0) was 1.9 mg l^{-1}. As 1 day passed, the liquid phase was decanted and analyzed for residual phenol.

From the sorption capacity a we estimated the surface coverage of the sorbents θ:

$$\theta = a/a_m, \quad (1)$$

where a_m is the amount of phenol required to saturate a monolayer (2.88 and 7.19 mg l^{-1} for SchS and MSchS, respectively), estimated previously from the Langmuir equation [9].

Conditions and results of the static experiments are summarized in Table 1.

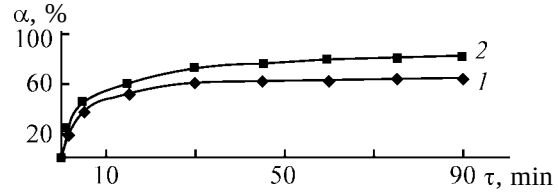

Fig. 1. Kinetic curves of the phenol recovery α with (*1*) SchS and (*2*) MSchS. Initial phenol concentration 1.9 mg l^{-1}. (τ) Time.

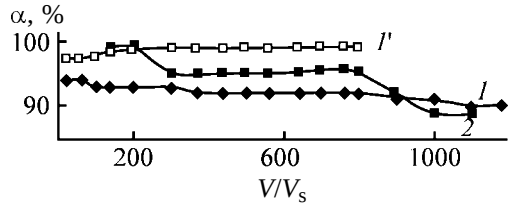

Fig. 2. Degree of phenol recovery α as a function of the ratio of the volume of the solution passed V to the sorbent volume V_s: (*1*, *1'*) SchS and (*2*) MSchS. Initial phenol concentration (mg l^{-1}): (*1*, *2*) 0.1 and (*1'*) 1.2.

Comparison of the residual phenol concentrations shows that, to attain the same degree of phenol recovery, the amount of MSchS can be about half that of SchS (94.5–96.0% recovery is reached at V_l/V_s = 10 with SchS and 5 with MSchS). The surface coverage with phenol in sorption was no more than 0.31%.

With increasing l : s, the sorption of phenol on SchS and MSchS somewhat increased, but the degree of phenol recovery decreased (in the case of MSchS, to 80% and even stronger), and the surface coverage increased to 1.4%.

With increasing sorption time from 1 to 7 days, the sorption on SchS increased to about 0.5 mg g^{-1} (θ ~ 7%), suggesting a considerable contribution of slow sorption of phenol from weak solutions. It may be suggested also that such a slow sorption reflects diffusion control of the sorption rate.

Table 2. Initial and residual phenol concentrations in dynamic sorption experiments

Sorbent	V_l/V_s	Phenol concentration, mg l^{-1}	
		initial solution	eluate
MSchS	88	0.1	<0.0005
	128	0.1	<0.0005
	168	0.1	0.0009
	238	0.1	0.0008
	298	0.1	0.0110
	368	0.1	0.0120
SchS	98	0.1	0.0060
	138	0.1	0.0060
	298	0.1	0.0060
	368	0.1	0.0090
	438	0.1	0.0100
	90	1.2	0.1900
	130	1.2	0.0200
	190	1.2	0.0100
	300	1.2	0.0100
	370	1.2	0.0100
	430	1,2	0.0100

Dynamic sorption experiments were performed with SchS and MSchS in fresh 0.1 and 1.2 mg l^{-1} aqueous phenol solutions. The solution was passed through a column 15 cm high and 3.5 cm in diameter. The sorbent volume in the column was 50 ml.

The eluate was analyzed for residual phenol at intervals of 100–200 column volumes. The solution feed rate was 3 volume parts per hour (relative to the sorbent volume).

In Figure 2 the degree of phenol recovery is plotted vs. the ratio of the volume of the solution passed to the sorbent volume (V/V_s) for the most dilute initial phenol solution (0.1 mg l^{-1}, which corresponds to 100 MPC). The curves demonstrate the possibility of practically 100% removal of phenol from 200 volumes of the solution with MShcS and of 95% removal from 800 volumes. The corresponding values for SchS are 94 and 92%.

Curve *1'* in Fig. 2 shows that, at the initial phenol concentration corresponding to 1200 MPC, 99–99.5% removal of phenol from more than 800 volumes of the solution can be realized with SchS.

The residual phenol concentration in the eluate at increasing number of the solution volumes passed through the column is given in Table 2 for two different initial concentrations of phenol.

The results show that, at an initial phenol concentration of 0.1 mg l^{-1}, the use of MSchS allows treatment of about 240 volumes of the solution to remove phenol to a level below MPC accepted for fishpond water. With further increasing volume, the residual phenol concentration remains within the limits accepted for industrial water.

After passing 300 volumes of the solution of the same initial concentration through SchS, the residual phenol concentration was found to be 0.006 mg l^{-1}, and after passing about 400 volumes, 0.01 mg l^{-1}. At the initial phenol concentration of 1.2 mg l^{-1}, the residual phenol concentration after passing 400 volumes was 0.01 mg l^{-1} also.

Adsorbed phenol cannot be removed from the surface of the sorbents by treatment with NaOH, suggesting the chemisorption mechanism.

The performance characteristics of the sorbents are summarized in Table 3.

As seen, with SchS and MSchS, at the initial phenol concentration of 0.1 mg l^{-1}, the residual phenol

Table 3. Performance characteristics of SchS and MSchS

Sorbent	c_0, mg l^{-1}	Performance characteristics
SchS	0.1	1180 volumes passed. Residual phenol concentration 0.03 mg l^{-1}. Sorption 0.152 mg g^{-1}. Surface coverage θ = 5.3%
MSchS	0.1	1094 volumes passed. Residual phenol concentration 0.020 mg l^{-1}. Sorption 0.142 mg g^{-1}. Surface coverage θ = 2.0%
SchS	1.2	801 volumes passed. Residual phenol concentration 0.028 mg l^{-1}. Sorption 1.038 mg g^{-1}. Surface coverage θ = 36.0%

concentration after passing 1100–1200 volumes of the solution was 0.030 and 0.020 mg l^{-1}, respectively, and the surface coverage was found to be not high, ranging from 2 to 5.3%.

After passing about 800 volumes of 1.20 mg l^{-1} solution through SchS, the residual phenol concentration was about 0.03 mg l^{-1} and the surface coverage, 36%. In this case, the residual phenol concentration (about 0.03 mg l^{-1}, which is lower than the initial phenol concentration in the other series of solutions) suggests the possibility of finished treatment of fishpond water to the MPC level (0.001 mg l^{-1}), if the sorbent bed will be increased or two columns will be used.

CONCLUSIONS

(1) Natural and modified schungites demonstrate high sorption characteristics in exhaustive purification of aqueous solutions to remove phenols.

(2) The use of the modified schungite sorbent allows finished treatment of more than 200 volume parts of an aqueous solution with the initial phenol concentration of 0.1 mg l^{-1} to remove phenol to the MPC level accepted for wastewaters from the fish industry.

(3) The surface coverage of the schungite sorbents with phenol in sorption from dilute solutions does not exceed 36%.

Abstract—The article reports on the impurity composition and toxicological hazard of the wastewater from production of chemicothermomechanical mass for manufacturing pressboard and different types of paper.

Pulp and paper industry consumes large amounts of wood and fresh water. Large amounts of wastewater are discharged into water basins, thus significantly contributing to environmental pollution. Conventional pulp production procedures are characterized by $\leq 50\%$ yield of the target product. The remaining 50% of the wood matter contaminates the environment as part of gas and dust emissions and wastewater (various compounds of lignin, lignin-like substances, phenolic compounds, and various sulfur-containing substances such as sulfur dioxide, hydrogen sulfide, methyl mercaptan, etc.).

This makes urgent development and introduction in pulp and paper industry of low-waste procedures. Of special interest is development of procedures for preparation of intermediate products in high yields from deciduous wood. Large-scale application of such procedures will allow simultaneous solution of three important problems: (1) to facilitate supply of industrial enterprises with wood raw materials by utilizing wood of lower quality, (2) to meet strengthening requirements on the environmental protection, and (3) to decrease the prime cost of the products.

Recently, numerous procedures have been suggested for preparing intermediate products in high yield. These procedures are mainly based on milling chips at elevated temperature and pressure. Production of thermomechanical (TMM), chemicothermomechanical (CTMM), and chemicomechanical (CMM) masses rapidly grows. The application field for these intermediate products is steadily widening, and they replace less economical cellulose in many applications [1, 2].

The yield of the target product in wood mass production is almost twice that in pulp production, and the amount of the process emissions and discharges decreases correspondingly. Replacement of soda hemicellulose by CTMM allows reduction of the specific (per ton of the end product, pressboard) consumption of water from 80 to 13 m^3 (by a factor of 6.15) [3]. Thus, a changeover to CTMM production brings appreciable environmental and economic benefits. At the same time, the wastewater from production of high-yield intermediate products is highly toxic, which is mainly due to the extractive substances passing into wastewater from wood [4, 5].

The wastewater is generated in the following production phases: (1) chips washing; (2) CTMM thickening; and (3) pressboard production on a pressboard-making machine (PMM).

The wastewater from wood pretreatment and CTMM production comes to a sewerage system; the PMM wastewater also comes partially to a sewerage system and partially, to a local plant for wastewater treatment by pressure flotation [3]. The fibers entrapped at the plant are utilized in pressboard production (incorporated into its formulation), and the decontaminated water is used for washing chips and waste paper.

A closed-loop water use system would allow even greater reduction of the amount of the wastewater

1070-4272/03/7605-0766$25.00

discharged. However, this requires knowledge of the chemical composition of the wastewater from CTMM production. Such data are also necessary for developing the most efficient and economical system for treatment of this wastewater.

The aim of this work is to identify the impurities and to make a toxicological assessment of the wastewater from production of CTMM and multilayer pressboard thereof, as well as to propose an efficient and economical method for its treatment.

EXPERIMENTAL

Samples for determining the chemical composition and toxicity of wastewater were taken from the circulating water freed from suspended matter at the pressure flotation plant and from the wastewater generated by the CTMM production shop. The flow rate of the forming wastewater was 250 $m^3 h^{-1}$. The results of the wastewater analysis by standard procedures are given below:

pH	7.0–9.9
Suspended matter, mg l^{-1}	300
BOD_5, mg O_2 l^{-1}	600
Oxidizability, mg O_2 l^{-1}	1000–1500
Ammonia, mg l^{-1}	2.2–2.8
Nitrates, mg l^{-1}	2.3–2.5
Nitrites, mg l^{-1}	0.3–1.2
Iron, mg l^{-1}	0.6–3.3
Phosphates, mg l^{-1}	2.1–2.9
Sulfates, mg l^{-1}	158–192
Chlorides, mg l^{-1}	85–112
Oil products, mg l^{-1}	0.01–0.20
COD (single determinations), mg O_2 l^{-1}	1500

To identify toxic compounds in the samples, we determined volatile organic compounds (VOCs) by gas chromatography-mass spectrometry (CC–MS).

The GC–MS analysis was carried out on a Shimadzu (Japan) instrumental complex comprising a GC-17A gas chromatograph, a QP 5000 mass spectrometer equipped with a quadrupole analyzer, and a data processing system. Ionization was effected by electron impact (ionizing electron energy 70 eV, ion source temperature 280°C). The instrument parameters were adjusted automatically. We used a 25 m × 0.2 mm capillary column made of melted quartz (0.33-μm-thick film of the DB-5 stationary phase; helium carrier gas, flow rate 1 ml min^{-1}). Liquid samples (1 μl) were introduced in the splitless (0.3 min), and gaseous samples (1 ml), in the split mode. The injector temperature was 250°C; the column was heated in a programmed mode from 40 to 270°C at a rate of 5 deg min^{-1} and kept at 270°C for 15 min.

Table 1. Content of low-boiling organic compounds in water samples as determined by head-space GC–MS analysis

Compound	Content in the sample, mg l^{-1}	
	circulating water	wastewater
Ethanol	0.10	0.15
Acetone	–	0.06
Dimethyl sulfide	–	0.02
Carbon disulfide	0.08	–
Butyral	–	0.05
Limonene	0.34	0.48

For analyzing low-boiling organic compounds, we took a 20-ml portion of each sample, saturated with sodium chloride, placed into hermetically sealed glass flasks with Teflon stoppers, thermostated for 1 h at 40°C, and analyzed by GC–MS the equilibrium vapor phase. The results are presented in Table 1.

For analyzing moderately volatile organic compounds, we took a 1-l portion of each sample. The analytical procedure consisted of successive repeated extractions of the aqueous sample with methylene chloride at pH 8 (a basic-neutral fraction) and pH 2 (acid fraction). Next, the fractions were combined, dried, concentrated, and aliquots were analyzed by GC–MS [7]. The results (tentative, semi-quantitative data) are presented in Table 2.

Tables 1 and 2 show that the samples analyzed contain a significant amount of VOCs from various classes: alcohols, aldehydes, ketones, acids, etc. Most of them are components of natural extractive substances contained in wood or are lignin degradation products.

Though only slightly contributing to COD of the wastewater, VOCs include highly toxic compounds. Table 3 lists the maximum permissible concentrations (MPCs) for some of them [8–10].

It should be noted that not nearly all the actual or potential polluting substances have their established MPCs. For example, such substances as guaiacol and *p*-ethylphenol have no MPCs but this by no means suggests that these compounds are not toxic.

Toxicological control consisted in biotesting with two testing objects from different taxonometric groups, *D. Magna* and *Paramecium Caudatum*.

Table 2. Content of moderately volatile organic compounds in water samples as determined by head-space GC–MS

Compound	Content in the sample, mg l^{-1}		Compound	Content in the sample, mg l^{-1}

* Compounds whose structures could not be established exactly due to the lack of reference samples and information about the chromatographic retention indices.

The concentration of dissolved oxygen in the samples was brought to the optimal level of 7.0–8.0 mg l^{-1}, and pH, to 7.5–8.0. The samples were filtered off using paper filters intended for biological studies. Each test took 96 h.

Table 3. MPCs of selected toxic compounds in water basins

Compound	PC, mg l^{-1}, in indicated water basins	
	sanitary and domestic	fisheries
Acetone CH_3COCH_3		0.05
Dimethyl sulfide $(CH_3)_2S$	0.01	1×10^{-5}
Carbon disulfide CS_2	1.0	1.0
Phenol C_6H_5OH	0.001	0.001
Dibutyl phthalate $C_6H_4(COOC_4H_9)_2$	0.2	0.001

The indices calculated in biotests were as follows. For *D. Magna*: A, the percentage of daphnias perished in the tested medium relative to the control water; LT_{50}, the average time within which 50% daphnias perished in the tested water; L_{dd50}, the degree of dilution at which 50% of daphnias survived in the tested water within 96 h; L_{dd0}, the minimal degree of dilution of the tested water at which daphnias survived within 96 h; and T, toxicity. For *Paramecium Caudatum*: T_{un}, the toxicity index for undiluted water; T_{16}, the toxicity index for water diluted by a factor of 16; and DT, the degree of toxicity.

The biotests performed (see Table 4) allow qualification of the water in the samples tested as moderately toxic with respect to *D. Magna* but as highly toxic with respect to *Paramecium Caudatum* cultures.

Thus, the wastewater generated by multilayer pressboard production from CTMM is characterized by a high content of suspended matter and toxic organic substances and, thus, needs treatment before discharg-

Table 4. Biotesting results

Water	pH_{in}	pH_{test}	O_{2in}	O_{2test}	*D. Magna*					*Paramecium Caudatum*

ing into sewerage system for the subsequent biological treatment.

Finely dispersed suspended and soluble organic impurities can be removed from wastewater by coagulation, adsorption, and biological methods. However, the recommended aerobic and anaerobic biological methods of wastewater treatment are unsuitable for enterprises lacking their own facilities for biological treatment of wastewater.

In our opinion, electrochemical coagulation is promising in this case. This process can be run in an electrolyzer provided with a set of aluminum or iron plates where the treated water flows in the interplate spaces [10].

Electrocoagulation offers such advantages as compactness and easy operation of the setup, no need in chemicals, and low sensitivity to the changing treatmental condition, as well as good structural and mechanic properties of the resulting slurry.

A drawback of electrocoagulation is increased power and metal consumption. The amount of sheet metal consumed can be decreased by using electrodes filled with metal chips which are metal processing waste.

We studied the treatment of wastewater generated by CTMM production in a specially assembled electrocoagulation cell. The initial wastewater was supplied to the bottom of the electrocoagulator and enriched with the required portion of the coagulant. The treatment efficiency was estimated from the permanganate oxidizability of the treated wastewater. The electric scheme provided permanent control over the current strength and voltage at the electrodes. The wastewater consumption in the installation was kept constant at 3 l h^{-1}.

The optimal results were obtained for the wastewater treated with aluminum electrodes at the current density of 8.5–9.5 A dm^{-2}, voltage of 30–35 V, and preliminary dilution by a factor of 2–4. Under these conditions, the averaged treatment efficiency was estimated from the permanganate oxidizability at 94%, and the current efficiency, at 55%.

It should be noted that wastewater from CTMM production contains large amounts of low-molecular-weight organic compounds which cannot be removed from water by coagulation. Thus, the efficiency achieved in this work should be regarded as high, though insufficient for the wastewater to be safely discharged or recycled into the production process. For this reason, we finally treated the wastewater by adsorption on activated carbon.

CONCLUSIONS

(1) Wastewater from production of chemicothermomechanical mass and multilayer pressboard thereof contains over 40 dissolved organic substances.

(2) The amounts of the pollutants contained in the wastewater generated by production of chemicothermomechanical mass and their toxicities were estimated.

(3) A method was proposed for local treatment of the wastewater generated by production of chemicothermomechanical mass.

Abstract—The efficiency of water pretreatment at heat and electric power plants using low-molecular-weight cationic Praestols (coagulants) in combination with lime, iron sulfate, and flocculant (high-molecular-weight anionic Praestol) was studied.

Desalted water for heat and electric power plants (HEPPs) is often prepared in two main stages: pretreatment to remove coarse, colloidal, and dissolved mineral and organic admixtures and demineralization with ion-exchange resins. Pretreatment is performed with mineral coagulants such as iron(II) sulfate and aluminum sulfate or chloride, with subsequent clarification of water and removal of precipitates using clarifiers and mechanical filters. As shown in [1], the pretreatment of water at about a half of heat and electric power stations in Russia is performed using iron(II) sulfate (liming and coagulation). In the recent decades, organic polymeric coagulants with low molecular weight and positive charge, providing destabilization of negatively charged colloidal particles and rapid flocculation, have found expanding application in advanced countries along with common mineral coagulants. In the presence of organic coagulants, the precipitate particles become coarser, and thus the solutions are easier clarified and filtered, whereas the mineral composition of water and its pH remain unchanged. Water pretreatment can be intensified by simultaneous use of organic and mineral coagulants and flocculants [2]. As shown in [3], iron(II) sulfate coagulant in combination with high-molecular-weight cationic and anionic Praestol flocculants shows high performance in the water pretreatment at heat and electric power plants.

In this work we studied the performance of low-molecular-weight cationic Praestol coagulants used in combination with lime, iron(II) sulfate, and flocculant (high-molecular-weight anionic Praestol) in water treatment at HEPP facilities.

EXPERIMENTAL

In the tests we used commercial[1] cationic Praestol 655 (sample K-1) [copolymer of acrylamide (AA) with *N*-acrylamidopropyl-*N*,*N*,*N*-trimethylammonium chloride (APTMAC)] and anionic Praestol 2530 (sample A) [copolymer of AA with sodium acrylate (Na-AA)]. The properties of these polymers are listed in Table 1. The samples of cationic Praestols (K-2–K-8) with various intrinsic viscosities [η] (Table 1) were prepared according to [4] by degradation of sample K-1 in 0.1% aqueous solutions in the presence of potassium persulfate (PP) radical degradation agent at [PP] = 0.06% (in water) and 50°C for various times. The above degradation conditions provided preparation of copolymers with various [η] and constant chemical composition of macromolecules [5]. The degradation process was monitored by viscometry [6]. The [η] values in the reaction mixture were calculated using the linear dependences $\eta_{sp}/c_p = f(c_p)$, obtained at isoionic dilution of the copolymer solutions with 0.5 M NaCl solution at 25°C using a VPZh-3 viscometer (d_c = 0.56 mm). The content of the APTMAC units in cationic Praestols was evaluated from the content of chloride ions, determined by mer-

curimetry [7], and the content of the Na-AA units in the anionic Praestols, by potentiometric titration [8].

In this work, iron(II) sulfate [GOST (State Standard) 6981–75] and saturated solution of construction lime (GOST 9179–79) were used as coagulants. Solutions were prepared in distilled water. The content of suspended particles and organic compounds in the purified water was evaluated by the turbidity and permanganate oxidizability of solutions, respectively. In accordance with standards [9], after pretreatment the permanganate oxidizability of water should comprise 40–50% of that of the initial water sample. The samples of the initial and clarified water were analyzed by common procedure [10] using chemically pure and analytically pure grade reagents. The coagulation pretreatment was performed using the Volga river water sampled at the water scoop of the Kazan HEPP-2 (total hardness 3.3 mg-equiv l^{-1}, alkalinity 2.3 mg-equiv l^{-1}). The liming, coagulation, and clarification of the natural water samples were carried out in 250-ml cylinders. For this purpose, natural water was successively treated with solutions of lime, iron(II) sulfate, and cationic Praestol; in some tests, anionic Praestol was also used. In accordance with [11], the lime dosage was calculated from the following expression using the data on the chemical composition of the initial water sample:

$$D_l = [CO_2]_i + A_i + D_c,$$

where $[CO_2]_i$ is the concentration of carbon dioxide in the initial water (mM), A_i is the alkalinity of the initial water (mg-equiv l^{-1}), and D_c is the coagulant dosage (mg-equiv l^{-1}).

All the reagents were added successively at 1-min intervals. Then the mixture was stirred on a magnetic stirrer for 5 min, and variation of the optical density of the resulting suspension was monitored on an LAM-1 device (λ 670 nm, *l* 35.2 mm). The measurements were carried out in the same cylinder (at a depth of 90 mm from the surface) after its placing in the device. After sedimentation, the precipitate was settled for 20 min and filtered off on a paper filter, and the resulting filtrate was analyzed for the permanganate oxidizability.

First, we evaluated the effect of cationic Praestols

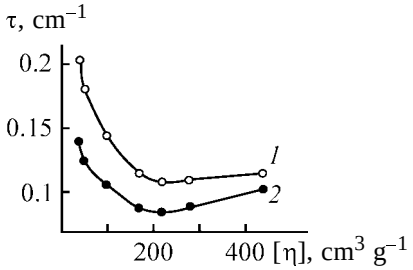

Fig. 1. Natural water turbidity τ (*1*) 5 and (*2*) 10 min after sedimentation start as a function of the intrinsic viscosity of the cationic Praestol solutions [η]. Concentration: lime 3.55 mg-equiv l^{-1} and cationic Praestol 0.4 mg l^{-1}.

Turbidity τ as a function of the sedimentation time *t* of natural water in the presence of (*1*) lime and iron(II) sulfate; (*2*) lime, iron(II) sulfate, and cationic Praestol (sample K-4); (*3*) lime, iron(II) sulfate, cationic Praestol (sample K-4), and anionic Praestol (sample A); and (*4*) lime, cationic Praestol (sample K-4) and anionic Praestol. (a) Concentrations: lime 3.8 mg-equiv l^{-1}, iron(II) sulfate 0.8 mg-equiv l^{-1}, and cationic Praestol 1 mg l^{-1}. (b) Concentrations: lime 3 mg-equiv l^{-1}, iron(II) sulfate 0.4 mg-equiv l^{-1}, cationic Praestol 1 mg l^{-1}, and anionic Praestol, 0.4 mg l^{-1}.

with various [η] on the water pretreated with lime. The data on the water turbidity, measured in 5 and 10 min after the sedimentation start, are shown in Fig. 1. As seen, the greatest decrease in the water turbidity is observed on adding cationic Praestol with [η] = 220 $cm^3 g^{-1}$, and further experiments were performed with this copolymer.

To determine the optimal dosage of the copolymer, we studied the dependence of the water turbidity 5 and 10 min after sedimentation start on the concentration of cationic Praestol with [η] = 220 $cm^3 g^{-1}$. As seen from Fig. 2, the optimal concentration of this copolymer is 1 mg l^{-1}.

Consider the effect of cationic Praestol ([η] = 220 $cm^3 g^{-1}$) additives on the turbidity (Fig. 3) and permanganate oxidizability (Table 2) after pretreatment of water with lime and iron(II) sulfate. As seen from Figs. 3a and 3b, the sedimentation rate of the precipitate particles increases with addition of cationic Praestol (curves *1*, *2*). The comparison of these curves at a given sedimentation time *t* also indicates that the degree of clarification increases with Praestol addition, which promotes more complete removal of organic impurities and decreases the permanganate oxidizability of water (Table 2). However, our attempt to decrease the dosage of mineral or organic flocculants failed, because in both cases the quality of water (with respect to the content of organic compounds) got worse.

It should be noted that water purification is noticeably improved on additional treatment of the clarified water with anionic Praestol 2530. Addition of the flocculant decreases the turbidity of water (Figs. 3a, 3b, curves *2*, *3*). This can be explained by coarsening of the aggregates due to the fact that the flocculant macromolecules form bridges between the flakes formed from colloidal and suspended particles in the course of coagulation, which, in turn, accelerates sedimentation. The content of organic compounds in water remains constant in the process (Table 3).

We also examined the possibility of excluding the mineral coagulant from the process of water treatment. The experimental data (Figs. 3a, 3b) show that high sedimentation efficiency with respect to suspended particles is retained (curves *3*, *4*), whereas the permanganate oxidizability of clarified water strongly in-

creases. As seen from our experimental data (Table 3 and Figs. 3a, 3b), the best results are obtained when adding mineral and organic coagulants in combination with anionic Praestol 2530.

CONCLUSIONS

(1) Cationic Praestol with $[\eta] = 220$ cm^3 g^{-1} can be used as organic coagulant for pretreatment of water for heat and electric power plants.

(2) The combined use of mineral and organic coagulants provides more profound removal of organic compounds from purified water.

(3) With addition of organic coagulant only, the rate of precipitate sedimentation increases, but the content of organic impurities in water grows also.

(4) The most exhaustive and rapid removal of organic compounds from water is ensured by combined use of mineral and organic coagulants with a flocculant, anionic Praestol 2530.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Consolidation and Melioration of Salted Sandy Soils Using a Compound of Acetone–Formaldehyde Resin with Silk Sericin

Abstract—Curing of the compound of acetone–formaldehyde resin with natural silk sericin in the presence of inorganic salts and its effect on a salted sandy soil were studied.

Acetone–formaldehyde resin (AFR) is cross-linked to form a three-dimensional network in aqueous solutions in the presence of a base catalyst and, being an efficient binder, is used in various compounds [1]. For example, development of the AFR compounds with biologically active substances (in particular, biopolymers), which can be used for consolidation of unstable salted sandy soils and their melioration, is of practical importance [2, 3]. A wide assortment of biopolymers is available for this purpose. In this work we studied a compound of AFR with sericin (SR), a globular protein obtained as by-product at uncoiling of natural silk cocoons [4, 5].

EXPERIMENTAL

The required compound was prepared using commercial acetone–formaldehyde resin (3M) as 65% aqueous oligomer solution. This resin forms a kinetically stable system at addition of the silk sericin in moderate amounts. It is known [1, 2] that AFR cross-linked in the presence of a catalyst (NaOH) at 10 : 1 ratio is used as a binder of neutral substances. This condition was taken into account in searching for the optimal composition of a compound of AFR with silk sericin and inorganic salts (S): Na_2SO_4, NaCl, $CaCl_2$, and $MgSO_4$. In our tests we also used the salt mixture NaCl–Na_2SO_4–$CaCl_2$–$MaSO_4$ (SM) with a 0.25 : 0.25 : 0.25 : 0.25 weight ratio. We found that the optimal component weight ratios are as follows: AFR–NaOH–SR, 10 : 1 : 2; AFR–NaOH–SR–S, 10 : 1 : 2 : 2; AFR–NaOH–S, 10 : 1 : 2; AFR–NaOH–SR–SM; 10 : 1 : 2 : 2, and AFR–NaOH–SM, 10 : 1 : 2.

The initial AFR solutions and their mixtures with SR and S are transparent colorless or light brown liquids. At curing, they acquire yellowish color and lose transparency, e.g., the intensity of the light transmission decreases to the greatest extent. The process was monitored using a Spectromom-410 unit and a polarization microscope (λ 560 nm).

The degree of AFR cross-linking in the samples was determined by extraction with water of the non-cross-linked polymer fraction, SR, and S from the cured compositions in a Soxhlet apparatus. The interaction of AFR with SR and S was studied by IR spectroscopy [6]. The experiments on the sand consolidation were carried out by the direct application of the AFR compound onto the surface of model systems of salted sandy soils. These model systems were prepared from the barkhan sand, which was thoroughly mixed with the salt solutions after its washing and screening through a sieve (0.125 cm pore size). After drying, the content of salts in the samples was about 2%, which is permissible for the plant growth. The average thickness of the surface layer consolidated with AFR compound was about 0.1 cm.

The mechanical strength of the consolidated sand layer was determined directly by the critical impact load (g) providing breakdown of the sample with a surface area of 1 cm^2 [7]. The efficiency of melioration was monitored by germination and growth of wheat seeds.

Under the laboratory conditions, the AFR systems were cured with deposition of a 0.1-cm layer on the cover glass surface. It was found that the light trans-

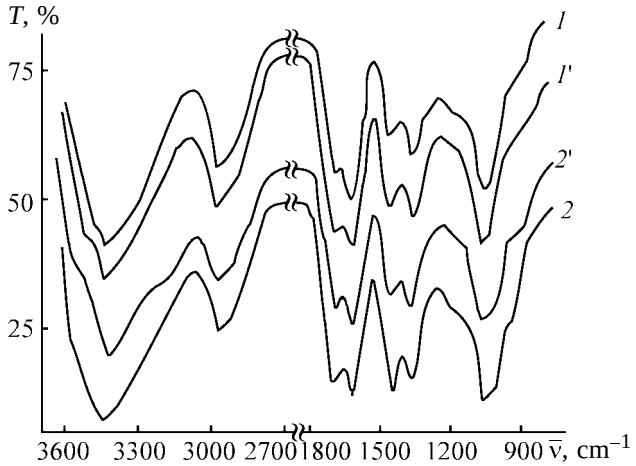

Fig. 2. IR spectra of the cured samples after water treatment: (*1*′) AFR–SM and (*2*′) AFR–SR–SM. (*1, 2*) The respective samples before water treatment.

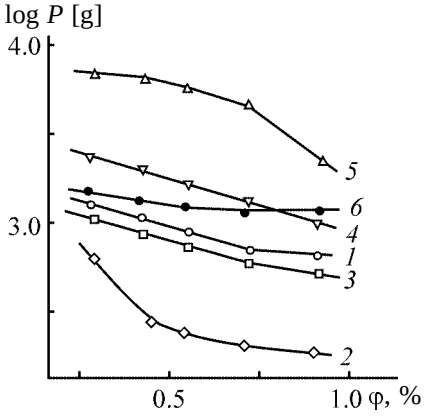

Fig. 3. Critical mechanical load *P* of the cured AFR–SR composition on consolidated salted sandy soil as a function of the volume fraction of water φ. Salt present in water: (*1*) NaCl, (*2*) Na_2SO_4, (*3*) $CaCl_2$, (*4*) $MgSO_4$, (*5*) SM, and (*6*) none.

mission through the samples strongly changes with curing. The AFR–NaOH–H_2O (10 : 1 : 2) system is cured completely in 30 min, and this time decreases to 10–15 min in the presence of Na_2SO_4 or NaCl. This is obviously due to the increasing concentration of sodium cations acting as catalyst in these systems; at the same time, the other salts or their mixtures and SR decelerate the curing. For example, the samples containing $MgSO_4$ and SR + SM mixture are cured in 90 and 80 min, respectively. This is probably due to the inhibiting effect of the corresponding ions on the AFR curing. As shown in [1], the rate of the AFR cross-linking strongly decreases in the presence of the other catalysts and fillers [1]. Based on our experimental data, the following degrees of the AFR cross-linking were determined (%): AFR, 70; AFR–SR, 65; AFR–Na_2SO_4, 60; AFR–NaCl, 62; AFR–$CaCl_2$, 72; AFR–$MgSO_4$, 75; AFR–SM, 68; and AFR–SR–SM, 66.

The reaction of AFR with SR and S was studied by IR spectroscopy. The IR spectra of the samples in question exhibit similar absorption bands at 2900 and 3400 cm^{-1}, characterizing the stretching vibrations of the CH_2, CH_3, and OH groups. The characteristic bands of the stretching vibrations of the C=O and CH_3 groups in AFR appear at 1440 and 1700 cm^{-1}. The intensity of these bands strongly depends on the additives: in the presence of SR, the intensity of the band at 1440 cm^{-1} increases, whereas in the case of inorganic salts S the intensity of these bands depends on particular metal ion. In general, these data suggest that filled AFR compounds are obtained without formation of new chemical bonds. After treatment with water, the intensity of the characteristic bands in the spectra of the cured compounds becomes close to that of the bands in the spectra of AFR cured without additives (Fig. 2). This trend is especially pronounced in the IR spectra of the samples cured in the presence of SM (Fig. 2). Our experimental data showed that the excess filler and non-cross-linked AFR fraction are efficiently removed with water.

The salted sandy soil consolidated using AFR compositions with SR exhibits certain mechanical strength. This resistance to the external effects strongly depends on the water content in the initial compound, which is confirmed by our experimental data characterizing the effect of various loads on the strength of a 0.1-cm layer of the salted sandy soil consolidated with AFR compound (Fig. 3). As seen, the strength of the consolidated soil layer decreases with increasing water content in the compound. In general, the strength characteristics of our experimental samples meet the requirements to soil-fixing agents [2].

Comparative data on the germination of wheat seeds in salted sandy soils consolidated with AFR compounds

Fixing agent	Fixing agent : product : H_2O	Germination, %
AFR : NaOH : H_2O = 5 : 0.5 : 100	1 : 5 : 10	80
SR : H_2O = 2 : 100	1 : 5 : 10	95
AFR : SR : NaOH : H_2O = 5 : 2 : 0.5 : 100	1 : 5 : 10	90
AFR : NaOH : H_2O : SM = 5 : 0.5 : 100 : 2	1 : 5 : 10	50
AFR : SR : NaOH : H_2O : SM = 5 : 2 : 0.5 : 100 : 2	1 : 5 : 10	85
No fixing agent	0 : 5 : 10	80

The sandy soil consolidated with AFR compound contains small amounts of water, which are insufficient for the crop (e.g., wheat) germination. The required water (in amounts by an order of magnitude greater than the weight of the AFR compound) was added directly into the soil. As a result, a sufficiently humid medium was formed under the consolidated soil layer (1-cm thickness), in which SR was gradually transferred. As a result, the soil was enriched with the biologically active substance.

To evaluate the melioration effect of the AFR–SR compounds, the germination and growth of wheat seeds were studied (see table). With the compound containing no SR, inorganic salts exhibit the negative affect on the dynamics of the seed germination.

It should be noted that SR, being added into the AFR compound, completely eliminates this negative effect and improves germination. It also enhances the performance of the AFR compound as a sand-fixing agent.

CONCLUSION

The strength properties of the salted sandy soil consolidated with the acetone–formaldehyde resin compound were determined, and the positive melioration effect of the compounds on the wheat seed germination was revealed.

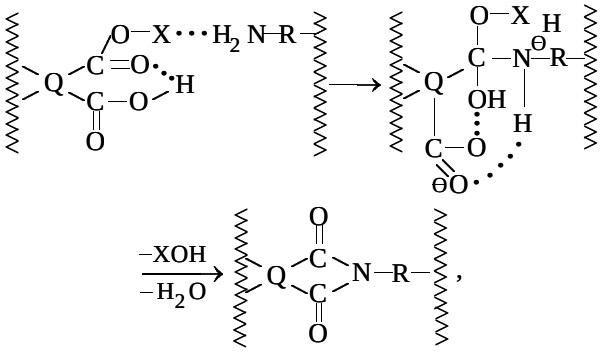
Abstract—Thermal reactions of H complexes formed by methyl and ethyl diesters of aromatic tetracarboxylic acids with diamines were studied by thermal analysis. Some kinetic parameters of formation and degradation of polyimides during thermolysis in the self-generated atmosphere were determined.

The problems of thermal stability and thermal transformations of H complexes formed by dimethyl dihydrogen benzophenonetetracarboxylate with a series of diamines were considered previously in the context of developing a process for production of foamed polyimides [1, 2]. Dialkyl dihydrogen arenetetracarboxylates are formed by dissolving the corresponding aromatic dianhydrides in refluxing alcohols [3–5]. Addition of various diamines to the resulting alcoholic solutions at room temperature causes spontaneous formation of H complexes. Probable structures of various H complexes were determined from kinetic data and by quantum-chemical calculations [6]; a mechanism of their thermal imidization, favorable from the energetic and steric viewpoints, was suggested.

An H complex (see below), when heated at a constant rate, undergoes transformations involving virtually simultaneous release of the alcohol and water in the first step and formation of the polyimide in the final step:



where

Q = 
R = 
X = $-CH_3$ or $-C_2H_5$.

In this work, using thermogravimetric (TG), differential thermal (DTA), and thermovolumetric (TVA) analyses, we examined how the chemical structure of the initial H complexes affects the kinetics of their thermal cyclization (imidization).

EXPERIMENTAL

The H complexes were prepared by the procedure described in [6]. The dried samples were subjected to vacuum thermolysis on a TVA installation [7]. The heating rate was varied from 3 to 7 deg min^{-1}. Some samples were kept at a fixed temperature (250 or 400°C) for 3 h. Pyrolysis in the self-generated atmosphere (SGA) was performed by a standard procedure on a C-1500 derivatograph (Hungary) at a heating rate of 5 deg min^{-1}.

A characteristic pattern of the evolution of volatile products in the course of thermal transformation of the H complex into polyimide at linear heating in a vacuum is shown in Fig. 1. It was demonstrated by the example of the H complex of dimethyl dihydrogen diphenyltetracarboxylate with an equimolar mixture of *m*-phenylenediamine and 4,4'-diaminodiphenylmethane that volatile imidization products (methanol and water) vigorously evolve in the range 80–200°C. It is seen that the reaction occurs in two overlapping steps. As expected, at the lower heating rate the peaks

1070-4272/03/7605-0778$25.00 © 2003 MAIK "Nauka/Interperiodica"

are observed at lower temperatures (100 and 140°C). As the heating rate is increased, the peak temperatures grow and the difference between them decreases. This indicates that the rate constants of the release of volatiles in the first and second steps of imidization are different; this difference is due to structural features of the system, which is confirmed in [2].

It should be noted that curve *1* in Fig. 1 also has a noticeable peak at 78°C, assignable to evolution of residual solvent, not incorporated into the complex. At the higher heating rate, this peak coalesces with the peak due to evolution of volatiles.

Thus, lower heating rate favors better separation of the two steps of thermal imidization of the H complex. The temperature of the first step of the evolution of volatile products decreases by approximately 40°C. On further heating in the range 170–300°C (Fig. 1), no volatile products are released, suggesting imidization completion.

To confirm this, we performed experiments in which the samples were heated at the same rate to 96 and 250°C and then kept at these temperatures for 3 h. Comparison of the observed weight losses with the calculated loss for the case of complete imidization shows that the amount of the released methanol and water, relative to the calculated amount, is 75–80% at 96°C and almost 100% at 250°C. This fact suggests that, on heating to 200°C, the H complex in question fully transforms into the polyimide, which is thermally stable up to 300°C. It should be noted that agreement between the experimental and calculated weight losses is far from being a common feature for all the H complexes under consideration. For example, the complexes containing fragments of bis(dicarboxyphenyl) ether, diaminodiphenyl ether, and ethyl esters show excessive weight loss when kept at 250°C, which may be due either to the presence of the residual solvent in the H complex or to structural differences between the forming polyimides and those considered above [8].

Further heating in the range 300–400°C (Fig. 1) is again accompanied by the release of volatiles, indicative of degradation of the formed polyimide. As in the case of thermal imidization, the peak position, shape, and intensity depend on the heating rate (variation of the heating rate is actually equivalent to variation of the heat treatment time). Apparently, the heating rate is a decisive factor in initiation of degradation and cross-linking starting at approximately 400°C. As seen from curves *1* and *2* in Fig. 1, the higher heating rate favors development of degradation reactions with the evolution of a large amount of volatiles. Furthermore, the structure of the H complex also affects the degradation of polyimides. Experiments on isothermal heating of all the samples at 400°C showed that, irrespective of the chemical structures of the ester and amine components, the weight loss varies within 40–55%. This indicates that, in the range 300–400°C, polyimides partially decompose. Above 400°C, the second step of thermal degradation is observed; the weight loss is 14–35% of the total weight, with the difference apparently associated with the structural features of the H complexes. The largest weight loss is observed with the samples derived from benzophenonetetracarboxylic acid, and the smallest weight loss, in those derived from ethyl esters.

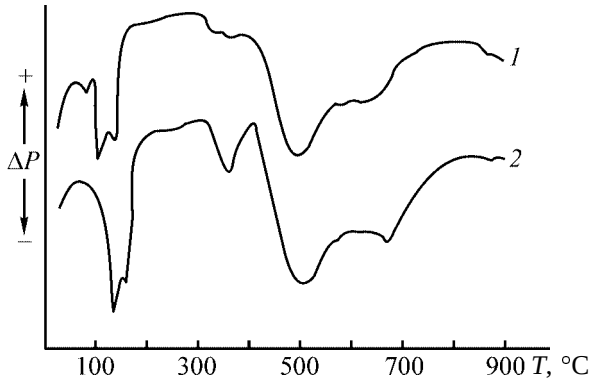


Fig. 1. TVA curves of thermolysis of the H complex formed by dimethyl dihydrogen tetracarboxylate with an equimolar mixture of *m*-phenylenediamine and 4,4'-diaminodiphenylmethane. (Δ*P*) Pressure difference in the TVA manometric system and (*T*) sample temperature. Heating rate, deg min^{-1}: (*1*) 3 and (*2*) 7.

The final products of thermal degradation of the H complexes in a vacuum are carbonized residues; their formation is complete at 800°C. Their weight does not exceed 15–20% of the initial sample weight.

In thermolysis of the H complexes in SGA, the yield of the carbonized residue is higher (~35%), demonstrating an appreciable effect of diffusion factors and certain oxidation reactions on the cross-linking of the H complexes and their imidization products. The TG and DTA data obtained under SGA conditions (Fig. 2) show that the alcohol and water are released in the range 130–200°C with a total weight loss of 16.6% (calculated weight loss 20%), showing an unresolved endothermic effect with a maximum at 143°C. In the range 270–410°C, in contrast to the TVA experiment, virtually no gases are evolved. Hence, in this range the imidization product undergoes internal rearrangement, probably with partial intermolecular cross-linking and certain ordering of the intramolecular organization. This is suggested by an endothermic

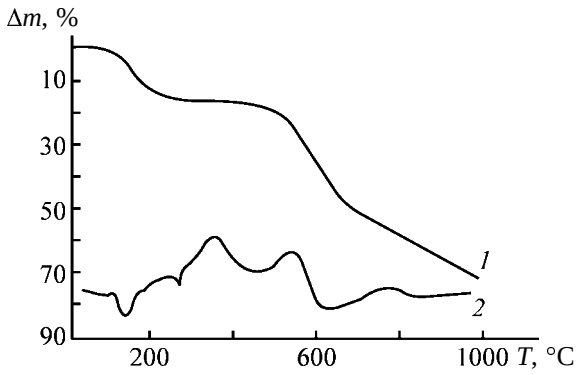

Fig. 2. (*1*) TG and (*2*) DTA curves of the same H complex as in Fig. 1. Heating rate 5 deg min^{-1}, SGA. (Δ*m*) Weight loss and (*T*) temperature.

effect at 270°C and an exothermic effect at 353°C, assignable to melting and crystallization or cross-linking of the ordered regions of the polyimide. Above 560°C, the polymer undergoes further degradation with an appreciable weight loss (~30%), followed by carbonization.

CONCLUSION

The chemical structure of H complexes formed by aromatic tetracarboxylic acid diesters with diamines affects the kinetics of their thermal imidization and of degradation and carbonization of the resulting polyimides. The yield of the carbonized product is 2–3 times higher when thermolysis is performed under the conditions of diffusion control.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Hydrolytic Copolycondensation of Ethyl Silicate with Cobalt and Manganese Salts

Abstract—Hydrolytic copolycondensation of ethyl silicate with cobalt salts and manganese chloride was studied under conditions of base (NH_4OH) catalysis.

Sol–gel process based on hydrolytic copolymerization of alkoxysilanes in aqueous–organic media is one of the most efficient methods of preparing polymetallosiloxanes [1, 2]. This reaction is difficult to control. Even when certain optimal conditions (pH, temperature, organic diluent and catalyst, reactant ratio) are followed, characteristics of the resulting cohydrolysis products are not always reproducible.

Earlier, we studied the possibility of controlling the sol–gel process, in particular, the synthesis of polycuprosiloxanes, by varying the copper salt anion [3]. Copper salts were taken because of their capability to form stable ammonia complexes within a wide pH range. Proceeding with these studies, we considered in this work the use in the sol–gel process of metals forming weaker complexes with ammonia.

EXPERIMENTAL

Commercial ethyl silicate-40 (partially hydrolyzed tetraethoxysilane), cobalt salts $Co(NO_3)_2 \cdot 6H_2O$, $CoCl_2 \cdot 6H_2O$, $CoSO_4 \cdot 7H_2O$, $Co(CH_3COO)_2 \cdot H_2O$, and manganese chloride $MnCl_2 \cdot 5H_2O$ were used as initial reagents.

Cobalt salts form ammonia complexes only with excess ammonia, and manganese salts form no ammonia complexes. The synthesis conditions were similar to those described in [3]. The products of hydrolytic copolycondensation were thoroughly washed by decanting, dried to the xerogel state at 120 ± 0.5°C for 16 h, and studied by thermal analysis (MOM derivatograph, heating rate 10 deg min^{-1} in air) and IR spectroscopy (Specord-75 IR spectrometer, KBr pellets). The sorbed water was determined gravimetrically after keeping the samples in a dessicator for 72 h at 98% relative humidity.

The hydrolytic copolycondensation of ethyl silicate with $CoSO_4$, $CoCl_2$, and $Co(NO_3)_2$ under conditions of base catalysis gives polymeric structures containing endo- and exoskeleton Si–O–Co–O and Si–O–Si groups, residual ethoxy groups, and isopropoxy groups, originating from ester interchange of the ethoxy groups.

Similar structures are probably formed with cobalt acetate and manganese chloride, but only at the reaction temperature of 45°C. This is confirmed by shift of the ν(Si–O) band relative to its frequency of 1093 cm^{-1} in the spectrum of silica xerogel containing no metal. The above shift depends of both salt cation and anion (for cobalt salts) (Table 1).

In the IR spectra of polycobaltoalkoxysiloxanes prepared from $Co(NO_3)_2$, the ν(Si–O) shift ranges from –33 to +20 cm^{-1}. This suggests formation of thermodynamically unstable structures with random distribution of mobile components in the siloxane matrix. In the case of $CoCl_2$ and $CoSO_4$, temperatures of 25 and 35°C, and reaction times of 3 and 5 h, the ν(Si–O) shift becomes approximately constant. The half-width $\Delta\nu_{1/2}$ and optical density *D* of this band, which characterize the degree of cross-linking, also show a clear trend in variation (Table 2). The shift of the band ν(Si–O) 1093 cm^{-1} and a decrease in both $\Delta\nu_{1/2}$ and optical density indicate that various polymeric structures are formed: from cross-linked to three-dimensional–cyclic or cyclic–linear structures mainly consisting of cyclic trimeric and tetrameric units bound by oxygen bridges [4]. The stabilization of the ν(Si–O) shift indicates their thermodynamic stability.

Cobalt acetate and manganese chloride at 25 and 35°C give more stable metal polysiloxane structures

* Shift: (+) to higher frequencies and (–) to lower frequencies.

compared to $Co(NO_3)_2$, as shown by a fixed position of ν(Si–O) and by regular variation of $\Delta\nu_{1/2}$ and *D*.

The constancy of ν(Si–O) shows that exoskeleton Si–O–M groups (M = metal) are primarily formed. Increase in the temperature to 45°C in all cases promotes deeper transformations and is accompanied by a decrease in the thermodynamic stability of the structure [in this case, the optical characteristics of the ν(Si-O) band at 1093 cm^{-1} change irregularly].

The formation of thermodynamically stable structures at 25 and 35°C with $CoCl_2$, $CoSO_4$, and $Co(CH_3COO)_2$ can be explained by the lower energy barrier of the reaction as compared to $Co(NO_3)_2$. However, the nitration (oxidation) of alkoxy groups with cobalt nitrate is more probable.

The specific structure of polymanganoalkoxysiloxanes is probably due to features of $MnCl_2$ behavior in aqueous ammonia, which is described by the following reactions:

$$Mn^{2+} + 2NH_4OH \rightarrow Mn(OH)_2 + 2NH_4^+,$$

$$2Mn(OH)_2 + O_2 + (2x - 2)H_2O \rightarrow 2MnO_2 \cdot xH_2O.$$

At 25 and 35°C, manganese dioxide only partially reacts with ethyl silicate to form mixed oxides and surface Si–O–Mn groups. At 45°C, the reaction shifts toward formation of intraskeleton (endo) Si–O–Mn groups.

The structural changes in Si–O–Si groups are characterized by the band of symmetrical stretching vibrations of the SiO_4 tetrahedron at 800 cm^{-1}, which overlaps, however, with bands of two other vibrations [4].

In the IR spectra of metal polymetalloalkoxysiloxane xerogels prepared from $Co(NO_3)_2$, the shift of this band is variable in sign and value. On the contrary, in the IR spectra of the polymers prepared with $CoCl_2$ and $CoSO_4$ at 25 and 35°C, this band shifts by 6 cm^{-1} to higher wave numbers, while at 45°C this shift is absent. In the spectra of the products prepared with $Co(CH_3COO)_2$ and $MnCl_2$, the band shifts (to lower wave numbers) only in products synthesized at 45°C, while at 25 and 35°C the band shift is absent. In all the above cases, the band half-width and optical density vary only slightly (within 23–26 cm^{-1} and 0.03–0.08, respectively).

All these data show that the polysiloxane structure

consisting of Si–O–Si fragments in the polymers prepared with $CoCl_2$ and $CoSO_4$ at 25 and 35°C also tends to rearrangements. At 45°C, the initial siloxane structure of these polymers does not change. On the contrary, in the polymers prepared with $Co(CH_3COO)_2$ and $MnCl_2$, the basic siloxane skeleton changes only when they are prepared at 45°C (at 25 and 35°C, the structure remains unchanged). The structure of the siloxane skeleton of polymetallosiloxanes prepared with cobalt nitrate is unstable. As a whole, the structure of polymetallosiloxanes is determined by the ratio of the rates of hydrolysis and copolycondensation depending on the salt anion (and cation) and reaction conditions.

Under the experimental conditions, polymetalloalkoxysiloxane xerogels (which are mainly metal-containing silicas) are formed. As shown by thermogravimetry, the content of metal-containing silica depends on the salt cation and anion and amounts to 86.0–90.5 wt %. The presence of small amounts of alkoxy groups is confirmed by the weight loss at 200–450°C and the corresponding exothermic effects in the DTA curves (Tables 3, 4).

In all cases, the exothermic peak shifts to higher temperatures when the synthesis time and temperature are increased. The DTA curves of polymetallosiloxanes based on cobalt salts have one exothermic peak shifted to higher temperatures by 5–10°C. In the case of $MnCl_2$, two exothermic peaks are observed at 210 and 310°C. Their shift with increase in the synthesis temperature and time amounts to 60 and 140°C, respectively. Depending on synthesis conditions, polymetallosiloxanes obtained are both low- and high-molecular-weight polymers (exothermic effects at 200–210 and 310°C, respectively). The high-molecular-weight polymers are formed under more rigid synthesis conditions (temperature, synthesis time). The larger weight loss by polymetallosiloxanes based on $Co(CH_3COO)_3$ and $MnCl_2$ is probably caused by condensation of the residual alkoxy groups.

Thus, the sol–gel process based on hydrolytic copolycondensation of ethyl silicate with cobalt and manganese salts in 2-propanol under conditions of base (NH_4OH) catalysis gives polymetalloalkoxysiloxanes with three-dimensional and cyclic–linear structures. This process can be controlled by the salt anion and cation, temperature, and synthesis time. Thermodynamically stable structures containing endo- and exoskeleton Si–O–M and Si–O–Si fragments are formed when the synthesis is performed with $CoCl_2$,

$CoSO_4$, and $Co(CH_3COO)_2$ at 25 and 35°C. In the case of cobalt acetate, Si–O–Co fragments are mainly formed on the surface by heterofunctional condensation

$$\equiv Si–OR + CH_3COOCo– \rightarrow \equiv Si–OCo– + CH_3COOR.$$

The kind of the starting salts also affects the water absorption by the polymetallosiloxanes synthesized. It amounts to 17.1, 29.4, 25.4, 28.9, and 32.5 wt % for $Co(NO_3)_2$, $CoCl_2$, $CoSO_4$, $Co(CH_3COO)_2$, and $MnCl_2$, respectively.

CONCLUSIONS

(1) The composition, structure, and properties of polymetallosiloxanes formed by hydrolytic copolycondensation of ethyl silicate with metal salts are determined by the salt anion and cation, and by the synthesis temperature and time.

(2) The synthesis of polymetallosiloxanes based on $CoCl_2$, $CoSO_4$, $Co(CH_3COO)_2$, and $MnCl_2$ in 2-propanol at 25 and 35°C under conditions of base (NH_4OH) catalysis gives thermodynamically stable polysiloxane structures with predictable characteristics. Structures with random distribution of mobile fragments of the siloxane matrix are formed when cobalt nitrate is used.

Received January 22, 2003

Abstract—A mathematical model of selective oxidation of methylcyclohexane with ozone–oxygen mixtures was substantiated.

The methylcyclohexane molecule has three nonequivalent C–H bonds (at primary, tertiary, and five secondary carbon atoms at the α-, β-, and γ-positions relative to the methyl substituent). Therefore, selective oxidation of this molecule at a definite C–H bond can hardly be expected, the more so as thermal oxidation of methylcyclohexane with oxygen occurs at a noticeable rate only at elevated temperatures (above 120°C) and is low-selective [1].

The procedures for oxidation and analysis of reaction products were described in [2]. Ozonolysis of methylcyclohexane is active at 20°C (Fig. 1) and yields hydroperoxides, alcohols, ketones, acids, and esters.

Among methylcyclohexyl hydroperoxides formed by oxidation of methylcyclohexane, the major isomer (95–96%) is 1-methylcyclohexyl hydroperoxide. Among methylcyclohexanols, all possible isomers are detected (Table 1), with 1-methylcyclohexanol prevailing. The yield of the tertiary alcohol decreases with increasing conversion, temperature, and ozone concentration (Table 1, Fig. 1). Among isomeric methylcyclohexanones, 2-methylcyclohexanone prevails (Table 1). As the methylcyclohexane conversion increases, the yield of the alcohols and ketones decreases, with a simultaneous slight increase in the relative yield of hydroperoxides, acids, and esters (Fig. 2). The tertiary hydroperoxide at low temperatures (20°C) is consumed in the reaction with ozone slowly (rate constant 19×10^{-3} l mol^{-1} s^{-1}); therefore, its yield increases with conversion of methylcyclohexane. Ozonolysis of methylcyclohexane is highly selective with respect to the yield of 1-methylcyclohexanol at conversions of up to 12%. An increase in the yield of acids in the developed ozonolysis of methylcyclohexane is due to further oxidation of secondary and tertiary methylcyclohexanols and isomeric methylcyclohexanones.

Among carboxylic acids, ozonolysis of methylcyclohexane yields monocarboxylic, dicarboxylic, and keto acids. The ratio of the yield of monocarboxylic acids to the total yield of keto and dicarboxylic acids in the examined temperature range (20–80°C, $[O_3]$ = 4 vol %) is 0.6–0.7 at the methylcyclohexane conversion of 12–82%. This ratio varies within a narrow range (0.4–0.7) [1] as the ozone concentration is varied within 2–4 vol %. The composition of the acids is given in Tables 2 and 3. Among monocarbox-

ylic acids, acetic acid prevails (70–87%). We also identified propionic, butyric, valeric, and capric acids. Among dicarboxylic and keto acids, we identified ε-ketoenanthic (16.2–35.1%), α- and β-methyladipic (40.7–53.2% in total), oxalic, succinic, methylsuccinic, α- and β-methylglutaric, and glutaric acids (Table 3). As the ozone concentration and temperature are increased, the yield of acetic and ε-ketoenanthic acids decreases. Keto acids are formed by ozonolysis of the tertiary hydroperoxide, 1- and 2-methylcyclohexanols, and 2-methylcyclohexanone [3–6].

Low-temperature ozonolysis of methylcyclohexane is a radical-chain reaction. Calculations show that, as in oxidation of cyclohexane, the chain-propagating species are alkoxy radicals rather than less active $RO_2^{\bullet}$ radicals. Alkoxy radicals are apparently generated by recombination of tertiary peroxy radicals and by reaction of $RO_2^{\bullet}$ radicals with ozone. The tertiary hydroperoxide is formed by cross recombination of $RO_2^{\bullet}$ and $HO_2^{\bullet}$ radicals and is mainly consumed with formation of 1-methylcyclohexanol.

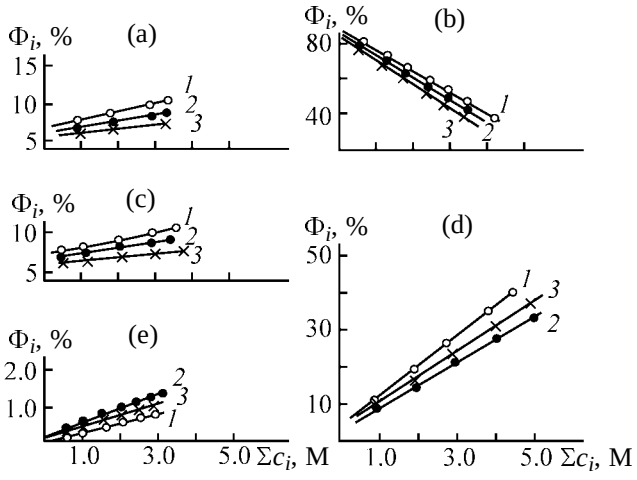

Fig. 2. Yield Φ_i of (a) hydroperoxides ROOH, (b) alcohols ROH, (c) ketones R=O, (d) acids RCO_2H, and (e) esters RCO_2R' as a fuinction of methylcyclohexanol conversion at [O_3] = 2 vol %. (Σc_i) Sum of ozonolysis products.

At low (4–7%) methylcyclohexane conversions, ozonolysis occurs to 92–93% at the tertiary C–H bond. For example, at 20°C ([O_3] = 0.5–2.5 vol %), the total yield of 1-methylcyclohexanol and 1-methylcyclohexyl hydroperoxide is 92–93%, that of other methylcyclohexanols and of methylcyclohexanones, 6–6.5%, and that of acids, 0.5–2%. The whole set of the data obtained allow us to propose the following mechanism of methylcyclohexane ozonolysis at low conversions:

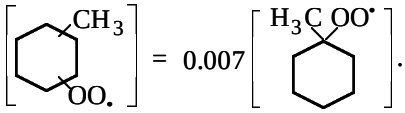
where k^{**} are the estimated values of the constants, refined during further optimization.

The steady-state concentrations of the ith radical are determined from the condition $d[X_i]/d\tau = 0$. Taking into account the yields of products formed by the attack of ozone and radicals at the tertiary and secondary C–H bonds of the methylcyclohexane molecule, we can write



The rates of elementary reactions (1)–(14) of methylcyclohexane ozonolysis are expressed as follows: $R_1 = k_1[RH][O_3]$, $R_2 = k_2[ROOOH]$, $R_3 = k_3 \times [ROOOH][O_3]$, $R_4 = k_4[O_3][HO_3^{\cdot}]$, $R_5 = k_5[HO_2^{\cdot}] \times [HO_3^{\cdot}]$, $R_6 = k_6[O_2^{\cdot}][R^{\cdot}]$, $R_7 = k_7[RO_2^{\cdot}]^2$, $R_8 = k_8 \times [RO_2^{\cdot}][HO_2^{\cdot}]$, $R_9 = k_9[RO_2^{\cdot}][O_3]$, $R_{10} = k_{10}[ROOH] \times [RO^{\cdot}]$, $R_{11} = k_{11}[O_3][ROOH]$, $R_{12} = k_{12}[RH][RO^{\cdot}]$, $R_{13} = k_{13}[HO^{\cdot}]^2$, and $R_{14} = k_{13}[RO_2^{\cdot}]^2$.

The initial reactant concentrations are [RH] = 7.8, [O_3] = 1.3×10^{-3}, and [O_2] = 5.6×10^{-3} mol l^{-1} s^{-1}. The concentrations of the radicals are found from the following relationships:

$$[RO_2^{\cdot}] = [(2R_2 + R_4 + R_{11} + \beta R_1)/(2k_7')]^{1/2},$$

$$[R^{\cdot}] = \frac{\beta R_1 + R_{12}}{[O_2]k_6},$$

$$[^{\cdot}OH] = [(\beta R_1 + R_4 + R_{11})/(2k_{13})]^{1/2},$$

$$[HO_3^{\cdot}] = R_3/([O_3]k_4 + k_5[HO_2^{\cdot}]),$$

$$[RO^{\cdot}] = (R_2 + R_3 + 2R_7 + R_9)/(k_{10}[ROOH] + k_{12}[RH]),$$

$$[HO_2^{\cdot}] = (R_2 - R_3 + R_4)/([RO^{\cdot}]k_8).$$

The constants k_5–k_7, k_{10}, k_{12}, k_{13}, and k_{13}' were taken from [7–12], and the constants k_1, k_9, and k_{11} were measured by us in special experiments.

The rates of consumption of methylcyclohexane (RH) and accumulation of 1-methylcyclohexanol (ROH_t), 1-methylcyclohexyl hydroperoxide (ROOH), hydrogen peroxide, sum of secondary methylcyclohexanols (ROH_s), methylcyclohexanones (R=O), and hydrotrioxide (ROOOH) are described by the differential equations

$$d[RH]/d\tau = -R_1 - R_{12}, \quad d[ROH]_t/d\tau = R_{10} + R_{12} + \alpha R_1,$$

$$d[ROOH]/d\tau = R_8 - R_{10} + \alpha R_{11},$$

$$d[H_2O_2]/d\tau = R_5 + R_{13}, \quad d[ROH]_s/d\tau = \delta R_1 + k'_{13}[R'O_2^{\cdot}]^2,$$

$$d[R{=}O]/d\tau = k'_{13}[R'O_2^{\cdot}]^2, \quad d[ROOOH]/d\tau = \gamma R_1 - R_2 - R_3.$$

Integration of this sytem of differential equations allows refinement of the constants k_1–k_{13}^{**} and coefficients α, β, γ, and δ. The values of these parameters are given in the scheme of the mechanism of methylcyclohexane ozonolysis. The calculated data reasonably agree with the experiment (Figs. 1–3). The steady-state concentrations of the radicals are as follows: $[RO_2^{\cdot}] = (1.32–1.36) \times 10^{-5}$, $[RO^{\cdot}] = (3.62–3.68) \times 10^{-10}$, $[^{\cdot}OH] = (3.13–3.21) \times 10^{-8}$, $[HO_2^{\cdot}] = (5.48–5.72) \times 10^{-7}$, and $[HO] = (1.04–1.07) \times 10^{-7}$ M (τ = 10–60 min).

According to the suggested mechanism, methylcyclohexane is consumed by the nonchain and chain pathways. Linear consumption (Fig. 3) is observed only at small conversions. In the developed process, the kinetic curves of methylcyclohexane (RH) consumption are nonlinear and are described by the following equation in the entire range of reactant concentrations up to deep conversions:

$$-d\left[\text{C}_6\text{H}_{11}\text{CH}_3\right]/d\tau = k_{app}[RH] = k_{1app}[RH][O_3] + k([RH]_0 - [RH])/[RH].$$

Computer processing of the experimental data gave the following expressions: $k_{1app} = 1.25 \times 10^2 \times e^{-(25500 \pm 3500)/RT}$ l mol^{-1} s^{-1} and $k = 3.5 \times 10^{-1} \times e^{-(25500 \pm 3500)/RT}$ l mol^{-1} s^{-1}.

The bimolecular rate constant of the reaction of 1-methylcyclohexyl hydroperoxide with ozone is low. However, in the developed reaction of methylcyclohexane ozonolysis, it is possible that the associate of 1-methylcyclohexyl hydroperoxide and 1-methylcyclohexanol (their association was detected by ^{1}H NMR [13]) reacts with ozone at the same rate as does nonassociated 1-methylcyclohexyl hydroperoxide. To reveal the role of this reaction in the overall ozonolysis of methylcyclohexane, we added at the stage of the developed reaction (20°C, $[O_3]$ = 4 vol %, 30 min after the start of the experiment) ^{14}C-labeled 1-methylcyclohexyl hydroperoxide. The specific activity of the added hydroperoxide decreases (Fig. 4) owing to both its consumption and dilution with the forming nonradioactive 1-methylcyclohexyl hydroperoxide. The labeled compound transforms into the following ^{14}C-labeled products: 1-methylcyclohexanol, ε-ketoenanthic acid, and acetic acid. From variation of the specific activity of the hydroperoxide in the course of the experiment, we calculated the rates of its formation. Taking into account the experimental rates of 1-methylcyclohexyl hydroperoxide accumulation, we calculated the rates of its consumption (Fig. 4).

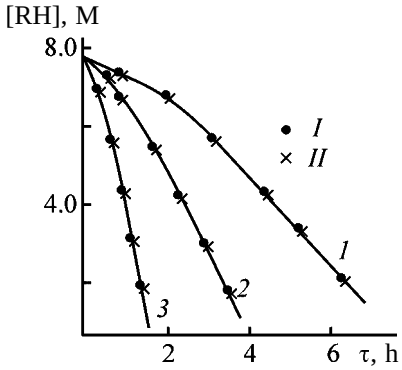


Fig. 3. Kinetic curves of consumption of methylcyclohexane RH ($[O_3] = 1.3 \times 10^{-3}$ M): (*I*) experiment and (*II*) calculation.

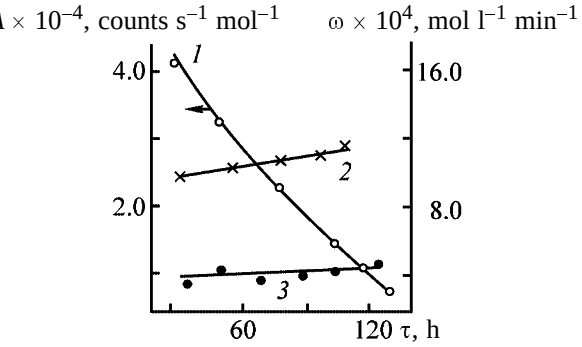

Fig. 4. Variation of the (*1*) specific activity *A* and of the rates ω of (*2*) formation and (*3*) consumption of 1-methylcyclohexyl hydroperoxide in the course of methylcyclohexane ozonolysis (20°C, $[O_3]$ = 4 vol %).

Among the products of 1-methylcyclohexyl hydroperoxide transformations, 1-methylcyclohexanol comprises only 6–7%. An increase in the rate of formation of the tertiary hydroperoxide with the conversion of

the hydrocarbon is apparently due to increase in the rate of $HO_2^{\bullet}$ generation. Unstable methylcyclohexyl hydrotrioxide may be a source of $HO_2^{\bullet}$. A decrease in the yield of hydrogen peroxide (Fig. 1), seemingly contradicting this assumption, may be due to catalysis of its decomposition with acids.

CONCLUSION

In contrast to nonselective high-temperature noncatalytic oxidation of saturated hydrocarbons containing primary, secondary, and tertiary C–H bonds, their low-temperature ozonolysis at small conversions, as demonstrated by the example of methylcyclohexane, occurs selectively at the tertiary C–H bond and yields the corresponding alcohols. The tertiary alcohols are formed by recombination of the $R^{\bullet}$ and $OH^{\bullet}$ radicals generated by primary initiation, by radical-chain transformations of tertiary hydroperoxides, and by attack of the starting substrate by $RO^{\bullet}$ radicals.

Abstract—Effect of the formation procedure on the structure and transport characteristics of poly(2,2,3,3,4,4,5,5-octafluoro-*n*-amyl acrylate)–polyamidoimide composite membranes in separation of O_2/N_2 gas mixture (air) over a wide temperature range is studied.

Studies of the structural features of multilayer polymer systems, as influencing their mass-exchange characteristics, are necessary in designing high-performance gas separation membranes. Among these systems are composite membranes (CMs) of the diffusion type, in which the surface of a microporous support with an asymmetrical cross section structure is coated from the side of a denser layer (skin layer) with a thin continuous layer of one or more polymers of different chemical nature (cover layer). If the cover layer is applied by deposition of a polymer from a dilute solution, pores of the skin layer may be partially or totally filled with this polymer. Therefore, composite membranes can be regarded as a morphologically complex multilayer object consisting of (a) polymer layer of the support with unfilled pores, (b) skin layer of the support with pores partially or totally filled with a polymer of the cover layer, and (c) cover layer over the support surface (Fig. 1).

To estimate the contribution of polymers composing a multilayer membrane to its selective transport properties, the Henis–Tripodi resistance model is used [1, 2]. According to this model, the selectivity of separation of a gas mixture (separation factor f) is controlled by the characteristics of all the nonporous layers of a composite membrane in combination (diffusion layer of a composite membrane). If the resistance of the CM cover layer to mass transfer of gases is considerably higher than that of the support, the total CM selectivity approaches that of the covering polymer. The reverse can be realized when pores of the skin layer of the support are partially or totally blocked with the covering polymer, i.e., when the support demonstrates a higher resistance to a gas flow as compared to the covering polymer. In this case, the mass transfer rate across the composite membrane is controlled by transport of gases across the support, and the separation selectivity approaches the value typical of the support polymer. As a result, the separation factor can change over a wide range from some intermediate values to those typical of the polymers composing the cover layer and the support, depending on the structure of the CM diffusion layer. Generally, the contribution of each polymer composing a composite membrane to the mass transfer can be characterized by some arbitrary parameter expressed as the product of the effective thickness of diffusion layer of this polymer (volume fraction of a given polymer in the diffusion layer) by its selectivity.

It should be pointed out that the basic principles of the resistance model were formulated without taking into account possible structural transformations in the boundary layer of the covering polymer at the support surface [3]. However, such an effect was demonstrated to occur in a series of polymer/inorganic support composites and also in polymer/polymer composites not related to membrane systems [3–5]. It was demonstrated that a polymer in such a boundary layer has a structure different from that typical of the same polymer, but in the layers more distant from the support surface. It is known also that the structural ordering in polymers, reflected in the nature of thermal (phase) transitions, has an effect on the gas permeability and selectivity of diffusion membranes [6, 7]. Par-

1070-4272/03/7605-0791$25.00

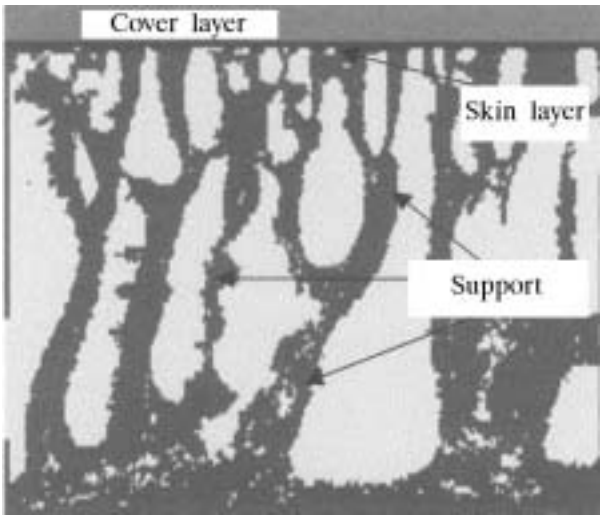

Fig. 1. Schematic representation of the cross section of a composite membrane.

ticularly, the selectivity of a diffusion membrane in separating binary gas mixtures (O_2, N_2, He, etc.) is determined by the diffusion coefficient ratio of the components to be separated, depending, therefore, on the nature of intra- and supramolecular structural organization of a polymer [8].

The selectivity of the existing diffusion CMs (gas-separation and pervaporation) is mostly consistent with that predicted by the Henis–Tripodi model [9–12]. However, for some composite membranes this was not the case [9, 11]. The most significant inconsistencies were found for CMs with cover layers from polymers having low glass transition points (T_g), especially for comb-shaped poly(2,2,3,3,4,4,5,5-octafluoro-*n*-amyl acrylate) (PFAA). Particularly, some CMs with a PFAA cover layer on the surface of an aromatic polyamidoimide (PAI) support demonstrated a higher selectivity in separating O_2 and N_2 (air) than that typical of both PFAA and the corresponding PAI taken separately. Therefore, the goal of this work is to study in more details the mechanism of selective transport of O_2/N_2 mixture across PFAA/PAI composite membranes and the effect of the structural features of a polymer of the cover layer on the transport properties.

EXPERIMENTAL

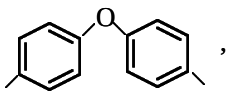
Poly(2,2,3,3,4,4,5,5-octafluoro-*n*-amyl acrylate) (T_g 248 K, MW 2.5×10^6) was synthesized according to the procedure described in [13] and used as a polymer of the cover layer. The polymer is characterized by a narrow unimodal molecular-weight distribution, as demonstrated by GPC with polystyrene as a reference.

To prepare asymmetrical porous supports, we used aromatic PAIs of the general formula

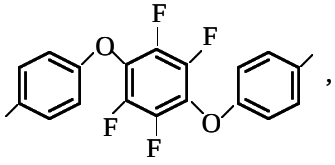
$$[–CO–R_1–CONH–R_2–NH–]_n,$$

where R_1 is a disubstituted 2-phenylisoindole-1,3-dione, and R_2 is as follows:

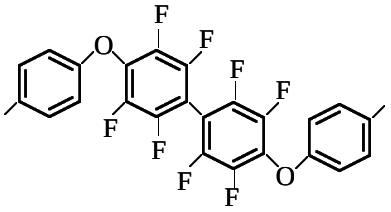
PAI-1



PAI-2



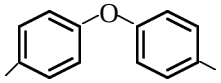
PAI-3



PAI-4

$–(CH_2)_3–Si(CH_3)_2–O–Si(CH_3)_2–(CH_2)_3–$
(5 mol %)

+



(95 mol %)

Microporous supports were prepared under similar conditions of the phase inversion process using wet molding [14]. Composite membranes were fabricated by casting a cover polymer solution on the support working surface under the conditions described elsewhere [9].

The transport properties of CMs were tested with regard to a mixture of the major components of air, O_2 and N_2, having close kinetic diameters of their molecules (3.46 and 3.64 Å, respectively) [15]. The gas permeability was determined chromatographically over the temperature range 303–393°C at a constant gas pressure loss on the membrane of 1 bar. The effective surface area of the samples was 28.3 or 5.7 cm^2.

The morphology of CMs was studied by the low-temperature chip method using scanning electron microscopy and also by the Cr–C replication of the surfaces using transmission electron microscopy [9, 15]. The cover layer thickness was estimated by

averaging values measured on various areas of the membrane.

X-ray photoelectron spectra were recorded on a PHI 5400 electron spectrometer (Perkin–Elmer) using $MgK_{\alpha_{1,2}}$ excitation. The operating vacuum in the spectrometer was 2×10^{-8} torr. The thickness of analyzable layer was 100 Å and less. The binding energy (E_b) scale was calibrated by C1*s* line of the benzene ring (E_b 284.7 eV [16]). Binding energies were determined to within 0.1 eV. The quantitative analysis was based on the integral intensities of photoelectron peaks and on the ionization cross sections included in the Perkin–Elmer software.

The SEM results revealed similar morphology of all PAI supports used [9, 14, 15]. PAI1–PAI-4 supports have finger-shaped pores in the base cross section, tapering in the direction of the skin layer surface (working surface of the support). According to the SEM data, the pores in the skin layer are no more than 200 Å in diameter. The use of the TEM surface replication method allowed more precise determination of the mean pore size on the surfaces of PAI-1 and PAI-3 supports (50 and 125 Å, respectively, at a broad spectrum of the pore size distribution) [15]. All the supports demonstrate similar surface topography. However, on passing from PAI-1 to fluorine-containing supports, the pore size somewhat increases and their profile becomes more perfect. The characteristics of pores of the surfaces, controlling the resistance of the supports to mass transfer, correlate with the gas permeability of the supports for N_2, which was found to be 4.1×10^{-3}, 95.2×10^{-3}, and 13.6×10^{-3} $cm^3\ cm^{-2}\ s^{-1}\ cm^{-1}$ Hg for PAI-1, PAI-2, and PAI-3, respectively. Similar correlation was also observed for PFAA–PAI composite membranes with close thicknesses of PFAA cover layers, whose gas permeability increased in the order PAI-1 < PAI-3 < PAI-2 (see results below). This result suggests that PFAA, having higher molecular weight, only insignificantly penetrates into pores of the skin layers of the PAI supports.

All the composite membranes under consideration have thin uniform layers of a covering polymer, characterized by a smooth surface of the PFAA layer and distinct interface with the support (with no remarkable filling of pores of the skin layer with the covering polymer). This allows application of the TEM data to estimating the effective thickness of the cover layer of composite membranes.

The transport properties of CMs in separation of the O_2/N_2 mixture (air) were analyzed in terms of the Henis–Tripodi resistance model. Characteristics of PFFA–PAI composite membranes and homogeneous films of polymers composing these membranes, determined under similar conditions, are given in Table 1. First of all, it should be pointed out that the selectivity coefficients $f(O_2/N_2)$ of all the composite membranes are higher than that typical of the covering polymer (f(PFAA) = 2.8). Increasing thickness of the cover

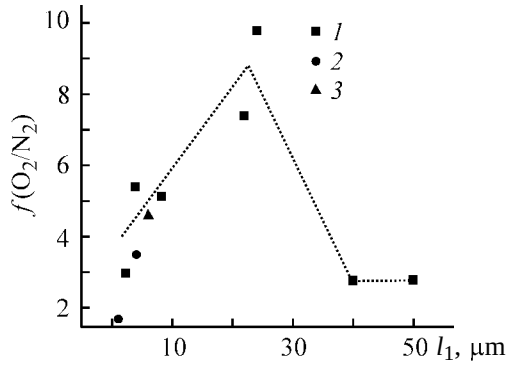

Fig. 2. Selectivity coefficient $f(O_2/N_2)$ as a function of the thickness l_1 of the cover layer of PFAA–PAI composite membranes. Support: (*1*) PAI-1, (*2*) PAI-2, and (*3*) PAI-3.

layer l_1 results in decreasing permeability of CM. In this case, for PFAA–PAI-1, PFAA–PAI-2, and PFAA–PAI-3 membranes, the nitrogen permeability decreases more rapidly than the oxygen permeability, resulting in a considerable increase in f from 3 to about 10. On the contrary, for PAI-4 coated with PFAA in n stages, increase in the selectivity is associated with increasing permeability for oxygen against the background of decreasing permeability for nitrogen.

These trends are clearly demonstrated in Fig. 2 in which f is plotted against l_1 for PFAA–PAI membranes. Analysis of this dependence is necessary not only for determining the general trend of f, but also for clarifying the question about predominant effect of the cover layer thickness on the selectivity of composite membranes. The dependence with a maximum, observed for PFAA–PAI-1, is consistent, in general, with that typical of the known composite membranes with cover layers from low-selective elastomers [1, 9, 11, 17–20]. However, the position of the maximum is remarkably different in our case. According to the resistance model, this position corresponds to the minimal effective thickness of the cover layer (sufficient for complete covering of the pores on the support surface, i.e., for formation of a diffusion layer of the composite membrane). Table 1 shows that, in the case of PFAA–PAI-1, this condition is met at l_1 = 4 μm (f > 5.1). Since for all the membranes of the PFAA–PAI-1 series, at $l_1 \geq 4$ μm, the total contribution of the support and skin layer (including pores covered by PFAA) to the total resistance of the composite membrane is constant, it should be expected that, with increasing l_1 within the experimental range, the selectivity will vary monotonically, tending to the value typical of PFAA (f = 2.8), rather than pass through an extremum. This is associated with increase in the volume fraction of the less selective polymer (PFAA) in the diffusion layer of CM and its contribution to the transport. However, actually, at l_1 = 22–30 μm the dependence has a maximum of the selectivity, whose values is considerably higher than that of PAI-1 (f = 7.4 at l_1 = 22 μm against 5.1 for PAI-1). At such a thickness of elastomer cover layers, the separating characteristics of the known CMs deteriorate, approaching those typical of the covering polymers [17–20]. At the same time, in the case of PFAA–PAI-1 composite membranes, the decrease in the selectivity to the value typical of PFAA (f = 2.8) is observed only at l_1 = 30–40 μm.

It should be pointed out that single coating of a PAI-1 skin layer with 2 wt % PFAA provides formation of a 2-μm cover layer, while two-stage coating gives approximately 8-μm cover layer. With 5 wt % PFAA, we also observed nonadditive increase in l_1 (4 μm at n = 1 and 22 μm at n = 2). Furthermore, small increase in the contact time of the support surface and the polymer solution in the course of second coating with 5 wt % PFAA results in formation of a 24-μm cover layer, the selectivity of the composite membrane being considerably increased (f = 9.8).

In the case of PAI-2, under similar conditions (n = 1, c = 2 wt %), a thicker cover layer is formed (about 1 μm, Fig. 2), which, evidently, is associated with larger pore size in the skin layer. After recoating, l_1 increases nonadditively from 1 to 4 μm, but to a lesser extent than with PAI-1. In the case of a PAI-3 support, at n = 1 and c = 2 wt %, a thicker cover layer is formed (about 3.5 μm), though the mean pore size on the PAI-3 support is larger as compared to the PAI-1 support. At the same time, PFAA–PAI-3 composite membranes are more selective than PFAA–PAI-1 membranes prepared at the same n and c.

Table 1 shows that, at close l_1 of about 4 μm, the selectivity of PFAA–PAI membranes increases in the order PAI-2 < PAI-3 < PAI-4 < PAI-1, for all the composite membranes being higher as compared to the corresponding PAI. The PFAA cover layers formed on various supports under similar conditions (same n and c, which corresponds to similar contribution of PFAA to formation of the effective diffusion layer of CM) differ from each other not only in the thickness, but also in the permeability for nitrogen (corrected for the transport characteristics of the support). Presumably, these differences are caused by the transport characteristics of the diffusion layers.

The contradictory results noted above can be interpreted with the assumption that PFAA cover layers formed on various PAI supports differ in the nature

and degree of structural organization. The observed trends are associated, evidently, not so much with participation of the polymer of the support in separation, but with the features of the supramolecular structure of PFAA in the cover layers of the composite membranes under consideration. Simultaneous considerable increase in f and l_1 on passing to two-stage coatings and also the trends in l_1 as a function of n suggest that these effects are caused not by compaction of the cover layer, but by formation of more ordered structure of the PFAA diffusion channels capable of distinguishing molecules of gases even close in size.

Evidently, in the stage of formation of the cover layer by adsorption of PFAA from a dilute solution, a structure is formed on the PAI support surface, which differs in the degree of ordering from that typical of the covering polymer in the bulk. Based on the general views of the dynamics of adsorption of macromolecules [4], it may be suggested that the structural ordering in the PFAA cover layer is controlled by just the adsorption structure formed in the course of contacting the support with a PFAA solution and fixed as a condensed cover layer (so-called primary structural effect).

This hypothesis is supported by the published data [21, 22] on structural self-organization of PFAA in both a solution and condensed state. X-ray diffraction study of PFAA showed that, despite the lack of fragments characterized by a remarkable level of nonuniformity, the X-ray diffraction pattern of amorphous PFAA demonstrates a definite order in arrangement of the backbone and side chains of the polymer. Having a considerably lower degree of ordering, the structure of amorphous PFAA in a continuous film is similar to that of its regular homologs with n 8 or 10, characterized by mutual arrangement of the side chains with formation of a hexagonal lattice in the plane perpendicular to the axis of the side difluoromethylene chain (mean diameter 5.7 Å). Based on the concept of the mesomorphic structure of comb-shaped polymers at $n = 10$, a 3D model was proposed, involving layers formed by antiparallelly arranged side groups.

Figure 3 shows the temperature dependences of the selectivity of PFAA–PAI-1 composite membranes with a 2-μm cover layer in the first (Table 1, sample no. 1) and second cycles of thermal treatment (Table 1, sample no. 2). As seen, the dependences have a maximum in both thermal cycles. The selectivity coefficients f determined for PFAA–PAI-1 composite membranes (sample nos. 1 and 5) just after the cycle heating to 393 K–cooling to the initial temperature are

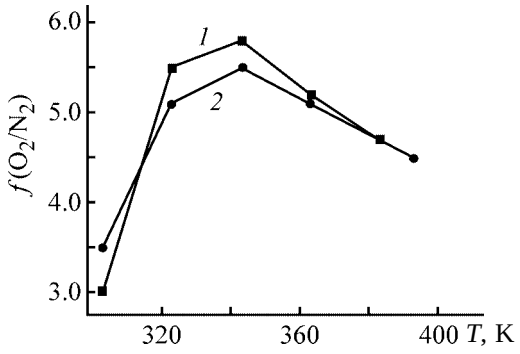

Fig. 3. Selectivity coefficient $f(O_2/N_2)$ of PFAA–PAI composite membrane (l_1 = 2 μm) as a function of the temperature T. (*1*) First and (*2*) second heating–cooling cycles.

given in Table 1. In this case we obtained the selectivity coefficients considerably higher than those before heating. At the same time, after the samples were heated, cooled, and held at 293 K for about 20 h, f returned to nearly the initial values (Fig. 3, curve *1*) [after the second thermal cycle and exposure to 293 K, f(303 K) = 3.2]. This effect is probably due to thermal transitions in the polymers composing the membrane. Since the covering polymer (PFAA) is characterized by a low glass transition point (T_g = 248 K), and that of the polymer of the support (PAI-1) (513 K) is much higher than the experimental temperature range studied in this work, one can speak of a characteristic thermal transition in just the PFAA cover layer. Evidently, the increase in the thermal mobility of the macromolecules, generally leading to regularly decreasing selectivity, in this case is compensated by some additional transformation of the supramolecular organization of PFAA in the cover layer (the secondary structural effect).

If the structuring mode in the cover layer really depends on the nature of the supporting polymer, this effect should be manifested in the temperature dependences of the selectivity of PFAA–PAI composite membranes with PAI-1–PAI-4, whose study, therefore, is of a particular interest.

The temperature dependences of $f(O_2/N_2)$ and P/l for PFAA–PAI-1 composite membranes with various l_1, and also for a PFAA continuous film formed on an inert support are given in Fig. 4A. The separating capacity of PFAA gets worse with heating, which is typical of homogeneous polymeric membranes, particularly those having a low T_g. For PFAA–PAI composite membranes, the $f(O_2/N_2)$–T curves have a maximum, and, starting from 343 K, f monotonically decreases in parallel to the curve observed for PFAA

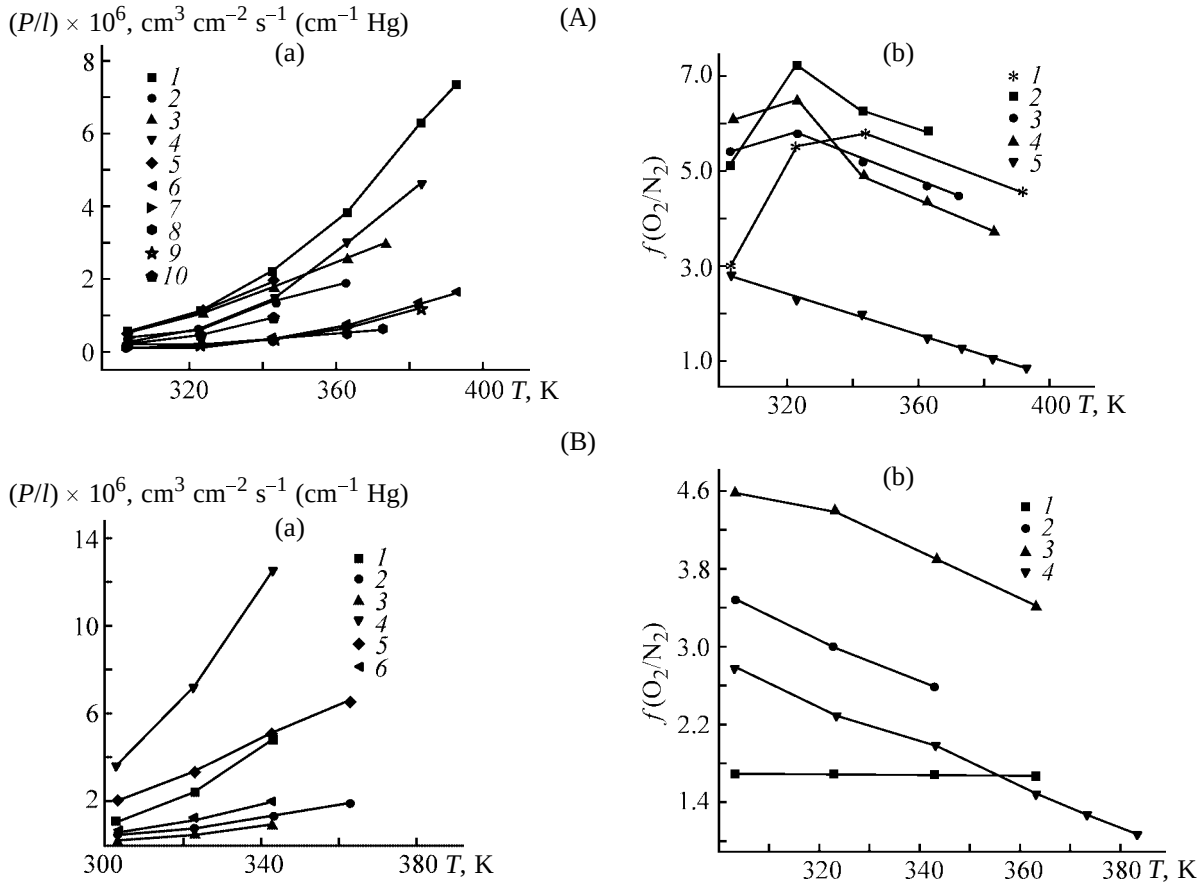

Fig. 4. Temperature dependences of (a) permeability P/l and (b) selectivity coefficient $f(O_2/N_2)$ of (A) PFAA–PAI-1 and (B) PFAA–PAI-2 and PFAA–PAI-3 having various thickness of the cover layers. (*T*) Temperature (K); the same for Fig. 5. (A) (a) P/l: (*1*–*5*) for O_2 and (*6*–*10*) for N_2; *c* (wt %): (*1, 2, 6, 7*) 2, (*3, 4, 8, 9*) 5, and (*5, 10*) continuous PFAA film; *n*: (*1, 3, 6, 8*) 1 and (*2, 4, 7, 9*) 2. (b) *c* (wt %): (*1, 2*) 2, (*3, 4*) 5, and (*5*) continuous PFAA film. (B) (a) P/l: (*1*–*3*) for N_2 and (*4*–*6*) for O_2; *c* (wt %): (*1, 2, 4, 5*) 2 and (*3, 6*) continuous PFAA film; *n*: (*1, 4*) 2 and (*2, 5*) 1; (*1, 4*) PAI-2 and (*2, 5*) PAI-3. (b) *c* (wt %) (*1, 3*) 2 and (*4*) continuous PFAA film; *n*: (*1, 3*) 1 and (*2*) 2; (*1, 2*) PAI-2 and (*3*) PAI-3.

(Fig. 4A). All the composite membranes of this series demonstrate higher selectivity as compared to the covering polymer in the bulk. The behavior of the curves in Fig. 4Ab (including the position of the maximum) reveals that heating to 343 K initiates transformation of the initial supramolecular structure of the cover layer of each CM (l_1 = 2–24 μm) into even more ordered "secondary" structure. It is clear that the observed effect cannot be related to some irreversible process, for example, removal of the residual solvent from the membrane, since the temperature dependences of *f* are similar in both the first and second heating–cooling cycles, as was demonstrated even for CM with l_1 = 2 μm, in which the pores of the skin layer are blocked with PFAA incompletely, and the selectivity at 303 K does not exceed that of PAI-1 (3.0 and 5.1, respectively) (Fig. 4).

The only conclusion that can be made from the above results is that some structural transformation of PFAA occurs in the cover layers of all the PFAA–PAI series studied (primary and secondary structural effects). However, it remains unclear whether the boundary effect is the only cause for ordering and whether the chemical nature of the supporting polymer and, therefore, the structural and energy characteristics of the support surface influence the primary and secondary effects in the PFAA cover layer. If it is the boundary effect that controls formation of the cover layer, the temperature dependences of $f(O_2/N_2)$ and P/l for PFAA–PAI-2, PFAA–PAI-3, and PFAA–PAI-4 should be similar to those for PFAA–PAI-1.

Figure 4B shows the temperature dependences of $f(O_2/N_2)$ and P/l for PFAA–PAI-2 and PFAA–PAI-3 composite membranes having practically identical thickness of the cover layer [4 and 3.5 μm, respectively, Table 1)]. On passing from PAI-2 to PAI-3, the permeability of the resulting membranes decreases, and the selectivity considerably increases. However,

generally, all the temperature dependences of the selectivity are parallel to the curve typical of PFAA (Fig. 5). Therefore, the range of thermal transformation (secondary structural effect) in lacking in the cases of PFAA–PAI-2 and PFAA–PAI-3, which, in comparison with data on PFAA–PAI-1 (Fig. 5), suggests that the structural organization of the coverung polymer depends on the chemical nature of the supporting polymer.

The same conclusion follows from comparative analysis of the transport properties of composite membranes formed on PAI-I and PAI-4 supports. Sample nos. 1 and 3 (PFAA–PAI-1) and 8 and 9 (PFAA–PAI-4) (Table 1) were prepared under similar formation conditions. Despite higher permeability and close thickness of the cover layer, PFAA–PAI-4 membranes are considerably more selective under the same conditions. The P/l–T curves (Fig. 5) show that, in contrast to PFAA–PAI-1, PFAA–PAI-4 membranes are characterized by higher permeability for oxygen. On passing from PFAA–PAI-1 to PFAA–PAI-4, the behavior of the temperature dependences of the selectivity changes. Above 343 K, the $f(O_2/N_2)$–T curves demonstrate no parallelism not only with the corresponding curves for PFAA–PAI-1, but also with the curves observed for the covering polymer. It may be suggested that membranes of the PFAA–PAI-4 type have cover layers in which the PFAA ordering mode strongly differs from that in PFAA on PAI-1–PAI-3 supports as well as in a continuous PFAA film.

Therefore, comparative analysis of the transport properties of PFAA–PAI composite membranes with PAI-1–PAI-4 supports and also of PFAA films reveals that the structural order levels in the cover layers on various supports are considerably different, in all cases differing from that characteristic of PFAA in the bulk. Formation of PFAA layers of different structural organization is reflected in the transport characteristics of the resulting composite membranes and cannot be interpreted by the boundary effect only. Evidently, changing chemical nature of the polymer on passing from PAI-1 to fluorine- and silicon-containing supports, accompanied by modification of the chemical structure of the surface, results in changes in the concentration and (or) nature of adsorption sites on this surface. The latter controls formation of the primary adsorption structure of PFAA in the boundary layer of each CM series, which, in its turn, governs the structural organization of PFAA layers more distant from the boundary.

Comparative angle-resolved XPS study of the boundary layers of PAI-1 and PAI-2 supports and

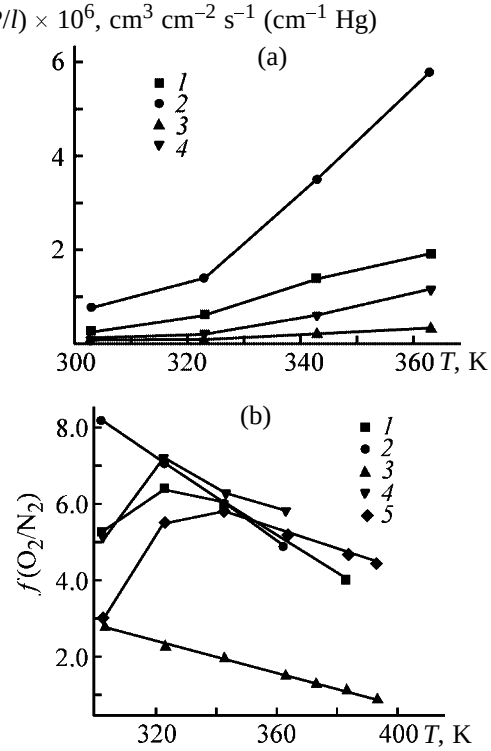

Fig. 5. Temperature dependences of (a) permeability P/l and (b) selectivity coefficient $f(O_2/N_2)$ of composite membranes with PAI-1 and PAI-4. (a) c = 2 wt %, n = 2; P/l: (*1*, *2*) for O_2 and (*3*, *4*) for N_2; (*1*, *3*) PAI-1 and (*2*, *4*) PAI-4. (b) c (wt %): (*1*, *2*, *4*, *5*) 2 and (*3*) continuous PFAA film; n: (*1*, *5*) 1 and (*2*, *4*) 2; (*1*, *2*) PAI-4 and (*4*, *5*) PAI-1.

PFAA–PAI model composite films with cover layers up to 100 Å thick allowed more accurate determination of the nature of the active sites on the working surface of the supports as well as the formation mode of the PFAA primary structure at the PAI-I surface. Varying the photoelectron sampling angle α, we performed layer-by-layer examination of the atomic composition near the surface of each sample at a depth of 96, 87, 70, and 26 Å, which correspond to sampling angles of 75°, 60°, 45°, and 15°, respectively. The chemical composition of the supports were demonstrated to be identical to that of the free surfaces, corresponding to the stoichiometry of PAI-1 or PAI-2 molecular units. As seen from Table 2, the atomic compositions of the surfaces of PAI-1 and PAI-2 supports are identical to those of deeper boundary layers (skin layers). Therefore, in the skin layers of the PAI-1 and PAI-2 supports, the macromolecules are arranged coplanarly to planes of the corresponding surfaces, which is consistent with X-ray diffraction data obtained for PAI-1-based films and supports [23].

Study of PFAA–PAI-1 film composites showed considerable differences between the state of the car-

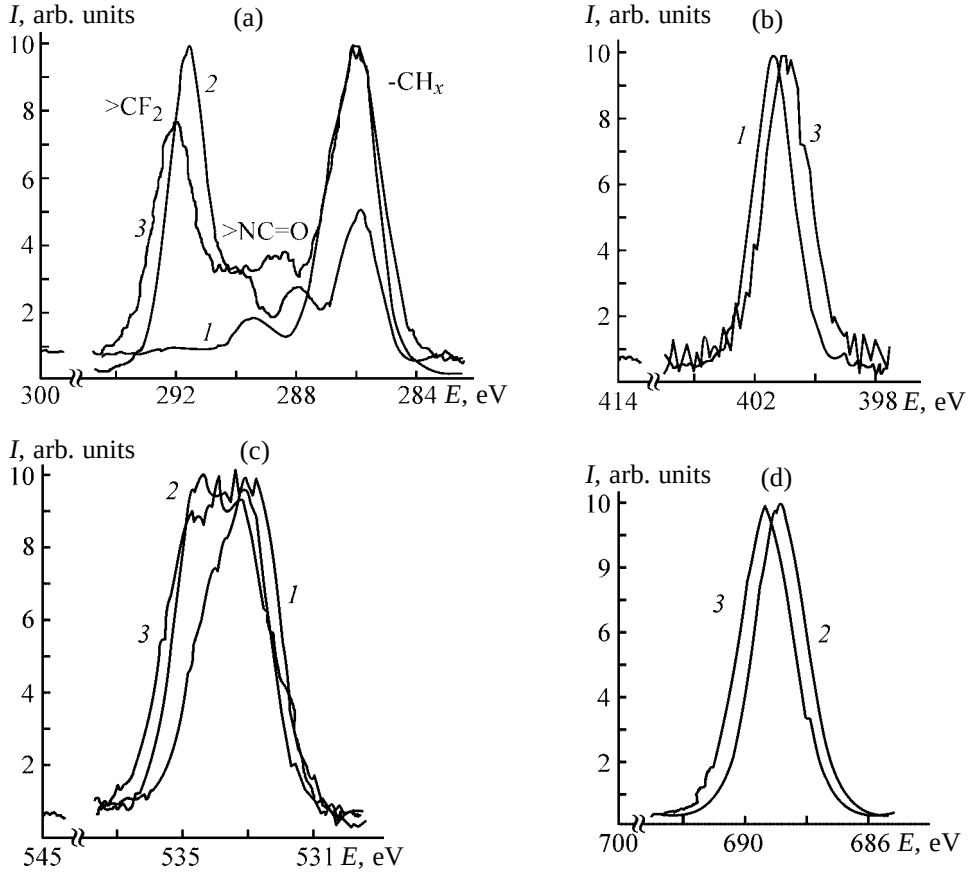

Fig. 6. X-ray photoelectron spectra of 1*s* core levels of (a) C, (b) N, (c) O, and (d) F in (*1*) PAI-1, (*2*) PFAA, and (*3*) PFAA–PAI-1 model composite. (*I*) Intensity and (*E*) binding energy.

bon atoms in both $-CF_2-$ groups of polyfluoroalkyl acrylate and –CON< groups of PAI near the PFAA/PAI-1 boundary ($\alpha = 45°$) and the state of these atoms on the surface of continuous films of the corresponding polymers. The chemical shifts of photoemission lines of these atoms are shown in Fig. 6a. The PE spectrum of nitrogen (contained in PAI-1 molecule only) (Fig. 6b) reveals that the investigated layer of the composite is at the PAI/polyfluoroacrylate boundary, as lines of the both polymers are observed. Change in the electronegativity (EN) of the nitrogen atoms of the >NC=O group (from 400.4 eV in PAI-1 to 400.0 eV in the composite) and of fluorine (from 688.8 eV in PFAA to 689.2 eV in the composite) at the cover layer/support boundary (Figs. 6b and 6d, respectively) relative to their characteristic values on the surface of PFAA and PAI-1 films is accompanied by decrease in the electron density on the carbon atoms (Fig. 6a) in $>CF_2$ groups (290.7 eV in PFAA and 292.2 eV in the composite) and also in EN of the carbonyl carbon (288.4 eV in PAI-1 and 289.2 eV in the composite). Changes in EN of the carbonyl oxygen from 531.8 eV in PAI-1 to 531.3 eV in the composite and from 532.0 eV in PFAA to 532.5 eV in the composite, and also changes in EN of oxygen in –C–O–C– (*E* 533.3 eV) and $-O-C-CF_2-$ groups (*E* 533.6 eV) to the state with *E* 534.0 eV also show that, at the interface, interaction of the electronic shells of fluorine (electron donor) and nitrogen atoms (electron acceptor), accompanied by redistribution of the electron density of neighboring atoms, is the most probable.

Table 2. Atomic composition of the boundary layers of PAI-1 and PAI-2 asymmetrical supports, determined at various photoelectron sampling angles α

PAI	α, deg	Content, %			
		C	O	N	F
PAI-1	15	76.00	15.65	8.35	–
	45	75.50	15.68	8.81	–
	75	76.22	14.72	9.06	–
PAI-2	15	68.36	12.81	5.31	13.52
	60	68.43	12.60	5.43	13.50

Finally, the results obtained reveal that (1) formation of PFAA cover layer in the course of adsorption from a dilute solution is accompanied by orientation of the fluorine-containing fragments (in the boundary layer at the support) in the direction to the PAI-1 surface; (2) the main adsorption sites on the support surface are, most likely, PAI-1 fragments containing >NC=O groups; and (3) the observed changes in the electronegativity of the fluorine and nitrogen atoms suggest the formation of stable adsorption structures, i.e., of the PFAA primary structure at the boundary with the support (primary structural effect).

CONCLUSIONS

(1) Comparative analysis of the experimental data shows that, in designing high-performance composite membranes of the diffusion type using the Henis–Tripodi resistance model, it is necessary to take into consideration not only the morphological features of the diffusion layers of membranes and selectivity and transport characteristics of polymers used, but also possible structural effects in the boundary layers of the covering polymer. The diffusion layers of composite membranes, formed in the course of adsorption interaction of a polymer from a dilute solution with the surface of a support based on another polymer, in some cases can demonstrate a structural organization different from that typical of the cover polymer in the bulk.

(2) It was demonstrated with an example of poly(2,2,3,3,4,4,5,5-octafluoro-*n*-amylacrylate)–polyamidoimide composite membranes that highly selective diffusion layers, particularly of low-selective elastomers, can be realized on the support by optimization of the chemical structure of PAI, i.e., by varying the nature and (or) concentration of adsorption sites on the support surface and, therefore, its energy characteristics. This allows manufacture of diffusion membranes whose separating characteristics differ from those predicted theoretically on the basis of the resistance model in that they surpass the selectivity of all individual polymers composing the composite membrane.

Abstract—The statistical ensembles of supramolecular formations (microdomains) on the surface of films of the polyamido acid derived from pyromellitic dianhydride and 4,4'-oxydiphenylenediamine and evolution of these ensembles in the course of thermal and chemical imidization were studied using the reversible aggregation model. The regular trends in variation of the distribution parameters (aggregation energy and mean microdomain size) in the course of thermal imidization were established. The distribution parameters were compared for polyimide films prepared by thermal and chemical imidization.

Aromatic polyimides (PIs) are heat-resistant polymers; they are used in various branches of engineering [1]. The most common polyimide material is that derived from pyromellitic dianhydride and 4,4'-oxydiphenylenediamine (PI PM). PI PM films are produced in Russia and the United States under the trade names Arimid and Kapton, respectively.

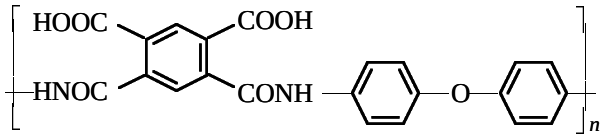
PI items are usually prepared in two steps. In the first step, the prepolymer, polyamido acid (PAA), is prepared in an aprotic solvent; in the second step, PAA items are heated stepwise to 300–400°C in a vacuum or in an inert medium (thermal imidization), or are kept in a dehydrating medium (chemical imidization) [1].

The morphology of PI PM films and its evolution in the course of solid-phase thermal transformation PAA → PI have been fairly well studied by X-ray scattering and electron microscopy [2, 3]. In particular, the scale-invariant nature of the supramolecular structure of the PI PM film surface was established using the fractal approach [3].

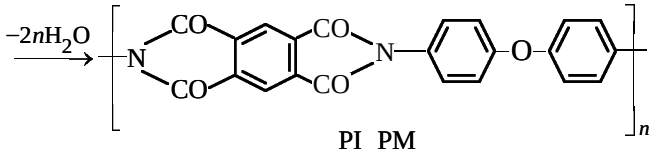
In this work, we studied by transmission electron microscopy the statistical ensembles of microdomains on the PAA PM film surface and their evolution in the course of thermal and chemical imidization.

EXPERIMENTAL

We studied films of PAA PM and its imidization product, PI PM, formed by the reaction



PAA PM



PI PM

The films (30–60 μm thick) were prepared from 12% solutions of PAA PM in dimethylformamide (DMF) by casting onto glass supports followed by drying in air at 50°C for 1 day.

Thermal imidization was performed in a vacuum by stepwise heating of PAA PM films to 400°C in a thermal cycling device at a rate of 2 deg min^{-1}. Chemical imidization was performed by keeping PAA PM films in a dehydrating mixture (solution of acetic anhydride, pyridine, and triethylamine in benzene [4]) until the *o*-carboxamide units of PAA completely cyclized. The absence of isoimide units in the cyclization product was checked by IR spectroscopy.

Electron-microscopic examination was performed with a Tesla BS-500 transmission electron microscope at a magnification from 40000 to 59000. To create a surface relief, PAA PM and PI PM films were etched from the air-contacting side with an oxygen high-

1070-4272/03/7605-0800$25.00

frequency (HF) discharge plasma, with subsequent vapor deposition of platinum and preparation of carbon–platinum (C–Pt) replicas [3, 5, 6]. A 100-W generator was the source of HF discharge. The discharge parameters were as follows: oxygen pressure 0.05 Pa, distance from the discharge gap to the film surface 0.2 m, and electron energy 4–5 eV. The etching time was varied from 15 (PAA PM) to 60 min (PI PM imidized at 350 and 400°C). Such an etching mode is considered as "mild," since the film surface is heated by no more than 50°C and the erosion of the layer surface is minimal [3, 5]. The C–Pt replicas were deposited on the etched film surface with a VUP-5 vacuum unit. The platinum shading angle was 45°, and the calculated thickness of the replicas, 5 nm.

Figure 1 shows the electron micrographs of single-step C–Pt replicas of the etched surface of films of (a) PAA PM, (b, c) PI PM prepared by thermal imidization, and (d) PI PM prepared by chemical imidization. Supramolecular formations (microdomains) of approximately spherical shape are clearly seen; their size depends on the imidization mode and conditions. The etched relief depth and distance between microdomains vary in the course of thermal imidization, reaching a maximum at 170–180°C, which may be due to removal of the disordered polymer phase with the residual solvent (DMF) and water formed in the course of thermal imidization [1].

Figure 2 shows the microdomain diameter distributions $h(y)$ obtained by statistical processing of the micrographs. In each micrograph we analyzed from 500 to 2900 structural formations. It is seen that, for both PAA PM and PI PM, in all the stages of thermal imidization and also after chemical imidization, the microdomain ensembles show monomodal asymmetric distributions which were described in terms of the reversible aggregation model [7, 8].

The model suggests that a substance in the liquid state undergoes continuous fluctuations, generating a sequence of equivalent microstructures, and only one of the set of possible configurations is realized on cooling. Structural elements (aggregates) are dynamic units characterized by a disordered internal structure. The aggregates continuously arise and disappear, giving rise to a set of optimized configuration of ensembles characterized by a steady-state aggregate size distribution. Formation of an aggregate ensemble can be represented as a set of simultaneously occurring reversible chemical reactions. The thermodynamic interpretation of the rate constant leads to the expression [7, 8]

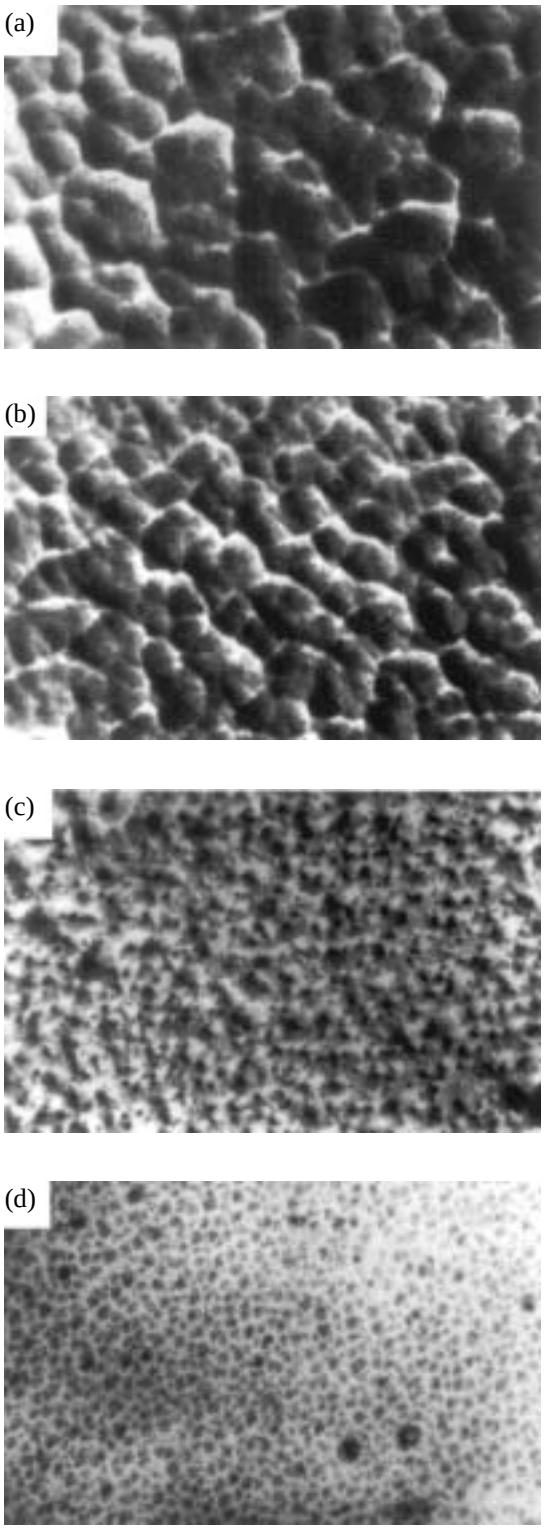


Fig. 1. Electron micrographs of C–Pt replicas taken from the surfaces of (a) PAA PM films; (b, c) PI PM films heated to 180 and 350°C, respectively; and (d) PI PM films prepared by chemical imidization. Magnification: (a, b) 44000 and (c, d) 40000.

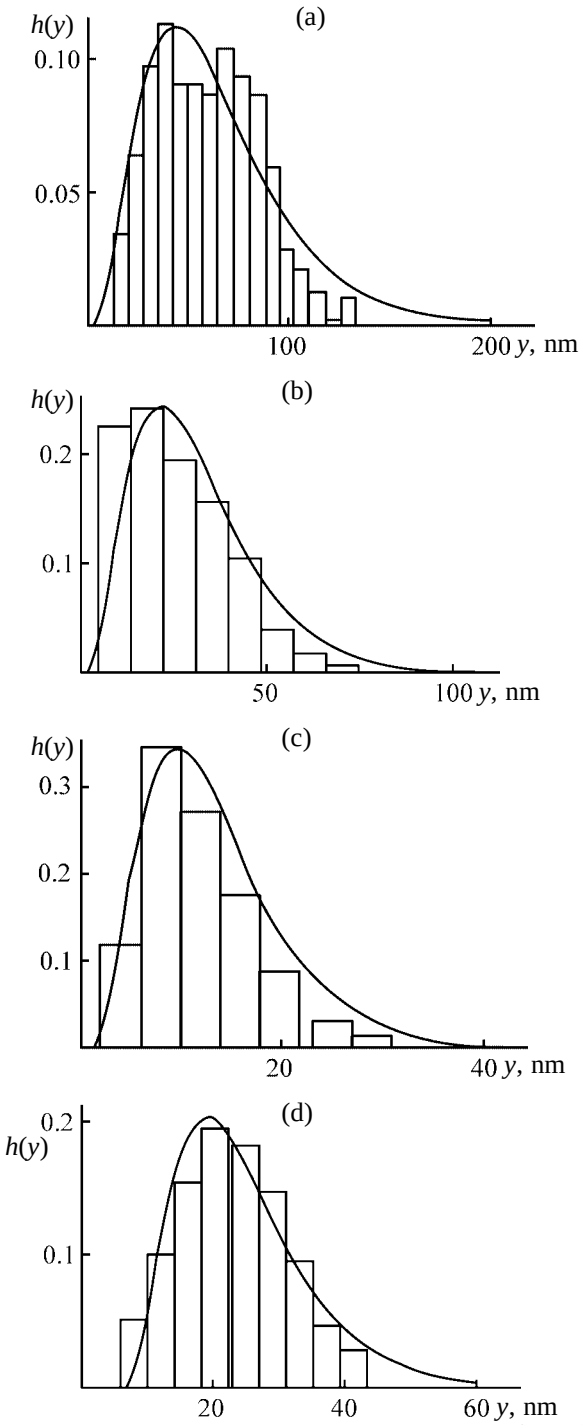

Fig. 2. Microdomain size distribution $h(y)$ on the surface of films of (a) PAA PM; (b, c) PI PM prepared at 180 and 350°C, respectively; and (d) PI PM prepared by chemical imidization.

$$h(y - y_0) = A(y - y_0)^2 \exp[-(y - y_0)\Delta U_0 (kT)^{-1}], \quad (1)$$

where A is a normalizing factor; $\Delta U \equiv (y - y_0)\Delta U_0$, energy of aggregate formation depending on the reduced linear size of the microdomain $(y - y_0)$; ΔU_0, standard aggregation energy per unit linear size of the microdomain, J m^{-1}; y_0, size of the microdomain nucleus; k, Boltzmann constant; and T, absolute temperature.

In statistical physics, Eq. (1) is a canonical distribution of the thermodynamic probability of the energy fluctuation (Gibbs distribution) at constant volume [9].

We successfully used this model previously for describing the microdomain diameter distribution on the surface of films of PAA derived from 3,3',4,4'-diphenyltetracarboxylic dianhydride and *p*-phenylenediamine (PAA DP PP) and its evolution in the course of thermal imidization, including the process in the presence of a thermal stabilizer [10, 11].

The results of calculations with Eq. (1) are shown in Fig. 2 as curves. In the calculations, the values of A, y_0, and ΔU_0 were taken as free parameters. Figure 2 shows that Eq. (1) fairly adequately describes the experimental microdomain diameter distribution on the surface of PAA PM and PI PM in all the steps of thermal imidization and after chemical imidization.

The mean microdomain diameter $\langle y \rangle$ in an ensemble was determined as the normalized population mean:

$$\langle y \rangle = \frac{\int_0^\infty (y - y_0)h(y - y_0)dy}{\int_0^\infty h(y - y_0)dy} = \frac{3kT}{\Delta U_0} + y_0. \quad (2)$$

Figure 3 shows how the distribution parameters [reduced standard aggregation energy U ($U = \Delta U_0/kT$) and $\langle y \rangle$] depend on the temperature of thermal imidization. As seen from Fig. 3a, in the initial step (50–130°C), U varies insignificantly, after which it decreases, reaching a minimum at about 160°C. It is known [1] that, in this temperature range, the PAA $\rightarrow$ PI transformation is accompanied by intense degradation with a decrease in the molecular weight of the polymer. In the range 180–200°C, the activation energy substantially grows, reaching a virtually constant level in the final step of thermal imidization (T > 300°C). In the process, the molecular weight of the polymer is restored [1]. The dependence $\langle y \rangle(T)$ in Fig. 3b shows an opposite trend. Such trends in variation of the distribution parameters were observed previously in studies of the effect exerted by thermal imidization on the morphology of PI DP PP films [10, 11].

In Fig. 3 we also compare the distribution parameters of the microdomain ensemble on the surface of

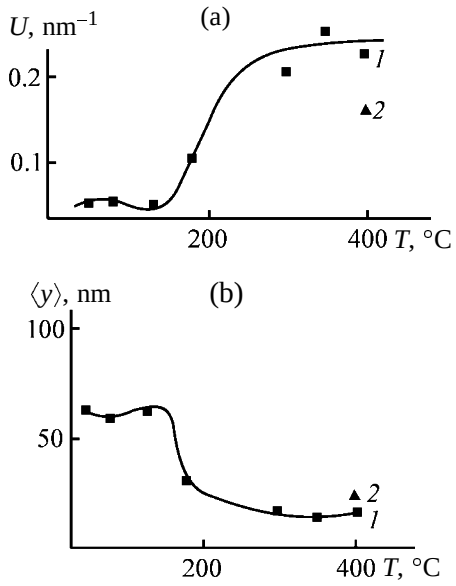

Fig. 3. (a) Reduced standard aggregation energy U and (b) mean microdomain diameter $\langle y \rangle$ as functions of the imidization temperature T. Imidization: (*1*) thermal and (*2*) chemical.

PI PM films prepared by thermal and chemical imidization. It is seen that the aggregation energy of the microdomain ensemble on the surface of a PI PM film prepared by thermal imidization is approximately 1.5 times higher compared to the film prepared by chemical imidization, i.e., the microdomain size distribution in the first case is narrower. Hence, microdomains on the surface of a PI PM film prepared by thermal imidization are more uniform in size. Furthermore, the mean size of microdomains on the surface of a PI PM film prepared by thermal imidization is approximately 1.5 times smaller compared to the film prepared by chemical imidization (15 and 23 nm, respectively). The previously revealed correlation between $\langle y \rangle$ and the mechanical strength of PI films [10, 11] suggests that the PI PM films prepared by thermal imidization will be stronger than those prepared by chemical imidization. Indeed, the strength of thermally and chemically imidized PI PM films determined in [12] appeared to be 200 and 160 MPa, respectively.

CONCLUSIONS

(1) The microdomain diameter distribution on the surface of films of a polyamido acid derived from pyromellitic dianhydride and 4,4'-oxyphenylenediamine and its evolution in the course of thermal and chemical imidization can be described in terms of the reversible aggregation model.

(2) The mechanical strength of polyimide films is inversely proportional to the mean diameter of microdomains.

(3) The surface of a polyimide film prepared by thermal imidization is characterized by the narrower microdomain size distribution and by the smaller mean microdomain diameter, as compared to the film after chemical imidization.

Received February 4, 2003

Abstract—The luminescence and scintillation properties of poly(methyl methacrylate) containing 1,1,3-trimethyl-3-phenylindan were studied.

Plastic scintillators (PSs), i.e., solid solutions of luminophores in polymeric matrices, are widely used as components of scintillation counters for detecting ionizing radiation. Light flashes (scintillations) arising under the action of radiation [1] are detected with a photomultiplier (PM). In PSs based on polystyrene, polyvinylstyrene, and polyvinylxylene, the primary fluorescence emitter is the polymer itself, efficiently transmitting the excitation energy to luminescence additives such as polyarenes and aryl-substituted oxazoles and oxadiazoles: *p*-terphenyl (PPP), 2,5-diphenyloxazole (PPO), 1,4-di(5-phenyl-2-oxazolyl)benzene (POPOP), 2-phenyl-5-(4-biphenylyl)-1,3,4-oxadiazole (PBD), etc. [1–3]. The transparency of these PSs is low because of absorption of UV and visible radiation by benzene groups of the polymer.

The PS containing poly(methyl methacrylate) (PMMA) having no absorption bands in the UV (250–400 nm) and visible ranges is highly transparent, but PMMA, in contrast to polymers containing a system of conjugated double bonds, shows no luminescence. Therefore, large (up to 20 wt %) amounts of luminescent aromatic compounds (naphthalene, its derivatives, etc.) acting as primary luminescence emitters are added to PMMA-based PSs as an active filler. The energy incident on the luminophore (playing the role of a secondary solvent) and on the polymeric matrix is absorbed by the luminophore. A weak emission of naphthalene (fluorescence quantum yield 0.17 [4]) is sensitized by an activator, luminescent additive with a strong intrinsic luminescence, such as PPO, PPP, or PBD [1–3]. The light emitted by the activators is shifted toward the range of the highest PM sensitivity by introduction of one more luminescent additive, a spectrum shifter, the most effective of which is POPOP [3]. Furthermore, this luminophore decreases the probability of absorption of the activator fluorescence by the solvent, eliminating self-absorption and making the system more transparent.

Naphthalene in more effective as intermediate solvent than any other known solvents [3]; however, it inhibits polymerization of methyl methacrylate; it is also toxic and volatile. In this work, we attempted to use for this purpose 1,1,3-trimethyl-3-phenylindan (TMPI), a cyclic α-methylstyrene dimer exhibiting fluorescence properties [5]. This compound is highly soluble in both methyl methacrylate [up to 25 wt % at room temperature and up to 60 wt % at 40°C (temperature of the polymer synthesis)] and PMMA (up to 60 wt %). In the course of methyl methacrylate polymerization, TMPI does not react with the propagating radical and is present in PMMA as a solute [6]. Furthermore, TMPI is nontoxic, nonvolatile, and highly resistant to heat, chemicals, and radiation [7, 8].

EXPERIMENTAL

PS samples were prepared by bulk polymerization of methyl methacrylate at 40°C in the presence of various amounts of TMPI, PPP, and POPOP, with substance initiation. The upper limits of the concentrations of the additives were determined by their solubility in the polymerizing mixture. Samples for studying scintillation characteristics were prepared as polished disks 20 mm in diameter and 10 mm high, and samples for optical studies, as disks 20 mm in diameter and 1 mm high.

1,1,3-Trimethyl-3-phenylindan was prepared as described in [9] and recrystallized from heptane. The

1070-4272/03/7605-0804$25.00

product purity was checked by GLC and by IR and ^{1}H NMR spectroscopy; mp 52°C, bp 183°C/20 mm Hg. PPP and POPOP were of scintillation chemically pure grade.

The absorption spectra of the luminophores in heptane were recorded on a Specord UV-Vis spectrophotometer. The fluorescence spectra of the luminophores in heptane and PMMA were taken on a Hitachi MPF-4 spectrofluorimeter. The luminescence excitation wavelength was 250 and 280 nm. The luminescence quenching constants were calculated according to [10].

The scintillation characteristics of PS were taken in a ^{137}Cs γ-radiation field. The light output was determined according to [11] by comparison with that of samples of a reference PS: PMMA + 15% naphthalene + 0.3% PPO + 0.06% POPOP [12]. The effective transparency of PS for the own emission was measured according to [13]. The light transmission was calculated according to the Lambert–Beer equation [10].

1,1,3-Trimethyl-3-phenylindan efficiently absorbs in the range 210–280 nm ($\varepsilon = 1.69 \times 10^3$ l mol^{-1} cm^{-1} at $\lambda = 269$ nm) and shows fluorescence with a short lifetime (8 ns) and quantum yield of 0.27 in the range 260–320 nm [5]. The transparency of TMPI at $\lambda >$ 300 nm allows its large amounts (up to 60 wt %) to be introduced into PMMA, which, in combination with the short fluorescence lifetime, makes TMPI promising for development of large PSs for detecting γ-radiation and long-path high-energy particles. Another favorable property of TMPI as a primary emitter is its high boiling point, so that, in contrast to naphthalene, TMPI does not volatilize from the scintillation formulation in the course of service.

As a sensitizer of TMPI luminescence we chose PPP exhibiting high quantum yield (0.93) and short lifetime (0.95 ns) of the fluorescence. The quantum yield of the PPP fluorescence is higher compared to TMPI; in this case, according to [10], the acceptor utilizes the quanta emitted by the donor more efficiently. In such cases, the number of quanta emitted by the mixture is higher than the total number of quanta emitted by the donor and acceptor in separate solutions.

The overlap integrals between the absorption bands of the acceptor and fluorescence bands of the donor are considerably larger than those of the absorption and luminescence bands of related molecules (Fig. 1), which is due to higher molar extinction coefficients of the acceptor ($\varepsilon = 3.4 \times 10^4$ l mol^{-1} cm^{-1}) and full

coincidence between the luminescence range of the energy donor (TMPI) and absorption range of the acceptor (PPP). As a result, the efficiency of the inductive-resonance dipole–dipole energy transfer is high.

As seen from Fig. 2, the TMPI luminescence is efficiently quenched by PPP and virtually is not observed at the PPP concentration $c \geq 3 \times 10^{-2}$ M.

The quenching effect of one luminescent additive on another may be due either to a chemical reaction between them or to energy transfer. Under the conditions of the polymer synthesis, these compounds are inert [6]. The luminescence quenching is due to the energy transfer from TMPI to PPP and, as follows from the linear dependence of $(I_0/I - 1)$ on *c* (Fig. 2, curve *2*), is described by the Stern–Volmer law [10] with the bimolecular quenching rate constant $K_q = 6.8 \times 10^9$ l mol^{-1} s^{-1} (PMMA, 298 K). To compare, in such a well-known formulation as naphthalene–PPO, the quenching rate constant appeared to be almost an order of magnitude lower: 8.7×10^8 l mol^{-1} s^{-1} (PMMA, 298 K).

* PMMA molecular weight 10×10^6. ** PMMA molecular weight 2×10^6.

To shift the luminescence spectrum of the TMPI–PPP binary system toward the range of the highest PM sensitivity, it is appropriate to use POPOP exhibiting a strong fluorescence in the range 370–480 nm; its absorption spectrum efficiently overlaps with the luminescence spectrum of PPP (Fig. 1). When PMMA samples containing TMPI, PPP, and POPOP are irradiated at λ = 280 nm (with no TMPI absorption), the intensity of the PPP luminescence grows as its concentration is increased to 1.15 M (Fig. 3a). Further increase in the PPP concentration decreases the fluorescence intensity, probably owing to concentration quenching, whereas the intensity of the POPOP emission remains unchanged. Apparently, the energy transfer from PPP to POPOP occurs faster than self-quenching of the PPP fluorescence. When similar samples are irradiated at λ = 250 nm, TMPI strongly absorbs the energy along with PPP. An increase in the PPP concentration is accompanied by quenching of the TMPI luminescence (Fig. 2) and enhancement of the PPP luminescence (Fig. 3b), probably, owing to increased probability of the energy transfer from TMPI to PPP. In turn, POPOP accepts the excitation energy from both TMPI and PPP, causing the light pulse in the emission range of this luminophore to grow in intensity with increasing PPP concentration.

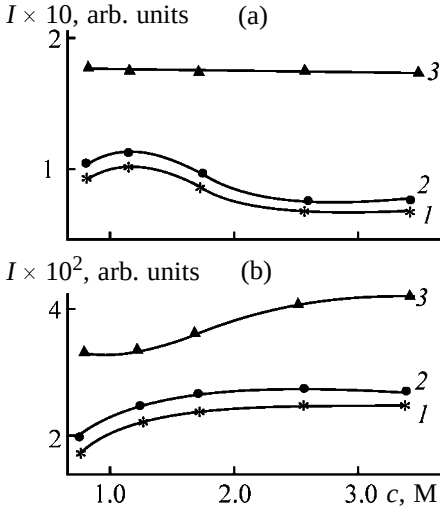

Fig. 3. Fluorescence intensity *I* of (*1*) PPP at λ = 338 nm, (*2*) PPP at λ = 323 nm, and (*3*) POPOP at λ = 415 nm as a function of the PPP concentration *c*. Excitation wavelength, nm: (a) 280 and (b) 250.

Calculations performed according to [14] show that, in the system TMPI (1.27 M, or 30 wt %)–PPP (8.5×10^{-3} M, or 0.2 wt %)–POPOP (3×10^{-4} M, or 0.01 wt %) in PMMA, the energy transfer from TMPI

to PPP occurs with 70% efficiency, and from PPP to POPOP, with 73% efficiency. As the PPP concentration is increased to 3.4×10^{-2} M, the efficiency of the energy transfer from TMPI to PPP increases to 96%.

The PMMA-based plastic scintillator containing TMPI, PPP, and POPOP is an optically uniform highly transparent block showing a high scintillation efficiency (table). The low extinction coefficients and high light transmission coefficients allow fabrication of a scintillator with the two times larger linear dimensions as compared to the scintillator containing the naphthalene–PPO–POPOP additives, with the other parameters being the same.

The scintillation efficiency of PMMA-based PS containing TMPI, PPP, and POPOP can be enhanced by introducing polystyrene fragments in the polymeric chain in the course of copolymerization of methyl methacrylate with styrene. Figure 4 shows that the PS scintillation efficiency grows with increasing content of styrene units (curve *1*). However, introduction of styrene units makes the scintillation block less transparent: The absorption coefficient of the material containing 15 wt % styrene units is as high as 0.015 cm^{-1}.

Copolymerization of α-methylstyrene with methyl methacrylate in the presence of TMPI, PPP, and POPOP yields a PS whose scintillation efficiency is even lower than that of PMMA-based PS, decreasing as the α-methylstyrene content is increased (Fig. 4, curve *2*). It is known that α-methyl groups in the polystyrene chain impair the scintillation characteristics of PSs; the scintillation efficiency of poly-α-methylstyrene is zero [2].

It should be noted that the scintillation efficiency of PMMA containing TMPI, PPP, and POPOP considerably grows with increasing TMPI content (Fig. 5, curve *1*) and only slightly grows with increasing PPP content (curve *2*).

The concentration dependence of the intensity of TMPI fluorescence passes through a maximum at 0.85 M (25 wt %) content in PMMA [5]. The scintillation efficiency of PS monotonically grows with increasing TMPI concentration; the curve is steeply ascending at TMPI content below 0.85 M and gradually flattens out at higher TMPI content (Fig. 5). The different trends in variation of the intensity of TMPI fluorescence in PMMA and of the PS scintillation efficiency suggest that the rate constant of the energy transfer from TMPI to PPP molecules in the scintillator is higher than the rate constant of self-

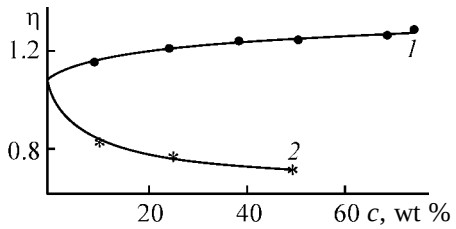

Fig. 4. PS scintillation efficiency η as a function of the content *c* of (*1*) styrene and (*2*) α-methylstyrene in the copolymer. Fig. 5. PS scintillation efficiency η as a function of concentration *c* of (*1*) TMPI and (*2*) PPP. PS composition, wt %: (*1*) PMMA + 0.2 PP + 0.01 POPOP + TMPI and (*2*) PMMA + 24.5 TMPI + 0.01 POPOP + PPP.

quenching. Also, this may due to physical differences between scintillation and luminescence. In excitation with, e.g., a ^{60}Co source (γ-ray energy 1.17 and 1.33 MeV), molecules pass to a higher excited state than in UV excitation (energy about 10 eV). The subsequent energy redistribution over vibrational levels can affect the scintillation light output.

The TMPI inertness in polymerization of methyl methacrylate allows wide variation of its concentration in scintillation blocks. The presence of large amounts of this luminophore in the polymerizing mixture results in dilution of the monomer and "smearing" of the gel effect (sharp acceleration of the polymerization on reaching 15–20% conversion of the monomer), which facilitates removal of the heat released in the process and prevents overheating of the block. The molecular weight of the polymer does not decrease, and the concentration of double bonds which can form by disproportionation termination of the propagating chain (a mechanism competing with recombination) and absorb in the short-wave range does not grow. It is known that double bonds reduce the

polymer transparency and enhance its sensitivity to external effects.

The high transparency and high light output are attained owing to a combination of TMPI with PPP and POPOP. All the additives used have several functions. They transfer the energy and ensure the maximally complete conversion of the incident energy to the light energy. They exhibit high radiation resistance and show radioprotective properties [15]. Owing to absorption of the energy incident on the polymer, followed by its emission in the form of fluorescence, they protect the polymer from the radiation aging, which is seen from the table. The numbers of radiation damages in the PMMA macromolecule decrease with increasing TMPI content, and the irradiation dose causing a 25% decrease in the light output grows. Prevention of the degradation of the polymeric base favors stabilization of the scintillation characteristics of PS in the course of service.

Thus, the use of TMPI as a luminescent additive to PMMA widens the range of luminophores suitable as secondary solvents for PSs, allows fabrication of large PS blocks (more than 100 mm thick and more than 2 m long), improves their scintillation characteristics, and enhances their resistance to heat, light, and radiation.

CONCLUSIONS

(1) Since 1,1,3-trimethyl-3-phenylindan absorbs in the short-wave range only, its addition to poly(methyl methacrylate) does not deteriorate the effective transparency of the polymer.

(2) The energy transfer from the donor (1,1,3-trimethyl-3-phenylindan) to acceptor (*p*-terphenyl) occurs at a high rate, virtually without energy loss.

(3) The plastic scintillator based on poly(methyl methacrylate) and containing as luminescent additives 1,1,3-trimethyl-3-phenylindan, *p*-terphenyl, and 1,4-di(5-phenyl-2-oxazolyl)benzene is characterized by low absorption coefficient (0.0020–0.0025 cm^{-1}) and high light output (110–130%) relative to the plastic scintillator with additions of naphthalene, 2,5-diphenyloxazole, and 1,4-di(5-phenyl-2-oxazolyl)benzene.

Abstract—The size of coherent scattering regions formed in carbon fibers was studied as influenced by the preparation conditions of the initial polyacrylonitrile thread and conditions of preliminary (~200°C) and flash high-temperature (~2400 and ~3200°C) thermomechanical treatments.

Carbon fibers with good mechanical properties are produced by multistep thermomechanical treatment (TMT) of polyacrylonitrile (PAN) threads at temperatures of up to 3200°C. Carbon fiber well-textured along the filament axis is formed after complex structural-chemical transformations during high-temperature treatment. The texture and average sizes L_{002} and L_{110} of the coherent scattering regions (CSRs) formed in the carbon fiber largely determine its physicochemical properties and depend on both preparation conditions of PAN threads and conditions of the thermomechanical treatment [1–6]. The dependence of the average sizes of CSRs (L_{002} and L_{110}) on the heat treatment temperature and the correlation of L_{002} and L_{110} were studied in [3–5]. Since flash thermal treatment lasts for no more than 10 s [1], CSRs are formed under strongly nonequilibrium conditions.

In this work we analyzed the average sizes of CSRs (L_{002} and L_{110}) formed in carbon PAN threads in the course of their preparation by flash thermal treatment of a braid of 7200 PAN threads at 2400 and then at 3200°C. The following experimental parameters were varied: (a) thermal stabilization conditions (extent of oxidation F of the threads determined by the procedure in [6]), (b) preparation conditions of the initial PAN thread (temperature and concentration of the precipitating solution), and (c) mechanical loading on the braid during the high-temperature treatment (variation of the relative elongation of the braid). In some experiments the time of the high-temperature isothermal treatment was also varied. The average values of L_{002} and L_{110} in carbon fibers was determined by conventional X-ray diffraction analysis (DRON-3 diffractometer, CuK_α radiation).

Experimental average sizes of CSRs (L_{002} and L_{110}) and the L_{110}/L_{002} ratio in carbon fibers prepared under different heat-treatment conditions are presented in Tables 1 and 2. Let us consider the influence of the thermal stabilization conditions on the average sizes of CSRs in the carbon fibers treated at 2400°C. The extent of oxidation F of PAN threads in the range from 0.44 to 0.7 was afforded by varying the temperature and time of the thermal stabilization. As seen from Table 1, the average sizes of CSRs in the carbon fiber prepared under these conditions appreciably differ. The L_{002} in the carbon fibers ranged from 2 to 2.5 nm, whereas L_{110} characterizing the length of carbon CRS varied in a wider range, from 4 to 11.6 nm. The minimal and maximal values of L_{110}/L_{002} were 1.9 and 5.4, respectively.

Carbon fibers with L_{002} and L_{110} in the range 1.9–2.5 and 5.9–7.4 nm, respectively, were prepared by varying in a wide range the axial mechanical loading providing 10 and 20% increase in the specific elongation as compared to the preset value. In these experiments, L_{002} and L_{110} changed to a similar extent ($L_{110}/L_{002} = 3$).

The preparation conditions of the initial PAN thread (temperature and concentration of the precipitating solution) negligibly affect L_{002} and L_{110}, which are in the range 2.1–2.3 and 3.9–5.2 nm, respectively. In these experiments, the L_{110}/L_{002} ratio varied from 1.9 to 2.4.

The average sizes $\bar{L}_{002}$ and $\bar{L}_{110}$ in all the samples prepared at 2400°C are 2.2 and 5.2 nm, respectively, and $\bar{L}_{110}/\bar{L}_{002} = 2.3$. The least-squares plot

of L_{002} vs. L_{110} is virtually parallel to the L_{110} axis (Fig. 1a).

This indicates that the sizes of CSRs in carbon fibers thermomechanically treated at the temperatures relatively low for carbon materials increase mainly along the carbon layers.

	T_7	8.4	35.4	4.2

treated at 3200°C reached 7.5 and 28.2 nm, respectively (i.e. they increased by a factor of 3.4 and 5.4, respectively, as compared to those in the thread treated at 2400°C), and the $\bar{L}_{110}/\bar{L}_{002}$ ratio reached 3.1 (i.e., it increased by a factor of 1.4). The sizes L_{002} and L_{110} in the carbon fibers range from 12 to 60 and from 5 to 10 nm, respectively (Tables 1, 2). As seen from Table 1, the largest CSR regions with L_{110}/L_{002} from 5.5 to 6.4 are formed in the threads pretreated at 2400°C with L_{110} exceeding 6.7 nm.

The L_{002} vs. L_{110} dependence for carbon fibers additionally heated at 3200°C can be fitted by a linear function $L_{002} = 0.065L_{110} + 6$ (see Fig. 1b). In this case, unlike carbon fibers heated at 2400°C, larger L_{002} corresponds to larger CSR size in the (110) direction. The L_{110} size in the direction along the filament axis can be substantially changed by mechanical drawing in the course of heat treatment (Table 2). The sizes of CSRs did not change when the isothermal heat treatment at 3200°C was shortened from 2.2 to 1 s.

Thus, CSRs are formed in carbon fiber upon flash high-temperature treatment. The sizes L_{002} and L_{110}

strongly and simultaneously increase upon additional heat treatment at 3200°C. The difference in the ratio of the length of CSRs to their height (L_{110}/L_{002}) for the threads heated both at 2400 and 3200°C is probably due to structural differences produced under different conditions of formation and thermal stabilization of PAN threads and different conditions of TMT.

CONCLUSIONS

(1) The L_{002} and L_{110} sizes of coherent scattering regions in the carbon fibers rapidly heated to high temperatures are determined by conditions of thermal stabilization and formation of polyacrylonitrile threads.

(2) The L_{002} and L_{110} sizes increase several times after additional high-temperature (~3200°C) thermomechanical treatment of the carbon fiber. In this case, the final structure also depends on the conditions of thermal stabilization and formation of the polyacrylonitrile thread.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Concentration of Ionic Acrylamide Copolymers, Ionic Strength, and Kind of the Electrolyte on the Thoms Effect

V. A. Myagchenkov and S. V. Chichkanov

Received January 13, 2003

Abstract—The influence exerted by the copolymer concentration, ionic strength, and kind of single- and multicharged ions on the reduced Thoms effect was examined for ionic acrylamide copolymers as additives reduciong the hydraulic resistance of turbulent aqueous-salt flows. Synergism and antagonism were detected for certain combinations of the polymer and electrolytes.

Ionic acrylamide (AA) copolymers, along with polyoxyethylene [1, 2], are relatively accessible synthetic water-soluble polymers showing much promise as additives decreasing the hydraulic resistance of turbulent water flows (Thoms effect) [3, 4]. When working with multicomponent aqueous solutions of various compositions (in particular, with aqueous-salt media), a topical problem is to find additional possibilities for enhancing the performance of ionic AA copolymers as turbulence quenchers. Available data on how the value of the Thoms effect (T) depends on the chemical nature of the electrolyte are extremely scarce: The only indication is that T decreases on introducing into the dispersion medium some 1–1 electrolytes (NaCl, KCl) [5–7].

In this work, we evaluated on the quantitative level how the chemical nature of single- and multicharged electrolytes and their binary compositions affects the performance of ionic (anionic and cationic) AA copolymers as additives decreasing the apparent viscosity of turbulent aqueous solutions. Also we determined the conditions of manifestation of the synergistic and antagonistic effects associated with the nonadditive contributions of the components (polymer and electrolyte) to the resultant macroscopic Thoms effect [8].

In the aqueous-salt solutions studied, the synergistic and antagonistic effects are highly probable owing to two facts: (1) multicharged electrolyte ions very strongly affect the conformation of flexible-chain macromolecules of ionic AA copolymers and the structure of the electrical double layer [9]; (2) capillary transport of aqueous-salt solutions of ionic AA copolymers was performed in flows of liquids with a weakly pronounced turbulence: For water, the Reynolds number $Re = 5.2 \times 10^3$ [10, 11]. It should be noted that, at low Re, the macromolecules did not undergo noticeable mechanical degradation in a turbulent flow through a capillary [12].

EXPERIMENTAL

Experiments were performed with cationic (C) and anionic (A_1 and A_2, differ in the content of ionic units) water-soluble AA copolymers. Sample A_1 was a random copolymer of AA with sodium acrylate (SA); $M = 7.3 \times 10^6$, content of ionic (acrylate) units $\beta = 41.0\%$. The copolymer was prepared by mild base hydrolysis of high-molecular-weight polyacrylamide (0.1% aqueous solution, 50°C, NaOH). Sample A_2 had a similar molecular weight ($M = 10.8 \times 10^6$) but different microstructure of macromolecules. It was purchased from Allied Colloids (the United Kingdom) under the trade name of Alcoflood 1175-A. This anionic copolymer of AA with SA ($\beta = 21.5\%$) was prepared by radical copolymerization of AA with SA in aqueous solution. Sample C was a random copolymer of AA with dimethylaminoethyl methacrylate hydrochloride; $M = 2.3 \times 10^6$, $\beta = 16.3\%$. It was prepared by radical copolymerization of the corresponding monomers in aqueous solution.

As multicharged electrolytes we used $K_4[Fe(CN)_6]$ with a quadruple-charged anion and $FeCl_3$ with a triple-charged cation, and also NaCl as a reference electrolyte.

The procedures for measuring the parameter T and the reduced Thoms effect $\gamma = T/c$ (c is the polymer concentration) are similar to those described in [8, 13].

1070-4272/03/7605-0813$25.00

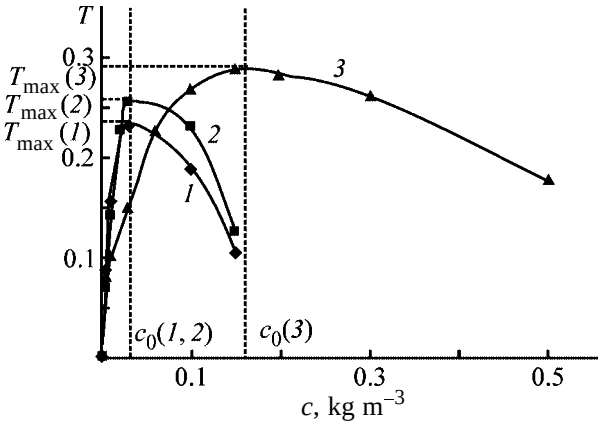

Fig. 1. Thoms effect T for nonionic AA copolymers as a function of copolymer concentration c: (*1*) A_1, (*2*) A_2, and (*3*) C.

Consider the concentration dependence $T = f(c)$ for three ionic AA copolymers: A_1, A_2, and C (Fig. 1). First, it should be noted that curves *1–3* have well-defined maxima; as the molecular weight M of the copolymers increases (going from C to A_1, A_2), the maximum shifts toward lower values of the argument: $c_0(1, 2) < c_0(3)$. The maxima in the curves $T = f(c)$ are apparently associated with the presence of a certain optimal concentration c_{opt} of ionic AA copolymers in the most active zone of quenching of turbulence waves, namely, in the near-wall zone of the capillary (zone I) [10]. In view of specific features of mass transfer of macromolecules in the turbulent mode of solution flow, the concentration c_{opt} differs from c_0, sometimes considerably, especially when strong changes in the conformational state of macromolecules (or macroions) in going from the laminar to turbulent mode of solution flow are taken into account [14]. The ascending portions of curves *1–3* at concentrations of AA copolymers below c_0 suggest that c_{opt} grows with increasing c; hence, the concentration of the most active local centers of quenching of turbulence waves, arising in the immediate vicinity of the capillary walls, varies in the same direction. The descending portions of the $T = f(c)$ curves at the concentrations $c > c_0$ suggest that the number of "effective" quenchers of the flow turbulence in zone I does not increase or increases only slightly.

In the descending portions of curves *1–3* in Fig. 1, the decisive role is played by an increase in the effective viscosity of solutions of ionic AA copolymers during transport to the capillary inlet. When viscous solutions pass along the pumping line (including the transition section at the capillary inlet), the mean velocity of the macroscopic liquid flow v decreases as compared to the similar parameter for the "internal reference," water. As a consequence of a decrease in v, the effective excess pressure in solution flow in a capillary decreases, and this trend is more pronounced at higher c. Obviously, the rate of solution transport through the capillary decreases in parallel with the excess pressure; hence, at copolymer concentrations $c > c_0$ an increase in c is accompanied by a decrease in T and γ.

In view of the inequalities $M(A_1)$, $M(A_2) > M(C)$, and $(\bar{R}^2)^{0.5}(A_1)$, $(\bar{R}^2)^{0.5}(A_2) > (\bar{R}^2)^{0.5}(C)$ [9], the relationsip between the parameters T in the region of the maxima in the $T = f(c)$ curves, namely, $T_{max}(C) > T_{max}(A_1)$, $T_{max}(A_2)$, is quite unexpected.

This apparently illogical inequality becomes understandable if we take into account specific features of electrostatic interactions of C, A_1, and A_2 macroions with the negatively charged surface of the capillary. For C macrocations, these interactions increase the potential energy of attraction U_{attr}, and for A_1 and A_2 macroanions U_{attr} decreases. As a result, the localized adsorption and the parameter c_{opt} increase for C macrocations and decrease for A_1 and A_2 macroanions, which ultimately results in increased $T_{max}(C)$ and decreased $T_{max}(A_1)$ and $T_{max}(A_2)$.

Let us then consider how the Thoms effect is manifested in more complex systems, namely, in disperse systems with added low-molecular-weight electrolyte. Preliminary experiments showed that, to obtain quantitative information on how the ionic strength J and chemical nature of the electrolyte influence the Thoms effect, it is most appropriate to keep constant the concentartion of the polymeric additive and add controlled amounts of electrolytes. For the electrolytes $K_4[Fe(CN)_6]$ and $FeCl_3$, the ionic strength was calculated as

$$J = 0.5(a_1 z_1^2 + a_2 z_2^2),$$

where a_1 and a_2, z_1 and z_2 are, respectively, the molar concentrations and charges of the first and second ions of the electrolyte in solution.

Taking into account the specific features of $T = f(c)$ dependences for the cationic (C) and anionic (A_1, A_2) AA copolymers, we chose two working concentrations, one of which corresponded to the ascending ($c < c_0$), and the other, to the descending ($c > c_0$) portion of the $T = f(c)$ dependence.

Figures 2a–2c show the $\gamma = f(J)$ dependences for all the examined ionic AA copolymers and electro-

lytes. Comparative analysis of these data allows some basic conclusions.

(1) For all the AA copolymers (C, A_1, A_2), the reduced Thoms effect γ strongly depends on particular electrolyte. This is clearly seen when comparing the γ values at fixed *J*.

(2) The shape of the $\gamma = f(J)$ curves in Figs. 2a–2c strongly depends on the copolymer concentration. At the concentrations of A_1, A_2, and C corresponding to the ascending portions of the curves $T = f(c)$, the reduced Thoms effect tends to decrease with increasing *J* (antagonistic effect), whereas at higher concentrations of the ionic AA copolymers, corresponding to the descending portions of the curves $T = f(c)$, γ tends to grow with increasing *J* (synergistic effect in the systems ionic AA copolymer–electrolyte). This difficultly predictable change in the behavior of ionic AA copolymer–electrolyte systems (transition from the synergistic to antagonistic effect) at variation of the copolymer concentration can be qualitatively understood taking into account that different functions of an electrolyte are manifested simultaneously. In particular, electrolytes participate in formation of the electrical double layer (EDL) at the capillary surface; they also affect the conformation and optimal concentration c_{opt} of macromolecules (macroions) of ionic AA copolymers in the most active zone of turbulence quenching (zone I) and the effective viscosity in the pumping line of the installation for studying the Thoms effect [13, 15].

(3) With increasing concentration of $K_4[Fe(CN)_6]$, the reduced Thoms effect for the cationic AA copolymer drastically decreases (Fig. 2c), and with $FeCl_3$ a similar trend is observed for the anionic AA copolymers (Figs. 2a, 2b). The primary cause of strong antagonistics effects observed in the systems ionic copolymer–multicharged electrolyte is associated with local electrostatic interactions of charged segments of A_1 and A_2 macroanions (or C macrocation) with Fe^{3+} cations {or $[Fe(CN)_6]^{4-}$ anions}, which sharply decrease the root-mean-square size of macromolecular coils and induce their globulization [14, 16].

This is supported by viscometric data for these systems (Fig. 3, curves *3*, *4*). When a multicharged ion has a like charge with a macroion (Fig. 3, curve *2*), and also when a 1–1 electrolyte (NaCl) is used in combination with both anionic and cationic copolymers, the decrease in the viscosity number and reduced Thoms effect with increasing *J* is appreciably less pronounced. An exception is the C–$FeCl_3$ system for which, although both the macroion and Fe^{3+} ion are positively charged, the viscosity number noticeably decreases with increasing *J*. (Fig. 3, curve *5*). Such a trend for the C–$FeCl_3$ system is due to intra- and intermolecular donor–acceptor interactions of Fe(III) with the carbonyl oxygen atom of monomeric (acrylamide) fragments of C macromolecules, which are accompanied by contraction of macromolecular coils {decrease in $(\overline{R}^2)^{0.5}$ [17, 18]}. Note that in C the concentration of nonionic (AA) units considerably exceeds the concentration of ionic units (β = 16.3%).

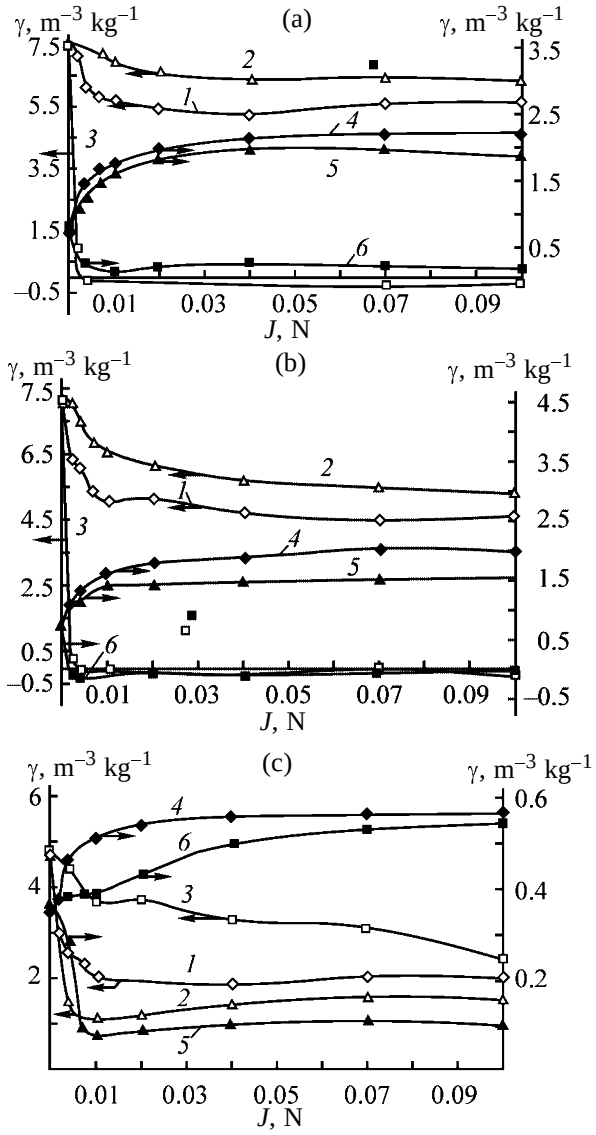

Fig. 2. Reduced Thoms effect γ as a function of the solution ionic strength *J* for ionic copolymers (a) A_1, (b) A_2, and (c) C. Polymer concentration, kg m^{-3}: (*1*–*3*) 0.03 and (*4*–*6*) 0.15. Electrolyte: (*1*, *4*) $K_4[Fe(CN)_6]$, (*2*, *5*) NaCl, and (*3*, *6*) $FeCl_3$.

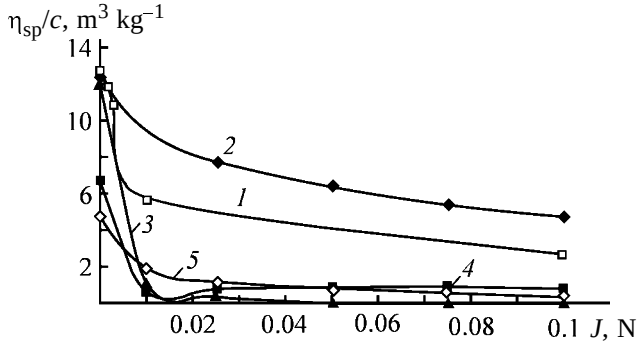

Fig. 3. Viscosity number η_{sp}/c of ionic copolymers (*1–3*) A_1 and (*4*, *5*) C as a function of the ionic strength *J*. Polymer concentration, kg m^{-3}: (*1–3*, *5*) 0.03 and (*4*) 0.1. Electrolyte: (*1*) NaCl, (*2*, *4*) $K_4[Fe(CN)_6]$, and (*3*, *5*) $FeCl_3$.

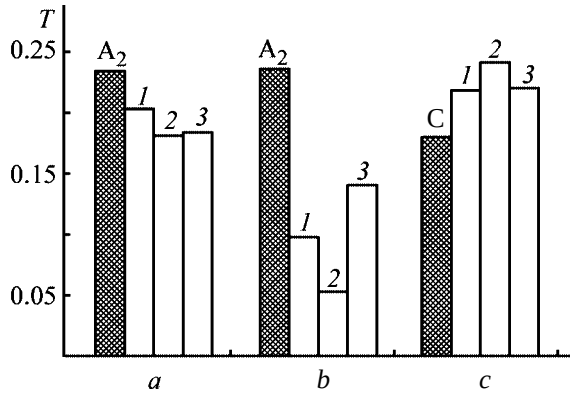

Fig. 4. Thoms effect *T* for copolymers (*a*, *b*) A_1 and (*c*) C as influenced by the order of adding binary electrolyte compositions. (A_1, A_2, C) Copolymer solution without electrolytes added. Polymer concentration, kg m^{-3}: (*a*, *b*) 0.03 and (*c*) 0.5. Electrolytes, g-equiv l^{-1}: (*a*) (E_1) 0.01 $K_4[Fe(CN)_6]$ and (E_2) 0.01 NaCl; (*b*) (E_1) 0.02 $K_4[Fe(CN)_6]$ and (E_2) 0.01 $FeCl_3$; and (*c*) (E_1) 0.01 NaCl and (E_2) 0.01 $FeCl_3$. Order of adding electrolytes: (*1*) first E_1, then E_2; (*2*) first E_2, then E_1; and (*3*) E_1 + E_2 simultaneously.

In view of the facts that *T* and γ strongly depend on particular electrolyte and interaction of active components in aqueous salt solutions involves many factors, it seemed interesting to study how binary electrolyte systems and the order of their addition affect the resultant macroscopic Thoms effect. Figure 4 shows that the parameter *T* depends on the order of adding components both for binary mixtures of multicharged and 1–1 electrolytes (Fig. 4, histograms *a*, *c*) and for a mixture of two multicharged electrolytes (Fig. 4, histogram *b*). The effect of the order of adding components was pronounced to a considerably greater extent for a mixture of $K_4[Fe(CN)_6]$ and $FeCl_3$ (Fig. 4, histogram *b*), which is quite understandable, since the interaction of the electrolytes is complicated by a redox reaction.

Thus, it is principally possible to enhance the Thoms effect by properly choosing the mode of adding binary electrolyte systems, so as to obtain a synergistic effect [8].

CONCLUSIONS

(1) The ionic strength and chemical nature of multicharged electrolytes strongly influence the reduced value of the Thoms effect.

(2) In multicomponent systems, active components (polymeric additive and electrolytes) can exhibit both synergism and antagonism with respect to the Thoms effect.

(3) With binary electrolyte systems, the value of the Thoms effect depends on the order of adding the components.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Formation of Se^0 Nanoparticles in an Aqueous Cationic Polyelectrolyte

Abstract—The nanostructures formed by reduction of Se(IV) in the selenite–ascorbate redox system in an aqueous solution of supermacromolecular polycation, poly[trimethyl(methacryloyloxyethyl)ammonium] methyl sulfate, were studied by static and dynamic optical scattering and flow birefringence.

Formation of uncharged metal nanoparticles of 1–100 nm size, which have energy-saturated surface and exhibit certain anomalies in physicochemical properties, is extensively studied [1].

However, such metal nanoparticles are unstable in aqueous solutions in the absence of stabilizing agents. One of the most promising procedures for preparing stable metal nanoparticles is reduction of their ionic species in polymer solutions. In the course of the pseudo-template synthesis, macromolecules and forming nanoparticles recognize each other, which allows control of the nanoparticle size by varying the structure and molecular weight of the polymer [2].

Such polymer-stabilized nanoparticles are of particular importance as highly selective catalytic systems and adsorption matrices for immunoassay, and, due to the rapid development of the biological nanotechnologies, as active components of drugs and transport systems for biologically active compounds [3–5].

However, much less attention was given to nonmetal nanoparticles, especially those of amorphous selenium(0) (nano-a-Se^0), which, in contrast to metal nanoparticles, can be described as an inorganic polymer containing predominantly the Se_6 and Se_8 ring fragments bound by the Se–Se covalent bonds [6]. Nano-a-Se^0 exhibits unique photoelectric and semiconductor properties and X-ray sensitivity; it is used as highly sensitive biological sensor for immunoassay [7] and chromatographically mobile affine reagent [8].

Moreover, selenium is an imperative element for normal vital activity, it exhibits antioxidantive, antimutagenic, immunnostimulating, and detoxication activity [9]. Therefore, selenium and its compounds are of particular interest as potential drugs.

As shown in [10], the reduction of sodium selenite with glutathione in aqueous solution of bovine serum albumin (BSA) yields red nano-a-Se^0, which is weakly toxic but retains the biologically active properties typical for ionic selenium species. It was found that these nano-a-Se^0 particles are predominantly stabilized by adsorption processes, in which the noncovalent (poorly understood at present) interactions of the BSA macromolecules with nanoparticles play the decisive role.

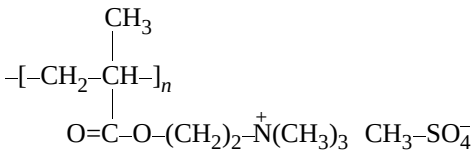
To reveal the nature of these interactions and their contribution to stabilization of nano-a-Se^0, we studied formation of selenium(0) nanoparticles in the presence of a synthetic polybase and analyzed the morphological characteristics of the resulting adsorbates by various optical methods.

EXPERIMENTAL

In our work we studied nanoparticles of a-Se^0 prepared by reduction of selenious acid (SA) with ascorbic acid in the presence of a polymer and without it.

The reagent purity was no less than 99.99%. The reduction kinetics was studied at the SA concentration of 1.7 mM at 20°C on a Specord M40 spectrophotometer (λ 320 nm).

As a polymeric stabilizer we used supermacromolecular poly[trimethyl(methacryloyloxyethyl)ammonium] methyl sulfate [polybase (PB)] with M_w 9×10^6 and intrinsic viscosity in 1 M $NaNO_3$ $[\eta]^{21} = 4.5$ dl g^{-1}:



1070-4272/03/7605-0818$25.00

The nanocomposites of PB and elemental Se in the 90 : 10 weight ratio were prepared by reduction of Se(IV) in solutions with a selenium concentration of 0.01%.

The variation of the apparent viscosity of PB solution with time in the course of SA reduction was monitored on a Brookfield rheoviscometer at a rotor rotation rate of 12 rpm.

The relative viscosity η_r was determined on an Ostwald capillary viscometer with a water outflow time of 120 ± 0.2 s at 21°C.

Using the flow birefringence (FBR) procedure [11], we evaluated the molecular dispersity of the resulting adsorbates in solutions using the gradient dependence of the FBR value Δn.

The FBR value Δn was determined in relation to the gradient of the rotor rotation rate g and PB concentration c at fixed concentration of selenium. We used a titanium dynamo-optimeter equipped with an internal rotor (4 cm high, with a 0.3 mm gap between the rotor and stator). All the measurements were carried out in the temperature-controlled solutions at 21°C to exclude changes in the viscosity and optical density due to the temperature gradient. The experimental setup was calibrated using phenylethyl alcohol with high FBR ($\Delta n/g$ 17×10^{-12}) and the polystyrene–bromoform system. The error in the FBR determination $[n] = \lim_{g \to 0, c \to 0} (\Delta n/gc\eta_0)$ (η_0 is the solvent viscosity) did not exceed 10%. The measurements were performed at $g < g_k$, where g_k is the velocity gradient at which the flow becomes turbulent.

In the general case ($dn/dc \neq 0$, where dn/dc is an increment of the solution refraction index, which comprised 0.155 and 0.214 for PB–H_2O and PB–Se^0–H_2O systems, respectively), the experimental $[n]$ value includes three effects: $[n] = [n]_e + [n]_{fs} + [n]_f$, where $[n]_e$ is the intrinsic anisotropy and $[n]_{fs}$ and $[n]_f$ are the micro- and macroform effects, respectively [11]. The total segmental anisotropy $[n]_e + [n]_{fs}$ is determined by the equilibrium rigidity of the polymer chain A and by the structure of a polymer unit, whereas $[n]_f$ is related to the asymmetry of the macromolecule (or particle) p by the following expression:

$$[n]_f = [(n_s^2 + 2)/3]^2[M_w(dn/dc)^2 f(p)]/(30\pi RTn_s)$$

$$= \text{const} M_9 (dn/dc)^2 f(p),$$

where M_w is the molecular weight of the adsorbate macromolecule; n_s, refractive index of the solvent; T, absolute temperature; R, universal gas constant; and $f(p)$, tabulated function of the ratio of axes of a rigid (impermeable for solvent) ellipsoid approximating a particle [11].

Thus, for macromolecular flexible-chain and moderately rigid-chain polymers ($A < 5$ nm) with insignificant optical anisotropy and low molecular weight of the monomeric unit, $[n] \sim [n]_f$, which allows direct determination of the parameter p from the experimental FBR values [11].

Using the elastic (static) light scattering method [12], we evaluated the molecular weight M_w and the size R_g of nanoparticles in question, and also their affinity for water solvent (from the second virial coefficient A_2). The amount of macromolecules adsorbed on the selenium nanoparticle surface was determined from the ratios of M_w for PB and its adsorbates. The reduced intensity of the solution scattering R_θ was determined using a Fica photogoniodiffusometer. The wavelength of the incident vertically polarized light was 546.1 nm. The measurements were performed at the scattering angles $\theta = 30°$–$150°$. The solutions and solvents were purified by centrifuging at 15×10^3 rpm for 1.0–1.5 h. The refractive index increments dn/dc were determined with an IRF-23 refractometer.

The experimental data on the light scattering were treated with the Zimm procedure by double extrapolation (to $c = 0$, $\theta = 0$) of the dependences of Kc/R_θ on $\sin^2(\theta/2) + kc$ (K is the calibration constant, and k is a numerical constant).

The average hydrodynamic parameters of the particles R_H were determined by the quasi-elastic (dynamic) light scattering method [13]. The parameter ρ^* characterizing the nanostructure conformation [14–17] was determined from the experimental ratio of R_g and R_H for the PB–Se^0 adsorbate.

The optical section of the unit for measurements of the dynamic light scattering was equipped with an ALV-SP goniometer (Germany) and an He–Ne laser (λ 632.8 nm, 20 mW). The correlation function of the scattered light intensity was evaluated with a 288-channel Photo Cor-FC correlator (Anteks Joint-Stock Company, Russia). The experimental data were treated by the Tikhonov's methods of cumulants and normalization using appropriate software.

In reduction of SA with ascorbic acid, the first-order rate constant with respect to SA was 1.56×10^{-3} s^{-1}, and it increased to 2.1×10^{-3} s^{-1} in the presence of PB. Without PB, the resulting Se^0 nanoparticles were unstable and formed aggregates in 3–4 days, which then precipitated. In the presence of

the polymer stabilizer, the nano-a-Se^0 particles were aggregation-stable for at least 6 months.

The apparent viscosity of the PB solution remained constant for 1 day, comprising about 200 cPs, and then it sharply decreased to 30 cPs, which suggests that the total number of the particles in the solution decreased owing to the adsorption of macromolecules on the surface of selenium nanoparticles. As seen from the comparison of the intrinsic viscosity of the initial PB and PB–nano-a-Se^0 adsorbate, the estimated [η] value decreased from 55 to 12 dl g^{-1}. At the same time, M_w for the adsorbate determined from the data of the static light scattering was 100×10^6, i.e., it increased by a factor of 11 as compared to the free PB macromolecules.

The second virial coefficient A_2 for this system is very small (0.1×10^{-4} cm^3 mol g^{-1}); it shows that the thermodynamic state of solution is close to ideal.

In aqueous solutions, the average hydrodynamic radius R_H for free PO macromolecules is 540 nm, whereas for selenium nanoparticles prepared in the absence of polymeric stabilizer it comprises 170 nm. The size of the PB-Se^0 adsorbate, evaluated from the dynamic and static light scattering data, is considerably smaller [R_g (rms radius of inertia) 70 nm, R_H 70 nm]. In this case, $\rho^* = R_g/R_H = 1$, which suggests almost ideal spherical shape of the adsorbate formed [14–17].

To determine the radius of the core selenium nanoparticles in the adsorbate, the aqueous PB-Se^0 solution was lyophilically dried, and the dry product was pelletized and studied by small-angle X-ray diffraction analysis. It was found that the radius of the spherical Se^0 particle was about 15 nm, i.e., it was smaller by nearly an order of magnitude than that of the particles prepared without polymeric stabilizer. Thus, in aqueous solution the thickness of the polymeric coating on the Se^0 nanoparticles is about 55 nm, i.e., macromolecules are strongly compacted upon adsorption.

The data on the optical properties of PB suggest that in aqueous solutions it is an impermeable strongly asymmetric swollen ball with asymmetry $p > 2$ [18]. On passing from the PB–H_2O system to the PB–Se^0–H_2O system, the optical anisotropy decreased from 10 000 to 6000 cm^4 s^2 g^{-2}, which is probably due to the changes in the macromolecule conformation.

It should be noted that, in the entire concentration (c) range studied, the PB–H_2O and PB–Se^0–H_2O systems retain the molecular-dispersion state of solutions. This is confirmed by the $\Delta n = f(g)$ dependences: at $g < g_k$, for any c, these dependences are well approximated by straight lines passing through the origin.

In the $[n] \sim [n]_f$ approximation for the PB–Se^0–H_2O system, our calculations of the parameter p showed nonspherical conformation of the nanostructure; $p = 2.1$, which corresponds to the conformation of the Gaussian ball [11]. However, the absence of the concentration dependence of the reduced optical anisotropy in the PB–Se^0–H_2O system indicates that the parameter p tends to 1, i.e., the conformation tends to spherical [11]. Since, even in the case of such rigid macromolecule as DNA, the shape of macromolecule adsorbates on metal nanoparticles is close to spherical [19], the $[n] \sim [n]_f$ approximation for the PB–Se^0–H_2O system is inadequate. In this case, a major contribution to the observed optical anisotropy is made by the segmental optical anisotropy probably related to high hydrophobicity of the PB monomer unit [20], and specifically the hydrophobic interactions of nonpolar macromolecule fragments with nano-Se^0 are responsible for adsorption.

Assuming nearly spherical conformation of the nanostructure, its packing coefficient k can be described by the following equation [21]:

$$k = NM_w^* \Sigma_i \Delta V_i / v^* M_0, \quad (2)$$

where $\Sigma_i \Delta V_i = 253$ Å^3 [21] is the van der Waals volume of the monomeric unit, which is the sum of the van der Waals volume increments of the separate atoms in this unit; M_w^*, molecular weight of the particle; N, number of the adsorbed polymer macromolecules; M_0, molecular weight of the monomeric unit; and v^*, adsorbate volume $[4\pi/3(R^*)^3]$.

The R^* value is the rms radius of inertia or the average hydrodynamic radius of an adsorbate, which are equal under the experimental conditions studied.

The parameter k was 0.7, which is typical for globular proteins (k 0.6–0.8). Thus, the adsorbate can be described as a compact approximately spherical nanostructure.

Our data are of particular interest for deeper understanding of the biological and catalytic processes occurring in the nature with participation of nanoparticles of elements. We found that such nanoparticles are adsorption matrices for biological polymers and chemical reagents, which provides high local concentrations of these compounds and can strongly accelerate biochemical and catalytic processes.

CONCLUSIONS

(1) Spherical particles of amorphous selenium about 15 nm in size were obtained by reduction of selenium(IV) in the presence of the selenite–ascorbate redox system in aqueous solution of a cationic polyelectrolyte.

(2) Sharp decrease in the intrinsic and apparent viscosity of the resulting polymer–Se^0–water solution indicates that the thermodynamic properties of this system become close to ideal, which suggests formation of aggregation-stable macromolecule adsorbates on selenium nanoparticles.

(3) As shown by the molecular hydrodynamics and optical data, the resulting adsorbate can be described as a supermacromolecular close-packed ($k \approx 0.7$) spherical nanostructure of nearly 70 nm size, containing about 11 macromolecules whose hydrodynamic radius in the free state would be 540 nm.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Polypyrrole Nanoparticles by Dispersion Polymerization

A. Yu. Men'shikova, B. M. Shabsel's, and T. G. Evseeva

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received December 24, 2002; in final form, January 2003

Abstract—The influence of pyrrole, oxidant ($FeCl_3$), and polymeric stabilizer (polyvinyl alcohol) concentrations and of temperature on the rate of redox dispersion polymerization of pyrrole, diameter of the forming particles, and their size distribution was studied with the aim to prepare polypyrrole nanoparticles.

Development of methods for controlling the size and surface properties of polypyrrole (PP) nanoparticles in the course of their synthesis by redox dispersion polymerization is an urgent problem, since PP shows promise as a conducting polymer. However, its mechanical strength and adhesion to other materials are poor, and it is virtually insoluble in common organic solvents, which complicates its processing. Therefore, it was suggested to prepare colloidal dispersions of PP nanoparticles and then to use them in formation of composite materials [1–6]. Conjugates of PP particles with biospecific ligands can be used for development of biosensors with an electric response on variation of the concentrations of biologically active substances [7]. The black color of PP particles also allows their use instead of colloidal gold as markers of linked bioligands for imaging of immunochemical reactions [7, 8].

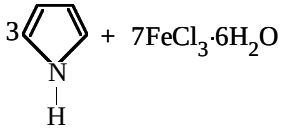
Polypyrrole dispersions can be prepared by pyrrole polymerization effected by an oxidant in the presence of soluble polymers which are adsorbed on precipitating PP particles and stabilize them, preventing further aggregation [1–5]. The nature of the polymeric stabilizer, its molecular weight, and concentration in the reaction mixture can appreciably affect both the size of the forming PP nanoparticles and the stability of PP dispersions in the course of their synthesis and subsequent storage. In preparation of composites, the polymeric stabilizer coating the PP nanoparticles can also take part in formation of interface structures, affecting thus the adhesion, interfacial electrical conductivity, and characteristics of the composite materials obtained.

The size of PP particles determines the structure of the composites and the thickness of interface layers. Therefore, the control of the size and size distribution of PP particles in the course of their preparation is an urgent problem. With the aim to solve this problem and to prepare aqueous PP dispersions differing in the particle size and concentration of the polymeric stabilizer in them, we examined the influence exerted by the concentrations of pyrrole, oxidant ($FeCl_3$), and polymeric stabilizer (polyvinyl alcohol, PVAl) and by the reaction temperature on the kinetics of redox dispersion polymerization of pyrrole and on the diameter and size distribution of the forming PP particles.

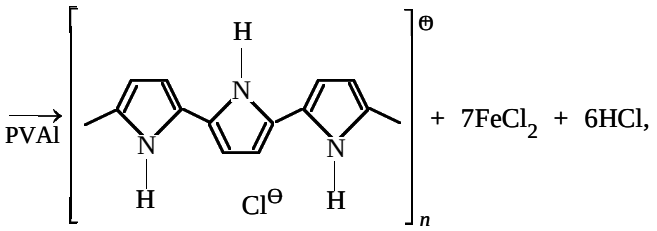
EXPERIMENTAL

Pyrrole and DMF were purified by vacuum distillation. As a dispersion medium we used double-distilled water. $FeCl_3$, $NaHSO_3$, and standard HCl solution (analytically pure grade) were used without additional purification. As a polymeric stabilizer we used two PVAl samples (Plastpolimer Research and Production Association, St. Petersburg) containing 11 [PVAl(I)] and 10 [PVAl(II)] mol % residual acetate groups. The batch of PVAl(I), 5/9 grade, was produced according to GOST (State Standard) 10779–81, and PVS(II), 13/16 grade, was a pilot batch. The viscosity-average molecular weight M of PVAl(I) and PVAl(II), calculated by the Mark–Kuhn–Houwink equation with the parameters $K = 2.0 \times 10^{-4}$ and $\alpha = 0.76$ [9] from the intrinsic viscosity in water at 25°C, was 1.7×10^4 and 5.0×10^4, respectively.

The compositions of the reaction mixtures in redox dispersion polymerization of pyrrole,



1070-4272/03/7605-0822$25.00



are listed in the table. The concentration of PVAl aqueous solutions was varied within 0.3–1.6 wt %. The oxidant ($FeCl_3$) concentration was calculated from the stoichiometric ratio $FeCl_3$: pyrrole = 7 : 3 for the monomer concentration in the aqueous phase of 1.0–2.7 wt %. In run nos. 1 and 2 it was 0.65; in run nos. 3 and 8–10, 0.32; and in run no. 6, 0.85 M.

Polymerization was performed both at room temperature (296 K) and at 277 K in a refrigerator. The diameters of PP particles were determined by electron microscopy (JEM 100 S electron microscope, JEOL, Japan).

The degree of pyrrole conversion in samples withdrawn in the course of the synthesis was determined by gas chromatography with *n*-amyl alcohol as internal reference. Polymerization was stopped by adding the sample into a solution containing 0.5 M $NaHSO_3$ and 0.1 M HCl. The conversion was determined with 5% accuracy.

In the course of polymerization, the initially transparent solution transformed into an intensely colored black PP dispersion; therefore, we could monitor how its optical density varies in the course of the synthesis. The electronic absorption spectrum of the PP dispersion in the visible and near-IR range (SF-26 spectrophotometer) is shown in Fig. 1. The PP dispersions prepared to determine the degree of pyrrole conversion chromatographically (25 μl) were diluted with water to 3 ml, and the light absorption at 1000 nm was measured (Fig. 1).

To study the seed polymerization of pyrrole in acid solution on Fe_3O_4 particles according to [10], we prepared a magnetic fluid by the reaction

$$FeCl_2 \cdot 4H_2O + 2FeCl_3 \cdot 6H_2O + 8NH_4OH = Fe_3O_4\downarrow + 8NH_4Cl + 20H_2O.$$

As a polymeric stabilizer of Fe_3O_4 particles we used PVAl(II) of 5 wt % concentration. In the magnetic fluid obtained, the Fe_3O_4 concentration was also 5 wt %, and the prevailing particle diameter, about 10 nm (Fig. 2f). However, coarser particles of irregular (not spherical) shape are also seen in the electron micrographs. This is due to aggregation of magnetic Fe_3O_4 particles.

Influence of the reaction mixture composition and temperature in redox dispersion polymerization of pyrrole on the diameter *d* of the forming PP nanoparticles

Run no.	PVAl* (wt %)	Pyrrole (wt %)	*T*, K	*d*, nm
1	0.6	2.0	296	Coagulation
2	0.6	2.0	296	80
3	0.9	1.0	296	60–100
4	0.8	2.7	277	60–100
5	0.3	1.0	277	90
6	0.5	1.0	277	90
7	0.8	1.0	277	70
8	1.6	1.0	277	70
9	0.8	1.0	296	60
10	1.6	1.0	296	50–70
11	0.7	1.4	296	30–50
12	0.7	1.4	296	20–40

* Run no. 1 was performed with PVAl(I), and the other runs, with PVAl(II).

The seed polymerization of pyrrole on Fe_3O_4 particles stabilized with PVAl is initiated by back dissolution of the magnetite particles in an acid medium

$$Fe_3O_4 + 8HCl = 2FeCl_3 + FeCl_2 + 4H_2O$$

and by oxidation of pyrrole with the forming Fe(III). The HCl concentration was 0.28 M, and content of Fe_3O_4 particles, 0.70 wt %; in the case of complete oxidation and dissolution of Fe_3O_4 particles, this corresponds to the Fe(III) concentration of 0.057 M. To localize the pyrrole oxidation on the surface of Fe_3O_4 particles, the monomer was added in a concentration of 0.21 M, which corresponds to its 16-fold excess

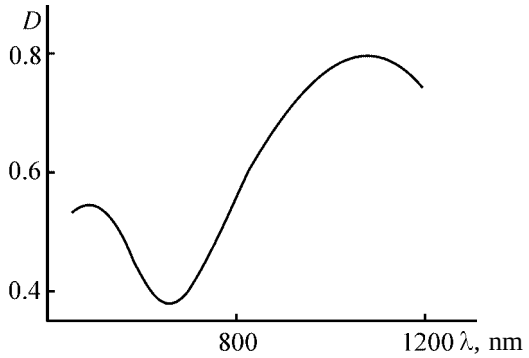


Fig. 1. Electronic absorption spectrum of PP dispersion: (*D*) optical density and (λ) wavelength.

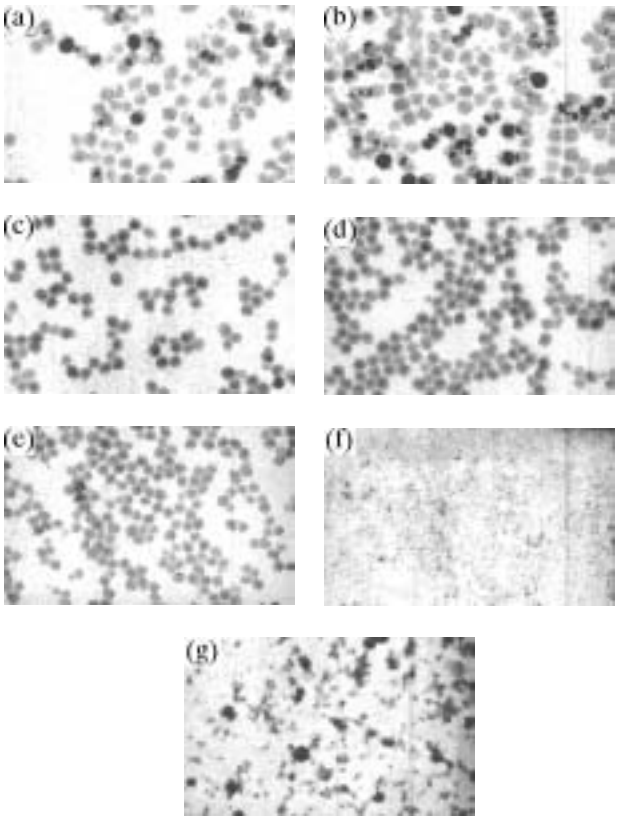

Fig. 2. Electron micrographs of PP particles prepared at PVAl(II) concentration of (a) 0.3, (b) 0.5, (c) 0.8, and (d) 1.6 wt %, and those of (f) magnetic fluid and (g) PP dispersion prepared with this fluid under argon. Polymerization temperature, K: (a–d) 277 and (e, g) 296. Magnification ×50 000.

over the oxidant, Fe(III). In run nos. 11 and 12, the reaction mixture composition was the same (see table), but run no. 12 was performed in an argon atmosphere to restrict oxidation of Fe(II) to Fe(III) with atmospheric oxygen in the bulk of the aqueous phase.

The influence of the redox dispersion polymerization of pyrrole in aqueous PVAl solutions on the size of the forming PP nanoparticles is illustrated by the table and Fig. 2. It is seen that the capability of PVAl to stabilize aqueous PP dispersion largely depends on the PVAl molecular weight. With PVAl(I), we have not obtained a stable PP dispersion; it coagulated in the course of the synthesis (run no. 1). On the contrary, PVAl(II) at the same concentration efficiently stabilized the PP dispersion. The dispersions obtained were characterized by a narrow particle-size distribution, and in some cases they could be regarded as monodisperse. This difference is presumably due to the higher molecular weight of PVAl(II). Owing to the high content of acetate groups, the PVAl(II) chain is diphilic, and the polymer, being surface-active, is efficient as a steric stabilizer.

We found that, at room temperature (296 K), the redox polymerization of pyrrole occurs at a high rate at its content in the aqueous phase of 1.0–2.7 wt %. However, as the pyrrole concentration is increased, the forming PP particles become coarser, with broadening of the particle-size distribution (see table, run nos. 9, 2, 4). Particles of irregular (nonspherical) shape were detected (run no. 4). This is due to increase in the $FeCl_3$ concentration (in stoichiometric proportion with the pyrrole concentration) and decrease in the surface charge of particles with increasing ionic strength, which results in certain destabilization of the dispersion [11]. Therefore, further experiments were performed at a pyrrole concentration in the aqueous phase of 1.0 wt %.

We examined how the reaction temperature affects the polymerization kinetics and particle-size distribution of PP. The polymerization time increased by a factor of 3–5 in going from 296 to 277 K (Fig. 3a). The mean diameters of the forming nanoparticles are similar at both temperatures, but in the samples prepared at room temperature the particle-size distribution is somewhat broader (see table). The increase in the PVAl concentration resulted in faster polymerizatiuon (Fig. 3a) and formation of finer PP particles (see table; Figs. 2a–2d). This may be due to strengthening of the structural-mechanical barrier formed by the water-soluble polymer at the particle surface, and also to an increase in the viscosity of the aqueous phase, preventing aggregation of PP particles in the stage of seeding. Thus, redox polymerization of pyrrole in aqueous PVAl solutions allows preparation of PP dispersions with the particle size ranging from 50 to 100 nm and narrow particle-size distribution.

Monitoring of the optical density of reaction mixtures in the course of pyrrole polymerization showed that the dependences obtained (Fig. 3b) run in parallel with the conversion curves (Fig. 3a). To evaluate the extent of correlation of the optical density and conversion, we calculated the degrees of conversion of pyrrole into PP as the ratios of the optical density of the reaction mixture at the instant of sampling in the course of the synthesis to the optical density of the ready PP dispersion. The degrees of conversion evaluated spectrophotometrically and determined chromatographically are compared in Fig. 4. The correlation coefficients of these quantities as functions of the time from the start of polymerization at PVAl concentration of 0.8 and 1.6 wt % are 0.93 at 296 K and 0.86 and 0.98, respectively, at 277 K. The satisfactory cor-

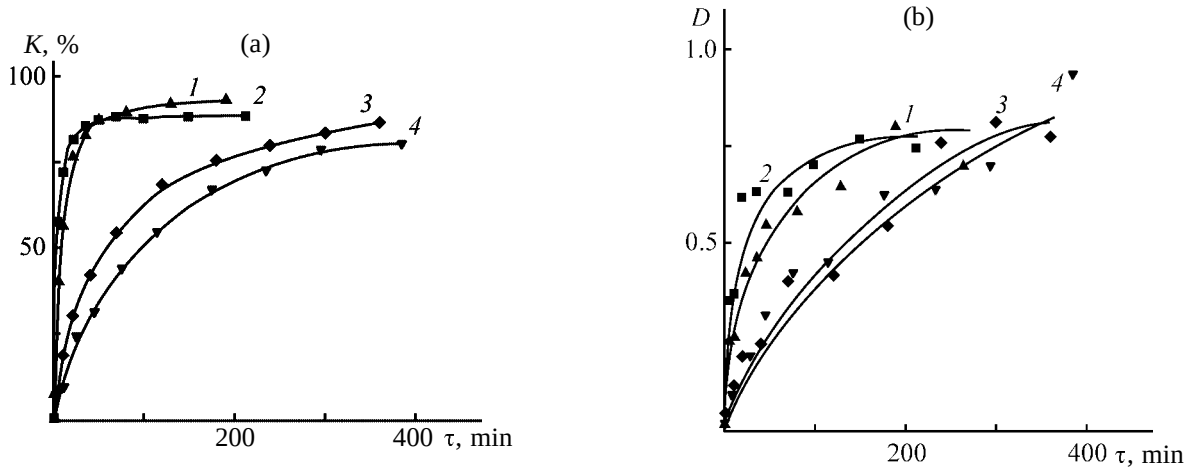

Fig. 3. (a) Degree of pyrrole conversion *K* determined by gas chromatography and (b) optical density *D* of the reaction mixture as functions of time τ from the start of polymerization at (*1*, *2*) 296 and (*3*, *4*) 277 K. relation between the optical density of the reaction mixture and degree of polymerization of the monomer determined chromatographically allows spectrophotometric evaluation of the PP conversion in the course of dispersion polymerization, which is a simpler procedure than gas chromatography.

A promising procedure for preparing composite particles is polymerization of various monomers, in particular, pyrrole in the presence of dispersions of metal oxides, silica gel, or polymeric microspheres having a narrow particle-size distribution [8, 12, 13]. Usually the size of seed particles varies in the submicrometer or micrometer range and considerably exceeds the thickness of the polymer layer formed on the particle surface. Here we used this approach for decreasing the size of the PP particles formed. As seeds we used nanoparticles of Fe_3O_4 magnetic fluid 10 nm in diameter, stabilized by PVAl (Fig. 2f). In the presence of HCl, these particles slowly dissolve to form $FeCl_3$. In this case, the redox polymerization of pyrrole occurs under the action of Fe(III) formed *in situ*. In the process, the reaction mixture changes the color from orange-yellow to black, which also allows spectrophotometric evaluation of the pyrrole conversion into PP.

It should be noted that the rate of seed polymerization of pyrrole may be limited by diffusion, because the Fe^{3+} ions and pyrrole molecules should diffuse toward each other through a PP layer arising on the surface of the growing particles. Under these conditions, the pyrrole polymerization proceeded until Fe_3O_4 nanoparticles dissolved completely, as indicated by the fact that the formed PP particles had no magnetic properties, and also by a considerable increase in their size as compared to the Fe_3O_4 seed nanoparticles.

Thus, seed redox polymerization of pyrrole on Fe_3O_4 nanoparticles in acid solutions allowed preparation of PP particles with the minimal size as small as 30 nm (run no. 11). However, at room temperature,

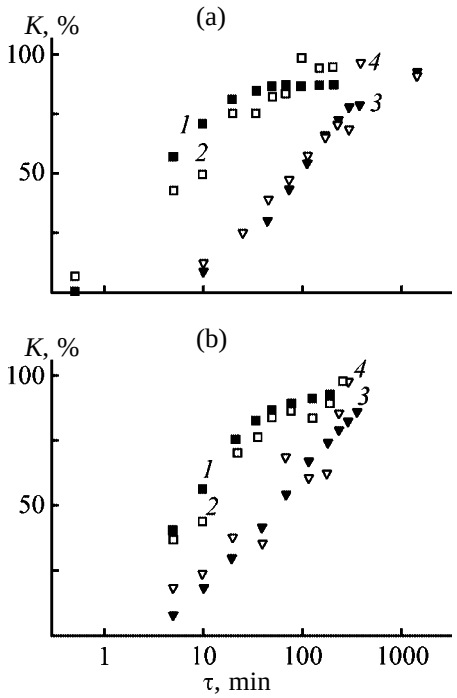

Fig. 4. Comparison of the degrees of pyrrole conversion *K* at (*1*, *2*) 296 and (*3*, *4*) 277 K, determined (*1*, *3*) by gas chromatography and (*2*, *4*) spectrophotometrically, as functions of the time τ from the start of polymerization. PVAl(II) concentration, wt %: (a) 0.8 and (b) 1.6.

coarser PP particles were also obtained. This may be due to too fast dissolution of Fe_3O_4 and diffusion of the Fe^{3+} ions to the bulk of the aqueous phase, where pyrrole could also polymerize. To prevent oxidation of the monomer with atmospheric oxygen, the reaction mixture was purged with argon before adding pyrrole (run no. 12). In this case, the diameter of the major fraction of the formed PP nanoparticles was decreased to 20–30 nm (see table), which may be due to more compact packing of the PP chains. However, the electron micrograph of this dispersion revealed also the presence of coarser particles of nonspherical shape (Fig. 2g). Apparnetly, these particles originate from pyrrole polymerization on aggregates of Fe_3O_4 particles present in the magnetic fluid. The impurity of these coarse particles can be separated from 20–30-nm PP nanoparticles by ultrafiltration.

CONCLUSIONS

(1) The main features of redox polymerization of pyrrole in aqueous solutions of polyvinyl alcohol were determined, and the conditions were found for preparing monodiserse polypyrrole particles 60–90 nm in diameter. A spectrophotometric method was suggested for evaluating the conversion of pyrrole into polypyrrole in the dispersions.

(2) Seed dispersion redox polymerization of pyrrole on Fe_3O_4 nanoparticles allows preparation of polypyrrole particles with the diameter as small as 20 nm.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermal Oxidation of Polyethylene Films Containing Dispersed Copper and Amine Antioxidant

D. G. Lin and E. V. Vorob'eva

Skorina Gomel State University, Gomel, Belarus

Received January 29, 2003

Abstract—Thermal oxidation of polyethylene filled with dispersed copper and containing an amine antioxidant was studied. The concentration ranges in which the catalytic effect of the metal on the polymer oxidation or the stabilizing effect of the antioxidant prevails were determined. Under certain conditions, dispersed copper enhances the stabilizing effect of the antioxidant.

It was found previously [1–3] that an amine oxidant (AO) Neozon D inhibits oxidation of polyethylene (PE) more efficiently when the polymer is in contact with metallic copper. For example, the induction period of oxidation (IPO) of PE films inhibited with Neozon D is longer when the films are in contact with a copper support, as compared to the films that are in contact with inert (e.g., glass) supports. This result is quite unexpected, since the copper support catalyzes oxidation of noninhibited PE [4–6] and accelerates the consumption of phenolic AOs acting by a similar mechanism, thus shortening the IPO [7]. Enhancement of the inhibiting activity of amine AO is observed not only in oxidation of PE films on copper supports [4, 7] but also in oxidation of PE films filled with dispersed copper [8]. This effect was attributed to a reaction of Neozon D with copper, yielding a more effective AO [1–3].

At the same time, the mechanism responsible for enhancement of the inhibiting power of the amine AO under conditions of contact of PE with copper is poorly understood. In particular, the relationship between the catalytic effect of copper on oxidation of PE and enhancement of the performance of Neozon D is unclear. These factors, apparently, affect IPO in opposite directions.

In this work, with copper-filled PE as example, we studied how the concentrations of the dispersed metal and Neozon D influence the inhibiting effect.

EXPERIMENTAL

Experiments were performed with powdered nonstabilized high-density PE prepared at low pressure on complex organometallic catalysts [GOST (State Standard) 16338–85, base grade 20306-005]. Copper powder (M1 grade) and Neozon D (β-phenylnaphthylamine, GOST 39–79) were introduced by mechanical blending. From blends of the polymer with the additives, we prepared by hot pressing (150°C, 30–90 s) films 30–200 μm thick, which were subsequently oxidized on KBr supports. In some cases, M1 copper foil was used as support. Oxidation was performed in air in ovens at 150°C.

The extent of oxidation was estimated from the IR transmission spectra. If oxidation was performed on a copper support, the film was separated from the support; with KBr supports, transparent in the IR range, this was unnecessary. The IR spectra were recorded on a Specord 75-IR spectrophotometer. The extent of PE oxidation was evaluated from the optical density of the carbonyl absorption band at 1720 cm^{-1}, using the band at 1460 cm^{-1} as internal reference. The IPO duration was determined from the kinetic curves of accumulation of carbonyl groups; the moment at which the extinction parameter (ratio of the optical density to the film thickness) reached 3–4 cm^{-1} was taken as the end of IPO.

When studying samples of inhibited and unfilled PE films oxidized on a copper support, we determined, along with the extent of PE oxidation, also the content of the transferred metal in the bulk of the polymer. Using ac voltammetry, we measured the metal concentration in solutions prepared from the ash residues of the polymer samples, with the subsequent recalculation to the metal content in the polymer. The procedure is described in more detail in [9].

Figure 1a shows data on oxidation of inhibited PE

1070-4272/03/7605-0827$25.00

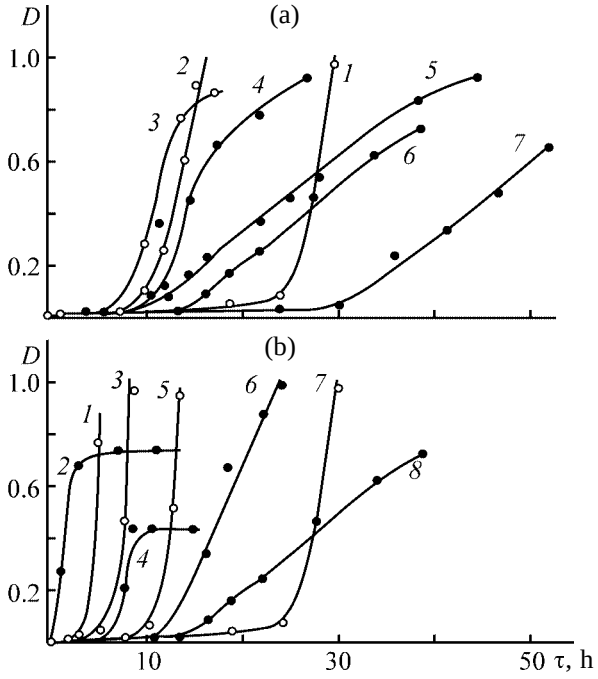

Fig. 1. Variation with oxidation time τ of the optical density D of the 1720 cm^{-1} band in the IR spectra of PE films containing various amounts of (a) copper filler and (b) AO. Film thickness 100 μm, oxidation temperature 150°C; the same for Fig. 2. (a) AO concentration 0.5 wt %; Cu concentration, wt %: (*1*) 0, (*2*) 1, (*3*) 3, (*4*) 5, (*5*) 7, (*6*) 10, and (*7*) 20. (b) Cu concentration 10 wt %; AO concentration, wt %: (*1*, *2*) 0, (*3*, *4*) 0.1, (*5*, *6*) 0.3, and (*7*, *8*) 0.5; polyethylene: (*1*, *3*, *5*, *7*) unfilled and (*2*, *4*, *6*, *8*) filled.

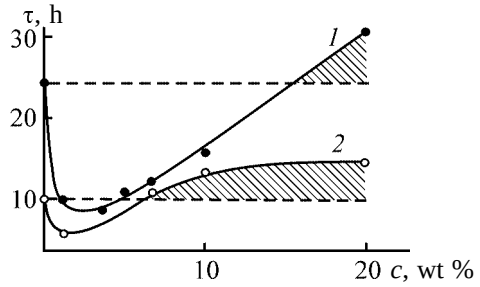

Fig. 2. Duration τ of IPO of PE films as a function of concentration c of dispersed copper in the polymer. AO concentration in the polymer, wt %: (*1*) 0.5 and (*2*) 0.3.

films (AO concentration 0.5 wt %) containing various amounts of the copper filler. As judged from IPO, at a filler concentration of up to 10 wt % the polymer oxidation is accelerated (Fig. 1a, curves *1*–*6*), and only at a higher copper content (e.g., 20 wt %) the inhibiting power of the amine AO is enhanced: IPO of the filled PE becomes longer than that of the unfilled polymer (Fig. 1a, curves *1*, *7*).

Data in Fig. 1a can be summarized by plotting the IPO duration vs. copper concentration in the polymer at an AO concentration of 0.5 wt % (Fig. 2, curve *1*). This dependence has a minimu at a filler concentration of about 3 wt %. As noted above, IPO is determined by two competing processes: catalysis of the polymer oxidation with copper and transformation of amine AO into a more effective product, also under the action of copper. Both these processes occur in the polymer layer adjacent to the filler particle surface. Apparently, at the Cu concentration from 0 to 3 wt %, the catalysis prevails (IPO decreases), whereas at higher Cu concentrations the transformation of AO becomes the major factor (IPO increases). At a Cu concentration exceeding 16 wt %, the IPO of the filled PE exceeds that of the unfilled PE, i.e., introduction of copper powder into inhibited PE enhances rather than lowers the oxidation resistance of the polymer. This range of the filler concentration is cross-hatched in Fig. 2 (curve *1*). As the copper concentration is increased above 16 wt %, the inhibiting effect becomes stronger.

It should be noted that the IPO duration measured in the experiment is an arbitrary characteristic of the oxidation resistance of the polymer. Actually we determine the time in which a certain small (comparable with the measurement sensitivity) amount of oxidation products is accumulated in PE under the experimental conditions (the extinction parameter of the 1720 cm^{-1} band reaches 3–4 cm^{-1}). By the end of this time, certain oxidative transformations have already occurred in the polymer, and therefore IPO, more precisely, characterizes the rate of these transformations. In other words, if IPO is longer, accumulation of the oxidation products in this step is slower. These reasonings are confirmed by the experimental results. For example, as the copper concentration in the polymer is increased from 3 to 20 wt %, the IPO duration increases (Fig. 2, curve *1*), and the oxidation rate evaluated from the kinetic curves of accumulation of carbonyl groups (Fig. 1a, curves *3*–*7*), on the contrary, decreases. Correspondingly, in the range of filler concentrations from 1 to 3 wt %, as IPO becomes shorter, the polymer oxidation accelerates.

Figure 1b shows how the AO concentration affects the PE oxidation at a constant concentration of the Cu filler (10 wt %). As seen, the effect of Cu becomes weaker with increasing AO concentration. For example, at an AO content of 0.3 wt %, addition of Cu increases the IPO from 8 to 11 h (Fig. 1b, curves *5*, *6*). On the contrary, addition of the same amount of Cu to PE containing 0.5 wt % AO shortens the IPO from 24 to 13 h, i.e., the filler apparently behaves as a catalyst (Fig. 1b, curves *7*, *8*). However, in any case an

increase in the AO concentration in PE filled with the same amount of Cu makes IPO longer, which is primarily due to slower accumulation of carbonyl groups in the initial step of the polymer oxidation (Fig. 1, curves *4*, *6*, *8*).

The effect of AO on oxidation of unfilled PE can be evaluated most accurately by comparing the plots of IPO duration vs. Cu filler concentration for different AO concentrations (Fig. 2, curves *1*, *2*). As the AO concentration is decreased from 0.5 to 0.3 wt %, the Cu concentrations corresponding to the minimum of the plot and to the point in which the IPO duration coincides with that for the unfilled polymer decrease.

Shortening of IPO on introducing dispersed copper (oxidation catalyst) into inhibited PE (Fig. 2, descending portions of curves *1*, *2*) is quite expected. It is known [10] that, as the concentration of the Cu filler in uninhibited PE is increased, IPO becomes shorter and the polymer oxidation accelerates. However, we found that in some cases filling of inhibited PE with copper makes IPO longer rather than shorter (Fig. 2, ascending portions of curves *1*, *2*). Such a trend may be due to more active reaction of Neozon D with the filler, yielding a more effective AO, at higher filler concentrations.

To check this assumption, we performed additional experiments. Inhibited PE films of various thicknesses were oxidized on copper supports, which in this case modeled the surface of the filler particles. Therefore, decreased film thickness was equivalent to decreased distance between the filler particles, i.e., to increased concentration of the filler in the polymer.

In the course of the experiment, we obtained the kinetic curves of accumulation of carbonyl groups in polymer films of various thickness. In parallel, we performed studies in which PE films were oxidized on an inert support (KBr plates) [10]. Figure 3 shows that the dependences of the IPO duration on the film thickness are opposite for the Cu and KBr supports (curves *1*, *2*). For PE films oxidized on a KBr support, IPO becomes longer with increasing film thickness, and with a Cu support it becomes shorter. Apparently, extension of the IPO with increasing concentration of Cu powder (Fig. 2, curve *1*) and with decreasing thickness of unfilled PE film oxidized on a Cu support (Fig. 3, curve *2*) are due to the same factor: increase in the specific area of the metal–polymer contact surface (ratio of the contact surface area to the polymer weight). Assuming that the copper particles used in the experiment (particle size about 6 μm) have a spherical shape, the presence of 5 to 33 wt % filler in a 100-μm-thick film will be equivalent, from the viewpoint of the contact surface area, to contact of a copper support with an unfilled PE film of the thickness from 200 to 30 μm, respectively.

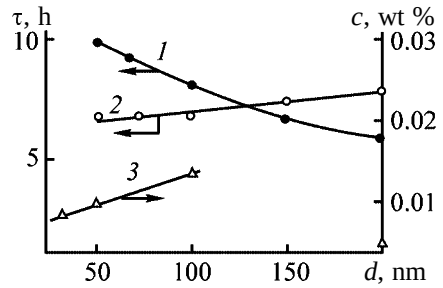

Fig. 3. IPO duration τ for unfilled PE films as a function of their thickness *d*. Support: (*1*) Cu and (*2*) KBr. AO concentration in the polymer 0.1 wt %, oxidation temperature 150°C. (*c*) Cu concentration. (*3*) Accumulation of Cu in PE films oxidized on Cu supports by the end of IPO.

It is known [4, 6] that the catalysis of PE oxidation in contact with Cu is due to transfer into the polymer of catalytically active Cu-containing compounds, products of contact reactions. Since the measured IPO duration is an arbitrary characteristic (in this step slow polymer oxidation already occurs), it was interesting to find whether variation of IPO duration for thin films is related to the rate of transfer of copper compounds. For this purpose, we studied how the thickness of a PE film correlates with the amount of copper compounds accumulated by the end of IPO. The results are shown in Fig. 3, curve *3*. It is seen that, as the film thickness is increased from 30 to 100 μm, the concentration of Cu transferred into the polymer grows. Apparently, in thin films Neozon D transforms into a more effective AO faster. As a result, the rate of oxidative transformations in the adhesion contact zone decreases, which results in decelerated transfer of copper compounds into the bulk of the polymer and in extension of the IPO.

CONCLUSION

Extension of the induction period of oxidation on introducing an oxidation catalyst, dispersed copper, into inhibited polyethylene is due to a decrease in the thickness of the polymer layer between the filler particles. As the layer of the polymer oxidized on a copper support surface is made thinner, transformation of Neozon D into a more effective antioxidant accelerates, which results in slower transfer of copper-containing compounds into the bulk of the polymer and in longer induction period of oxidation.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Micromethod of Estimating the Reactivity of Cellulose to Acetylation

R. Z. Pen, P. V. Mironov, and O. A. Kolmakova

Siberian State Technological University, Krasnoyarsk, Russia

Received October 23, 2002; in final form, March 2003

Abstract—A micromethod was developed for estimating the reactivity of cellulose to acetylation by monitoring temperature variation in the process.

Since acetylation of cellulose with acetic anhydride is an exothermic process, a series of methods for determining the acetylation rate and estimating the cellulose reactivity are based on temperature measurements, with the reaction being carried out under adiabatic conditions [1]. According to generally accepted analysis methods, cellulose acetylation is carried out by the homogeneous procedure in a Dewar vessel. For analysis, 10 g of air-dry cellulose and 239 ml of acetylating mixture are taken [2]. In the reaction of cellulose with the acetylating mixture, the temperature of the reaction mixture increases from 20°C to 36°C.

To carry out of the process in a calorimeter, 3.5 g of cellulose and 365 ml of the acetylating mixture are taken. Cellulose placed in the calorimeter shaft is ejected into the acetylating mixture. In the process, the temperature of the reaction mixture increases by 10–15°C [3].

Among the most significant drawbacks of this procedure are considerable increase in the temperature of the reaction mixture, which distorts the kinetic parameters of the process. In addition, relatively large amounts of cellulose required for measurements are inconvenient for laboratory studies.

Here we studied the possibility for estimating the rate of cellulose acetylation using a non-adiabatic microcalorimeter under the conditions close to isothermal.

EXPERIMENTAL

The measuring system consists of two batteries of thermocouples connected by the differential scheme and attached to an emf amplifier, which allows recording of the temperature difference in the cells of microcalorimetric blocks. The signal from the emf amplifier is recorded on a diagram tape in the form of the plot time τ (s)–temperature difference ΔT (°C). The nominal sensitivity of the device (from the diagram) was 7.5×10^{-5} W mm^{-1}.

Cellulose was activated before acetylation. For this purpose, 0.5 g of pulverized air-dry cellulose was uniformly moistened in 0.5 cm^3 of glacial acetic acid in a 15 cm^3 bottle and placed in a thermostat at 80°C for 1 h, after which it was kept at room temperature for 2 h.

The acetylating mixture was prepared by mixing acetic anhydride, acetic acid, and concentrated sulfuric acid in the volume ratio of 50 : 100 : 1, respectively. A 2 cm^3 portion of this mixture was placed into the reaction vessel of the measurement cell of the device. Activated cellulose (5–10 mg) was attached to the end of the sample holder with a very thin wire and placed into the acetylating mixture. The instant of immersion was considered as the reaction start (τ = 0).

A typical diagram of temperature variation in the reaction mixture is shown in Fig. 1. The ascending

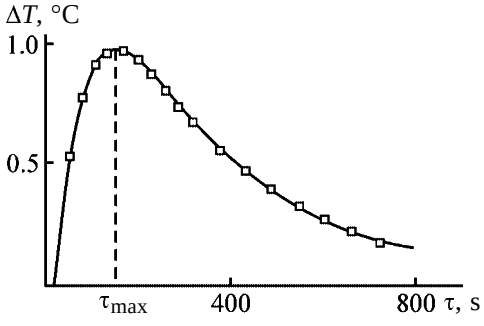

Fig. 1. Variation of temperature of the reaction mixture ΔT in time τ. The points were transferred from the recorder, and the solid line is calculated by Eq. (12).

1070-4272/03/7605-0831$25.00

branch of the curve reflects increase in the temperature due to the heat released in exothermic reactions, and the descending branch, decrease in the temperature due to heat diffusion.

Acetylation of cellulose (C) with formation of cellulose acetate (CA) can be described by the scheme

$$C + (CH_3CO)_2O \rightarrow CA + CH_3COOH + Q, \quad (1)$$

where Q is the total heat effect of cellulose acetylation and reaction of acetic anhydride with water.

Since acetic aldehyde is in a large excess, we can assume zero partial kinetic order of reaction (1) with respect to this reactant and the first order with respect to cellulose. Then, the equation for the reaction rate can be written in the form

$$d[CA]/d\tau = k_1([C]_0 - [CA]), \quad (2)$$

where $[C]_0$ is the cellulose concentration (weight fraction) in the reaction mixture in the beginning of the reaction (at $\tau = 0$), [CA] is the current concentration of cellulose acetate, and k_1 is the reaction rate constant (s^{-1}).

The solution of Eq. (2) is known:

$$[CA] = [C]_0[1 - \exp(-k_1\tau)]. \quad (3)$$

The amount of the released heat Q is in direct proportion to the amount of the formed cellulose acetate, i.e., the following relationship is valid:

$$Q = a[1 - \exp(-k_1\tau)], \quad (4)$$

where a is a coefficient taking into account the amount of the reaction mixture and the thermal effect of the reaction.

When considering the weight m and heat capacity C of the reaction mixture as constants, we can pass from Eq. (4) to the equation for increase in temperature ΔT due to the heat released in the reaction, in which coefficient A_1 includes, along with a, also m and C values.

$$\Delta T_1 = A_1[1 - \exp(-k_1\tau)]. \quad (5)$$

If the temperature of the device and surrounding before the reaction was T_0, the temperature in the measuring cell should increase to T_1 owing to the heat released in the reaction:

$$T_1 = T_0 + \Delta T_1. \quad (6)$$

The rate of cooling of the reaction mixture is in direct proportion to the difference in temperature between the measuring cell and the surrounding [4]:

$$\frac{d}{d\tau}(\Delta T_2) = -k_2(T_1 - \Delta T_2 - T_0), \quad (7)$$

where ΔT_2 is decrease in temperature in the measuring cell due to heat emission, and k_2 is a coefficient.

After substitution of expressions (5) and (6) in relationship (7), we obtain

$$\frac{d}{d\tau}(\Delta T_2) = -k_2\{T_0 + A_1[1 - \exp(-k_1\tau)] - \Delta T_2 - T_0\}$$

$$= k_2\Delta T_2 - k_2A_1[1 - \exp(k_1\tau)]. \quad (8)$$

The equation similar to Eq. (8) describes the rate of variation of the final product concentration in two successive first-order reactions. The solution of Eq. (8) is [5]

$$\Delta T_2 = A_1[1 + k_1(k_2 - k_1)^{-1}\exp(-k_2\tau) - k_2(k_2 - k_1)^{-1}\exp(-k_1\tau)]. \quad (9)$$

Subtracting Eq. (9) from Eq. (5), we obtain

$$\Delta T = \Delta T_1 - \Delta T_2 = A_1k_1(k_2 - k_1)^{-1}[\exp(-k_1\tau) - \exp(-k_2\tau)]. \quad (10)$$

The device records the dependence

$$y = f(\tau), \quad (11)$$

where y is the deviation of the recorder pen, proportional to ΔT.

According to Eq. (10), this dependence can be approximated by the equation

$$\hat{y} = Ak_1(k_2 - k_1)^{-1}[\exp(-k_1\tau) - \exp(-k_2\tau)], \quad (12)$$

where A is a compensating factor proportional to the initial amount of cellulose in the measuring cell.

Dependence (12) has a maximum at time τ_{max} (Fig. 1) determined from the condition

$$(dy/d\tau)_{\tau=\tau_{max}} = 0, \quad (13)$$

from which we obtain

$$\tau_{max} = (k_2 - k_1)^{-1}\ln(k_2/k_1). \quad (14)$$

Average	0.91	0.0122	0.00266	0.992	0.00614
Variance	0.14	1.59×10^{-5}	2.92×10^{-7}	–	1.38×10^{-6}

The best least-squares estimates for A, k_1, and k_2 are determined from the condition of minimization of the functional

$$\Psi = \Sigma(y - \hat{y})^2 \rightarrow \min. \quad (15)$$

The minimum of Ψ was found by the Marquardt method (StatGraphics Plus 5.0 package, Nonlinear Regression software, Marquardt method). The quality of approximation was characterized by the coefficient of determination (the square of estimated coefficient of Spirman multiple correlation R^2):

$$R^2 = 1 - \Sigma(y - \hat{y})^2/\Sigma(y - \bar{y})^2. \quad (16)$$

The results of analysis of ten different samples of unbleached pulp, significantly different in the yield from wood and degree of delignification, are given in Table 1. High coefficients of determination (close to 1) show that Eq. (12) satisfactorily approximates experimental curves.

For comparison, a sample of prehydrolyzed cellulose of cold elevation [GOST (State Standard) 21 101–83] was acetylated by the procedure described in [3] and by the proposed procedure. The reactivity of cellulose was characterized by the rate constant of acetylation with the correction for the reaction temperature [3]. The results of comparison are as follows: by the existing procedure, $k_1 = 0.0108\ s^{-1}$ and by the proposed procedure, $k_1 = 0.0103\ s^{-1}$.

In the physical sense, the coefficient k_2 is equivalent (within a constant factor) to the coefficient of heat transfer from the reaction mixture, i.e., under conditions of the specific analysis it can be considered as a device constant. The results of evaluation of the parameters of Eq. (12) with the average $k_2 = 0.00266$ confirm the validity of this assumption. In this case, Eq. (14) unambiguously relates k_1 to τ_{max} (Fig. 2).

Hence, the reactivity of cellulose to acetylation can be characterized by the τ_{max} value, determined directly from the process diagram (Fig. 1). For comparison of the cellulose samples with respect to this characteristic, it is more convient to use the reciprocal value $1/\tau_{max}$, since its dimension (s^{-1}) coincides with the dimension of the reaction rate constant k_1.

It should be noted that τ_{max} is independent of the amount of cellulose (it is not nexessary to weigh activated cellulose introduced into the measuring cell), which significantly simplifies the analytical procedure. It is only essential that the weight of cellulose

Table 2. Parameters of Eq. (12) under condition k_2 = constant = 0.00266

Sample no.	A	k_1, s^{-1}	R^2	$1/\tau_{max}$, s^{-1}
1	0.9	0.0141	0.995	0.00696

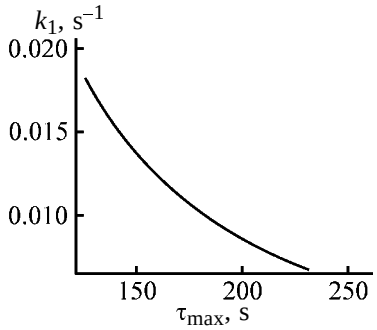

Fig. 2. Rate constant of the reaction k_1 as a function of time in which the maximal difference in temperature is attained, τ_{max}.

should be considerably (by 2–3 orders of magnitude) lower than the total weight of the reaction mixture, since, in this case, the influence of small variation in temperature ΔT in the measuring cell can be neglected and the process conditions can be considered as isothermal.

CONCLUSION

The proposed procedure of cellulose acetylation in a non-adiabatic microcalorimeter and mathematical processing of the results allow fast and accurate estimation of the reactivity of cellulose microamounts to acetylation. The convenient characteristic for comparison of the samples is $1/\tau_{max}$, reciprocal time in which the maximum in the τ–ΔT diagram is attained.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Conducting Composite of Polyaniline and Wood

Abstract—Production of a new conducting composite material based on polyaniline and wood by simple one-stage synthesis from aniline and wood sawdust is described. The material characteristics were studied in relation to the synthesis conditions and composition.

Antistatic materials are the most important application of conducting polymeric composites. The required level of the specific conductivity is low, 10^{-5}–10^{-6} S cm^{-1}. These composites are also used for electric heaters, conducting adhesives, and radiation-shielding coatings [1]. Traditional conducting composites are produced with carbon black or metallic fillers. However, the main problems of these materials are deterioration of the mechanical characteristics of the polymeric matrix on addition of the required amount of a conducting additive and also aging of composites, i.e., decrease in the conductivity caused by phase segregation of the material or oxidation of conductive additive.

In recent years, much more attention is given to production of conductive materials based on polyconjugated polymers having intrinsic specific conductivity of 10^{0}–10^{2} S cm^{-1} in the doped state [2]. Although the mechanical characteristics of conjugated polymers are relatively poor, procedures were developed for combining these polymers with classical dielectric polymers and for producing of conductive composites with the required mechanical characteristics. Addition of polyconjugated polymers imparts new useful properties to a composite. Unique optical, magnetic, and oxidative characteristics of these materials significantly extend their fields of application in comparison with traditional antistatic substances. New materials are used for electromagnetic screening, corrosion protection of ferrous and non-ferrous metals, and nonlinear optics; they are used for production of electrochromic devices and gas-distributing and pervaporation membranes [3].

Polyaniline (PA) is characterized by the resistance to the action of the environment, ready availability of raw materials, and the simplicity and low cost of synthesis. Therefore, it was the first commercially produced polyconjugated polymer. Fairly high conductivity and the possibility of varying the molecular weight of the polymer over a wide range make this polymer the most suitable for production of conductive composite materials. In recent years, numerous PA composites with synthetic polymers, inorganic substances, and natural compounds were produced [4].

Among natural materials, wood is of great importance. The interaction of PA with the main components of wood, cellulose and lignin, was the subject of recent studies. Based on water-soluble forms of cellulose, stable aqueous colloids of PA with the conductivity of 10^{-2} S cm^{-1} were prepared [5]. Flexible and transparent films produced from the composite with cellulose acetate have a conductivity of 10^{-1} S cm^{-1} even at PA content less than 5 wt %. The specific conductivity of 10^{-1} S cm^{-1}, more than sufficient for antistatic materials, is reached even at a PA content of 0.5 wt % [6–11]. The PA composites with cross-linked cellulose having the conductivity of 10^{-2} S cm^{-1} were produced. The compatibility of the polymers is good, which may be due to formation of hydrogen bonds between hydroxy groups of cellulose and amino groups of PA [12].

Blends and composites of PA with lignin and its derivatives were studied. Polyaniline is compatible with lignin owing to the interaction of the –NH– fragments with hydroxy and carbonyl groups of the natural polymer [13, 14]. The use of lignosulfonate for doping of PA results in formation of self-organizing polyelectrolyte complexes generating films with alternating layered structure [15, 16]. The use of similar structures for corrosion inhibition is suggested.

Data on composites of PA with wood are lacking. At the same time, sawdust is a material with valuable

1070-4272/03/7605-0835$25.00

consumer characteristics; it is a porous matrix suitable for production of composites with bulk conductivity. It is a cheap and readily available product; as a rule, it is a waste from woodworking industry whose utilization is an urgent problem. Here we describe the production of a conducting composite based on PA and milled wood and the characteristics of the composite material depending on its composition and synthesis conditions.

EXPERIMENTAL

In the experiments we used milled spruce wood (sawdust fraction 0.25–1.00 mm); aniline and ammonium persulfate $(NH_4)_2S_2O_8$ purchased from Aldrich; and 75% orthophosphoric acid purchased from Vekton.

The composite was synthesized as follows. Spruce sawdust (2 g) was added at 20°C with gentle stirring to 100 ml of a polymerization mixture containing aqueous aniline and ammonium persulfate. The molar ratio of the oxidizing agent and monomer was kept equal to 1.25. The polymerization mixture was acidified with orthophosphoric acid, since the rate of cellulose hydrolysis in this acid is the lowest. Acidic medium is required for the synthesis and subsequent efficient doping of PA. The resulting composite material was filtered off and dried in air and then in a vacuum at 40°C for 48 h.

To determine the amount of PA bonded to the wood surface, the composite was dispersed in a large volume of aqueous H_3PO_4 and washed on a fine (0.2-mm) sieve to remove free PA.

The progress of exothermic polymerization of aniline was monitored by variation of the temperature of the polymerization mixture with a THERMO TM-120 Sigma digital thermometer.

The composition of the material was determined from its yield and checked by elemental analysis.

The conductivity of the samples in the form of pellets 13 mm in diameter and 1 mm thick, produced by pressing in a vacuum at 700 MPa, was determined at 20°C. For the samples with the specific conductivity more than 10^{-3} S cm^{-1}, we used the four-point method modified by van der Pauve at direct current, and for the samples with lower conductivity we used the bridge method with alternating current.

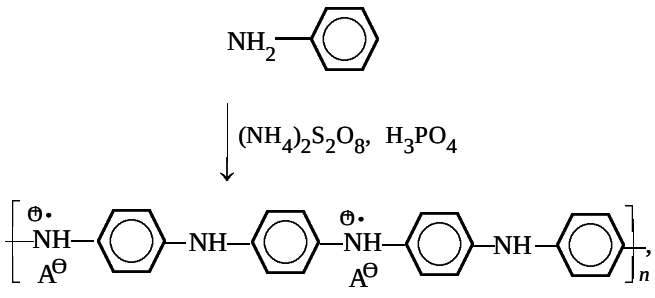
Thermal gravimetric analysis of the composite was carried out on a MOM C derivatograph at a heating rate of 1 deg min^{-1} in an air flow of 50 cm^3 min^{-1} in corundum crucibles; weighed portion 50 mg.

Absorption spectra of aniline solutions were recorded on a Lambda 20 Perkin–Elmer spectrometer.

Polyaniline produced in the absence of wood at the initial concentration of the monomer of 0.2 M had the conductivity of 3.38 S cm^{-1} and contained 11 wt % nitrogen and 12 wt % phosphorus. Spruce wood had the conductivity of 6.3×10^{-15} S cm^{-1}, and within the experimental error, contained no nitrogen and phosphorus, while according to published data [17] spruce wood contains 0.1 wt % nitrogen and 0.02 wt % phosphorus. The conductivity of spruce wood kept in 0.2 M acidic aniline solution for 2 days was 1.15×10^{-14} S cm^{-1}.

Polyaniline is a powder with extremely low solubility; its melting point exceeds the temperature of polymer degradation. Therefore, production of composite materials based on polyaniline by the standard procedures such as mixing in melt or solution, as a rule, is impossible. In such cases, polymerization *in situ* finds growing application. The procedure consists in the direct polymerization of a monomer at the surface of a composite matrix. A comprehensive study of this procedure showed that, in the course of synthesis, PA forms tightly sorbed layers at various types of surfaces immersed in the polymerization mixture. Porous milled wood having developed surface can serve as suitable dielectric matrix carrying the conducting polymer layer.

The composite was synthesized by immersion of spruce sawdust into an aqueous polymerization solution containing aniline, H_3PO_4, and $(NH_4)_2S_2O_8$. As a result of aniline oxidation, the conducting form of PA is formed:

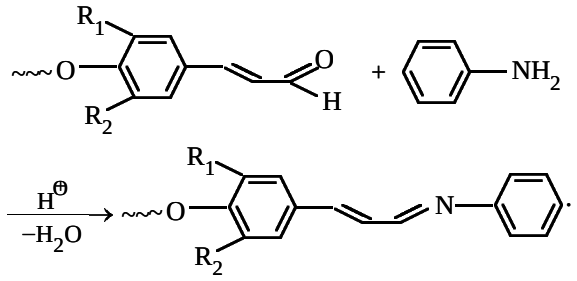


where A^- is $1/3\,PO_4^{3-}$, $1/2\,HPO_4^{2-}$, or $H_2PO_4^-$.

However, wood is a complicated natural material hydrolyzable in acidic medium and oxidizable in the presence of strong oxidizing agents such as $(NH_4)_2S_2O_8$. It was necessary to check whether the synthesis of the composite is complicated by side

processes decreasing the yield of the polymer or resulting in degradation of the wood material.

A contact of spruce wood with acidified aqueous solution of aniline results in instantaneous bright yellow coloration of wood. It was found that coloration is caused by the reaction of aniline with functional groups of lignin, whose content in spruce wood is 28 wt % [17]. Under these conditions, cellulose produced from spruce wood gave no coloration. The reactions carried out with model compounds showed that similar yellow coloration appears in the reaction of acidic solutions of aniline with cinnamaldehyde, one of the main structural units of lignin. Thus, the most probable explanation of the product coloration is the reaction of aniline with conjugated aldehyde groups of lignin:



Formation of Schiff bases with further extension of the conjugated chain shifts the absorption band to the visible range and gives rise to coloration. However, the fraction of aniline participating in this reaction is low. The spectral analysis of polymerization solutions of aniline before and after addition of sawdust showed that the loss of the monomer, monitored by the strong absorption bands of aniline in the range 250–300 nm, did not exceed 10^{-5} mol per 2 g of wood. Hence, the color reaction can noticeably contribute to the process only at low aniline concentrations. In other cases, it is not competitive with polymerization.

It was found that the polymerization rate and characteristics of the resulting material were independent of the order in which the components of polymerization solution were added to the sawdust (Table 1). Preliminary keeping of wood in solution of aniline or ammonium persulfate for 1 h gave the same results as in the case of addition of sawdust directly to the prepared polymerization mixture. This suggests that wood is not hydrolyzed or oxidized in the system.

Polymerization of aniline is an exothermic process. The reaction rate and degree of conversion of the monomer can be evaluated from the rate of temperature variation in the polymerization mixture and the heat effect of the reaction [18]. Variation of the temperature in time during aniline polymerization both in the presence and in the absence of wood material is shown in Fig. 1. Close location of the curves suggests that the presence of spruce wood does not substantially affect the mechanism and degree of conversion of the monomer. Thus, we can conclude that the components of the polymerization mixture do not affect the wood material, and, vice versa, aniline in the presence of wood polymerizes as in the presence of an inert matrix.

Table 1. Polymerization of aniline in the presence of wood at various orders of mixing the reactants*

Procedure of mixing the reactants**	τ, min	α, %	æ, S cm^{-1}
(An + Ox) + W	22	97	0.41
(An + W) + Ox	21	100	0.52
(Ox + W) + An	25	98	0.39

* (τ) Polymerization duration and (α) degree of PA conversion.
** (An) Aniline, (Ox) ammonium persulfate, and (W) milled wood.

The results of synthesis of the composite at various molar concentrations of the monomer (aniline) are listed in Table 2. With decreasing concentration of aniline c_a, the process duration increases and the yield of PA and its content in the composite decrease. The conductivity of the samples increases with increasing content of PA in the composite material from 6×10^{-15} for pure spruce wood to 5.1×10^{-1} S cm^{-1} for the composite containing 64 wt % PA (composite 1). At a high concentrations of polyaniline, the conductivity of the composite (Fig. 2) is close to that of pure PA (3.38 S cm^{-1}) produced under the similar conditions.

Starting from the existing concepts of the PA polymerization mechanism, we can distinguish two processes: so-called "surface" and "bulk" growth of polymer chains [19, 20]. The surface process is responsible for formation of a polymer layer at the surface

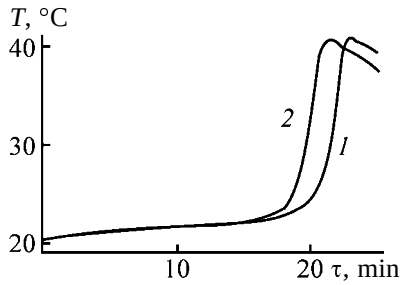


Fig. 1. Variation of the temperature of aniline polymerization T in time τ (*1*) in the absence and (*2*) in the presence of sawdust. Aniline concentration 0.2 M.

0.25	18	100	64	5.1×10^{-1}	28	1.8×10^{-1}
0.2	22	93	57	3.4×10^{-1}	15	5.2×10^{-2}
0.1	58	85	37	7.1×10^{-2}	10	3.3×10^{-2}
0.05	140	79	22	5.2×10^{-3}	5	1.9×10^{-3}
0.01	>300	36	2	8.4×10^{-6}	1	4.5×10^{-9}
0.005	>300	0	0	3.1×10^{-10}	0	8.0×10^{-11}
0.001	>300	0	0	1.0×10^{-10}	0	7.0×10^{-12}

of a matrix immersed in polymerization solution. Depending on the polymerization conditions, these layers have thickness from tens to hundreds of nanometers and are characterized by high adhesion of the polymer to the matrix. The bulk process is polymerization of aniline in the solution bulk with formation of a PA precipitate, whose adhesion to various materials is as low as that of the polymer powder. The ratio of contributions of surface and bulk processes is governed by the polymerization conditions and surface type.

To estimate the contribution of both processes in production of the wood composite, the composite material was washed on a fine sieve to remove PA nonbonded to the surface. As seen from data listed in Table 2 (composite 2), in this process the fraction of PA in the composite decreases, on the average, by 2/3 as compared to the initial value. In this experiment, the PA content was determined not only from the weight loss but also by elemental analysis of the composite for nitrogen. Under these conditions, the ratio of weight fractions of PA formed by the bulk and surface processes is 2/1 (Table 2). This ratio of contributions of the two reactions is kept at all the initial concentrations of the monomer.

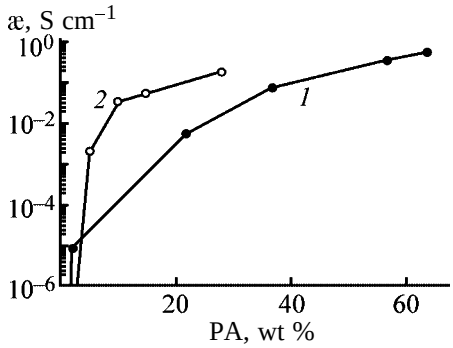

Fig. 2. Specific conductivity æ of (*1*) composite 1 and (*2*) composite 2 as a function of PA content.

The conductivities of the samples containing only surface-bonded PA (composite 2) are listed in Table 2. Despite the fact that the total amount of the conductive polymer substantially decreased, the conductivity of the composite decreased insignificantly. This suggests that the composite conductivity is mainly governed by the PA layer formed by surface polymerization. Addition of a powder-like PA precipitate, increasing the amount of PA in the composite by a factor of 2, only slightly improves its conductivity. According to the dependence of the conductivity on composition (Fig. 2), the conductive paths in the composite begin to form even at the PA content of 1–2 wt %. This low percolation limit is typical for composites consisting of dielectric particles coated with a conducting polymer [21, 22]. The results obtained suggest that special procedures of synthesis of composite materials based on PA are more efficient than addition of PA powder to a dielectric matrix.

In the course of synthesis of the composite material, we used orthophosphoric acid. It is incorporated in the composite as PA dopant. According to elemental analysis, the phosphorus content in neat PA is 12 wt %, and in the composite it varies from 6.0 wt % to several tenths of per cent depending on the content of the conductive polymer. It is well known that addition of phosphorus even in the amount of several per cents substantially improves the fire resistance of wood and items thereof [23]. A fairly high content of phosphorus in the form of phosphate anions incorporated into the composite will surely improve the fire resistance of the material.

The results of thermal gravimetric analysis of spruce wood and composite containing 28 wt % PA are shown in Fig. 3. In the first stage of thermal degradation of spruce wood (up to 120°C), the weight loss is 10%, which corresponds to removal of sorbed water and volatile substances. With further heating, after a small plateau of thermal stability (150–250°C),

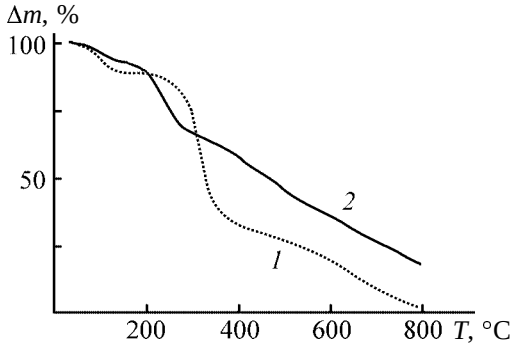

Fig. 3. Thermal gravimetric analysis of (*1*) spruce wood and (*2*) composite containing 28 wt % PA. (Δ*m*) Weight loss and (*T*) temperature.

the main weight loss proceeds at a high rate up to 360°C. Further burning of the pyrolysis residue (approximately 40%) proceeds more slowly up to complete decomposition of the sample at 800°C.

Thermal decomposition of the composite proceeds differently. The initial weight loss (up to 130°C) is caused by removal of water and volatile substances of wood. The subsequent stage of thermal degradation (200–300°C) involves several processes, one of which is dedoping of PA (240–270°C), responsible for the loss of the composite conductivity in this temperature range. Abrupt weight loss (30%) observed in spruce wood in the range from 250 to 360°C does not occur in the composite. The remaining 70% of the composite weight is lost at a constant rate comparable with the rate of burning of the pyrolysis residue. However, 18 wt % of the material remains at 800°C.

CONCLUSIONS

(1) A new conductive composite material based on polyaniline and milled wood with the specific conductivity of approximately 10^{-1} S cm^{-1} was obtained.

(2) The composite is prepared by one-stage polymerization of aniline in the presence of sawdust, i.e., the wastes from wood working can be used as main raw materials.

(3) The conductivity of the composite is mainly governed by the layer of polyaniline sorbed at the wood surface in the course of synthesis and only slightly depends on the presence of the powder-like precipitate of polyaniline.

(4) The study of the thermal stability and measurements of the sample conductivity at elevated temperature showed that the composite loses conductivity in the range 240–270°C, which is caused by thermal dedoping of polyaniline.

BRIEF COMMUNICATIONS

Niobium(V) Recovery from Titanium-Containing Sulfate Solutions

V. G. Maiorov and A. I. Nikolaev

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received January 10, 2003

Abstract—The separation of niobium(V) from titanium(IV) by extraction with tributyl phosphate containing an amine, followed by precipitation from sulfate media with organic coagulants, was studied.

The problem of niobium(V) and titanium(IV) separation arises in treatment of some types of secondary raw materials, e.g., alloys and intermediate solutions, from sulfuric acid processing of titanoniobates [1]. The most efficient separation is attained in the fluoride extraction system. However, along with undoubted advantages, the fluoride system has significant drawbacks (corrosiveness, toxicity, short supply and high cost of hydrofluoric acid, and environmental problems associated with utilization of fluorine-containing wastes). In this work we studied separation of niobium(V) from titanium(IV) in a system containing sulfuric acid only.

Tributyl phosphate (TBP) is one of the most widely used neutral organic solvents. From sulfuric solutions Nb(V) is extracted with TBP better than Ti(IV). According to [2, 3], the degrees of extraction of Nb(V) and Ti(IV) from 8 M H_2SO_4 are about 50 and 15%, respectively, which is insufficient for the recovery of Nb(V) and its separation from Ti(IV). Tri-*n*-octylamine (TOA) is known [3] to extract Nb(V) much better than TBP. Therefore, it was of interest to test TBP with small additions of technical-grade trialkylamines (TAA), analogs of TOA, as extractant (especially as such a system is expected to show a synergistic effect [3]). The initial sulfuric acid solution contained (M) 0.06 Nb(V), 0.45 Ti(IV), and 0.25 $(NH_4)_2SO_4$. Pure-grade TBP and TAA containing about 70 vol % TOA were used. The extraction was performed for 30 min. The distribution of Nb(V) and Ti(IV) was monitored by chemical analysis.

The experimental data are shown in Table 1. As seen, the separation of Nb(V) and Ti(IV) is improved as both the concentration of H_2SO_4 and the amount of TAA in the system are increased [at the expense of growth of the TAA content in the extractant and of the volume ratio of the organic and aqueous phases ($V_o : V_{aq}$)]. Upon threefold successive treatment of the aqueous solution (8.5 M H_2SO_4) with fresh portions of the extractant (30 vol % TAA in TBP; $V_o : V_{aq}$ = 2 : 1), the total extraction of Nb(V) was about 90%, and the coextraction of Ti(IV) was less than 10%. Washing of the extract with an H_2SO_4 solution ensures additional removal of Ti(IV) from Nb(V) (Table 2). Niobium hydroxide, which contained after

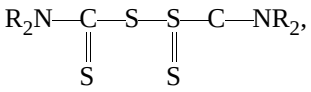
0.08	0.14	3.9	PEI	0.8	97.9	55	5.6
0.10	0.81	2.6	PEI*	1.2	99.3	18	3.2

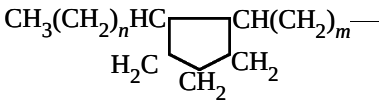
* With preliminary reduction of Ti(IV) to Ti(III) with metallic iron.

calcination less than 2 wt % TiO_2, was obtained by back extraction with ammonia water.

Similar data were obtained when using another organic additive to TBP, tetranaphthenylthiuram disulfide

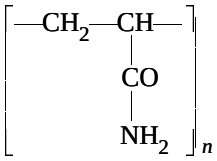


where R is a naphthenic radical (n + m = 8–14)

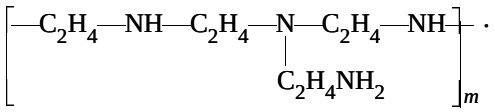


After extraction of niobium(V), titanium(IV) can be isolated by known methods, e.g., by hydrolysis.

We also studied the selective precipitation of niobium(V) from titanium-containing sulfuric acid solutions with organic coagulants like polyacrylamide (PAA)



and polyethylenimine (PEI) [4]



The experimental data are given in Table 3. Organic coagulants allow efficient separation of niobium(V) from titanium(IV). Presumably, the process involves a chemical reaction rather than coagulation proper. Anionic sulfate complexes of the elements are bonded by nitrogen-containing groups of coagulant (by analogy with amine extraction) to form compounds that are precipitated. A disadvantage of using coagulants is the necessity to take them as dilute aqueous solutions (~0.5 wt % PAA and 2–10 wt % PEI), which inevitably leads to dilution of sulfuric acid solutions of titanium.

If sulfuric acid solution contains tantalum(V) in addition to niobium and titanium, then in the extraction process tantalum remains in the aqueous phase along with Ti(IV), whereas in the process with coagulants it selectively coprecipitates with niobium(V). Preliminary experiments showed that, in hydrochloric acid solutions, the target components behave similarly.

CONCLUSIONS

(1) Nb_2O_5 containing less than 2 wt % TiO_2 can be obtained by extraction of niobium(V) from titanium-containing sulfuric acid solutions with tributyl phosphate containing an amine.

(2) Niobium(V) can be separated from titanium(IV) by selective precipitation with organic coagulants, namely, polyacrylamide and polyethylenimine.

BRIEF COMMUNICATIONS

Synthesis of Cyclic Organic Carbonates from C_3–C_{16} Epoxides

G. V. Rybina, S. S. Srednev, and L. I. Bobyleva

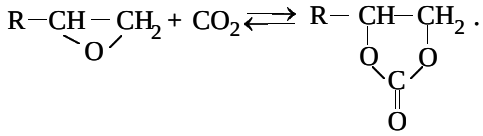
Yaroslavl State Technical University, Yaroslavl, Russia

Received October 28, 2002; in final form, March 2003

Abstract—Cyclic organic carbonates were prepared from epoxides (derivatives of C_3–C_{16} olefins, C_4 and C_8 dienes, styrene; epichlorohydrin) in the presence of a catalytic system consisting of $CoCl_2 \cdot 6H_2O$ and dimethylformamide.

Cyclic organic carbonates are used in oil refining as extractants of aromatic hydrocarbons, and also in synthesis of drugs and plant protection agents. Of particular interest for industrial organic synthesis is preparation of nitrogen-containing polymers from cyclic carbonates [1].

Cyclic organic carbonates are prepared in industry by reactions of epoxides with CO_2 in the presence of alkali metal halides:



This process, however, requires high pressures (3–10 MPa) and temperatures (180–220°C) [2].

It was suggested previously [3] to perform this reaction in the presence of a Co(II) or Ni(II) halide and dimethylformamide (or dimethylacetamide). With this catalytic system, it appeared possible to decrease the reaction temperature (to 120–130°C) and pressure (to 1.0–1.5 MPa), and also to prepare vinylethylene carbonate by carboxylation of divinyl oxide at a high rate and with a high selectivity with respect to the target product [4].

Our goal was to test the suggested catalytic system for synthesis of cyclic carbonates from epoxides of various structures, containing aliphatic (saturated and unsaturated), aromatic, and other substituents.

Carboxylation was performed at 130°C and CO_2 pressure of 1.5 MPa; the starting mixture contained 25.0 wt % epoxide and 2.50 wt % $CoCl_2 \cdot 6H_2O$. The reaction time was 120 min. The results are listed in the table.

The cyclic carbonates were isolated by vacuum fractionation; their purity was no less than 98.5%. The purity, composition, and structure of the target products were confirmed by chromatography, chemical analysis, and ^{13}C NMR spectroscopy.

EXPERIMENTAL

The starting epoxides were prepared by hydroperoxide oxidation of appropriate olefins and isolated by distillation. The main substance content was no less than 98.5%. The solvent, catalyst, and auxiliary substances met the requirements of the corresponding State Standards. Carboxylation of epoxides was performed in a temperature-controlled stirred metallic vessel.

The reaction products were analyzed by gas–liquid chromatography on an LKhM-8 MD device (3000 × 3-mm steel column, stationary phase 15% diisooctyl sebacate + 1.5% sebacic acid on Chromaton N AW-DMCS). 1-Propanol was used as internal reference. Chemical analysis was performed according to [5]. The ^{13}C NMR spectra were recorded on a Tesla BS-576A spectrometer (25.142 MHz, internal reference HMDS).

CONCLUSION

A catalytic system consisting of $CoCl_2 \cdot 6H_2O$ and dimethylformamide is effective in synthesis of cyclic carbonates from various saturated and unsaturated epoxides.

INFORMATION

Fifth Chemical Forum "Tekhnokhimiya-2003"

The Fifth Chemical Forum "Tekhnokhimiya-2003" (Technical Chemistry 2003) was held in St. Petersburg on March 19–23, 2003. The forum was organized by Lenekspo Open Joint-Stock Company, Prikladnaya Khimiya Russian Scientific Center (PKhRSC), Prometei Central Research Institute of Structural Materials (PCRISM), and All-Union Research Institute of Corrosion (Moscow), with the support of Ministry of Industry and Science of the Russian Federation, Administration of St. Petersburg, and Russian Chemical Society. Within the framework of the forum were held Fifth Conference "Teknokhimiya" and Sixth International Scientific and Technical Conference "New Materials and Technology for Corrosion Protection," and also thematic exhibitions "New Materials and Technologies for Corrosion Protection," "Chemical Industry," "Industrial Ecology and Safety," and "Instruments, Equipment, and Apparatus." Simultaneously, the Tenth International Exhibition "Ecology of a Large City" was held within the framework of the International Ecological Forum.

At present, the chemical industry is one of the most rapidly developing branches of the domestic economy. The appearance of a great number of new plants with different kinds of property and the tendency toward replacement of imported goods by home-made products make necessary an intensive information exchange between participants of the market of chemical technologies and separate plants. At the same time, the development of chemical industry is closely associated with introduction of environmentally safe technologies, raw material processing, and utilization of wastes.

The Program of the Fifth Conference "Tekhnokhimiya" included reports devoted to technological reequipment and modernization of chemical plants and solution of problems associated with industrial ecology and safety. All the reports can be divided into two groups: "High Technologies, Technological Equipment, and Analytical Monitoring in Manufacture of Chemical Products" and "Ecology and Industrial Safety in Chemical Industry." In both groups, most of reports were presented by staff members of PKhRSC. At present, this is the leading Russian scientific center in the field of chemistry and chemical technology. It is aimed to formulate the scientific and technological policy in chemistry-related branches of industry and to develop and implement the most important state programs. The main avenues of research at PKhRSC are as follows: chemistry and technology of fluorine-containing compounds, basic and fine organic synthesis, products of inorganic synthesis, membranes, sorbents and catalysts for technological and ecological purposes, ultrapure substances, composites and polymeric materials, isotopically labeled compounds, processes and apparatus of chemical technology, scientific foundations of design of versatile chemical shops on the basis of modular equipment, and means of control and automation. A prominent place is occupied by studies in the field of chemistry of the defense and aerospace complex of Russia, conversion of defense industries, and utilization of military products. The main avenues of research were reflected in reports presented by participants of the "Tekhnokhimiya" conference.

V.S. Leont'ev and P.Yu. Smykalin discussed physicochemical and mathematical foundations for intensification and modernization of processes and apparatus for reequipment of chemical industries. The authors noted that the problems of modernization of industrial processes and apparatus are multilevel and many-parametric. Models of the first (lower), second (medium), and third (upper) levels are analyzed. V.S. Shpak and co-authors considered chemical and technological problems associated with internal-combustion engines and means of transportation in Russia. V.G. Barabanov, B.N. Maksimov, G.I. Kaurova, *et al.* summarized the results of studies in the field of chemistry and technology of fluorine compounds, carried out at PKhRSC. The applied research is done in the following directions: Freons for various purposes (refrigerants, solvents, fire-extinguishing agents, etc.); fluorine-containing monomers for fluoroplastics; thermally and chemically stable oils, lubricants, dielectric liquids; fluoroaromatic compounds. Much success has been achieved in all of these directions.

D.S. Pashkevich and V.G. Barabanov reported on the development of a process for synthesizing fluorine-containing compounds using elemental fluorine in order to perform conversion of fluorine plants. At present, elemental fluorine is available commercially. The processes developed at PKhRSC served as

1070-4272/03/7605-0844$25.00

a basis for creating a number of works at Russia's plants manufacturing elemental fluorine. There are large-tonnage shops for production of fluorine compounds at major fluorine-manufacturing plants, such as Galogen Open Joint-Stock Company (SF_6, WF_6, BF_3, C_3F_8), Kirovo-Chepetsk Chemical Combine (SF_6, $C_{10}F_{18}$), and Angarsk Electrolysis Chemical Combine (CF_4).

E.E. Gusarov, Yu.P. Malkov, and M.A. Rotinyan discussed in their report an integrated process for plasmochemical elimination of organohalogen substances and wastes and cleaning of industrial equipment to remove these contaminants. The authors noted that many halogen-containing compounds, which had been widely used in the industry and are still stored in large amounts, and also industrial wastes containing these compounds, are highly hazardous for humans and the environment. To compounds of this kind belong, in the first place, ozone-destroying Freons, polychlorobiphenyls, and toxic halogen-containing wastes from chemical industries. For example, according to the authors' data, about 2 million tons of various ozone-destroying Freons have been accumulated in the world and require environmentally safe elimination. The world's stock of polychlorobiphenyls, which are one of the main sources of such superecotoxicants as dioxins, is estimated at 760 million liters. Also reported were advantages and high efficiency of the plasmochemical process in elimination of organohalogen substances.

An important issue associated with the development of new effective adsorbents and localizers for recovering and eliminating spills and preventing contamination of the environment with petroleum products and other inflammable and toxic liquids was considered in the report presented by S.V. Polyakov and co-authors.

Together with staff members of PKhRSC, representatives of other institutions also presented a number of reports. B.V. Gidaspov and V.G. Dedukh (Azot-Vzryv Closed Joint-Stock Company) considered problems associated with manufacture of explosives for industrial purposes. Ammonium nitrate is the most widely used oxidizing agent in substances of this kind. It is produced in Russia on a rather large scale (more than 8 million tons was manufactured in 2002). The present-day economic situation in Russia's industry and agriculture leads to the following distribution of the whole manufactured amount of ammonium nitrate: 70–80% exported, 10–15% used in agriculture as fertilizer, and 5–10% used in manufacture of industrial explosives. The authors analyze the requirements to the quality of ammonium nitrate used to produce explosives and assess the state of affairs at plants manufacturing ammonium nitrate. The proposed liberalization of the market of natural gas may lead to a significant rise in its price. At the same time, average expenditure of natural gas for manufacture of 1 ton of ammonium nitrate at Russia's plants exceeds the average world's level by a factor of 1.8–2.0, and the overall expenditure of electric power, by a factor of more than 2. The factory cost price of ammonium nitrate has already become close to the disbursing price, and the profitability is as low as 5–10%.

The report by E.A. Vlasova and N.V. Mal'tseva (St. Petersburg State Technological Institute) was devoted to development of sorbents and catalysts for solving environmental problems.

Domestic developers of anticorrosion materials and technologies and representatives of some foreign companies took part in sessions of the International Scientific and Technological Conference "New Materials and Technology for Corrosion Protection." The reports they presented covered a wide variety of problems: new protective coatings and technologies of their application, inspection of the corrosion state of equipment and structures, economical and environmental aspects of means and methods of corrosion protection, licensing and certification of means and techniques of corrosion protection, corrosion risk insurance, and methods for monitoring and diagnostics of corrosion.

Modern problems of corrosion resistance of steels and corrosion protection of equipment in oil refining and petrochemical industries were considered in the report presented by Yu.I. Archakov (VNIIneftekhim Open Joint-Stock Company, St. Petersburg). The author noted that, in view of the substantial scale of the industries and large dimensions of the equipment employed, wide use of special stainless steels and alloys is impossible for economic reasons. At the same time, the working media used in various stages of oil processing are corrosion-active. Particularly complicated is corrosion protection at elevated temperatures and high pressures. The author analyzed a complex of promising techniques for corrosion protection of equipment for various working conditions and types of corrosion-active media. V.V. Burlov and G.F. Palatik (VNIINeftekhim Open Joint-Stock Company, St. Petersburg) reported the results obtained in studying the efficiency of industrial amide–imidazoline inhibitors for corrosion protection of installations for primary oil processing.

The report by S.S. Vashchilova (Emlak Closed

Joint-Stock Company) was devoted to new paint-and-varnish materials offered by Emlak Company for protection of various kinds of oil processing equipment working under standard atmospheric conditions and in corrosive media. V.L. Zhak, M.D. Sarachuk, and V.S. Rammo (Gamma Ltd., St. Petersburg) reported on the development of water-dilutable epoxy paint-and-varnish materials. Coatings based on the materials manufactured by the company are intended for protection of steel, aluminum–magnesium, and zinc-plated surfaces under atmospheric conditions, at increased humidity, in saline and alkaline media, and also in oils and petroleum products. The problems associated with raising the longevity of paint-and-varnish coatings were considered in the report by V.D. Pirogov and M.A. Mikhailova (PCRISM, St. Petersburg).

G.Yu. Kalinin and co-authors (PCRISM) reported on the development of a high-strength austenite nitrogen-containing steel. The steel shows good characteristics as regards corrosion cracking and intergranular and pitting corrosion. S.Yu. Mushnikova *et al.* (PCRISM) reported the results obtained in a comparative study of resistance to pitting, crevice, and intergranular corrosion, and also to corrosion cracking, of high-nitrogen (05KhAN4B, 0.13N) and carbon (07Kh16R4B) steels. It was found that replacement of carbon with nitrogen in a moderately alloyed chromium–nickel steel 05Kh16AN4B improves significantly its resistance to pitting and crevice corrosion in chloride solutions, compared with the 07Kh16N4B steel unalloyed with nitrogen and containing about 0.07% C.

I.A. Susorov and co-authors (Kronos-SPb Open Joint-Stock Company, St. Petersburg) reported on the development and commercial production of a number of new anticorrosion materials for various industries and presented their basic technical characteristics. The products manufactured by Kronos-SPb St. Petersburg paint-and-varnish plant have been known for more than 60 years. Together with production of new materials, the company continues to manufacture the conventional alkyd, acryl, and perchlorovinyl enamels and primers. Susorov *et al.* presented data on application-ready primer-paint Surik Svintsovyi (Red Lead), whose industrial use was allowed by the State Sanitary and Epidemic Control Commission. The same company offers Germokron-ZhD corrosion-protective coating stable in mineralized corrosive media.

V.I. Trusov (Notekh Research and Production Plant, St. Petersburg) noted the advantages of a new rust converter Notekh-K (concentrate) and described fields of its application.

In this brief journal review, it was only possible to dwell on selected, most characteristic reports. Extended abstracts of all reports presented at both conferences and the official alphabetic catalog of exhibitors, participants of thematic exhibitions, can be found in a special publication by Lenekspo.

In view of the subject fields and goals of the Teknokhimiya-2003 chemical forum, it seems quite reasonable that the Tenth International Exhibition "Ecology of Large City" was held on the same days (March 19–22, 2003). The main goal of the exhibition was to demonstrate the best examples of domestic and foreign products, equipment, services, technologies, and scientific and applied developments in the field of ecology. In accordance with these circumstances, the subject of the exhibition covered the following directions: environment protection and restoration, wastewater purification, water treatment and supply, waste management, recycling industry, methods for monitoring of air contaminants and systems for air purification, protection and restoration of arable lands, efficient use of energy. More than 50 companies from Russia and Poland took part in the exhibition.

Simultaneously with the exhibition, two scientific and applied symposia were held: "Water Treatment and Water Supply, Topical Problems and Experience of Their Solution" and "Improvement of Water Quality as a Source of Health for Population."

Russian Journal of Applied Chemistry, Vol. 76, No. 5, 2003, p. 847. Translated from Zhurnal Prikladnoi Khimii, Vol. 76, No. 5, 2003, p. 875.

BOOK REVIEWS

Surzhko, O.A., *Resurso-tekhnologicheskie problemy elektroliticheskogo polucheniya binarnykh splavov s nevzaimodeistvuyushchimi komponentami* (Resource-Related and Technological Problems Associated with Electrolytic Production of Binary Alloys with Noninteracting Components)

Rostov-on-Don, 2001, 108 pp.

Despite the complicated title, the brief monograph actually presents results of an experimental study of electrolytic production of cobalt–lead alloys and data on properties of the alloys obtained. The introductory chapters contain general evidence. The book comprises an introduction, six chapters, conclusion, and a bibliographic list with 96 references to works of mainly domestic authors.

The introduction (pp. 4–6) notes a certain interest aroused by the properties of alloys belonging to systems with noninteracting components. Very brief Chapter 1 (pp. 6–10) discusses the possibility of replacing rare and expensive components with lower-cost formulations having similar properties. Naturally, such a replacement requires detailed substantiation in each particular case. Chapter 2 (pp. 10–23) considers specific features of the structure and properties of electrolytic alloys with noninteracting components. The author focuses attention on alloys with magnetic properties. Chapter 3 (pp. 23–42) is devoted to theoretical foundations of formation of electrolytic alloys. Chapter 4 describes the experimental techniques applied by the author to study the cobalt–lead system: chemical, spectral, and X-ray structural analyses and measurement of magnetic characteristics. Chapter 5 (pp. 50–76) contains evidence about electrodeposition of a cobalt–lead alloy from a pyrophosphate electrolyte with rather complex composition. The interaction of the electrolyte components was studied by measuring electronic absorption spectra. Chapter 6 (pp. 76–94) presents data on the phase composition and magnetic and corrosion properties of an electrolytically prepared cobalt–lead alloy.

The conclusion (p. 94–99) summarizes the main results of the study performed. It is shown that the pyrophosphate electrolyte with various additives, proposed by the author, can be used to obtain alloys in the cobalt–lead system in a wide range of compositions (14 to 91 wt %). A suggestion is made, concerning the possible mechanism by which pyrophosphate complexes of cobalt and lead are discharged at the cathode. A study of the phase composition demonstrated that lead-based solid solutions with cobalt content of up to 10–12 wt % can be formed. Also noted is the formation of a new phase whose nature could not be identified so far. The obtained cobalt–lead alloys possess ferromagnetic properties.

The main importance of the monograph is, in my opinion, in its second part (Chapters 4–6) which presents experimental results. Unfortunately, the general theoretical chapters (Chapters 1–3) are written without due clarity, the equations presented are virtually not commented at all, and a number of annoying inaccuracies can be found.

The book may be of interest for specialists in electroplating.

BOOK REVIEWS

Nikitin, M.K. and Mel'nikova, E.P., *Khimiya v restavratsii* (Chemistry in Restoration)

St. Petersburg: Tekhinform, 2002, 304 pp.

The original and needed reference book considers chemical processes occurring in restoration of architectural monuments, paintings, sculptures, pieces of art made of stone, wood, metal, glass, ceramics, fabrics, paper, and leather, and presents a vast body of evidence concerning materials used in restoration work. The first edition of the reference book was published by Khimiya publishing house in 1990 and was met with lively interest by readers both in Russia and other countries. The authors of the book are known specialists in the field of restoration.

The reference book comprises an introduction, ten chapters, and appendix. In the brief introduction (pp. 5–7), the authors, in particular, mention the importance of carrying out conservation work, which neutralizes the detrimental action of numerous damaging factors associated with the general environmental situation. Chapter 1 (pp. 8–40) presents criteria to be used in choosing materials for restoration of historical and cultural monuments. Particular attention is given to polymeric materials (both synthetic and natural), organosilicon compounds (polyorganosiloxanes, polyorganosilazanes). Also presented are data on organic solvents that can be used in restoration works.

Chapter 2 considers chemical materials used in restoration of paintings in oil or distemper on canvas, fresco on lime plaster, paintings in distemper on wood (restoration of icons), polychromic wooden sculpture, and wax articles. Chapter 3 (pp. 73–98) is devoted to restoration of stone articles, sculptures in museums and stone buildings and structures, ant to protective-decorative dressing of facades. The set of necessary chemical materials to be used, depending on a particular task to be accomplished, is very wide. Prominent place among such materials is occupied by polymeric solutions and epoxy resins. Small Chapter 4 (pp. 99–108) contains evidence about chemical materials used in restoration of concrete and armored-concrete buildings and structures. Polymeric cements, composites containing fast-cured mineral binders with polymers, are widely used to reinforce buildings, glue together fragments of sculptures, and for other purposes. Concrete and armored-concrete surfaces are hydrophobized and reinforced with solutions of polyalkylhydridosiloxanes in organic solvents or corresponding emulsions. Surfaces of concrete structures can also be reinforced by impregnation with epoxy or polyester resins.

Chapter 5 (pp. 107–127) describes chemical materials used in restoration of wooden objects or articles. It considers measures for integrated protection of wood in historical buildings and structures, articles found in archaeological excavations, sculpture, furniture, and museum exhibits. Fire and biological protection of wood, its conservation and reinforcement, and deposition of protective-decorative coatings are envisaged. Various polymeric materials are widely used in these procedures.

Chapter 6 (pp. 126–201) discusses chemical materials used to conserve and restore articles made of metals: copper, bronze and other copper alloys, iron, cast iron, tin, lead, and noble metals. A wide variety of processes are considered for each of the metals. These include cleaning of metals to remove corrosion products, choice of solders and fluxes for soldering, use of polymeric materials in gluing, chemical or electrochemical deposition of coatings, and inhibition of corrosion processes. A great number of different formulations are presented. Chapter 7 (pp. 202–214) contains information about chemical materials used in restoration of enamels, glass articles, porcelain, and ceramics. Chapter 8 (pp. 215–233) is devoted to chemical materials used in restoration of various kinds of fabrics. Chapter 9 discusses restoration of paper and paper documents. The authors note that the difficulties encountered in restoration of works of art on paper consist in the wide diversity of the materials used, their varied degree of preservation, and different ways of creating images on paper. Detergents, bleaching agents, reagents for removing spots from paper,

1070-4272/03/7605-0848$25.00

antimicrobial means, paper stabilization, and reinforcing formulations for decrepit paper are described. Chapter 10 (pp. 247–269) presents evidence concerning chemical materials used in restoration of articles made of bone, leather, and semiprecious stones.

The appendix (pp. 270–285) presents in the form of tables the basic characteristics of chemical substances used in restoration: inorganic acids, organic acids and salts, organic solvents, cellulose ethers and esters, synthetic polymers, biocides of various kinds. The book is supplied with a list of recommended literature, summary in Russian and English, and index.

The reference book is written by expert scientists and creates rather good impression. As regards manner of presentation, the book is understandable for a wide audience of readers, irrespective of their professional training.

Received November 27, 2002; in final form, February 2003

Abstract—Published data concerning the ways to control the kinetic parameters of vinyl chloride polymerization and molecular-weight characteristics of polyvinyl chloride through directed modification of the reactivity of the growing macroradical are considered.

Polyvinyl chloride (PVC) is one of the most important large-scale polymers. In the world production volume, it ranks second to low-density polyethylene, standing far ahead of polypropylene and high-density polyethylene [1–3]. The reason is that, depending on a synthetic procedure (polymerization in the bulk, suspension, microsuspension, or emulsion), temperature, modifiers, and processing conditions, PVC can be used for manufacture of a wide variety of plastics (rigid or soft, transparent or colored). PVC goods find wide application in manufacture of artificial leather, pipes, plastisols, glues, insulating and construction materials, etc. [1, 3–5].

The basic method for PVC production is radical polymerization of vinyl chloride (VC) [1, 4, 6–10], whose obvious advantages are good reproducibility and technological simplicity. However, synthesis of high-quality PVC under heterogeneous conditions poses a number of problems. First of all, this is the low initial rate of polymerization, whose spontaneous increase in the course of the process gives rise to the so-called gel effect. Nonuniform course of polymerization has negative effect on the formation of macromolecules and supramolecular structures, and, therefore, on the performance characteristics of the resulting polymer. It has been demonstrated that the gel effect results in lower thermal stability and composition inhomogeneity and higher polydispersity of the polymer [1, 4, 9–15]. The process conditions also influence the quality of the polymer. Among them are temperature, choice of necessary additives (emulsifiers and modifiers in suspension and emulsion polymerization and also chain transfer agents) [1, 11, 17–19], stirring mode, crust and "fish eye" formation [1, 10, 13], etc.

Devising advanced methods for controlling polymeric chain growth in radical polymerization of, in particular, VC is among the priority lines of the development of the macromolecular chemistry. It is well known that the gel effect and molecular-weight characteristics can be controlled using methods based on reactions competing with the main process. These methods include, first of all, direct introduction of chain transfer agents (mercaptans, halogenated hydrocarbons, etc.) and inhibitors (quinones, phenols, allyl derivatives, and dithiocarbamates) in the polymerizate [4, 10, 12]. Among ather methods are optimization of the temperature mode [4, 9, 19–22], addition of compounds promoting decomposition of peroxides [14, 23, 24], and use of new initiators or intiator mixtures [19, 22, 24–32].

Recently, methods of other kind have been proposed for chain growth control, based on coordination of a growth radical to organoelement compounds or stable radicals. These methods allow effective control of both the VC polymerization kinetics and formation of the polymer macromolecule. In this review, we examine new approaches to control of the VC polymerization kinetics and molecular-weight characteristics of PVC.

RADICAL POLYMERIZATION OF VC IN THE PRESENCE OF ORGANOELEMENT COMPOUNDS

Organic compounds of nontransition elements in combined with oxidants, have long been known as initiators of low-temperature polymerization of vinyl monomers, among them VC [4]. The reason is that reactions of alkyl and mono- and dialkoxy derivatives

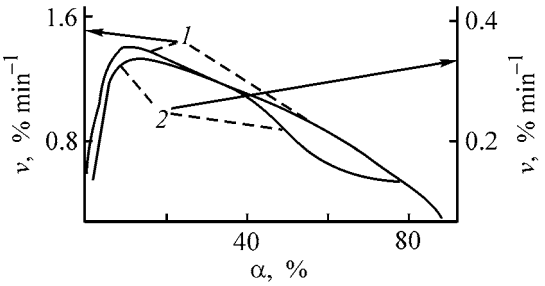

Fig. 1. Kinetic curves of VC polymerization: (*1*) in the bulk and (*2*) in suspension at 20°C in the presence of the triisobutylborane–organoelement peroxide initiator [22]. (v) Polymerization rate and (α) conversion; the same for Fig. 2. Triisobutylborane concentration (mol %): (*1*) 0.8 and (*2*) 0.06. (*1*) *tert*-Butylperoxyphenyldimethylsilane (0.2 mol %) and (*2*) di(*tert*-butylperoxy)triphenylantimony (0.2 mol %).

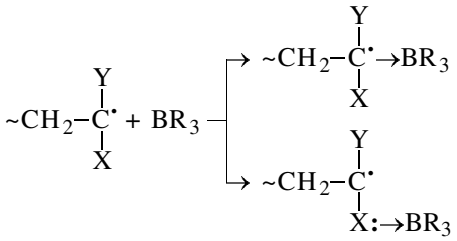
of Group II–IV nontransition elements with oxygen and peroxides mostly proceed homolytically [33–37]. The performance of the indicated initiator systems is largely governed by the structure of an organoelement compound used. It has been demonstrated that, in the case of diethylzinc and diethylcadmium, the conversion in 6 h does not exceed 5–7%, whereas with triisobutylborane it is about 40% [4] (this compound shows promise as the most efficient initiator of polymerization of vinyl monomers [19, 22, 34, 36, 38–41].

In the early 1980s, G.A. Razuvaev and coworkers proposed systems based on trialkylboranes and thermally stable organic peroxides, containing Group IV–V elements as efficient initiators for polymerization of vinyl monomers, which allow the process to be performed to high conversions over a wide temperature range [19, 22, 38–55]. A specific feature of polymerization in the presence of the indicated compounds is that a monomer directly participates in the chain initiation stage [34, 39–41].

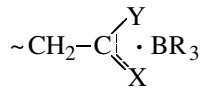
In the case of VC, polymerization proceeds by an uncommon mechanism. It is characterized by high initial rate, which approaches a maximum at 15–20% conversion; after that the process goes quite smoothly (Fig. 1) until virtually complete (90–98%) conversion of the monomer [22, 42].

Taking into account the observed high chain propagation rate and certain trends in physicochemical characteristics of the homo- and copolymers synthesized in the presence of an initiator system constituted by alkylboron and organoelement peroxide, Grishin and Moikin [56–60] suggested that the components of the initiator not only participate in the initiation stage, but also, being weak Lewis acids, have a direct effect on the propagation and termination of the chain by virtue of coordination of the growth radical to the organoelement additive [61, 62].

Such interaction can occur directly at the reactive center (with participation of an unpaired electron) or at a functional group [scheme (1)], or at both centers simultaneously (with delocalization of the unpaired electron) [scheme (2)]:



(1)



(2)

where X is the functional group, and Y, a hydrogen atom or methyl group.

This enhances the electron-acceptor capacity (electrophilicity) of a growing macroradical and also its reactivity toward the multiple bond of the monomer. Quantum chemical calculations and ESR data [58, 59, 63] confirm the possibility of such an interaction. Similar complexes of vinyl monomers with metal halides (Lewis acids) have been well known for a long time and studied in detail (see, e.g., the monograph [64]).

Direct involvement of organic compounds of boron, aluminum, and some other coordination-unsaturated elements in chain propagation has been demonstrated for a wide variety of monomers [57–60, 65, 66], with organic peroxides and azobis(isobutyronitrile) (AIBN) used as initiators, and organoelement compounds added in concentrations comparable with that of the initiator.

In the case of VC, introduction of an trialkylborane into a system polymerizing in the presence of dicyclohexyl peroxydicarbonate (DCPD) leads to a considerable increase in the initial polymerization rate and weakening of the gel effect: in the presence of the organoelemental additive, the initial rate of VC polymerization at 30°C is nearly twice that in the case of initiation with DCPD but without additive [67]. It has been demonstrated that PVC formed in the presence of trialkylboranes is characterized by high syndiotacticity index [19, 67], increased softening point [19, 22, 43, 44], and enhanced heat resistance [22, 68].

Semenycheva [22] and Dodonov *et al*. [48] reported synthesis of C-90 high-molecular-weight PVC under favorable temperature and time conditions (20–30°C, 7–8 h) with a binary initiator system, triisobutylborane–di(*tert*-butylperoxy)triphenylantimony. Addition of catalytic amounts of aluminum alkoxides (diethylaluminum ethoxide and ethylaluminum dietoxide) to a system with AIBN also decreases the autoacceleration, providing smooth polymerization of VC [67, 69].

Results on copolymerization of VC with alkenes (Table 1) under conditions typical of VC polymerization (50°C, 3–5 atm) [67, 69] give additional evidence in favor of the coordinated radical mechanism of VC polymerization in the presence of organoelement additives. It should be pointed out that VC copolymers with ethylene and α-olefins show promise as plastics: they are easily workable and have high elongation at break, impact resilience, etc. Furthermore, addition of even a small amount (5–10%) of alkene units to PVC considerably decreases the cost of the polymer. The unavailability of effective initiators hinders large-scale production of the copolymers indicated. It follows from Table 1 that, in the presence of organoaluminum compounds raising the electrophilicity of the growth radical by virtue of its coordination to an aluminum alkoxide, it is possible to obtain in high yield a polymer containing alkene (ethylene and propylene) units. The presence of propylene units in PVC has been confirmed by IR spectroscopy [67].

Initiator systems based on alkylboranes and Group IV organoelement peroxides enable copolymerization of VC with ethylene and α-olefins over wide composition range at high rate and product yield under mild conditions [50, 53, 70]. The use of systems constituted by trialkylborane and organoelement peroxide leads to pronounced equalization of the copolymerization constants. For example, in copolymerization of VC with ethylene and other olefins, the composition curve is S-shaped, and the copolymer composition in the monomer mixture is virtually constant over the olefin concentration range from 30 to 70 mol %, irrespective of the monomer mixture composition [53, 70]. It should be pointed out that raising the initiator concentration at constant monomer ratio in the mixture leads to a decrease in the viscosity of the resulting copolymers and a slightly (by 5–6%) increase in conversion [50].

It has been demonstrated that PVC containing alkene units differs from ordinary PVC in its physicochemical characteristics. In particularly, the intrinsic viscosity and molecular weight M of the VC/ethylene copolymer decrease with increasing mole fraction of ethylene. The Fickentscher constant characterizing the molecular weight of this polymer (K_f = 40–70 [4]) is also considerably lower as compared to PVC synthesized with the indicated initiators (Table 1) [22, 67, 69]. Decreased K_f of PVC makes its plasticity better [4, 7], which is important from the practical standpoint.

Table 1. Copolymerization of VC with alkenes in the presence of organoaluminum compounds (0.2 mol %) [67] [initiator AIBN (0.2 mol %), T = 323 K]

* Organoelement compounds were added as benzene solutions (benzene content in the polymerizate was 15 wt %).

Therefore, the use of coordination-unsaturated organoelement compounds directionally affecting the reactivity of macroradicals is an effective method for control of polymer chain growth in radical polymerization of VC.

Another possible way to control the polymer chain lifetime, aimed at synthesis of compositionally uniform polymers, is use of stable radicals.

"LIVING" POLYMERIZATION OF VC

In recent years, a new concept of controlled radical polymerization through the "living" mechanism is intensively developed. The essence of the "pseudoliving polymerization" (term "living polymerization" is used as well) is as follows [53, 71–75]. Catalytic amounts of specific reactive additives are added to the polymerizate. Among them are, for example, stable radicals or their sources, complex ions of variable-valence metals, and other chain-terminating agents ($X^{\bullet}$) capable of reversibly interacting with growing radicals ($R^{\bullet}$) to give a labile adduct (R–X), which then de-

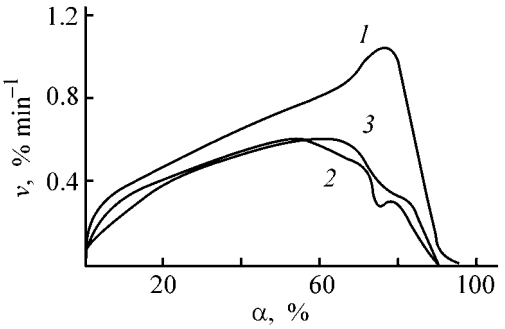

Fig. 2. Kinetic curves of VC polymerization in the presence of BPN at 50°C. BPN concentration (%): (*1*) 0, (*2*) 0.005, and (*3*) 0.1. Initiator DCPD (0.1 mol %) [80].

composes under certain conditions to regenerate the same growing radical.

Despite that "pseudoliving" radical polymerization is a relatively new line in the chemistry of controlled radical processes, quite a few organic and organometallic compounds allowing realization of radical polymerization through the "living-chain" mechanism have been proposed. However, the absolute majority of relevant studies is devoted to polymerization of styrene and its homologs and also of acrylates and methacrylates. Only few reports deal with controlled radical polymerization of VC. First of all, this is caused by the fact that stable carbon-centered and nitroxyl radicals are mostly used as grows regulators, most often, 2,2,6,6-tetramethyl-1-piperidinyloxyl (TEMPO) and its analogs; nitrogen- and sulfur-containing iniferters {term "iniferter" is composed of English abbreviations for the elementary stages of radical polymerization, namely, initiation (ini), transfer (fer), and termination (ter) [72]}; and also transition metal halides [53, 72–75]. Most of the known regulators effectively operate only at relatively high temperatures (100–130°C), being, therefore, absolutely impracticable in polymerization of VC as a gaseous monomer.

Table 2. Characteristics of PVC synthesized in the presence of BPN [81] ([DCPD] = 0.1 mol %, T = 50°C)

* Sample obtained by postpolymerization, with fresh portion of the monomer added on reaching 58% conversion.

** Sample obtained by postpolymerization, with fresh portion of the monomer added on reaching 52% conversion.

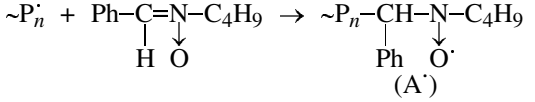
Therefore, those regulators show promise for controlled polymerization of VC which, being taken in combination with peroxides and azo compounds serving as common radical initiators, are capable of generating stable radicals directly in a polymerization system (*in situ*) at a temperature of PVC synthesis (about 50°C). For example, we have proposed previously to use the well-known spin trap, *N-tert*-butyl-α-phenylnitrone (BPN) as an effective regulator of the polymer chain lifetime in polymerization of a series of vinyl monomers, including VC [76–80].

Polymerization of VC in the presence of BPN demonstrates all the most significant signs of pseudoliving polymerization: (1) the gel effect degenerates (Fig. 2); (2) the process goes to high conversion (~90%); (3) the molecular weight of the resulting PVC linearly increases with conversion {Table 2, see the intrinsic viscosity [η] and weight-average (M_w) and number-average (M_n) molecular weights} (4) the molecular-weight distribution (MWD) of PVC is unimodal and the mode is regularly shifted toward the high-molecular-weight region with increasing conversion; and, finally, (5) the polydispersity (M_w/M_n) of the polymer remains virtually unchanged over the conversion range 4–48%, being equal to 1.7–1.8 (Table 2).

With the conversion increasing further, the polydispersity of PVC grows, but remains considerably lower than that in ordinary radical polymerization [77, 80]. In this case, M_w/M_n = 2.2 at 89% conversion (Table 2). A similar increase in the polydispersity has been observed at a conversion of 50% and more in polymerization of acrylic monomers through the pseudoliving chain mechanism in the presence of triphenylmethyl radicals [81, 82], suggesting a decrease in the contribution of pseudoliving polymerization to the polymer formation at high degrees of conversion. It is known that, in the case of ordinary radical polymerization of VC, the molecular weight of PVC remains unchanged throughout the process [4, 7], and no shift of the molecular-weight distribution mode toward higher molecular weights is observed [4, 7, 83].

To obtain additional evidence in favor of the pseudoliving mechanism of VC polymerization in the presence of BPN, we performed postpolymerization of VC [80]. A fresh portion of VC was added to PVC obtained in the presence of BPN, and polymerization was carried out in the same mode. The MWD patterns of the samples obtained by postpolymerization were unimodal, as in the case of PVC synthesized in the presence of BPN, and, with the conversion increasing in the course of postpolymerization, the mode continued to shift steadily toward higher molecular weights. Table 2 shows that, in this case, the molecular weight of PVC increases, and the polydispersity of the polymer obtained by postpolymerization in the presence of BPN (sample nos. 7 and 8) is well comparable with that of PVC at high degree of conversion (sample no. 6). The results obtained on polymerization of VC in the presence of BPN open the door for controlled chain growth and production of PVC with prescribed molecular-weight characteristics under ordinary industrial conditions. It is well known [73] that, in postpolymerization and synthesis of block and star copolymers, living cationic and anionic polymerization processes are used. Using the pseudoliving chain mechanism in radical polymerization of VC is the tool for extension of its practical use to, e.g., synthesis of PVC with wide range of M under ordinary industrial conditions.

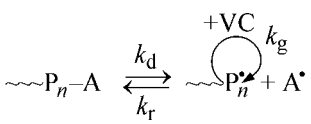
On the basis of the available experimental data, the following scheme of chain propagation in the presence of BPN has been suggested [76, 80]. In the first stage, BPN reacts with the growing macroradicals (~$P_n^{\bullet}$) to form stable nitroxyl radicals ($A^{\bullet}$):



$$\sim P_n^{\bullet} + Ph{-}C(H)=N(\downarrow O){-}C_4H_9 \rightarrow \sim P_n{-}CH(Ph){-}N(\downarrow O^{\bullet}){-}C_4H_9 \quad (A^{\bullet})$$

$$\sim P_n^{\bullet} + A^{\bullet} \rightleftarrows \sim P_n{-}A$$

Then the nitroxyl spin adducts ($A^{\bullet}$) react with growing radicals (~$P_n^{\bullet}$) to give labile terminal groups. This reversible reaction causes alteration of the "sleep" and "watch" periods in the "life" of the polymeric radical. In this case, chain growth proceeds through successive addition of monomer molecules to the macroradical (radical initiation). By analogy with polymerization of acrylic monomers through the living-chain mechanism [84], synthesis of PVC in the presence of nitroxyl spin adducts or their sources can be represented as



$$\sim\sim P_n{-}A \underset{k_r}{\overset{k_d}{\rightleftharpoons}} \sim\sim P_n^{\bullet} + A^{\bullet} \quad (+VC,\ k_g)$$

where k_d is the dissociation rate constant of the adduct ~P_n–A; k_r, the recombination rate constant of the radials $P_n^{\bullet}$ and $A^{\bullet}$; k_g, the growth rate constant.

CONCLUSION

The above analysis revealed the considerable recent progress in directed synthesis of PVC. Addition of ultralow concentrations of reactive additives allows significant and, what is the most important, directed modification of the reactivity of macroradicals and control of polymer chain growth. It is of primary importance that some organoelement compounds and spin traps are reactive under mild temperature conditions, being taken in a concentration comparable with that of the initiator.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Separation of Alkali Metals

I. A. Tikhomirov, A. A. Orlov, and D. G. Vidyaev

Tomsk Polytechnic University, Tomsk, Russia

Received April 26, 2002

Abstract—A new gallam-exchange technique for separation of alkali metals was developed. The alkali metal separation factors were determined for the gallam-exchange systems LiGa–NaOH, LiGa–KOH, and KGa–NaOH. The effect of temperature and concentration of the exchanging phases on the separation factors were studied for the systems LiGa–NaOH and LiGa–KOH. Kinetic parameters of lithium, sodium, and potassium element exchanges were determined. The properties of gallam-exchange and amalgam-exchange systems were compared.

At present, special-purity materials find increasing use in technology; the requirements to these materials are growing steadily. Special purity is necessary in certain cases for alkali metals.

In practice, alkali metals are separated and purified by the amalgam-exchange technique [1, 2]. Its main disadvantage consists in that it uses large amounts of highly toxic mercury, which results in environment contamination and makes more complicated the equipment and safety measures in the separation industry. In this context, studies aimed to develop high-performance and environmentally safe methods for separation of alkali metals become topical.

An environmentally safe gallam-exchange technique for purification and separation of alkali metals, in which an intermetallic compound of gallium and alkali metal, gallam, is used instead of amalgam, was developed in [3].

The present study is concerned with separation of alkali metal pairs, Li and Na, Li and K, Na and K, in exchange between a gallam and a hydroxide solution of one of these metals.

Typical parameters of the efficiency of one or another separation technique and, in particular, of the gallam exchange, are the separation factor α and kinetic parameters of the exchange and decomposition of an intermetallic compound (gallam) brought in contact with aqueous solutions of an alkali metal hydroxide. The exchange rate depends on the rate of interfacial electrochemical reactions and on the rate of reagent supply from the bulk of the phases to the interface. Therefore, the aim of the study was to determine the separation factors for the indicated pairs of alkali metals and the kinetic parameters of the exchange process and thus to evaluate the efficiency of gallam-exchange systems in separation and purification of alkali metals.

EXPERIMENTAL

The gallam used in the experiments was obtained by direct dissolution of metallic lithium of LE-1 brand in chemically pure gallium (99.99% of the main substance) [3]. Hydroxide solutions were prepared from chemically pure NaOH and KOH and distilled water.

The experimental laboratory installation is shown schematically in Fig. 1. The exchange was studied in

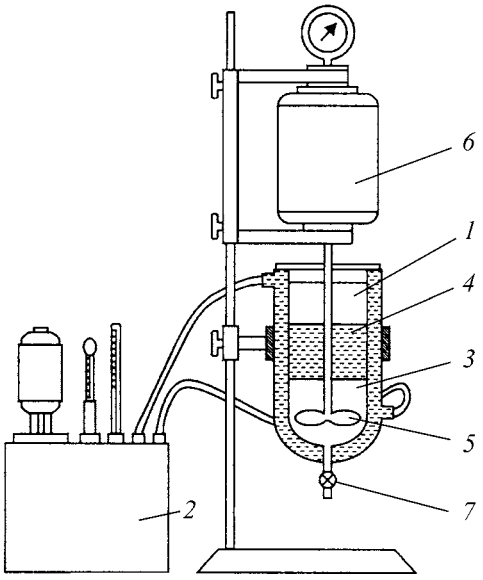

Fig. 1. Schematic of experimental laboratory installation.

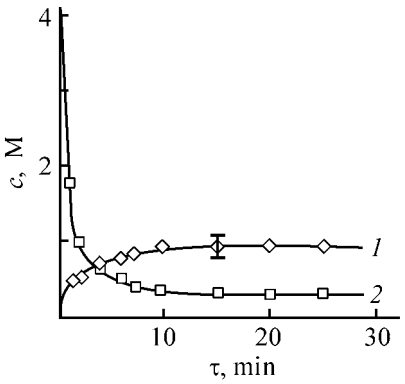

Fig. 2. Variation of sodium content c in (*1*) lithium gallam and (*2*) sodium hydroxide solution in the course of the exchange. Initial concentration of gallam 0.95 M, and that of hydroxide solution 4.0 M; temperature 40°C. (τ) Time.

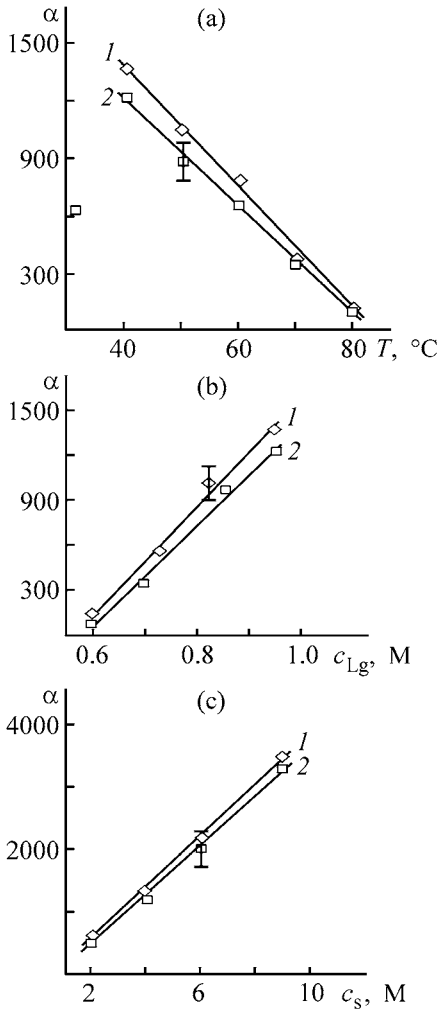

Fig. 3. Separation factor α vs. (a) temperature T, (b) concentration c_{Lg} of lithium gallam, and (c) concentration c_s of hydroxide solutions. Initial concentration of gallam (a, c) 0.95 M, (a, b) that of hydroxide solutions 4.0 M, (b, c) temperature 40°C. System: (*1*) LiGa–NaOH and (*2*) LiGa–KOH; the same for Fig. 4.

a cylindrical cell *1* 30 mm in diameter, equipped with a water-jacket. Thermostat *2* maintained a constant temperature. In the course of the experiments, gallam *3* was poured in a beaker and then hydroxide solution *4* was added. Phases were mixed by a propeller stirrer *5* rotated by electric motor *6* at a rate of 750–800 rpm. The gallam was not dispersed in the course of stirring. The phase contact area was calculated as the area of the cone formed in stirrer rotation at the gallam–solution interface.

After a run was complete, the hydroxide solution was sampled from the upper part of the exchange cell, and the gallam was discharged through a stop-cock *7* and decomposed with distilled water. The content of the components being separated was determined using an FPA-2 flame photometer in the solution obtained upon the gallam decomposition and in the hydroxide solution sampled from the exchange cell.

The experiments have shown that the equilibrium in the LiGa–NaOH, LiGa–KOH, and NaGa–KOH systems is attained within ca. 15 min. The typical shape of curves characterizing the kinetics of equilibration in the LiGa–NaOH system is shown in Fig. 2. The separation factor α was calculated for all the systems from the results of experiments performed under varied initial conditions. Each experiment was carried out in two replications. The separation factors for the Li and Na and Li and K pairs in the corresponding gallam-exchange systems were found to depend on temperature and on concentrations of the gallam and the alkali solution. The influence of these factors is shown in Figs. 3a–3c.

The experiments with the KGa–NaOH system were carried out only at 40°C and the following starting concentrations of the reacting phases (M): potassium gallam 0.92 and sodium hydroxide solution 4.0. The value of α was 1.7 under these conditions.

The kinetic parameters (rate constant of the exchange reaction, exchange current density, and half-exchange time) of the alkali metal (lithium, sodium, and potassium) exchange processes were calculated for all the systems by the known technique [2, 4, 5].

The experimental values of the kinetic parameters of the exchange processes for the LiGa–NaOH and LiGa–KOH systems are shown in the table.

The following values of the kinetic parameters were obtained for the KGa–NaOH system: τ_e = 39 s, I_e = 30.22 kA m^{-2}, and K_e = 1.51 × 10^{-2} cm s^{-1}.

The plots in the ln K_e–$10^3/T$ coordinates are straight lines (Fig. 4). Consequently, the rate constant of el-

Kinetic parameters of exchange between lithium gallam and aqueous solutions of sodium and potassium hydroxide at various temperatures

Parameter*	Temperature, °C					Parameter*	Temperature, °C

* (τ) Half-exchange time, (I_e) exchange current density, and (K_e) rate constant of exchange.

ement exchange is expressed within the temperature range under study by the Arrhenius equation

$$\ln K_e = -\frac{E_e}{RT} + K'_e,$$

Here E_e is the activation energy of the element exchange reaction (J mol^{-1}); R, the gas constant (J mol^{-1} K^{-1}); K_e, the exchange rate constant (cm s^{-1}); K'_e, the integration constant (cm s^{-1}); T, the absolute temperature.

For the LiGa–NaOH and LiGa–KOH systems, we determined the activation energies of the exchange reactions, E_e (kJ mol^{-1}), and integration constants K'_e (cm s^{-1}) to be 13.44 ± 0.76, 1.18 and 14.13 ± 1.10, 1.48, respectively.

Comparison of the rate constants of the element exchange in the LiGa–NaOH, LiGa–KOH, and KGa–NaOH systems suggests that the exchange rates in all the systems are approximately equal at 40°C. In addition, the exchange current densities in all the systems under study are rather high, up to tens of kiloamperes per square meter.

A comparison of the results obtained with the data [3, 6] on the kinetics of decomposition of a gallam brought in contact with hydroxide aqueous solutions showed that the ratio K_e/K_d (K_d is the rate constant of gallam decomposition) for the LiGa–NaOH and LiGa–KOH systems varies within the temperature range under study from 40.9 and 39.9 at 80°C to 77.2 and 76.3 at 40°C, respectively. For the KGa–NaOH system, the K_e/K_d ratio was 70.6. Consequently, the rate of exchange in these systems is much higher than the rate of decomposition, which allows us to maintain that a manyfold multiplication of the single-stage separation effect is possible in this case.

Comparison of the kinetic parameters of alkali metal exchange in the gallam-exchange systems LiGa–NaOH, LiGa–KOH, and KGa–NaOH with similar data for amalgam-exchange systems [1, 2] shows that the rates of element exchange in the gallam and corresponding amalgam systems are approximately equal.

In the gallam systems LiGa–NaOH and LiGa–KOH, the values of α at 40°C are nearly an order of magnitude lower than those in similar amalgam systems at 20°C [1]. However, the high separation factors in gallam systems make it possible to achieve an appreciable separation of alkali metals (95–99%) even in a single exchange process.

The separation factor for the gallam system KGa–NaOH at 40°C is approximately half that in the corresponding amalgam system at 20°C [2]. However, the rate of the element exchange in this system is significantly higher than the rate of potassium gallam decomposition, which allows a manyfold enhancement of the single-stage separation effect.

On the whole, the good kinetics of the element exchange, high separation factors of alkali metals (lithium, potassium, and sodium) in the gallam-ex-

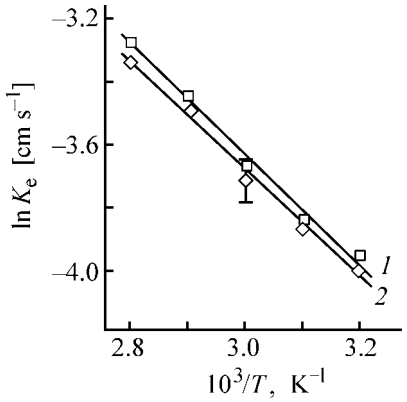

Fig. 4. Dependence of exchange rate constant K_e on temperature T. Starting concentration of gallam 0.95 M, that of hydroxide solutions 4.0 M.

change systems under study, and the environmental safety of the gallam technique show its promise for separation and purification of alkali metals (lithium, sodium, and potassium).

CONCLUSIONS

(1) Separation factors of alkali metals in the gallam systems investigated decrease with increasing temperature. Raising the concentrations of exchanging phases leads to higher α.

(2) The rate of exchange of alkali metals increases with temperature and significantly exceeds the rate of their decomposition within the temperature range investigated, which allows manyfold enhancement of the single-stage separation effect.

(3) The separation factors of alkali metals in gallam systems at 40°C are approximately an order of magnitude lower than those in similar amalgam systems at 20°C.

(4) The exchange rate of alkali metals in gallam systems is comparable with that of the same metals in amalgam systems.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Composition and Physicochemical Properties of Cobalt Molybdophosphates

N. I. Radishevskaya, L. A. Egorova, and V. V. Kozik

Department of Macrokinetics, Tomsk Scientific Center, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received June 19, 2002; in final form, January, 2003

Abstract—Cobalt molybdophosphates were synthesized. The composition of the compounds was confirmed by IR spectral, thermogravimetric, X-ray phase, and atomic-emission analyses. The influence of the composition on the thermochromic properties of the compounds was demonstrated.

Recently, the interest in iso- and heteropoly compounds, whose structural features and nature of chemical bonding govern a wide variety of physicochemical and functional properties, has increased considerably. Their structure and conditions of their preparation are being studied intensively.

Heteropoly compounds of transition metals are of scientific and practical interest. Introduction of a cation with variable oxidation state makes it possible to obtain new inorganic materials with charge transfer [1].

The present communication reports the results obtained in studying preparation conditions and thermal stability of cobalt molybdophosphates.

Cobalt heteropoly molybdates were synthesized from weakly acid aqueous solutions by methods: from 12-molybdophosphoric acid and from molybdenum(VI) oxide (alkaline fusion), sodium hydrophosphate, and cobalt(II) chloride.

The composition and structure of the obtained substances were identified by differential thermal [Q 1500 derivatograph (Hungary), heating rate 10 deg min^{-1}] and X-ray phase (DRON-3M installation) analyses. The incorporation of phosphorus in the composition of the salts was confirmed by atomic emission analysis (ISP-30 spectrograph). The content of chloride ions in the solid phase was determined by mercurimetry. The type of heteropoly anions was established by IR spectroscopy in the range 4000–400 cm^{-1} (Specord M-80, KBr pellets). The energy gap was calculated from reflection spectra (Specord M-40).

The reaction of 12-molybdophosphoric acid with a minor excess of cobalt(II) chloride at pH 5–6 results in precipitation of a lilac-colored lacunar form of cobalt(II) 11-molybdophosphate $Co_2H_3[PMo_{11}O_{39}] \cdot 11H_2O \cdot 2HCl$ from solution, with a dark gray substance formed at the solution–air boundary. The compound obtained by the reaction of MoO_3 with $CoCl_2$ in a nearly neutral medium can also be identified as cobalt(II) 11-molybdophosphate with composition $Co_2H_3[PMo_{11}O_{39}] \cdot 20H_2O \cdot 3HCl$. The results obtained in studying the effect of the pH of the medium, nature of initial components, and synthesis conditions on the formation of cobalt heteropoly compounds are listed in Table 1.

Cobalt molybdophosphates obtained by the two methods described have similar IR absorption spectra (Fig. 1). The stretching and bending vibrations ν(Mo=O), ν(P–O), ν(Mo–O), ν(Mo–O–Mo), ν(–O–),

Table 1. Effect of the nature of initial reagents and synthesis conditions on the product composition P : Mo = 1 : 12, pH 5–6

and δ(P–O) at 960, 910, 870, 815, 720, 510 cm^{-1}, respectively, characterize the formation of Keggin-type structures [2].

The stretching P–O vibration, which appears in the IR spectrum of $[PMo_{12}O_{40}]^{3-}$ as a high-intensity band at 1060 cm^{-1}, is split into two components (1080, 1050 cm^{-1}) in the case of the lacunar form $[PMo_{11}O_{39}]^{7-}$ [3].

The bands at 845, 670, and 620 cm^{-1} correspond to stretching vibrations ν(Co–O) bond, and the band at 420 cm^{-1}, to ν(Co–Cl).

Vibrations ν(–OH) of surface OH groups bound to cobalt are observed at 3710 cm^{-1} [4, 5].

Cobalt salts obtained by precipitation with cobalt(II) chloride from molybdophosphoric acid solutions decompose under heating in the same way as $H_3[PMo_{12}O_{40}] \cdot nH_2O$ acid does. Two endothermic effects corresponding to loss of adsorbed and crystallization water are observed in the range 50–150°C (Fig. 2). According to our calculations, the loss of substance corresponds to 11 mol of water per 1 mol of the compound. The activation energy of dehydration is 53 kJ mol^{-1}, the reaction is first-order. An endothermic effect accompanied by removal of water from the inner coordination sphere is observed at 335°C. This is confirmed by the shift of the characteristic frequencies in the IR spectra of samples annealed at 500°C as compared with the initial sample (Fig. 1). After thermolysis, a strong absorption band at 940 cm^{-1} and a high-intensity peak at 600 cm^{-1}, which correspond to, respectively, stretching vibrations of the MoO_2^{2+} group and bending vibrations δ(O–P–O) in the $P_2O_7^{4-}$ group, appear in the IR spectrum of the salt. Also, a slight rise in the intensity of the peak at 420 cm^{-1}, associated with stretching vibrations ν(Co–Cl), is observed. The absorption band ν(Co–O) at 845 cm^{-1} is retained. The absorption bands at 820 and 780 cm^{-1} are attributable to asymmetric stretching vibrations ν(Mo–O) of the tetrahedral $[MoO_4]^{2-}$ group. The intensity of the peak associated with vibrations of the bridging oxygen in the octahedral group decreases substantially and the peak is shifted from 740 to 700 cm^{-1} (shoulder at 700 cm^{-1}). This points to thermal decomposition of the original structure of the heteropoly salt.

The cobalt salt obtained from MoO_3, Na_2HPO_4, and $CoCl_2$ decomposes in a single stage, which apparently involves loss of water. The salt is a mixture of cobalt and dioxomolybdenum(VI) chlorides, phosphates, and molybdates. Thermogravimetric calcula-

tion shows that the salt contains 20 H_2O molecules. The activation energy of dehydration is 110 kJ mol^{-1}, the reaction is first-order. The decomposition yields mostly the $(MoO_2)(HPO_4)$ and $CoMoO_4$ phases. This is confirmed by analysis of the characteristic frequencies in the IR spectral range. A strong absorption band of the MoO_2^{2+} group is observed at 940 cm^{-1}. Broad peaks corresponding to stretching and bending vibrations of the HPO_4^{2-} group appear at 1000–1200 and 550–650 cm^{-1}. The intensity of the absorption band ν(Co–Cl) at 420 cm^{-1} slightly increases. The intensity of the absorption band associated with vibrations of the bridging oxygen decreases and the band is shifted from 740 to 710 cm^{-1}. The spectra of cobalt(II) molybdophosphates synthesized by the two methods show a significant decrease in the intensity of the peak at 3600–3000 cm^{-1}, which is characteristic of stretching vibrations of adsorbed and crystallization water, after annealing. The absorption band ν(OH) at 3700 cm^{-1} is shifted to 3680 cm^{-1}. The intensities of the peaks corresponding to bending vibrations of OH groups [4–6] change as follows: that of the peak at 1640 cm^{-1} decreases considerably, and the absorption at 1450 cm^{-1} disappears completely. The data obtained are in agreement with the results of [7].

The differences observed in thermal decomposition of salts of cobalt 12-molybdophosphates synthesized in the two ways are clearly seen in the DTA curves. In the first case, absorbed and crystallization water is lost in two stages, and in the second, in a single stage. However, when the salt synthesized from 12-molybdophosphoric acid is subjected to thermolysis, loss of water is observed at 350–400°C. Presumably, this water is removed from the inner coordination sphere. An X-ray phase analysis demonstrated that cobalt 11-molybdophosphates prepared in different ways have virtually identical X-ray diffraction patterns.

When molybdophosphoric acid reacts with cobalt(II) chloride, a dark gray substance is formed at the solution–air boundary, which is due to a redox reaction in air, in which the oxidation states change from Co^{2+} to Co^{3+} and from O_2^0 to O^{2-}. MoO_2Cl_2 and $NaCo^{2+}Co^{3+}(MoO_4)_3 \cdot 4H_2O$ are formed, which was confirmed by X-ray phase analysis.

The content of chloride ions in cobalt 11-molybdophosphates, determined by mercurimetry, is listed in Table 2.

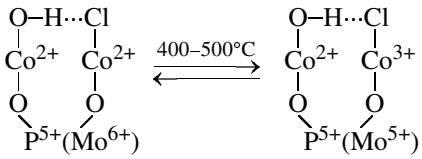
The results of atomic-emission analysis of cobalt 11-molybdophosphates obtained by the two methods indicate that phosphorus does enter into the composition of the salts (approximately 1.5 wt %).

Table 2. Content of chloride ions in cobalt molybdophosphates (pH 5–6)

Salt	Cl^-, mg l^{-1}	Cl^- in heteropoly salt, mol
$Co_2H_3[PMo_{11}O_{39}] \cdot 11H_2O \cdot 2HCl$ (from acid)	3.5	2
$Co_2H_3[PMo_{11}O_{39}] \cdot 20H_2O \cdot 3HCl$ (from MoO_3)	5.3	3

The cobalt salts obtained possess thermochromic properties and have a Keggin-type lacunar structure, with their color varying from lilac to dark gray. The temperature at which the salts change their color before and after annealing is 400–450°C.

The thermally reversible change of color by the compounds obtained is attributable to the previously suggested mechanism of charge transfer via the inner-sphere redox process



Thus, the reversible change of color of the compounds under consideration, which is observed at 400–450°C, is associated with electron transfer along the chain

$$Co^{2(3)+}—O—Mo^{6(5)+}.$$

When the temperature is raised, Co^{2+} is oxidized to Co^{3+}, and Mo^{6+}, reduced to Mo^{5+}. In the case when the temperature is lowered, a reverse electron transfer takes place.

Compounds obtained under similar conditions from cobalt(II) salts with another anion exhibit no thermochromic properties, which may result from different positions of the chloride and other ligands in the spectrochemical series for Co(II)/Co(III). The cobalt(II) molybdophosphates obtained belong to wide-bandgap semiconducting materials. The energy gap calculated from reflection spectra in the visible spectral range is 2.55 eV for molybdophosphoric acid and varies for cobalt salts from 3.23 (salts obtained from the acid) to 3.47 eV (salts obtained from MoO_3). The structure indicated undergoes irreversible destruction above 500°C, with loss of thermochromic properties.

CONCLUSIONS

(1) Cobalt heteropoly salts $Co_2H_3[PMo_{11}O_{39}] \cdot 11H_2O \cdot 2HCl$ and $Co_2H_3[PMo_{11}O_{39}] \cdot 20H_2O \cdot 3HCl$ synthesized in aqueous solutions at nearly neutral pH have a Keggin-type lacunar structure.

(2) The compounds obtained are wide-bandgap semiconductors and can be used as thermochromic materials. Cobalt(II) molybdophosphates change coloration reversibly. The thermochromic properties of cobalt 11-molybdophosphates are preserved after multiple annealing of the salts.

Abstract—The structure of cleaved mica particles and the influence of cleavage conditions on surface properties of mica were studied by IR spectroscopy.

In recent years, there has been considerably increased interest in processing of mining tailings, whose utilization frequently yields products that are in short supply.

The consumption of raw mica is mainly limited to large-plate phlogopite and muscovite, which are starting materials for radio electronics and radio engineering. At the same time, demand for fine (small-size) mica is virtually absent.

The problem of full utilization of mica raw materials can be solved solely by developing new technologies for utilization of small mica fractions, now going to wastes. It is known that the crystal size is not an important parameter for pigments used in manufacture of paint-and-varnish materials, rubber fillers, and plastics [1]. The finer the initial mica, the lower the amount of energy consumed for its cleavage and grinding, and the cheaper the final product obtained.

Splitting and grinding of mica is accompanied by destruction of the interlayer space, with deformation or destruction of the crystal lattice and the resulting change in the surface properties of mica, owing to the appearance of an uncompensated structural charge [2]. These changes determine the quality of ground micas and the possible field of their use.

The aim of this study was to analyze structural changes and surface properties of phlogopite and muscovite cleaved by different methods.

EXPERIMENTAL

Phlogopite used in the study was obtained from mica-ore-dressing tails of the Kovdor deposit, and and muscovite was a by-product of mica production in Karelia. The starting material consisting of 1×2-cm^2 plates was subjected to chemical and electrochemical cleavage and then ground on a ball mill in wet mode. The <63-μm fraction was used in the study.

In chemical cleavage, mica was treated with 0.5 M sulfuric acid for 120 h [3]. Leaching of the structure-forming (cross-linking) elements disturbs the neutral charge of a mica pack and leads to its cleavage. Electrochemical cleavage [4] is based on leaching of potassium ions into the liquid phase on applying a potential difference to an aqueous mica suspension, with the mica pack disrupted by the uncompensated charge of the cleavage planes.

The cleaved mica was studied by the diffusion reflection IR Fourier spectroscopy. The chemical composition of the samples was determined with an ICP–QMS mass-spectrometer. The crystallinity of structure was characterized using a Siemens D 5000 diffractometer, and the specific surface area was measured by the BET method on a Micrometric 2000 instrument. The liquid phase was analyzed with a Perkin–Elmer 3100 atomic-adsorption spectrometer, and the degree of recovery of the components into solution was calculated.

The data presented in Fig. 1 give insight into the behavior of the main cross-linking cations of mica in its splitting. Evidently, the degree of cation leaching is higher in chemical treatment, compared with electrochemical treatment in a neutral medium. Irrespective of a cleavage method, the degree of leaching of octahedral cations exceeds that for tetrahedral cations. The decrease in the specific surface area S_{sp} of

the electrochemically cleaved particles (see table) is due to a decrease in their thickness, which results from more complete splitting and smoothening of their surface. S_{sp} of the chemically cleaved samples increases twofold as compared with the initial value. Micrographs of particles of this kind (Fig. 2b) indicate that their edges are corroded because of the partial splitting and the resulting formation of new basal surfaces.

after electrochemical cleavage	4.5	2.13
after chemical cleavage	12.67	14.65

A spectroscopic study demonstrated that the loss of large cations into the liquid medium is closely related to changes in the octahedral and tetrahedral layers of mica. For cleaved muscovite (Fig. 3a), the intensity of vibrations at 3600 cm^{-1}, associated with intrasphere bonds, e.g., AlOH, grows [5]. It has been confirmed that the intensity of this band is independent of crystal orientation [6]. Muscovite cleavage in an aqueous medium as a result of deformation distortions and loss of potassium ions facilitates proton incorporation into the structure to give a hydroxonium ion for compensating the charge in a tetrahedron. For chemically cleaved muscovite, the band due to low-frequency stretching vibrations of OH^- groups at 3315 cm^{-1} is revealed more clearly, and the set of peaks in the 1800–1537 cm^{-1} range is due to bending vibrations of adsorbed water molecules.

Strong adsorption bands in the 1000–1025 cm^{-1} range belong to Si–O stretching vibrations and are

weakly related to the lattice vibration bonds. By contrast, the Si–O vibration bonds characterized by bands at 400–550 and 750 cm^{-1} are strongly related to other vibration bonds [7]. The rise in the intensity of the 750 cm^{-1} band and the low-frequency shift of the 536 cm^{-1} band, which are associated with Si–O–Al tetrahedral vibrations [8], result from an increase in the Si–O–Al bond length and point to deformation of the tetrahedral layer. The increase in the intensity of the 930 cm^{-1} band results from a decrease in the magnesium(II) content in the octahedral environment. The appearance of a clearly pronounced band at 1062 cm^{-1} is due to asymmetric vibrations of the Si–O–Si bond. Evidently, fast exchange reactions between the potassium ions and the proton in chemical cleavage are accompanied by hydroxylation of the tetrahedron vertex and rupture of the bond between the oxygen atom of silicon-oxygen tetrahedron and the octahedral cation. Leaching of octahedral magnesium(II) cations and aluminum(III) leads to weakening of siloxane bonds and promotes loss of silicon(IV) from the tetrahedral layers. In electrochemical cleavage in neutral media, the mobility of octahedral cations and aluminum(III) decreases, and loss of silicon(IV) into solution is hindered by slow rupture of aluminum bonds in the lattice. On the whole, it was noted that, irrespective of muscovite cleavage conditions, formation of hydrated forms of the starting layered structure is observed, with all basic structural characteristics of the starting phase retained. This is confirmed by the X-ray diffraction pattern demonstrating only a slight redistribution of the reflection intensities, which is associated with the defectiveness of the structure (Fig. 4).

For cleaved phlogopite (Fig. 3b), no significant changes in the range of OH^- group vibrations was observed. This is so because the loss of K^+ from the mineral is commonly accompanied by oxidation $Fe^{2+} \rightarrow Fe^{3+}$ [9], and there is no need for protonation of surface groups to neutralize the negative charge. The weak band at 3664 cm^{-1} in the spectra of the starting and cleaved phlogopite reflects the presence of Fe(III) in the octahedral position. For electrochemically cleaved mica, an increase in the intensity of the 1650 cm^{-1} peak corresponding to bending vibrations of water was observed. In chemical cleavage, changes in the tetrahedral layer manifest themselves in a low-frequency shift of the Si–O stretching vibration band at 985 cm^{-1}, resulting from the increase in the Si–Al–O bond length and appearance of a new band at 1041 cm^{-1}, associated with asymmetric vibrations of the Si–O–Si bond. The band at 456 cm^{-1} can be ascribed to the $Si–O–M^{2+}_{tetr}$ (M = Mg, Fe) bond

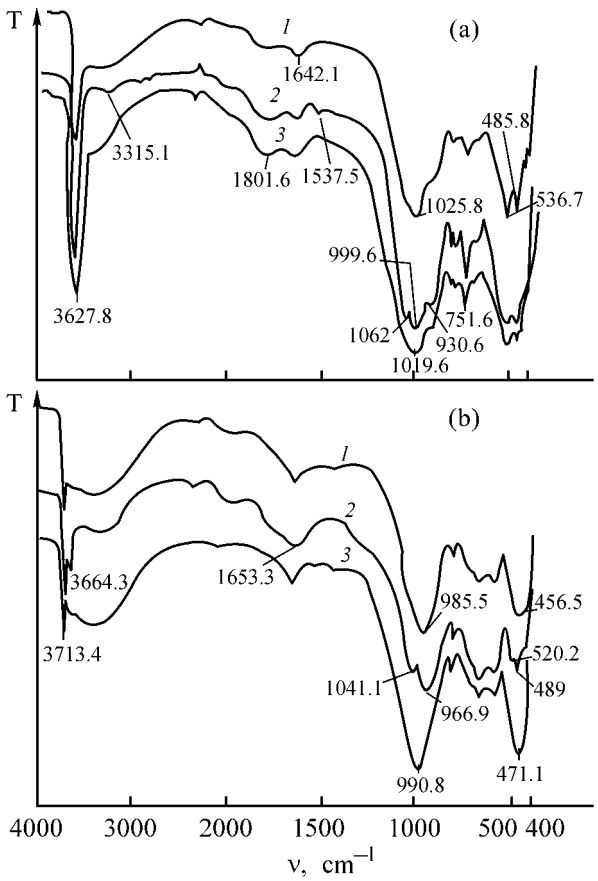

Fig. 3. IR spectra of (a) muscovite and (b) phlogopite. (T) Transmission and (ν) wave number. Mineral: (*1*) initial and after (*2*) electrochemical and (*3*) chemical cleavage.

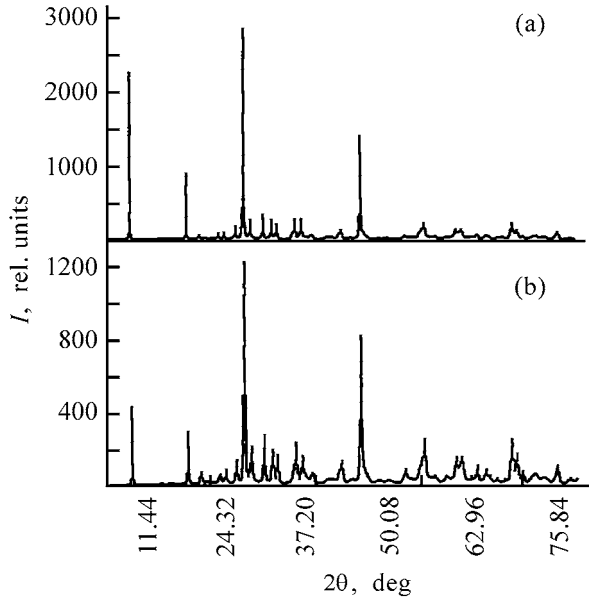

Fig. 4. X-ray diffraction patterns of muscovite. (*I*) Intensity and (2θ) Bragg angle. Mineral: (a) initial and (b) after electrochemical cleavage.

[10]. In iron(III) oxidation, this band is observed at 520 cm^{-1}, and the Si–O–Mg bond is manifested at lower frequencies, which is due to the increased length of the M^{2+}–O–Si bond and to its more polar character.

Thus, the cleavage of mica leads to the structural changes in mica particles (formation of hydrated forms, isomorphic substitutions in octahedral layers, and deformation distortion in tetrahedral layers), which can affect mica properties. In particular, the appearance of an uncompensated structural charge on the basal surface as a result of isomorphic substitution enhances the ion-exchange and sorption properties of such minerals.

Use of finely ground mica as a pigment imposes stringent requirements upon the state of the surface of mica particles [11]. A scanning spectral analysis of the mica surface demonstrated that nonuniform dissolution of the basal and lateral surfaces of minerals occurs in chemical cleavage (Fig. 5). This leads to defect formation and edge corrosion. Deposition of a titanium coating onto such particles yields pigments that are nonuniform across their thickness, which impairs their optical properties and, consequently, quality.

CONCLUSIONS

(1) The crystal structure of mica cleaved by different methods was studied by IR spectroscopy. Cleavage of mica leads to changes in the octahedral and tetrahedral layers. In addition, protonation of aluminum bonds, caused by leaching of interlayer potassium ions, was observed for muscovite.

(2) Chemical treatment causes corrosion of edges of cleaved particles. This results from different rates of dissolution of their basal and lateral surfaces.

ACKNOWLEDGMENTS

The study was supported financially by the Swedish Institute (Stockholm).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation of Stable Copper Dispersions by Redox Reactions of Cu(II) Salts with Sulfur-containing Reducing Agents and Properties of the Dispersions

I. N. Terskaya, V. V. Budanov, and L. V. Ermolina

Ivanovo State University of Chemical Engineering, Ivanovo, Russia

Received November 13, 2002

Abstract—A procedure was developed for preparing copper dispersions that can be used as catalytic systems in electroless metallization of insulators by chemical reduction of Cu(II) salts with sodium hydroxymethanesulfinate (rongalite) or thiourea dioxide in aqueous-alcoholic media.

Chemical precipitation of metals is widely used to obtain sols [1, 2]. Conventional reducing agents used for this purpose are aluminum hydride, borohydride, aminoborane, and hypophosphite [3, 4]. However, sols of metals obtained with the use of these reducing agents contain significant amounts of impurities and have a broad particle size distribution. It is known [3, 5, 6] that colloids of most metals are rapidly oxidized by atmospheric oxygen, water, and other oxidants. This impairs the stability and catalytic activity of colloid solutions and makes difficult their practical use.

It has been found previously that sodium hydroxymethanesulfinate (HMS) $HOCH_2SO_2Na$ and thiourea dioxide (TUDO) $(NH_2)_2CSO_2$ are effective reducing agents for metal ions [7]. Chemical reactions of HMS or TUDO with Cu^{2+} and Ni^{2+} ions yield high-purity (up to 99.9% metal) precipitates of the metals with particle size of up to 1 μm for Cu and 0.5 μm for Ni, with the introduction of an alcohol (butanol or decanol) into the reaction system increasing the degree of dispersion of the resulting powders. In this context, it was of interest to study the possibility of improving the aggregative stability of the above-mentioned dispersions with the purpose of obtaining stable systems. This communication reports the results obtained in a study of HMS and TUDO application for obtaining metal dispersions with rather high aggregative stability and controllable degree of dispersion.

EXPERIMENTAL

Copper dispersions were prepared as follows. An aqueous solution of $CuSO_4$ was added to an aqueous solution of TUDO or HMS (chemically pure salts). Thiourea dioxide was prepared from chemically pure thiourea by oxidation with hydrogen peroxide according to the known technique [8], or a commercial-grade product was used after twofold recrystallization from water. Sodium hydroxymethanesulfinate was also obtained from a commercial-grade product by twofold recrystallization from water. The concentration of a metal salt was varied within the limits 5×10^{-3}–5×10^{-2} M, and the concentration of a reducing agent was selected so that its 10–20-fold excess was provided. The reduction reaction was carried out in glass temperature-controlled vessels at fixed temperature (40–80°C). To stabilize the resulting dispersions, protective colloids (gelatin, agar-agar, polyvinyl alcohol, glycerol, and also alcohols, such as butanol and decanol) were added to a solution in various proportions (from 0.5 up to 10 vol %).

Spectra of the copper dispersions were taken on a Specol-210 spectrophotometer. The particle size was determined by turbidimetry [9], using the theory of light scattering in disperse systems, for which Rayleigh's equation does not hold. The particle radii were calculated by Heller's empirical equation [9]. The sizes and amounts of particles were also determined using a Tesla BS-300 electron microscope. Both the methods yielded average sizes of particles coinciding to the first significant digit.

The formation of a copper dispersion was judged from the appearance of a characteristic red-brown coloration and from the presence of Tyndall's cone. The stability of the dispersion was characterized by the period of time from the instant of its prepara-

0.5	"	Gelatin	5 day

tion to that of the onset of sedimentation. The variation of the degree of dispersion and that of the particle size of a dispersed phase with time were monitored in parallel.

It is known [3] that colloid solutions can be formed in organic media, and use of microemulsions is a promising way to obtain colloids with controllable degree of dispersion.

Table 1 lists data on the effect of solvent composition and reducing agent (HMS and TUDO) concentrations on the stability of the dispersions[1] under study. It can be seen that the dispersion of Cu^0, which retains stability for 25 days, is formed when Cu^{2+} is reduced in an aqueous-alcoholic medium (butanol concentration not exceeding 10 vol %) in an excess of a reducing agent (concentrations 0.1 and 0.5 M) at 313 K and in the presence of stabilizing additives. The thus obtained solutions have intense red-brown color and a typical absorption spectrum shown in Fig. 1, curves *4* and *5*. It was noted in [5] that a monodispersed colloid solution shows an absorption peak at wavelengths in the range 550–650 nm. Therefore, the presence of an absorption band at λ = 570 nm in the spectra (Fig. 1) indicates that the method suggested makes it possible to obtain a copper dispersion with rather narrow range of degrees of dispersion.

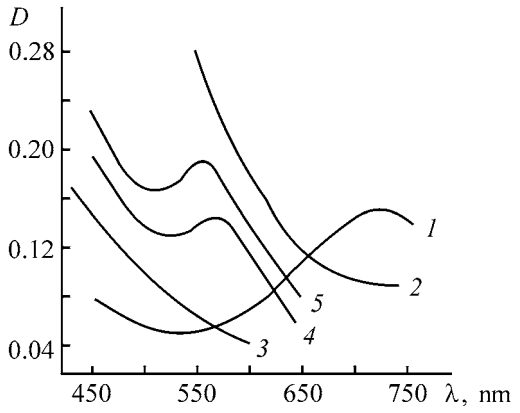

Fig. 1. Absorption spectra. D is optical density and λ is wavelength. Concentration: copper(II) 5×10^{-2}, TUDO 0.1 M; T = 298 K. (*1*) $CuCl_2$, aqueous solution; (*2*) TUDO, aqueous solution; (*3*) gelatin, aqueous solution (3 wt %); (*4*) solution of colloid copper in water–butanol medium (9 : 1); (*5*) solution of colloid copper in water–butanol (9 : 1)–gelatin (3 wt %) medium.

The electron-microscopic data (Figs. 2a and 2b) show that the use of gelatin additions allows the average size of dispersed phase particles to be decreased by an order of magnitude. In this case, the fraction of particles with average size of 1.5 μm constitutes approximately 90% of the dispersed phase weight, whereas in the absence of these additives (glycerol-water medium), the average size of copper particles is 20–30 μm, and the precipitate itself is more polydispersed (Fig. 2b).

It is necessary to note that the copper dispersions are stable up to 373 K; however, they abruptly lose aggregative stability upon dilution with water. With increasing HMS concentration, the stability of copper dispersions decreases, whereas the excess of TUDO does not affect its stability (Table 1). This is attributable to the fact that, unlike TUDO, HMS is a strong electrolyte (sodium salt of hydroxymethanesulfinic acid) [9].

Copper dispersions were found to change red-brown color for green under the action of light (λ = 350–780 nm). It is known that monodispersed systems are less stable against photooxidation than polydispersed systems [10]. The following processes are possible in solution under the action of light:

$$Cu^0(\text{polydispersed}) \overset{h\nu}{\rightleftharpoons} Cu^0(\text{monodispersed}), \quad (1)$$

$$Cu^0(\text{polydispersed}) \overset{h\nu}{\rightleftharpoons} Cu^+ + e. \quad (2)$$

The reversibility of process (2) is confirmed by the fact that the absorption spectrum of the solution

[1] Within the indicated life time of a system, the average size of dispersed phase particles, determined by electron microscopy, remained virtually constant.

obtained upon exposure of a copper dispersion to light is identical to that of a true Cu(I) solution. When the solution subjected to the action of light is placed in the dark, the red-brown color is not restored. However, heating of this solution yields a solution of dispersed copper again. Conceivably, this transition occurs either as a result of disproportionation

$$2Cu^{+} \xrightarrow{t} Cu^{0} + Cu^{2+}, \quad (3)$$

or under the action of a reducing agent

$$Cu^{+} + TUDO\,(HMS) \xrightarrow{t} Cu^{0}. \quad (4)$$

It is necessary to note that the rate of photooxidation of copper dispersions is essentially reduced when butanol is added to them, together with gelatin, during preparation. Probably, the stabilizing role of alcohols is due not only to specific solvation and suppression of diffusion processes, but also to their reducing properties.

It was noted in [10] that copper colloid solutions have high catalytic activity in oxidation of CO, various hydrocarbons, and methanol, and also in chemical metallization of fiber-glass laminate in manufacture of printed circuit boards and elastic screening and microwaves-reflecting materials based on metallized fabrics. Despite that solutions of colloid copper rank somewhat below palladium activators, they have several advantages: the number of operations is reduced because the intermediate stages of article washing after activation and the necessity for palladium recovery from sewage are eliminated, and also the possibility of decomposition of chemical-metallization solutions upon introduction of palladium-activated samples into a bath is ruled out.

Copper dispersions obtained by reduction of Cu(II) salts with HMS or TUDO were studied as activators for electroless nickel plating on carbon fibers and glass articles. The procedures are based on the reduction of Ni^{2+} ions from an ammine complex by the sulfur-containing reducing agents HMS and TUDO [11, 12]. The surface of samples was activated by various methods: by treatment with standard [based on palladium(II) or tin(II) salts] and copper colloid solutions stabilized with gelatin additions and also by treatment with low-temperature atmospheric plasma. It was found that that the activation of samples with a copper colloid solution yields metallic films with high adhesion strength: it was rather difficult to detach a film from the substrate surface by mechanical force (with a steel trowel). A comparative estimate of the effect of the activator nature on the strength of

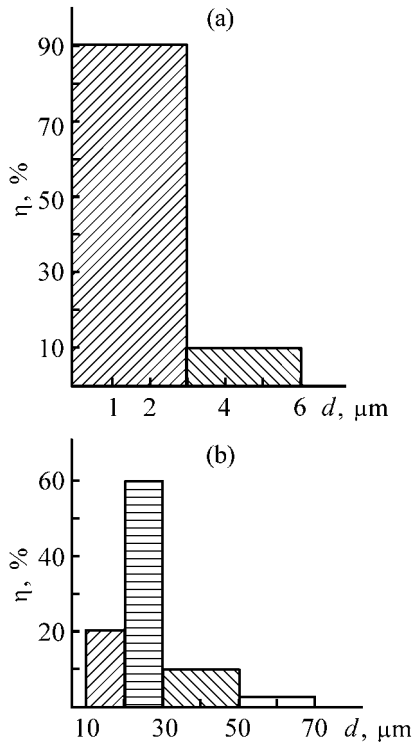

Fig. 2. Distribution of copper particles, η, with respect to size *d*. Medium: (a) 3% gelatin solution, (b) 50% glycerol solution.

adhesion of nickel films to a substrate was made using the "ultrasonic" method (UD-20 ultrasonic disintegrator). Nickel-plated samples were placed in a vessel with distilled water, so that the focusing attachment of the vibrator was at a distance of 10 mm from the sample surface. The instants τ_1 and τ_2 of, respectively, the destruction onset and final destruction of a nickel film on a sample under the action of ultrasound were determined. As the conditional time of complete destruction was chosen that when the diameter of a destruction zone reached 5 mm and more. The thickness *h* of a metal coating was determined in parallel for each sample by gravimetry. The metallization stage was performed under the same conditions: nickel(II) concentration 0.1 M, TUDO concentration 0.2 M; T = 343 K; τ = 15 min.

The results obtained in studying silicate-glass samples are listed in Table 2. It can be seen that activation with solutions of palladium(II) and tin(II) chlorides and with a copper colloid solution in gelatin provides virtually the same thickness of a metal film (~1.7 μm). However, the highest adhesion strength is achieved for samples activated with a copper colloid solution stabilized with gelatin (destruction time as long as 20 min). Similar results were obtained when studying the efficiency of various methods for activation of

Table 2. Effect of a method for activation of silicate glass samples on thickness and adhesive properties of nickel coating

Activation method	τ_1, min	τ_2, min	*h*, μm
$PdCl–2H_2O$, 0.5 g l^{-1} HCl_{conc}, 10 ml l^{-1}	6	9	1.77
$SnCl_2–2H_2O$, 0.25%, HCl_{conc}, up to 1 ml l^{-1}	9	12	1.72

and with copper colloid solution in gelatin	12	20	1.25

carbon fiber and molybdate glass. The plasma activation of the glass, both by itself and in combination with activation with a copper colloid solution, does not yield any appreciable positive results (Table 2). Thus, the combination of butanol additives (up to 10 vol %) with gelatin in preparation of dispersed copper makes it possible to obtain monodispersed systems, which are stable for up to a month and have high activating capacity in electroless copper plating.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Sol–Gel Synthesis of Monodispersed SiO_2 Nanoparticles in the Presence of Organic Amines

Abstract—Preparation of monodispersed SiO_2 nanoparticles of varied size by hydrolysis of tetramethoxysilane and polycondensation of the hydrolysis products was studied as influenced by the basicity and nucleophilicity of organic amines.

In 1967, Stöber and Fink [1] showed that hydrolysis of silicon alkoxides in the presence of ammonia yields SiO_2 nanoparticles with narrow particle size distribution. Since that time, suspensions of particles of this kind became commercially available and found wide application in electronics and for preparing composites, monolithic glasses for optics, etc. [2, 3]. It is also known that hydrosols of these particles yield colloids with alternating structure (colloidal crystals), which are unique models for fundamental study of various types of interparticle interactions [4, 5] and crystallization from solution [6].

Although obvious progress has been achieved in the synthesis of SiO_2 nanoparticles, the results obtained are poorly reproducible [7]. To enhance the reproducibility, the effect of various factors on the size of SiO_2 nanoparticles was examined. In particular, the type of the initial alkoxysilane and alcohol used as the solvent, temperature of the sol–gel process, alkoxysilane concentration, alkoxysilane-to-water ratio, ammonia concentration, and rate of alkoxysilane addition were varied [1, 7–9]. However, there is one more factor affecting formation of a SiO_2 dispersion in the course of a sol–gel process: nature of the base catalyst, not examined in previous papers. Let us consider chemical reactions involved in this process [10]:

$$\equiv Si{-}OR + H_2O \underset{\text{Etherification}}{\overset{\text{Hydrolysis}}{\rightleftarrows}} \equiv Si{-}OH + ROH, \quad (1,2)$$

$$\equiv Si{-}OR + HO{-}Si\equiv \underset{\text{Alcoholysis}}{\overset{\text{Condensation}}{\rightleftarrows}} \equiv Si{-}O{-}Si\equiv + ROH, \quad (3,4)$$

$$\equiv Si{-}OH + HO{-}Si\equiv \underset{\text{Hydrolysis}}{\overset{\text{Condensation}}{\rightleftarrows}} \equiv Si{-}O{-}Si\equiv + H_2O. \quad (5,6)$$

Hydrolysis of silicon alkoxide yields silanols [reaction (1)] which can condense by reactions (3) and (5). When the sol–gel process is performed in an alkaline solution, reactions of alcoholysis (4) and hydrolysis (6), which are responsible for growth of SiO_2 particles with a definite size distribution, prevail. The rate of all of these reactions is acceptable only in the presence of catalysts. However, the mechanism of the base catalysis was reduced in the literature and, in particular, in a comprehensive monograph [11] to a bimolecular nucleophilic attack (S_N2–Si) of the hydroxide anion at the silicon atoms of alcoxysilane to give a five-coordinate intermediate which eliminates the alcohol molecule ROH (hydrolysis) or the RO^- anion (condensation). Thus, it is assumed that the sol–gel process involving hydrolysis of a silicon alcoxide and condensation of the hydrolysis products is controlled exclusively by the concentration of OH^- anions. Any organic base, in particular a nitrogen-containing compound, can be considered a proton acceptor. Its strength can be estimated from the pK_a of the conjugated acid:

$$:NR_3 + H_2O \rightleftarrows HN^+R_3 + OH^-. \quad (7)$$

However, the processes occurring in the sol–gel system incompletely fit in the logical path: (i) increase in the strength of the organic base, (ii) increase in the concentration of OH^- anions, and (iii) acceleration of the hydrolysis and condensation. For example, it is known that, although F^- is a weaker base than NH_3,

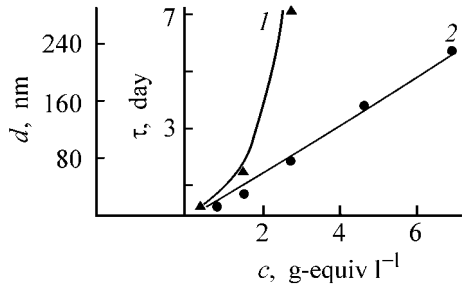

Fig. 1. (*1*) Average size *d* of SiO_2 particles and (*2*) gelation time τ vs. the 4-(dimethylamino)pyridine **V** concentration *c* in sol–gel systems 1–4 and 5b.

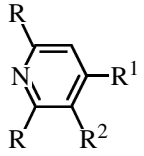
gelation of tetraethoxysilane solutions in the presence of KF is substantially faster than in the presence of the same amount of ammonia [11]. It is believed in this case that the F^- anion is close in size to the OH^- anion and can increase the coordination of the silicon atom in alkoxysilane [12]. In other words, not only proton affinity of the catalyst [Eq. (7)] but also its nucleophilicity (attack of its lone electron pair at the silicon atom of alkoxysilane) should be taken into account when describing the mechanism of the sol–gel process.

The nucleophilicity of a Lewis base depends on many factors, including the type of the chemical reaction involving this base [13]. In this study, we analyzed hydrolysis of tetramethoxysilane (TMOS) and polycondensation of the hydrolysis products in an alkaline solution in the presence of amines whose nucleophilicity was varied by changing the steric and electronic environment of the nitrogen atom.

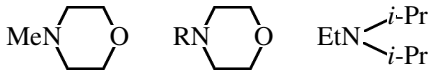
Thus, the present study was concerned with conditions for obtaining monodispersed SiO_2 nanoparticles and development of methods for preparative synthesis of this material.

EXPERIMENTAL

Base hydrolysis of TMOS and polycondenstaion of the hydrolysis products were studied in the presence of the following thermally and chemically stable organic amine cata lysts: pyridine (**I**), 4-methylpyridine (**II**), 3-ethyl-4-methylpyridine (**III**), 2,6-dimethylpyridine (**IV**), 4-(dimethylamino)pyridine (**V**), *N*-methylmorpholine (**VI**), piperidine (**VII**), *N*-methylpiperidine (**VIII**), and ethyldiisopropylamine (**IX**):



I–V



VI **VII, VIII** **IX**

Here R = R^1 = R^2 = H (**I**); R = R^2 = H, R^1 = Me (**II**); R = H, R^1 = Me, R^2 = Et (**III**); R = Me, R^1 = R^2 = H (**IV**); R = R^2 = H, R^1 = NMe_2 (**V**); R = H; (**VII**); R = Me (**VIII**).

TMOS and amines **I**–**IX** were distilled on a 10 TP column at atmospheric and reduced (15–760 mm Hg) pressure, with fractions boiling in the 0.5°C range collected. Amine **V** was recrystallized from alcohol. Sol–gel synthesis of SiO_2 nanoparticles was performed in a glass reactor equipped with a double water jacket, magnetic stirrer, dropping funnel, and reflux condenser. Appropriate amine, ethanol, and water were placed in the reactor. An ethanolic solution of TMOS (25 ml) was added with vigorous stirring at 70°C within 3 min. We prepared 13 sol–gel systems with TMOS : water : ethanol = 1 : 25 : 110. The mole fraction of amines is given below:

Sol–gel system	1	2	3	4	5a	5b	5c
Amine	**I**	**II**	**III**	**IV**	**V**	**V**	**V**
Mole fraction	7.0	1.4	1.4	1.4	0.35	1.4	2.8

Sol–gel system	5d	5e	6	7	8	9
Amine	**V**	**V**	**VI**	**VII**	**VIII**	**IX**
Mole fraction	4.9	7.0	1.4	1.4	1.4	1.4

The particle size was determined with an EM-125 electron microscope at accelerating voltage of 75 kV. The samples were prepared by applying the suspension (in some cases, diluted by a factor of 2–3 with alcohol) to a carbon-reinforced collodion support.

The organic amines were chosen so that the acidity constants of their conjugated acids and their boiling points varied widely:

Amine	**I**	**II**	**III**	**IV**	**V**
bp, °C [15]	115	145	198*	143–145	
pK_a, 20°C [16]	5.20	6.02	6.46	6.77	9.70

Amine	**VI**	**VII**	**VIII**	**IX**	Ammonia
bp, °C [15]	115–116**	124	106	127	
pK_a, 20°C [16]	7.38	11.3	10.20	10.50	9.25

* At 25°C [1, 5]. ** At 750 mm Hg.

All the experiments can be divided into three groups. In the first group, we varied the concentration of 4-(dimethylamino)pyridine **V** (sol–gel systems 5a–5d, Fig. 1). In the second, we varied the sub-

stituients in the pyridine ring (sol–gel systems 1–4 and 5b). Electron micrographs of SiO_2 particles formed in these systems are shown in Fig. 2. In experiments of the third group, we used strong organic bases **V**–**IX**.

Prior to discussing the results obtained, the following should be noted. First, the resolution of the microscope used does not allow determination of particles smaller than 10 nm in diameter. Second, separate SiO_2 nanoparticles can be obtained only when TMOS is strongly diluted with ethanol and water, which promotes hydrolysis and alcoholysis of the Si–O–Si bonds in the sol–gel systems [Eqs. (4), (7)] [17]. Otherwise gelation of the sol is complete in less than 10 min in the presence of pyridine catalyst and is almost instantaneous in the presence of bases **V**–**VIII**.

The size of silica particles prepared by hydrolysis of TMOS and polycondensation of the hydrolysis products in the presence of 4-(dimethylamino)pyridine grows linearly with increasing amine concentration (Fig. 1). At amine concentration of 0.35 g-equiv l^{-1}, the particle size is close to the detection limit, whereas at amine concentration of 7 g-equiv l^{-1}, it is 210–240 nm. Since particles formed in alkaline solution are negatively charged and repel one another [18], they grow by the condensation mechanism through dissolution of smaller particles. These smaller particles are not perfectly spherical, with pointed projections and irregularities (Fig. 2b). It is these projections and irregularities that have an excess energy and initiate, in the first place, rupture of the Si–O–Si bonds. Hence, as silica particles grow, their shape becomes more spherical (Figs. 2c, 2d).

It should be noted that the dissolution and condensation to form an ensemble of spherical particles compete with polymerization gelation. Each of these processes prevails at a definite base concentration. Heating of sol–gel system 5b for 30 min does not cause particle coarsening but accelerates the gelation. Thus, at low catalyst content, small silica particles susceptible to polycondensation with inclusion of a solvent and to gelation are formed owing to insufficiently fast rupture–formation of Si–O–Si bonds. At high catalyst content (Fig. 2e, 7 g-equiv l^{-1}), large particles are formed. In this case, the sol degrades by sedimentation and subsequent coagulation. Sols prepared at a catalyst content of about 0.5 g-equiv l^{-1} are stable for many days (Figs. 2d, 2d).

It should be noted that all the above processes of silica nanoparticle formation in sol–gel systems 5a–5e are fast. Electron micrographs taken immediately after the reaction completion, i.e., several minutes after the onset of hydrolysis of TMOS and polycondensation of the hydrolysis products, are shown in Figs. 2a–2e. Such a high rate is provided by high basicity and nucleophilicity of 4-(dimethylamino)pyridine. When amines **I**–**IV** having a similar structure and lower basicity are used as catalysts, all these processes are strongly decelerated. Hardly visible particles are formed on heating at 70°C for 4 h in the presence of 4-methylpyridine (Fig. 2g). Silica particles generated in the presence of 3-ethyl-4-methylpyridine **III** within the same time are slightly larger. When the least basic amine, pyridine, was used, visible particles (Fig. 2f) were formed only after keeping the sol–gel system at 70°C for 8 h and then at room temperature for 8 days. The behavior of sol–gel systems 1–3 correlates with an increase in the amine basicity. However, no visible particles appear when sol–gel system 4 containing 2,6-dimethylpyridine is heated for 4 h, although the basicity of this amine is substantially higher than that of amines **I**–**III**.

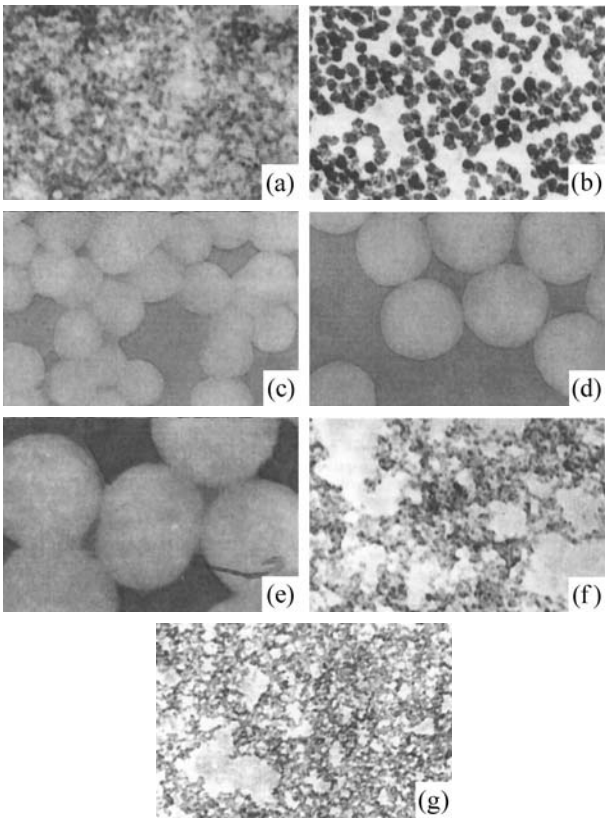


Fig. 2. Electron micrographs of SiO_2 particles prepared in sol–gel systems (a) 5a, (b) 5b, (c) 5c, (d) 5d, (e) 5e, (f) 1 and (g) 2. Magnification ×100 000 (100 nm in 1 cm); the same for Fig. 3.

Thus, the mechanism of formation of silica nanoparticles in the presence of organic amines must involve an attack on the silicon atoms by the lone elec-

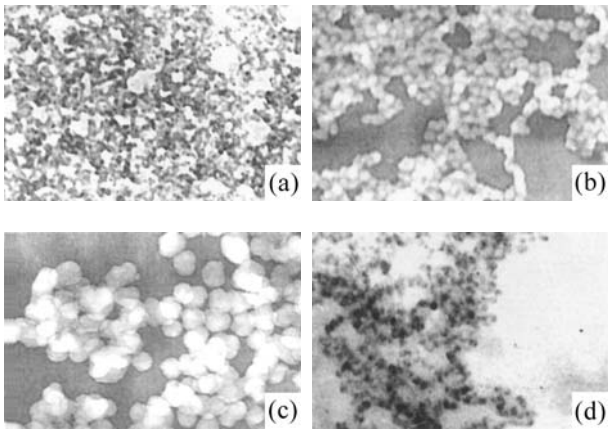

Fig. 3. Electron micrographs of silica particles formed in sol–gel systems (a) 6, (b) 8, (c) 7, and (d) 9.

tron pare of the nitrogen atom. If the electron pair is less accessible, as in, e.g., amine **IV**, owing to steric hindrance caused by two methyl groups, the sol–gel process is decelerated, i.e., it is controlled by the nucleophilicity, rather than basicity of the catalyst.

Clearly, this assumption is true when strongly basic amines **V**–**IX** are used as catalysts. Electron micrographs of SiO_2 particles prepared by the sol–gel process catalyzed with these amines are shown in Fig. 3. Hardly visible silica particles about 10 nm in diameter are formed in the presence of *N*-methylmorpholine (Fig. 3a). The diameter of silica particles grows with increasing amine basicity in the order *N*-methylmorpholine **VI** < 4-(dimethylamino)pyridine **V** (Fig. 2b) ~ *N*-methylpiperidine **VIII** (Fig. 3b) << piperidine **VII** (Fig. 3c). However, when less nucleophilic sterically hindered ethyldiisopropylamine is used, the particle size sharply decreases despite the high basicity of the amine (Fig. 3d).

CONCLUSIONS

(1) The procedure developed for preparative synthesis of monodispersed SiO_2 nanoparticles gives well-reproducible results and requires simple equipment.

(2) When a strongly basic amine ($pK_a > 9$) is used as catalyst, the particle size grows almost linearly with its increasing concentration.

(3) Catalytic hydrolysis of TMOS and polycondensation of the hydrolysis products to form SiO_2 nanoparticles are governed not only by the concentration of hydroxide anions in a solution (i.e., by basicity of an amine), but also by the nucleophilicity of the amine.

ACKNOWLEDGMENTS

We are grateful to I.A. Drozdova for performing electron microscopic studies.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Saturated Vapor Pressure in a System Constituted by Anthranilic Acid and Hydrogen Fluoride

Abstract—The saturated vapor pressure in a system constituted by anthranilic (*o*-aminobenzoic) acid and hydrogen fluoride was studied by the static method in the temperature range 0–90°C. The isotherms of vapor pressure as a function of solution composition were approximated using the least-squares method.

Synthesis of *o*-fluorobenzoic acid by the diazotization method involves a stage in which a solution of anthranilic acid (AA) in hydrogen fluoride is prepared, with the subsequent diazotization and thermal decomposition of a diazonium salt formed. To preclude loss of hydrogen fluoride in the above stages and to study the kinetics of diazonium salt decomposition, data on saturated vapor pressure in the AA–HF system are necessary.

EXPERIMENTAL

The saturated vapor pressure in the AA–HF system was measured on an installation including the following units (Fig. 1):

(1) Vessel *1* for charging a mixture under study and a calibration vessel *2* for vapor sampling are mounted within heat-insulating jackets *3* and *4*, in which an ethylene glycol solution, fed from a SZhML-19/2,5-I1-9

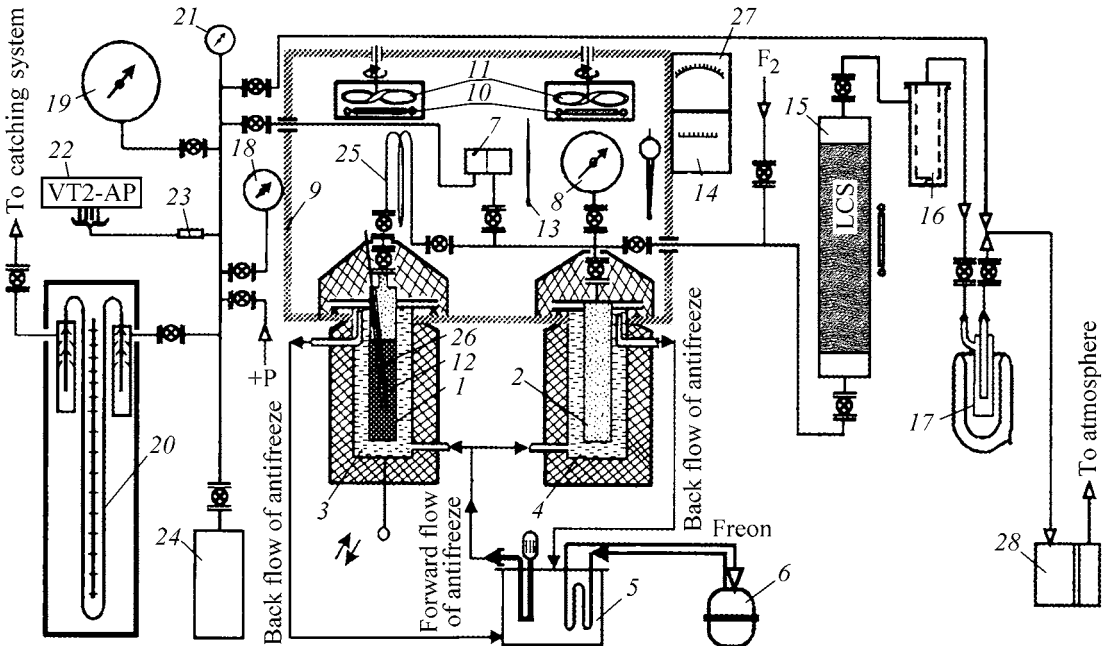

Fig. 1. Schematic of the experimental setup. (*23*) Pressure gage, (*24*) calibration vessel, (*25*) helical compensator, (*26*) thermocouple pocket, (*27*) secondary gage, (*28*) rough-pressure pump; for the remaining notations see text.

1070-4272/03/7606-0879 $25.00 © 2003 MAIK "Nauka/Interperiodica"

thermostat *5*, is circulated. Ethylene glycol is cooled by a refrigerating compressor *6* or heated by heaters built in the thermostat *5* to ensure the required range of working temperatures. The vessels *1* and *2* are connected to a pressure measurement system.

(2) The system for vapor-pressure measurements consists of two DP-5 pressure reducers *7* with measurement ranges 0–50 and 0–300 mm Hg and an MO-11202 reference gage *8* (0.4 accuracy rating), mounted within an air thermostat *9*. The thermostat *9* is equipped with heaters *10*, fans *11*, Chromel–Copel thermocouple *12*, mercury thermometer *13*, and KSP-4 control potentiometer *14*.

(3) The vacuum system includes a pump protection unit, a unit for measuring the pressure in the reference chamber, and a 2NVR-5DM rough-vacuum pump. The first unit consists of a sorption column *15* filled with granulated sorbents [sodium fluoride, lime chemical sorbent (LCS)], porous-metal filter *16*, and freezing trap *17* cooled with liquid nitrogen. The pressure in the reference chamber of DP-5 is measured with an MO-11202 reference gage *18* (0.4 accuracy rating), V-1227 reference vacuum gage *19* (0.25 accuracy rating), open mercury pressure gage *20*, OBMB-1-160 vacuum gage *21* (1.5 accuracy rating), and VT-2AP thermocouple vacuum gage *22* with a PMT-4 lamp *23*.

The error in pressure measurement was ±0.5, ±1.5, and ±5 for pressures of up to 50, 300, and 6500 mm Hg, respectively. The temperature in the thermostat was maintained constant to within ±0.05°C.

As main construction materials were used nickel, stainless steel, and copper, with fluoroplast-4 serving as laying material. The inner surfaces of the vessels *1* and *2* were preliminarily polished mechanically and chemically.

Prior to tests, all the surfaces of the pipelines and valves contacting with the corrosive medium were passivated with elementary fluorine for 24, h with gradual heating to 100°C.

We used AA [GOST (State Standard) 14310–78] and anhydrous hydrogen fluoride of A brand satisfying the requirements of GOST 14022–88, which corresponds to 99.95 wt % pure substance and more. The purity of AA was verified by the melting point method (mp 143°C).

Initial samples were prepared in a sealed cell in argon dried by circulation in a column packed with LCS and NaA zeolite.

Prescribed amounts of AA and HF were weighed on an analytical balance in a thoroughly washed and dried Teflon flask and placed in vessel *1*. The vessel was sealed, cooled with liquid nitrogen, and evacuated to residual pressure of less than 0.1 mm Hg. Vessel *1* with a mixture of prescribed composition was placed in a jacket *3* and connected to a pressure measurement system. Ethylene glycol with required temperature was fed into the jacket, with the temperature in the air thermostat maintained at 5–8°C above that in the jacket. The vessel *1* was subjected to vibration treatment. As the instant of time at which equilibrium was attained in the system was taken that when the vapor pressure reached a constant value. The pressure was indicated by readings of the reducers *7* and reference gage *8*.

The saturated vapor pressure in the AA–HF system was studied by the static method in the temperature range 0–20°C at a step of 5°C and 30–90°C at a step of 10°C for solutions containing 8.79, 17.41, 21.70, 23.41, 28.08, 32.74, and 36.03 wt % AA. The contents above 36.03 wt % were not studied, because the AA solubility at 20°C does not exceed 40 wt %.

The experimental data on the dependence of saturated vapor pressure on solution composition in the temperature range 0–90°C are presented in Table 1.

Table 1. Saturated vapor pressure at different solution compositions

* The saturated vapor pressures of pure solvent (hydrogen fluoride) in relation to temperature [1].

The AA–HF system consists of components with strongly different saturated vapor pressures (standard boiling point of HF is 19.5°C, and AA sublimation temperature, 143°C). Therefore, the vapor phase is considerably enriched in hydrogen fluoride in the entire temperature range studied, and the AA vapor pressure can be neglected.

The dependence of saturated vapor pressure over a solution of solid substances in volatile solvents is expressed by Raoult's law:

$$\frac{p_i^0 - p_i}{p_i^0} = \frac{\Delta p}{p_i^0} = \frac{n_2}{n_1 - n_2} x_2, \qquad (1)$$

where p_i^0 is the saturated vapor pressure over pure solvent; p_i, the solvent vapor pressure over a solution of given concentration; $\Delta p/p_i^0$, the relative decrease in the solvent vapor pressure; n_2 and n_1, the number of moles of the solute and solvent, respectively.

The values of the relative decrease in the vapor pressure of the solvent for given compositions, as calculated by Eq. (1) and averaged over the temperature range 0–90°C, are presented below:

AA, mole fraction	$\Delta p/p_i^0$	AA, mole fraction	$\Delta p/p_i^0$
0.015	0.159	0.049	0.504
0.029	0.233	0.066	0.855
0.036	0.319	0.072	0.883
0.043	0.395		

It can be seen that the $\Delta p/p_i^0$ ratio grows with increasing solute concentration. This indicates that the solvent interacts with the solute.

The experimental data presented in Table 1 were processed by means of the least-squares method, using the Clausius–Clapeyron equation [2] in integral form

$$\log p = A - B/T, \qquad (2)$$

where A is a constant; $B = \Delta H_{vap}/2.3R$; $R = 1.986$ cal mol^{-1} deg^{-1}, the universal gas constant; ΔH_{vap}, the molar heat of vaporization (cal); T, temperature (K).

Figure 2 shows the temperature dependence of the vapor pressure on temperature, as calculated by Eq. (2) for different solution compositions.

The dependence of the boiling point of the AA–HF solution on composition at 760 mm Hg is presented in Fig. 3.

In addition, the experimental data were processed using the Kirchhoff–Eigen equation (3), Kirchhoff–Rankine–Du'pre equations (4, 5), and Antoine's equation (6) [3]:

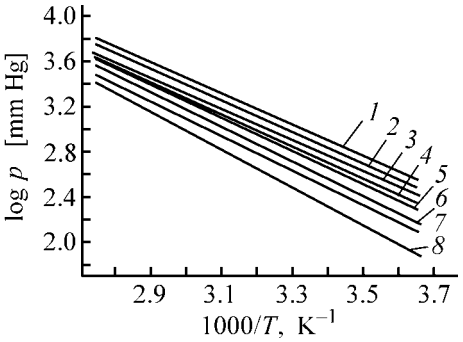

Fig. 2. Hydrogen fluoride vapor pressure p vs. temperature T for different compositions of the AA–HF system. (*1*) HF; AA content (mol %): (*2*) 0.015, (*3*) 0.029, (*4*) 0.036, (*5*) 0.043, (*6*) 0.049, (*7*) 0.066, and (*8*) 0.072.

* (r) Correlation coefficient.

ΔH_{vap}, for fixed compositions in the temperature range 0–90°C are listed in Table 2, along with the correlation factors calculated for each of the above equations.

The average relative error of experimental data processing for Eqs. (2), (3), (4), (5), and (6) was 4, 3, 3.5, and 3.5%, respectively.

Figure 4 shows the dependence of the molar heat of vaporization of the solvent on solution composition, as calculated by the Clausius–Clapeyron equation [4]:

$$\Delta H_{vap} = 0.95RB\left(\frac{T}{T - 43}\right)^2, \quad (7)$$

$$B = \frac{\ln (p_2^0/p_1^0)}{\frac{1}{t_1 + 230} - \frac{1}{t_2 + 230}}, \quad (8)$$

where p_1^0 and p_2^0 are the vapor pressures at temperatures t_1 and t_2, respectively.

The molal rise in the boiling point (ebullioscopic constant, or boiling constant) for the AA solutions in HF was 7.059 ± 0.012 deg mol^{-1}.

CONCLUSIONS

(1) The saturated vapor pressure in the anthranilic acid–hydrogen fluoride system was studied by the static method for solutions containing 8.79, 17.41, 21.70, 23.41, 28.08, 32.74, and 36.03 wt % anthranilic acid at 0–90°C. It was shown that, in the concentration range studied, the system is not azeotropic and exhibits negative deviations from Raoult's law.

(2) The experimental data obtained were processed using the Clausius–Clapeyron, Kirchhoff–Eigen, Kirchhoff–Rankine–Du'pre, and Antoine's equations, with average relative error of 4, 3, 3.5, and 3.5%, respectively. It was found that the Kirchhoff–Eigen equation describes the temperature dependence of the saturated vapor pressure with the highest precision.

(3) The molar heats of vaporization, ΔH_{vap}, were determined for fixed compositions in the temperature range 0–90°C.

(4) The molal rise in the boiling point of the anthranilic acid solution in hydrogen fluoride was 7.059 ± 0.012 deg mol^{-1}.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Distribution of Microimpurities among Phases of Converter Matte from Pechenganikel' Combine

L. N. Ertseva, O. V. Korotkova, P. S. Seregin, and I. G. Fokeeva

Institut Gipronikel' Open Joint-Stock Company, St. Petersburg, Russia

Received April 8, 2003

Abstract—Scanning electron microscopy and X-ray fluorescence microanalysis were applied to study the distribution of zinc, lead, arsenic, antimony, and tin among phases of the converter matte from the Pechenganikel' combine.

In manufacture of nonferrous metals at plants of the Kola Mining and Smelting Company (KGMK), it is possible to process secondary raw materials containing considerable amounts of impurities, such as Zn, Pb, Sn, As, and Sb. In waste processing, these impurities pass into various half-products (matte, dusts, return slag). Owing to the high content of nonferrous metals, return materials are recycled into various stages of the smelting process, which results in gradual accumulation of impurities in some metallurgical half-products and, in the end, in that these impurities pass into commercial products. In this context, it becomes important to study the behavior of microimpurities in different stages of metallurgical processes at KGMK.

The main source from which the microimpurities under study come into the smelting process is the metallic copper waste processed in vertical converters at the copper shop of the Severonikel' combine [1]. The converter slag, into which a large amount of microimpurities passes, is a return material processed in ore-thermal furnaces and horizontal converters at the smelting shop. This is how Pb, Zn, As, Sb, and Sn impurities find way into the converter matte of the Pechenganikel' combine.

Further ingress of the microimpurities into nickel and copper concentrates depends on their distribution among phases of the converter matte delivered to flotation separation.

The real content of the impurities under study in industrial converter mattes is rather low (wt %): As 0.13; Pb 0.03; Zn, Sn, and Sb up to 0.01. In view of this circumstance, increased amounts of these metals were introduced in laboratory into the copper matte in order to elucidate the mechanism of microimpurity distribution among the concentrates. Zinc, lead, arsenic, antimony, and tin (in metallic form) were introduced (0.1 and 0.5 wt %) into a weighed portion of the converter matte.

Experiments were done in an induction furnace in the atmosphere of argon. A weighed portion was melted in a crucible (heating rate of 1 deg min^{-1}) and then kept at 1300°C for 15–20 min and slowly cooled with the furnace. The system for control over the furnace heater allowed programmed cooling.

A sample of a typical converter matte from the Pechenganikel' combine was chosen for study [2]. Converter matte composition (wt %): S 22.2, Fe 2.9, Co 0.7, Ni 39.9, and Cu 30.6.

The converter matte samples with introduced impurities were studied using scanning electron microscopy (SEM) and X-ray fluorescence microanalysis (CamScan scanning electron microscope with ED spectrometer and LINK ISIS 200 processing unit). Under the chosen analytical conditions, the minimum determinable content of Ni, Cu, Co, Fe, Zn, Pb(M_α), As(L_α), Sb(L_α), and Sn(L_α) was 0.03–0.04 wt %. (M_α and L_α are the characteristic lines of X-ray emission for the elements under study).

It was established that solid converter matte has a structure typical of such products (Fig. 1a): the matrix of the sample is constituted by nickel sulfide, which is close in composition to heazlewoodite Ni_3S_2 (Hz_{SS}) and contains structures formed in eutectic or eutectoid decomposition (Fig. 1b). Rounded copper

1070-4272/03/7606-0884 $25.00 © 2003 MAIK "Nauka/Interperiodica"

sulfide inclusions, which are typical of the converter matte structure, were found in the matrix of the heazlewoodite solid solution. Copper sulfide has a structure typical of the case of decomposition of a solid solution and corresponds in its average composition to a chalcosine–bornite solid solution Cu_2S–Cu_5FeS_4 $(Cc–Bn)_{SS}$. The sample contains virtually no well-formed crystals of the metallic phase.

The general view of a sample with 0.1 wt % impurities is shown in Fig. 1a.

The sample contains (Fig. 1c) minor amounts of metallic copper in the form of typical lens-like inclusions at the boundaries of nickel and copper sulfide phases, minute inclusions of lead sulfide (also at the phase boundaries between nickel and copper sulfides), and rounded inclusions of zinc sulfide in the bulk of the chalcosine–bornite solid solution (Fig. 1d).

The compositions of all the structural constituents of the sample (with the exception of lead sulfide) are listed in the table. Analysis of these data shows the following.

(1) Lead is contained in the sample as a separate PbS phase; other structural constituents contain no lead impurities.

(2) Zinc is distributed among the chalcosine–bornite solid solution and metallic copper. In view of the small volume of metallic copper, it can be concluded that the main part of zinc is contained in the chalcosine–bornite solid solution. It is noteworthy that the zinc sulfide phase is precipitated within the bulk of the copper solid solution, which is, in all probability, due to a decrease in its solubility in copper sulfide at lower temperatures.

(3) Arsenic, tin, and antimony are concentrated in nickel sulfide, with the maximum content of these impurities observed in the structural constituents formed in eutectoid decomposition, especially in the metallic phase. This means that the impurities are concentrated in crystallization of the residual melt. The metallic phase, which is present in the form of regular crystals, has composition typical of converter mattes and does not contain any of these impurities, since its crystallization occurs in early stages of cooling.

Figure 2a shows the general view of a sample containing 0.5 wt % impurities. As regards the main constituents, the sample differs from the preceding one only slightly. The differences are as follows: the content of metallic copper is much lower, the metallized

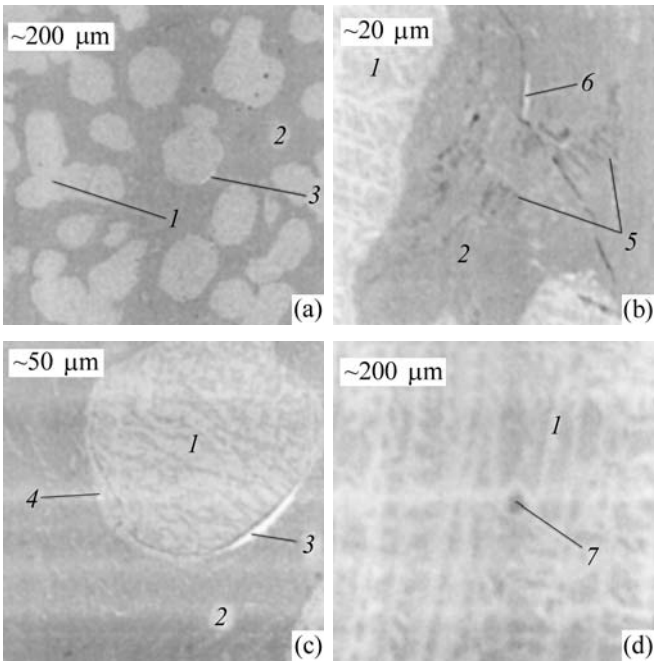

Fig. 1. Structure of a converter matte sample containing 0.1 wt % microimpurities. (a) General view, (b) structures formed in decomposition of a heazlewoodite solid solution, (c) inclusions of metallic copper and lead sulfide, (d) inclusions of zinc sulfide. (*1*) Chalcosine–bornite solid solution, (*2*) heazlewoodite solid solution, (*3*) metallic copper, (*4*) lead sulfide, (*5*) monosulfide solid solution (M_{SS}), (*6*) metallic component, and (*7*) lead sulfide.

phase in the structure formed in decomposition of nickel sulfide has the form of thin needle-like inclusions oriented in a certain direction (Figs. 2b, 2c); rounded and dendritic zinc sulfide crystals and inclusions of the metallic copper–silver phase are observed within the globules of the chalcosine–bornite solid solution; no separate phases of lead are observed in the sample; an iron–zinc oxide phase not associated with any other phase is found in the sample.

Needle- or thread-like inclusions of the metallized phase (Fig. 2b) are untypical of copper–nickel converter mattes cooled in equilibrium or nearly equilibrium mode. Introduction of an additional impurity even in amount of 0.1% can strongly affect the composition and shape of crystals growing from the melt. According to Saratovkin [3], if even at least a single atom of an impurity substance is present at a distance of 1000 interatomic spacings from the face of a growing crystal and the lattice constant is about 5 Å, then, when the face moves over a distance of 0.5 μm, it encounters a monomolecular layer of the impurity component, which hinders further crystal growth. The blocking layer can be removed via convection or diffusion. As is known, convection only exists in

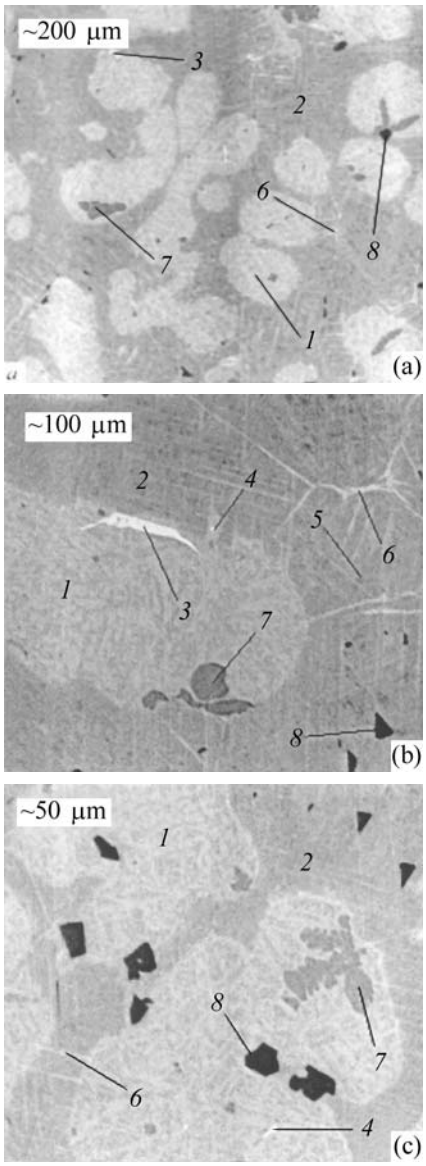

Fig. 2. Structure of a converter matte sample containing 0.5 wt % microimpurities. (a) General view; (b, c) structures formed in decomposition of a heazlewoodite solid solution and precipitation of metallic copper, lead and zinc sulfides, and oxide phase. (*1*) Chalcosine–bornite solid solution, (*2*) heazlewoodite solid solution, (*3*) metallic copper, (*4*) copper–silver metallic phase, (*5*) monosulfide solid solution (M_{SS}), (*6*) metallic component, (*7*) lead sulfide, and (*8*) oxide phase.

the case when different layers in the system under study have different densities, and at sufficiently slow cooling of the converter matte, the convection flows are insignificant.

Now, diffusion is considered for the case when the impurity component does not form a solid solution with the substance of the growing crystal. As a rule, the diffusion rate is insignificant as compared with the crystal growth rate, and the crystal can only grow so as to move over the maximum possible distance at the minimum possible expenditure of the building material in the direction where this material is available. The crystal starts to form thin outgrowths and takes a thread- or needle-like shape.

If an impurity is a surfactant with respect to a crystal growing from solution or forms a solid solution with the substance of the crystal, then a change in surface tension at the solution–crystal interface necessarily affects the type of the crystal growth mechanism and the kinetics of crystal growth. This also refers to the case when a crystal of a new phase is formed from a solid solution in, e.g., an eutectoid transformation.

The compositions of all the structural constituents of the samples are listed in the table. In crystallization of converter mattes under nearly equilibrium conditions, the eutectoid decomposition of the high-temperature form of nickel sulfide in the presence of iron and cobalt is complete at 470–480°C. The product formed in this stage of decomposition is (Fe, Ni, Co)S_{SS}, which contains, in accordance with the crystallization rules [4, 5], the main part of "unassimilated" impurity elements (see table).

Analysis of the data in the table shows that none of the structural constituents contains lead, and zinc is distributed among zinc sulfide, oxide phase, metallic copper, and chalcosine–bornite solid solution. Zinc sulfide, which contains virtually no copper, can be formed both in direct sulfidization of metallic zinc introduced into the matte, with the zinc sulfide phase remaining heterogeneous (mp > 1600°C), and on lowering the melt temperature. Arsenic is associated with nickel phases: heazlewoodite solid solution, monosulfide solid solution, and metallized phase from the structure formed in decomposition of nickel sulfide. Antimony and tin are also associated with nickel phases, with the main part of these impurities contained in the metallized component formed in decomposition of the heazlewoodite solid solution. The oxide phase is, in all probability, formed in the course of remelting, since it contains considerable amounts of zinc and tin impurities. The absence of zinc in a sample that is richer in microimpurities can be accounted for by the ingress of particles from the upper part of the ingot into the sample. This conclusion is also confirmed by the presence in the composition of the given sample of iron oxide particles, which can only be formed on the ingot surface. By contrast, the sample with microimpurity content of 0.1% contains particles from the lower part of the ingot, which is enriched in the lead phase.

Composition of structural constituents of converter matte samples with varied impurity content

Impurity content, wt %	Structural constituent of converter matte	Composition, wt %										
		S	Fe	Co	Ni	Cu	Zn	As	Ag	Sn	Sb	Pb

* Average value.

** Oxygen content 28–29 wt %.

Thus, a study of the microstructure of the converter matte samples revealed that, at the content used in the experiments, antimony, tin, and arsenic form no independent phases and are virtually entirely concentrated in the nickel-containing phase of the converter matte. Zinc is present in the chalcosine–bornite solid solution as an independent sulfide phase within the copper-containing phase. Lead is sulfidized to form an independent phase at the boundary of chalcosine–bornite globules.

It would be expected that, in flotation separation of the converter matte from the Pechenganikel' combine, arsenic, antimony, and tin must mostly pass into the nickel concentrate, and zinc, into the copper concentrate, with the question as to how lead is distributed remaining open, since the behavior of zinc depends to the greatest extent on the flotation process parameters.

Abstract—Problems associated with synthesis of silica gels with prescribed pore characteristics from stabilized silica sols with controlled colloid particle size, obtained in the metastable solubility region of the system SiO_2–H_2O (8.5–9.5), are considered.

Conventionally, silica gels are synthesized from alkali metal silicates by precipitation with an acid [1–5]. The silica gels prepared using this technique have a number of disadvantages: poor reproducibility of pore characteristics, impossibility to control growth of primary structure-forming colloid particles in the course of gelation, necessity for removal of a considerable amount of alkali metal cations, etc.

Strict requirements (narrow pore size distribution, reproducible pore characteristics, high mechanical strength, etc.) are imposed on sorbents and supports for high-efficiency liquid chromatography. However, silica gels prepared from soluble silicates cannot satisfy these requirements completely.

Directed synthesis of sorbents with prescribed pore characteristics has always been and still is a topical task. Therefore, a search for methods that could solve the problem of control and reproducibility of pore characteristics is an important issue.

A possible way to control the porous structure of silica gels is to use sols of silicic acid as starting material [1, 6–8]. The size distribution of colloid particles of a silica sol determines, in the end, the pore size distribution (in gelation without precipitation), and the size of particles themselves determine the specific surface area of the silica gels obtained.

There exist various methods for obtaining silica sols [9–17]. These methods use polysilicic acid (PSA) prepared by ion-exchange conversion of a liquid glass solution (3.5–4.0 wt % SiO_2, SiO_2/Na_2O = 3.25) as starting material [9].

To gain better understanding of how SiO_2 colloid particles grow in the SiO_2–H_2O system, it is necessary to consider some questions associated with nucleation of a new phase. A silica solution is subjected to homogeneous nucleation. At high pH values, associates of silicate ions, which contain up to 5–10 SiO_2 units, are mostly present in silicate solutions. For silica, there exists a certain possibility of formation of a dense octameric structure, which can form colloid particles about 1 nm in size. As the $SiO_2 : M_2O$ ratio becomes greater than 2 : 1, three-dimensional corpuscular "colloid species" start to form in solution, which eventually become nuclei [1].

It has been shown that nucleation of a new phase in early stages of polycondensation, with the number and size of nuclei depending on the initial supersaturation in the system, results in that, further, this process starts to occur by the heterogeneous mechanism [18, 19].

Nucleation occurs in the SiO_2–H_2O system at low supersaturation values. The equilibrium solubility of silica in water at room temperature is 0.007 wt % (in terms of SiO_2) [1]. Consequently, to ensure growth of colloid particles of silicon dioxide, it is necessary to clearly delineate the metastable solubility region in the SiO_2–H_2O system. Particles grow in the metastable state, and both the particle growth and nucleation occur at high degree of supersaturation [20–22].

The polysilicate fraction is characterized by narrow polyion size distribution, which is due to the fact that small particles are more soluble than large particles. This leads to fast change in particle size distribution, to the point of total homogeneity [1].

Nucleation and further growth of colloid SiO_2 particles at high pH values make it possible to work with more concentrated solutions, easily control the metastable region by varying the pH of the medium (which

1070-4272/03/7606-0888 $25.00 © 2003 MAIK "Nauka/Interperiodica"

yields colloid particles more uniform in size), and suppress secondary nucleation.

When SiO_2 particles grow without formation of secondary growth centers, the supply rate of feeding sol becomes important. In this case, the particle surface on which further growth proceeds without secondary nucleation, becomes the rate-determining factor [15].

EXPERIMENTAL

SiO_2 colloid particles grow upon addition of freshly prepared PSA (3–4 wt % SiO_2) to the starting alkali solution under stirring. The process is carried out in a vacuum-evaporation installation at boiling temperature of 80–85°C [16, 17]. The acid is introduced at a rate equal to the evaporation rate of the system in such a way that the volume of the system remains invariable during the entire growth stage.

Figure 1a shows the pH value of the system as a function of the PSA feed factor in sol synthesis by the first scheme. In this case, the volume of the initial solution was 50% of the total PSA volume. As growth criterion served the final pH value, which must not be lower than 6.5 to preclude gelation of the system.

Figure 1b shows the pH value of the system as a function of the PSA feed factor in sol synthesis by the second scheme. In this case, the volume of the initial solution was 25% of the total PSA volume. According to this scheme, the pH of the medium in which colloid particles grow is well-controlled by periodic addition of a 0.1 M NaOH solution. Four growth modes were studied, with the lower limit of the pH of the growth medium controlled: (1) pH 8.0, (2) pH 8.5, (3) pH 9.0, and (4) pH 9.25.

All silica sol samples were gelated by addition of a 0.1 M HNO_3 solution to pH 6.0–6.2. After aging of the samples obtained, they were washed with distilled water, dried at 150°C for 2 h, and calcined at 500°C for 4 h.

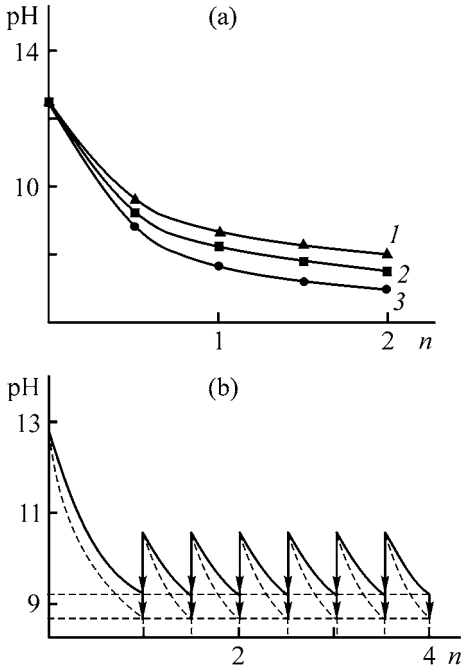

Fig. 1. pH of the system vs. PSA feed factor n. SiO_2 sol obtained by (a) first and (b) second scheme. (a) *Digits at curves* correspond to sample numbers in the table.

The size of colloid particles of the silica gels was determined by titration by the Searce method [1]. The pore characteristics of silica gel samples were determined by the methods of thermal desorption (TD) [23, 24], benzene sorption [25], and mercury porosimetry (MP) (on Pore-Sizer 9300 porosimeter).

All the reagents used (NaOH, HNO_3, HCl, NaCl) were of chemically pure grade.

The table lists colloid particle sizes of silica sols synthesized by the first scheme (Fig. 1a) at dif-

Characteristics of silica sols and silica gels

Sample no.	S_{sp}, $m^2 g^{-1}$				Average size of silica sol particles, nm	Pore volume, $cm^3 g^{-1}$	Average pore diameter in silica gel, nm	pH_{fin}
	TD	MP	Searce	$S_{sp.av}$

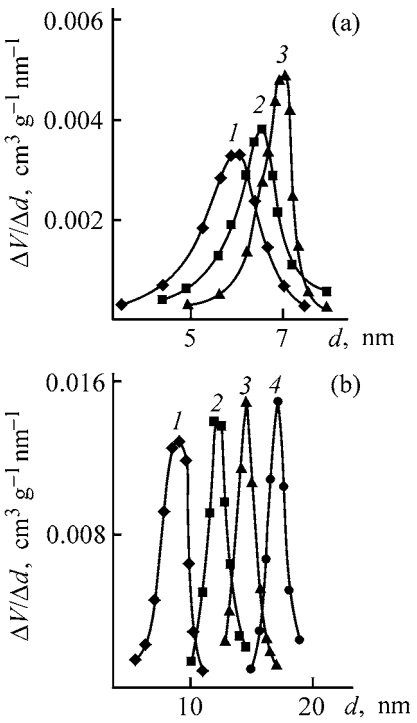

Fig. 2. Pore size (d) distribution for silica gels obtained from silica sols by (a) first and (b) second schemes. Final pH value: (a) (*1*) 6.8, (*2*) 7.2, and (*3*) 7.8; (b) (*1*) 8.0, (*2*) 8.5, (*3*) 9.0, and (*4*) 9.25.

ferent final pH values, and also pore characteristics of silica gels obtained on their base.

Figure 2a shows the pore size distributions of the silica gels studied. It can be seen that, in the case when SiO_2 colloid particles cease to grow at comparatively high pH values of 7.8, the silica gel obtained from such a silica sol possesses a narrower pore size distribution (curve *3*). At lower pH values (6.8 and 7.2), mainly secondary nucleation occurs, with the result that the pore size distribution for silica gels prepared from such silica sols becomes broader (curves *1*, *2*). It follows from the table and Fig. 2a that silica sols with colloid particles not larger than 8 nm in size can be obtained. Synthesis of silica sols with larger colloid particles by this scheme becomes impossible, since part of PSA is to be added to the system outside the metastability region (pH < 8.0), which leads to polydispersity of the system owing to formation of new growth centers.

Figure 2b shows the pore size distribution for silica gels obtained from silica sols synthesized by the second scheme. The table lists sizes of colloid particles of these silica sols obtained at different pH values and pore characteristics of silica gels synthesized on their base.

Raising substantially the pH of the medium at regular intervals (Fig. 1b) not only prevents formation of secondary growth centers, but also leads to dissolution of minute nuclei formed via fluctuation aggregation. The comparatively high pH values of the medium (> 8.5) favor predominant growth of the already existing nuclei without formation of new growth centers. This makes it possible to obtain silica sols with prescribed particle size.

It follows from Fig. 2b and the table that silica gels with rather narrow pore size distribution can be obtained from these silica sols. It should also be noted that this method of silica sol preparation allows growth of SiO_2 colloid particles to 15 nm and more.

CONCLUSIONS

(1) The most favorable conditions for growth of SiO_2 colloid particles without secondary nucleation are created at pH 8.5–9.5.

(2) Silica sols with prescribed particle size can be obtained and silica gels with reproducible pore characteristics can be synthesized on their base.

SORPTION AND ION-EXCHANGE PROCESSES

Thermodynamic Study of Iron(III) Sorption on Clay

Abstract—Sorption of Fe(III) cations on Cambrian blue clay is discussed in term of the Langmuir isotherm. The thermodynamic characteristics of sorption were determined. The Gibbs energies of formation of sorbed Fe(III) aqua and hydroxo cations were calculated. The role of hydroxo complexes in sorption was considered.

Earlier, we proposed a method for deactivation of soils by washing with iron(III) salt solutions [1]. The Fe^{3+} cation has high charge and relatively small radius. Owing to the high ionic potential (z/r), iron(III) replaces other cations, including ^{137}Cs and ^{90}Sr radionuclides, in ion-exchange reactions on the mineral surface. A process was developed for decontamination of soil to remove ^{90}Sr under natural conditions [2, 3], but comprehensive physicochemical data are required for its optimization. It was shown in [4] that ^{90}Sr is fixed mainly by the clay. In this study, we analyzed sorption of Fe^{3+} on Cambrian blue clay $K_2Al_4[Al_2Si_6O_{20}](OH, F)_4$ with specific surface area of 5.86 $m^2\ g^{-1}$ [5]. A thermal analysis showed that this clay belongs to the hydromicaceous type.

The sorption Γ (mol kg^{-1}) was determined under static conditions at V/m 10 ml g^{-1} and clay sample weight of 3 g as the difference between the concentrations of the initial (c_0) and equilibrium (c_∞) solutions by the formula $\Gamma = (c_0 - c_\infty)V/m$. Initially, the clay was treated with 1 M HCl, washed with water to pH 3, and dried to air-dry state. A solution of $FeCl_3$ was also acidified to pH 3. The time of equilibrium attainment, in which the iron(III) concentration in the solution became constant, amounted to 5–6 h; in the experiments the time of phase contact was no less than 1 day. The iron(III) content was determined from the intensity of the absorption band of the thiocyanate complex at 480 nm. The sorption isotherm obtained from the experimental data listed in Table 1 is shown in Fig. 1. The distribution coefficient of iron(III) between the solid and liquid phases was calculated by the formula

$$D_{s/l} = \frac{(c_0 - c_\infty)Vd}{c_\infty m \gamma_{Fe^{3+}}},$$

where c_0 and the c_∞ are initial and equilibrium Fe^{3+} concentrations in the aqueous phase, respectively (M); V, solution volume (m^3); d, solution density (kg m^{-3}); m, clay sample weight (kg); and $\gamma_{Fe^{3+}}$, Fe^{3+} activity coefficient in the equilibrium solution calculated by the Davies equation [6].

It follows from Table 1 that the Fe^{3+} distribution coefficient at equilibrium pH 3.1 ± 0.3 is 27 ± 4. The sorption isotherm can be described by the Langmuir equation, as indicated by the linear relationship between reciprocal sorption and reciprocal concentration in accordance with equation

$$\frac{1}{\Gamma} = \frac{1}{\Gamma_\infty} + \frac{1}{\Gamma_\infty K}\frac{1}{c_\infty},$$

where Γ_∞ is the limiting sorption (mol kg^{-1}) and K is the Langmuir constant.

The absolute term of the equation is equal to inverse limiting sorption, 0.026 mol kg^{-1} for Fe^{3+}, which is consistent with Γ_∞ in the sorption isotherm.

Table 1. Data for building the iron(III) sorption isotherm on clay

$c_0 \times 10^4$, M	pH_{eq}	$c_\infty \times 10^4$, M	$\Gamma \times 10^4$, mol kg^{-1}	$D_{s/l}$	$\gamma_{Fe^{3+}}$

The landing site area of Fe^{3+}, calculated by the formula

$$S_M = \frac{S_{sp}}{\Gamma_\infty N_A},$$

where N_A is the Avogadro number, is equal to 38×10^{-20} m^2. Hence, the radius of the sorbed iron(III) cation is 348 pm. This value should be regarded as the average effective radius of sorbed $Fe^{3+} \cdot nH_2O$, $Fe(OH)^{2+} \cdot mH_2O$, and $Fe(OH)_2^+ \cdot qH_2O$ cations, which is greater than that for Sr_{aq}^{2+} 302 pm [4] (309 pm by Stokes), since the ionic potential and, correspondingly, the degree of hydration of iron(III) cations are higher.

The Langmuir constant K was determined from the slope of the linear dependence in Fig. 2 to be 731.

The distribution coefficient and K found by us, describe the set of the following equilibria:

$$Fe_{aq}^{3+} \rightleftarrows Fe_{ads}^{3+}, \quad (1)$$

$$Fe(OH)_{aq}^{2+} \rightleftarrows Fe(OH)_{ads}^{2+}, \quad (2)$$

$$Fe(OH)_{2\ aq}^{+} \rightleftarrows Fe(OH)_{2\ ads}^{+}. \quad (3)$$

Here, account is taken of the main iron(III) species (with known thermodynamic parameters) existing in the solution at pH 3.1. The sorption of polymeric iron(III) species was neglected. Sorption of iron(III) in the above approximation is described by Eqs. (1)–(3) with coefficients m, n, and p:

$$\frac{n}{m} = \frac{[Fe(OH)^{2+}]}{[Fe^{3+}]} = \frac{K_{h,1}}{[H^+]}, \quad (4)$$

$$\frac{p}{m} = \frac{[Fe(OH)_2^+]}{[Fe(OH)^{2+}]} = \frac{K_{h,2}}{[H^+]}, \quad (5)$$

$$m + n + p = 1. \quad (6)$$

The hydrolysis constants of iron(III) cations are $K_{h,1} = 6.74 \times 10^{-3}$ and $K_{h,2} = 3.09 \times 10^{-3}$ [7]. The concentration of hydroxonium cations was determined from the experimental pH value of 3.1. Then, $m = 0.024$, $n = 0.20$, and $p = 0.776$. The overall equation of iron sorption is as follows:

$$0.024Fe_{aq}^{3+} + 0.2Fe(OH)_{aq}^{2+} + 0.776Fe(OH)_{2\ aq}^{+}$$
$$\rightleftarrows 0.024Fe_{ads}^{3+} + 0.2Fe(OH)_{ads}^{2+} + 0.776Fe(OH)_{2\ ads}^{+}. \quad (7)$$

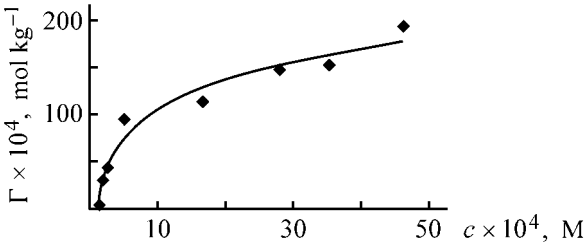

Fig. 1. Isotherm of Fe(III) sorption on Cambrian blue clay: (Γ) sorption and (c) iron(III) concentration; the same for Fig 2.

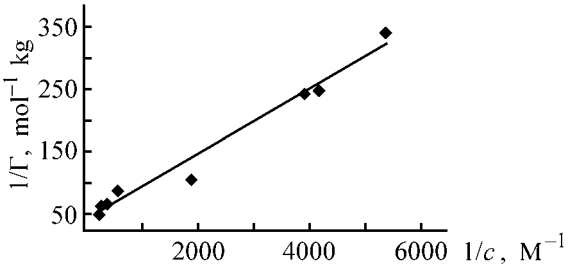

Fig. 2. Linearized form of the isotherm of iron(III) adsorption on clay.

The Gibbs energy of reaction (7) was determined from the overall distribution coefficient

$$\Delta_7 G_{298}^0 = -RT \ln D_{s/l} = -8.2 \pm 0.3 \text{ kJ mol}^{-1}.$$

Let us calculate the equilibrium constants of equilibria (1)–(3):

$$\Delta_7 G_{298}^0 = m\Delta_1 G_{298}^0 + n\Delta_2 G_{298}^0 + p\Delta_3 G_{298}^0. \quad (8)$$

Hence,

$$D = D_1^m D_2^n D_3^p, \quad (9)$$

where D is the experimental overall distribution coefficient of iron(III) and D_n are partial distribution coefficients of particular iron species among reactions (1)–(3), equal to

$$D_1 = \frac{[Fe_{ads}^{3+}]}{[Fe_{aq}^{3+}]}, \quad (10)$$

$$D_2 = \frac{[Fe(OH)_{ads}^{2+}]}{[Fe(OH)_{aq}^{2+}]}, \quad (11)$$

$$D_3 = \frac{[Fe(OH)_{2\ ads}^{+}]}{[Fe(OH)_{2\ aq}^{+}]}, \quad (12)$$

$$D = \frac{[Fe(OH)_{ads}^{2+}] + [Fe(OH)_{2\ ads}^{+}]}{c}. \quad (13)$$

Table 2. Thermodynamic characteristics of sorption of iron(III) cations on clay

Reaction	$\Delta_f G^0_{298}(Cat^{z+}_{aq})$ [7]	$\Delta_f G^0_{298}(Cat^{z+}_{ads})$	$\Delta_f G^0_{298}$	K_{eq}
	kJ mol^{-1}			
$Fe^{3+}_{aq} \rightleftarrows Fe^{3+}_{ads}$	–4.52	–22.1	–17.6	1200
$Fe(OH)^{2+}_{aq} \rightleftarrows Fe(OH)^{2+}_{ads}$	–229.37	–239.6	–10.2	60
$Fe(OH)^{+}_{2\ aq} \rightleftarrows Fe(OH)^{+}_{2\ ads}$	–452.29	–459.7	–7.4	20
$Sr^{2+}_{aq} \rightleftarrows Sr^{2+}_{ads}$ [4]	–563.9	–569.6	–5.7	10

In (13), the contribution of Fe^{3+} to the sorption was neglected because of its small concentration. The solution of system (9)–(13) gives D_2 and D_3:

$$D_3 = \frac{Dc - [Fe(OH)^{2+}_{ads}]}{[Fe(OH)^{+}_{2\ aq}]} = \frac{Dc - K_2[Fe(OH)^{2+}_{aq}]}{[Fe(OH)^{+}_{2\ aq}]}. \quad (14)$$

Substituting in (14) $D = 27$, $[Fe(OH)^{+}_{2\ aq}] = 0.2c$, and $[Fe(OH)^{2+}_{aq}] = 0.776c$ and assuming the exchange constant of various iron(III) species to be approximately unity (in this case, $D_1 \approx D_2^{1.5}$, $D_2 \approx D_3^2$, and $D_1 \approx D_2D_3$), we obtain $D_1 = 1200$, $D_2 = 60$, and $D_3 = 20$. Hence, $\Delta_1G^0_{298} = -17.6$, $\Delta_2G^0_{298} = -10.2$, and $\Delta_3G^0_{298} = -7.4$ kJ mol^{-1}. The thermodynamic characteristics of reactions (1)–(3) allow calculation of the Gibbs energies of formation of sorbed iron(III) cations and of the sorption equilibria (Table 2).

Consider the thermodynamics of ion exchange of iron(III) and strontium(II) cations on the clay surface. In this case, three exchange reactions proceed simultaneously:

$$1/3Fe^{3+}_{aq} + 1/2Sr^{2+}_{ads} \rightleftarrows 1/3Fe^{3+}_{ads} + 1/2Sr^{2+}_{aq},$$
$$\Delta_{15}G^0_{298} = -3.02 \text{ kJ equiv}^{-1},\ K_{15} = 3.4, \quad (15)$$

$$1/2Fe(OH)^{2+}_{aq} + 1/2Sr^{2+}_{ads} \rightleftarrows 1/2Fe(OH)^{2+}_{ads} + 1/2Sr^{2+}_{aq},$$
$$\Delta_{16}G^0_{298} = -2.25 \text{ kJ equiv}^{-1},\ K_{16} = 2.5, \quad (16)$$

$$Fe(OH)^{+}_{2\ aq} + 1/2Sr^{2+}_{ads} \rightleftarrows 1/2Fe(OH)^{+}_{2\ ads} + 1/2Sr^{2+}_{aq},$$
$$\Delta_{17}G^0_{298} = -4.55 \text{ kJ equiv}^{-1},\ K_{17} = 6.3. \quad (17)$$

The Gibbs energy of the overall reaction of iron(III) ion-exchange with strontium can be calculated by the equation

$$\Delta_\Sigma G^0_{298} = 0.072\Delta_{15}G^0_{298} + 0.4\Delta_{16}G^0_{298} + 0.776\Delta_{17}G^0_{298} = -4.65 \text{ kJ mol}^{-1}.$$

Then, the overall constant of the ion exchange equilibrium is 6.5. Hence, we can conclude that Sr^{2+} cations pass into the solution when washing soil with an iron(III) salt solution. The constants obtained can be used for calculating the volume of washing solution and the number of washing cycles required for achieving the necessary degree of soil deactivation [2, 3].

The average dynamic charge of iron(III) cations in the ion-exchange reaction with strontium cations on the clay surface was calculated by the method of Gamayunov *et al.* [8] by the formula

$$K_{ex} = \frac{\sqrt[z]{D_{Fe}}}{\sqrt{D_{Sr}}}.$$

After substitution in Eq.(1) of $K_{ex} = 6.5$, $D_{Sr} = 10$, and $D_{Fe} = 27$, we obtained $z = 1.1$. In [8], $z = 0.72$–0.98 was obtained for Fe(III) sorption by humic acids. The z value calculated in the present study is somewhat greater, which can be accounted for by acidification of the solution to pH 3 and clay transformation into the H form.

CONCLUSIONS

(1) Sorption of iron(III) by Cambrian blue clay is described by a Langmuir isotherm with a constant of 731. The maximum sorption is 0.026 mol kg^{-1}. The landing site area of iron(III) cations is 38.0 Å, and the effective radius of the hydrated cation is 348 pm. The distribution coefficient of iron(III) between the solid and liquid phases at equilibrium pH 3.1 ± 0.3 is 27 ± 4.

(2) The constant of strontium(II) substitution with iron(III) on the clay surface is 6.5. This shows that ^{90}Sr can be displaced from contaminated soils by washing with iron(III) salt solutions.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Methylene Blue Dye by Activated Carbon Fibers

O. Yu. Mukhina, I. A. Piskunova, and A. A. Lysenko

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received March 15, 2002; in final form, February 2003

Abstract—The sorption of Methylene Blue on carbon fibers with various pore structures was studied. The dye sorption was analyzed as influenced by the initial concentration, temperature, time, and solution pH.

Activated carbons and carbon fibers are widely used as sorbents for purification of wastewaters and for fine treatment of drinking water [1, 2]. The sorption volume and pore size distribution primarily determine the adsorption capacity of carbon materials. Microporous materials effectively sorb small molecules, whereas mesoporous materials are the most efficient in sorption of large molecules, especially from liquid media. Moreover, the size, shape, charge, and concentration of sorbate species, solution pH, concentration of other compounds in solution, and the protonation of the ionic groups on the sorbent surface (if present) and its surface charge should be taken into account in studying sorption processes. In many cases, sorption is influenced by temperature and flow velocity of the solution from which the sorption is performed [3].

Although the sorption of dyes and, in particular, Methylene Blue (MB) on activated carbons has been long studied, the mechanisms of diffusion and retention of such large organic molecules in the sorbent structure are still poorly understood [4–6]. It should be noted that the experimental dependences of the dye adsorption would allow prediction of the adsorption behavior of other large organic molecules, such as pesticides, organochlorine compounds, humic acids, and proteins [7–9].

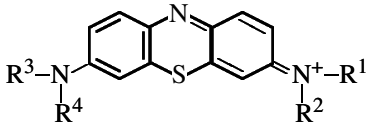
The practical goal of the study was to determine (for the example of Methylene Blue) the feasibility and rate of rendering harmless wastewaters containing dyes [4–6, 10].

EXPERIMENTAL

In our study we used activated carbon fibers (ACFs) prepared by carbonization of hydrated cellulose fibers at 700°C with subsequent steam activation of the carbonized products at 800°C. The resulting fibers have different sorption volumes and pore structures; the ACF properties are listed in Table 1.

To study the pore structure of the samples, we measured the isotherms of benzene sorption–desorption. The pH of the aqueous extract was determined after keeping the ACF sample in distilled water at room temperature (ACF : H_2O ratio 1 : 200) for 1 day in a sealed vessel; then the fiber was separated and the solution pH was determined.

Methylene Blue was used in the form of quaternary ammonium chloride; its structure is given below:



$R^1 = R^2 = R^3 = R^4 = CH_3$.

The molecular weight of the dye is 284 (without hydrochloric acid), and the molecular size, 14.3 ×

Table 1. Properties of activated carbon filers

Parameter	ACF-1	ACF-2	ACF-3
Sorption volume for benzene, $cm^3\ g^{-1}$	0.28	0.50	0.63

		Degree of recovery, %	9.3	42.6	43.3
		Solution pH after sorption	3.4	3.5	3.3

6.1 × 4 Å. The dye is well soluble in water, the solution is stable in the pH 2–11 range, and the maximum light adsorption is observed at 597 nm [6, 12, 13].

The MB sorption was carried out under static conditions (sorbent: solution ratio 1 : 500, agitation by rocking at a rate of 125 min^{-1}) from solutions with different initial concentrations of the dye and, in some cases, at different temperatures and pH values. The amount of the sorbed dye was determined from the difference of the dye concentrations in the initial solution and in solution after sorption, evaluated using an MKMF-1 spectrophotometer (l 10 mm) [14].

The influence of the initial concentration c and initial acidity of the solution on the dye recovery, equilibrium pH values, and actual sorption is illustrated in Table 2. In this experimental series, the sorption time t was 24 h.

As seen from Table 2, all the initial MB solutions were acidic. With increasing initial concentration of the dye from 1.5 to 9.4 mM, pH decreases from 4.2 to 2.5. This decrease in the solution pH is probably due to the hydrolysis of MB as a quaternary ammonium chloride. In sorption of MB, the solution pH often increases owing to a decrease in the dye concentration in solution and to sorption (neutralization) of hydrochloric acid on the carbon fibers. In the presence of oxygen in aqueous solutions, the activated carbon fibers can generate hydroxy ions [15], which can increase the solution pH.

The isotherms of MB sorption on the ACF samples are shown in Fig. 1; these isotherms are plotted in the coordinates of the linear Langmuir equation [16]:

$$c_i/a_i = 1/(a_\infty K) + c_i/a_i, \quad (1)$$

where a_i and a_∞ are the actual and limiting sorption capacities (mmol g^{-1}); c_i, the equilibrium MB concentration in the external solution (mM); K, adsorption equilibrium constant.

As seen from Fig. 1, a linear dependence of the sorption capacity is observed in the entire range of equilibrium concentrations, which indicates the formation of an ideal adsorption solution. The equation constants (limiting sorption capacity and equilibrium

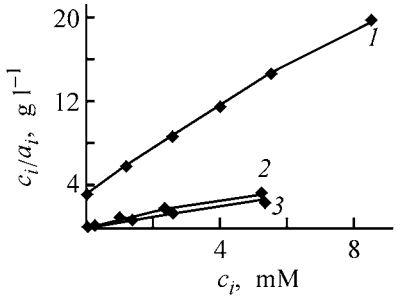

Fig. 1. Isotherms of MB sorption on fibers with various pore structures at 20°C. (c_i) Equilibrium concentration of MB and (a_i) sorption capacity. Sorbent: (*1*) ACF-1, (*2*) ACF-2, and (*3*) ACF-3; the same for Fig. 2.

Table 3. Langmuir equation constants

Sorbent	a_∞, mol l^{-1}	K
ACF-1	0.49	0.60
ACF-2	1.92	8.68
ACF-3	2.08	24.04

constant), determined graphically, increase steadily from ACF-1 to ACF-3 (Table 3).

As seen from Table 3, a_∞ and K rapidly increase with the appearance of mesopores in ACF-2 and ACF-3 (Table 1); this trend can also be related to increasing radius of the micropores.

In the crude approximation, we can calculate the volume of adsorbed MB molecules at their closest packing in a single monolayer on the sorbent surface:

$$V_\infty = a_\infty N_A V_m, \quad (2)$$

where N_A is the Avogadro constant and $V_m = 14.3 \times 6.1 \times 4 \times 10^{-24}$ cm^3 is the MB molecule volume.

Thus, we can evaluate the volumes of the adsorbed MB molecules for the ACF-1, ACF-2, and ACF-3 samples to be 0.10, 0.40, and 0.44 cm^3 g^{-1}, respectively. As seen from a comparison with the data given in Table 1, micropores in ACF-2 and ACF-3 samples are almost completely filled with sorbed MB molecules, whereas in ACF-1 nearly half of the volume of micropores is used. This fact indicates that the geometric size of micropores in ACF-1 does not allow accommodation of the MB molecules simultaneously on two pore surfaces, if we assume that dye molecules are arranged on the carbon surface as washers (4 Å high) and the width of the micropore is comparable with this value. Thus, the pore structure of the carbon sorbents can be easily determined from the sorption capacity for MB [3].

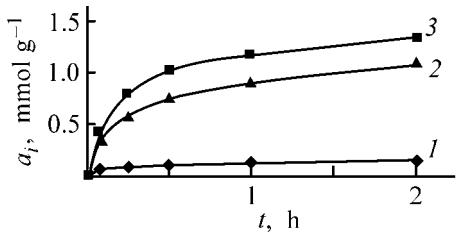

Fig. 2. Kinetic curves of MB sorption on fibers with various pore structures, initial MB concentration 4.7 mM, 20°C. (a_i) Sorption and (t) time; the same for Fig. 4.

The limiting sorption capacities a_∞ of ACF-2 and ACF-3 sorbents are approximately equal, although the total sorption volume and the volume of micropores in the ACF-3 sample are greater. This fact suggests that, owing to the features of size distribution of micropores in ACF-3 sample, certain micropores are inaccessible to MB molecules. Hence, sorbents with high content of micropores are not appropriate in some cases for sorption of large organic molecules. Moreover, ACFs containing only micropores whose size is comparable with the size of organic molecules (ACF-1) are also inefficient, because the sorption proceeds slowly owing to the absence of transport mesopores and to steric hindrance, and some micropores do not participate in sorption. This is confirmed by our data on the sorption kinetics (Fig. 2).

The diffusion coefficients were evaluated using the method of the kinetic curve moments [17], which allows estimation of the diffusion coefficients without solving a of system of kinetic equations. These moments are defined as areas over the kinetic curve which are commonly found graphically. To eliminate this approximate operation, the following kinetic equation was proposed in [18] can be used:

$$\gamma = 1 - \exp(-\delta t^n), \quad (3)$$

which gives analytical expressions for the first moment of the kinetic curve:

$$M_1 = \delta^{-1/n}\Gamma(1 + 1/n) \quad (4)$$

and for the effective diffusion coefficient in an infinite cylinder (fiber) of radius R:

$$D_{eff} = 0.125R^2/M_1, \quad (5)$$

where δ and n are constants, $\Gamma(x)$ is the tabulated gamma function, and $\gamma = a_i/a_\infty$.

The δ and n constants were determined graphically, by plotting the experimental data in the coordinates corresponding to the linear forms of Eq. (3): $\ln(1-\gamma) = f(t^n)$ and $\ln\ln(1-\gamma)^{-1} = f(\ln t)$.

The experimental data are satisfactorily described by Eq. (3) at $n = 0.3$. The effective diffusion coefficients (D_{eff}) calculated from Eqs. (4) and (5) are 0.39×10^{-17}, 2.3×10^{-17}, and 6.0×10^{-17} m^2 s^{-1} for ACF-1, ACF-2, and ACF-3, respectively. At the same time, the effective diffusion coefficient depends on the equilibrium solution concentration. The dependence of the effective diffusion coefficient of the concentration of the equilibrium solution for ACF-2 is shown in Fig. 3 (curve *1*). With increasing concentration, D_{eff}

decreases, which may be due to the aggregation of the molecules in solution.

Temperature strongly affects the dye sorption. The kinetic curves of MB sorption on the ACF-2 fiber at various temperatures are shown in Fig. 4. The temperature dependence of the effective diffusion coefficient for ACF-2 is shown in Fig. 3 (curve *2*).

As seen from Fig. 4, with the temperature increasing from 20 to 95°C, the sorption grows from 1.09 to 1.74 mmol g^{-1} (t = 2 h); the sorption rate increases simultaneously: at 20°C the half-sorption time is 25 min, at 65°C, 5 min, and at 95°C, 3 min. These results are in good agreement with published data [9].

The activation energies for temperature ranges 20–65 (E_a = 48.8 kJ mol^{-1}) and 65–95°C (E_a = 20.3 kJ mol^{-1}) were estimated from the temperature dependence of the effective diffusion coefficient (Fig. 3, curve *2*), approximated by the Arrhenius equation. It is known that dye molecules are solvated in solution and can form aggregates of several molecules in dilute solutions and in the sorbent phase [19]. With increasing temperature, the rate of diffusion grows, probably owing to breakdown of the solvation shells of the molecules and their aggregates. This is confirmed by a significant decrease in the activation energy (Fig. 3, curve *2*).

Our experimental data showed that sorption is almost independent of the solution acidity (or basicity) in the pH 2.4–11 range.

At 20°C, only up to 25% of the MB dye can be desorbed from the fiber with water. Subsequent treatment with NaCl solution did not provide dye desorption, and further treatment with 0.1 N HCl for 24 h allowed additional recovery of only 1% of MB.

Our experimental data suggest that at least 25% of the dye is weakly sorbed on the sorbent surface (physical bonding [3]). The absence of additional desorption of the dye upon treatment with NaCl and HCl solutions and the stability of sorption in a wide pH range show that ion exchange does not contribute to the sorption process.

CONCLUSIONS

(1) The sorption capacity and sorption rate were found to grow with increasing sorption volume of the sorbents.

(2) The limiting sorption capacities and constants of adsorption equilibrium with Methylene Blue for all the carbon fiber samples studied were calculated from the adsorption isotherms using the Langmuir equation.

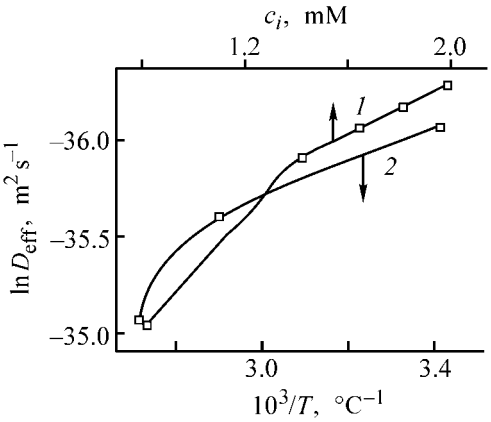

Fig. 3. Effective diffusion coefficient D_{eff} vs. (*1*) concentration c_i and (*2*) temperature T of the equilibrium MB solution for ACF-2 sorbent.

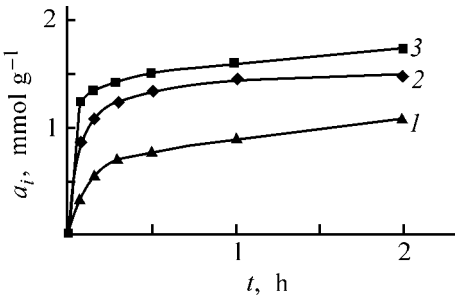

Fig. 4. Kinetic curves of MB sorption on ACF-2 fiber at various temperatures. Temperature (°C): (*1*) 20, (2) 65, and (*3*) 95.

(3) The effective diffusion coefficients in the 20–65 and 65–95°C range were calculated. These data allowed determination of the activation energies and gave insight into the mechanism of dye sorption in the fiber structure.

(4) It was established that sorption of Methylene Blue is approximately constant in the pH 2.4–11 range.

(5) Treatment of the carbon fiber with water resulted in approximately 25% desorption of the dye. Upon subsequent treatment with NaCl and HCl solutions, further desorption of the dye was insignificant.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Fulvic Acids from the Neva River on Anion Exchangers Based on Styrene–Divinylbenzene Copolymer

G. V. Slavinskaya

Voronezh State University, Voronezh, Russia

Received February 10, 2003

Abstract—Sorption of fulvic acids (FA) on anion exchangers based on styrene–divinylbenzene copolymer was studied.

All the surface and underground waters contain humic substances, among which fulvic acids (FAs) prevail. The FA content exceeds that of humic acids (HA) by a factor of 10–30 [1–4]. Fulvic acids are undesirable impurities in potable and industrial waters. The coagulation and sorption on activated carbon remove humic substances unefficiently. More efficient purification can be achieved by water treatment with porous anion exchangers [4–6]. In order to improve preparation of ultrapure water, a wide variety of sorbents should be tested to find the anion exchangers with the maximum selectivity with respect to organic pollutants and, especially, fulvic acids.

EXPERIMENTAL

In this study, we tested the following anion exchangers based on styrene–divinylbenzene copolymer (DVB): widely used strongly basic AV-17P resin with quaternary ammonium base sorbing sites, medium-basic ANT-511 anion exchanger (Research Institute of Plastics, Moscow, Russia), and Wofatit AD-41-anion exchanger with tertiary amino groups (St. Bitterfeld Chemiekombinat, Germany). We also tested weakly basic IA-1 and IA-2 polycondensation ion exchangers derived from *m*-phenyldiamine with primary and secondary amino groups (Research Institute of Plastics, Nizhni Tagil, Russia) [5].

Before use, all the anion exchangers were conditioned by alternating treatment with 1 M NaOH and HCl [7]. The amount of removed impurities was determined by the optical density of the filtrates at 220 nm. The conditioning was performed until the optical densities (D_{220}) of the washing solution at the inlet and outlet of the column became equal. In the course of conditioning, the IR spectra of anion exchangers were recorded.

The quarternary ammonium bases have ionization constants $K_b \approx 10^{-1}$–10^{-2} (pK_b = 1–2). The tertiary amino groups are less ionized: $K_b \approx 10^{-3}$–10^{-5} (pK_b = 3–5). The basicity of primary and secondary amino groups depends on their location in the anion-exchanging polymer. When linked with aliphatic chains, they have $K_b \approx 10^{-3}$–10^{-5} (pK_b = 3–5); when bound to aromatic rings (directly or through a methylene group), they have considerably lower ionization constants: $K_b \approx 10^{-6}$–10^{-9} (pK_b = 6–9) [8, 9].

The ionization constants of low-basic amino groups of IA-1 and IA-2 anion exchangers were refined by potentiometric titration with 0.1 M HCl at constant ionic strength (0.1 M KCl). Upon adding each portion of the titrant, the mixture was allowed to stay for 14 days. We found that the ionization constants of different batches of weakly basic anion exchangers, calculated by the Henderson–Hasselbach method [10], are close to 2×10^{-8} (pK_b = 7.8).

In this study, we used fulvic acids recovered from the Neva River by the technique reported in [3]. These FAs were purified to remove mineral impurities and then identified by physicochemical methods. The FA content in the aqueous solutions was determined specrophotometrically, using the calibration plot of $D_{205} - D_{250}$ vs. FA concentration. The calibration solutions were prepared by dissolving weighed portions of ash-free FA. It is known that the optical density of aqueous solutions of FA in the ultraviolet range decreases with increasing wavelength [1, 3]. Therefore, the cal-

ibration curves were constructed at different wavelengths. Such calibration curves allow determination of the FA concentration (c_{FA}) over a wide range without dilution of the samples.

Taking into account that the shape of the output curve of ion-exchange sorption is a function of both the equilibrium and kinetic sorption characteristics [11, 12], the FA sorption on the anion exchangers was studied under dynamic conditions. In these experiments, a sorbent was placed in a column with cross section of 0.92 cm^2. The sorbent bed height was 18–20 cm; the flow velocity, 10 ± 1 m h^{-1}; initial FA concentration, 17 ± 0.5 mg l^{-1}; and pH, 3.2 ± 0.1.

The mutual arrangement of the output curves (Fig. 1) of FA sorption shows that the strongly basic anion exchanger sorbs FAs somewhat more weakly than the less ionizable resins. On filtering 700 column volumes of the FA solution, the FA content in the filtrate was $(0.1–0.15)c_0$ and $0.25c_0$ for weakly basic and strongly basic anion exchangers, respectively.

The isotherms of FA sorption on anion exchangers based on styrenedivinylbenzene copolymer were obtained under static conditions. The sorbent and liquid phases were brought in contact for 15 days at 20 ± 1°C with intermittent stirring for 8 h, followed by standing for 16 h. The sorption isotherms (Fig. 2) have a convex shape and are fairly well described by the Freundlich equation [13]

$$a = \beta c_\alpha,$$

where a is sorption; c, sorbable substance concentration in the liquid phase; β, parameter characterizing sorption of the sorbable substance at its concentration 1 mg l^{-1}; α, empirical parameter varying from 0.1 to 0.5 [14].

It is known that tap water contains up to 10 mg l^{-1} FA [1, 3, 4], i.e., it is a dilute FA solution. As seen from the above equation, the efficiency of sorption treatment of water to remove FA is governed by the β parameter at low FA concentrations. The values of β and limiting FA sorption after 15-day contact with different anion exchangers are given below:

Anion exchanger	β(±3), mg g^{-1}	a_∞(±5), mg g^{-1}
ANT-511	122	375
Vofatit AD-41	41	610
AV-17-2P	62	485

Comparison of these results and those in Fig. 2 shows that the highest sorption activity is exhibited by ANT-511 anion exchanger in dilute solutions, despite its lowest sorption capacity for FA.

The sorption of large organic molecules decreases the moisture content of the anion exchangers, which hinders transfer of the sorbable components into a granule [15]. This steric hindrance deteriorates the sorption kinetics. Furthermore, the pore water volume and transfer of sorbable components into the sorbent granule depend on the degree of cross-linking.

In order to elucidate how the cross-linking agent (DVB) affects the sorption capacity of the anion exchanger for FA, we obtained the output curves of FA sorption on AV-17-P anion exchangers containing 2, 12, and 20% DVB. We also studied the FA sorption on AV-17-8 gel-like anion exchanger, which is a nonporous analogue of AV17P. The total exchange capacity (TEC), content of weakly and strongly basic amino groups, moisture content of AV-17 anion exvaried with varied DVB content, determined by standard techniques [16], are listed in the table.

Characterization of AV-17 anion exchanger madifications

Anion exchanger	TEC (±0.02), mg-equiv g^{-1}	Basic group content (±0.02), mg-equiv g^{-1}		Moisture content, g H_2O/g	FA sorption (±0.05), mg cm^{-3}
		strongly basic	weakly basic		
AV-17-2P	4.53	2.98	1.55 (34.2)*	3.44	3.01
AV-17-8	3.12	2.38	0.74 (23.8)	1.41	2.11
AV-17-12P	2.84	2.03	0.81 (28.5)	1.20	1.08
AV-17-20P	2.13	2.00	0.13 (6.1)	1.13	0.61

* Content of weakly basic amino groups, %.

These results show that all the sorbents tested contain both weakly and strongly basic amino groups, and the amount of weakly basic amino groups decreases with increasing content of the cross-linking agent (DVB). The most cross-linked AV-17-20P anion exchanger contains predominantly strongly basic amino groups. For all of the anion exchangers, the TEC and moisture content decrease with increasing DVB content. Thus, our sorption experiments failed to establish an unambiguous correlation between the sorption capacity with respect to FA and the degree of cross-linking.

The output curves of FA sorption were obtained using a 17.2 ± 0.5 mg l^{-1} FA aqueous solution at pH ~4.2. As seen from the table and Fig. 3, the sorption capacity decreases in the order AV-17-2P > AV-17-8 > AV-17-12P > AV-17-20P with increasing degree of cross-linking. It should be noted that, although AV-17-8 is a nonporous anion exchanger, its TEC and the shape of the output sorption curve follow the general relationships typical of the sorbent series under consideration.

We found that the maximum sorption capacity for FA is exhibited by AV-17-2P anion exchanger with the minimum DVB content (2%). This sorbent is characterized by the highest moisture content and TEC. The more cross-linked anion exchangers AV-17-12P and AV-17-20P, which contain, respectively, 12 and 20% DVB, have virtually the same moisture content (1.20 and 1.13 g H_2O/g anion exchanger). However, AV-17-12P contains a considerably larger amount of weakly basic groups, which increases its sorption capacity as compared to AV-17-20P. However, it is not improbable that the sorption capacity of the anion exchangers under consideration is governed not only by ionic groups, but also by the pore size. Although the data on the moisture content show that the total pore volume of AV-17-12P and AV-17-20P are close, we can expect that the pores of more strongly cross-linked AV-17-20P anion exchanger are narrower than those of AV-17-12P. This factor hinders transfer of FA molecules into AV-17-20P globules, and, therefore, FAs are predominantly sorbed on the sorbent surface.

The sorption service life of ANT-511 (Fig. 4a) and AV-17-2P (Fig. 4b) in water treatment to remove FA

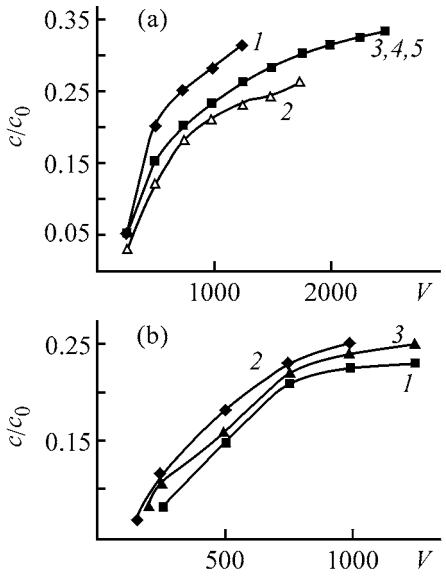

Fig. 4. Output curves of FA sorption on (a) ANT-511 and (b) AV-17-2P anion exchangers. *Digits at curves* are numbers of the filtration cycle.

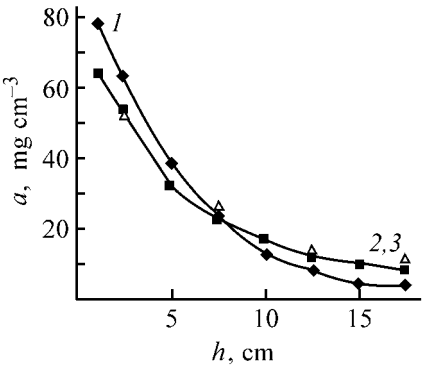

Fig. 5. FA distribution along a column packed with (*1*) IA-2, (*2*) Wofatit AD-41, and (*3*) ANT-511 anion exchangers. (*a*) FA content in the anion exchanger and (*h*) bed length.

was determined under dynamic conditions with sorption–desorption filtration cycles. In these experiments, 800 to 2500 column volumes of FA aqueous solution was passed through a column. We found that, after the first filtration cycle, the sorption efficiency of AV-17-2P anion exchanger slightly decreases, presumably owing to incomplete FA desorption. By contrast, the sorption efficiency of ANT-511 anion exchanger remains unchanged even after treatment of 11000 column volumes of water to remove FA in five successive filtration cycles.

The IR spectra of a dry residue of FA-containing water filtered through an anion exchanger showed that the chemical nature of the organic matter sorbed on the anion exchanger depends on the kind of a sorbent. With a strongly basic anion exchanger, the dry residue of the filtrate contains no FA carboxy groups but shows the presence of the aliphatic chains. At the same time, on filtering through ANT-511 and IA-2 resins, the filtrates are depleted of aliphatic components, but the carboxy groups appear. These results show that water treatment to remove organic impurities should be carried out by successive filtration through strongly, medium, and weakly basic anion exchangers.

In water treatment with two-stage sorption, the weakly basic anion exchangers were used and regeneration was carried out with 2% NaOH. The strongly basic anion exchangers were regenerated with an alkaline–salt solution (2% NaOH + 10% NaCl) [4]. Upon successive filtering through ANT-511 (Wofatit AD-41) and AV-17-P at a filtration velocity of 10 m h^{-1}, the FA content in the initial model solution decreases from 21.8 to 4.6–5.1 mg l^{-1}.

Similar results were obtained in successive filtration of water through polymerization anion exchangers of different basicities and weakly basic condensation anion exchangers. After successive filtration of an aqueous solution (800 column volumes) through IA-1 (IA-2)–AV-17-P and IA-1 (IA-2)–Wofatit AD-41 column systems, the average FA content in the filtrate did not exceed 4.8 mg l^{-1}. Our results show that the weakly and medium-basic anion exchangers remove FA to a similar extent. We studied also FA distribution along an anion-exchange column. In these experiments, column was saturated with fulvic acids and then divided into 3-cm parts. These fragments were treated with an alkaline solution to desorb FAs. Figure 5 demonstrates the FA distribution along the column. This figure shows that saturation of IA-1 weakly basic anion exchanger with FA is stronger in the upper layer and weaker in the lower layer; this resin is more effective than strongly basic anion exchangers. With strongly basic resins, the FA sorption is lower, and the sorption front is more diffuse.

The long-term bench tests showed that successive filtration through IA-2 weakly basic condensation and AV-17-2P strongly basic polymerization anion exchangers ensures efficient purification of Neva water to remove FAs and HAs. Taking into account these results, an anion-exchange sorption unit was installed into an industrial desalination device with output capacity of 2 m^3 h^{-1}. Installation of such a unit eliminates the need for coagulation water treatment. The chemical oxygen demand of desalinated water prepared by this technique does not exceed 1 mg O_2 l^{-1}, which meets the requirements to industrial water.

CONCLUSIONS

(1) The sorption capacity of anion exchangers based on styrene–divinylbenzene copolymer with respect to fulvic acids increases with decreasing degree of ionization of ionic groups or the content of the cross-linking agent.

(2) Strongly basic anion exchangers predominantly sorb the fulvic acid fractions containing ionic carboxylate groups; the medium and weakly basic anion exchangers sorb nonionic organic impurities.

(3) Two-stage sorption treatment of water to remove fulvic acids by successive filtering through columns packed with anion exchangers of different basicities decreases the organic impurity content to a level corresponding to deionized water with chemical oxygen demand less than 1 mg O_2 l^{-1}.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Industrial Oil by Expanded Graphite

M. V. Savos'kin, A. P., Yaroshenko, V. N. Mochalin, and B. V. Panchenko

Litvinenko Institute of Physicoorganic Chemistry and Coal Chemistry, National Academy of Sciences of Ukraine, Donetsk, Ukraine

Received May 13, 2002; in final form, April 2003

Abstract—Sorption of industrial oil by expanded graphite prepared from residual graphite hydrosylfate at 300–900°C was studied. The sorption isotherms of both neat oil and oil from its aqueous suspension were measured. The sorption capacity for oil was studied as influenced by the specific surface area and specific volume of expanded graphite sorbent.

As previously shown by the method of direct sorption, expanded graphite is a highly efficient sorbent for petroleum (1 g of the sorbent sorbs up to 80 g of petroleum) [1–5]. Expanded graphite has also been proposed [6, 7] as a sorbent of various fats and oils; however, no quantitative sorption parameters were reported in these studies and the dependenes of the sorption on the sorbent properties were not evaluated. In this study we analyzed sorption of industrial oil by expanded graphite as influenced by the properties and preparation conditions of the graphite. For this purpose we used pure industrial oil (direct sorption) or aqueous oil emulsions.

We used residual graphite hydrosulfate prepared by the procedure described in [8]. The sorbent was prepared by flash heating of residual graphite hydrosulfate in a muffle furnace at temperature ranging from 300 to 900°C. The samples were kept at 300–500°C for 5 min and then at 600–900°C for 2 min. We measured the specific surface area S_{sp} ($m^2\ g^{-1}$), specific volume V_{sp} ($cm^3\ g^{-1}$), and specific sorption of industrial oil W_{sp} ($g\ g^{-1}$) for all samples of expanded graphite. The BET specific surface area was determined by low-temperature argon adsorption in accordance with GOST (State Standard) 13 144–79. The specific volume was calculated as the reciprocal of the bulk density of the sorbent, which, in turn, was determined in accordance with GOST (State Standard) 14 922–77.

Sorption of neat I-20 industrial oil and sorption of this oil from an aqueous emulsion were studied at 20°C. In the first case, a weighed portion of the sorbent was placed in a glass vessel, carefully wetted with excess oil (25 g), and kept for 30 min to complete the sorption. Then the vessel was covered with perforated metal foil and unsorbed oil was allowed to drain down for 1 day. The oil sorption was determined gravimetrically [9].

Oil sorption from an aqueous emulsion was performed by the following procedure. An oil emulsion was prepared by stirring a mixture of oil with 1 dm^3 of distilled water with a magnetic stirrer. The oil concentration c_{oil} ($g\ dm^{-3}$) was varied from 0.08 to 20 $g\ dm^{-3}$. A weighed portion of the sorbent was added to the emulsion and the mixture was stirred for 15 min. The sorbent was then quantitatively separated by filtration through a paper filter, dried at 100°C, and weighed. The oil sorption on the paper filter was determined in a blank experiment. In special experiments, we found that there are no losses of sorbed oil during drying of the sorbent.

The properties of the sorbents prepared at temperatures from 300 to 900°C are presented in the table.

We measured the sorption isotherm of I-20 industrial oil from neat oil and its aqueous emulsion on

the sorbent prepared at 900°C. We used this sorbent since it is characterized by the maximum specific surface area, maximum specific volume and, as previously shown [9], by the maximal sorption capacity for petroleum. The sorption isotherms are shown in Figs. 1a and 1b.

Both isotherms are typical of sorption processes. The specific sorption of neat oil grows almost linearly with increasing oil-to-sorbent weight ratio up to values slightly exceeding 40 (Fig. 1a). The slope of the isotherm in this range is close to unity, i.e., the whole amount of oil is sorbed by the expanded graphite. At a ratio of about 100, the isotherm flattens out. The sorption capacity of the expanded graphite for industrial oil W_{sp}^{max} (g g^{-1}), determined from the sorption isotherm, is about 70 g g^{-1}. It should be noted that this value is close to the sorption capacity of expanded graphite for petroleum, determined by the direct sorption procedure [9].

When the oil is sorbed from its aqueous emulsion, the specific sorption grows linearly with the oil concentration increasing up to 4 g dm^{-3} and then flattens out. The maximum sorption of oil from the emulsion (the sorption capacity), determined by cubic interpolation of the experimental data, is about 20 g g^{-1} at oil concentration of 6.7 g dm^{-3}.

We studied how the temperature at which expanded graphite was prepared affects the oil sorption from an aqueous emulsion. In these experiments, the oil concentration (6.7 g dm^{-3}) was close to that at which the isotherm of oil sorption by expanded graphite prepared at 900°C starts to flatten out. Since the sorption capacity of graphite expanded at 900°C is highest among the samples prepared in the range from 300 to 900°C, the above choice of emulsion concentrations ensures that the values obtained for all the samples studied fall on the plateaus of the sorption isotherms, i.e., allows determination of their sorption capacities.

As seen from Fig. 2a, the sorption capacity of expanded graphite determined in the experiment with an oil emulsion grows linearly with increasing sorbent preparation temperature. This is due to a linear rise in the specific surface area and specific volume of the sorbent with increasing preparation temperature (see table; Figs. 2a, 2b). The influence exerted by the specific surface area and specific volume of the samples on the sorption capacity of graphites expanded at 300–900°C for oil from an aqueous emulsion is described by the following two-parameter linear regression equation $W_{sp} = 0.592S_{sp} + 0.415V_{sp}$ ($r = 0.995$). As determined from Student's t-test at the confidence level of 0.95, the coefficient at parameter S_{sp} is significant and the significance of the coefficient

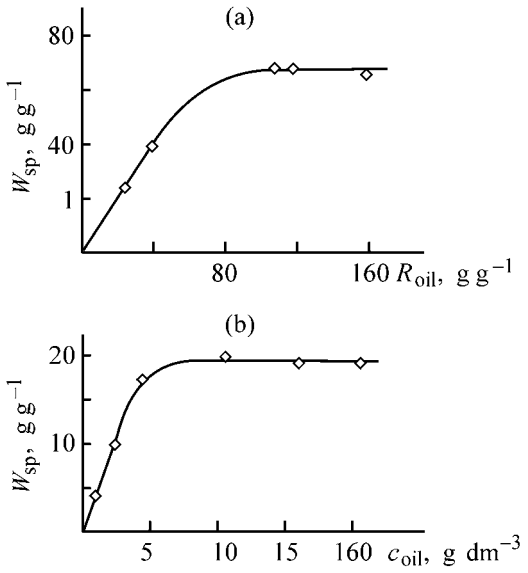

Fig. 1. Isotherms of sorption of I-20 industrial oil at 20°C by expanded graphite prepared from residual graphite hydrosulfate at 900°C. (W_{sp}) Sorption capacity of expanded graphite, (R_{oil}) initial oil/sorbent ratio, (c_{oil}) oil concentration in aqueous emulsion. (a) Direct sorption and (b) sorption from aqueous emulsion.

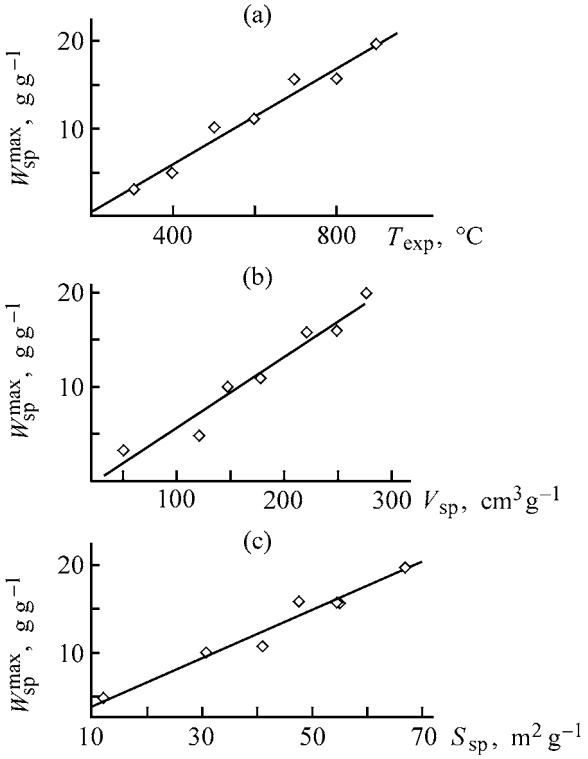

Fig. 2. Sorption capacity of expanded graphite, W_{sp}^{max}, for oil from an aqueous oil emulsion vs. (a) sorbent preparation temperature T_{exp}, (b) specific volume of the sorbent V_{sp}, and (c) specific surface area of the sorbent, S_{sp}.

at V_{sp} is close to the limiting significance value. The latter fact is probably due to strong correlation between S_{sp} and V_{sp} ($r = 0.95$). Our results show that oil sorption from an aqueous emulsion depends on both the specific volume and the specific surface area of the sorbent. As determined from the regression equation, 60% of oil is sorbed on the sorbent surface, and 40%, in the bulk of the sorbent.

It should be noted that the sorption capacity of expanded graphite for oil from an aqueous emulsion is lower by a factor of 3.5 than that for neat oil. This difference cannot be due to higher oil concentration in neat oil, since the sorption capacity levels off at 6.7-g dm^{-3} oil concentration in the emulsion. This cannot be accounted for by preferential sorption of water, either, since the surface of the expanded graphite is hydrophobic. Even if water is sorbed in the first steps, it will be desorbed from the sorbent by hydrophobic oil. The lowering of the sorption capacity in an aqueous emulsion as compared to the direct sorption experiment is presumably due to structural transformations of expanded graphite under the action of water. Indeed, the specific surface area and specific volume (parameters responsible for the sorption capacity of expanded graphite) of the samples wetted with water and then dried decrease by a factor of 2–3.

CONCLUSION

Expanded graphite is an efficient sorbent for industrial oil. The sorption is controlled by both the specific volume and the specific surface area of the sorbent. Graphite expanded at 900°C has the maximum sorption capacity and can be used in practice. The capacity of this sorbent for neat oil is about 70 g g^{-1}. When oil is sorbed from its aqueous emulsions, the sorption capacity decreases to 20 g g^{-1}, but remains sufficient for effective application of the sorbent.

SORPTION AND ION-EXCHANGE PROCESSES

Nondestructive Surface Sampling with Polymethyl Methacrylate Doped with Alkali Metal Cations

G. V. Lyamina, E. P. Knyazeva, and G. M. Mokrousov

Tomsk State University, Toms, Russia

Received June 20, 2002

Abstract—Sorption of copper and copper oxide from the alloy surface by poly(methyl methacrylate) doped with alkali metal cations was studied with the aim to develop nondestructive sampling of metals from the surface. The sampling efficiency was studied as influenced by the content of alkali metal cations and water in the polymeric matrix.

Nondestructive methods for studying and analyzing the surface require, as a rule, complex equipment, are expensive, and cannot be used for express analysis on the site. Therefore, development of a nondestructive express analysis of various objects for the content of metals and their compounds is a topical problem.

The aim of this study was to demonstrate the possibility of using a polymeric formulation based on polymethyl methacrylate and alkali metal trifluoroacetates (MPMMA) [1, 2] as a sorbent for nondestructive express sampling of metals and their oxides from the surface of an alloy containing 74 wt % silver and 26 wt % copper.

EXPERIMENTAL

In chemical analysis, polymers are mainly used in the form of solutions and films immobilized on the surface of a conducting material [3, 4]. In this study, we used MPMMA in the form of plates (organic glasses) pre- pared by bulk polymerization of methyl methacrylate (MMA) mixed with an appropriate alkali metal trifluoroacetate [1]. The salt concentration was varied from 1 to 6 mol per 1 kg of MMA. Some of the samples were kept for 1 day in desiccators at a humidity ω of 47, 58, and 80%; the water content in the samples depended on the nature and content of a modifier (Table 1). We studied sampling from the surface of a copper-containing alloy. The polymers were mechanically pressed against the surface with a 5 kg cm^{-2} force for 20 min. The contact time was determined experimentally (Fig. 1).

The sorption of copper and its oxides by MPMMA was determined voltammetrically with mercury and amalgam (HgNa) electrodes (contact time 5 min) by the procedure described in [5, 6]. The copper sorption was measured with the first electrode, and the sorption of copper and its oxides, with the second. After a contact of the mercury or amalgam electrode with the polymer surface, a differential voltammogram was recorded in 0.1 M KCl at potential sweeping in the range from –0.8 to 0.0 V at a rate w = 30 mV s^{-1}. The potential was measured relative to 0.1 M silver chloride electrode.

The copper sorption by the polymer depends on the nature of metal cations introduced into the poly-

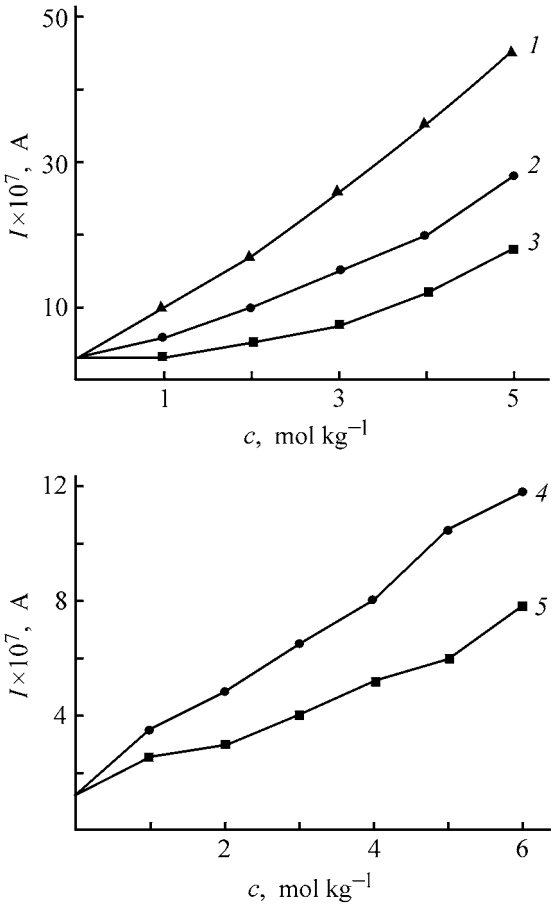

Fig. 3. Voltammetric signal I of amalgam electrode, characterizing the copper sorption by MPMMA, vs. the content c of (*1–3*) CF_3COOK, (*4*) CF_3COONa, and (*5*) CF_3COOLi in the polymer. Polymers were kept in desiccators with humidity (%) of (*1, 4, 5*) 80, (*2*) 58, and (*3*) 47.

mer (Fig. 2) and on their hydration properties (Fig. 3, Table 1). The activity of alkali metal cations grows in the order $Li^+(Na^+) < K^+$, which is probably due to the difference in their ionic radii. As the ionic radius increases, the positive charge is shielded, the bonding of the cation with the terminal groups of the polymeric matrix is weakened, and the mobility of the cation grows.

The sorption activity of MPMMA samples containing Li^+ and Na^+ cations increases after keeping the samples in a humid atmosphere. This is due to an increase in the radius of the hydration shell of the alkali metal cations, which is the most pronounced for lithium. Correlation analysis of the results of voltammometric determination of copper shows that the sorption capacity of MPMMA depends on the content of alkali metal trifluoroacetate. The sorption grows with increasing CF_3COOK concentration in the polymer (Fig. 3, curves *1–3*). The sorption capacity of the CF_3COOK-modified polymer for copper oxides increases after keeping the polymer in a humid atmosphere. This is also the case for elemental copper, but the analytical signal is lower by an order of magnitude. The sorption of both forms of copper by the polymer kept at $\omega = 80\%$ is the strongest, and by the polymer kept at $\omega = 47\%$, the weakest.

In the case of a polymer containing CF_3COONa, the rise in the sorption of elemental and oxidized copper species with increasing modifier content is observed for the polymer kept at 80% humidity (Fig. 3, curve *4*) and not observed for a polymer kept at 58% humidity.

The sorption of copper oxides by MPMMA containing CF_3COOLi grows with increasing modifier content only for the samples kept at 80% humidity (Fig. 3, curve *5*). The content of the lithium salt has virtually no effect on the sorption of copper oxide. Thus, the polymers modified with lithium and so-

dium salts and kept in a humid atmosphere are characterized by copper sorption dependent on the modifier content and by improved reproducibility of the analytical results (Table 2).

The copper sorption was determined gravimetrically. CF_3COOLi-doped MPMMA (modifier content 5 mol kg^{-1}) sorbs 0.0011 ± 0.0002 g of copper after contact with a 1-cm^2 surface of a copper plate for 7 days.

Sorption of elemental copper and its oxides by MPMMA is probably due to potential difference across the polymer/sample interface, which is confirmed by emf generation in the Cu | MPMMA | Pt system. After a contact of the polymer with a sample, the absorption band of water sorbed by alkali metal cations (ν = 3500 cm^{-1}) broadens and becomes unsplit, which indicates hydrogen bonding between water molecules. The bands of the functional groups of the polymer and those of alkali metal trifluoroacetates incorporated in the polymeric matrix are not shifted. These facts suggest that copper sorbed by MPMMA is in the form of an aqua complex weakly bound to the polymer matrix. After prolonged contact of MPMMA with a copper-containing sample (60 days), the polymer turns blue. The sorption properties of MPMMA with respect to copper and its oxides do not change for up to 4 years.

CONCLUSIONS

(1) Polymethyl methacrylate doped with potassium cations exhibits the best sorption properties with respect to copper. The sorption of copper and its compounds from the sample surface by this polymer is the strongest. The reproducibility of analysis of the sample surface for copper with a polymeric formulation composed of polymethyl methacrylate and CF_3COOK, kept in a humid atmosphere, is the best.

(2) The formulation composed of polymethyl methacrylate and alkali metal salts is promising for nondestructive analysis of the surface of copper-containing samples.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Voltammetric Determination of Tin(II) and Iron(II) on Mechanically Renewed Graphite Electrode in Tin-Plating Electrolyte

L. I. Skvortsova and A. Zh. Medvedev

Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

Received January 22, 2003

Abstract—The analytical properties of the cathodic peak of tin(II) reduction and the anodic peak of iron(II) oxidation on a graphite electrode were studied with the electrode surface mechanically renewed directly in a solution before applying a potential in each measurement. The influence of the organic components of the phenolsulfonic tin-plating electrolyte on the cathodic current of tin(II) reduction and anodic current of iron(II) oxidation was studied. A dc voltammetric method was proposed for determining tin(II) directly in the phenolsulfonic tin-plating electrolyte, and iron(II) after the electrolyte is diluted tenfold with a 0.5M H_2SO_4 supporting solution.

Tin is one of the few metals, whose compounds are not harmful to humans. For this reason, it is used to coat any items associated with storage and manufacture of food products. Tin coatings are also used for electrochemical protection of steels and for imparting good electrical conductivity to contact surfaces. Tin is electroplated in both acid and alkaline solutions. Acid electrolytes are prepared by dissolving tin(II) salts in sulfuric, hydrofluoric, tetrafluoroboric, phenolsulfonic, and sulfamic acids. The most widely used in industry are sulfate electrolytes containing a 0.5–1.0 N solution of $SnSO_4$ in 1.5–2 N sulfuric acid, which hinders tin(II) hydrolysis and raises the electrical conductivity of the solution [1]. Dense, compact, finely grained tin deposits with structure relatively uniform across the thickness are obtained from acid electrolytes in the presence of some surfactants.

Electrolytes based on tin(II) phenolsulfonate in *n*-phenolsulfonic acid are less subject to tin(II) oxidation than sulfate electrolytes [2]. The stability of this electrolyte and the coating quality at high current densities are also markedly improved upon addition of a surfactant.

In this study, we verified the possibility of monitoring the content of tin(II) and iron(II) by dc voltammetry in a phenolsulfonic tin-plating electrolyte. This electrolyte is used for tin coating of steel tape in the Ferrostan technology. Its standard composition is (g l^{-1}): Sn^{2+} ions (in the form of $SnSO_4$) 30, *n*-phenolsulfonic acid 75.8 (66%), and ESNA (ethoxylated α-naphtholsulfonic acid) as surfactant additive 6.7. Since the Ferrostan technology uses anodes made of metals other than tin, the content of tin(II) in the electrolyte decreases continuously. According to the technical regulations, the tin(II) concentration in electrolyte is maintained within 30 ± 1 g l^{-1}. For this reason, it is necessary to monitor its content at regular intervals of time and adjust it by adding a concentrated $SnSO_4$ solution. The most common industrial method for determining tin(II) is volume iodatometric or iodometric titration [3].

A method is known for direct voltammetric determination of tin(II) in chloride solutions [4]. This technique is based on recording the anodic peak of tin(II) electrooxidation on a graphite electrode at a potential $E_p = 0.3$ V. It was noted in [4] that a peak of Sn^{4+} reduction is observed in addition to the cathodic peak of Sn^{2+} reduction at $E_p = -0.68$ V, and, therefore, the latter cannot be used for determining tin(II) content in a chloride medium. Tin(II) is reduced to metal in a 1M H_2SO_4 solution on mercury electrode at a half-wave potential $E_{1/2} = -0.46$ V [5].

When in use, tin-plating electrolyte continuously accumulates Fe^{2+} ions, which affect adversely the coating quality at concentrations higher than 10 g l^{-1}.

This necessitates monitoring of the iron(II) concentration in tin-plating electrolytes on regular basis. Electrooxidation of Fe^{2+} to Fe^{3+} on a mercury electrode in a sulfate supporting electrolyte occurs at $E_{1/2}$ = +0.54…+0.60 V [6]. Among organic supporting solutions, the oxalate solution is more commonly used for voltammetric determination of Fe^{2+}, since the half-wave potential of iron(II) oxidation in this solution is ±0.24 V [7].

The method of direct voltammetric determination of Sn^{2+} and Fe^{2+} ions on a graphite indicator electrode served as basis for developing a procedure for monitoring the content of these ions in a phenolsulfonic tin-plating electrolyte. The influence of all electrolyte components on the peak currents of each ion to be determined was studied and conditions of microelectrode polarization were chosen.

EXPERIMENTAL

Voltammograms were recorded with a PA-2 polarograph and N-307 plotter in a three-electrode cell with a saturated calomel reference electrode and auxiliary graphite electrode. The graphite indicator electrode was in the form of a cylindrical rod made of cured epoxy resin (external diameter 4 mm). Its electrically active part (2 mm in diameter) made of a hardened graphite formulation was situated along the rod axis. The working surface of the indicator electrode (rod edge) was renewed at regular intervals directly in the test solution by cutting-off mechanically a 0.5-μm surface layer on a special device [7, 8]. The surface was always renewed before applying the electrode potential. The potential sweep rate was varied from 10 to 100 mV s^{-1}.

Model electrolyte solutions were prepared according to prescription by dissolving organic components in distilled water and adding a calculated weighed portion of $SnSO_4$ and $FeSO_4 \cdot 7H_2O$. Preliminarily, the tin content in the reagent (pure grade) was found by iodatometric titration (starch indicator) [1], and the iron(II) content in a freshly recrystallized reagent, by theoretical calculation. Since tin(II) and iron(II) are easily oxidizable, all solutions were prepared from separate weighed portions of a reagent in a deoxygenated supporting solution.

As supporting solutions were chosen sulfuric, hydrochloric, oxalic, and phenolsulfonic acids. The voltammogram of a sulfate supporting electrolyte shows in the cathodic region a peak due to reduction of dissolved oxygen, which completely disappears after argon is passed through the solution for 5 min. The polarization curve of cathodic reduction of tin(II) to metal on a graphite electrode in a 0.2M H_2SO_4 supporting solution shows a clearly pronounced and well-resolved peak at E_p = –0.66 V. A study of the influence exerted by phenolsulfonic acid, ENSA surfactant, and iron(II) compound on the cathodic peak of tin(II) reduction demonstrated that the qualitative and quantitative characteristics of the tin(II) peak in a sulfate supporting electrolyte are not affected by these components. The calibration plot of the peak current of tin(II) reduction against its concentration in a 0.2M H_2SO_4 solution is a straight line emerging from the origin. However, at Sn^{2+} content exceeding 10 g l^{-1}, the slope of the calibration plot changes somewhat.

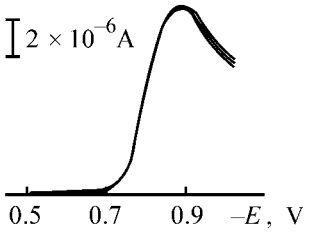

Fig. 1. Voltammograms of Sn^{2+} cathodic reduction on mechanically renewed graphite electrode in phenolsulfonic electrolyte for tin plating. $c_{Sn^{2+}}$ = 10 g l^{-1}, V = 50 mV s^{-1}, and n = 5. (E) Potential; the same for Figs. 2 and 3.

Compared with the sulfate supporting electrolyte, the potential of the Sn^{2+} reduction peak in a phenolsulfonic electrolyte containing 76 g l^{-1} *n*-phenolsulfonic acid and 6.7 g l^{-1} ENSA is shifted to the negative region and, depending on the bulk concentration of tin(II), falls within E_p = –0.90…–0.95 V. The linear run of the $I_p = f(c_{Sn^{2+}})$ calibration plot for Sn^{2+} reduction in a phenolsulfonic electrolyte is preserved. The reproducibility of voltammograms of tin(II) oxidation is demonstrated in Fig. 1 for five curves. The relative standard deviation of the peak current for tin(II) concentration of 30 g l^{-1} in this electrolyte at n = 8 and P = 0.95 does not exceed 0.006.

As is known, Sn^{2+} ions are easily oxidized by atmospheric oxygen, so the Sn^{4+} ions are always accompanying. A study of the electrochemical behavior of Sn^{2+} ions in a 0.5M sulfate supporting solution demonstrated that Sn^{4+} ions are cathodically reduced on a graphite indicator electrode at potentials E_p = –0.80…–0.87 V. The difference between the potentials of tin(II) and tin(IV) peaks in this supporting solution is insignificant (–0.15…–0.2 V). In those cases, when Sn^{2+} and Sn^{4+} are present simultaneously, an overall voltammogram is recorded in a sulfate supporting solution. Another situation is observed in a phenolsulfonic supporting solution. Addition of a tin(IV) com-

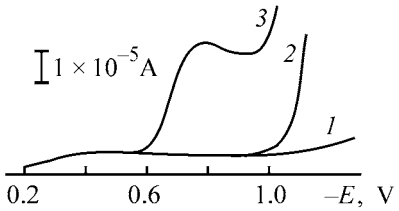

Fig. 2. Voltammograms of cathodic reduction of Sn^{2+} and Sn^{4+} in phenolsulfonic electrolyte for tin plating. V = 100 mV s^{-1} and $I = h \times 10^{-5}$ A cm^{-1}. (*1*) Supporting solution of phenolsulfonic electrolyte, (*2*) supporting solution with addition of Sn^{4+} ($c_{Sn^{4+}}$ = 0.17 g l^{-1}), (*3*) solution 2 with addition of Sn^{2+} compound ($c_{Sn^{2+}}$ = 0.28 g l^{-1}).

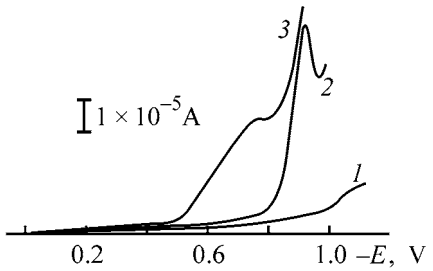

Fig. 3. Voltammograms of supporting solutions and iron(II) oxidation on renewed graphite electrode V = 50 mV s^{-1} and $I = h \times 10^{-5}$ A cm^{-1}. (*1*) 0.5 M H_2SO_4 solution with addition of Sn^{2+} ($c_{Sn^{2+}}$ = 3 g l^{-1}), (*2*) phenolsulfonic electrolyte diluted tenfold with 0.5 M H_2SO_4 solution, (*3*) supporting solution *2* with addition of Fe^{2+} ($c_{Fe^{2+}}$ = 2 g l^{-1}).

pound to the phenolsulfonic supporting solution shifts somewhat the onset potential of hydrogen evolution in the voltammogram, but the peak of the Sn^{4+} cathodic electroreduction is not recorded before the region of hydrogen evolution (Fig. 2, curve *2*). At the same time, the peak of Sn^{2+} reduction is preserved without any change in its shape (Fig. 3, curve *3*).

It should be noted that the reproducibility of the current and potential of the tin(II) reduction peak depend on the state of the surface of the graphite electrode. In the absence of mechanical renewal, with the deposit on the surface of the graphite electrode dissolved electrochemically, the potential of the subsequent peak of tin(II) reduction shifts to the cathodic region by approximately 0.10 V. In addition, the reproducibility of the peak current decreases by an order of magnitude and more. After the mechanical renewal of the graphite electrode is resumed, all the parameters of the peak of tin(II) reduction are restored.

Thus, the experiments on model solutions showed that the content of tin(II) can be determined by voltammetry rapidly, and in a simple way, directly in a phenolsulfonic tin-plating electrolyte from the current of its reduction peak in the cathodic region of polarization of the graphite electrode.

Fe^{2+} ions are oxidized to Fe^{3+} on a graphite electrode in all the supporting solutions chosen for the experiment. In a sulfate solution (0.2–0.5 M H_2SO_4), Fe^{2+} is oxidized anodically at +0.33 V. The peak of tin(II) oxidation is not recorded in this potential range in sulfate solutions (Fig. 3, curve *3*), in contrast to chloride solutions, i.e., the presence of tin(II) in a solution does not affect the current of the iron(II) oxidation peak. In the $I_p = f(c_{Fe^{2+}})$ calibration plot, the current of iron(II) oxidation in a sulfate supporting solution is proportional to bulk concentration of iron(II) within the range 0.1–15 g l^{-1}.

In the voltammogram measured in freshly prepared phenolsulfonic supporting electrolyte, two current peaks are recorded in the anodic region, with the first of these observed at E_p = +1.05 V. Apparently, oxidation products of organic compounds are accumulated in the supporting electrolyte during its storage, which leads to an increased number of the anodic peaks observed. In a solution of phenolsulfonic electrolyte, i.e., in the presence of the organic compounds mentioned above, the potential of the iron(II) oxidation peak is shifted by 0.45 V to the positive region, reaching a value E_p = +0.78 V. Voltammetric determination of iron(II) directly in a phenolsulfonic electrolyte is complicated by the presence of a neighboring peak of phenolsulfonic acid oxidation (Fig. 3, curve *2*). The shape of the iron(II) oxidation peak is distorted somewhat (flattened), since there is no portion of current drop after the maximum because of an increase in the current, associated with the subsequent peak of oxidation of organic compounds (phenolsulfonic acid and SAA). This fact makes it difficult to measure the current of the iron(II) oxidation peak. A tenfold dilution of phenolsulfonic acid with sulfuric acid is sufficient for obtaining an analytical signal of iron(II) that is suitable for measurements (Fig. 3, curve *3*). In such a supporting solution, tin(II) does not affect the current of iron(II) oxidation peak, either. The linear calibration plot for the current of the iron(II) peak was obtained in a phenolsulfonic electrolyte diluted with 0.5 M sulfuric acid within the range 1–15 g l^{-1} iron(II).

To improve the peak parameters, electrochemical oxidation of iron(II) was studied in a 0.2 M solution of oxalic acid (pH ≈ 3). The peak of iron(II) oxidation in this supporting electrolyte is shifted somewhat to the cathodic region and has a more clearly pronounced shape than that in the sulfate solution. Unfortunately, tin(II) is also oxidized in the oxalate supporting solution in the anodic region. For this reason, oxalic acid

cannot be used as supporting solution in determining iron(II) in tin-plating electrolytes. To obtain reliable results in voltammetric determination of iron(II), it is important to renew mechanically the surface of the graphite electrode in the solution being analyzed each time before recording a voltammogram, similarly to the case of tin(II). This makes it possible to obtain peaks with well-reproducible intensities (see table). Presumably, electrochemical renewal of the electrode surface without cutting off a spent layer is insufficient, since such a renewal changes the shape of the iron(II) peak, with the peak becoming flattened and disappearing completely in the subsequent tests. Probably, iron(II) oxidation is hindered in this case by adsorption of organic components (phenolsulfonic acid, surfactant, and products of their oxidation) of the solution on the graphite electrode.

To determine tin(II), phenolsulfonic tin-plating electrolyte (25–30 cm^3) was charged into an electrolyzer with electrodes, the surface of the graphite indicator electrode was renewed by cutting off a 1–2-μm layer, the potential of polarization onset was set at –0.4 V relative to a saturated Calomel electrode, and the cathodic peak of tin(II)was recorded in the potential range –0.9 … –0.95 V at a sweep rate of 100 mV s^{-1}. The peak current was measured and the tin(II) concentration in the electrolyte was found from the calibration plot.

To determine iron(II), 5 cm^3 of phenolsulfonic electrolyte was placed in a 50-cm^3 volumetric flask, and 0.5 M H_2SO_4 was added to the marker. The mixture was stirred and part of it was poured into the electrolyzer. The surface of the graphite indicator electrode was renewed by cutting off a ~1–2-μm layer, the onset potential of polarization was set at 0.0 V, and the peak of the anodic oxidation of iron(II) was recorded at a potential sweep rate of 50 mV s^{-1}. The current of the iron(II) peak at +0.78 V was determined, and the iron(II) concentration was found from the calibration plot.

The results obtained were verified by the "fed–found" method on model solutions of phenolsulfonic electrolyte, and also on technological electrolytes taken from a working electrolyzer, by comparing the results of voltammetric determination with the previously obtained data of chemical analysis. Table lists the results of a voltammetric determination of tin(II) and iron(II) on a renewed graphite electrode.

The good reproducibility and correctness of the results obtained in model solutions can be attributed to the fact that the analysis was done in freshly prepared solutions. Apparently, a slight deviation of the results of voltammetric determination in technological solutions from the previous data of chemical analysis stems from the fact that they were obtained at different times. Oxidation processes permanently occur in an electrolyte, which results in that the concentration of the cations being determined varies somewhat.

The voltammetric method has the following advantages: it is fast, simple, and can be automated. The time necessary for analyzing a single sample for the content of two components is less than 10 min.

CONCLUSION

A fast instrumental method for determining on-line the content of tin(II) and iron(II) by dc voltammetry on a graphite mechanically renewed electrode in phenolsulfonic tin-plating electrolyte with linear potential sweep was developed.

Abstract—Cyclic voltammetry was applied to study the effect of addition of 2,2'-dipyridyl on joint electroreduction of Te(IV) and Cd(II) from sulfuric acid solutions on glassy carbon and titanium electrodes. The optimal potentials of electrodeposition of CdTe films were determined and the structure of these films was studied by means of X-ray phase analysis.

The method of electrochemical deposition of thin films of semiconducting compounds, with underpotential deposition of the second component (UPD method) was described by Stickney *et al.* [1]. Later, this technique has been used to obtain very thin films of a semiconducting compound, CdTe [2–6]. This method can be conveniently applied to obtain a photosensitive material at common pressures and temperatures.

Cadmium telluride is a semiconductor with energy gap of 1.44 eV and one of the best suitable materials for use in devices for solar energy conversion.

The known method for obtaining CdTe films includes electrodeposition from sulfuric acid solutions containing 0.5 M $CdSO_4$ and 4.5×10^{-3} M K_2TeO_3 at pH 1.4–1.6 and temperatures of 85–90°C [3, 5]. A low rate of CdTe deposition from these solutions, which results from the low concentration of tellurium(IV) in the electrolyte, has been noted. Therefore, a number of researchers suggested to use complex compounds of tellurium in nonaqueous electrolytes [7] or ammonia media [8]. The choice of an electrolyte and electrodeposition conditions strongly affects the structure and phase composition of the deposits obtained [4, 5].

The present study is concerned with conditions of CdTe electrodeposition from sulfuric acid solutions, with addition of 2,2'-dipyridyl as a complexing agent for cadmium and a surfactant. Account is taken of the fact that, in acid solutions, 2,2'-dipyridyl is adsorbed on the electrode in the form of protonated molecules [9].

EXPERIMENTAL

The experimental procedure was described in detail in [10, 11]. As working electrodes served glassy carbon and titanium disk-shaped electrodes with apparent surface area of 0.07 cm^2. A platinum coil with large surface area (1.5 cm^2) was used as auxiliary electrode. All the potentials obtained experimentally in this study are given relative to a silver chloride reference electrode. Before carrying out an experiment, the surface of working electrodes was subjected to mechanical treatment with finely dispersed Al_2O_3 and then washed with distilled water. The structure of cadmium telluride films was studied using a DRON-4 instrument with Co-radiation. For this purpose, cadmium telluride films were deposited onto 1×1 cm glassy carbon or titanium plates.

As supporting electrolyte served 0.45 M Na_2SO_4 + 0.05 M H_2SO_4 solution.

To reveal specific features of the electrochemical reactions leading to the formation of CdTe compound, cyclic voltammetric curves of joint reduction of Cd(II) and Te(IV) ions in a sulfuric acid solution at a glassy carbon electrode were measured (Fig. 1a). In the first reduction cycle (curve *1*), the voltammetric curve shows a Te(IV) ion reduction wave (E_{max} = –0.26 V) by the reaction

$$Te(IV) + 4e \rightarrow Te^0 \quad (1)$$

and a Cd(II) ion reduction wave (E_{max} = –0.8 V) by the reaction

$$Cd(II) + 2e \rightarrow Cd^0. \quad (2)$$

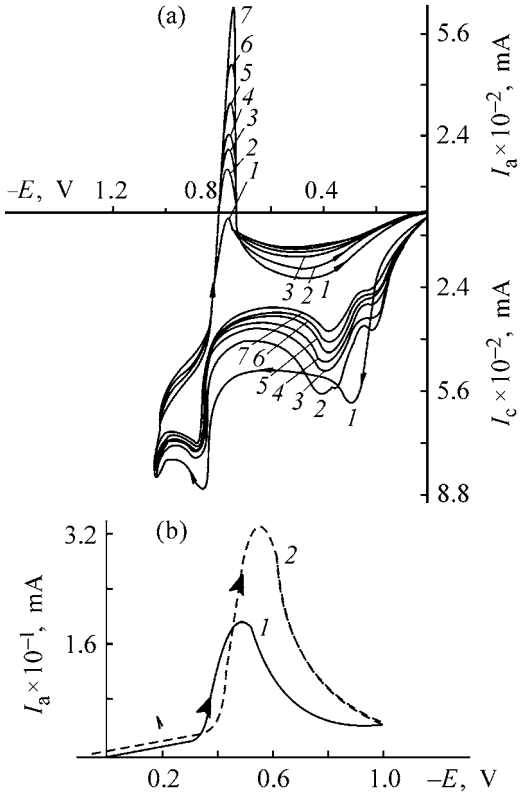

Fig. 1. Voltammetric curves of joint discharge–ionization of Te(IV) and Cd(II) ions on a glassy carbon electrode in sulfate electrolytes of various compositions. (*I*) Current and (*E*) potential; the same for Figs. 2–4. (a) $c_{Te(IV)} = c_{Cd(II)} = 1 \times 10^{-3}$ M. (b) $c_{Te(IV)} = 0.98 \times 10^{-3}$ M; $c_{Cd(II)}$ (M): (*1*) 0 and (*2*) 0.5×10^{-3}.

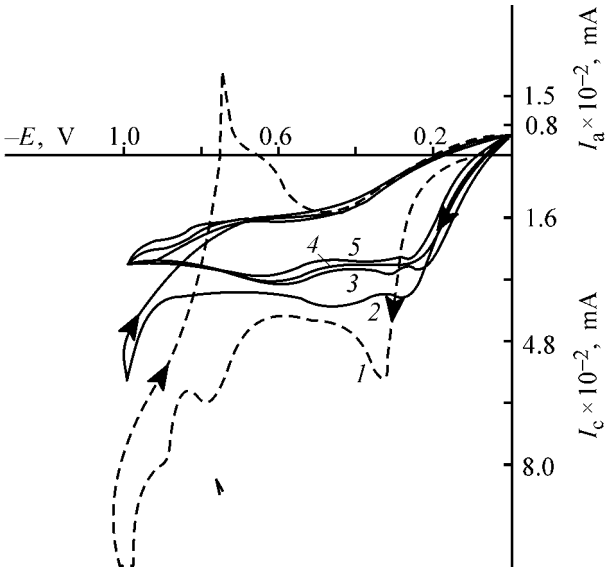

Fig. 2. Cyclic voltammetric curves of CdTe reduction on a glassy carbon electrode in the presence of 2,2'-dipyridyl. Cycling range 0…–1.1 V, $c_{Te(IV)} = c_{Cd(II)} = c_{dipy} = 1 \times 10^{-3}$ M. *Digits at curves* correspond to cycle numbers.

The peak of reduction of metallic tellurium to telluride ions

$$Te^0 + 2e \rightarrow Te^{2-}, \quad (3)$$

which is characteristic of reduction of elementary tellurium and commonly appears at the limiting current of Te(IV) reduction at negative potentials, is not observed. In the second reduction cycle (Fig. 1a, curve *2*), the Te(IV) reduction wave in the voltammetric curves is shifted to more positive potentials, the current of Te(IV) reduction decreases, and an additional reduction wave with characteristic peak ($E_{max} = -0.35$ V) appears. The height of the Cd^{2+} reduction wave increases with respect to the limiting current of Te(IV) reduction. When the potential sweep direction is changed, the anodic voltammetric curves show a rise in the height of the peak corresponding to oxidation of metallic cadmium ($E_p = -0.7$ V).

In the subsequent reduction cycles (curves *3–7*), the Te(IV) reduction current and the current of the additional wave decrease, but the Cd(II) reduction wave becomes more pronounced [the difference of the limiting current of Te(IV) and the current corresponding to the Cd(II) peak grows], which leads to an increase in the amount of metallic cadmium on the electrode surface and to a rise in the oxidation current of metallic cadmium in the reverse run of the voltammetric curves.

Figure 1b (curve *2*) shows that formation of the CdTe compound shifts the anodic peak of tellurium oxidation to Te(IV) to more positive potentials to $E = 0.56$ V. The shift is 0.06 V.

Figure 2 shows cyclic voltammetric curves of joint reduction of Te(IV) and Cd(II) on a glassy carbon electrode in a sulfuric acid electrolyte in the presence of 1×10^{-3} M of 2,2'-dipyridyl. In the first cycle (Fig. 2, curve *1*), the voltammetric curve shows a Te(IV) reduction wave, which is peaked at $E_{max} = -0.3$ V, a peak of Cd(II) reduction ($E_p = -0.8$ V), and a wave of 2,2'-dipyridyl reduction ($E_{1/2} = -0.85$ V). A peak corresponding to Cd^0 oxidation to Cd^{2+} ($E_p = -0.73$ V) appears in the anodic region. In the second and subsequent cycles (Fig. 2, curves *2–5*), the cathodic curves show a shift of the Te(IV) reduction wave to less negative potentials and a significant decrease in the current of Te(IV) reduction. An additional Cd(II) reduction wave, which is clearly observed in an acid solution containing no 2,2'dipyridyl at potentials more negative than –0.3 V [12–16], is weakly manifested in the presence of 2,2'-dipyridyl. In the absence of 2,2'-dipyridyl, the anodic peak of Cd^0 oxidation to Cd^{2+} grows with increasing number of deposition cycles

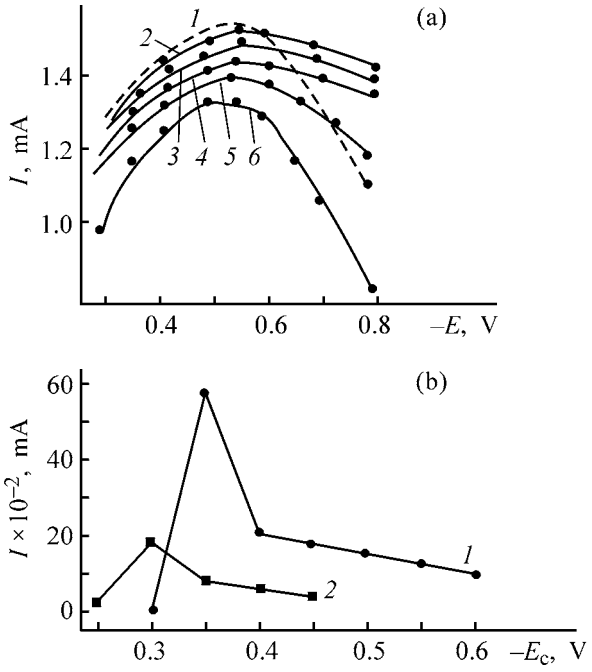

Fig. 3. Effect of CdTe deposition potential on the current of anodic peaks of oxidation (a) in the presence of 2,2'-dipyridyl and (b) without it on (a) glassy carbon and (b) titanium electrodes. (a) c_{dipy} (M): (*1*) 0, (*2*) 1.7×10^{-4}, (*3*) 3.4×10^{-4}. (*4*) 6.7×10^{-4}, (*5*) 1×10^{-3}, and (*6*) 2.7×10^{-3}. (b) Concentration (M): (*1*) 1×10^{-3} Te(IV) and 1×10^{-3} Cd(II), (*2*) 1×10^{-3} Te(IV) and 1×10^{-2} Cd(II).

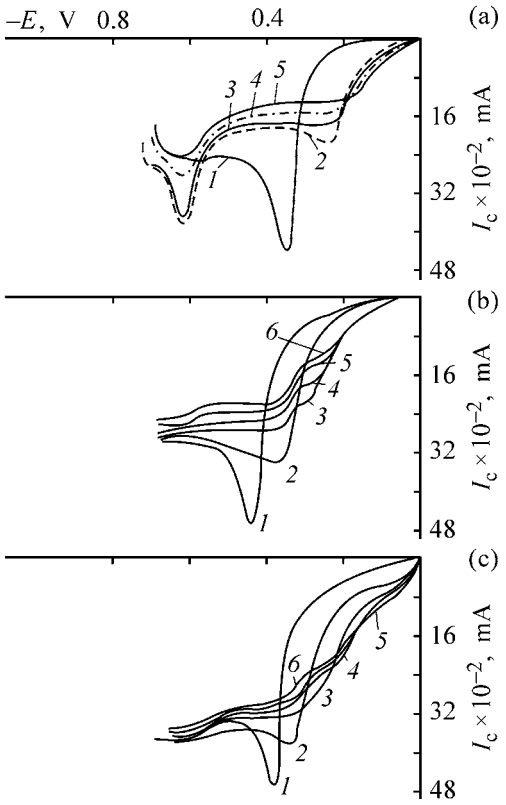

Fig. 4. Voltammetric curves of cathodic deposition of Te(IV) and Cd(II) on an unrenewed titanium electrode. Potential sweep rate V_s = 10 mV s^{-1}. Concentration (M): (a–c) 1×10^{-3} Te(IV), (b, c) 1×10^{-3} Cd(II), (c) 2.5×10^{-4} dipy.

(Fig. 1a), whereas in the presence of this compound, this peak is virtually not observed at all (Fig. 2). This indicates that electrodeposition of cadmium is hindered in the presence of 2,2'-dipyridyl.

Also, the influence exerted on the height of anodic peaks of CdTe oxidation by the potential of CdTe deposition onto a glassy carbon electrode in a sulfuric acid electrolyte at various 2,2'-dipyridyl concentrations was studied. The concentrations of tellurium(IV) and cadmium(II) were 1×10^{-3} M, and that of 2,2'-dipyridyl was varied from 1.7×10^{-4} to 2.7×10^{-3} M. The deposition potentials were in the range from –0.3 to –0.8 V. Before measuring anodic voltammetric curves, CdTe was deposited onto the electrode surface at the chosen cathodic potentials with electrolyte stirring for 30 s. With increasing 2,2'-dipyridyl concentration, the heights of anodic peaks of cadmium telluride oxidation decrease, i.e., the amount of CdTe deposit on the electrode surface becomes lower (Fig. 3a). At low 2,2'-dipyridyl concentrations (up to 1×10^{-3} M), the range of cadmium telluride electrodeposition expands. Deposition of cadmium telluride on the surface of the glassy carbon electrode is possible at these 2,2'-dipyridyl concentrations at potentials ranging from –0.2 to –0.8 V. However, at higher 2,2'-dipyridyl concentration (2.7×10^{-3} M), the range of electrodeposition becomes markedly narrower. The maximum amount of cadmium telluride electrodeposited from a sulfuric acid electrolyte in the presence of 2,2'-dipyridyl is observed at electrodeposition potential E = –0.5 V (Fig. 3a).

Joint electrodeposition of tellurium(IV) and cadmium(II) at their equal concentrations in the electrolyte (1×10^{-3} M) was also studied by analyzing cyclic voltammetric curves of cathodic deposition onto the titanium electrode. In Figs. 4a–4c, these curves are compared with cyclic curves of tellurium(IV) electrodeposition onto a titanium electrode. As in all of the above-described experiments, the second and subsequent curves of Te(IV) reduction (Fig. 4a) show a significant shift of the reduction potential in the positive direction, which is due to reduction of Te(IV) at the surface of an electrode partly covered with metallic tellurium and to a gain in the crystallization energy. In the absence of cadmium(II),

two stages of tellurium(IV) reduction to tellurium(0) and then to tellurium(–2) is clearly observed in all deposition cycles. The decrease in the height of the first Te(IV) reduction wave with increasing number of cycles may be associated with the possible decrease in the amount of $HTeO_2^+$ cations at the electrode surface in unstirred solutions because of the reaction between Te(IV) and Te(–2) to give finely dispersed Te(0) or with a change in the conductivity of the tellurium-coated electrode.

The half-wave potential for the first stage of reduction changes from second to sixth cycle only slightly (Fig. 4a). It may be assumed that adsorption of dispersed tellurium formed by reaction (1) at the electrode has virtually no effect on the reduction potential.

The general appearance of the first wave in the voltammetric curve of electroreduction is preserved when there occurs joint reduction of tellurium(IV) and cadmium(II) (Fig. 4b). However, the second peak of tellurium(0) reduction to telluride ions in the range of negative potentials under study (up to –0.8 V) disappears in this case. This points to firm binding of telluride into a compound with cadmium. The cadmium reduction wave, which must have appeared at a potential of –0.7 V at the titanium electrode, is also absent at the chosen relative concentrations of Te(IV) and Cd(II). Preliminary experiments revealed that the cadmium reduction wave is observed at this potential if the cadmium(II) concentration exceeds severalfold the concentration of tellurium(IV).

It can be seen from Fig. 4b that a clearly pronounced additional wave appears in the third and subsequent reduction cycles. Additional reduction current appears at a potential of –0.3 V. The limiting current of this wave preserves its value as far as –0.75 V. The nature of this additional wave has been discussed previously [14, 17]. This wave is due to underpotential reduction of cadmium at a tellurium-coated electrode by the so-called UPD reduction mechanism. The potential of cadmium(II) reduction is shifted by approximately 0.470 V because of the high Gibbs energy of CdTe compound formation, which is equal to –92.8 kJ mol^{-1} [1]. Therefore, the reaction of reduction at potentials of the additional wave can be written as

$$Cd^{2+} + 2e + Te^0_{surf} \rightarrow CdTe. \quad (4)$$

Despite that the subsequent reduction cycles occur at the electrode surface partly covered with a CdTe deposit, the additional reduction wave remains well pronounced. Analysis of the reduction potentials (Fig. 4b) shows that the potential of the additional wave of cadmium(II) reduction virtually coincides, in the first and second cycles, with the potential of the tellurium(IV) reduction wave, which occurs with substantial overvoltage at the clean surface of the titanium electrode.

Introduction of 2,2'-dipyridyl additive raises the limiting current of the additional reduction wave (Fig. 4c). This effect may be due to adsorption on the electrode of complexes formed by cadmium and 2,2'-dipyridyl, which act as additional source of cadmium ions in reaction (4). The amount of CdTe deposit accumulated on the electrode surface was determined from the oxidation current of this compound under assumption that the current is proportional to the amount of the substance on the electrode.

The oxidation peak height grows with accumulation of CdTe on the titanium electrode. The heights of oxidation peaks of CdTe accumulated during 120 s with stirring at different potentials without 2,2'-dipyridyl were used to choose the potential at which the greatest amount of CdTe is deposited. The deposition was done on a titanium electrode at potentials in the range $E = -0.30\ldots-0.60$ V. Figure 3b (curve *1*) shows that the highest oxidation current is observed if the CdTe deposit is accumulated at $E = -0.35$ V.

Deposition of CdTe at this potential in the presence of 2,2'-dipyridyl in different concentrations demonstrated that the greatest amount of CdTe is deposited at 2,2'-dipyridyl concentration of 2.5×10^{-4} M. Deposition of CdTe with accumulation for 120 s at different potentials in the presence of 2.5×10^{-4} M 2,2'-dipyridyl confirmed that the highest current of CdTe oxidation corresponds to potential $E = -0.35$ V.

Also, the effect of varying the ratio of initial cadmium and tellurium concentrations on conditions of CdTe deposition onto a titanium electrode was studied. On raising the concentration of cadmium by a factor of 10 (1×10^{-3} M K_2TeO_3 + 1×10^{-2} M $CdSO_4$), the height of the peak of tellurium(IV) reduction to tellurium(0) decreases as compared with that in the voltammetric curve for Cd : Te = 1 : 1, and the currents of cadmium oxidation and reduction increase in proportion to its concentration in solution. In this case, the peak of CdTe oxidation at the titanium electrode is not observed in the anodic region. At high content of cadmium in the electrolyte, the peak of CdTe oxidation becomes noticeable when the oxidation curve is measured after accumulation of cadmium telluride for 120 s ($E = -0.30$ V) under stirring, which indicates that the amount of CdTe electrodeposited in the presence of a large excess of Cd(II) ions in the

electrolyte is smaller. Figure 3b (curve *2*) shows that the maximum current of CdTe oxidation corresponds to a deposition potential $E = -0.30$ V, i.e., the optimal potential of CdTe deposition is shifted to less negative values in the presence of an excess amount of cadmium ions in the electrolyte. In this case, the current of CdTe oxidation is much lower than the oxidation currents observed at equal Cd and Te concentrations in the electrolyte.

On the basis of the results obtained, the following electrolytes and potentials for electrodeposition of CdTe compound in 0.45 M Na_2SO_4 + 0.05 M H_2SO_4 as supporting electrolyte were chosen: 1×10^{-3} M $CdSO_4$ + 1×10^{-3} M K_2TeO_3 and 1×10^{-3} M $CdSO_4$ + 1×10^{-3} M K_2TeO_3 + 3.4×10^{-4} M dipy at $E = -0.50$ V on glassy carbon electrode; 1×10^{-3} M $CdSO_4$ + 1×10^{-3} M K_2TeO_3 and 1×10^{-3} M $CdSO_4$ + 1×10^{-3} M K_2TeO_3 + 2.5×10^{-4} M dipy at $E = -0.35$ V on titanium electrode.

These electrolytes were used to obtain CdTe deposits on large planar electrodes with surface area of 1 cm^2. An X-ray phase analysis of these deposits was made.

Figure 5 shows X-ray diffraction patterns of cadmium telluride films on a glassy carbon electrode. It can be seen that the film obtained at 90°C (Fig. 5b) is characterized by more distinct reflections of the CdTe compound. The reflections from the substrate are poorly pronounced. This means that the electrodeposition process yielded a film whose crystal structure is well formed. By contrast, electrodeposition at a temperature of 30°C (Fig. 5a) gives a more amorphous film whose X-ray pattern is complicated by reflections associated with carbon mainly constituting the glassy carbon electrode. This confirms the conclusion that electrodeposition should be carried out in conventional electrolytes at elevated temperatures to ensure better crystallization conditions.

In the case of electrodeposition of cadmium telluride from a sulfuric acid electrolyte containing 2,2'-dipyridyl, the X-ray diffraction pattern changes. Figures 5c and 5d show diffraction patterns of CdTe films deposited at 30 and 90°C and $E = -0.5$ V. It can be seen that addition of 2,2'-dipyridyl favors crystallization and makes it possible to obtain a crystalline film with well-pronounced structure at low temperature and the optimal electrodeposition potential equal to –0.5 V.

The shift of the electrodeposition potential to the negative direction has unfavorable effect on the structural characteristics of a film. When this potential

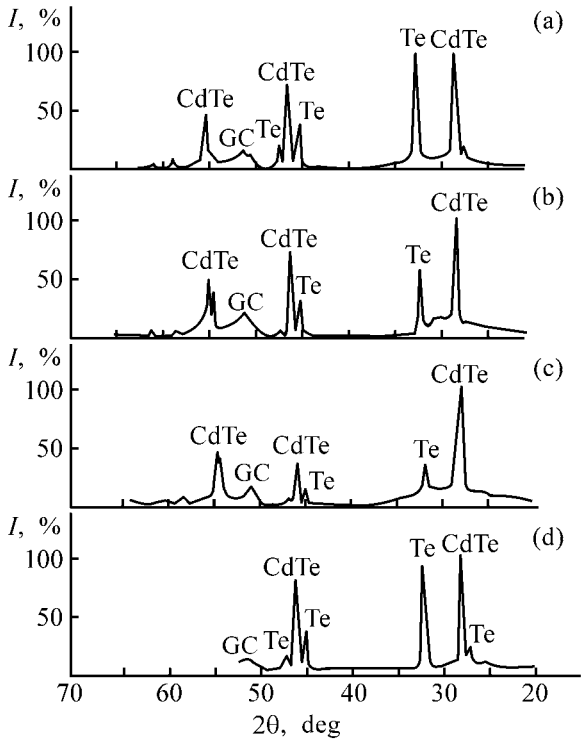

Fig. 5. X-ray diffraction patterns of CdTe films on glassy carbon electrode. (I) Intensity and (2θ) Bragg angle; the same for Fig. 6. Concentration (M): (a–d) 1×10^{-3} Te(IV) and 1×10^{-3} Cd(II) and (c, d) 3.4×10^{-4} dipy. Temperature (°C): (a, c) 30 and (b, d) 90.

approaches the electrodeposition potential of cadmium (–0.8 V), the X-ray diffraction pattern is affected adversely. The films obtained are thin, the reflections are unclear, and the whole pattern is complicated by carbon reflections.

Raising the concentration of 2,2'-dipyridyl changes the X-ray diffraction pattern: CdTe films become thinner, but the density and adhesion of these films are higher than those in films obtained without addition of 2,2'-dipyridyl.

Tellurium is present in the form of a separate phase in all of the X-ray diffraction patterns, with a decrease in the intensity of tellurium peaks in comparison with CdTe peaks observed when electrodeposition onto a glassy carbon electrode is performed at 30°C, 2,2'-dipyridyl concentration of 3.4×10^{-4} M (Fig. 5c), concentration ratio Cd : Te = 1 : 1 ($c_{Cd(II)} = c_{Te(IV)} = 1 \times 10^{-3}$ M), and electrodeposition potential $E = -0.5$ V.

Thus, it was established that, by introducing minor concentrations of 2,2'-dipyridyl into an electrolyte, one can obtain a well-formed crystalline deposit as a CdTe film with lowered content of the free tellurium phase at low temperatures.

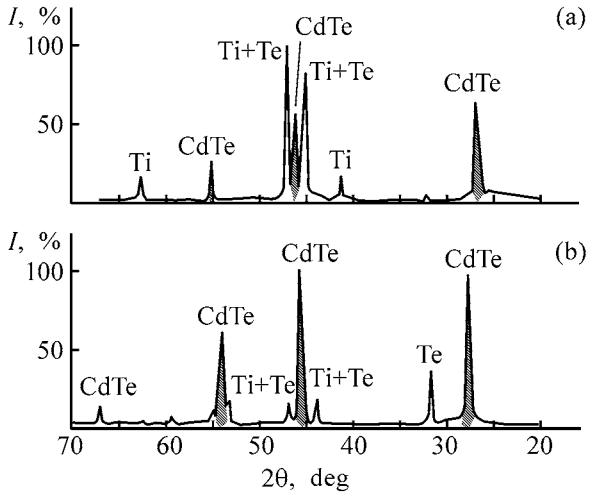

Fig. 6. Effect of 2,2'-dipyridyl on X-ray diffraction patterns of CdTe films on titanium electrode. Deposition conditions: $E = -0.35$ V, $t = 90$°C. 2,2'-dipyridyl concentration (M): (a) 0 and (b) 2.5×10^{-4}.

Figure 6 shows X-ray diffraction patterns of CdTe films deposited at 90°C onto a titanium electrode at $c_{Te(IV)} = c_{Cd(II)} = 1 \times 10^{-3}$ M without 2,2'-dipyridyl (Fig. 6a) and with addition of 2.5×10^{-4} M 2,2'-dipyridyl at the choses optimal deposition potential $E = -0.35$ V (Fig. 6b).

It can be seen from Fig. 6 that a significant decrease in the content of the free tellurium phase and predominance of CdTe reflections are observed under these conditions. The results obtained suggest that the titanium substrate exerts a specific influence on the deposit structure. The favorable effect of 2,2'-dipyridyl addition on the structure of the CdTe deposit on titanium is only observed in the case of deposition at 90°C and a 1 : 1 ratio of the cadmium and tellurium concentrations in the electrolyte. (Fig. 6b). The X-ray diffraction pattern in Fig. 6b characterizes the formation of a well-structured CdTe film with 100% main peak intensities and a pronounced decrease in the relative content of the tellurium phase to 20%.

CONCLUSIONS

(1) In joint electrodeposition of cadmium(II) and tellurium(IV), cadmium is reduced at more positive potentials than its standard potential, with the CdTe compound formed.

(2) Introduction of 2,2'-dipyridyl into a sulfuric acid electrolyte makes higher the limiting current of the additional cadmium reduction wave.

(3) Use of an electrolyte containing equal amounts of cadmium(II) and tellurium(IV) and minor addition of 2,2'-dipyridyl [$(2.5–3.4) \times 10^{-4}$ M] makes it possible to obtain CdTe deposits at 30°C and to diminish the content of the free tellurium phase.

Received January 15, 2003

Abstract—Processes occurring in a cycled nickel-zinc battery with positive nickel oxide electrode fabricated from spherical nickel hydroxide on foamed-nickel support and the influence exerted by its physicochemical parameters on changes in the electrolyte composition and on inter- and intraelectrode mass transfer of zinc was studied.

Until recently, positive electrodes with metal-ceramic (MC) support have been predominantly used in nickel-zinc (NZ) batteries, because, in contrast to compacted electrodes, they are not "poisoned" by zinc ions. The successful use of electrodes made of spherical nickel hydroxide in nickel-cadmium (NC) and nickel-metal-hydride (NMH) batteries posed the question of their suitability for NZ batteries, too. First, use of spherical nickel hydroxide could help in solving the problem of poisoning of a compacted nickel oxide electrode (NOE), since introduction of hydroxide compounds of cobalt into the electrode stabilizes the electrode capacity in the presence of zinc [1]. Second, use of an active paste composed of spherical particles, which can be well compacted, and lightweight foamed support could improve the energy-related characteristics of a battery [2, 3]. In addition, a study of processes occurring in NZ batteries with compacted NOE is of particular interest for revealing the influence of its physicochemical parameters on processes occurring in the electrode itself and at the zinc electrode.

It seems impossible to use for this purpose, for prognosticating the characteristics and service life of NZ batteries, data obtained for NC and NMH batteries, since processes in NOE in the nickel–zinc system occur under different conditions.

This study is concerned with prototype NTs-25 batteries differing from previously developed batteries only in the positive electrode: in these batteries the NOE with MC support onto which nickel hydroxide is deposited is replaced with NOE with compacted active mass composed of spherical nickel hydroxide on foamed-nickel support at the same number of electrodes and same apparent surface area.

The advantage of spherical nickel hydroxide prepared by the technology developed in [2] over the materials previously used in compacted electrodes is due not only to the possibility of denser (by a factor of 1.2–1.5) packing of its particles, but also to its higher conductivity. Cobalt hydroxide introduced into the electrode during its fabrication is transformed, in the course of NOE forming, into a compound with conductivity of 10^{-2} S cm^{-1}, which is several orders of magnitude higher than the conductivity of $Ni(OH)_2$, equal to 10^{-5} S cm^{-1} [4].

In the case of dense packing of nickel hydroxide particles modified with cobalt, a rather high solid-phase conductivity is ensured in NOE. Simultaneously, the conditions of ion transport in the liquid phase change fundamentally. The pore size in the active paste of the electrode in question are of the same order of magnitude as particle size, but the pores are closed. Therefore, their role in transport of electrolyte ions within the electrode is insignificant. By contrast, nickel hydroxide particles are distributed in the electrode of the MC type over the inner surface of coarser and deeper pores, which creates conditions for involvement of electrolyte ions in current transport deep inside the electrode.

EXPERIMENTAL

The electrodes for the batteries under study were fabricated by the technology described in [2, 3]. As starting material served nickel hydroxide composed

of 1–30-μm particles with predominant radius of about 10 μm. The active mass was pasted onto a foamed-nickel support and then the electrodes were compacted to a required thickness. The electrode parameters (amount and composition of paste, electrode thickness) were calculated in such a way that the prototype electrode should have capacity comparable with that of the MC electrode used in the NTs-25 battery. This made it possible not only to compare the parameters of the batteries under study with those of the existing batteries, but also to reveal specific features of processes occurring in compacted electrodes with foamed-nickel support.

Table 1 lists the initial parameters of the batteries under study.

The batteries were tested in a ventilated variant with low-pressure valves (0.4×10^2 kPa). In choosing the conditions of fabrication of prototype NOE and in performing tests, account was taken of the possible influence exerted by specific structural features of the active paste under study and by an additive introduced on the occurring processes and the electrochemical parameters of the NZ battery.

Nickel hydroxide with structure of the β type, used in the experiments, was chosen as optimal after testing several batches. It contained 5.6% Co and 3.2% Zn, which corresponds, for cobalt, to the range of optimal values (5–7%) found in [5] in an electrochemical and Raman study of nickel hydroxide of β type, $Ni_{1-x}Co_x(OH)_2$ [or $Ni_{1-x}Co_xOOH$].

Spherical nickel(II) hydroxide commonly contains, in addition to cobalt, 2–4% Zn(II), which is introduced to prevent formation in the electrode of the gamma phase of NiOOH, which has irregular and easily destructible structure. The presence of such an amount of zinc does not impair the service characteristics of NOE.

According to [6], up to 10 mol % zinc(II) can be introduced into NOE, with the structure of the β type preserved, and this does not affect adversely the parameters of the electrode. The solubility of the zinc component of the forming intercalation compound in alkaline solutions is approximately 2 orders of magnitude lower than the solubility of zinc oxide [7], i.e., the intercalating zinc remains in the active paste.

In cycling of NZ batteries with metal-ceramic NOE, more than 20% zinc(II) is accumulated in the electrodes. In battery charging, zinc is deposited within NOE pores as an independent ZnO phase [8]. It was observed that accumulation of zinc oxide in such great amounts does not affect adversely the parameters of MC NOE.

The tests were carried out with account of the data obtained in [4], where the mechanism of the activating action of cobalt compounds on the electrochemical activity of $Ni(OH)_2$ was studied and the composition of the oxide compound, which has electronic conduction and serves as active component, was determined. The charging was done in the rather intensive mode [with a current of 0.1–0.2 *C*] recommended in [4], which favors formation of the $Ni_{1-x}Co_xOOH$ phase on the basis of β-CoO_2H. In discharges, the potential was not allowed to decrease below 0.1 V relative to the mercury oxide reference electrode (in 7 M KOH solution) in order to preserve the activity of this compound. The potential only decreased below this value when performing two deep discharges, with no more than 20% of the total capacity taken off, in view of the necessity for oxidation of the reduced phase accumulated in the zinc electrode.

The extent to which an electrode fabricated from spherical $Ni(OH)_2$ is charged in forming depends on the excess capacity imparted in the course of charging. At a capacity of 150% in terms of the $Ni(OH)_2 \rightarrow Ni(OH)_3$ conversion, a degree of charging equal to 90–95%, which is preserved in subsequent cycling, can be achieved in 2 or 3 cycles [2]. However, such a charging mode was found to be unacceptable for

Table 2. Modes of NTs-25 battery testing

Mode	Charging				Discharge	
	I (A) in indicated stage		U_c, V	C, A h	I, A	U_c, V
	I	II				
Forming cycles:						
1st	3	–	1.98–2.05	33	3	1.2
2nd	3	–	1.98–2.05	33	3	1.2
Cycling	7–5	1.5–1	1.98–2.05	28–20	5	1.2
Deep discharge (126th cycle)	5	1	1.98–2.05	22	5	0.1–0.0

a ventilated NZ battery with 2.3/1 capacity ratio of the negative and positive electrodes.

The NTs-25 batteries studied were formed in two cycles. The charging current was 3 A, and 120% of capacity calculated for the conversion of $Ni(OH)_2$ into $Ni(OH)_3$ was imparted to the positive electrode in each cycle. The nickel use factor was 0.6.

In the subsequent working cycles, the batteries were charged with a current of 7–5 A in stage I and 1.5–1.0 A in stage II, without allowing the voltage to rise above 2.05 V in each stage, and discharged with a current of 5 A to final voltage of 1.2 V. In some cycles, the electrode potentials were measured relative to a mercury oxide electrode. The tests were done at room temperature.

Because of the increase in the amount of reduced phase in the zinc electrode in the process of cycling, its content became so high by 125th cycle that subsequent complete charging of the batteries was impossible. Therefore, they were subjected to deep discharge with a current of 5 A to a final voltage of 0.1–0 V, after which the battery capacity again stabilized at 24–22 A h (Table 2).

In cycling for 200 cycles, one battery of each batch was disassembled at regular intervals of time to inspect the state of the electrodes and to analyze the active paste and the electrolyte. The data obtained were compared with similar results of tests of NTs-25 batteries with MC NOE. It was found that the charging voltage of the batteries under study is somewhat lower than that of batteries with MC NOE (Fig. 1). This reflects the specificity of the processes at the NOE, which mostly occur in the inner-diffusion mode at low concentration of OH^- ions in the reaction zone in a battery with MC electrode, and in the outer-diffusion mode in the batteries with spherical nickel hydroxide, which are the subject of this study. The distribution of current within the MC electrode is largely due to the low conductivity of nickel hydroxides. In view of the high conductivity of the $Ni_{1-x}Co_xOOH$ compound contained in the positive electrode, the current in the batteries under study mostly flows in the solid phase and the electrochemical process occurs at the surface.

The difference in current distribution between the electrodes being compared is particularly pronounced in the case of deep discharge (Fig. 2). In the NOE

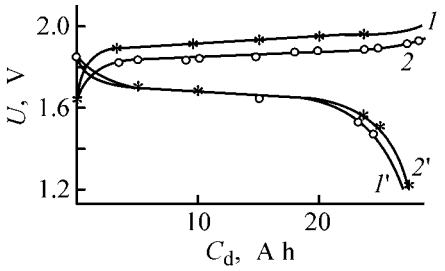

Fig. 1. Variation of the voltage U during (*1, 2*) charging and (*1'*, 2') discharge of NZ batteries with (*1, 1'*) NOE made of spherical nickel hydroxide on foamed-nickel support and (*2, 2'*) metal-ceramic electrode. (C_d) Discharge capacity; the same for Fig. 2.

with spherical nickel hydroxide, studied here, the potential rapidly shifts toward negative values, as far as the potential of hydrogen evolution, after the main part of the active paste is reduced. The discharge of a zinc electrode with excess capacity continues, after a short-time shift of the potential toward positive values, with simultaneous evolution of hydrogen at the NOE, until the charged phase contained in it is exhausted.

In additional discharge of MC NOE, the potential shifts more slowly. This indicates that, as the potential decreases, the process involves surface area with undischarged active paste, on which additional discharge of nickel hydroxide occurs at decreasing potential of the zinc electrode. The subsequent evolution of hydrogen at the NOE is accompanied by a similar gradual reverse shift of the potential of the zinc electrode toward negative values (Fig. 2).

The specific features of the processes occurring at NOE made of spherical nickel hydroxide give rise to differences in how the state of the active paste of the electrodes and the electrolyte composition vary in cycling of the batteries being compared. This, in the first place, refers to the inter- and intraelectrode mass transfer of zinc.

In NOE with MC support, zinc accumulates in pores, mainly as ZnO, through decomposition of the zincate complex under conditions of anodic polarization and incomplete chemical dissolution of zinc in the case of cathodic polarization [8].

In view of the increased conductivity of the solid spherical nickel hydroxide and hindered current transport in the electrolyte in pores, the electrochemical process in electrodes made of spherical $Ni(OH)_2$ is concentrated at the electrode surface and is accompanied by less pronounced changes in concentration in the diffusion layer. Therefore, accumulation of zinc in the electrode is slow and has another dynamics. In contrast to the MC electrode, in which mass transfer ceases after 50–60 cycles, the content of zinc in the NOE under study grows at a constant rate (Fig. 3). It is noteworthy that there exists a virtually complete correspondence between the mass of zinc lost by the negative electrode and that accumulated in the NOE (Fig. 4). The difference of these quantities approximately corresponds to the amount of zinc that passed into the electrolyte.

The difference in dynamics between the processes under consideration may be due to the following. In the absence of conditions for decomposition of the zincate complex in the diffusion layer of the electrode, accumulation of zinc may occur as a result of its introduction into the nickel hydroxide structure. The occurrence of this process and the degree of its involvement in zinc transport can be judged from the solubility of zinc contained in NOE in KOH solutions [7]. A chemical analysis of the positive electrode made of spherical nickel hydroxide, performed after 200 cycles, demonstrated that zinc accumulated in the electrode does not dissolve in a 5 M KOH solution (this concentration is established in the battery electrolyte in the course of cycling). After keeping the electrodes in KOH, 85.5% of the total amount of zinc accumulated in the NOE in cycling remains in the electrodes. Thus, loss of zinc from the negative electrode and its accumulation in NOE are due to introduction of zinc into the nickel hydroxide structure by intercalation.

Simultaneously with the decline in interelectrode transport of zinc in batteries with spherical NOE, compared with the MC electrode, the intraelectrode mass transfer of zinc within the negative electrode itself also decreases. This follows from the distribution of phases of the active paste along the electrode height in the course of cycling (Table 3).

It can be seen that no loss of zinc is observed in the upper part of the electrode. There only occurs

Table 3. Phase distribution in the active paste of the zinc electrode in NZ battery with NOE made of spherical nickel hydroxide in the course of cycling*

Phase of active paste	Phase content, %											
	1st cycle			63rd cycle			110th cycle			200th cycle		
	1	2	3	1	2	3	1	2	3	1	2	3

* 1, 2, and 3 stand for upper, middle, and lower parts of the electrode, respectively.

its insignificant redistribution into the middle part of the electrode. Under similar conditions of cycling of the MC NOE, only about 60% of the active paste is retained in the upper part of the zinc electrode already by 100th cycle. The comparison performed suggests that redistribution of zinc over the surface of the negative electrode is largely due to redistribution of current in NOE. In the course of cycling of the MC electrode, the extent to which its upper part is charged grows, since the conductivity of the active paste is higher in this region. This also leads to gradual overcharging of the upper part of the zinc electrode and the resulting loss of its shape [9].

In electrodes with spherical nickel hydroxide the distribution of current is more uniform, since the difference in conductivity between $Ni(OH)_2$ and NiOOH is compensated for by the influence of the electrically conducting cobalt compound.

The concentrations of KOH and K_2CO_3 vary in the initial period of cycling of the battery under study (up to 30 cycles) (Fig. 5). Then the content of KOH and K_2CO_3 stabilizes. Such a kind of variation of the electrolyte composition indicates that this variation is due to gradual transfer to the electrolyte of carbonates originally contained in the active paste of the electrodes and in separators. As shown by previous studies [10], the KOH concentration established in the battery (4.5 M) is sufficient for ensuring stable operation in cycling conditions of the NOE under study.

CONCLUSIONS

(1) Electrodes fabricated from spherical nickel hydroxide with addition of electrically conducting cobalt compounds ensure effective current transport in the solid phase and occurrence of the anodic process in the outer-diffusion mode. In this case, the charging of the electrode is accompanied by less pronounced, compared with that in the inner-diffusion mode, decrease in the concentration of OH^- ions in the reaction zone, which does not impair the stability of the zincate complex. Zinc mainly accumulates in the nickel oxide electrode fabricated from spherical nickel hydroxide as a result of its introduction into the structure of the positive electrode. The resulting disturbance of equilibrium in the reversibly operating system is compensated for by loss of the corresponding amount of zinc from the negative electrode.

(2) Use of spherical nickel hydroxide in nickel-zinc batteries makes it possible to markedly decelerate the deshaping of the zinc electrode owing to increased uniformity of current distribution in the nickel oxide electrode in the presence of cobalt compounds and, correspondingly, in the zinc electrode, too.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Current Density Distribution as Parameter of Electroionite Process

N. N. Zubets

Voronezh State University, Voronezh, Russia

Received January 29, 2003

Abstract—The effect of artificially preset current density distribution in an electroionite apparatus on the extent of water demineralization is considered. The change in the extent of demineralization on varying the distribution of one and the same current between parts of apparatus at the inlet and outlet of diluate is explained.

In [1], specific features of current density distribution along the height of an electroionite apparatus, i.e., electrodialyzer with ion-exchange filler in its chambers, were considered and the following was shown. In an electrodialyzer with inert separators, the local current density decreases in the direction of diluate supply. By contrast, in an electroionite apparatus, the tendency toward a decrease in the local current density becomes less pronounced, and this parameter may even grow with increasing current strength and electrical conductivity of the ion-exchange filler. In the present study, the effect of current density distribution on the efficiency of the electroionite apparatus and, in particular, on the degree of demineralization is considered.

In all the known studies concerned with the current density distribution in an electrodialyzer, this distribution has only been considered under natural conditions and special provisions were made to prevent disturbance of this natural distribution. In [2], it was noted that, in principle, an artificial current density distribution can be created, but it was only meant to create conditions under which certain model concepts can be implemented. In the present study, an artificial current density distribution is regarded and used as a preset process parameter.

EXPERIMENTAL

A three-chamber electrodialyzer with MK-40 cation-exchange membrane on the cathode side and MA-41I anion-exchange membrane on the anode side was used. The depth of the diluate chamber was 1 mm, and that of electrode chambers, 10 mm; the width of all the chambers was 10 mm, and the height, 120 cm. A grid woven from alternating bands with cation- and anion-exchange properties and bulk conductivity was placed in the diluate chamber [3, 4]. Tap water subjected to back osmosis treatment and having electrical resistivity of 30 kΩ cm was fed from below upwards into all the chambers at a rate of 2 cm s^{-1}. The anode was made of platinum. A stainless steel cathode was separated, along its height, into two equal parts. A variable resistor was switched into the circuit of each of these parts in series with an ammeter. The average, over the entire apparatus area, current density was always set to a constant value of 0.1 mA cm^{-2}. The electrical resistivity of the diluate was measured with a Tesla BM 484 semiautomatic bridge in a thermostated flow-through cell at a temperature of 20°C.

Dividing the electrode into only two parts allows characterization of the current distribution by only a single dimensionless parameter α defined as the ratio between the strength of the current flowing through the upper part of the apparatus to the total current strength.

Without additional resistors, i.e., in the case of a natural current distribution, the value of α was 0.47 for the ion-exchange filler used [1]. When resistors of up to 20 kΩ were switched into the circuit of the upper part of the apparatus, α decreased to 0.08, and on switching the same resistors into the circuit of the lower part, α increased to 0.96. The limiting values of α (0 and 1) can be formally obtained by entirely switching off, respectively, the upper or lower part of the cathode.

The figure shows the dependence of the electrical resistivity ρ of the diluate on the α value set with resistors. With increasing load on the upper part of

Electrical resistivity ρ of demineralized water vs. preset value of α. Average current density 0.1 mA cm^{-2}, diluate flow velocity 2 cm s^{-1}.

the apparatus, the electrical resistivity grows, and only in the case of completely switched-off lower part, ρ decreases somewhat. The direct dependence of ρ on α shows that more favorable conditions for deep desalination are created when the zones of the lowest diluate concentration and highest current density coincide, i.e., when the probability of exceeding manyfold the limiting diffusion current density is the highest. According to the conventional concepts of electrodialysis, this must have led to a decrease in current efficiency; however, the rise in ρ actually points to a more effective action of the current.

This behavior can be accounted for by specificity of deep electrodialysis demineralization. When the electrical conductivity of a solution approaches, because of the presence of dissolved salts, the background value determined by the electrical conductivity of the medium, the remaining salt ions mostly pass from solution into the ion-exchange resin as a result of ion exchange, rather than under the action of the electric field. For this to occur, it is necessary that a sufficient fraction of the ion-exchange material filling the diluate chamber should be present in the hydrogen and hydroxide forms. Just this objective is achieved when most part of the current is passed through the upper, lying closer to the diluate outlet, part of the apparatus. Thus, it may be concluded that, at least in the outlet part of the apparatus, the following demineralization mechanism is operative at a sufficiently high current density: decomposition of water at the heteropolar contact of ion-exchangers, sorption of hydrogen ions and hydroxy ions by ion-exchangers, ion exchange of these ions for dissolved salt ions, and removal of salt ions across unipolar contacts of ion exchangers and membranes and, through the latter, into the concentrate. This charge transfer mechanism does not lead to a decrease in the current efficiency, since ions of the medium, which are involved in the transport, do not find way into the concentrate, with the transfer chain ending there with transfer of salt ions. Presumably, the energy expended for dissociation of water is not lost completely, since hydrogen ions an hydroxy ions are returned into the diluate and, upon molization, release energy, which heats the diluate and thereby facilitates dissociation of other water molecules.

Such a demineralization mechanism is not new and may be operative for mixed ion-exchange filler of any kind. However, for the woven grid used in the experiment, it is the most probable mechanism for two reasons. First, ions of the medium, which arrive at the ion-exchange grid and move within it, may traverse a relatively long path, with high probability of their exchange for salt ions. Second, the heteropolar contacts of ion exchangers are abundant and virtually do not include contacts that could serve as a source of mineralization.

The point is that, both in the case of multilayer charging of the chamber with a mixed bed of granulated ion exchangers and with a grid woven from bands with ion-exchange properties and different polarities of counterions, there exist equal numbers of heteropolar contacts with "diluate" and "concentrate" geometric arrangement. However, in the case of a grid there is a good, multiple electrical contact between all parts of each monopolar part of the grid and the corresponding membrane. Since the ion exchanger has immeasurably higher electrical conductivity than the surrounding demineralized water, the electric voltage applied to the diluate chamber must drop nearly entirely across the solution. In this case, the electric potentials of all parts of a monopolar half of the grid and of the corresponding membrane must be nearly the same. Consequently, the electric potentials of all points of the cation-exchange part of the grid must be more negative than the potentials of all points of the anion-exchange part, since just this relationship is observed between the electric potentials of the corresponding membranes delimiting the diluate chamber. In this case, it is of no importance on which sides of a heteropolar contact are the cation- and anion-exchanger. In other words, when the diluate chamber is filled with a mixed bed of ion-exchangers in the form of a woven grid, all the numerous heteropolar contacts operate as diluate contacts, irrespective of their geometric orientation.

When most of the current flows through the inlet zone of the apparatus, in which the diluate concentration is higher, the ratio of the current density to solution concentration becomes more uniform over different points of the chamber. In this case, the probability of appearance of zones in which the limiting

diffusion current density is much exceeded becomes lower, with the correspondingly decreasing probability of ion-exchange absorption of salt ions from solution and diminishing share of charge transfer by the mechanism described above.

Further analysis of the data in the figure poses a question as to why the diluate quality is not the same at the limiting values of the distribution factor (0 and 1). Formally, it must have been of no importance which half of the apparatus, upper or lower, is working. However, it is apparent that at different electric potentials of two neighboring, but separated from each other, parts of the cathode, a current will flow between them across the electrode solution. In this case, the electric charge passing through the ammeter must be partly transferred to the switched-off part of the cathode, and then to the anode through the switched-off part of the electrodialyzer. A certain amount of charge transfer between the two zones of the apparatus necessarily occurs on connecting an additional resistor to one of them.

This means that the real α deviates somewhat from that found from ammeter readings toward its natural value corresponding to a normally connected electrode with equal electric potentials in all of its parts. Consequently, the whole apparatus actually works on switching-on any of the two halves of the cathode, but the operation modes are somewhat different in two limiting cases ($\alpha = 0$ and $\alpha = 1$). At $\alpha = 0$, a greater part, even though not the whole of the current is concentrated in the inlet part of the apparatus. A noticeable desalination of the solution occurs in the inlet part, whereas the diluate quality in the upper part of the apparatus is nearly not improved at all, since the current density in this zone is insufficient for the ion-exchange mechanism of deep desalination to be operative. By contrast, at $\alpha = 1$, a low current density at the inlet is sufficient for preliminary desalination through electromigration, which is common with electrodialysis, and high current density at the outlet converts ion exchangers into the hydrogen and hydroxide forms, thereby favoring deep desalination with intense ion exchange. As a result, the electrical resistivity of the diluate at $\alpha = 1$ much exceeds that at $\alpha = 0$. This confirms, to a certain extent, the feasibility of the above mechanism of deep desalination.

Apparently, the optimal value of α corresponds to such a process in which there occurs pronounced preliminary desalination in the inlet zone of the apparatus and, at the same time, the current density in the outlet zone is sufficiently high for converting a required amount of ion exchangers into the hydrogen and hydroxide forms. In the case in question, this optimum corresponds to $\alpha = 0.85–0.90$.

CONCLUSIONS

(1) The degree of demineralization of water in its electroionite treatment depends on how the preset current density is distributed over the electroionite apparatus along the direction of dilate feed.

(2) The degree of demineralization can be raised substantially by artificially redistributing the current density.

(3) There exists a certain optimal ratio of current densities at the diluate entry into, and exit from the apparatus.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Specific Features of Porous Silicon Synthesis in Aqueous-Alcoholic Solutions

I. L. Baranov, L. V. Tabulina, and L. S. Stanovaya

Belarussian State University of Information Science and Radio Electronics, Minsk, Belarus

Received July 18, 2002; in final form, April 2003

Abstract—The uniformity of growth of porous silicon layers, electrochemical parameters of their synthesis, surface resistance, and morphology of porous structure in aqueous and aqueous-alcoholic electrolytes (H_2O–$C_nH_{2n+1}OH$, n = 1, 3–5) was studied.

Porous silicon (PS) formed in electrochemical anodic treatment of single-crystal silicon in HF-based electrolytes has been studied extensively [1]. However, its use in semiconductor electronics is restricted by high nonuniformity of its morphological structure. This is particularly characteristic of lightly doped *n*-type silicon [2, 3]. Nevertheless, the interest in PS, demonstrated by specialists developing designing-and-technological variants of semiconductor electronic circuits with varied degree of integration, is unwaning [4, 5]. Studying the specific features of PS film formation in relation to properties of the employed electrolytes is a topical task.

In continuation of previously commenced investigations [6], the present study is concerned with the influence exerted by the properties of alcohol components of the electrolytes on the uniformity of growth of PS layers, their porosity, and surface resistance, and also on electrochemical characteristics of pore formation processes, such as effective valence and current efficiency. The study is aimed to determine what electrolytes with alcohol solvents of HF are the most appropriate for synthesis of PS films in semiconductor microelectronics.

EXPERIMENTAL

PS layers were formed in darkness at current density of 10 mA cm^{-2} in the course of 60 min on lightly doped KEF-20 (100)Si substrates. The electrochemical cell used for this purpose was described in [6]. As starting electrolyte served 48% hydrofluoric acid. As organic solvents of HF were used alcohols $C_nH_{2n+1}OH$ (n = 1, 3–5). The influence of ethanol on PS synthesis was described in [6]. The concentration of alcohol ingredients of the electrolytes used in the study was varied within the range 0.5–15.0 M. The uniformity of PS film formation on the surface of the silicon anode, the corresponding porosities, pore morphology, effective valence, and current efficiency were deterined using procedures described in [6–8]. The surface resistance of PS layers was measured using a four-probe ac technique. The electrodes of the four probe measuring device, spaced by 1 mm, were made of titanium.

To gain better understanding of how the alcohol components of the electrolyte affect the pore morphology and uniformity of PS film growth on the surface of silicon substrates, similar studies were carried out for solutions with HF diluted with water. In calculating the dilution, it was taken that 48% hydrofluoric acid corresponds to a solution with zero amount of added water.

The growth rate of PS layers and uniformity of their distribution over the surface of the silicon anode in aqueous electrolytes is illustrated by Fig. 1. It can be seen that dilution of HF with water leads first to gradual, and then to fast decrease in the growth rate of PS films. The scatter of PS layer thicknesses is wide (±30 μm) in all cases (Fig. 1, curve *1*). The variation of their porosity indicates that the most pronounced rise in this parameter occurs when electrolytes with water concentration exceeding 30 M are used (Fig. 1, curve *2*). As revealed by an electron-microscopic study, this tendency is due to abundant formation of branches on walls of the growing pores. As a result, the morphology of the porous structure of PS layers synthesized in aqueous electrolytes can be interpreted as tree-like.

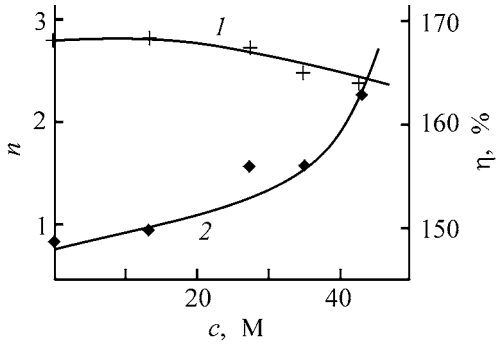

Fig. 2. (*1*) Effective valence *n* and (*2*) current efficiency η of electrochemical dissolution of silicon vs. water concentration *c* in electrolyte.

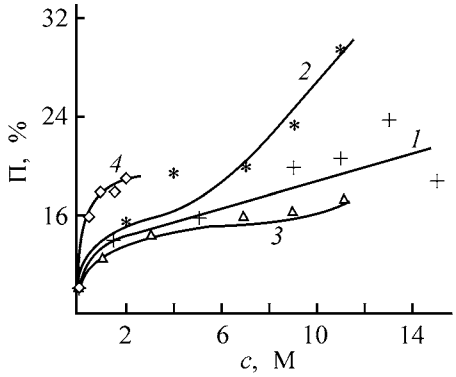

Fig. 4. PS layer porosity Π vs. alcohol concentration *c* in electrolyte.

The effect of dilution of HF with water on the process of pore formation in PS synthesis is due to a certain weakening of the influence exerted on it by electrochemical factors. This is indicated by changes in the effective valence and current efficiency (Fig. 2). As follows from the dependences presented here, the effective valence decreases within the range 2.8–2.6, i.e., only slightly (Fig. 2, curve *1*). The current efficiency changes more substantially, with its values growing steadily. The limiting value exceeds 160% in the given case (Fig. 2, curve *2*). This means that dilution of HF with water favors chemical dissolution of silicon. However, since no acceleration of SiF_2 (intermediate product of electrochemical dissolution of silicon) formation is observed, this points to weak influence of chemical reactions on the arrival of charge carriers (holes) at the Silelectrolyte interface. This gives rise to a nonuniform front of silicon etching on the anode surface and a tendency toward formation of narrow side channels on pore walls, probably, because of spontaneous dissolution of silicon. The occurrence of electroless processes of this kind in water on the surface of PS was also reported in [9].

It should be noted that the surface resistance R_s of PS layers synthesized in electrolytes of the system H_2O–HF is independent of the dilution of HF with water and equals 15–20 $\Omega\,cm^{-2}$. The order of magnitude of R_s points to high ion mobility on the PS surface, which can be accounted for both by sorption of H_2F^+ or H_3O^+ ions on the surface and by its hydrophilic properties.

When PS is synthesized using electrolytes with alcohol components, film formation depends on the molecular weight of the organic additives (Fig. 3, curves *1–4*). In a narrow range of concentrations (0–1 M), the growth rate of PS layers increases. In subsequent dilution of HF with the alcohol components, the intensity of PS formation decreases. The rate of PS film growth changes to a greater extent for alcohols with $n \geq 3$ (Fig. 3, curves *2–4*). The scatter of PS film thicknesses over the surface of the silicon anode does not exceed ±16 μm in all of the aqueous alcoholic electrolytes used. The highest uniformity of their distribution is achieved in the case of solutions with addition of 2-propanol (Fig. 3, curve *2*). These same layers show the highest porosity (Fig. 4, curve *2*).

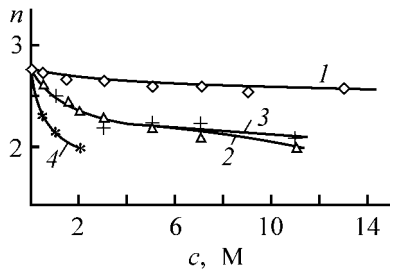

Fig. 5. Effect of alcohol concentration c in electrolyte on effective valence n of silicon dissolution.

The alcohol components with $n \geq 3$ strongly affect the variation of the effective valence (Fig. 5, curves *2–4*). The value of this electrochemical parameter of the process of PS formation in electrolytes belonging to the system HF–H_2O–*i*-C_3H_7OH decreases from 2.8 (for 48% hydrofluoric acid) to 2.0 when the concentration of the organic component reaches a value of 11 M (Fig. 5, curve *2*). The corresponding current efficiencies grow to 200%. This indicates that chemisorption of the alcohol components of the electrolytes favors formation on the PS surface of additional positive charge carriers, which accelerate the SiF_2 formation.

Thus, chemical dissolution of silicon in aqueous-alcoholic electrolytes is more intimately related to electrochemical processes occurring in PS synthesis. Electron-microscopic studies demonstrated that the morphology of the porous structure of PS layers synthesized in electrolytes of the system H_2O–HF–$C_nH_{2n+1}OH$ is not represented by system of branching channels. The diameter of their voids is approximately 1.3–1.5 times that in PS layers synthesized in aqueous electrolytes at the same dilution of HF. Raising the molecular weight of the alcohol components of the electrolytes favors expansion of the pore voids. Their orientation coincides to a greater extent with the direction of the flowing current, compared with the case of PS layers synthesized in aqueous electrolytes. This is particularly pronounced for the porous structure of PS layers synthesized in electrolytes with 2-propanol, with concentration exceeding 1 M. In this case, the shape of pore voids can be interpreted as needle-like.

The R_s values for PS layers synthesized in electrolytes with alcohol components are approximately 3 to 4 orders of magnitude higher than the corresponding values for PS films of the same thickness, synthesized in aqueous electrolytes. In this case, the higher the molecular weight of an organic substance, the greater R_s. This indicates that chemisorption of the alcohol ingredients of the electrolyte on the PS surface is due to formation of coordination bonds between hydroxy groups in their molecules and atoms in the solid phase.

It was noted in [10] that a similar adsorption mechanism changes the electrical parameters of adjacent defects on the semiconductor surface and the field effect of these defects extends as far as several lattice constants. This shifts the Fermi level of semiconducting silicon toward the valence ?band and creates positive charge on the silicon surface. It should be noted that this process may also be favored by formation in electrolytes of the system H_2O–HF–$C_nH_{2n+1}OH$ of $C_nH_{2n+1}OH_2^+$ cations, as it occurs in alcoholic solutions of hydrochloric acid [11]. These cations possess abnormally high mobility [11] and raise by an order of magnitude the mobility of Cl^-, H_3O^+, and OH^- ions, thereby making much higher the electrical conductivity of the solutions. In the $C_nH_{2n+1}OH_2^+$ group, the highest mobility is observed for cations formed from *i*-C_3H_7OH. These data reveal, probably, one of the major reasons why all characteristics of pore-formation on the surface of the silicon anode are changed to the greatest extent in electrolytes of the system H_2O–HF–*i*-C_3H_7OH (Figs. 4 and 5, curves *2*).

In view to the presence of $C_nH_{2n+1}OH_2^+$ cations in alcoholic electrolytes with HF, account should also be taken of the particular specificity of the influence exerted by the cations on the state of the solid surface, which is commonly covered with a hydrated oxide film. This influence is manifested in that, despite having the charge of the same sign as the solid phase, organic cations are adsorbed on its surface owing to their high adsorption potential. This leads to hydrophobization of the surface, shielding of the electrical double layer, and the resulting decrease in the electrokinetic potential in electrolytes [12].

In processes occurring in electrochemical treatment of materials in aqueous-alcoholic electrolytes with HF, these factors make the current distribution of the matrix substance surface more uniform and accelerate the mass-exchange of reagents within the forming pores. In synthesis of PS films, this creates conditions for their formation with more uniform, over the anode surface, porous structure morphology [13] with pore voids oriented along the current flow direction, which is actually the case in electrolytes with 2-propanol.

Thus, the presence of alcohol components in solutions with HF favors formation on the surface of a silicon wafer of PS films with uniform thickness and more regular porous structure. The best suitable for this purpose are electrolytes containing 2-propanol. Their use makes it possible to obtain PS films best

satisfying the requirements of the technology of semiconductor integrated circuits.

CONCLUSIONS

(1) In aqueous-alcoholic electrolytes, the growth rate of porous silicon films and their porosity depend on the concentration of the alcohol components and their molecular weight. The most uniform distribution of porous silicon films with thickness of 80 μm and more on a lightly doped *n*-type silicon is achieved in their synthesis in electrolytes containing more than 1 M of 2-propanol.

(2) Introduction of alcoholic complexes into electrolytes changes the effective valence and current efficiency of porous silicon synthesis. In electrolytes containing 2-propanol, the current efficiency increases to 200%, and the effective valence decreases to 2.

(3) The morphology of the porous structure of porous silicon layers synthesized in electrolytes with 2-propanol is represented by needle-like pores whose voids are oriented along the direction of the flowing current.

(4) The positive influence of the alcohol components on synthesis of porous silicon layers is due to the formation in the electrolytes with HF of $C_nH_{2n+1}OH_2^+$ ions whose chemisorption and high adsorption potential favor uniform distribution of the current over the surface of the silicon anode and intensify the mass-exchange of reagents in the forming pores.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Potentiometric Method for Evaluation of Protective Properties of Polymeric Coatings

V. S. Kolosnitsyn, I. F. Gladkikh, N. M. Cherkasov, and L. V. Sheina

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia
Poisk Research Center, Ufa, Bashkortostan, Russia

Received February 11, 2003

Abstract—A new method is proposed for evaluation of protective properties of polymeric coatings. The method allows evaluation of the corrosion rate of a coated metal by means of potentiometric indication.

One of the main difficulties encountered in developing new polymeric coatings is rapid evaluation of their protective properties. Several methods have been proposed, which allow prognostication, with varying reliability, of the service life of protective coatings. These methods include impedance meagerment and impedance spectroscopy, conductometry, and some others [1–4]. However, none of these techniques enables unambiguous assessment of protective properties of coatings.

The method developed in this study, which makes it possible to evaluate the rate of metal corrosion under a protective coating, is based on measuring the time of destruction by corrosion of a metal layer of known thickness under a protective coating. It is proposed to use potentiometric indication for determining the instant of time at which the corrosion process is complete. Potentiometric indication can be applied in those cases when the electrochemical potential of an electrode made of a metal under study changes dramatically after its destruction by corrosion. This can be achieved by using two-layer bimetallic indicator electrodes. The surface layer of the indicator electrode is to be fabricated from the metal under study, and the inner layer, from a metal whose potential in the corrosive medium is more positive than the potential of the metal under study. The most convenient support is copper, since its potential in corrosive media is more positive than the potentials of the majority of construction metals and alloys. In a test, the potential of the indicator electrode is first determined by the potential of a metal under study, e.g., iron, and after its destruction by corrosion, by the potential of the support metal.

The aim of this study was to assess the possibility of applying the potentiometric method to study properties of protective coatings.

EXPERIMENTAL

To ensure rapid evaluation of protective properties of coatings, it is very important to choose correctly the thickness of the surface layer of the bimetallic indicator electrode. Use of electrodes with thick surface layer makes longer the testing time. Small thickness of the surface layer may give rise to rather significant errors because of the possible scatter of its thickness. In most cases, the rate of metal corrosion under a coating must not exceed 0.1 mm/yr (~1.14×10^{-2} μm h^{-1}), which ensures a 20–30-year service life of a technical structure, e.g., pipeline. If it is taken that the acceptable duration of corrosion studies must not exceed 500–1000 h, then the most convenient thickness of the layer of metal under study is 5–10 μm.

In this study, iron, which is the most widely used construction material, was chosen as the metal of the surface layer. Copper was used as the material of the support. To rule out edge effects, the study was carried out with cylindrical electrodes having spherical lower end. The electrode area was 15 cm^2. An iron layer 10 μm thick was deposited onto the surface of the copper electrode by electroplating from a chloride electrolyte [5]. Corrosion studies were performed in glass cells communicating with the atmosphere. The electrode potential was measured with a V7-23 digital voltmeter relative to a silver chloride reference electrode. As corrosive medium served 0.5 M (3%)

1070-4272/03/7606-0936 $25.00 © 2003 MAIK "Nauka/Interperiodica"

aqueous solution of NaCl. As protective coating was used Asmol varnish [TU (Technical Specification) 5623-002-16 802 026–94].

The experiments were done as follows. Electrolyte was poured into a glass cell in which the electrode under study and reference electrode were placed. The cell communicated with the atmosphere through a special aperture. The tests were done at temperatures ranging from 18 to 25°C. All the potentiometric measurements were made after thermostating the cells at 25°C in an air thermostat.

To assess the reliability of the results obtained, the corrosion rate of a steel St.3 electrode was studied in parallel under similar conditions. In studying the corrosion behavior of steel electrodes, each test was interrupted after stable potential was attained and corrosion products were accumulated in amounts sufficient for analysis. The corrosion products were carefully removed from an electrode under study and transferred to solution, together with the corrosion products accumulated in the electrolyte. Then the resulting solution was subjected to complexometric titration to determine the content of iron ions [6]. The results obtained in analysis were used to calculate the corrosion rate. Further, the experiment was continued, following the same procedure. The electrodes were again placed in the cell, poured over with fresh electrolyte, and the cycle described above was repeated. The experiment was done several times, until stable results were obtained. To assess their reproducibility, 3 to 4 parallel runs were performed.

The study was carried out for the example of two-layer bimetallic electrodes with and without a protective coating. The potential of metallic electrodes in a corrosive medium is determined by several simultaneously occurring chemical and electrochemical processes. To determine the steady-state potentials, the variation of the potential of steel and copper electrodes was studied in preliminary experiments. The data obtained are shown in Fig. 1. It can be seen that, during first hours after bringing the steel and copper electrodes in contact with a corrosive solution, their potentials shift into the cathodic region. This can be accounted for by a change in the pH value and composition of the near-electrode layer of the electrolyte in the course of corrosion. The potentials of both the copper and steel electrodes stabilize in 25–30 h. The stabilized potentials remain invariable within several thousand hours.

Because of the difference between the properties of electroplated deposits of iron and steel, it could be expected that they should behave differently in electrochemical regard, too. However, as shown by the results of the study, the manners in which the potentials of a steel electrode and a two-layer bimetallic "iron-on-copper" electrode vary are virtually the same.

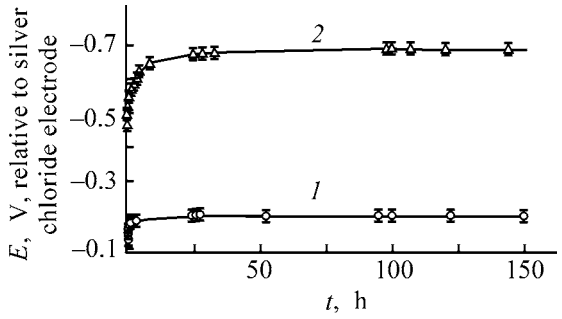

Fig. 1. Chronopotentiograms of (*1*) copper and (*2*) iron electrodes in 3% NaCl solution. (*E*) Potential and (*t*) time; the same for Fig. 2.

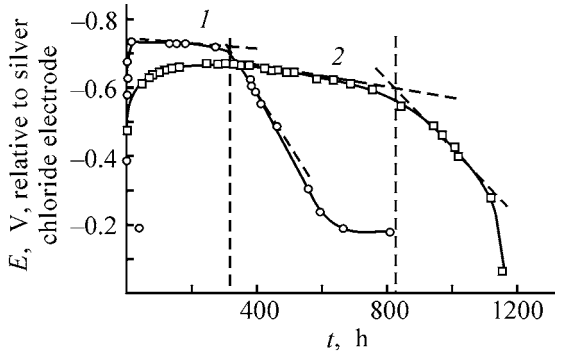

Fig. 2. Chronopotentiograms of two-layer bimetallic "iron-on-copper" electrodes in 3% NaCl solution. (*1*) Without coating and (*2*) with a single-layer coating with Asmol varnish.

Chronopotentiograms of two-layer bimetallic electrodes with and without a protective coating are shown in Fig. 2. It can be seen that the electrode potentials start to shift, in 310 h for an electrode without coating and 830 h for a coated electrode, toward the anodic region, reaching in the end the potential of the copper electrode. The instant of time at which the potentials start to shift, found as an intersect of two tangents to linear portions of the chronopotentiograms, points to the time of the through damage of the iron layer. The time of complete iron dissolution can be found from the intersect of tangents to the transition and final portions of the chronopotentiograms.

To determine the true corrosion rate of a coated metal by the method of the thin-layer electrode, it is necessary to correctly determine the time of corrosion destruction of the indicator layer of the metal. With account taken of the roughness of this layer and the positive and negative deviations from its integral-

Analytically determined corrosion rates v_c

t, h	Amount of corrosion products, g		$v_c \times 10^5$, g cm^{-2} h^{-1}		$v^*_{c.av}$	
	sample no. 1	sample no. 2	sample no. 1	sample no. 2	10^5 g cm^{-2} h^{-1}	10^2 μm h^{-1}
190	0.0319	0.0282	1.12	0.99	1.06	1.38
96	0.0218	0.0210	1.51	1.45	1.48	1.92
71	0.0185	0.0133	1.74	1.25	1.50	1.95
109	0.0189	0.189	1.16	1.16	1.16	1.51
96	0.0194	0.0277	1.35	1.93	1.64	2.13

* ($v_{c.av}$) Average corrosion rate.

average thickness considered to be equiprobable, it may be assumed that, in the middle of the transition portion, the actual dissolution depth of the layer is, to a first approximation, close to its integral-average thickness.

To assess the reliability of the data obtained, corrosion rates of iron, found by analysis of the amount of corrosion products (see table) and yielded by chronopotentiometry, were compared. The corrosion rates v_c found from the results of potentiometric studies are presented below:

Time of completion of a corrosion process	$v_c \times 10^2$, μm h^{-1}
Appearance of through damage	3.23
Time found at the middle of the transition portion	2.00
Completion of corrosion destruction	1.61

It can be seen that the corrosion rates obtained by different methods are in satisfactory agreement.

The relative error of the analytically found mean-arithmetic value of the average corrosion rate, with respect to the corrosion rate calculated at the middle point of the transition portion of the chronopotentiogram, was about 10%. The corrosion rate found from the time corresponding to the middle of the transition portion of the chronopotentiogram is the closest to the corrosion rate found analytically.

The time of destruction of the uncoated and coated metal under study can be used to calculate the coefficient of protective action of a coating, K_{pr} (cm^{-1}):

$$K_{pr} = \frac{t_{mc} l_m}{t_m l_{mc} l_c},$$

where t_m is the time of dissolution of the layer of an uncoated metal under study (h); t_{mc}, the time of dissolution of coated metal (h); l_c, the coating thickness (cm); l_m, the thickness of the metal electrode under study (cm); l_{mc}, the thickness of the coated metallic electrode under study (cm).

The service life of a metal under protective coating, T (h), can be found as

$$T = T_m K_{pr} l_{pr},$$

where T_m is the service life of uncoated metal (h); K_{pr}, the coefficient of protective action of a coating, (cm^{-1}); l_{pc}, the thickness of the protective coating (cm).

The average corrosion rate of St.3 steel was 1.37×10^{-5} g cm^{-2} h^{-1}.

The linear velocity of steel dissolution can be readily calculated from the data in the table to be 1.78×10^{-6} cm h^{-1} or 1.78×10^{-2} μm h^{-1}.

CONCLUSION

The potentiometric method using a two-layer bimetallic electrode can be successfully applied to evaluate the protective properties of polymeric coatings.

CATALYSIS

Properties of Mixed Polyfunctional Fluoride Catalysts for Synthesis of Pyridine Bases from Acetylene and Ammonia (Methanol)

R. A. Khamidullaev and D. Yusupov

Tashkent Chemical Engineering Institute of Uzbekistan Republic, Tashkent, Uzbekistan

Received March 5, 2003

Abstract—New catalysts based on cadmium, zinc, chromium, iron, and aluminum compounds were synthesized and their properties were studied. A pilot catalyst batch was obtained and tested on a pilot installation.

Pyridine and its homologs are widely used in production of chemicals and pharmaceuticals and in agriculture [1, 2]. The interest in these compounds increased after the appearance of pesticides of selective and total action such as Reglon, Fusilad, Parskvat, Lontrel, etc. [3].

Among the known methods for preparing pyridine bases, their synthesis from acetylene and ammonia (methanol) is the most promising [4–7]. Wide industrial use of this method is impeded by the lack of highly active and stable catalysts. The available catalysts for synthesis of pyridine bases from acetylene and ammonia work with constant activity for 72 h at best [8, 9].

Formation of pyridine bases from acetylene and ammonia or acetylene, ammonia, and methanol is a result of complex combination of parallel-successive reactions accompanied by vinylation, dehydrocyclization, isomerization, trimerization, etc.

In the gas phase, this is only possible with polyfunctional catalysts.

An analysis of published data on the mechanism of acetylene and amine activation showed that *d*-metal (zinc, cadmium, chromium, iron, cobalt, etc.) compounds, which are also active in reactions of addition of various molecules to acetylene can catalyze ammonia and amine vinylation in the gas phase. Such compounds are typical catalysts for dehydrogenation and dehydration [10, 11].

Studies of promotion of cadmium and zinc compounds with metal fluorides and X-ray diffraction analysis of other polyfunctional catalytic systems showed that, during catalyst preparation, zinc, cadmium, iron, and aluminum form hydroxofluorides Cd(OH)F, Zn(OH)F, $Al(OH)_2F$, $Al(OH)F_2$, etc., which are, probably, responsible for the high catalytic activity of the catalysts [12, 13].

The zinc and cadmium ions favor activation of acetylene and ammonia molecules, and the basic centers on the catalyst surface (O^-, F^-, OH^-) favor formation of amide groups from ammonia and amines:

$$M(OH)F(NH_3) \begin{cases} \nearrow MF(NH_2) + H_2O \\ \searrow M(OH)(NH_2) + HF \end{cases}$$

where M is Zn^{2+}, Cd^{2+}, Fe^{2+}, etc.

An X-ray diffraction study showed that the catalysts are fairly active in the semiamorphous-crystalline state, in which they contain chemically bound water. With the calcination temperature from 450 to 650°C, the fraction of the crystalline phase grows, the content of chemically bound water decreases, and hydroxofluorides start to decompose. As a result, the specific surface area and activity of the catalyst decrease.

We found that, when catalysts contain, along with zinc, cadmium, and aluminum hydroxofluorides, also 3.0–5.0 wt % zinc and chromium(III) [or iron(III)] oxides, they are fairly active, selective, and stable in synthesis of pyridines from acetylene, and ammonia (methanol). Taking this circumstance into account, we synthesized more than 30 catalysts; their compositions and properties are listed in Table 1.

As seen, the KTsZhKhA-5 catalyst is the most active and stable in synthesis of 2- and 4-methylpyridines, while the KTsKhZhA-6 catalyst is the best in synthesis of pyridine and a mixture of isomeric

methylpyridines. Promotion of zinc-chromium-aluminum and zinc-chromium-iron-aluminum catalysts with 1.5–3.0 wt % cadmium, zinc, and aluminum fluorides raises the acetylene conversion and catalyst productivity by a factor of 1.5–2.0. In the process, the loss of cadmium metal from the catalyst is probably prevented by introduction of cadmium fluoride into the defective spinel structure characteristic of γ-Al_2O_3 and by its fixation in this structure.

To determine the dependence of the activity of catalysts on their texture properties, we measured the specific surface area, acidity, pore radius and volume, phase composition, and mechanical strength of the catalysts. The acidity of the KtsKhZhA-6 catalyst strongly differs from that of the other catalysts. It acidifies water within the first 20 s by 1.2 pH units; after 40 min, the pH value stabilizes. The other catalysts acidify water by 0.4 to 0.8 pH units within the first 20–30 s (see figure).

Probably, it is hydroxofluorides that produce acidic centers on the catalyst surface. The presence of hydroxofluorides on the catalyst enhances sorption of acetylene, ammonia, and methanol molecules, with the result that their molecules are polarized.

Table 2. Characterization of synthesis of pyridine bases on KTsKhZhA-6 catalyst [T 280–360°C, W_{tot} 150–180 h^{-1}, $C_2H_2 : NH_3 = 1 : 2$ (vol : vol)]

Synthesis time, h	T, °C	Acetylene conversion, %	Catalyzate composition, wt %			
			2-methylpyridine	4-methylpyridine	acetonitrile	sum of by-products
0–30	280	98.0	35.5	16.4	32.0	15.0
30–60	290	95.0	39.6	23.2	26.0	13.0
60–90	300	92.0	42.0	21.0	21.0	10.0
90–120	310	90.0	44.0	24.0	16.0	25.0
120–150	320	86.0	47.0	22.0	12.0	19.0
150–160	330	82.0	51.0	25.0	8.0	26.0
180–200	340	70.0	53.0	27.0	3.0	17.0

It was found that, in the first 60 h, the selectivity of a fresh catalyst with respect to pyridine yield is unstable; the major products are acetonitrile, benzene, propionitrile, etc. After 70 h, the process selectivity becomes stable, and the acetonitrile content in the catalyzate gradually decreases (Table 2).

After 180 h of work and subsequent regeneration, the catalyst becomes completely ripened. In this case, the content of acetonitrile, by-products, and tars in the catalyzate does not exceed 20–25%.

We found that the specific surface area of the catalyst decreases with time by 30 $m^2 g^{-1}$ on the average. Simultaneously, its mechanical strength increases by approximately 0.8–1.0 MPa. It should be noted that, in the course of catalyst operation, a new crystalline phase is formed, which makes the catalyst more stable.

The KTsKhZhA-6 catalyst was tested in the continuous mode for 1500 h in synthesis of pyridine and isomeric methylpyridines from acetylene, ammonia, and methanol. The following optimal process parameters were found: temperature 360–440°C; acetylene : ammonia : methanol molar ratio 1.0 : 2.0 : 0.8; total space of the velocity 100–200 h^{-1}. The catalyzate (organic layer) obtained under these conditions has the following composition (wt %): pyridine 28.0–33.0, 2-methylpyridine 12.0–25.0, 3-methylpyridine 18.0–21.0, 4-methylpyridine 12.0–15.0, with the remainder being higher pyridines, acetonitrile, and tars.

Thus, new catalysts based on cadmium, zinc, chromium, iron, and aluminum oxides and fluorides were developed and tested in synthesis of pyridine bases from acethylene, ammonia, and methanol.

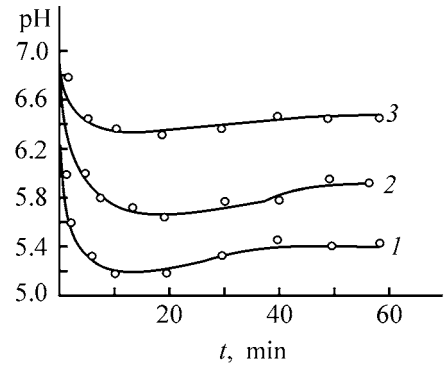
The catalysts were prepared by suspending, followed by molding, drying, and calcination. Aluminum hydroxide (calcination loss 33.0%) was used as support.

X-ray diffraction patterns of the catalysts were recorded on a DRON-2 diffractometer (Cu_{K_α} radiation). The specific surface area was measured by the BET method. The catalyst acidity was determined pH-metrically with a pH-673 pH-meter equipped with an ESL-43-07 glass electrode. The pore structure of the catalyst was studied by mercury porosimetry.

The catalytic condensation of acethylene with ammonia and methanol was performed in a 25 × 1000 mm cylindrical stainless steel flow-through reactor. The temperature, space velocity, and ratio of the initial components were varied.

The reaction products were analyzed by GLC [Chrom-5 chromatograph, Apiezon-M (12–15 wt %) on Celite 545 as stationary phase, column temperature 120°C, toluene as internal reference, carrier gas helium, flow rate 2.4 $l\,h^{-1}$].

The products were separated by catalyzate fractionation on a 30-TP column and identified by their physical constants and also by obtaining their picrates and chloroplatinates.



Variation with time t of pH of water contacting with the catalyst surface. Catalyst: (*1*) KTsKhZhA-6, (*2*) KTsZhKhA-5, and (*3*) KTsMA-4.

PRODUCTION AND USE OF NEW MATERIALS

Experience of Control over Process of Chemical-Informational Synthesis

V. B. Aleskovskii, S. G. Klochev, A. D. Misharev, and A. I. Romanychev

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia

Received February 26, 2003

Abstract—Conditions under which various kinds of carbon nanoparticles are obtained by thermal oxidative conversion of methane in chlorine in the temperature range 20–500°C were studied. The influence exerted by conditions of synthesis of nanodispersed carbon on the properties of its samples was analyzed.

According to the theory of chemical-informational synthesis [1–6], desired products can be obtained with minimum energy expenditure and maximum productivity by performing synthesis far from equilibrium, with programmed departure from equilibrium, and "quenching" these metastable products with minimum possible delay. Experience shows that mostly low-molecular-weight products are formed in one mode of methane burning [7, 8], and supramolecular products of oxidative condensation of methane, in another [9]. Use of flame as a reaction zone bounded on all sides allows localization of a high-temperature chemical process, which enables sufficiently fast quenching, and allows control over its rate by varying not only hydrodynamic, but also thermal conditions, e.g., by changing one method of cooling of burning products for another.

EXPERIMENTAL

This paper presents the results obtained in experiments on fine control over the process of oxidative condensation of methane, which makes it possible to preset not only the degree of condensation of hydrocarbon chloroderivatives, but also parameters of supramolecules of these highly condensed synthesis products. Pipeline methane (98% methane, 0.7 ethane, 0.2 propane, 0.07 butane) and oxidizing gas "khlor" Cl_2^* obtained by reacting calcium hypochlorite with hydrochloric acid were used in the experiments. This gas contained (vol %): chlorine 46.5, HCl 24.4, nitrogen 20.8, oxygen 5.5, water 0.85, and CO_2 1.95. The oxidative conversion of methane was performed in a tubular reactor by burning the gas in a flow of chlorine. Solid reaction products were separated from gaseous products in a separator. The elemental analysis of the resulting solid products was made by their burning in oxygen in the presence of a catalyst and by ESCA; the specific surface area was measured by the method of low-temperature adsorption of nitrogen; IR spectroscopy, mass spectrometry, and electron microscopy were also employed.

A study of solid products of methane conversion demonstrated that they are composed of nanosize carbon particles enveloped with a shell composed of a solid solution or layers of benzene chloroderivatives [9]. These derivatives are rather easily evaporated on heating to 300–350°C in a vacuum, with the organic shell removed and the carbon core of the particles stripped. Carbon samples were studied on an MS-1301 mass spectrometer, in which a sample was heated from room temperature to 1200°C. On heating a sample to 300°C, the mass spectrum shows high-intensity lines corresponding to $C_6Cl_4^+$, $C_6Cl_4H^+$, $C_6Cl_5^+$, $C_6Cl_5H^+$, $C_6Cl_6^+$ and higher-molecular-weight substances (up to $C_{28}H_{14}$), with hexa- and pentachlorobenzene being the main desorption products; the intensity ratio for $C_6Cl_6^+$ and $C_6Cl_5H^+$ is approximately 1.5 : 1. In the temperature range 300–1200°C, desorption of organic products from a sample terminates virtually completely. Thus, thermal treatment at 300°C and higher results in that a sample is completely freed of a shell and becomes pure carbon at 1200°C.

As objects of further investigation served samples subjected to thermal treatment in a vacuum at 300°C for 1–1.5 h, with 25–30% of their mass lost. A study of these samples with a Tesla BC-613 electron microscope (at magnification of 80 000) demonstrated that they are composed of particles 100 to 300 Å in size, which form chain-like structures.

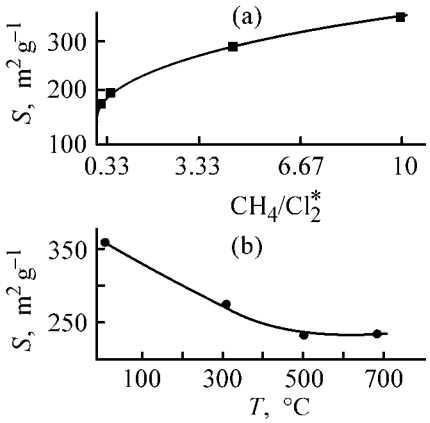

Fig. 1. Specific surface area S of a carbon sample vs. (a) flow rate ratio CH_4/Cl_2^* and (b) reactor heating temperature T.

One of the most important characteristics of carbon products is their specific surface area. The specific surface area of the samples under study depends both on the ratio of reagent flow rates and on the synthesis temperature.

Figure 1a shows the dependence of the specific surface area of the samples (after removal of a shell composed of organic products) on the flow rate ratio of methane and "khlor" (Cl_2^*, a mixture of chlorine, oxygen, HCl, nitrogen, etc.).

It can be seen that the specific surface area of carbon samples grows with increasing excess of methane; however, the yield of carbon black particles decreases. The results obtained were used to choose the optimal flow rates of gases fed into the conversion process (ml min^{-1}): CH_4 230 and Cl_2^* 68. Under these conditions, a rather large amount of carbon particles with specific surface area of about 300 $m^2 g^{-1}$ is formed.

The specific surface area of carbon samples is strongly affected by the temperature of external heating of the reactor. In some experiments, the reaction zone was preliminarily heated with an electric furnace to 20–680°C, and then oxidative conversion of methane was performed under the same conditions in a Cl_2^* flow. The experiments were done at the previously chosen optimal ratio of methane and Cl_2flow rates (see Fig. 1b).

Elemental composition of carbon-containing sample

Element	Content, wt %

It can be seen from Fig. 1b that, on raising the reactor temperature, the specific surface area of the carbon samples obtained decreases. The maximum specific surface area of samples obtained without additional heating was 360 $m^2 g^{-1}$. The size of particles, calculated from their specific surface area, is approximately 10 nm, and that following from electron-microscopic data falls within the range 10–30 nm. The difference can be accounted for by particle aggregation.

Industrial carbon black, which has specific surface area exceeding 100 $m^2 g^{-1}$, retains such a high degree of dispersity for short time only [6]. The specific surface area of the carbon samples synthesized in the present study remained unchanged for 20 days. After 100 days, it decreased somewhat, but still remained rather high (250–270 $m^2 g^{-1}$). The highest specific surface area was observed for carbon samples stored for a long time in the initial state (without removing the organic shell) and subjected to temperature treatment in a vacuum immediately before measuring the specific surface area. Apparently, the shell composed of benzene chloroderivatives, which is formed in the course of synthesis and covers the carbon particles, prevents their aggregation. In "encapsulated form," dispersed particles retain high specific surface area for a long time. It follows from the aforesaid that a reproducible method for obtaining and stabilizing carbon nanoparticles, with their physicochemical properties long preserved, has been found.

The elemental composition of the carbon samples was studied by burning them in a flow of oxygen and by ESCA. Analysis for the content of carbon, hydrogen, and nitrogen was made on a Hewlett Packard 185B Carbon Hydrogen Nitrogen Analyzer. However, this technique yielded understated values of carbon content in the samples, probably, because of the incomplete burning of carbon in a flow of oxygen during the time of analysis (50 s). In further studies, the content of carbon was determined by burning a sample in a flow of oxygen in the presence of a catalyst (in the course of 20 min), using a procedure described in [10]. The content of other elements in the samples synthesized was determined by ESCA. This technique does not record hydrogen, and, therefore, the concentrations of elements were corrected with account of the content of hydrogen. The thus obtained elemental composition of carbon-containing samples is listed in the table.

Both these analytical techniques yield data on the content of carbon in the samples under study, which are in rather good agreement. Studying the mechanism of transformations occurring in the course of synthesis is complicated by the wide variety of possible chemical reactions involving free radicals. However, analysis of the products formed in oxidative condensation of methane burning in a chlorine flow confirms the validity of the scheme suggested in [7]. Chlorine removes from methane all its four hydrogen atoms to form carbons

$$CH_4 + 2Cl_2 \rightarrow C + 4HCl.$$

Carbon atoms immediately combine to form carbon nanoparticles:

$$nC \rightarrow [C]_n.$$

The nanoparticles react with chlorine to give chlorine-containing carbon

$$[C]_n + 0.5mCl_2 \rightarrow [C]_nCl_m.$$

On the surface of $[C]_nCl_m$ particles, there occur reactions yielding an organic shell composed of benzene chloroderivatives

$$6CH_4 + 15Cl_2 \rightarrow C_6Cl_6 + 24HCl$$

(it is known that synthesis of hexachlorobenzene is performed in the presence of activated carbon.) In view of the fact that the shell of nanoparticles synthesized in oxidative conversion of methane in its burning in a "khlor" flow is composed of organic benzene derivatives, it may be assumed that, before being subjected to thermal treatment at above 300°C, the carbon-containing particles themselves are constituted by partly chlorinated aromatic structures.

CONCLUSIONS

(1) It is confirmed by a new experiment that monodisperse "technical-grade carbon"—nanodispersed carbon, can be obtained in the temperature range 20–500°C. A homologous series of supramolecules of nanodispersed carbon is formed in the given temperature range.

(2) The synthesis can be guided in a desired direction by changing the mode of diffusion burning, i.e., it can be controlled by varying the synthesis conditions.

(3) The efficiency of chemical-informational synthesis is high: it occurs in high yield at moderate temperatures, needs no catalysts, and makes it possible to prescribe properties of target products.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Prognostication of Pneumatic Fractionation of Free-flowing Bulk Materials

V. A. Kirsanov

Southern-Russian State Technical University, Novocherkassk, Russia

Received January 22, 2003

Abstract—A mathematical method for prognostication of results obtained in fractionation of free-flowing bulk materials with account of the input particle concentration is described. Using this method makes it possible to substantiate the choice of the optimal design of contact units in cascade pneumatic classifiers for various technological conditions.

Of particular importance for ensuring efficient separation of free-flowing bulk materials in cascade pneumatic classifiers is prognostication of the results of the process. Solution of this problem reduces to substantiation of the optimal separation boundary ensuring the maximum yield of the target product with account of the technological requirements to quality. The previously developed mathematical models for prognostication of the optimal parameters of the process in question have been constructed without considering the input concentration of particles in an apparatus, which governs its output capacity [1, 2].

Let us consider a process of separation of a polydisperse mixture, which is aimed to obtain a coarse fraction of a certain granulometric composition, the product in the given case. Technological requirements, as a rule, restrict the maximum content of contaminating fractions and the minimum content of the commercial fraction; the output of the commercial product must be the highest. Thus, the constraint on the content of contaminating fractions in the product can be written as

$$\sum_{i=1}^{m} r_{\mathrm{k}i}^{\mathrm{cont}} \le k,$$

where i and m are the initial and final numbers of the contaminating fractions in the product; $r_{\mathrm{k}i}^{\mathrm{cont}}$, the content of ith contaminating fraction in the product; k, the maximum content of contaminating fractions in the product.

The constraint on the content of valuable fractions in the product is written in a similar way

$$\sum_{i=a}^{b} r_{\mathrm{k}i}^{\mathrm{val}} \ge L,$$

where a and b are the initial and final numbers of the valuable fractions in the product; $r_{\mathrm{k}i}^{\mathrm{val}}$, the content of ith valuable fraction in the product; L, the minimum content of the valuable fraction in the product.

To these constraints should be added the condition ensuring the maximum yield of the product, γ_{k}, which has the form $\gamma_{\mathrm{k}} \to \max$. Then, with account of the relations

$$r_{\mathrm{k}i} = \Phi_{\mathrm{k}i} r_i / \gamma_{\mathrm{k}}, \quad \gamma_{\mathrm{k}} = \sum_{i=1}^{n} \Phi_{\mathrm{k}i} r_i,$$

(where $\Phi_{\mathrm{k}i}$ is the degree of fractionation recovery of ith fraction from the initial mixture into the product, and r_i is the content of ith fraction in the initial mixture), the following system, which is a mathematical model applicable to solution of the problem at hand, can be written:

$$\begin{gathered} \sum_{i=1}^{m} r_{\mathrm{k}i}^{\mathrm{cont}} = \sum_{i=1}^{m} \left(\Phi_{\mathrm{k}i} r_i \Big/ \sum_{i=1}^{n} \Phi_{\mathrm{k}i} r_i \right) \le k, \\ \sum_{i=a}^{b} r_{\mathrm{k}i}^{\mathrm{val}} = \sum_{i=a}^{b} \left(\Phi_{\mathrm{k}i} r_i \Big/ \sum_{i=1}^{n} \Phi_{\mathrm{k}i} r_i \right) \ge L, \\ \gamma_{\mathrm{k}} = \sum_{i=1}^{n} \Phi_{\mathrm{k}i} r_i \to \max. \end{gathered} \tag{1}$$

The degree of fractionation recovery is sufficiently well approximated with the Plitt function [3]

1070-4272/03/7606-0946 $25.00 © 2003 MAIK "Nauka/Interperiodica"

$$\Phi_{ki} = 1 - \frac{100}{1 + (x_i/x_b)^P}, \quad (2)$$

where x_i is the average grain size of ith class, and P is the efficiency factor characterizing the steepness of the fractionation separation curve $\Phi_k(x)$.

As optimization parameters in solving the given problem serve the separation boundary x_b and the Eder–Mayer number $\chi = x_{25}/x_{75}$, where x_{25} and x_{75} are sizes, according to the separation curve, of particles 25 and 75% recovered into the coarse product. The Eder–Mayer number and the efficiency factor are related by $\chi = (1/9)^{1/P}$ [4]. The parameters characterizing the efficiency of the separation process depend both on the design of contact units (CU) of cascade pneumatic classifiers and on the input particle concentration μ.

Figure 1 shows experimental dependences $P = f(\mu)$ for pneumatic classifiers with CU of various designs [5]. This dependence is approximated by an equation of the following type

$$P = c_1\mu^2 + c_2\mu + c_3. \quad (3)$$

The values of the coefficients c_1–c_3 are listed in the table for all the apparatus under study. Substituting the $P = f(\mu)$ dependence in Eq. (2), we obtain an expression for Φ_k for each apparatus design in relation to the input particle concentration μ.

For example, for a pneumatic classifier with triple-flow CU, the degree of fractionation recovery can be calculated using the equation

$$\Phi_{ki} = 1 - \frac{100}{1 + (x_i/x_b)^{-0.004\mu^2 - 0.21\mu + 5.01}},$$

The problem in question is tackled with by determining the optimal separation boundary x_b at which the condition (1) is valid, by solving by computerized marching method with preset step the system of inequalities (1) at different P in relation to the input particle concentration μ.

The given mathematical model was applied to prognosticate the results obtained in separation of filling materials (stock) of roasting furnaces[1] in order to make recommendations concerning the choice of the optimal CU design. The CU were mounted in the separation chamber of pneumatic classifiers with output capacity of 15 ton h^{-1}. The technological conditions required that a certain granulometric composition of the stock should be ensured, with the content of particles less than 500 μm in size not exceeding 5%. In this case, the content of valuable fractions must not be less than 70%. The averaged granulometric composition of the stock is given below:

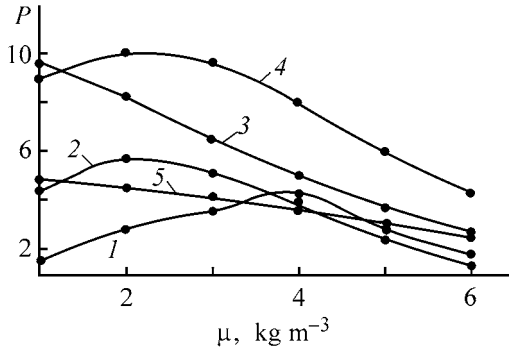

Fig. 1. Efficiency factor P of pneumatic classification vs. particle concentration μ in the apparatus. Apparatus: (*1*) hollow; with contact units: (*2*) lamellar, (*3*) double-flow, (*4*) steplike, and (*5*) triple-flow.

Sieve mesh, μm	1000	630	400	
Partial residues	24.6	10.7	8.5	
Sieve mesh, μm	315	200	160	
Partial residues	6.6	11.2	9.4	
Sieve mesh, μm	100	63	50	Tray
Partial residues	12.9	10.3	1.8	4.0

The mathematical model was used to compute parameter values in order to solve the problem mentioned above for the given composition of the filling material. The separation efficiency was preset using the Eder–Mayer number and the P factor (in Plitt's approximation) for particle concentration in the flow, μ, varying from 0.5 to 6.5 kg m^{-3} with a step of 0.5 kg m^{-3}.

Coefficients in Eq. (3)

Apparatus	c_1	c_2	c_3
Pneumatic classifier:			
hollow	–0.33	2.33	–0.45
with lamellar CU	–0.34	1.54	3.45
with double-flow CU	0.04	–1.67	11.20
with steplike CU	–0.40	1.74	7.74
with triple-flow CU	–0.04	–0.21	5.01

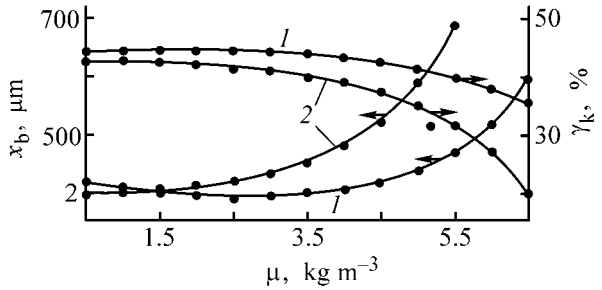

Fig. 2. Yield γ_k of coarse product and boundary particle size x_b vs. particle concentration in the apparatus. Apparatus with (*1*) steplike and (*2*) double-flow CU.

Figure 2 shows the results of calculation as a dependence of the yield of the finished product, γ_k, and boundary particle size x_b on the concentration μ for apparatus with steplike and double-flow CU. It can be seen that the maximum yield for the given pneumatic classifiers is 42%. Such a low yield of the stock of required granulometric composition can be accounted for by the fact that the content of valuable fractions in the initial filling material is 43.8%, and that of contaminating fractions, 56.2%. In this case, the limiting particle concentration μ = 5 kg m^{-3}, since, for a steplike unit, an increase in particle concentration from 0.5 to 5 kg m^{-3} has virtually no effect on the value of γ_k. The optimal parameters are, in this case, γ_k = 41.2% and x_b = 450 μm (P = 6.8, χ = 72.5%). Raising the concentration of the solid phase leads to a decrease in the yield of the finished product, steep rise in loss of valuable fractions, and increase in the boundary size of particles. Use of double-flow CU for solving the problem in question is inefficient since the yield of the finished product decreases dramatically when μ exceeds 3 kg m^{-3}. The optimal parameters for apparatus with double-flow CU are as follows: γ_k = 40.1% and x_b = 410 μm (at P = 7.4 and χ = 74.2%).

CONCLUSION

It is advisable to use, to separate filling materials with boundary particle size of 500 μm, a pneumatic classifier with steplike contact units, which ensures somewhat higher yield of stock with required granulometric composition and prescribed quality restrictions and has higher output capacity. The latter is particularly important, since the yield of stock is relatively low because of the increased content of contaminating fractions in the initial material.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Kinetic Characteristics of Back-Osmosis Separation of Aqueous-Organic Solutions

V. L. Golovashin, S. I. Lazarev, and O. A. Abonosimov

Tambov State Technical University, Tambov, Russia

Received April 9, 2002; in final form, November 2001

Abstract—Back-osmosis separation of aqueous solutions of morpholine and hydroquinone on an industrial back-osmosis installation was studied in relation to the concentration and flow velocity of a solution in the intermembrane channel. The behavior of the main kinetic characteristics of separation as influensed by physical conditions of the separation process was analyzed and accounted for.

An important problem of industrial organic synthesis is utilization of waste industrial solutions and wastewater with low concentration of dissolved substances. The most promising methods for purification and concentration of these aqueous solutions are membrane separation techniques and, in particular, back osmosis. In a number of reports [1–4], results obtained in separation of aqueous solutions of low-molecular-weight organic substances by back osmosis were presented. However, the experiments described were carried out on laboratory installations, without due account of the concentration polarization, which strongly affects the separation process under industrial conditions.

The present communication reports the results obtained in studying separation of aqueous solutions of morpholine and hydroquinone on an industrial back-osmosis installation. These data are necessary both for analyzing mass-transfer processes and constructing mathematical models of the process and for developing engineering procedures for calculation of back-osmosis installations.

The experiments were done on an MRR 5-21K-01 industrial back-osmosis installation equipped with ERO-E-950/6.5 back-osmosis units of the roll type, with an MGA-95K composite cellulose acetate membrane.

The installation is shown schematically in Fig. 1. The roll units were preliminarily washed to remove glycerol impurities formed in storage and fabrication and mounted in the back-osmosis apparatus (Fig. 2) in the following sequence: the first ERO unit 7 was fixed in the cover *1* with a seal *2*. Then the cover was mounted in the apparatus case *3*, and the joint was tightened with a seal *4* and fixed with a locking ring *5*. A second ERO unit was connected to the first with adapter *6* and fixed in the apparatus case similarly to the first one. Then the feed liquid tank E1 (Fig. 1) was filled with 200 l of water and the valve Vr1 was opened. The pump P was switched on and the pressure in the system was gradually raised to 4.0 ± 0.5 MPa with a throttle valve Th. The mem-

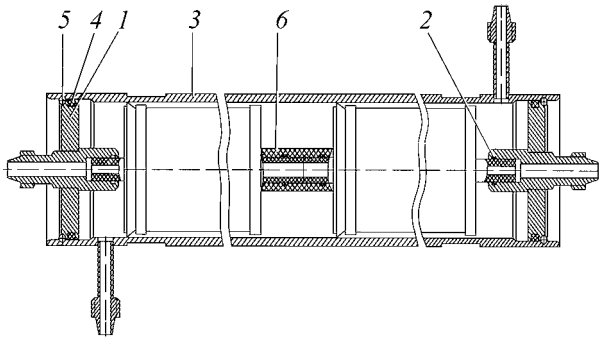

Fig. 2. Back-osmosis apparatus.

branes in the roll units were pressurized for 4 h at 4.0 ± 0.5 MPa in a flow-through mode to constant throughput. Then water was discharged from vessel *3* and the installation. The feed liquid tank E1 was filled with 200 l of an aqueous solution of a substance under study. The necessary flow rate of the feed liquid was set on the basis of readings of the rotameter R1. On switching-on the pump P and raising the pressure in the hydraulic system of the installation to the working value with the throttle valve Th, a control run was performed in the course of 4 h. The permeate and retentate were discharged into the feed liquid vessel E1. The pressure in the system was monitored with pressure gage G and electromechanical pressure gage EMG. Then the installation was switched off and kept filled with the solution for a long time (10–12 h).

The technique described above was also used to perform the working run with varied flow rate of the feed liquid. The solute concentrations (concentrations of dissolved substances) were determined by photometry [5]. The readings of the rotameters R1 and R2 were used to calculate the volumetric flow rates of the retentate and permeate.

On the basis of the experimental results, the retention factor k (%) and specific flow rate J ($m^3\ m^{-2}\ s^{-1}$) of the solvent were calculated for the membranes

$$k = (1 - c_{per}/c_f), \quad (1)$$

$$j = V/(F\tau), \quad (2)$$

where c_{per} and c_f are the solute concentrations in the permeate and feed solution (kg m^{-3}); V, the volume of permeate obtained during a run (m^3); F, the working surface area of the membranes (m^2); τ, the run duration (s).

The influence exerted by the solute concentration on the separation process was studied. To analyze the effect of mode parameters on the separation process, additional experiments were carried out at solution flow velocity in the intermembrane channel varied from 0.036 to 0.18 m s^{-1}. The results obtained (Tables 1 and 2) give insight into the relationship between the solubility of substances and the sorption capacity of a membrane.

Let us consider the effect of the solution flow velocity in the intermembrane channel on the specific flow rate of the solvent across the membrane. It can be seen from Table 1 that the solution flow velocity strongly affects the specific flow rate of the solvent. The increase in the specific flow rate of the solvent is due to a weaker influence of the concentration polar-

ization [6]. It should also be noted that, in the case of morpholine, the osmotic flow of the solvent across the membrane is an important factor. When the solution flow velocity in the intermembrane channel is raised, the agitation in the near-membrane layers is improved, with the result that the osmotic flow rate decreases and, consequently, the specific flow rate of the solvent increases.

Raising the solution concentration leads to a decrease in the specific flow rate of the solvent. This is a consequence of two effects: the increase in the solution concentration in the near-membrane region leads, on the one hand, to clogging of pores in the membrane as a result of interaction of the solute with the material of the active layer of the membrane [7, 8], and, on the other, to an increase in the osmotic pressure of the solvent at the membrane surface [9] and, as a consequence, to a decrease in the specific flow rate of the solvent.

Let us consider the effect of concentration and flow velocity of the solution on the retention factor of the membrane for dissolved substances. Morpholine and hydroquinone are polar substances and can form hydrogen bonds with the membrane material [10]. In this case, three-dimensional polymolecular structures composed of solute and solvent molecules can be formed both in the near-membrane region and in the solution bulk. Also, sorption of solutes by the active layer of the membrane causes partial clogging of pores, with the result that the membrane permeability to the solute decreases. It is these effects that lead, combined, to a rise in the retention factor of the membrane with increasing concentration of dissolved substances.

The fact that the membrane has different retention factors for the solutes can be explained as follows. The solute is transferred across the membrane by two flows: convective (with the solvent) and diffusion [11]. The amount of substance transported by any of these flows depends on the sorption capacity of the membrane [7, 8]. The membrane has different sorption capacities for morpholine and hydroquinone. The latter is strongly sorbed by the membrane, and the former, in smaller amounts. The following pattern is observed in adsorption from solutions: a substance is sorbed from solution the better, the lower its solubility in the solvent (water) [12]. Hydroquinone, being a weak acid, shows limited solubility in water [10] (P_{max} = 67 kg m^{-3} at 20°C) and, therefore, is well sorbed by the membrane surface. As a result, the retention factor for morpholine exceeds that for hydroquinone.

Raising the solution flow velocity over the membrane leads to better agitation of near-membrane layers, with the result that the solute concentrations in the flow core and in the near-membrane region become equal and, as a consequence, the amount of substance transferred by the convective flow decreases. The decrease in the solute concentration in the near-membrane region also leads to a fall in the concentration gradient on both sides of the membrane, with the transmembrane diffusion flow decreasing. Acting together, these effects result in that the retention factor of the membrane grows with increasing velocity of solution flow over the membrane.

CONCLUSIONS

(1) The retention factor of the membrane and the specific flow rate of the solvent across it are higher for well-water-soluble morpholine, compared with the poorly soluble hydroquinone. At morpholine concentrations of 0.86–1.84 kg m^{-3}, the specific flow rate of the solvent is (5.92–5.49) × 10^{-6} m^3 m^{-2} s^{-1}, and the retention factor, 80–79%. At hydroquinone concentrations of 1.045–2.28 kg m^{-3}, the specific flow rate of the solvent is (4.25–3.98) × 10^{-6} m^3 m^{-2} s^{-1}, and the retention factor, 13–16%.

(2) With the solution flow velocity in the intermembrane channel increasing within the range 0.036–0.18 m s^{-1}, both the retention factor and the specific flow rate of the solvent grow [k = 47.52–76.23% and J = (4.05–5.92) × 10^{-6} m^3 m^{-2} s^{-1}, for an aqueous solution of morpholine and k = 13–20% and J = (3.4–4.9) × 10^{-6} m^3 m^{-2} s^{-1} for an aqueous solution of hydroquinone].

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of 4-Amino-4'-nitrodiphenyl Sulfide

V. S. Pilyugin

Research and Technological Institute of Herbicides and Plant Growth Regulators, Academy of Sciences of Bashkortostan Republic, Ufa, Bashkortostan, Russia

Received January 9, 2003

Abstract—The possibility of preparing 4-amino-4'-nitrodiphenyl sulfide by reaction of chlorobenzene with sodium sulfide in a two-phase system composed of water and organic solvent in the presence of a phase-transfer catalyst under continuous hydroacoustic treatment was examined.

4-Amino-4'-nitrodiphenyl sulfide **I** is an intermediate in production of 3,4,4'-triaminodiphenyl sulfide, the synthetic precursor of antihelminth agents of the 5(6)-(4'-aminophenylthio)-2-aminobenzimidazole series [1].

Thioethers (sulfides) are prepared by condensation of alkyl halides or nitro-substituted aryl halides with sodium sulfide [2–4].

Synthesis of thioethers by reaction of thiocyanates with alcohols under heating in the presence of stoichiometric amounts of alkali or alkaline-earth metal hydroxides or alcoholates or those of tertiary amines is described in a patent [5].

Dialkyl sulfides can also be prepared by reaction of alkyl chlorides with an aqueous or aqueous-alcoholic solution of alkali metal sulfide in an autoclave at high pressure [6]; diaryl sulfides are synthesized by reaction of appropriate nitrochlorobenzenes in dimethylformamide (DMF) with an aqueous solution of sodium sulfide in the presence of finely divided sulfur [7] or in refluxing alcohol with fine powder of a preliminarily fused mixture of sodium sulfide and sulfur [8].

There are numerous procedures for reducing nitro compounds to the corresponding amines [9]; in some cases, it is possible to selectively reduce one of the nitro groups of polynitro compounds with a calculated amount of sodium (or ammnonium) sulfide (or hydrosulfide) [9].

A procedure has been developed for preparing 4,4'-diaminodiphenyl sulfide **I** by reaction of 4-nitrochlorobenzene **II** with sodium sulfide in DMF, followed by reduction of the resulting 4,4'-dinitrodiphenyl sulfide with iron powder in aqueous alcohol in the presence of ammonium chloride under heating [10].

Hodson and Wilson [11] prepared diphenyl sulfide **I** as follows. A solution of **II** in absolute ethanol is heated almost to reflux, and an aqueous solution of sodium sulfide is added in small portions. The resulting mixture is refluxed with stirring for 10 h. Yield of **I** is about 20% (mp 138–142°C).

According to Radulova and Tapalova's procedure [12], a mixture of **II** with water and sodium sulfide is heated, an additional portion of **II** is added, and, after prolonged heating, toluene is added; the yield of **I** is about 68% (mp 143–144°C).

Zasosov and Gal'chenko prepared sulfide **I** by adding a portion of **II** to a boiling aqueous solution of sodium sulfide. After stirring for a certain time, the next portion of **II** is added, and the mixture is refluxed with stirring. Then an additional small amount of aqueous sodium sulfide solution is introduced, and the mixture is refluxed with stirring. The resulting mixture is steam-distilled to remove unchanged **II**; yield of **I** 77–80% (mp 145–147°C, from toluene).

Raiziss *et al.* [14] refluxed a mixture of Na_2S, water, and a part of the required amount of **II**, after which they added the remaining part of **II**, with the refluxing continued. The resulting mixture was steam-distilled; yield of **I** 80% (mp 141–413°C, from ethanol).

Aminonitrodiphenyl sulfides can also be prepared by reaction of alkaline solutions of substituted aminothiophenols with alcoholic solutions of halonitrobensenes [15–20].

All the above procedures for preparing sulfides **I** are time- and labor-consuming; the yield and quality of the target product are poor. The procedures involve

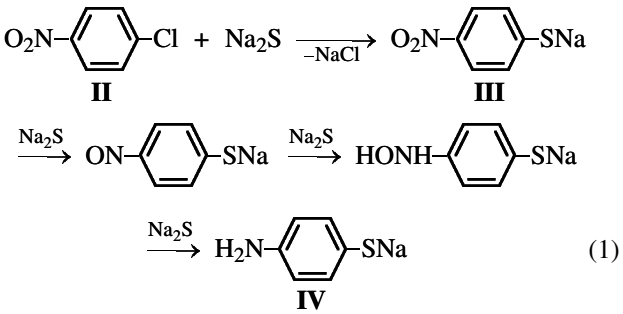
** Addition of PEG-400.

numerous auxiliary operations or require difficultly available chemicals. Therefore, none of these procedures has been introduced on the commercial or semicommercial scale.

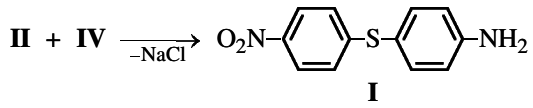
In this study, we developed an improved procedure for preparing sulfide **I**, based on the reaction of nitrochlorobenzene **II** with sodium sulfide in a two-phase system constituted by water and organic solvent (chlorobenzene, toluene, chloroform, etc.) under heating in the presence of a phase-transfer catalyst (PTC: quaternary alkylammonium salts, polyethylene glycol PEG-400, etc.), with simultaneous hydroacoustic treatment of the reaction mixture.

Reaction of **II** with sodium sulfide involves a number of steps: formation of sodium 4-nitrothiophenolate **III** and its successive reduction with sodium sulfide to the nitroso, hydroxylamino, and finally, amino derivatives. Sodium 4-aminothiophenolate **IV** mainly accumulates in the aqueous phase.



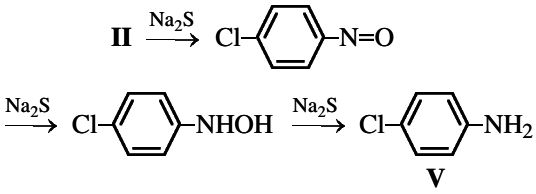
(1)

Sulfide **I** is formed by the reaction of **IV** with the remaining part of **II**:



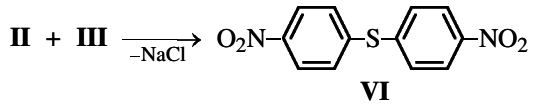
(2)

An impurity of *p*-chloroaniline **V** is formed by reduction of the nitro group via a series of intermediates:



(3)

An impurity of 4,4'-dinitrodiphenyl sulfide **VI** is formed by the reaction of **III** with **II**:



(4)

Thiophenolate **III** and products of its sequential reduction to **IV** are water-soluble and, when formed, pass to the aqueous phase. The compounds mainly occurring in the organic phase are sulfide **I**, chloronitrobenzene **II**, chloroaniline **V**, and also dinitrodiphenyl sulfide **VI** formed in small amounts.

The optimal parameters of sulfide **I** preparation (temperature, reaction time before adding phase-transfer catalyst, water : organic solvent and **II** : Na_2S ratios) are those at which, before adding the phase-transfer catalyst, the amount of **V** is the smallest, compound **VI** is virtually absent, approximately half of **II** is converted to salt **IV** and passes to the aqueous phase, and the other half remains in the organic phase (Table 1).

When a phase-transfer catalyst (PEG-400 etc.) is added at this instant of time to the reaction mixture and the mixture is subjected to intense hydroacoustic treat ment, the transfer of salt **IV** from the aqueous to organic phase and its reaction with chloronitrobenzene **II** in the organic phase to form sulfide **I**, also dissolving in the organic phase, are sharply accelerated. In most cases, in synthesis of **I**, chlorobenzene (Table 2) or toluene (Table 3) is used as organic solvent.

The advantage of chlorobenzene is that, in contrast to toluene, this solvent (and solution of **I** in it) can be subsequently used for preparing 4-amino-3,4'-dinitrodiphenyl sulfide. Furthermore, as follows from

3.12	1.5	6	89	90
3.12	1.0	7	90	90

Tables 2 and 3, chlorobenzene, compared to toluene, ensures higher yield and quality of **I**.

Laboratory experiments on development of a procedure for preparing **I** (Table 2) show that the best synthesis conditions are as follows. Temperature schedule: 80–85°C in the stage of adding Na_2S, keeping for 0.5 h at 80–85°C after adding the whole amount of Na_2S; heating to 96–102°C for 0.5–1.0 h before adding phase-transfer catalyst (PEG-400); addition of PEG-400 and subsequent reaction at 96–102°C. Ratios: water : chlorobenzene (by volume) 2.5 : 1.0, chlorobenzene : **II** (by weight) 1.00 : 1.17, **II** : Na_2S (molar) 1.0 : 1.7, and **II** : PEG-400 (by weight) 1.000 : (0.014–0.017). Under these optimal conditions, sulfide **I** is prepared relatively simply in a yield of no less than 92%, with the main substance content of no less than 93 wt %. The process was developed on a semicommercial scale (160-l reactor with immersed device for hydroacoustic treatment [21]).

EXPERIMENTAL

The reaction mixtures and crude products in the stage of preparation of **I** were analyzed qualitatively by TLC and quantitatively by HPLC, and identified by IR and ^{13}C NMR spectroscopy.

The IR spectra were recorded with a Jasco 810-IR spectrometer in the 4000–400 cm^{-1} range using CCl_4 solutions or mulls in mineral oil. The ^{13}C NMR spectra were measured on a Bruker CXP-100 spectrometer at a working frequency of 22.63 MHz under conditions of total proton decoupling or without it; solvent DMSO, internal reference HMDS. The signal assignment was based on the chemical shifts, coupling constants, multiplicities, and relative intensities; data for related model compounds and results of calculation of magnetic shielding in an aromatic ring were also taken into account.

The TLC analysis was performed on Silufol plates; the development involved reduction with an $SnCl_2$ solution, diazotization of the resulting anilines, and azo coupling with 1-naphthol; eluent C_6H_6 : C_2H_5OH, 10 : 1 by volume.

Quantitative HPLC analysis was performed with an Altex model 330 liquid isocratic chromatograph equipped with a model 110 pump, a model 153 detector, model 210 20-μl loop dosing units, and 30-, 50-, and 100-μl SNR Hamilton microsyringes. Separation and analysis of a mixture of nitrobenzene **II**, sulfide **I**, dinitro sulfide **VI**, and chloroaniline **V** were performed on a stainless steel column (25 cm × 4.6 mm i.d.) packed with Ultraspher ODS phase (grain size 5 μm). The products were analyzed and identified using water–acetonitrile (20 : 80 to 30 : 70 by volume) eluent and diphenyl as internal reference.

A glass reactor equipped with a reflux condenser was charged with the required amounts of water and organic solvent (chlorobenzene, toluene, chloroform, etc.), after which crystalline chloronitrobenzene **II** was added. The mixture was vigorously stirred with a hydroacoustic device mounted on the reactor lid and heated to 65–70°C; in so doing, chloronitrobenzene **II** gradually dissolved in the organic phase. Then crystalline $Na_2S \cdot 9H_2O$ (or its aqueous solution prepared in advance) was added in small portions so as to keep the reaction temperature within 80–85°C. When solid sodium sulfide was added, the temperature first noticeably decreased owing to endothermic dissolution of Na_2S and then sharply increased owing to fast exothermic reaction (with the Na_2S solution prepared in advance, the temperature variations are weaker). Therefore, Na_2S should be added carefully, since overheating of the reaction mixture (above 80–85°C) causes side reactions.

After adding the whole amount of Na_2S, the mixture was vigorously stirred at 80–85°C with a built-in device for hydroacoustic treatment for an additional 30 min, after which it was heated to 96–102°C and stirred at this temperature for 0.5–1 h. Then, a phase-transfer catalyst (PEG-400 or quaternary alkylammonium salt) was added in the amount of 1–4% relative to the charged chloronitrobenzene **II**, and the mixture was vigorously stirred at 96–102°C with the hydroacoustic treatment for 6–7 h.

After reaction completion and phase separation, the lower aqueous salt solution was separated and discarded, and the organic layer was washed with hot water with vigorous stirring to remove the inorganic salts and organic intermediates more completely. After phase separation, the lower organic layer (a solution of crude sulfide in chlorobenzene, toluene, or chloroform) was poured into a crystallizer and cooled to 0°C. The precipitated crystals of **I** were filtered off, washed with water, and dried at 60–70°C.

CONCLUSION

The reaction of 4-nitrochlorobenzene with sodium sulfide in a two-phase system constituted by water and organic solvent (chlorobenzene, toluene, chloroform, etc.) in the presence of a phase-transfer catalyst (PEG-400, quaternary alkylammonium salts, etc.) added after a definite period of time, under vigorous hydroacoustic treatment and at temperature maintained

in the ranges 80–85 (addition of Na_2S, before adding phase-transfer catalyst) and 96–102°C (phase-transfer step), gives 4-amino-4'-dinitrodiphenyl sulfide in a yield of no less than 92%, with the main substance content of no less than 93%.

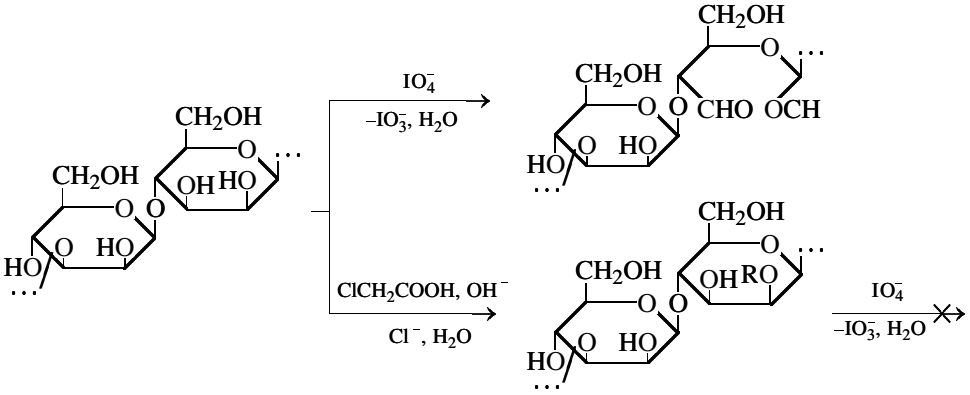
Received December 10, 2002; in final form, March 2003

Abstract—The distribution of functional groups in the monomeric unit of carboxymethyl rhodexman was studied by periodate oxidation and ^{13}C NMR.

Rhodexman, linear β-1,3-β-1,4-*D*-mannan produced by *Rhodotorula rubra* yeast culture, occupies a particular place among polysaccharides. It is virtually nontoxic; it normalizes the blood coagulation system, exhibits pronounced antilipidemic and radiation-protective activity, and enhances the nonspecific resistance of a living body [1]. A semisynthetic pharmaceutical Rhonasan exhibiting antisclerotic effect and hypoglycemic activity was developed on the basis of sulfated rhodexman. Its surpasses the analogs produced beyond Russia in safety (low toxicity) and other properties [2]. It seems also promising to develop physiologically active polymers based on carboxymethyl rhodexman (CMR). In this study we analyzed the distribution of carboxymethyl groups in CMR with the aim to find conditions for preparing the standardized product and elucidate factors affecting its reactivity. Rhodexman was alkylated with monochloroacetic acid in isopropyl alcohol in the presence of an alkali [3]. CMR samples were isolated and purified as described in [4] and were characterized by the degree of carboxymethylation C_{cm} (number of carboxymethyl groups per monomeric unit of the polysaccharide), which was calculated from the results of conductometric and volumetric titration [4]. The CMR samples used in this study had C_{cm} = 0.18–1.07.

To determine the predominant alkylation direction in CMR samples with various degrees of substitution, the number of α-glycol groups was determined by periodate oxidation:



We took into account that the number of α-glycol groups in the CMR sample decreases by 1 mol only when the alkylation occurs in the 1,4-linked monosaccharide fragment at the C^2–O and/or C^3–O positions. Carboxymethylation at the other positions of the rhodexman polymeric chain does not affect the results of periodate oxidation. Examination of the correlation between the number of α-glycol groups and C_{cm},

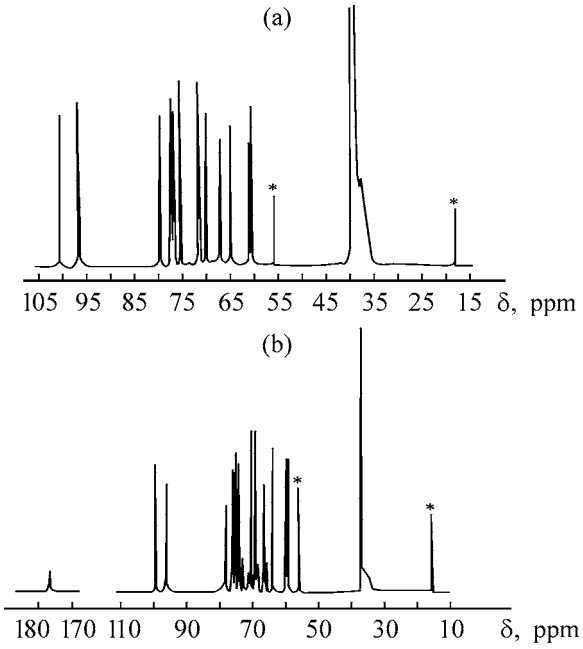

Fig. 3. ^{13}C NMR spectra of (a) rhodexman and (b) CMR (C_{cm} = 0.25). (δ) Chemical shift. The signals belonging to residual ethanol used for precipitation of rhodexman or CMR are marked with an asterisk.

provided that the substituents are distributed over the polysaccharide chain uniformly, allows evaluation of the relative reactivities of various monosaccharide fragments of rhodexman.

Oxidation of polysaccharide samples was performed with sodium metaperiodate in acetate buffer solution (pH 4.1) [5]. The oxidant consumption was monitored spectrophotometrically (λ 222.5 nm) [3].

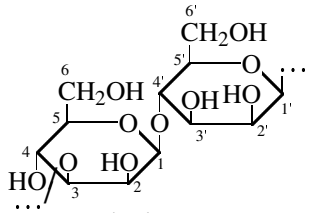
We found that, in CMR samples with C_{cm} = 0.2–1.0, as compared to the initial rhodexman, the content of α-glycol groups decreases by 0.42 mol per mole of introduced carboxy groups (Figs. 1, 2).

Since only 66% of rhodexman units linked by the β-1,4-glycoside bond are oxidized with periodate, it seems that the polysaccharide is alkylated randomly. At C_{cm} = 1.0, there is 0.66 mol of the substituent per 0.66 mol of 1,4-linked monosaccharide fragments, including 0.42 mol of carboxymethyl groups at the C^2–O and/or C^3–O positions (in the case of purely random distribution, the content of such groups would be 0.44 mol). However, there are indications in the literature that, among two vicinal secondary hydroxy groups of cellulose, only one is substituted by the carboxymethyl group, and the probability of substitution at C^2–O is two times higher than at C^3–O [6]. This fact is due to repulsion between the negatively charged chloroacetate ions and carboxymethyl groups at position 2 or 3 [7]. Experiments on dextran carboxymethylation also showed that monosubstitution decreases the reactivity of the remaining OH groups: by approximately 50% at the β-position and 30% at the γ-position [8]. It is also known that, in 1,4-glucans, the primary hydroxy groups are alkylated almost as readily as the groups at the C^2 position. Published data on the direction of carboxymethylation of cellulose, dextran, and other polysaccharides [9–11] suggests that carboxymethyl groups in CMR are located at the C^2–O position in 1,4-linked monosaccharide units of rhodexman and at the C^6–O position in 1,3- and 1,4-linked units.

To determine the direction of rhodexman carboxymethylation, we measured the ^{13}C NMR spectra of samples of the initial polysaccharide and carboxymethylrhodexman with C_{cm} = 0.25 and 0.7 (Figs. 3a, 3b). The assignments are given in the table.

As shown in [12, 13], alkylation of the OH groups of the pyranose ring shifts the signals of the carbon atoms linked to these groups downfield by 6–12 ppm, which is due to conformational changes in the carbohydrate chain and mannose units. In our case, the signals of the C^6 and $C^{6'}$ atoms linked to OH groups decrease in intensity, and new, less strong signals appear at 71.0 and 73.1 ppm, assignable to the C^6 and

Signal assignment for carbon atoms of mannopyranose units of rhodexman and carboxymethyl rhodexman samples



Rhodexman

Carbon atom	δ_C (ppm) at indicated C_{cm}			Carbon atom	δ_C (ppm) at indicated C_{cm}		
	0	0.25	0.7		0	0.25	0.7
1	96.7	98.3	98.0	4	65.0	66.7	66.4
1'	100.3	101.7	101.4	4'	77.2	78.4	78.1
2	66.9	69.0	68.7	5	76.9	77.7	77.5
2'	70.0	73.1 (76.5)*	71.9 (75.2)	5'	75.5	76.5	76.3
3	79.5	80.6	80.4	6	61.1	62.6 (73.1)	61.7 (72.4)
3'	71.8	73.8	72.9	6'	60.6	61.07 (71.0)	61.3 (71.2)

* The signals of carbon atoms at which the O atoms underwent carboxymethylation are given in parentheses.

$C^{6'}$ atoms linked to the carboxymethylated O atoms. Thus, the C^6 and $C^{6'}$ signals are shifted by 9–10 ppm. Also, the signal of the $C^{2'}$ atom linked to the OH group decreases in intensity, and new signals appear at 75.2–76.5 ppm, assignable to the $C^{2'}$ atom linked to the carboxymethylated O atom; the $C^{2'}$ signal is thus shifted by 3–4 ppm (see table).

The small shift of the signals of the carbon atoms bearing nonalkylated OH groups, relative to the spectrum of the initial rhodexman, is due the fact that, when recording the CMR spectrum, the chemical shift scale was not corrected by the DMSO signal. Comparison of the spectra of the initial and modified rhodexman reveals new signals in the carboxymethylated sample at 176–179 ppm, assignable to the carboxyl carbon atom. This signal is split, suggesting two different positions of the carboxy groups. From the intensity ratio of these signals, it is possible to estimate the ratio of carboxymethyl groups in positions 6, 6', and 2'.

Thus, in alkylation of rhodexman, about 60–70% of carboxymethyl groups appear at the C^6–O position of both monosaccharide units, and 30–40%, at the C^2–O position of the β-1,4-linked units, which is consistent with the results of periodate oxidation. Carboxymethylation does not occur at the C^3–O and C^4–O positions, and at the C^2–O atom of the β-1,3-linked unit the alkylation probability is low.

CONCLUSION

The ^{13}C NMR spectra and results of periodate oxidation show that, in alkylation of rhodexman with monochloroacetic acid in isopropyl alcohol in the presence of 30% NaOH, about 60–70% of carboxymethyl groups appear at the C^6–O position in both kinds of monosaccharide units, and 30–40%, at the C^2–O position of the β-1,4-linked units.

Received January 30, 2003

Abstract—The kinetic features and composition of products of 1-methylcyclohexanol ozonolysis were studied.

In low-temperature selective ozonolysis of methylcyclohexane involving cleavage of the C–H bond, 1-methylcyclohexanol (MCHl) is formed by recombination of $R^{\cdot}$ and $^{\cdot}OH$ radicals after primary initiation, radical-chain transformations of 1-methylcyclohexyl hydroperoxide, and attack of $RO^{\cdot}$ radicals at the starting substrate [1].

In the developed process, the forming MCHl is consumed, and the selectivity with respect to MCHl decreases. In this study, we analyzed the features of MCHl transformation in ozonolysis. The substrate was oxidized and the products analyzed by the procedures described in [2].

An examination of the kinetic features (Fig. 1) and composition of products of MCHl ozonolysis (40–115°C, $[O_3]$ = 1–4 vol %) [2–8] showed that oxidation of this alcohol yields hydrogen peroxide, MCHl α-hydroperoxide, mono- and dicarboxylic acids, ε-ketoenanthic acid (Table 1), and esters. The ratio of monocarboxylic and steam-undistillable acids is within 0.25–0.30, being virtually independent of temperature, ozone content in the oxidizing gas, and reaction time.

The selectivity of MCHl ozonolysis with respect to acids (Fig. 2) grows with increasing conversion and temperature.

40	360	75	10.3	5.2	6.5	3.0	–	–	–	–	–
70	240	78.3	9.7	4.2	5.5	2.3	6.5	11.5	18.2	20.5	44.3
80	210	79.7	9.5	3.7	5.1	2.0	5.0	6.1	33.7	10.0	45.2
100	180	81.9	9.3	3.0	4.3	1.5	7.2	9.0	30.5	15.3	38.0
115	120	83.2	8.6	2.5	3.7	1.8	6.3	6.8	24.5	20.4	42.0
25% conversion											
40	540	75.5	10.6	4.7	6.3	4.0	1.5	9.5	25.5	32.0	31.5
70	420	77.0	10.0	4.5	5.7	2.8	1.5	9.0	20.0	27.0	42.5
80	300	78.0	9.8	4.1	5.6	2.5	2.2	7.8	35.0	12.5	42.5
100	300	80.0	9.5	3.5	5.0	2.0	4.6	9.5	32.0	19.0	35.0
115	240	81.5	9.0	3.1	4.5	1.9	4.8	7.3	30.2	20.6	37.1

At low temperatures (40–60°C) the selectivity with respect to esters weakly decreases with increasing MCHl conversion, apparently, owing to their consumption. At higher temperatures (70–115°C), the rates of both MCHl esterification by monocarboxylic acids (primarily acetic acid) and ozonolysis of esters increase [1]. However, the esterification rate is higher; therefore, with increasing conversion, the yield of esters weakly grows. The selectivity of peroxide formation decreases with increasing MCHl conversion.

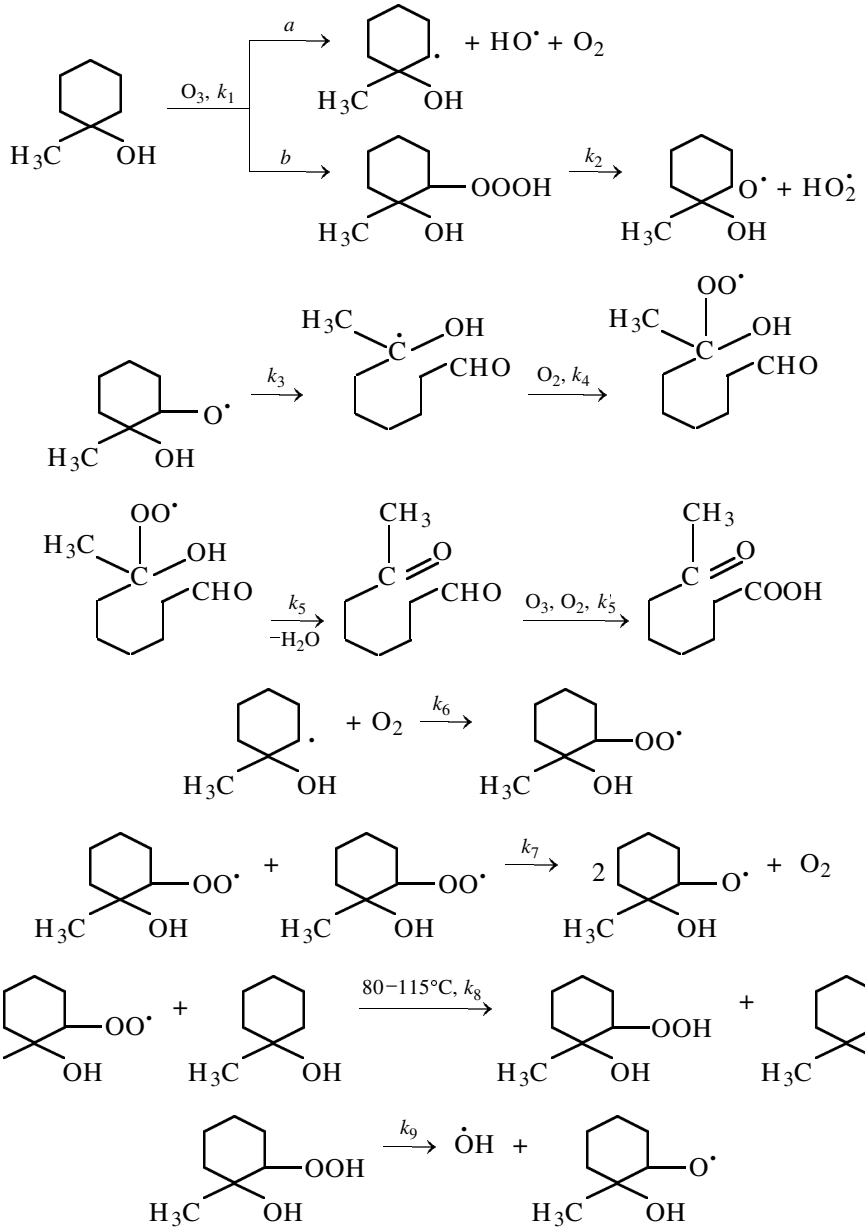
The ozone concentration (Fig. 1) affects only slightly the ratio of acids and esters accumulating in MCHl oxidation products. Table 1 shows that, with increasing temperature (at the same conversion), the content of acetic acid grows, and that of propionic, butyric, valeric, and caproic acids decreases. In the course of MCHl ozonolysis, the C_3–C_6 acids undergo decarboxylation and oxidation with cleavage of the C–C bond, as judged from experiments with labeled acids [1].

Tables 1 and 2 show that, with increasing ozone content, the yields of ε-ketoenanthic and glutaric acids grow and that of α-methyladipic acid decreases. The parallel variation of the content of methylsuccinic and methyladipic, and of glutaric and ε-ketoenanthic acids suggests their genetic relationship: lower carboxylic acids are formed by ozonolysis of higher dicarboxylic acids and ε-ketoenanthic acid. This has been confirmed in experiments with labeled acids [9].

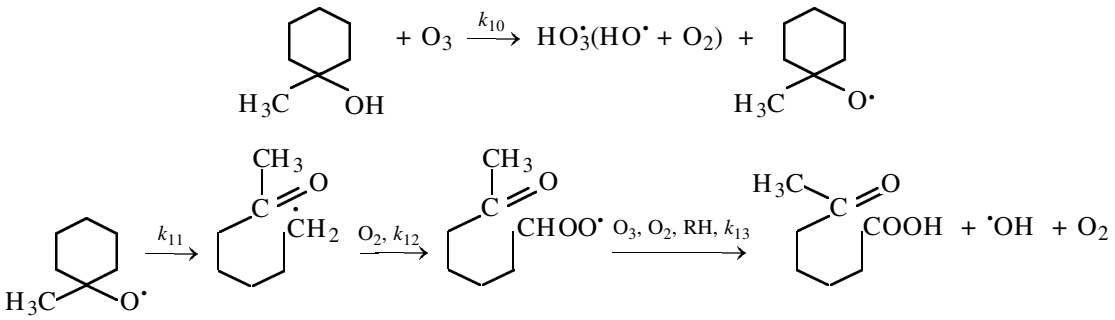
Thus, the major products of MCHl ozonolysis are ε-ketoenanthic and α-methyladipic acids. ε-Ketoenanthic acid is formed in isomerization of 2-hydroxy-2-methyl-1-cyclohexyloxy and 1-methyl-1-cyclohexyloxy radicals with ring opening, accompanied by oxidation by oxygen and ozone, and also in ozonolysis of MCHl α-hydroperoxide (at elevated temperatures) or α-hydrotrioxide (at 10–70°C).

Table 2. Composition of dicarboxylic and keto acids formed in MCHl ozonolysis (100°C, 300 min)

Acid	Content, mol %, at indicated ozone concentration, vol %			
	1	2	3	4
Methylsuccinic	10.5	6.0	4.5	4.6
Succinic	23.5	17.0	12.1	9.5
Glutaric	13.0	19.0	23.2	32.0
α-Methyladipic	41.5	38.5	36.4	19.0
ε-Ketoenanthic	11.5	19.5	24.2	35.0

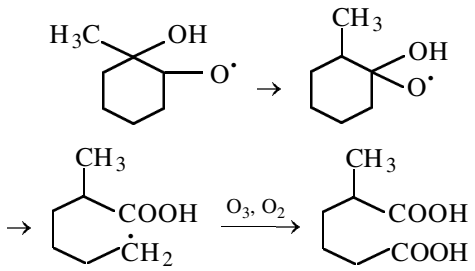


The probability of ozone attack at the O–H bond in MCHl, which is stronger than the C–H bond, is low. However, the alkoxy radical formed by this and other pathways [10] also contributes to formation of ε-ketoenanthic acid by ring opening, followed by reaction with oxygen and ozone:



It has been shown [10] that the source of the 1-methyl-1-cyclohexyloxy radical at high temperatures is the adduct of hydrogen peroxide with MCHl [10]. 2-Hydroxy-2-methyl-1-cyclohexyloxy radical can also form by decomposition of unstable MCHl hydrotrioxide and recombination of the 2-hydroxy-2-methyl-1-peroxycyclohexyl radical.

α-Methyladipic acid is presumably formed in ozonolysis of MCHl by the following pathway:



Lower mono- and dicarboxylic acids are partially formed by further ozonolysis of ε-ketoenanthic and α-methyladipic acids.

Figure 3 shows the typical kinetic curves of MCHl consumption in ozonolysis. The tertiary alcohol is consumed with autoacceleration. The experimental results were fitted with the equation

$$-d[ROH]/d\tau = k_1[ROH]_0[O_3]_0 + k_2([ROH]_0 - [ROH])[ROH] = k_{app}[ROH], \quad (1)$$

where [ROH] and $[ROH]_0$ are the running and initial MCHl concentrations, respectively (M); k_{app} is the apparent rate constant (min^{-1}).

The first reaction order with respect to MCHl and ozone was found from the initial reaction rates. Thus, the first term in Eq. (1) is determined by bimolecular reaction of MCHl with ozone, and the second implicitly takes into account the reactions of the products with ozone and radicals with MCHl. The constants k_1 and k_2 were determined by computer fitting for each particular dependence at different initial con centrations of the reactants and were then refined by numerical integration of the set of differential equations in the whole range of the initial concentrations of the alcohol and ozone.

The consumption of MCHl in ozonolysis in the examined range of temperatures and ozone concentrations is described by Eq. (1) at the following constants k_1 and k_2, $l\ mol^{-1}\ s^{-1}$:

$$k_1 = (1.2 \pm 0.1)\exp[-(16500 \pm 2500)/RT], \quad (2)$$

$$k_2 = (1.42 \pm 0.11)\,10^{-3}\exp[-(16500 \pm 2500)/RT]. \quad (3)$$

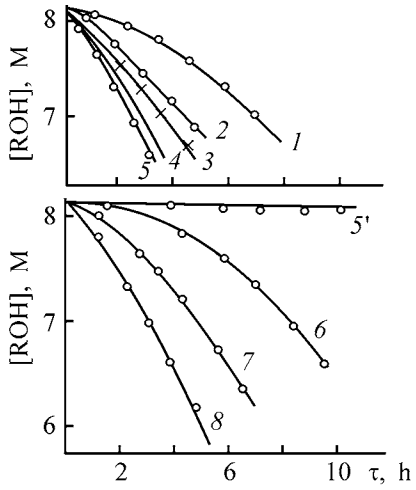


Fig. 3. Kinetic curves of MCHl (ROH) consumption. (*1–5*) $[O_3]$ = 4 vol %; (*5'*, *6–8*) T = 100°C. T, °C: (*1*) 40, (*2*) 60, (*3*) 70, (*4*) 100, and (*5*) 115. $[O_3]$, vol %: (*5'*) 1, (*6*) 2, (*7*) 4, and (*8*) 4.

When discussing the mechanism of MCHl ozonolysis, we disregarded the MCHl association [10].

CONCLUSIONS

(1) Consumption of 1-methylcyclohexanol in ozonolysis at 10–115°C and ozone concentrations in the range 1–4 vol % is described by Eq. (1), with the constants k_1 and k_2 calculated from Eqs. (2) and (3).

(2) 1-Methylcyclohexanol is oxidized by ozone to form hydrogen peroxide, 1-methylcyclohexanol α-hydroperoxide, C_2–C_6 monocarboxylic acids, dicarboxylic acids (succinic, methylsuccinic, glutaric, α-methyladipic), ε-ketoenanthic acid, and esters of these acids with the starting alcohol.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Evolution of Statistical Ensembles of Microdomains on the Surface of Films of Rigid-Chain Polyimide during Thermal Imidization

S. V. Bronnikov, T. E. Sukhanova, and M. Ya. Goikhman

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received March 19, 2003

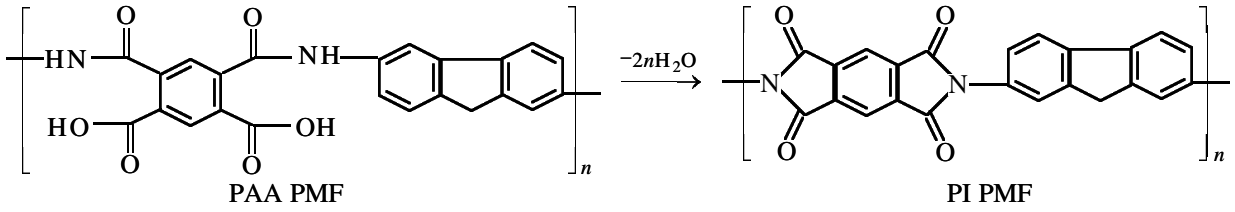
Abstract—Statistical ensembles of microdomains formed on the surface of polyimide films based on pyromellitic dianhydride and 2,7-diaminofluorene during thermal imidization were described in terms of the model of reversible aggregation using the electron-microscopic data. Parameters of the statistical distribution were determined for each ensemble depending on the film heating temperature.

The supramolecular structure of rigid-chain polyimide based on pyromellitic dianhydride and 2,7-diaminofluorene (PI PMF), which was prepared by thermal imidization (TI), has been studied earlier by small-angle X-ray scattering [1] and electron microscopy [2]. These studies have shown that the ordered phase of the polymer heated to 400°C is constituted by crystallites which are part of larger supramolecular formations, microdomains [1]. Electron micrographs of ultrathin cross sections and low-temperature chips confirmed the domain structure of PI PMF films upon TI [2]. More recent studies based on the fractal approach [3] revealed the scale-invariant nature of the PI PMF film surface.

In this study, we continue the electron-microscopic investigations of the supramolecular structure or the PI PMF film surface by analyzing the statistical ensembles of microdomains evolving in the course of TI.

EXPERIMENTAL

The objects of our study were films of PAA PMF (PAA is polyamido acid) and films of the product of its TI, PI PMF, formed by the reaction [4]



The PAA PMF films with thickness of 40 ± 5 μm were prepared from a 10% solution of the polymer in dimethylformamide (DMF) by casting onto glass substrates followed by drying in air at 50°C for 1 day to constant weight.

Thermal imidization was carried out by stepwise heating of the PAA PMF films to 400°C at a rate of 2 deg min^{-1}. Each step was followed by film detachment from the substrate and etching on the air-exposed side in a plasma of oxygen high-frequency glow discharge [5]. The etching conditions were as follows: electron energy 5 eV; oxygen pressure 0.05 Pa; ionization angle 90°; distance between the discharge zone and the film surface 0.2 m; etching time 15 (PAA PMF), 30 (PI PMF heated to 125 and 250°C), and 60 min (PI PMF heated to 350 and 400°C). These are "mild" ionization parameters: Etching leads to heating of the film surface to ≤50°C and a minimal ero-

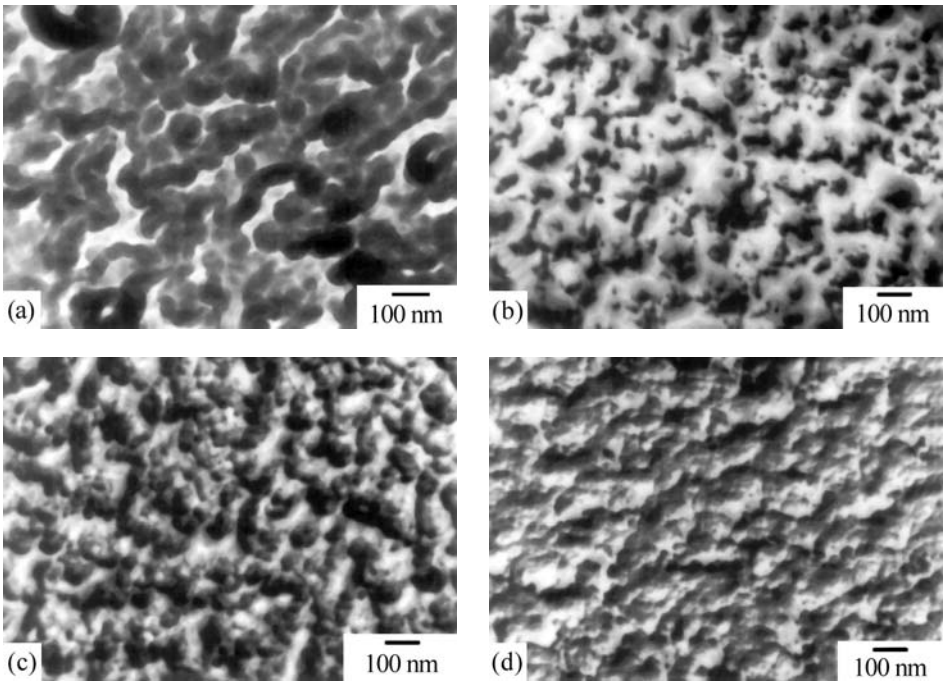

Fig. 1. Electron micrographs of carbon-platinum replicas of the surface of (a) PAA PMF films and PI PMF films heated to (b) 125, (c) 250, and (d) 400°C.

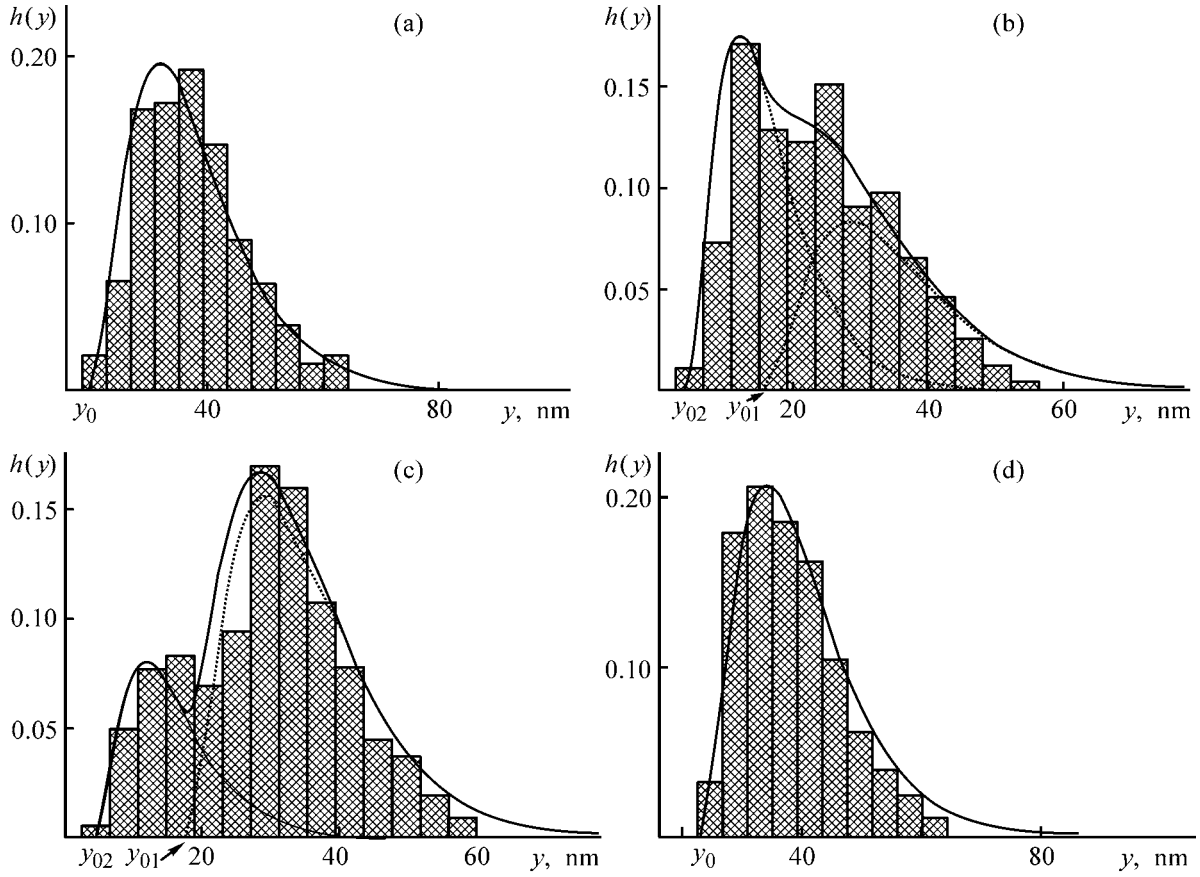

Fig. 2. Distribution $h(y)$ with respect to diameter y of the microdomains on the surface of (a) PAA PMF films and PI PMF films heated to (b) 125, (c) 250, and (d) 400°C.

sion of the surface layers [3, 6]. Platinum was deposited by sputtering on the etched film surface at an angle of 45°, whereupon one-stage carbon-platinum replicas were prepared. Micrographs of the replicas were obtained with a BS-500 (Tesla) transmission electron microscope at a $\times 40\,000$ magnification.

Figure 1 presents the electron micrographs of the carbon-platinum replicas from the etched surface of the PAA PMF and PI PMF films heated to 125, 250, and 400°C. It is seen that the film surface is constituted by nearly spherical microdomains. Comparative analysis of these micrographs revealed changes (most profound in the films heated to 250–300°C) in the depth of the etched profile. This may be due to removal of the disordered phase of the polymer with the residual DMF and water formed during TI.

Figure 2 presents the results of statistical processing of the micrographs as a plot of distribution of the microdomains with respect to their diameter $h(y)$. From 960 to 1500 microdomains were analyzed on each micrograph.

The histograms for the PAA PMF film (Fig. 2a) and the PI PMF film heated to 400°C (Fig. 2d) demonstrate a monomodal size distribution for the microdomain ensemble on the surface, with a maximum near 30 nm. In the histograms of the PI PMF films heated to 125 and 250°C (Figs. 2b, 2c), two superimposing ensembles of microdomains can be distinguished, one of which (major) preserves a size distribution maximum near 30 nm, and the other (additional) exhibits a maximum near 12 nm.

The monomodal distributions were analytically described by the following expression, derived in terms of the reversible aggregation model [7, 8] and resulting from the canonical distribution of the energy fluctuations at a constant volume [9]:

$$h(y - y_0) = A(y - y_0)^m \exp\left[-\frac{(y - y_0)\Delta U_0}{kT}\right], \quad (1)$$

where, A is the normalization factor; $(y - y_0)\Delta U_0$, the aggregation energy, which is a product of the reduced size of the aggregate in the ensemble $(y - y_0)$ and the standard aggregation energy ΔU_0, J m^{-1}; y_0, size of the smallest aggregate; k, Boltzmann constant; T, absolute temperature; m, dimensionality of the space in which the aggregate grows ($m = 2$ for the surface).

The key parameter in expression (1) is ΔU_0 which governs the equilibrium size distribution pattern for the aggregates. Obviously, the bimodal distributions should be described by an equation which is the sum

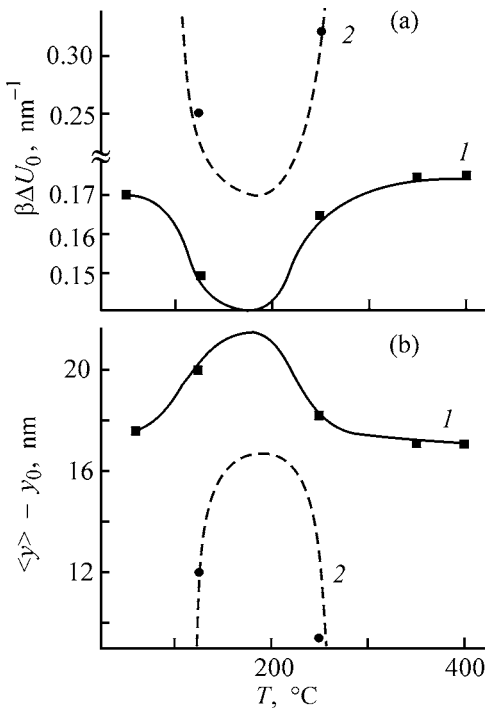

Fig. 3. (a) Reduced standard aggregation energy $\beta\Delta U_0$ and (b) average reduced diameter of microdomains, $\langle y\rangle - y_0$, vs. the film heating temperature T. Ensemble: (*1*) major and (*2*) additional.

of two expressions (1) with different A, y_0, and ΔU_0 parameters.

The lines in Fig. 2 represent the results of calculations by Eq. (1). For bimodal distributions, dashed lines show the distributions for each mode. The numerical values of the parameters A, y_0, and ΔU_0 (for bimodal distribution, A_1, A_2, y_{01}, y_{02}, ΔU_{01}, and ΔU_{02}) were used in calculations as free quantities. Our results suggest that the size distribution of the microdomains, both monomodal (at 50 and 400°C) and bimodal (at 125 and 250°C), can be described in terms of the reversible aggregation model. Therefore, the condition for optimization of the size of the aggregate ensemble is met in the course of TI [7, 8].

A practically important characteristic of the distribution is the average size of the aggregate in the ensemble. It is defined as the normalized expectancy

$$\langle y\rangle - y_0 = \frac{\int_0^\infty (y - y_0)\,h(y - y_0)\,\mathrm{d}y}{\int_0^\infty (y - y_0)h\,\mathrm{d}y} = \frac{(m + 1)kT}{\Delta U_0}. \quad (2)$$

Figure 3 presents the reduced standard aggregation energy $\beta\Delta U_0$ ($\beta \equiv 1/kT$) and the reduced average diameter ($\langle y\rangle - y_0$) of the microdomains as functions

of the film heating temperature for both statistical ensembles of microdomains. Let us consider first the temperature dependences of these parameters for the case of the major ensemble, namely, $\beta\Delta U_{01}(T)$ and $(<y_1> - y_{01})(T)$.

When the films are heated to 125°C, $\beta\Delta U_{01}$ tends to decrease, and $(<y_1> - y_{01})$, correspondingly, to increase. As known, imidization at temperatures within 100–180°C involves active chemical transformation PAA PMF → PI PMF, which is accompanied by evolution of water and degradation products of the DMF associates [4]. These processes are responsible for a decrease in the molecular weight of the polymer, which is at a minimum near 180°C [4].

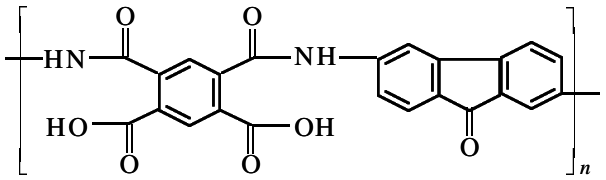
This suggests the existence of extrema near 180°C, namely, a minimum for $\beta\Delta U_{01}(T)$ and a maximum for $(<y_1> - y_{01})(T)$. At this temperature, aggregation is the most active, and the aggregates in the ensemble have the largest average size.

Within 125–180°C, a second (additional) ensemble is formed, whose reduced standard aggregation energy $\beta\Delta U_{02}$ at 125°C exceeds $\beta\Delta U_{01}$ by nearly a factor of 1.7. Therefore, the microdomains in the second ensemble have smaller average size than those in the main ensemble. At 125°C, the peak height in the distribution pattern for the second ensemble is more than twice that for the first ensemble. This means that the number of microdomains in the second ensemble exceeds that in the first.

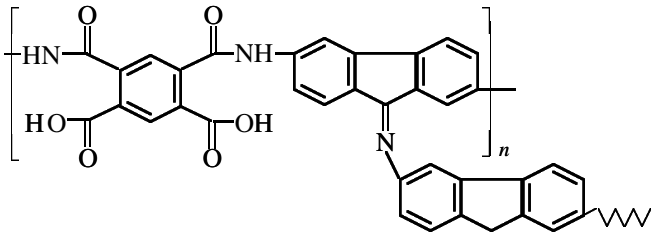
Under further heating (>180°C), the forming imide moieties decelerate aggregation in both ensembles. At 250°C, the number of microdomains in the first (major) ensemble exceeds that in the second ensemble. At high temperatures, within 350–400°C, $\beta\Delta U_{01}$ attains a constant value which slightly exceeds the initial value (at 50°C), and the second ensemble of microdomains disappears: The aggregation energy of the second ensemble becomes infinitely large, and the average diameter of the microdomains in it, infinitely small (Fig. 3).

Similar trends in variation with heating temperature of the standard aggregation energies and average diameters of the microdomains in the major ensemble were observed in our previous studies of statistical ensembles of microdomains in the surface layers of films of polyimides derived from 3,3',4,4'-diphenyltetracarboxylic dianhydride and *p*-phenylenediamine [10, 11], as well as from pyromellitic dianhydride and 4,4'-oxyphenylenediamine [12]. However, the microdomains of these polymers form only one statistical ensemble throughout the TI temperature range of 50–400°C. It can be assumed that the bimodal distribution of the microdomains in the partially imidized PI PMF films is due to specific features of the chemical structure of the polymer.

Bell [13] showed that, in the course of drying and TI, polyamido acids containing fluorene units in the backbone undergo cross-linking, primarily, via oxidation of the methylene group of the fluorene unit into carbonyl fluorenone group. In the case of PAA PMF, this yields the following macromolecules



Under heating to 125–180°C, the polymer chain in the PAA PMF macromolecules actively degrades into oligomeric fragments [4]. This significantly increases the concentration of the terminal amino groups, which react with fluorenone units yielding 3D cross-linked structures with azomethine bonds at the cross-linking sites:



Such structures, probably, form the second statistical ensemble whose microdomain size distribution pattern is illustrated by the histograms in Figs. 2b and 2c.

Further heating of the films within the 180–300°C range leads to active TI in the polymers, accompanied by water elimination. The easily hydrolyzable azomethine intermolecular bonds degrade into amine and fluorenone groups, and the polymer structure becomes linear again. These processes, along with the reactions of resynthesis and increase in the molecular weight of he polymer, are responsible for the specific features of the distribution of the microdomain size in PI PMF in early TI stages.

CONCLUSIONS

(1) The reversible aggregation model was used to describe how the distribution of the microdomains with respect to diameter on the surface of films of

the polyimide derived from pyromellitic dianhydride and 2,7-diaminofluorenone varies during thermal imidization.

(2) The microdomains on the surface of films of polyamido acid and completely imidized poyamide form one statistical ensemble, and in the case of a partially imidized polyamide, two ensembles, one of which is probably constituted by intermediate cross-linked structures.

(3) Regular trends were revealed in variation of the parameters of the microdomain distribution with respect to diameter in the course of imidization.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Precondensation of a Mixture of Epoxy-4,4'-Isopropylidenediphenol and Phenol-Formaldehyde Oligomers in Solution

A. N. Krasovskii and V. N. Filippov

Pigment Open Joint-Stock Research and Production Company, St. Petersburg, Russia

Received January 31, 2003

Abstract—Kinetic viscosity curves $\eta(t)$ for solutions of a mixture of epoxy-4,4'-isopropylidenediphenol and phenol-formaldehyde resins in Cellosolve at 333 K were studied. The optimal precondensation time t was determined for the oligomer mixture in solution in the presence of orthophosphoric acid.

In [1–4], various mechanisms of thermal precondensation of a mixture of epoxy-4,4'-isopropylidenediphenol oligomer (EO) and phenol-formaldehyde oligomer (PFO) in Cellosolve solution were considered. The kinetic curve of the viscosity of the EO–PFO mixture during thermal precondensation has an extremum. The EO and PFO molecules form polymolecular complexes via hydrogen bonding.

Sukhareva *et al*. [5] demonstrated that the corresponding sizes of the oligomer aggregates during precondensation of the EO–PFO mixture in solution pass through an extremum. An electron-microscopic examination [6] showed that, with increasing precondensation time t, the radius of the particle aggregate in the epoxy-phenol coatings cured at 483 K first decreases from 500 to 50 nm and then increases to 100 nm. This allowed Sukhareva *et al.* to suggest that the optimal precondensation time t of the oligomer mixture corresponds to the minimum size of the particle aggregates in solution.

It is known [1, 3, 4, 7, 8] that curing of epoxy-phenol formulations involves concurrent reactions between methylol (butoxy) groups in PFO and epoxy (hydroxy) groups of EO and formation of dimethyl ether bridges between the methylol groups in PFO. In the presence of orthophosphoric acid H_3PO_4, the epoxy groups in EO are consumed at a high rate, yielding mono-, di-, and triphosphates [9]. On the whole, thermal precondensation of the oligomer mixture in solution improves the compatibility of EO and PFO, yielding a uniform chemical network of epoxyphenol polymer upon curing of an oligomer formulation [1, 2].

In [10, 11], we suggested a cluster mechanism of aggregation of oligomers during their thermal precondensation in solution. The cluster model [12, 13] distinguishes three main kinetic stages of thermal precondensation of the EO–PFO mixture in solution and the corresponding three topological types of surface structure of the cross-linked epoxy-phenol polymer in various kinetic stages of precondensation of oligomers [11]. Also, this approach allows a wellfounded choice of the molecular parameters and concentrations of the oligomers in solution for precondensation [10, 11].

The principles of the cluster lattice model [12–14] can be useful in quantitative description of the thermal precondensation kinetics of the oligomer mixture in solution. In this context, we studied the kinetic viscosity curves $\eta(t)$ for solutions of the oligomer mixture under shear flow during thermal precondensation. We analyzed the precondensation time of the oligomers as influenced by the N_1(EO)/N_2(PFO) molar ratio and the content of orthophosphoric acid in the EO–PFO mixture and the shear rate g.

EXPERIMENTAL

The molecular weight distributions for oligomer sample nos. 1 and 2 were determined by viscometry and gel-permeation chromatography (Shodex KF-803 column; solvent tetrahydrofuran; 5–10-μl samples; eluent flow rate 1 ml min^{-1}; spectrophotometric detector, λ = 250 nm) [15]. The number-average molecular weight M_n and the M_w/M_n ratios (M_w is the weight-average molecular weight) for sample nos. 1

and 2 are listed in Table 1. The intrinsic viscosities [η] of sample nos. 1 and 2 in C solution were determined by the procedure from [16].

The time dependences of the viscosity, η(t), for the mixture of epoxy-4,4'-isopropylidenediphenol (E-05) and phenol-formaldehyde (based on 4,4'-isopropylidenediphenol and formaldehyde) (DFFr) resins (Pigment Research and Production Company) in Cellosolve solution were studied at N_1(E-05)/N_2(DFFr) ratios within 0.7–1.5.

The viscosity of the oligomer mixture in solution was measured on a Rheotest-2 rotary viscometer with a coaxial-cylinder working unit at 333 K and shear rate g = 27–81 s^{-1}. The viscosity η was measured accurately to within 5 mPa s, and temperature, to within 0.5 K. The choice of the specific dynamic modes for measuring the viscosity η was governed by the dependences of the shear rate g on the shear stress τ for E-05 and the E-05–DFFr mixture in C solutions (Fig. 1).

We estimated the concentrations c of E-05 and DFFr in C solutions for N_1/N_2 = 1 at 26.7 and 9.12 g dl^{-1}, respectively (Table 2), from the concentration dependences of the relative viscosity, η_{rel}-vs.-c, for the oligomers in solution by the algorithm proposed by us in [11]. For example, the concentration c = 26.7 g dl^{-1} calculated for N_1/N_2 = 1 corresponds to formation of a continuous network of intermolecular contacts in E-05 in solution, and c(DFFr) = 9.12 g dl^{-1}, to a fractal transition $D_1 \rightarrow D_2$ or to formation of discrete aggregates of DFFr molecules [11]. Orthophosphoric acid was introduced into the E-05–DFFr mixture as a 25% H_3PO_4 solution in C 40 min after the onset of precondensation of the oligomers at 333 K. The orthophosphoric acid concentration in the oligomer mixture was varied from 14 to 500% (with the concentration corresponding to 0.25 g H_3PO_4 per 36 g of the E-05–DFFr mixture taken as 100% [17]) (Table 3). The measurement of the precondensation time was started 20–30 min after mixing the oligomers. The precondensation time t was 90 min at a minimum and ca. 400 min at a maximum.

Thermal precondensation of the oligomer mixture in solution is described by nonmonotonic viscosity curves [η](t) comprising descending, ascending, and leveling-off sections. The η-vs.-t curves retain their extrema with varying molar ratio N_1/N_2, H_3PO_4 concentration in the oligomer mixture (or $N_3/(N_1 + N_2)$ ra-

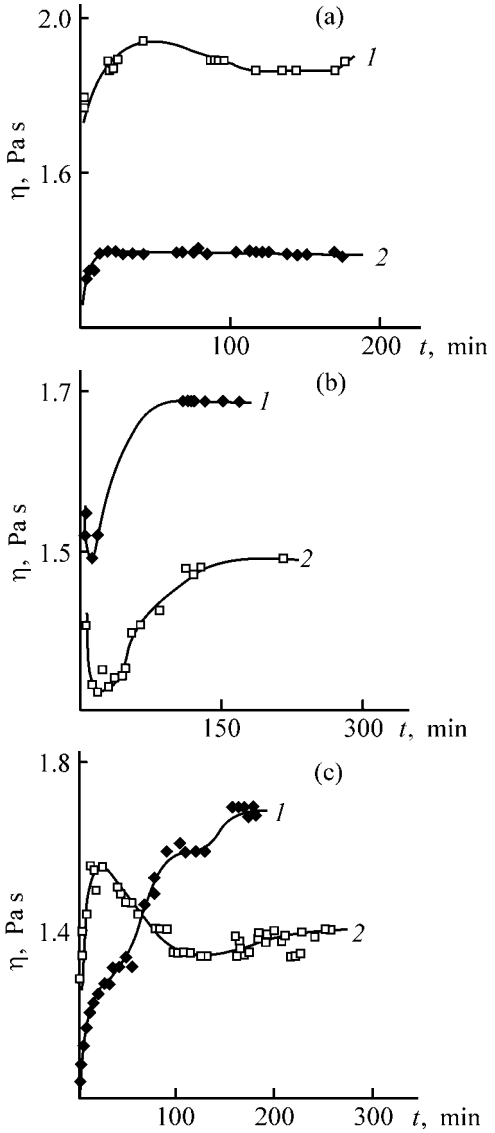

Fig. 3. Kinetic curves of the viscosity η, of the E-05–DFFr mixture in Cellosolve solution at the N_1/N_2 ratio of (a) 1.5, (b) 1, and (c) 0.7 (333 K). Shear rate g, s^{-1}: (*1*) 27 and (*2*) 81.

tio), and shear rate g. However, the positions of these extrema and sections vary with N_1/N_2, $N_3/(N_1 + N_2)$, and g (Figs. 2–4, Table 3).

The η(*t*) curves can be described, to a first approximation, by a scaling relation for the viscosity η as a function of the reduced time $\tau = \gamma t$ [14]:

$$\ln \eta \sim [\eta]c[w(1 + \gamma t)]^{(3-2D)/D}. \quad (1)$$

Here, γ is the kinetic constant depending on the particle concentration, shear rate g, and temperature, as well as on the H_3PO_4 content; D, the fractal dimension of the oligomer aggregates; and w = 0.637, a random packing coefficient for hard spheres [12].

According to expression (1), the viscosity η of the oligomer mixture in solution varies with the fractal dimension D of the mixed aggregates of the oligomer molecules. The position of the maximum (or minimum) in the η(*t*) curves is determined by the kinetic constant γ, which, in turn, varies with the N_1/N_2 molar ratio, orthophosphoric acid concentration in the mixture, and shear rate g.

The density ρ of the aggregates of E-05 and DFFr molecules can be represented as a function of the precondensation time t [14]:

$$\rho(t) \sim w^{(3-D)/D}([\eta]c/\ln \eta)^{(3-D)/(3-2D)}. \quad (2)$$

The density of the mixed aggregates of the oligomer molecules varies nonmonotonically along the η(*t*) curve (Table 4). One can distinguish four kinetic stages of variation of the density ρ and the fractal dimension D of the oligomer aggregates. In the initial and intermediate precondensation stages, ρ and D decrease, and in the final stage, increase.

The plots of the viscosity η vs. precondensation time t at varied N_1/N_2 ratios (without orthophosphoric acid in the oligomer mixture at g = 27 s^{-1}) have a minimum at $N_1/N_2 = 1$ and a maximum at $N_1/N_2 > 1$ (Fig. 2). In the former case, the viscosity of the oligomer mixture in solution attains a limiting value at $t > 100$ min, and in the latter, at $t > 150$ min. For $N_1 = N_2$, the extremum in the η(*t*) curve is reached in shorter times t than those for $N_1 \neq N_2$. Near the minimum in the η(*t*) curve, the mixed elementary oligomer aggregates have a fractal dimension D equal to 1.5 ($N_1/N_2 = 1$), and the maximum in the η(*t*) curves at $N_1/N_2 > 1$ corresponds to $D < 1.5$ (Fig. 2).

The time in which the viscosity η of the oligomer mixture takes a limiting value is also strongly dependent on g. For example, at g = 27 s^{-1} ($N_1/N_2 = 1$), the limiting viscosity is attained within $t \approx 100$ min, and

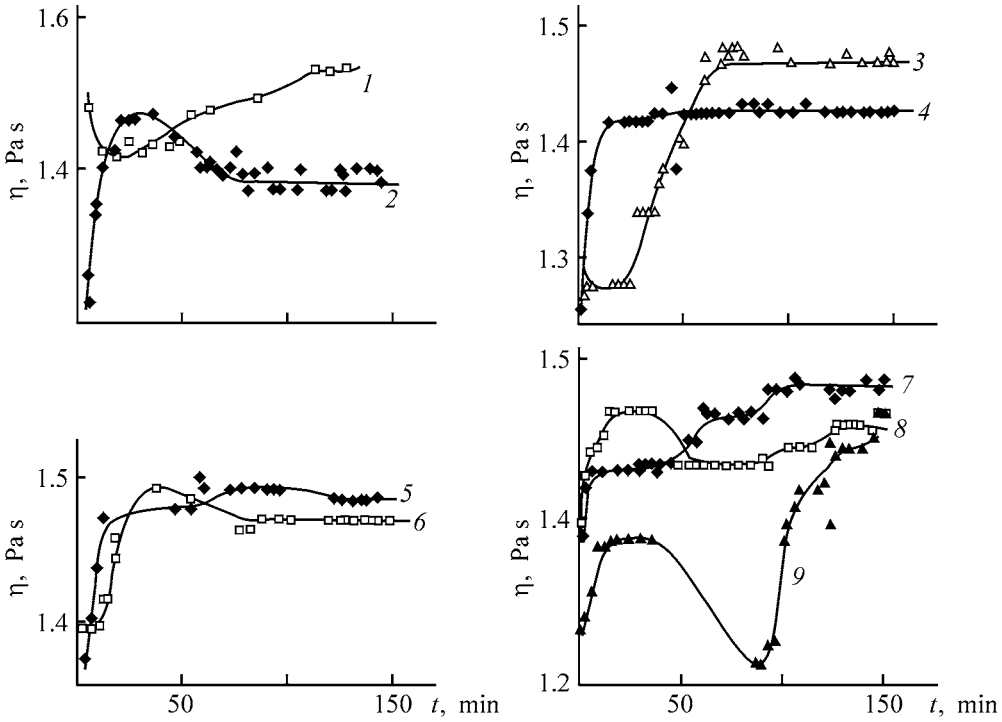

Fig. 4. Kinetic curves of viscosity η of the E-05–DFFr mixture in Cellosolve at different concentrations of orthophosphoric acid in the mixture. N_1/N_2 = 1, g = 81 s^{-1}, 333 K. H_3PO_4 concentration, %: (*1*) 0, (*2*) 100, (*3*) 14, (*4*) 30, (*5*) 50, (*6*) 75, (*7*) 125, (*8*) 150, and (*9*) 490.

at g = 81 s^{-1}, within $t \geq 200$ min (Fig. 3). For g = 81 s^{-1} and N_1/N_2 = 0.7, the viscosity η attains a limiting value at t = 150 min, and for g = 27 s^{-1}, does not attain it at $t \geq 200$ min (Fig. 3). At relatively small g values, the time of attainment of the limiting viscosity η in the oligomer mixture is the shortest at N_1/N_2 = 1.

Thus, without H_3PO_4 in the oligomer mixture in solution, the time of attainment of a limiting value of the viscosity η is the shortest at N_1/N_2 = 1. For small g values, the kinetic constant g at N_1/N_2 exceeds that at N_1/N_2 = 0.7 or under excess of DFFr in solution (Figs. 2, 3).

Orthophosphoric acid is a cross-linking agent for EO [9]. Therefore, with H_3PO_4 introduced into the oligomer mixture (N_1/N_2 = 1) in the early precondensation stage, the kinetic constant γ increases relative to that in the oligomer mixture containing no H_3PO_4 (Fig. 4, curves *1*, *2*). In this case, the extremum in the η(t) curves shifts to smaller times t, and the time corresponding to attainment of the limiting viscosity η in the oligomer mixture varies with the H_3PO_4 concentration (Fig. 4, curves *1*–*9*).

The η(t) curves obtained on introducing H_3PO_4 into the oligomer mixture at $N_3/(N_1 + N_2) < 0.07$ are identical to those obtained in the absence of H_3PO_4. A viscosity maximum in the η(t) curve is observed at $N_3/(N_1 + N_2) \approx 0.1$, and the limiting value of the viscosity η is attained at t = 90–120 min. At $N_3/(N_1 + N_2) \approx$ 0.7, the viscosity η of the oligomer mixture does not attain a limiting value at t > 240 min.

The data in Table 3 suggest a correlation between the limiting viscosity η of the oligomer mixture in

** The density was calculated by the expression $\rho = w^{(3-D)/D}([\eta]c/\ln \eta_{rel})^{(3-D)/(3-2D)}$, where $\eta_{rel} = \eta/\eta_0$ is the relative viscosity of the oligomer mixture in solution, and η_0, solvent viscosity.

solution and the time of its attainment, as well as between the optimal precondensation time t and the H_3PO_4 concentration (N_3) in the mixture, when the acid is introduced 40 min after mixing the oligomers. These data suggest that the precondensation time t is at a minimum at $N_3/(N_1 + N_2) \approx 0.1$; in this case, the limiting viscosity η of the oligomer mixture in C solution is also at a minimum.

In other cases like, e.g., at relative deficiency of H_3PO_4 [$N_3/(N_1 + N_2) < 0.1$] in the oligomer mixture, the precondensation time increases. At orthophosphoric acid concentrations appreciably exceeding the optimal value in the oligomer mixture [$N_3/(N_1 + N_2)$ = 0.2–0.7], the $\eta(t)$ curve oscillates, and the mixture viscosity η does not attain a limiting value within a fairly long period of time t (Table 3; Fig. 4, curves *7*–*9*). Under these conditions, the oligomers are not fully compatible.

The cluster mechanism of thermal precondensation of oligomers in solution accounts for a decrease in the mixture viscosity due to degradation of the particle aggregates and formation of mixed oligomer aggregates in the initial and intermediate stages, as well as the viscosity growth and saturation in the final stages of the process due to formation of an infinite cluster from EO and PFO molecules [18] (Table 4). These precondensation stages are characterized by a change in the fractal dimension D of the particle aggregate and in the kinetic constant γ which is also dependent on g.

CONCLUSIONS

(1) The kinetic viscosity curves $\eta(t)$ of the mixture of epoxy-4,4'-isopropylidenediphenol and phenol-formaldehyde oligomer mixture in Cellosolve are described by a scaling relation for reduced time and exhibit an extremum. The positions of the extrema and of the sections corresponding to decrease, growth, and leveling-off of the viscosity η in the $\eta(t)$ curves are determined by the molar ratio N_1/N_2 of the oligomers, concentration of orthophosphoric acid in the mixture, and shear rate g.

(2) The thermal precondensation time of the oligomers in solution can be determined as the time t of attaining the limiting viscosity of the mixture, whose plot against the H_3PO_4 concentration has an extremum. The corresponding time t is at a minimum at H_3PO_4 concentration in the mixture close to $N_3/(N_1 + N_2) \approx 0.1$. The optimal concentration of H_3PO_4 in the oligomer mixture is primarily governed by the formation of dihydrogen phosphate esters of epoxy-4,4'-isopropylidenediphenol oligomer.

(3) The precondensation time can be made shorter by introducing orthophosphoric acid in the initial stage of the process, which involves formation of mixed aggregates of oligomer molecules.

Abstract—The composition and structure of the products formed in base hydrolysis of Nitron D polyacrylonitrile fiber were studied by ^{13}C NMR.

Hydrolysis of acrylonitrile polymers and copolymers yields water-soluble polymers widely used in various branches of industry and agriculture [1]. Recently, the interest in structural studies of hydrolysis products has increased, and, along with traditional IR spectroscopy and elemental analysis [2–5], the ^{13}C NMR spectroscopy finds growing use [6].

The products of base hydrolysis of polyacrylonitrile fibers are used in production of adhesives, polyelectrolyte hydrogels, and binders for composite polymeric materials [7]. However, up to now, their structure has not been studied by ^{13}C NMR.

The aim of this study was to analyze by ^{13}C NMR the products of base hydrolysis of Nitron D polyacrylonitrile fiber, terpolymer of acrylonitrile, methyl acrylate, and 2-acrylamido-2-methylpropanesulfonic acid with the weight ratio of acrylnitrile, methyl acrylate, and 2-acrylamido-2-methylpropanesulfonic acid units equal to 89.4 : 9.3 : 1.3. Base hydrolysis of Nitron D was performed at the boiling temperature of the solution for 3 h. According to published data [2–5], under these conditions the nitrile group of the initial polyacrylonitrile fiber is completely hydrolyzed, and the ratio of the concentrations of the acrylamide and carboxylate units in the resulting copolymer depends on the weight ratio of alkali and polyacrylonitrile fiber. In the experiments, the ratio of the amounts of NaOH and Nitron D was varied from 1.38 to 2.50 mol per 100 g of dry fiber.

EXPERIMENTAL

Base hydrolysis was performed in a 1-l round-bottom flask with a reflux condenser. The amount of Nitron D in the flask, recalculated to dry fiber, was 100 g. Sodium hydroxide was preliminarily dissolved in distilled water. The total weight of water in the flask was 550 g, and the amount of added alkali, 55, 75, and 100 g (1.38, 1.88, and 2.50 mol, respectively).

The ^{13}C NMR spectra of hydrolyzates, shown in Fig. 1, confirm published data on the chemical composition of products formed in base hydrolysis of polyacrylonitrile fibers and allow more precise determination of the ratio of acrylamide and carboxylate units in

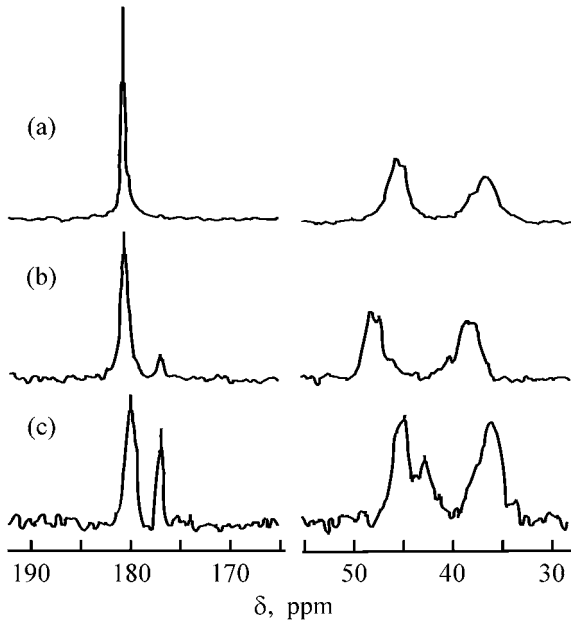

Fig. 1. ^{13}C NMR spectra of base hydrolyzates of Nitron D fiber. (δ) Chemical shift. Amount of NaOH per 100 g of dry fiber (mol): (a) 1.38, (b) 1.88, and (c) 2.5.

the copolymer formed in base hydrolysis. The ^{13}C MNR spectrum of the hydrolyzate produced at a NaOH to Nitron D ratio equal to 1.38 mol per 100 g of dry fiber is shown in Fig. 1a. There are lines of the copolymer containing acrylamide and carboxylate units. These units were identified from the spectra of polyacrylamide (PAA) and sodium polyacrylate (PANa) with the use of published data [8] and the spectra of specially synthesized homopolymers. The spectral lines were assigned as follows: δ 179.7 (CO, PANa), 176.6 (CO, PAA), 44.8 (CH, PANa), 42.5 (CH, PAA), and 36.2 ppm (CH_2, PAA and PANa). Analysis of the integral intensities of the lines corresponding to carboxamide and carboxylate carbon atoms and also of the lines of methine carbon atoms gives the ratio of molar concentrations of acrylamide and carboxylate units equal to 33 : 67, in good agreement with data obtained by IR spectroscopy and elemental analysis [2–4].

The spectrum of the hydrolyzate produced at a NaOH to Nitron D ratio equal to 1.88 mol per 100 g of dry fiber (Fig. 1b) contains, similarly to the previous case (Fig. 1a), lines of acrylamide and carboxylate units. However, their ratio is different 17 : 83. Along with the integral intensities, chemical shifts are also diffrent, which suggests the formation of a copolymer.

Only PANa is formed at a NaOH to Nitron D ratio equal to 2.50 mol per 100 g of dry fiber (Fig. 1c). This result is the most interesting, since it fundamentally differs from published data [2–4]. Contrary to results of IR spectroscopy and elemental analysis [2–4], the ^{13}C NMR spectra do not reveal the presence of acrylamide units in the hydrolyzate produced at high NaOH to Nitron D ratio (2.50 mol per 100 g of dry fiber). It is evident that NMR data are the most reliable, since the signals of acrylamide and carboxylate units are clearly separated, which allows determination of the concentration ratio of these units with high accuracy. IR spectroscopy is significantly less accurate in this respect: with increasing ratio of concentrations of carboxylate and acrylamide units in the copolymer, the characteristic bands begin to overlap, which gives high error in quantitative estimation. The results of elemental analysis revealing the presence of nitrogen in the hydrolyzate cannot prove the presence of acrylamide units in macromolecules, either, since nitrogen can belong to ammonium carboxylate present in the hydrolysis product along with sodium carboxylate. In none of the cases were detected signals of nitrile groups (δ = 120 ppm) in the soluble copolymer. This suggests that, under the conditions of the experiment, nitrile groups were completely hydrolyzed.

The solutions of hydrolyzates whose characteristics are illustrated by data shown in Fig. 1 had pH > 9, i.e., in all cases carboxylate groups had negative electric charge and acrylamide groups had no charge. Under these conditions, the interaction of acrylamide and carboxylate groups of copolymer, possible only at low pH values and affecting the positions and intensities of the ^{13}C NMR signal [9], could not affect the obtained concentration ratios of these functional groups.

Thus, the ^{13}C NMR spectra show that, at a alkali to Nitron ratio equal to 2.5 mol per 100 g of dry fiber, the molar content of acrylamide groups in the hydrolyzate of Nitron D polyacrylonitrile fiber decreases virtually to zero, i.e., the polymeric part of the hydrolyzate is nearly pure sodium polyacrylate, rather than a copolymer of acrylamide with sodium acrylate.

The process was carried out at the boiling point of the reaction mixture for 3 h. During this period, all nitrile groups of the initial polymer entered into the reaction at any concentration of sodium hydroxide within the range examined, and the fiber was completely converted into a water-soluble product.

Polyacrylamide and sodium polyacrylate were synthesized by radical polymerization in solution at 50°C. The standard redox system constituted by ammonium persulfate and *N*,*N*,*N*',*N*'-tetramethylethylenediamine in the equimolar ratio (concentration 4.4×10^{-3} M) was used as initiator. The synthesis of PAA was carried out in 10% aqueous solution of acrylamide. PANa was synthesized in 20% aqueous solution of acrylic acid in the presence of an equimolar amount of NaOH. The samples for analysis were prepared by drying in a desiccator at 60°C to constant weight.

The ^{13}C NMR spectra were recorded on a BS-587A (Tesla) spectrometer operating at 20 MHz. Approximately 10% solutions of copolymers in D_2O were placed in standard ampules (10 ml). The spectra were recorded without NOE; the pulse delay exceeded $7T_1$, where T_1 is the longest spin-lattice relaxation time. The signals were assigned by the DEPT technique [8] using model compounds. Chemical shifts were measred relative to acetone-d_6 used as internal reference (δ = 30.2 ppm).

The relative error in quantitative determination of the content of acrylamide and acrylate units did not exceed 7%.

CONCLUSION

A ^{13}C NMR study showed that base hydrolysis of Nitron D polyacrylonitrile fiber under conditions

providing complete conversion of nitrile functional groups of the initial polymer is accompanied by formation of either copolymer of acrylamide with sodium acrylate or pure sodium polyacrylate, depending on the ratio of sodium hydroxide and the polymer.

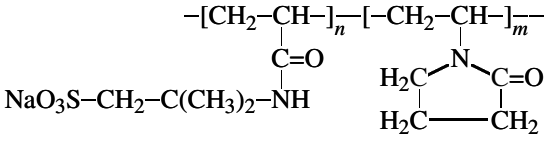
Abstract—The kinetics of controllable degradation of *N*-vinylpyrrolidone–sodium 2-acrylamido-2-methylpropanesulfonate copolymers in aqueous solutions under the action of degrading agents at 25–50°C were studied by viscometry. The efficiency of controlling the molecular weight of copolymer was estimated.

Degradation of water-soluble polymers in solutions under the action of degrading agents is a promising method for chemical modification of polymers, which allows control of their molecular weight and performance [1]. To elucidate the possibility of producing partially degraded copolymers of *N*-vinylpyrrolidone (N-VP) with sodium 2-acrylamido-2-methylpropanesulfonate (Na-AMS), with controllable molecular weight (MW), we studied the features of degradation Na-VP–Na-AMS copolymers in aqueous solutions in the presence of radical initiators at 20–50°C. This study was stimulated by the lack of data on degradation of these copolymers and by their practical significance as effective flocculants [2] and adhesion and antistatic agents [3]. These copolymers also attract attention as thickeners, stabilizers, and complexing agents for various branches of industry and medicine [4, 5].

EXPERIMENTAL

In this study, we used copolymers of N-VP with Na-AMS with the content of N-VP and Na-AMS units equal to 50 mol % and varied intrinsic viscosity:



Sample	no. 1	no. 2	no. 3	no. 4
$[\eta]$, $cm^3\ g^{-1}$	120	410	360	300

Copolymer sample no. 2 was produced by copolymerization of monomers in aqueous solutions at low degree of conversion (less than 4%) by the procedure similar to that described in [6]. The copolymer samples nos. 1, 3, and 4 were prepared by degradation of copolymer no. 2 under mild conditions in 0.1% aqueous solutions in the presence of potassium persulfate (PS) at 60°C, which provided the identity of the composition of the copolymers.

PS, hydrogen peroxide (HP), and a redox system constituted by PS and sodium sulfite (SS) were used as degradation initiators. All the reagents used were of chemically pure grade. Solutions were prepared in distilled water [GOST (State Standard) 6709–72].

Degradation was carried out in aqueous solutions of N-VP–Na-AMS copolymers under the action of radical initiators. The course of degradation was monitored viscometrically [7]. The process was carried out in a glass reactor with a jacket for thermal stabilization, magnetic stirrer, thermometer, connecting pipe for sampling, and VPZh-3 capillary viscometer for monitoring the viscosity of the reaction mixture [7]. The viscometer was equipped with a jacket for thermostatic control at the same temperature as that in the reactor.

The prepared aqueous solution of the copolymer was charged into the reactor and brought to the required temperature, after which a degrading agent was added, with this instant of time taken as the start of degradation. In the course of degradation, we measured at certain intervals the outflow time of the copolymer solution in the reactor, t_1, with a viscometer and determined the reduced viscosity η_{sp}/c_p, where c_p is the copolymer concentration. The values of η_{sp}/c_p

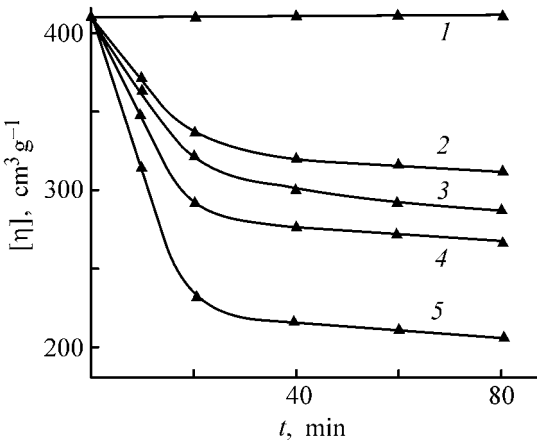

Fig. 1. Variation of [η] with time t in the course of degradation of N-VP–Na-AMS copolymer (sample no. 2) at different concentrations of PS. c_p = 0.1%, 50°C. [SP]/[copolymer]: (*1*) 0, (*2*) 0.01, (*3*) 0.02, (*4*) 0.04, and (*5*) 0.08.

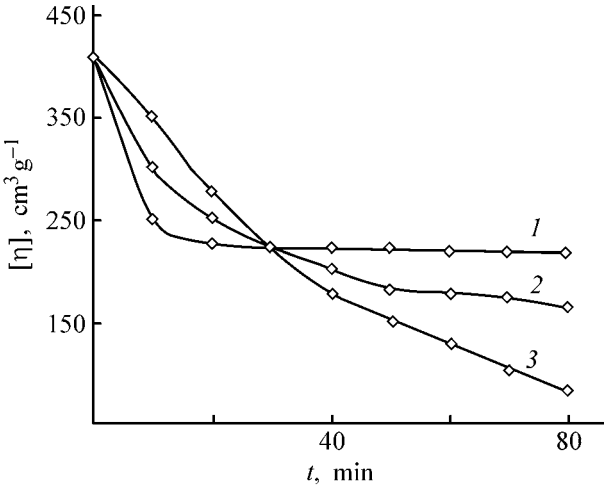

Fig. 2. Variation of [η] with time t in the course of degradation of N-VP–Na-AMS copolymer (sample no. 2) under the action of different degrading agents. [Degrading agent]/[copolymer] = 0.08, c_p = 0.1%, 50°C. Degrading agent: (*1*) PS, (*2*) HP, and (*3*) PS–SS, 1 : 2 (by weight).

were referred to the instant of time $t = t_2 + t_1/2$, where t_2 is the time elapsed from the onset of degradation to the start of measuring t_1. Then we plotted the dependence $\eta_{sp}/c_p = f(t)$. In the course of degradation, the reaction solution was sampled at certain intervals to determine [η].

The measurements of [η] were carried out in a VPZh-3 viscometer (d = 0.56 mm) in 0.5 M NaCl at 30°C. The values of [η] were determined from the linear dependence $(\eta_{sp}/c_p) = f(c_p)$ as $[\eta] = \lim(\eta_{sp}/c_p)$ at $c_p \to 0$. From the [η] values measured at constant copolymer composition, solvent, and temperature for copolymers with identical molecular characteristics, we evaluated MW of the copolymer, since, according to the Mark–Houwink–Kuhn equation, $[\eta] \sim MW$.

The content of ionic units in the copolymer composition was evaluated by elemental analysis for sulfur [8].

For potentiometric measurements we used a pH meter (pH-121) with a measuring glass electrode (ESL 65-07) and an auxiliary silver chloride electrode (EVL 1M3).

With the aim to prevent deterioration of the performance of N-VP–Na-AMS copolymers, commonly observed at high extents of degradation, we selected as optimum such degradation conditions which provided formation of partially degraded copolymers and allowed viscosimetric monitoring of degradation. The optimal degradation conditions were established based on previous studies [1]. Degradation was carried out in 0.1–1% aqueous solutions of copolymers at 25–60°C in the presence of radical degrading agents, taken in the amount of 1–8% relative to the copolymer weight. To exclude the complicating effect of the difference between the molecular characteristics of N-VP–Na-AMS copolymers, all experiments were carried out on sample no. 2, produced at a low degree of conversion, which provided the constancy of the molecular weight, average composition, and composition heterogeneity of the copolymer.

Let us consider the effect of degrading agents on degradation of N-VP–Na-AMS copolymer (sample no. 1). The experiments were carried out in 0.1% solutions of the copolymer at 50°C. The influence of PS concentration on the variation of [η] in the course of copolymer degradation is shown in Fig. 1. Without initiator, the [η] values do not vary with time (curve *1*), suggesting the absence of noticeable degradation of the copolymer. Variation of [η] values on adding PS suggests that degradation occurs. Its intensity grows with increasing concentration of degrading agent and reaction duration (curves *2–4*). Similar variations in [η] were observed in degradation of the copolymer under the action of another initiator, HP.

Under experimental conditions, degradation of the copolymer under the action of radicals $R^{\bullet}$ generated by decomposition of initiators proceeded with the rupture of carbon–carbon bonds in the backbone of the macromolecule, which occurred by the random law without depolymerization. In this case, the initiating centers could be monomer units joined "head to head." The general scheme of degradation of N-VP–Na-AMS copolymer under the action of radicals $R^{\bullet}$ is similar to that described in [1].

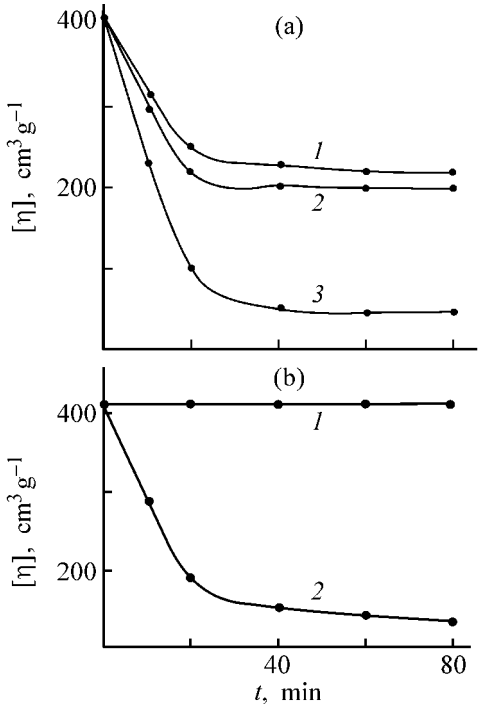

Fig. 3. Variation of [η] with time t in the course of degradation of N-VP–Na-AMS copolymer (sample no. 2) at different temperatures (c_p = 0.1%). (a) [PS]/[copolymer] = 0.08. T (°C): (*1*) 40, (*2*) 50, and (*3*) 60. (b) [PS]/[SS] = 1 : 2 (by weight), 25°C. [PS + SS]/[copolymer]: (*1*) 0 and (*2*) 0.24.

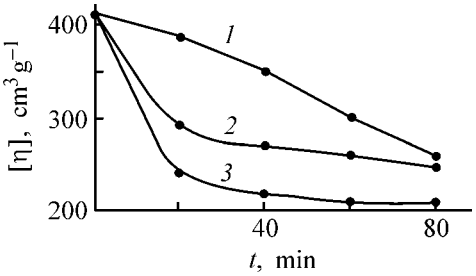

Fig. 4. Variation of [η] with time t in the course of degradation of N-VP–Na-AMS copolymer (sample no. 2) at different copolymer concentrations. [PS]/[copolymer] = 0.08, 50°C. c_p (%): (*1*) 1, (*2*) 0.5, and (*3*) 0.1.

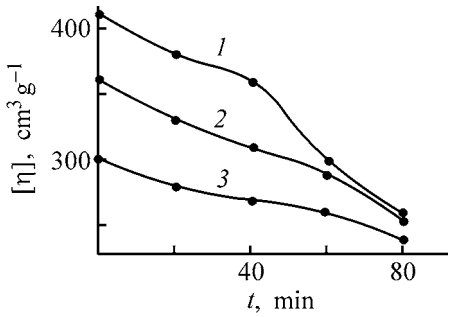

Fig. 5. Variation of [η] with time t in the course of degradation of N-VP–Na-AMS copolymer with the same composition and different initial values of [η]. [PS]/[copolymer] = 0.08, c_p = 1%, 50°C. [η], cm³ g^{-1}: (*1*) 410 (sample no. 2), (*2*) 360 (sample no. 3), and (*3*) 300 (sample no. 4).

The results of degradation of N-VP–Na-AMS copolymer in 0.1% solutions at 50°C under the action of different degrading agents at their equal concentrations in the solution are shown in Fig. 2. As seen, the initial degradation rate decreases in the order PS > HP > PS–SS, and the limiting degree of the copolymer degradation in 80 min varies in the reverse order.

The influence of temperature on the variation of [η] of the copolymer in the course of degradation was estimated in the range 40–60°C, with other reaction conditions fixed (Fig. 3a). Figure 3a shows that the initial rate and the limiting degree of degradation increase with temperature. This is caused by an increase in the concentration of radicals generated by decomposition of the initiator and including degradation of the copolymer.

To elucidate the possibility of low-temperature degradation of the N-VP–Na-AMS copolymer in 0.1% solution, we carried out experiments at 25°C using the PS–SS redox system as degrading additive. The results of these experiments (Fig. 3b) show that degradation of the copolymer is not observed without the PS–SS initiating system (curve *1*), and in the presence of this system degradation proceeds efficiently (curve *2*). The possibility of degradation of copolymer macromolecules at 25°C is caused by intensification of the PS decomposition under the action of SS reducing agent and rise in the concentration of free radicals in the system.

With the aim to elucidate how the concentration of N-VP–Na-AMS copolymer affects degradation, experiments were carried out in 0.1–1% solutions, other degradation conditions being the same. The results of this series of experiments are shown in Fig. 4. At all of the copolymer concentrations studied, the [η] values drastically decrease as a result of rupture of the C–C bonds in the macromolecular backbone. It also follows from Fig. 4 that, with increasing copolymer concentration, the intensity of its degradation decreases. This is caused by an increase in the viscosity of the reaction medium, which results in a slower diffusion of the degrading agent to the macromolecule.

The influence of MW of the initial N-VP–Na-AMS copolymer on degradation process is illustrated in Fig. 5. The experiments performed with the copolymer samples of the same chemical composition and under the same conditions suggest intensification of

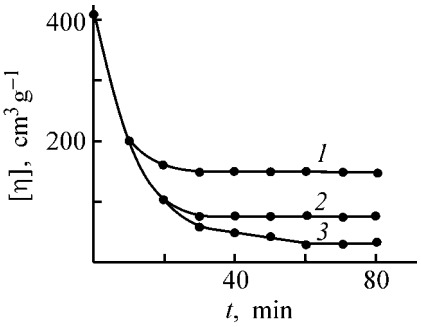

Fig. 6. Variation of [η] with time *t* in the course of degradation of N-VP–Na-AMS copolymer (sample no. 2) (*1, 2*) in the presence of KI and (*3*) without it. [PS]/[copolymer] = 0.08, [PS]/[KI] = 1 : 1 (by weight), 60°C. Time of KI addition (min): (*1*) 10 and (*2*) 20.

degradation with increasing [η] of the initial copolymer samples. These results are in good agreement with published data [9] on variation of MW of polyacrylamide in the course of degradation. It is evident that, with increasing MW, the content of weak bonds (e.g., abnormally "head to head" bonded units) subjected to rupture grows. This is in good agreement with the general features of polymer degradation [10]. In addition, at the same number of ruptures per macromolecule, the decrease in the MW is more significant for a copolymer with higher molecular weight.

We also evaluated the effect of KI additions on degradation of N-VP–Na-AMS copolymer in 0.1% solution in the presence of PS at 60°C. Figure 6 shows that addition of KI at various degradation stages results in weaker decrease in [η] (curves *1*, *2*) as compared to the run without addition of KI (curve *3*). This is apparently caused by the reaction of KI with the radical $R^{\bullet}$, generated from the initiator, according to the scheme

$$2KI + 2R^{\bullet} + 2H_2O \rightarrow 2KOH + 2RH + I_2.$$

These data suggest that KI is a stabilizer for solutions of N-VP–Na-AMS copolymer and can be used for controlling MW of the copolymer in its degradation. The data on stabilizing characteristics of KI in the system studied are in good agreement with the possibility of stabilization of hydrolyzed PAA solutions under the action of KI, shown previously in [11].

The above results give grounds to believe that controllable degradation of N-VP–Na-AMS copolymer in aqueous solutions in the presence of radical initiators can be used as a facile route to copolymers with controllable MW.

CONCLUSIONS

(1) Partially degraded copolymers of *N*-vinylpyrrolidone and sodium 2-acrylamido-2-methylpropanesulfonate, with molecular weight controllable in a wide range (an order of magnitude and more), can be produced by degradation of macromolecular copolymers in aqueous solutions under the action of radical degrading agents at 25–50°C.

(2) The initial rate of copolymer degradation increases with temperature, reaction duration, and concentration of various degrading agents, and decreases in the order potassium persulfate > hydrogen peroxide > system potassium persulfate–sodium sulfite. Addition of KI inhibits the degradation.

(3) Degradation is intensified with decreasing concentration of the copolymer and its increasing molecular weight.

Abstract—A comparative study is made of sorption interaction of individual lysozyme and lysozyme as component of chicken egg white with KMDM-6-5 carboxylic cation exchanger.

Among problems arising in studying interactions of biologically active compounds with charge-bearing surfaces of polymers, the effect of the composition of a multicomponent mixture on the sorption is of a particular importance. The same problem arises in developing processes of chromatographic separation and purification of biologically active compounds on polymeric sorbents.

It is known that ion-exchange chromatography is among the most efficient and cost-effective methods used for primary recovery of target components from complex biological raw materials. In some specific cases, the use of selective high-capacity sorbents [1] allows separation of a target component from a complex mixture in a single stage. Even at a target component concentration of about fractions of a percent or several percent, proper choice of an ion-exchange sorbent and sorption conditions can provide increase in the component concentration in the eluate to several tens of percent [1].

At the same time, the result of sorption depends on the component concentration in the mixture, as demonstrated by experiments with model mixtures of proteins [2, 3]. Helfferich and Klein proposed a mathematical model that takes into account the mutual influence of components in sorption. They introduced the concept of the competitive and synergistic sorption mechanisms [4]. If proteins interact with the pore surface of a sorbent by the synergistic mechanism with multilayer sorption of the proteins, separation of the components in a dynamic column experiment is virtually impossible. By the optimal conditions of sorption are meant those under which sorption of proteins proceeds in competition for sites on the sorbent pore surface, but not by the synergistic mechanism. In this case, proper choice of the desorption mode will allow elution of the target component only.

The goal of this study was to optimize the conditions of ion-exchange sorption/desorption of lysozyme from a multicomponent mixture on a carboxylic cation exchanger, using the competitive sorption mechanism.

EXPERIMENTAL

In the study, we used chicken egg white (CEW) lysozyme from the Ferrein Joint-Stock Company. The product contains 97% protein (MW 14 600). Lysozyme has isoelectric point at pH 10.7–11.2 and maintains its activity in neutral solutions [5–7]. As a lysozyme-containing multicomponent mixture we used CEW (preliminarily frozen and then warmed to room temperature).

As cation exchangers we used SGK-7 and KMDM-6-5 cross-linked carboxylic polyelectrolytes. The former was obtained by copolymerization of acrylic acid with divinylbenzene in the presence of a modifying solvent [8]. The sorbent is composed of white spherical granules with macroporous structure. The static exchange capacity of SGK-7 for Na^+ is 9.0 mg-equiv g^{-1} dry sorbent; specific volume, 4.7 ml g^{-1}; apparent ionization constant, pK 6.4. The pK was determined by potentiometric titration [9]. The KMDM-6-5 carboxylic cation exchanger (from the Institute of Macromolecular Compounds, Russian Academy of Sciences) is a copolymer of methacrylic acid and *N*,*N*'-hexamethylenedimethacrylamide. It is a cross-linked heteropolymer. Its total exchange capacity for Na^+ is 9.5 mg-equiv g^{-1} dry sorbent; specific volume, 10.5 ml g^{-1}; 1 g of wet sorbent occupies a volume of 1.02 ml; pK 6.7. The moisture content of the swollen polymer is 90%. The grain size of the swollen sorbents (both SGK-7 and KMDM-6-5) ranges from 315 to 500 μm.

Parameters of sorption of lysozyme from egg white on KMDM-6-5 carboxylic cation exchanger at 20°C

Form of sorbent	pH	τ, h	Lysozyme concentration in indicated phase		Specific activity of eluate, lA ml^{-1}
			CEW, lA ml^{-1}	sorbent, lA g^{-1}	
H-	6.4	2	0.6	385	3.6
	6.3	3	0.3	468	1.5
Na-	9.3	2	0.6	470	9.6
	9.0	3	0.3	540	6.5
H–Na-	7.3	3	0.3	468	2.3

The lysozyme concentration was determined spectrophotometrically (λ = 274 nm, molar extinction coefficient of lysozyme 38.9 [10]) and also by the method described in [11].

Before sorption experiments, egg white was fourfold diluted with 0.1 N phosphate buffer, to decrease the solution viscosity. Sorption of lysozyme from egg white was performed by the static method in a vessel with stirrer rotation at 30–50 rpm. The activity of lysozyme expressed in lA units was determined by the turbidimetric method based on the ability of lysozyme to destroy cell walls of *Micrococcus lysodeikticus* [5]. A suspension of cells of *Micrococcus lysodeikticus* was prepared in an 0.066 M phosphate buffer (pH 6.2), to obtain an optical density of 0.6–0.7 at a wavelength of 570 nm. To 3 ml of the substrate was added 0.5 ml of the enzyme solution with lysozyme concentration of up to 1 mg ml^{-1}. After 15-min incubation at 37°C, the optical density at 570 nm was measured again. Preliminarily, we plotted a calibration curve for a standard sample of lysozyme (at lysozyme concentration of 1 mg ml^{-1}, the activity was 19 ± 1 lA ml^{-1}).

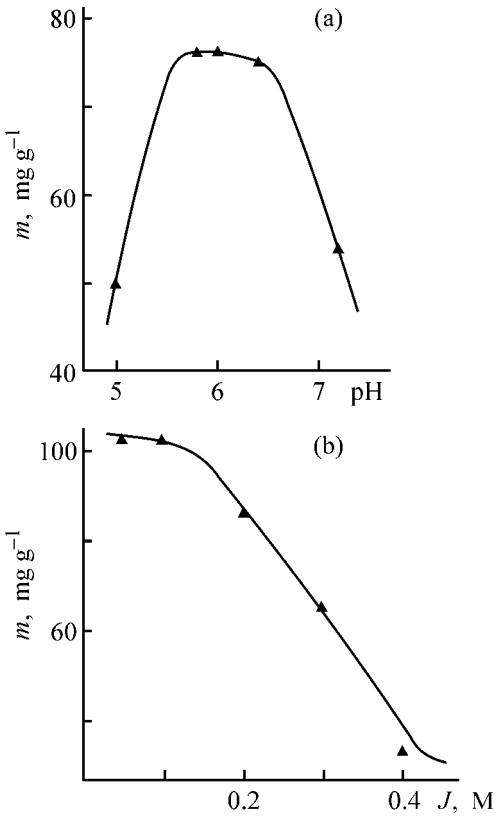

Fig. 1. Sorption *m* of individual lysozyme vs. (a) pH and (b) ionic strength *J*.

Chicken egg white itself is a buffer solution with high buffer capacity. Therefore, not attempting to adjust the pH of CEW, we studied the influence exerted by the sorbent preparation thechnique on the sorption of lysozyme from two CEW samples on various forms of KMDM-6-5.

Data in the table show that the lysozyme concentration in the sorbent phase, specific activity of the eluate, and the lysozyme yield increase on passing from the H form to the H–Na and Na forms. This can be interpreted as follows. It has been demonstrated previously [1] that the maximum sorption of proteins, having the isoelectric point in the acidic region, on carboxylic cation exchangers is observed near the isoelectric point of the protein, whereas that of proteins having the isoelectric point in the alkaline region, near the p*K* of the cation exchanger (p*K* 6.7 for KMDM-6-5). We have demonstrated that the maximum sorption of individual lysozyme occurs at pH 5.8–6.4 (Fig. 1a). Sorption of egg albumen (macrocomponent of egg white) is at a maximum at pH 5.0 (sorption occurs in the pH range from 3.5 to 5.5). Since the content of egg albumen in CEW is several times that of lysozyme (lysozyme content in CEW is 2–4% [10]), in sorption at pH 6 (optimal pH for sorption of lysozyme), albumen is also considerably sorbed, which, evidently, decreases the sorption of lysozyme At pH 7.2–7.5, the sorption of individual lysozyme decreases by no more than 30–35% (Fig. 1a), and that of egg albumen is negliigble under these conditions.

In the alkaline range, i.e., on passing from the H to Na form of the sorbent, the synergistic mechanism changes for the competitive one (although, in this case, there is nothing for lysozyme to compete with), and purely ion-exchange sorption of lysozyme (alkaline protein) occurs, whereas acidic proteins are not sorbed, forming no second sorption layer on the surface of the already sorbed protein. The lack of the second sorption layer allows subsequent elution of individual lysozyme.

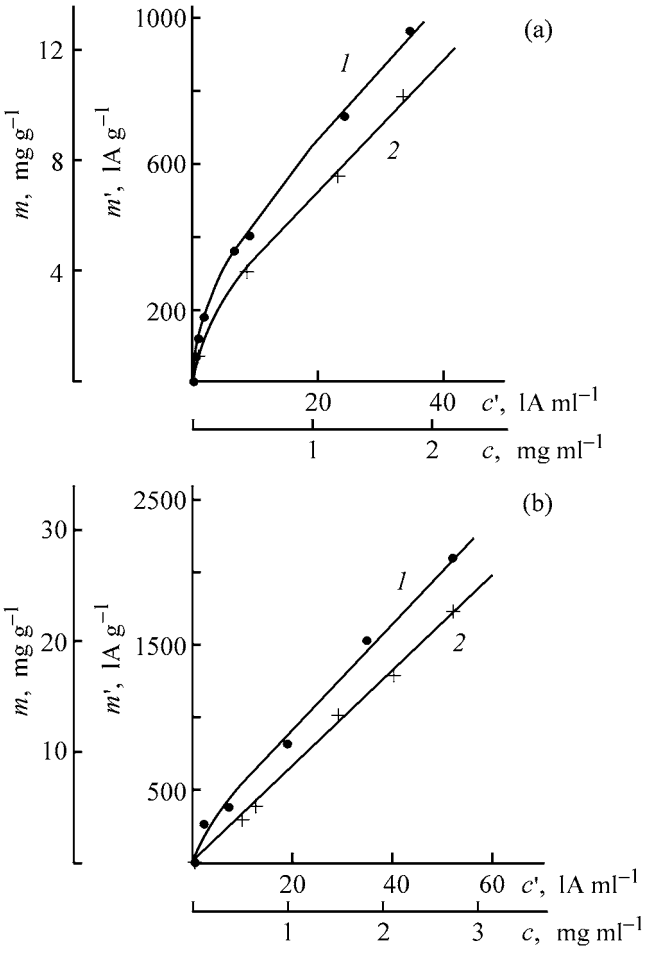

Fig. 2. Sorption isotherms of lysozyme from CEW on (a) KMDM-6-5 and (b) SGK-7. (m, m') Concentration and activity of lysozyme in the sorbent phase; (c, c') concentration and activity of lysozyme in the solution. Temperature (°C): (*1*) 20 and (*2*) 8.

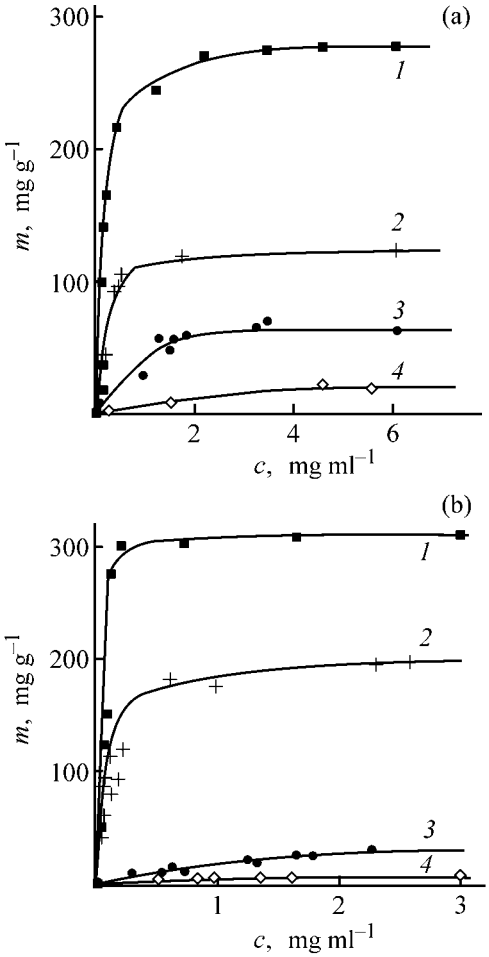

Fig. 3. Sorption isotherms of individual lysozyme on (a) KMDM-6-5 and (b) SGK-7. (m) Lysozyme concentration in the sorbent phase and (c) lysozyme concentration in the solution. Ionic strength (M): (*1*) 0.1, (*2*) 0.15, (*3*) 0.25, and (*4*) 0.5.

A study of the effect of the ionic strength on the sorption of individual lysozyme revealed that, over the NaCl concentration range 0–0.1 M, the sorption capacity of the sorbent remains virtually unchanged, but decreases with J increasing further. Taking these results and data given in the table into account, all further experiments were carried out with KMDM-6-5 and SGK-7 sorbents in the H–Na form. The sorbents were preliminarily treated with 0.05 M phosphate buffer (pH 7.2). This pH value was selected because lysozyme loses its biological activity at higher pH [5, 6].

The sorption isotherms of lysozyme directly from CEW on KMDM-6-5 and SGK-7 are shown in Fig. 2 for the above-indicated conditions at two different temperatures. The results indicated that temperature has only slight effect on the sorption. Therefore, the experiments could be carried out without temperature control. The temperature effect was studied because in most cases, sorption was performed from solutions obtained after defrosting an initially frozen CEW. The sorption isotherms of lysozyme at room temperature were then used to determine the sorbent volume required for sorption of the maximum amount of the protein from CEW.

Figure 3 shows the sorption isotherms of individual lysozyme at pH 7.2 on KMDM-6-5 and SGK-7 cation exchangers at different ionic strengths. As seen, the ionic strength strongly influences the sorption, with the sorption decreasing by a factor of up to several tens. Comparison of Figs. 2 and 3 reveals that the overal effect of all the components contained in CEW on the sorption is comparable with that exerted by the ionic strength in the range from 0.25 to 0.5 M.

Evidently, under these conditions, the efficiency of sorption of lysozyme from CEW is small. Nevertheless, raising the sorbent to CEW ratio allows recovery of up to 85% of lysozyme contained in the initial mixture.

Desorption of lysozyme from both KMDM-6-5 and SGK-7 was performed at ionic strength increased to 1 M. Comparison of the compositions of the eluates obtained after sorption of CEW on the sorbents in the H and H–Na forms shows that, in the case of the H forms, the eluate contained 30–35% lysozyme, 20–25% other proteins, and nonprotein matter the balance. In sorption on the H–Na forms, the eluate contained 50–60 lysozyme, traces of other proteins, and nonprotein matter the balance.

CONCLUSION

In sorption of proteins from complex multicomponent mixtures, it is not always advantageous to carry out the process under conditions ensuring the maximum sorption efficiency with respect to a target component. It was demonstrated for the example of lysozyme that less tight binding of the protein to the sorbent can provide a gain in the sorption selectivity.

Abstract—The cellulose-producing power of the VKM V-800 *Acetobacter xylinum* strain under conditions of static culture was studied. The culture medium was optimized with the aim to increase the cellulose yield and obtain highly crystalline cellulose I with molecular weight of about 5×10^5.

A considerable progress in studies of cellulose biosynthesis, development of the concepts of structural hierarchy of cellulose, and discovery of two crystalline modifications, CI_α and CI_β, in native cellulose samples stimulated in the past decade active studies of evolutionarily different celluloses on the molecular and supramolecular levels. The structure of native celluloses is extensively studied by biochemical, genetic, physicochemical, and also theoretical methods [1–12].

The most success has been gained in studies of cellulose produced by *Valonia ventricosa* alga and of bacterial cellulose produced by *Acetobacter xylinum* (CAX) [3].

Two polymorph families of crystalline cellulose I are distinguished: that rich in the I_α form (algal and bacterial celluloses) and that rich in the I_β form (cellulose of higher plants and animal cellulose) [7–10]. Electron diffraction studies showed that, in the metastable I_α phase, cellulose chains are packed to form a triclinic cell (space group $P1$) with a single tie chain, and under certain conditions, this phase transforms into the thermodynamically stable monoclinic I_β structure (space group $P2_1$) with two macrochains in the unit cell [7, 10]. The I_α/I_β ratio for celluloses of various origins forms in the course of biosynthesis and is not directly related to the degree of crystallinity of a polymeric sample. For example, in the cellulose produced by *Valonia ventricosa* alga (degree of crystallinity 100%) I_α/I_β = 60/40, and in the animal cellulose produced by *Halocynthia*, with the same degree of crystallinity, this ratio is 10/90 [12].

It has been found [9] that the degree of transformation of structures I_a and I_b during heat treatment of cellulose samples is independent of the initial crystallinity. In this context, a fundamental question arises concerning exact ultrastructural localization of each phase. This question was answered to certain extent in recent papers [13, 14]; the procedure used was based on different reactivities of the I_α and I_β phases. The conclusion of [13, 14] that the I_α phase is situated on the surface of microcrystals or microfibrils was also confirmed by the data of high-resolution atomic-force microscopy [15].

Numerous papers published in the past five years show that the ratio and sizes of structural modifications I_α and I_β and their mutual arrangement depend both on the evolutionary origin of cellulose samples and on the biosynthesis conditions, varying from one sample to another [16].

The efforts of many research teams are aimed today at revealing the factors responsible for variation of the I_α/I_β ratio in the course of cellulose biosynthesis.

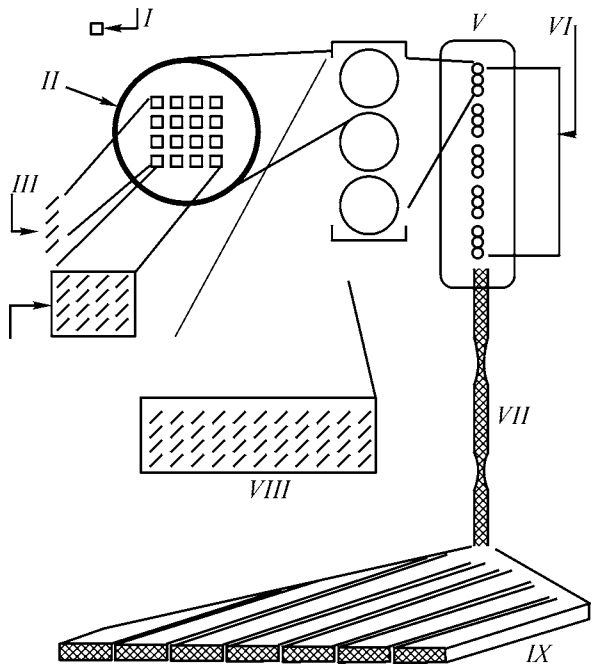

Fig. 1. Scheme of the structure of linear TC of *A. xylinum* bacterium, illustrating the formation of a mini-sheet from four glucan chains and of a mini-crystal from 16 chains by a subunit: (*I*) catalytic site of a glucan chain, (*II*) TC subunit, (*III*) mini-sheet, (*IV*) mini-crystal of one TC subunit, (*V*) TC triplet, (*VI*) linear series of Acetobacter TC triplets, (*VII*) ribbon of microfibrils, (*VIII*) crystalline microfibril of three TC subunits, and (*IX*) 10–100 microfibrils/ribbon. Three TC subunits form a crystalline microfibril, and 10–100 subunits form a ribbon.

Particular attention is given to crystallization of bacterial CAX as a model system for which the I_α/I_β ratio varies with strain and cultivation conditions (e.g., addition of chemicals to culture medium, variation of temperature) [3, 4, 16].

The interest in fine details of biosynthesis and structure of CAX is due to the possibility of preparing chemically pure cellulose by an environmentally acceptable procedure and using it in diverse branches of medicine [17] and engineering [18]. Various structural levels of CAX are discussed: the structure of the terminal complex (TC) itself; its subunit; fine structural elements formed: mini-sheet, mini-crystal, microfibril, and ribbon [3, 11]. Brown [3] suggested a scheme (Fig. 1) illustrating the shape and size of a linear TC and their correlation with the microfibril size. Each TC subunit includes 16 catalytic sites forming four mini-sheets, which, in turn, form a mini-crystal. A microfibril is formed from three TC subunits, and a ribbon, from 10–100 microfibrils. Experiments on CAX cultivation with addition of Tinopoal dye showed that the macrochain packing varies with dye concentration. At low dye concentrations, the microfibril formation is disturbed. At high dye concentrations, only mini-sheets of glucan chains are obtained in the form of tubular cellulose; in the course of washing or photoisomerization, this structure can transform into a microfibril [11].

Attempts are made to affect, via the composition of the culture medium, the capability of *A. xylinum* strains to produce ribbons and their aggregates with more perfect structural characteristics. It has been shown [19] that addition to the culture medium of antimetabolites, such as nalidixic acid and chloramphenicol, makes bacterial cells longer and, as a consequence, results in production of wider ribbon aggregates.

The effect of polymeric additives on the formation of CAX microfibrils of various sizes and the mechanism of crystallization of cellulose I_α and I_β in them are discussed in [20–22]. It was found that addition of carboxymethyl cellulose or xyloglucan to the culture medium reduces formation of the I_α phase, increasing the I_β fraction; according to an electron-microscopic examination, this is associated with a decrease in the width of CAX microfibrils. Similar effects have also been observed by other authors [23] upon introduction of oligo- and polysaccharides into the culture medium. Samples of CAX and its composites have been prepared under various synthesis conditions with addition of lignin–carbohydrate complexes or specific polysaccharides to the culture medium; an X-ray diffraction study of these samples has shown that some additives increase the content of the I_β phase, and, in some cases, the crystal structure does not change (the I_α phase remains) or low-crystalline composites are obtained [23].

Our goal was to reveal a correlation between the structural organization of CAX macrochains in the course of the syntheses, suggested in [3] (Fig. 1), and structural parameters of cellulose macrosamples in the course of drying of CAX gel films. Here, we report the results of optimization of the CAX synthesis by the VKM V-880 *A. xylinum* strain and the structural features of CAX samples, which were evaluated by X-ray diffraction analysis and dielectric spectroscopy.

EXPERIMENTAL

The cellulose synthesis by the VKM V-880 *A. xylinum* strain maintained at the Microbiology Chair, St. Petersburg State University, was performed in a culture medium containing aqueous solutions of yeast extract (YE), glucose, peptone, ethanol, and

wort in optimized concentrations, at pH 5.9–6.0. The seed was a 48-h *A. xylinum* culture grown in a medium containing YE and wort (6° Baling scale) in 1 : 1 ratio, with 2 wt % glucose and 1 vol % ethanol. Cultivation was performed at 29–30°C for 6–7 days, after which CAX was separated and intermittently washed with boiling 0.5–1% aqueous NaOH to remove *A. xylinum* cells. Then CAX was washed to remove NaOH with distilled water, 0.5% acetic acid solution, and again distilled water to neutral reaction. The resulting CAX was stored either as a gel film (in distilled water at 5°C) or (after autoclave sterilization) at room temperature, or it was dried in a vacuum at 40°C and stored in the dry state. The procedure was optimized by additive-lattice experimental design [24]; the five varied factors were concentrations of the components of the medium, and the cellulose yield was determined at different factor values.

X-ray diffraction patterns (DRON-2 diffractometer and RKV-86 X-ray camera, Ni-filtered Cu_{K_α} radiation) were measured for the initial CAX gel films cleaned to remove the culture medium, and also for the films from which a certain amount of water was removed (before and after drying in air at room temperature to the air-dry state). The dielectric properties of CAX were measured with a TR-9701 device in the frequency range 1–100 kHz at temperatures from –140 to 120°C. A two-electrode cell with chrome-plated brass electrodes and Teflon insulation was used. The measurements were performed in dry air with 30–60-μm-thick film samples dried in a vacuum at 60°C.

It is known that *A. xylinum* well develops in culture media containing glucose and some other monosaccharides as carbon sources, and also yeast extract as growth factor and source of nitrogen [25]. To determine the cellulose-producing power of the VKM V-880 *A. xylinum* strain, the culture medium based on the initial medium containing glucose, YE, and peptone was optimized. The effect of organic additives, wort and ethanol, on the biosynthesis of cellulose was elucidated [26]. Determination of the cellulose yield from culture media of 25 different compositions showed that, at the optimal combination of the components (7 wt % glucose, 0.3 wt % YE, 30 vol % wort, 0.3 wt % peptone, 3 vol % ethanol), up to 50 g of air-dry cellulose is obtained from 1 m^2 of the reactor surface.

It has been found previously that CAX can be synthesized on culture media with various cheap sources of carbon: industrial wood hydrolyzates, peat hydrolyzates, molasses, and other media containing monosaccharides [27, 28]. To determine the structural characteristics of CAX synthesized by the VKM V-880 strain, we used gel films prepared in a medium containing 2% glucose, 0.2% peptone, 0.3% YE, and 2 vol % ethanol. The IR absorption bands and X-ray reflections of these samples were found in the ranges characteristic of cellulose I. Determination of the molecular weight of CAX by sedimentation and diffusion in cadoxen gave an M_{SD} value of 5×10^5. The polydispersity index M_z/M_w determined by correlation laser spectroscopy in cadoxen [26] was approximately 1.1. All these data are nicely consistent with the CAX characteristics available from the literature [29].

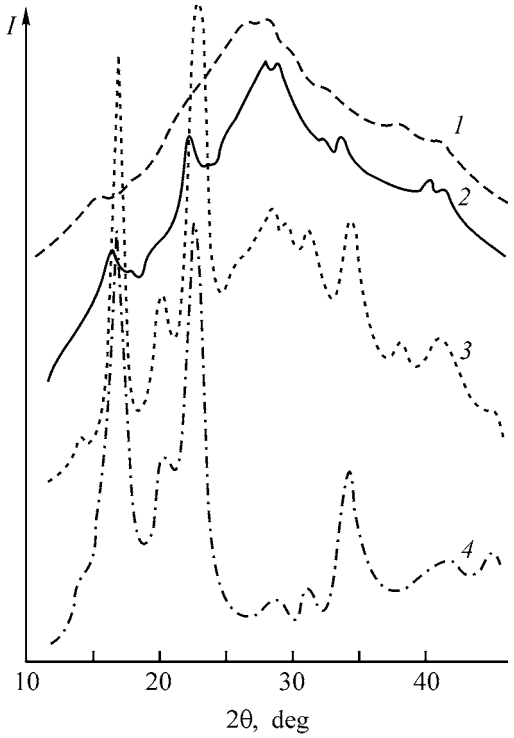

Fig. 2. Diffraction patterns of CAX in various steps of gel film drying. (*I*) Intensity and (2θ) Bragg angle; the same for Figs. 4–6. (*1*) Initial gel films with the dry polymer : water ratio of 1 : 100; (*2*) CAX sample squeezed to remove 50% of water; (*3*) sample dried at 20°C for 3 h; (*4*) sample dried in a vacuum at 40°C.

Since the X-ray diffraction patterns obtained from CAX gel films dried under various conditions differed from those reported in [23, 30], it seemed appropriate to study in more detail the kinetics of water removal from the CAX gel film in the course of drying.

The diffraction pattern of the initial gel film with the dry polymer : water ratio of 1 : 100 (Fig. 2, curve *1*) is characterized by a broad maximum at 2θ =

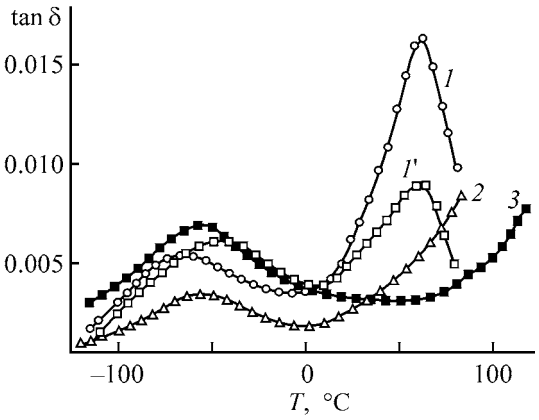

Fig. 3. Temperature dependence of the dielectric loss tangent tan δ for (*1*, *1*') CAX, (*2*) CAX heated to 100°C in a vacuum in the course of measurement, and (*3*) dried cotton linter. Measurement frequency, kHz: (*1–3*) 1 and (*1*') 10.

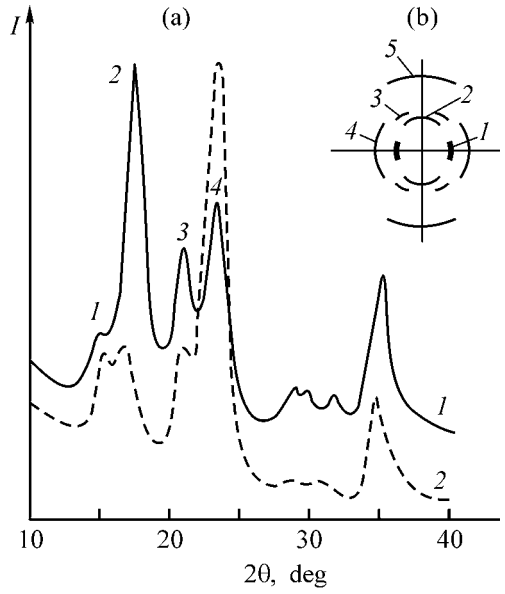

Fig. 4. (a) Diffraction patterns and (b) scheme of X-ray pattern obtained at (a) perpendicular and (b) parallel incidence of the X-ray beam relative to the plane of the dry sample. Sample: (a) (*1*) CAX and (*2*) LC; (b) CAX.

20°–40°. When 40–50% of the initial water is removed from the gel film, clear reflections appear against the background of this halo at 2θ 15°–16°, 23°, 27°, 32°–34°, and 40°–42°, with the broad maximum in the range 25°–30° being preserved (Fig. 2, curve *2*). After drying this sample in air at 20°C for 2–3 h, the reflection positions and intensities changed (Fig. 2, curve *3*). A noticeable diffuse background remained in the range 2θ = 20°–40°, and the reflections corresponding to *d* 0.532, 0.435, 0.390, and 0.259 nm became the strongest. In the X-ray patterns of the CAX films dried in a vacuum at 40°C (Fig. 2, curve *4*), the positions of these four reflections remained unchanged, whereas the diffuse halo virtually disappeared.

However, the samples dried under these conditions still contained water molecules, as suggested by the CAX relaxation properties determined by dielectric spectroscopy [31]. Figure 3 shows the temperature dependence of the dielectric loss tangent, $\tan\delta = f(T)$, for samples of CAX and, for comparison, cotton linter cellulose (LC). For samples of both CAX and LC, $\tan\delta_m$ passes through a maximum at negative temperatures (about –60°C, 1 kHz). According to the concept of the relaxation properties of cellulose [31–33], this range of dielectric loss in CAX must be associated with relaxation of the dipole polarization and mobility of primary hydroxy groups of cellulose molecules. Above 0°C, the dielectric loss increases. At 60–70°C, the loss decreases irrespective of the measurement frequency (curves *1*, *1*'); heating in a vacuum enhances this trend (curves *1*, *2*). This fact suggests removal of compounds increasing the electrical conductivity from the sample bulk (in the given case, this is, most probably, water [33]).

Simultaneoulsy, $\tan\delta_m$ decreases, and the maximum shifts from –60°C to higher temperatures. This suggests disappearance of the plasticization effect associated with the presence of water molecules forming hydrogen bonds with primary hydroxyls. The break-down of the hydroxyl–water complexes does not cause the peak of $\tan\delta_m$ to grow in intensity, which may be due to involvement of the released OH groups in a new system of intermolecular hydrogen bonds. Comparison of the dependences $\tan\delta = f(T)$ for CAX and LC samples (Fig. 3, curves *2*, *3*) shows that the maximal value of $\tan\delta_m$ at –60°C for CAX is two–three times lower than for LC. Since the height of the peak at –60°C is determined by the amount of primary OH groups that can participate in thermal motion and this motion can occur in defective areas only, it can be presumed that bacterial cellulose, compared to linter cellulose, is characterized by a more regular network of hydrogen bonds and a more regular structure [31–33]. Indeed, the X-ray diffraction patterns of CAX and LC samples showed that CAX films were more ordered (Fig. 4a, curve *1*); all the reflections of CAX were indexed in the monoclinic system of modification I, which is a two-phase system of CI_α and CI_β.

Particular attention should be given to the range 2θ = 13°–18° in the diffraction pattern of CAX. It is seen that the $\bar{1}10$ reflection (2θ = 15°) of the CAX

film (Fig. 4a, curve *1*) is considerably weaker as compared to LC (Fig. 4a, curve *2*). At the same time, the intensity of the reflection at $2\theta = 16°50'$ [sum of (110) and (002) reflections] is many times higher as compared to LC and varies from one sample to another.

To reveal a planar texture in CAX films, we measured the X-ray patterns with the plane of the dried sample arranged in parallel with the incident X-ray beam. Figure 4b shows the scheme of the five major reflections of CAX, denoted by the corresponding numerals in Fig. 4a.

We revealed an appreciable redistribution of the reflection positions and intensities. A reflection with $d = 0.607$ nm ($2\theta = 15°$), corresponding to the reflection from the $\bar{1}10$ planes, is clearly seen in the equatorial region. A reflection in the meridional region at $d = 0.523$ nm [reflection from the (002) planes] is clearly seen against the background of a weak ring reflection at $2\theta = 17°$. The (110) reflection in the equator is absent; only a weak "ring" reflection from (110) planes with $d = 0.532–0.535$ nm is observed.

As for the other reflections, the weak third reflection at $2\theta = 20°40'$ is detected in the vicinity of the meridional region and is undoubtedly a sum of reflections from the (102) and (012) planes of the monoclinic lattice with $d = 0.437$ and $d = 0.432$ nm. In the equatorial region, there is a fairly strong fourth reflection with $d = 0.389–0.392$ nm, corresponding to the reflections from the (200) planes in which hydrogen-bonded cellulose chain molecules are arranged to form parallel layers. Finally, the fifth reflection with $d = 0.259–0.260$ nm, which is a superposition of moderately strong reflections from the system of planes (004), (220), (031), and (023), is clearly seen in the meridional region of the X-ray pattern of a CAX film taken from the end side, i.e., it characterizes the periodicity along the polymeric chain.

Thus, aggregates of CAX microfibrils are arranged in the plane of the dried film, forming an axial texture whose axis is perpendicular to the film plane. Since the (110) reflection ($2\theta = 15°$) is only manifested in the majority of samples when the X-ray beam is parallel to the sample surface, it can be concluded that, in the crystallites constituting CAX ribbons, the ($\bar{1}10$) planes of the monoclinic cell are arranged parallel to the macrosample, i.e., an axial-planar texture arises [34].

Comparison of the diffraction patterns of CAX films (VKM V-880 strain) prepared in this study and CAX samples produced by the ATCC 53524 strain

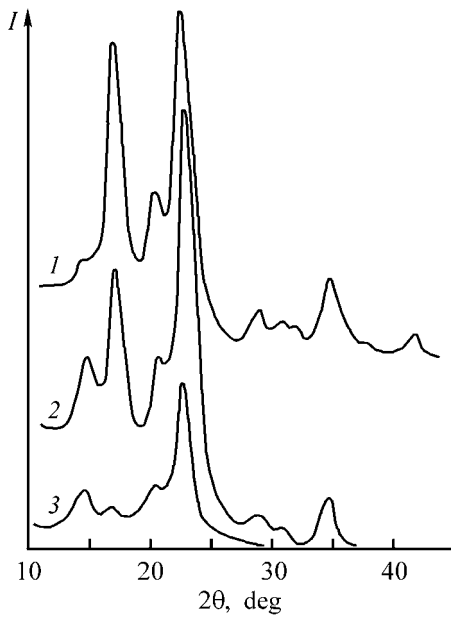

Fig. 5. Diffraction patterns of CAX samples dried (*1*) at 40°C and (*2*) lyophilically after freezing the gel film at –30°C; (*3*) CAX sample (ATCC 53524 strain) dried in the course of freezing [23].

[23] reveals differences in the intensities of some reflections (Fig. 5). This may be due to different procedures of sample preparation. The films were dried on glass supports at room temperature or at 40°C in a vacuum; they had an axial-planar texture. The CAX sample dried in the course of freezing [23] had an isotropic polycrystalline structure (Fig. 5, curve *1*). To eliminate the texturing effect, we changed the drying procedure: A gel film was first frozen at –30°C and then dried lyophilically. However, after such a treatment, the axial-planar texture of the CAX film was preserved, even though to a considerably lesser extent (Fig. 5, curve *2*).

The use of isotropic polycrystalline samples for X-ray diffraction analysis allowed resolution of reflections at 2θ 15° and 17° and their assignment to the I_α and I_β modifications [23]. For the textured samples under consideration, this is impossible. However, the presence of the (002) reflection on the meridian of the diffraction pattern (Fig. 4b) obtained at parallel arrangement of the CAX sample plane relative to the incident X-ray beam indicates that the gel film contains an appreciable amount of the monoclinic I_β phase with the parameters $a = 0.801$, $b = 0.817$, $c = 1.036$ nm (macromolecular axis), and $\beta = 97°$, suggested in [10].

The diffraction patterns of CAX films prepared using, in the biosynthesis step, such carbon sources as industrial hydrolyzates of wood, peat, and liquors

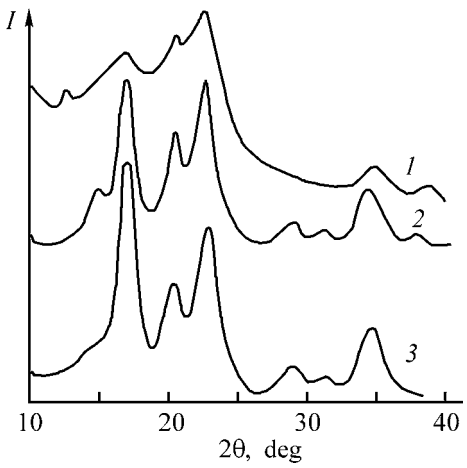

Fig. 6. Diffraction patterns of CAX samples prepared using different carbon sources. Medium: (*1*) containing wood hydrolyzate, (*2*) standard [26], and (*3*) containing glycerol.

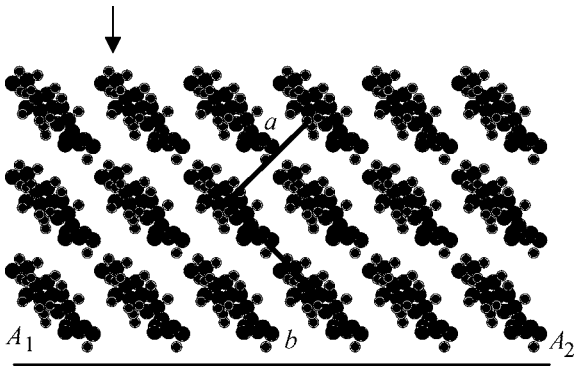

Fig. 7. Model of cellulose chain packing (projection onto the *ab* plane) in the monoclinic cell. (A_1–A_2) Orientation of ribbon microfibrils in the macrofilm plane. The arrow shows the direction of mini-sheets in the course of biosynthesis.

from pulp-and-paper and fruit-and-berry productions [27, 28] show that, depending on conditions of cultivating *A. xylinum*, the CAX produced does not always have the cellulose I structure (Fig. 6, curve *2*); in some cases, it is a mixture of the cellulose I and cellulose II modifications (Fig. 6, curve *1*). The biosynthesis conditions also govern the extent of microfibril orientation in the plane of the CAX film. For example, using glycerol as the carbon source, we observed in CAX samples a clear axial-planar texture (Fig. 6, curve *3*).

Thus, comparison of the diffraction patterns of the CAX gel films dried by different procedures or prepared under different cultivation conditions with the data given in [23, 30] shows that, under conditions of our experiments, a texturing effect arises. Furthermore, the previously published electron diffraction data [35] in combination with the X-ray diffraction patterns for CAX of the VKM V-880 strain suggest that, in the textured samples, the content of the I_β modification exceeds that of the I_α modification.

The possibility of obtaining different I_α/I_β ratios in CAX ribbon formations depending on the conditions of cultivating *A. xylinum* was discussed in [15, 23]. These papers consider the shear stresses in thin planar ribbon ensembles of CAX in the course of simultaneous crystallization and twisting. The ribbons are twisted owing to rotation of bacteria during their forward motion in a culture medium. Aggregation of microfibrils yields wide (40–60 nm) ribbons; their twisting gives rise to end stresses, inducing formation of the I_α structure. On the contrary, the I_β structure is formed in the central parts of the ribbons. If the ribbons are less twisted or microfibrils have smaller transverse size, the number of the stressed regions is considerably smaller, which favors formation of the I_β structure in CAX. Bowling *et al.* [36] observed untwisting of CAX ribbons during degradation of cellulose chains effected by fungus cellulases. This rotary motion was explained by lifting of bending stress and formation of relaxing conformations.

Presumably, in our case the CAX ribbons, orienting on the surface of the culture medium, form a network of hydrogen bonds via primary hydroxy groups, which can prevent twisting of ribbon ensembles and result in a higher content of the I_β structure, compared to I_α, in textured CAX samples.

Proceeding with the concept suggested in [4], we propose a model of cellulose chain packing in the projection onto the *ab* plane for the monoclinic cell with two macromolecules (Fig. 7). The A_1–A_2 line denotes the directing defining the orientation of microfibrillar ribbons on the surface of the culture medium. Such an orientation of glucoside fragments on the microfibril surface explains the presence of a large amount of water molecules hydrogen-bonded with primary hydroxyls. As seen from Fig. 7, the C^6–OH groups are arranged at the phase boundary along the A_1–A_2 line; according to the theoretical calculations [6], these groups have the *tg* conformation in the triclinic I_α structure and the *gt* conformation in the monoclinic structure, participating in the latter case in the hydrogen bonding between the mini-layers. The direction of mini-layers (this concept was suggested in [3]; Fig. 1) is marked in the scheme with an arrow. It is seen (Fig. 7) that the mini-layers are perpendicular to the culture medium surface.

It is known that CAX gel films can retain from 100 to 200 g of water per gram of dry polymer, preserving

a high intrinsic tensile strength (up to 2 kgf mm^{-2}) [26]. The X-ray patterns suggest that the microfibrillar ribbons oriented on the film surface act not only as a reinforcing network but also as hydrophilic layers capable of interacting with a large amount of water molecules. According to electron-microscopic data [35], the diameter of the aggregates is about 50 nm, and their length is extremely large. Microfibrillar aggregates occupy an insignificant part of the gel film volume, which allows introduction depending on the degree of film drying, of diverse systems into gel films. For example, it has been shown that a CAX gel film is an excellent carrier of such antiseptics as Catapol and Poviargol containing silver clusters [37, 38].

CONCLUSIONS

(1) The composition of the culture medium was optimized with the aim to attain the maximal yield of cellulose produced by *Acetobacter xylinum*. The VKM V-880 strain of *A. xylinum* is capable of synthesizing high-molecular-weight cellulose in a static culture using a wide range of carbon sources.

(2) The kinetics of structural transformations that occur in this cellulose when water is removed from gel films in the course of drying was studied by X-ray diffraction and dielectric spectroscopy. It was shown that, in the dried films of highly crystalline cellulose, an axial-planar texture is formed in which crystallographic planes ($\bar{1}10$) of the monoclinic cell (d = 0.61 nm) are arranged parallel to the sample plane.

(3) To describe the packing of ribbon aggregates in the plane of a cellulose film, a model was suggested according to which the mini-sheets constituting the aggregates are arranged in the perpendicular direction relative to the phase boundary between the culture medium and air.

Received July 16, 2002; in final form, March 2003

Abstract—The influence of ultrasonic cavitation on the rate of acid hydrolysis of gelatinized starch under the action of ultrasonic field or strong mechanical stresses in a rotary-pulsating activator is discussed. The dependences of the hydrolysis rate on the starch concentration, acid content, temperature, and intensity of mechanical action on the system are analyzed.

Hydrolytic degradation with rupture of the glycoside bond is one of the most practically significant reactions involving starch. The intensification of starch hydrolysis is an urgent problem; it is of theoretical and practical importance. The possibility of enhancing the reactivity of gelatinized starch by intensive mechanical treatment in a rotary-pulsating activator (RPA) [1] has been poorly studied as yet. In such devices, a material is exposed to combined action of ultrasonic vibrations and strong shear stresses. Some features of the effect of such treatment in RPA on the state of starch hydrogels have been reported previously [2, 3]. The possibility of accelerating reactions of starch hydrogel with low-molecular-weight reagents by mechanical treatment was studied in [4] for the example of permanganate oxidation. Previously, it has been considered that shear strains are decisive factor in the enhancement of the starch reactivity. However, our new experimental data on the effect of both shear-free ultrasonic field [5] and RPA treatment on the state of starch hydrogels suggest that the role of the shear and ultrasonic action in the course of mechanical intensification of chemical processes in the gelatinized starch should be revised.

In this study, we examined the possibility of intensifying acid hydrolysis of starch under the influence of ultrasonic field and combined ultrasonic and shear treatment in a rotary-pulsating activator.

EXPERIMENTAL

In this study, we used corn starch [GOST (State Standard) 7697–82]. Starch hydrogels to be mechanically treated were prepared by cooking a starch suspension on a water bath at 90°C for 15 min.

The acid hydrolysis of gelatinized starch was performed by three methods: in a temperature-controlled vessel with ordinary stirring, in a temperature-controlled beaker with ultrasonic treatment (UZDN-2T ultrasonic pulverizer), and in a temperature-controlled RPA chamber.

Starch hydrogels were treated in a UZDN-2T ultrasonic pulverizer at 22 kHz; the volume density of the acoustic energy, determined by calorimetry, was 1.34 W cm^{-3}.

Starch hydrogels were also treated in a laboratory RPA. The working chamber of the activator is formed by a rotor and a stator, which are equipped with special fittings. The gap between the rotating and fixed elements of the working chamber in a given operation mode determines the tangential stresses in the liquid-phase material treated. The rotor rotation rate was varied in the 1000–5000 rpm range, and the gradients of the shear rate, within $(0.5–17.4) \times 10^4$ s^{-1}.

To confirm the occurrence of ultrasonic cavitation in the RPA working chamber, we used the standard test reaction $Fe^2 \rightarrow Fe^{3+}$ in an acidic medium. This reaction does not occur in the absence of ultrasonic cavitation [6]. The same reaction was used to determine the amount of ultrasonic energy absorbed by the material (using chemical dosimetry).

The starch concentration in the gels was 2–8%, and the process temperature, 20–70°C; the sulfuric acid concentration was varied within 0.03–0.15 M, and the time of mechanical treatment was 10–90 s.

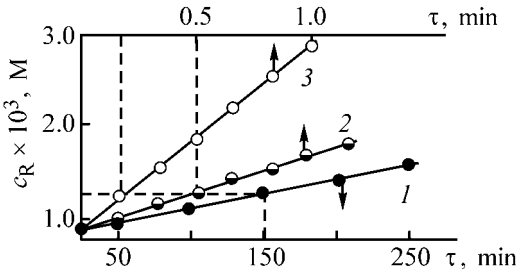

Fig. 1. Concentration c_R of the reducing groups accumulated in the starch hydrogel in the course of hydrolysis performed in (*1*) thermostat, (*2*) UZDN-2T, and (*3*) RPA vs. time τ; starch concentration 2 wt %, acid concentration 0.03 M.

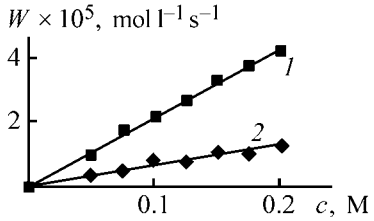

Fig. 2. Average rate W of accumulation of the reducing groups in the starch hydrogel vs. the sulfuric acid concentration c in the course of hydrolysis performed in (*1*) RPA and (*2*) UZDN-2T.

The rate of starch hydrolysis was determined from the data on accumulation of reducing groups [7]. In our case, the standard procedure to monitor the hydrolysis rate by a decrease in the solution viscosity, used under the common reaction conditions [8], is inapplicable, because hydrolysis under strong mechanical stresses is accompanied by mechanical dispersion of the starch (crushing of grains and their parts) and, thus, by a significant decrease in the viscosity, even in the absence of chemical reagents.

To analyze the origin of the mechanical (including ultrasonic) effect on the starch hydrolysis, we studied the dependences of the hydrolysis rate on temperature and concentrations of starch and acid and compared the results obtained for all the three treatment procedures.

It was found that, at the same temperatures and acid concentrations, application of a mechanical stress strongly accelerates the accumulation of the reducing groups. As seen from Fig. 1, one and the same concentration of the reducing groups, 1.25×10^{-3} M, is reached in 150 min in the case of the ordinary stirring, and in 30 and 13 s, respectively, in an ultrasonic field and after the RPA treatment. Before the experiments, we carried out blank tests in which the starch hydrogels were exposed to mechanical treatment without addition of acid. In this case, no increase in the concentration of the reducing groups was found. This fact indicates that the cavitation itself does not produce any significant amount of the reducing groups under the experimental conditions studied.

It is known that, under the conventional conditions (no mechanical stresses), the rate of the acid hydrolysis of starch is described by a first-order equation. The reaction rate is directly proportional to the acid concentration and is independent of the starch concentration [9]. Upon application of an ultrasonic field or upon RPA treatment, the accumulation rate of the reducing groups is a linear function of the acid concentration (Fig. 2).

To determine the kinetic order of the reactions proceeding in starch hydrogels under mechanical stress, we should take into account the features of the concurrent mechanically induced structural transformations. The kinetic dependences $\ln(c_0/c) = f(\tau)$, obtained for these reactions, are linear only up to a certain degree of hydrolysis, i.e., at some instant of time the rate constants calculated from the first-order kinetic equations begin to decrease. A decrease in the reaction rate constants with increasing degree of starch hydrolysis has been found previously for common reaction conditions [8]. This is probably due to the accumulation in solution of linear dextrins forming compact structures with higher energy of intermolecular interaction, which increases their hydrolytic stability. For comparative evaluation of the effect of various mechanical stresses on the reaction rate, we used the rate constants corresponding to the linear portions of the $\ln(c_0/c) = f(\tau)$ curves. The rate constants of the reactions performed in RPA and in an ultrasonic field are (on the average) higher by three orders of magnitude than those recorded for reactions performed under the ordinary reaction conditions at the same temperature and acid concentration.

Under the ordinary conditions, the hydrolysis rate of gelatinized starch is independent of the starch concentration in the hydrogel. The initial viscosity of these hydrogels varied within a wide range (0.01–1000 Pa s). The independence of the starch hydrolysis rate from the solution viscosity suggests that the process is kinetically controlled, and thus a strong decrease in the solution viscosity during the mechanical treatment cannot lead to pronounced changes in the hydrolysis rate under mechanical stress.

To evaluate how the mechanical degradation of the initial structure of the starch hydrogel affects the reaction rate, we performed a series of tests with pretreatment of hydrogels in RPA and UZDN-2T at 20°C. Immediately after such a treatment, the samples were

placed in a temperature-controlled flask, the required amount of acid (0.15 M) was added, and the hydrolysis as performed under the ordinary conditions at 60°C.

As seen from the table, after mechanical activation of the starch hydrogels the rate of its hydrolysis increases by nearly an order of magnitude, and this effect significantly decreases with increasing starch concentration. The dependence of the degree of reaction acceleration on the intensity and time of mechanical pretreatment is ambiguous. For example, after ultrasonic treatment of the starch hydrogel for 30 s, the increase in the reaction rate is greater than that after treatment for 60 s. This is probably related to the fact that [3], under strong mechanical stress, the breakdown of the initial gel structure is accompanied by formation of new compact structures through orientation and aggregation processes.

The above processes probably account for the dependence of the hydrolysis rate of starch on its concentration in the course of the reaction in an ultrasonic field or under ultrasonic treatment combined with mechanical shear stress in RPA (Fig. 3). Under ultrasonic treatment, the hydrolysis rate slightly decreases with increasing starch concentration, which is due to a decrease in the efficiency of the ultrasonic degradation of starch with its increasing concentration. The increase in the rate of the reaction performed in the RPA chamber with starch concentration decreasing to 2–3 wt % can be accounted for by the fact that the static pressure in the working chamber sharply grows with decreasing hydrogel viscosity, which, in turn, increases the erosion activity factor [10]. In other words, the degradation of the starch hydrogel structures is more profound at small concentrations. The rise in the rate of hydrolysis performed in RPA with growing starch concentration is due to an increase in the contribution of the shear stresses to the breakdown of the initial gel structure, and also to general activation of the system with simultaneous decrease in the contributions of the orientation and aggregation processes.

Without mechanical treatment, no hydrolysis of gelatinized starch is observed at acid concentration of 0.15 M and 20°C; in any case, no increase in the concentration of reducing groups was observed, at least, in the first 2–3 h. At 60°C and the same acid concentration, the hydrolysis rate is appreciable. The activation energy of the reaction without mechanical activation was calculated to be 206 kJ mol^{-1}.

The effect of temperature on the rate of acid hydrolysis of starch under high-intensity mechanical treatment (RPA and UZDN-2T) is ambiguous. For example, at 20–45°C the reaction rate is almost independent of temperature, which is typical of mechanochemical and, in particular, sonochemical reactions. At 60°C, the process appreciably accelerates. However, the activation energy is still significantly smaller (34 kJ mol^{-1}) than that of the reaction under the ordinary conditions. Above 50°C, the temperature dependence becomes stronger with decreasing rotor rotation rate n (Fig. 4a). The higher the rotation rate n,

the smaller the contribution of temperature to the rate acceleration. Thus, we obtain above 50°C a combined thermomechanical intensification of the process, and this is not a mechanochemical reaction in pure form. At lower temperatures, when the reaction does not occur at a given acid concentration under ordinary conditions and the reaction rate in RPA is independent of temperature, we can regard this process as mechanochemical, which allows calculation of the mechanochemical yield of the reducing groups (namely, the terminal hemiacetal carbon atoms C_1) formed in the course of hydrolysis.

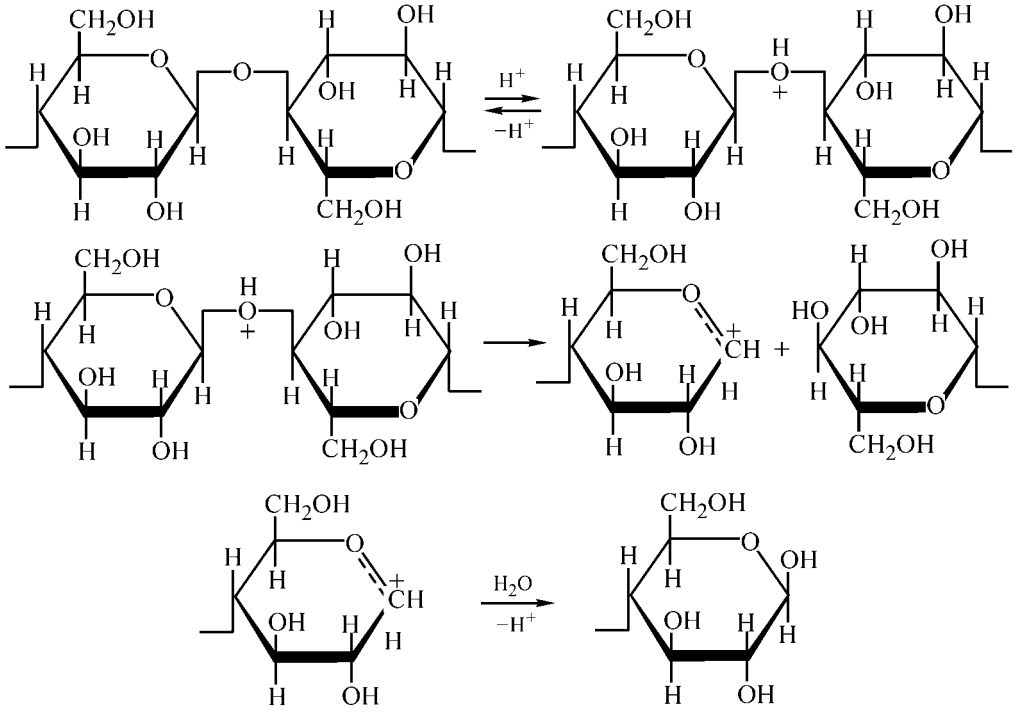
In our calculations, we took into account that formation of a single terminal reducing group corresponds to a single event of hydrolytic cleavage of the glycoside bond. The second terminal carbon atom C_4, situated before degradation on the other side of the glycoside bond, is not a reducing group. The number of reducing groups formed per 100 eV of absorbed energy E was calculated from the equation [6]:

$$F = \frac{\Delta c N_A}{1000 W_{ac}} \frac{100}{6.25 \times 10^{18} \tau},$$

where Δc is the change in the concentration of the reducing groups (CHO) in time τ; N_A, Avogadro number; W_{ac}, acoustic power density (W cm^{-3}); τ, time of mechanical treatment (s).

The acoustic power was measured by the method of chemical dosimetry, using a standard test system ($FeSO_4$ in 0.8 N H_2SO_4). For RPA and UZDN-2T, the acoustic power density was 2.57 and 1.34 W cm^{-3}, respectively. The sonochemical yields for UZDN-2T were 0.07–0.10 and the mechanochemical yields (RPA), 0.034–0.152 reducing group per 100 eV of absorbed energy. The close sonochemical (ultrasonic treatment) and mechanochemical (RPA) yields indicate that the acceleration of the acid hydrolysis under mechanical treatment in RPA is primarily related to the ultrasonic component of the combined treatment or, more precisely, to ultrasonic cavitation, because specifically the ultrasonic cavitation is the origin of the chemical effects in the ultrasonic field [11]. The contribution of the shear strains to the intensification of the hydrolysis of gelatinized starch in RPA is probably smaller than the cavitation effect.

The role of cavitation in aqueous solutions consists only in the decomposition of water molecules in cavitation voids to give H$^\cdot$ and OH$^\cdot$ radicals. The hydrolytic degradation of polysaccharides in the presence of acids proceeds by the following scheme: (1) protonation of the oxygen atom in the glycoside bond with formation of an oxonium ion, (2) dissociation of the oxonium ion with rupture of the glycoside bond and formation of the glycosyl cation, and (3) reaction of this cation with water:



Under the cavitation conditions, the limiting stage of formation of the glycosyl radical-cation and its further reaction with water are probably accelerated due to participation of the free radicals formed in water sonolysis.

As seen from Fig. 4b, the maximum reaction rate is observed at rotor rotation rate of 4000 rpm, whereas at 5000 rpm, the hydrolysis rate decreases. With increasing rotation rate, the frequency of ultrasonic vibrations in the RPA working chamber grows, and such an increase in frequency can decrease the rate of the sonochemical reactions [6].

CONCLUSIONS

(1) Under strong mechanical stresses (including ultrasonic treatment), the rate of acid hydrolysis of gelatinized starch increases, on the average, by three orders of magnitude. In this case, the acoustic cavitation is a decisive factor in the system activation, whereas the mechanically induced structural changes in starch hydrogels lead to an increase in the reaction rate by nearly an order of magnitude.

(2) The sonochemical yields of the reducing groups formed during the acid hydrolysis of starch under the ultrasonic filed and mechanical treatment in the rotary-pulsating activator were, respectively, 0.07–0.10 and 0.034–0.152 group per 100 eV.

Abstract—The swellability of a new material for protective coatings, ASMOL (asphalt–resin oligomer), in water and aqueous salt solutions was studied gravimetrically and by thermogravimetric analysis.

Pipelines are today the main means of transportation of crude oil, petroleum products, and natural gas. Various protective coatings are used for preventing pipeline corrosion. The reliability of protective coatings largely determines the failure-proof operation of pipelines. For example, almost 40% of all pipeline failures are due to corrosion damage.

The diversity of soil and climatic conditions under which pipelines are exploited, and also high mechanical and thermal loads impose stringent requirements upon protective coatings. The insufficient assortment of corrosion-protective materials produced in Russia and the growing requirements to their quality call for development and production of new insulating coatings suitable for diverse service conditions.

The first representative of a new generation of protective coatings is ASMOL (asphalt–resin oligomer) [1, 2]. ASMOL is a product of catalytic reaction of propane-precipitated asphalt with bottom residues from regeneration of dimethylformamide in isoprene production. ASMOL is a uniform product incorporating compounds of varied chemical nature. The main difference between ASMOL and asphalt is the presence in ASMOL of compounds containing highly polar functional groups and exhibiting chemical and surface activity: amide, sulfone, and sulfonic acid groups. Therefore, ASMOL has high adhesion to metals.

An important service parameter of polymeric protective coatings, determining the rate of metal corrosion, is their swellability in water and aqueous salt solutions. Therefore, we analyzed in this study the swellability of ASMOL in water and aqueous NaCl solutions.

EXPERIMENTAL

The swellability of ASMOL was determined in water and in 3, 6, and 9% NaCl solutions gravimetrically and by thermogravimetric analysis.

Two types of ASMOL samples were tested. Samples of the first type were neat 1.2–1.3-mm-thick ASMOL plates of the area 6 cm^2, and samples of the second type, St.3 steel plates coated on both sides with a 1.2–1-3-mm layer of ASMOL. The surface area of the ASMOL-coated steel plates was also 6 cm^2. In fabrication of samples of the second type, the coating continuity was checked visually.

Samples prepared for tests were placed in hermetically sealed vessels filled with water or aqueous salt solution and kept at room temperature (20–25°C) for a prescribed time. To determine the amount of absorbed water, samples were removed from the vessel, water drops were removed from the surface with filter paper, and the samples were weighed on an analytical balance. For thermogravimetric studies, a piece of the swollen material was separated from one of replicate samples. After weighing, the samples were returned to the same vessels. The swollen samples were weighed at 20–60-h intervals depending on the moisture absorption rate.

Thermogravimetric experiments with ASMOL were performed on an MOM derivatograph (Hungary). The sample weight was 100–200 mg. Thermal degradation of ASMOL samples was performed in open corundum crucibles in air. With the aim of uniform heating, the crucibles were placed in a quartz beaker. Aluminum oxide was used as reference. The heat-

1070-4272/03/7606-1002 $25.00 © 2003 MAIK "Nauka/Interperiodica"

ing rate was 5 deg min^{-1}. Samples were heated to 500°C. The error in determination of the weight loss did not exceed 0.2%.

To obtain reproducible results, we performed no less than three replicate runs. The experimental error did not exceed 5%.

Usually the parameter set by standards is the swellability of a protective material in water in 24 h. Although this parameter does characterize the tendency of a protective material to interact with water, it does not fully reflect the true protective properties of coatings based on this material, because such a short testing time is insufficient for the thermodynamic equilibrium to be attained. Therefore, we performed longer tests, for up to 5000 h.

The results of ASMOL swellability tests are shown in Figs. 1–3. It is seen that the ASMOL swellability is appreciably affected by two factors: time elapsed after ASMOL fabrication and concentration of salt solution. Therefore, the tests were performed in solutions with various NaCl concentrations, using ASMOL samples stored for 3 and 8 months after fabrication.

The water absorption in 24 h by ASMOL samples stored for 3 months after fabrication was 2.4% from water, 1.45% from 3% NaCl, 1.25% from 6% NaCl, and 1.12% from 9% NaCl solution. That is, the swellability of ASMOL is somewhat higher than that of asphalts [the swellability (water absorption) of asphalts under similar conditions is about 0.2%].

The swellability of ASMOL largely depends on the salt concentration (Fig. 1). In all the media, the kinetic curves of swelling do not flatten out. It should be noted that the ASMOL swelling curve in water differs essentially in shape from the curves obtained in salt solutions. In salt solutions, the water absorption rate considerably decreases in the initial period, becomes constant after 1000–1500 h, and remains on this level till the end of the tests. In distilled water, the curve has a complex shape. Its initial portion is similar to the initial portions of the water absorption curves in salt solutions. However, in contrast to salt solutions, the water absorption rate does not become constant. After 2500 h, the water absorption rate starts to grow sharply. After a 4500-h test, the water absorption was as large as 100% relative to the initial sample weight.

The complex shape of the water absorption curve suggests that the process is multistage. A microscopic examination showed that, in ASMOL samples kept in distilled water for 1500–2000 h, micropores and microcracks appear, which grow in size during longer tests. In 4000–4500 h, the samples break down.

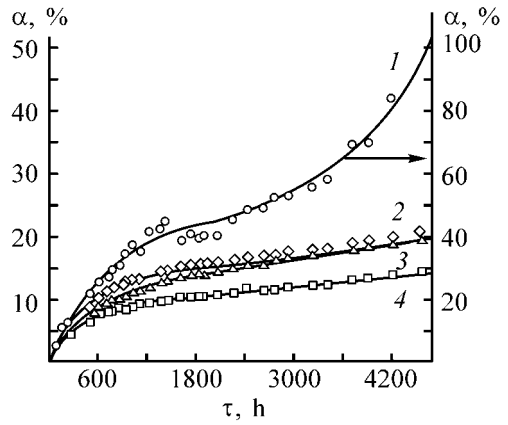

Fig. 1. Swellability of ASMOL protective coating in various media. Time interval between ASMOL fabrication and start of the tests 3 months; the same for Fig. 3. (α) Swellability and (τ) time; the same for Figs. 2 and 3. (*1*) Distilled water, (*2*) 3% NaCl, (*3*) 6% NaCl, and (*4*) 9% NaCl; the same for Fig. 3.

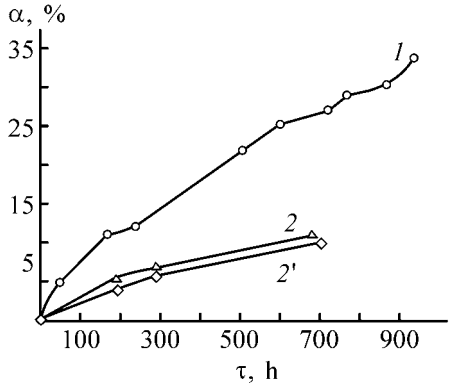

Fig. 2. Influence of the time elapsed after ASMOL fabrication on its swellability in distilled water. Time from ASMOL fabrication, months: (*1*) 3 and (*2*, *2'*) 8. Determination procedure: (*2*) gravimetric and (*2'*) thermogravimetric.

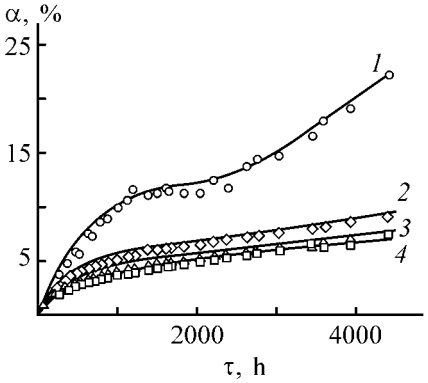

Fig. 3. Swellability of ASMOL protective coating on a steel support in various media.

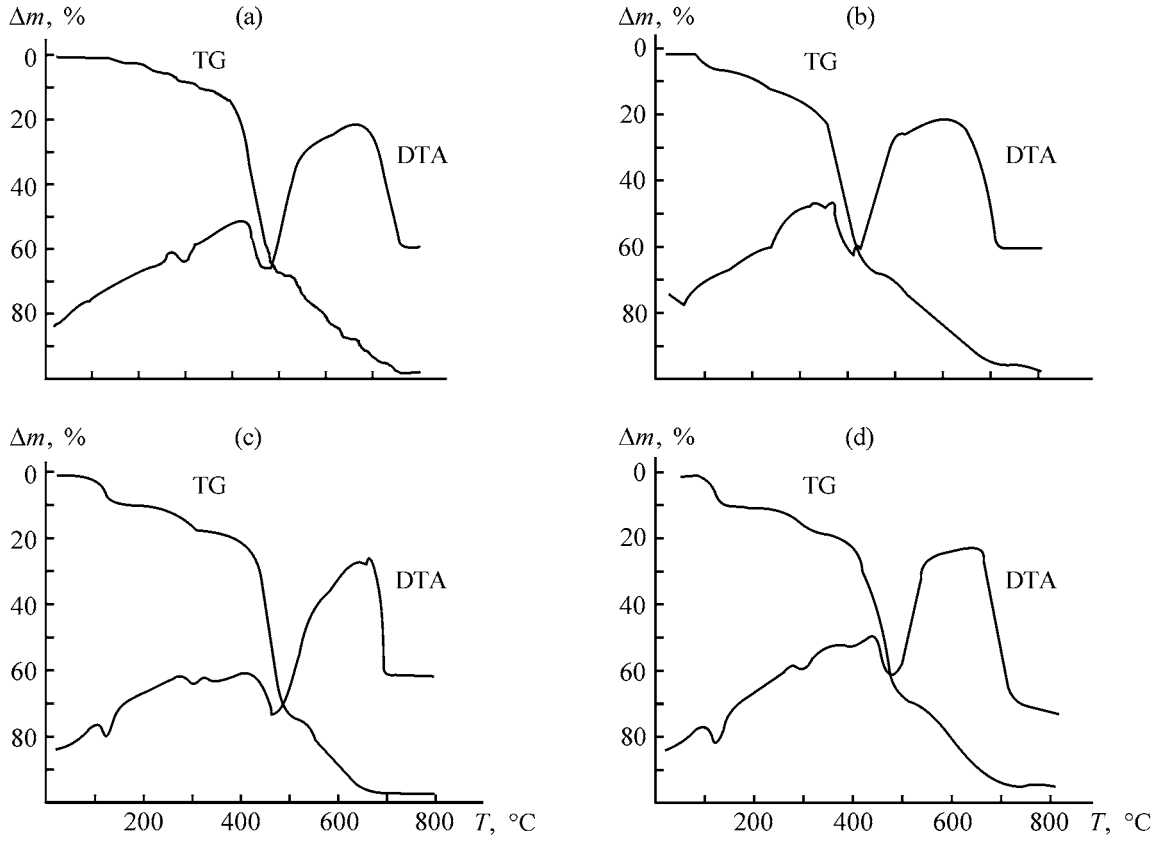

Fig. 4. Thermograms of an ASMOL protective coating: (a) unswollen and (b–d) swollen in distilled water for 312, 480, and 768 h, respectively. (Δm) Weight loss and (T) temperature.

The water absorption by ASMOL in salt solutions is by a factor of 5–6 lower than that in distilled water, decreasing as the salt concentration is increased. According to a microscopic examination, even after 4500-h tests the sample structure is not altered appreciably.

The swellability in water of ASMOL samples stored for 8 months after fabrication was lower than that of the samples stored for 3 months (Fig. 2) and amounted to 1.9% in 24 h. In 1000 h, the swellability of the former samples was lower by a factor of 3.

Experiments on water absorption of ASMOL on a steel support were performed with the samples stored for 3 months after fabrication.

We found that the swellability of ASMOL on a steel support was considerably lower than that of the neat sample (Fig. 3) and amounted in 24 h to 0.7% in water, 0.65% in 3% NaCl, 0.5% in 6% NaCl, and 0.4% in 9% NaCl solution. In 5000 h, the swellability of ASMOL on a steel support in distilled water was about 25%, i.e., it was four times lower than the swellability of the neat ASMOL sample. The swellability of ASMOL on a steel support in salt solutions is approximately half that of neat ASMOL. It should be noted that, despite different water absorption values, the curve of water absorption by ASMOL samples on a steel support is similar in shape to the curves obtained with neat ASMOL samples.

An examination of ASMOL samples on a steel support after 4500-h exposure to water and salt solutions showed that their external surface, initially lustrous black, became dark gray and dull (to 0.1–0.2-mm depth). The internal layers of ASMOL remained virtually unchanged in appearance. The ASMOL layer contacting the metal was harder than the initial ASMOL and had a brownish tint. The adhesion of ASMOL to the steel surface was very high; ASMOL could be separated only by cutting with a scalpel. Thermogravimetric studies showed that water is distributed in the ASMOL coating nonuniformly. The highest moisture content is observed in external ASMOL layers. The layers adjacent to the metal surface contain virtually no water.

To confirm the results of gravimetric studies of the ASMOL swellability and elucidate the character of water binding with ASMOL, we performed thermo-

gravimetric experiments. The curves obtained gravimetrically and thermogravimetrically (Fig. 2) virtually coincide.

The thermograms of ASMOL kept in distilled water for various periods of time are shown in Fig. 4. It is seen that the shape of the TG curves depends on the time of contact with water.

The TG curves of ASMOL samples kept in water have portions assignable to water removal. According to the TG curve of an ASMOL sample kept in water for 312 h, the weight loss occurs in a single stage at 70–100°C. The ASMOL samples kept in distilled water for 480 and 768 h lose weight in two stages: at 70–100 and 280–300°C. The presence of two portions of the weight loss in the TG curves suggests the two-stage mechanism of water removal. Apparently, in the first stage, at 70–100°C, physically adsorbed water located in ASMOL micropores is removed. The second stage, at 280–300°C, involves removal of water tightly bound to ASMOL components. This may be water that hydrates the sulfo groups of aromatic sulfonic acids present in ASMOL.

The IR studies confirmed this assumption. In the IR spectra of samples kept in water for 480 and 768 h, the stretching and bending absorption bands of water molecules had a complex shape.

Our studies showed that, in contrast to asphalt, a traditional material widely used for corrosion protection of pipelines, ASMOL absorbs more water. This is due to the presence of polar components such as sulfonic acids, sulfones, carboxylic acids, amines, amides, etc. The presence of these compounds imparts to ASMOL, on the one hand, high adhesion to metals and, on the other, increased swellability in water and salt solutions. However, our studies showed that increased swellability of ASMOL in water does not affect negatively its protective properties. By contrast, certain water absorption by ASMOL may be a favorable factor.

In the presence of small amounts of water at the steel–ASMOL interface, the sulfonic acids of ASMOL react with oxide films and corrosion products inevitably present on the metal surface, to form iron sulfonates. Chemical etching of the metal enhances the adhesion of ASMOL to the metal surface. Iron sulfonates partially dissolve in ASMOL and partially form a separate finely dispersed phase. Finely dispersed solid products of ASMOL reaction with steel are uniformly distributed in the surface layer of the coating, reinforcing it and thus enhancing the protective properties. Since sulfonic acid salts are hydrated considerably more weakly than free sulfonic acids, the swellability of ASMOL in water decreases as these salts are formed. This was confirmed by the thermogravimetric studies which showed that the ASMOL layer adjacent to the metal surface contains virtually no moisture.

Active sulfonic acids present in ASMOL gradually react with aromatic compounds to form sulfones, which are inert and highly stable. As the content of free sulfonic acids decreases, the swellability of ASMOL in water decreases, with the material becoming similar in this property to petroleum asphalts.

CONCLUSIONS

(1) ASMOL, a new corrosion-protective material, efficiently protects steel.

(2) Aromatic sulfonic acids and water present in ASMOL ensure formation of a strong protective layer at the steel–ASMOL interface.

(3) Active sulfonic acids present in ASMOL undergo spontaneous chemical transformations in the course of several months, yielding inert compounds; as a result, the swellability of ASMOL-based coatings decreases.

Thermodynamic Characteristics of Ni_3S_2 Compound Formation

A. G. Morachevskii and L. B. Tsymbulov

St. Petersburg State Polytechnic University, St. Petersburg, Russia
Gipronikel' Institut Open Joint-Stock Company, St. Petersburg, Russia

Received May 6, 2003

Abstract—Published data on thermodynamic properties of the Ni_3S_2 compound in the liquid and solid states are compared and discussed.

Compounds and melts of the nickel–sulfur system play important role in the technology of processing of copper–nickel sulfide ores. Procedures performed at relatively high temperatures with liquid and solid phases require detailed analysis. The nickel–sulfur system is characterized by complex phase diagram; at least five compounds, Ni_3S_2, Ni_7S_6, NiS, Ni_3S_4, and NiS_2, are formed, with the first three having two (low- and high temperature) modifications each. In the sulfur-rich part of the system, a separation region is observed [1].

The compound Ni_3S_2 containing 26.7 wt % S is of particular interest in technological regard. Its low-temperature phase is, to within error of analysis, a stoichiometric compound, known as heazlewoodite mineral contained in copper–nickel sulfide ores and other natural formations. The high-temperature phase, $Ni_3S_{2\pm x}$, having wide region of homogeneity, is stable above 823 ± 10 K. Alloys of the Ni–S system, corresponding to the composition Ni_3S_2, are in liquid state above 1073 K.

All the publications considered here are concerned with the standard Gibbs energy of formation of the Ni_3S_2 compound in solid or liquid states from solid nickel and diatomic molecular sulfur vapor (S_2, 1 atm) as a function of temperature. First data on the thermodynamics of Ni_3S_2 formation were obtained by Vol'skii and summarized in a monograph [2]. On the basis of these data, the standard Gibbs energy of Ni_3S_2 formation was estimated in the reference book by Gerasimov' *et al.* [3] to be (kJ mol^{-1}):

T, K	773	973	1173	1373	1573
ΔG_T^0, kJ mol^{-1}	–96.36	–80.00	–58.32	–47.36	–37.71

A ΔG_T^0 value of –177.6 kJ mol^{-1} for Ni_3S_2(s) at 1000 K was reported later by Rosenqvist [4], also on the basis of a study of the solid–vapor equilibrium.

Lin *et al.* [5] studied the thermodynamic properties of alloys belonging to the Ni–S system in the solid state in the central region of compositions in ample detail by the method of heterogeneous equilibrium. For the Ni_3S_2 compound, the following $\Delta G_T^0 = f(T)$ (kJ mol^{-1}) dependence was obtained within the temperature range 845–1040 K:

$$\Delta G_T^0 = -279.47 + 0.1028T. \quad (1)$$

Correspondingly, $\Delta G_{100}^0 = -176.67$ kJ mol^{-1} at 1000 K, which virtually coincides with the results of [4]. Mehrotra *et al.* [6] determined the standard Gibbs energy of N_3S_2 formation in solid (973–1089 K) and liquid (1089–1173 K) states by measuring the EMF in a cell with $ZrO_2 + Y_2O_3$ solid oxygen-conducting electrolyte. In contrast to the liquidus temperature of 1073 K, obtained previously for a composition corresponding to the Ni_3S_2 compound, a value of 1089 K was found in [6], which is, however, of no fundamental importance. The following results were obtained (kJ mol^{-1}):

$$\Delta G_T^0(Ni_3S_2, s) = -312.71 + 0.1297T, \ 973–1089 \text{ K}, \quad (2)$$

$$\Delta G_T^0(Ni_3S_2, l) = -252.80 + 0.0747T, \ 1089–1173 \text{ K}. \quad (3)$$

The enthalpy of melting of the phase of stoichiometric composition Ni_3S_2 is 59.91 kJ mol^{-1}. For alloys in the solid state

T, K	973	1000	1050	1089
ΔG_T^0, kJ mol^{-1}	–186.5	–183.0	–176.5	–171.4

1070-4272/03/7606-1006 $25.00

For alloys in the liquid state:

T, K	1089	1100	1150	117
ΔG_T^0, kJ mol^{-1}	–171.4	–170.6	–166.4	–165.2

The ΔG_T^0 values reported in [6] are close to the results obtained in [4, 5] at comparable temperatures. The above enthalpy of melting differs significantly from that (24.27 kJ mol^{-1}) reported by Kubashewski and Alcock [7], but is close to the value of 47.28 kJ mol^{-1}, obtained by Nagamori and Ingraham [8].

Hsieh and Chang [9] used the EMF method with zirconium dioxide solid electrolyte to study the equilibrium in the system Ni–S–O at $P(SO_2)$ = 1 atm. The constituents of such an equilibrium are the equilibria in the corresponding binary systems. Based on an analysis of published data, the authors of [9] recommended Eq. (1) for calculating ΔG_T^0 of Ni_3S_2(s). The error involved was estimated to be ±6 kJ mol.

Osadchii *et al.* [10] also demonstrated the possibility of using a solid electrolyte with anionic conductivity in a study of equilibria in the Ni–S–O system (at 850–1050 K). The data obtained were used to estimate, in particular, the ΔG_T^0 values for Ni_3S_2(s). In [10], these values were compared with those obtained previously by studying the heterogeneous equilibrium [5] (kJ mol^{-1}):

T, K	850	900	950	1000	1050
ΔG_T^0, kJ mol^{-1} [10]	–186.0	–181.9	–176.6	–170.2	–162.7
ΔG_T^0, kJ mol^{-1} [5]	–192.1	–187.0	–181.8	–176.7	–171.5

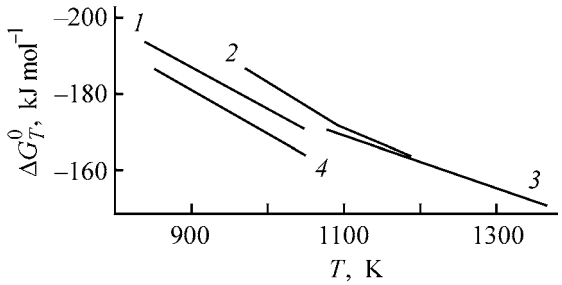
Let us consider data obtained in determining ΔG_T^0 for liquid Ni_3S_2. Nagamory and Ingraham [8] used the method of heterogeneous equilibria for studying the thermodynamic properties of the Ni–S system ($0.22 \le x_{Ni} \le 0.46$) at 973–1373 K. According to the data of [8], the standard Gibbs energy, ΔG_T^0, of Ni_3S_2(l) formation from solid nickel and gaseous sulfur (S_2, 1 atm) is expressed as a function of temperature by the equation (kJ mol^{-1}) [8]:

$$\Delta G_T^0 = -242.3 + 0.0665T \pm 0.8. \quad (4)$$

Equation (4) yields the following values of ΔG_T^0 (kJ mol^{-1}):

T, K	1073	1173	1273	1373
ΔG_T^0, kJ mol^{-1}	–170.6	–164.6	–156.3	–150.7

The $\Delta G_T^0 = f(T)$ dependence is plotted in the figure, according to the data of [5, 6, 8, 10]. With account of inaccuracies ranging from ±6.0 to ±8 kJ mol, the disagreement between results of these studies is not too pronounced. It seems reasonable to recommend use of the data presented in [5] for calculating equilibria involving solid Ni_3S_2 at 850–1050 K and the results of [8] for Ni_3S_2(l) in the temperature range from T_m to 1373 K. In this case, account should be necessarily taken of the standard states for nickel and sulfur, chosen in [5, 8]. According to [3], the ΔG_T^0 values from the monograph [2] are in error. This monograph presents data for heterogeneous equilibria involving Ni–S melts and $H_2S + H_2$ vapor, with equilibrium constants expressed in the ideal form.



Standard Gibbs energy ΔG_T^0 of Ni_3S_2 formation vs. temperature T, according to the data of different studies. Standard state: solid nickel and diatomic S_2 vapor at P = 1 atm. Data: (*1*) [5], (*2*) [6], (*3*) [8], and (*4*) [10].

Synthesis of Intermetallic Compounds $LaNi_5$ and $NdNi_5$ from Mixed Basic Carbonates of Lanthanum or Neodymium and Nickel

A. G. Burlakova, L. S. Volkov, and S. P. Shilkin

Institute for Problems of Chemical Physics, Russian Aacademy of Sciences, Chernogolovka, Moscow oblast, Russia

Received January 17, 2003

Abstract—The possibility of obtaining powdered $LaNi_5$ and $NdNi_5$ intermetallic compounds by reaction of mixed basic carbonates $La_2Ni_{10}(CO_3)_8(OH)_{10} \cdot 54H_2O$ and $Nd_2Ni_{10}(CO_3)_8(OH)_{10} \cdot 14H_2O$ with calcium hydride in a hydrogen flow at 1073 K and 10^5 Pa was studied.

Powdered intermetallic compounds of rare-earth and 3*d*-transition metals are used as hydrogen-sorbing materials [1] and materials for fabrication of magnets with high magnetic characteristics [2]. The production of such materials includes the stage of alloying of appropriate metals in electric-arc or vacuum induction furnaces with the subsequent grinding of the alloys under the action of hydrogen [1, 3, 4] or under exernal mechanic action in various ball-type activating mills [5, 6].

Presently, attention is attracted in laboratory and industrial practice to reduction-diffusion methods for obtaining intermetallic compounds containing rare-earth and 3*d*-transition elements. These techniques include reduction of mixtures of metal oxides, hyroxides, chlorides, carbonates with various reducing agents in hydrogen or an inert medium [2, 7, 8]. The advantage of this method is that it yields powdered intermetallic compounds with narrow fraction distribution and controlled chemical composition without stages of alloying and mechanic grinding of the alloys.

This communication describes synthesis of basic carbonates $La_2Ni_{10}(CO_3)_8(OH)_{10} \cdot (H_2O)_x$ and $Nd_2Ni_{10}(CO_3)_8(OH)_{10} \cdot (H_2O)_y$ and their reduction with calcium hydride in hydrogen with the aim of obtaining the intermetallic compounds $LaNi_5$ and $NdNi_5$.

To prepare mixed basic carbonates of lanthanum(III) [or neodymium(III)] and nickel(II), we dissolved starting $Ni(OH)_2$ in a solution of $LnCl_3 + 10HCl$ (Ln–La, Nd) in the ratio Ln : Ni = 1 : 5 under heating without boiling. Then we filtered the solution, added a solution of Na_2CO_3 to the filtrate in the ratio $Ln^{3+} : CO_3^{2-} = 1 : 4$, and added, in the course of 0.5 h under conditions of vigorous stirring, a 1.2 N solution of NaOH in the amount corresponding to the ratio $Ln^{3+} : OH^- = 1 : 5$. The suspension was allowed to settle for 15–20 h, then filtered, and the precipitate was dried in air at room temperature for 20–30 h. The powders obtained were X-ray-amorphous. According to IR spectral and chemical analysis data, their empirical composition corresponded to the formulas: $La_2Ni_{10}(CO_3)_8(OH)_{10} \cdot (H_2O)_x$ ($x \approx 54$) and $Nd_2Ni_{10}(CO_3)_8(OH)_{10} \cdot (H_2O)_y$ ($y \approx 14$).

To elucidate the role of molecular hydrogen and calcium hydride in reduction of mixed basic carbonates of La(III) [or Nd(III)] and Ni(II) with the abovementioned composition, we carried out the reaction in two stages. In the first stage, we placed a molybdenum container with a weighed portion of a mixed basic carbonate in a quartz reactor 20 mm in diameter and 600 mm in length, the reactor was purged with argon, the temperature in the hot zone of the reactor was raised to 1023 K for La(III) and Ni(II) basic carbonate and to 873 K for Nd(III) and Ni(II) basic carbonate, and the reactor was kept at these temperatures with flowing hydrogen for 2.5–3 h. The completion of the reaction was judged from termination of water drop formation in the cold part of the reactor. Thereafter the heating was switched off and the reaction mixture was cooled to room temperature in flowing hydrogen, then the reactor was purged with argon for 0.25 h, and the reaction products were discharged in an inert atmosphere. According to the results of X-ray phase analysis, the powders obtained were mix-

1070-4272/03/7606-1008 $25.00 © 2003 MAIK "Nauka/Interperiodica"

tures of nickel with lattice constant a_0 = 0.3521 nm and hexagonal modifications of La_2O_3 with a_0 = 0.4000, c_0 = 0.6340 or Nd_2O_3 with a_0 = 0.3963, c_0 = 0.6301 nm, which is in good agreement with published data and points to the absence of reaction between these compounds in the solid phase.

In the second stage, powders of Ni and La_2O_3 or Ni and Nd_2O_3 were mixed with CaH_2, placed in the same reactor, and kept in flowing hydrogen for 2.5–3 h at 1273 K. After cooling the reaction mass first in flowing hydrogen and then in argon, the reactor was discharged. In the case of lanthanum, the powder was washed first with distilled water cooled to 273 K, and then with ethanol and diethyl ether. The resulting dried powder was composed of the intermetallic compound $LaNi_5$. According to the results of chemical analysis:

Found (wt %): La 31.95, Ni 68.00.
$LaNi_5$.
Calculated (wt %): La 32.12, Ni 67.88.

An X-ray phase analysis of the powder indicated that only a single phase is present, which corresponds to the intermetallic compound $LaNi_5$ crystallizing to give hexagonal crystals with lattice constants a_0 = 0.5010 and c_0 = 0.3970 nm.

According to the results of reaction gas chromatography, the content of oxygen in the sample obtained was 0.2 wt %; a chemical analysis demonstrated that the content of calcium and chlorine did not exceed 0.1 wt %.

Since neodymium salts are more susceptible to hydrolysis than lanthanum salts, the desired compound was isolated from the reaction mixture using magnetic separation [9]. According to the results of chemical analysis:

Found (wt %): Nd 32.87, Ni 66.96.
$NdNi_5$.
Calculated (wt %): Nd 32.95, Ni 67.05.

As indicated by reaction gas chromatography, the content of oxygen in the sample obtained was about 0.2 wt %. The compound $NdNi_5$ crystallizes to give hexagonal crystals with lattice constants a_0 = 0.4963 and c_0 = 0.3974 nm, which is in reasonable agreement with published data for the reference intermetallic compound $NdNi_5$ obtained in an electric arc furnace (a_0 = 0.4926 and c_0 = 0.3957 nm) [10].

The size of powder particles, calculated in the approximation of their spherical shape, is about 220 nm for $LaNi_5$ and 400 nm for $NdNi_5$.

The powders of intermetallic compounds, obtained by the above procedure absorb about 6 mol of hydrogen per 1 mol of intermetallic compound in the reaction with hydrogen. The enthalpies of hydrogenation of the samples under study in the region of the $\beta \rightarrow \alpha$ transition, calculated from the experimental dependence of $\log(P[H_2])$ on inverse temperature, are (kJ mol^{-1} H_2): ΔH = –33.0 for $LaNi_5$ (ΔH = –32.9 for a molten alloy) and ΔH = –30 for $NdNi_5$ (ΔH = 30.1 for a molten alloy).

Thus, the reactions of mixed basic carbonates of composition $La_2Ni_{10}(CO_3)_8(OH)_{10} \cdot 54H_2O$ and $Nd_2Ni_{10}(CO_3)_8(OH)_{10} \cdot 14H_2O$ with calcium hydride in flowing hydrogen yield $LaNi_5$ and $NdNi_5$ powders without stages of alloying of the corresponding metals or their mechanic grinding.

EXPERIMENTAL

In this study, we used commercial pure-grade $Ni(OH)_2 \cdot 0.25H_2O$, basic nickel carbonate containing 47.6% nickel(II), chemically pure-grade Na_2CO_3, NaOH, hydrochloric acid, metallic lanthanum of 99.9% purity, 99.85% pure neodymium, 99.99% pure nickel, and calcium hydride of purity 99.9% with respect to H_2. Hydrogen-sorption characteristics of $LaNi_5$ and $NdNi_5$ powders were studied on a high-pressure installation by plotting isotherms of hydrogen pressure against the composition of the hydride phase at various temperatures [11].

We used a metal-hydride battery [12] as a source of high-purity hydrogen. The composition of the hydride phases formed in the reactions of intermetallic compounds with hydrogen, calculated from pressure changes in a calibrated system, was refined by a standard procedure of sample combustion in flowing oxygen. The thermodynamic characteristics of hydride formation were determined from the dependence of the equilibrium pressure of H_2 in the regions of the $\beta \rightarrow \alpha$ transition on inverse temperature.

We prepared the reference intermetallic compounds $LaNi_5$ and $NdNi_5$ by alloying calculated amounts of La or Nd with Ni in an electric arc furnace with a permanent tungsten electrode in the atmosphere of high-purity argon. The alloy samples were subjected to threefold remelting and then to homogenizing annealing at 950–1000 K for 500 h with the subsequent quenching in water at 273 K. The X-ray studies were carried out using the powder technique on an ADP-1 diffractometer (Cu_{K_α} radiation) equipped with a microcomputer controller. The error in determining the lattice constants did not exceed 0.0004 nm. The elemental chemical analysis of mixed basic carbonates

of La(III) or Nd(III) with Ni(II) and analysis of the final products of their reactions with CaH_2 and H_2 were carried out by the standard procedures.

All the operations involving loading and discharging of reactors, including sampling for analysis, were carried out in the atmosphere of argon.

CONCLUSION

Powders of the intermetallic compounds $LaNi_5$ and $NdNi_5$ were obtained without stages of high-temperature alloying and mechanic grinding of alloys. The compounds crystallize to give hexagonal crystals with lattice constants $a_0 = 0.5010$, $c_0 = 0.3970$ and $a_0 = 0.4963$, $c_0 = 0.3974$ nm, respectively.

Mechanochemical Treatment of Electrolytic Manganese Dioxide

Yu. S. Kononov, A. M. Zhizhaev, and V. V. Patrushev

Institute of Chemistry and Chemical Technology, Siberian Division, Russian Academy of Sciences, Krasnoyarsk, Russia

Received February 13, 2003

Abstract—The influence exerted by mechanical activation of electrolytic manganese dioxide under conditions ensuring insulation of the system from a reducing agent on parameters of chemical batteries based on the Zn–MnO_2 electrochemical system was studied.

Mechanochemical treatment of solid phases used as components of chemical power cells must change parameters of the power cells themselves because of the activation of components of the electrochemical system. However, the previously obtained data demonstrated a dramatic decrease in electric energy output for a Zn–MnO_2 power cell based on mechanically activated electrolytic manganese dioxide (EMD) [1]. The reason is that MnO_2 is partly reduced to Mn_2O_3 by iron from drum walls and grinding bodies in the course of grinding. As one more reducing agent in joint activation serves amorphous carbon (carbon black) added to improve the conductivity of the solid phase in fabrication of a manganese-zinc power cell. As a result, the cathode paste is virtually completely deactivated. Of interest is a study of the influence exerted on cell parameters by mechanical activation of EDM-2, with the activating system insulated from the reducing agent. This can be achieved by using drums lined with agate (or nephrite, or jasper) and the corresponding ball charge.

EXPERIMENTAL

As object of study served manganese dioxide synthesized electrolytically from sulfate media by a procedure described previously in [1]. The mechanical activation was done in dry mode in agate drums with agate grinding balls (diameter 10 mm) in a Fritch Pulverizette-5 mill (Germany). A weighed portion of EMD was 10 g, and the ball charge, 100 g. The mill worked in the batch mode, with acceleration factor of 12g [2]. Since this device is less energy consuming than the previously used M-3 centrifugal-planetary mill, the treatment duration was raised to 1, 5, and 10 min. The samples were subjected to X-ray phase analysis (XPA) on a DRON-3 diffractometer with Cu_{K_α} radiation at a scanning rate of 1 deg min^{-1}.

The prototype manganese-zinc power cell was fabricated from the initial and activated EMD fractions by a procedure also described in [1]. A 2.5-g weighed portion of initial or activated EMD powder was mixed with 0.3 g of carbon black to improve the electrical conductivity. The mixture was wetted in a measuring cell with 5 ml of electrolyte (10% $ZnCl_2$ + 20% NH_4Cl) and a zinc electrode was pressed against it. The discharge curve was recorded with a load of 10 Ω to U_{fin} = 750 mV.

Figure 1 shows discharge curves for samples based on the initial EDM-2 and that subjected to mechanical activation under the indicated conditions for 1, 5, and 10 min. The initial sample is characterized by a discharge curve with U_0 = 1810 mV and specific capacity of the active paste of 84 A h kg^{-1}. Discharge to U_{fin} = 750 mV occurs in 2.5 h (Fig. 1, curve *1*), which conforms to standard requirements to manganese-zinc power cells [3]. The discharge curves of activated samples are characterized by higher open-circuit voltage (with difference of up to hundreds of millivolts) and more prolonged discharge (Fig. 1, curves *2–4*), which, combined, give an increased specific capacity. Already after 1 min of mechanical activation, the discharge duration of a manganese-zinc power cell to 750 mV increases to 3 h. For manganese dioxide activated during 5 min, the discharge continues for nearly 4 h (Fig. 1, curve *3*). The specific capacity of the given EMD sample is as high as 122 A h kg^{-1}, which exceeds by nearly a factor of 1.5 that in the control sample (without activation). For power cells based on EDM-2 activated for 10 min, the parameters are somewhat inferior to those in the initial period of

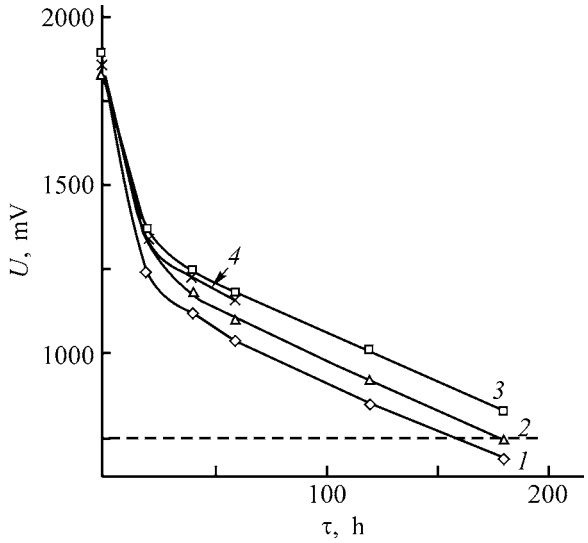

Fig. 1. Discharge curves of prototype manganese-zinc power cells fabricated from (*1*) initial and (*2–4*) mechanically treated MnO_2 powders. (*U*) Voltage and (τ) time. Duration of mechanical treatment (min): (*2*) 1, (*3*) 5, and (*4*) 10; the same for Fig. 2.

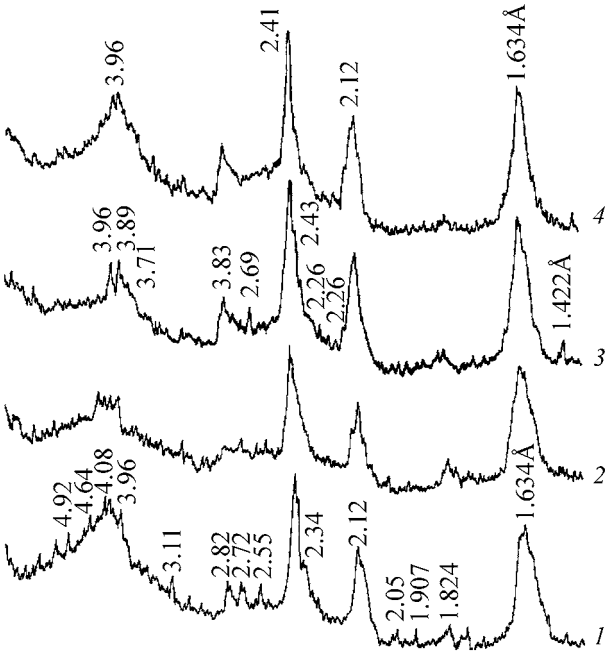

Fig. 2. X-ray diffraction pattern of (*1*) initial and (*2–4*) mechanically activated MnO_2 samples.

activation (Fig. 1, curve *4*). In further recording the discharge curve, a wide scatter of data obtained in parallel runs was observed, with, however, the parameters remaining, on the whole, better than those of the control samples. The irreproducibility of results is probably associated with heating of the material in prolonged mechanical activation. Heat elimination cannot be achieved because of the low heat conductivity of the agate material of the mill. A local rise in temperature leads to oxygen elimination from the crystal lattice of manganese dioxide to give a continuous series of nonstoichiometric manganese oxides, extending as far as bixbyite Mn_2O_3, with the fraction of the electrically active material decreasing [3, 4].

A certain role in the improvement of parameters of a manganese-zinc power cell can be played by surface renewal and by decrease in EMD particle size. However, additional experiments demonstrated that grinding of an initial sample in an agate mortar, with particle size decreasing from 0.16 to 0.063 mm, does not lead to any noticeable changes in the amount of electric energy produced. The contribution of the dimension factor is insignificant in the given case. In all probability, the electric energy output can be raised in the given conditions because of the higher manganese dioxide utilizing factor [3].

According to XPA (Fig. 2, curve *1*), the initial EMD sample is composed of a mixture of electrically active γ- and ε-MnO_2 (*d* 3.96, 2.41, 2.12, 1.634 Å JCPDS, 14–644, 30–820) with admixture of ramsdellite α-MnO_2 (*d* 4.64, 4.08, 2.55, 1.907 Å, JCPDS, 7–222) and pyrolusite β-MnO_2 (*d* 3.11 Å, JCPDS, 24–735) [3, 4]. Present in minor amounts are $Mn(O,OH)_2$ (*d* = 2.34 Å, JCPDS, 17–510) and oxide of the MnO_x series with $x < 2$ (e.g., $MnO_{1.88}$, *d* = 4.92 Å etc., JCPDS, 5–673). The presence of inert constituents is also seen from the shape of the peak at *d* = 1.634 Å, since closely spaced high-intensity lines of several forms of manganese dioxide overlap in this region. These lines show, however, a sufficient noncoincidence and form a broad serrate peak.

After mechanical activation for even 1 min, the amount of inert impurities becomes smaller, which is seen from a decrease (to the background level) in the intensity of peaks at *d* 2.40–3.00 and 4.20–6.00 Å (Fig. 2, curve *2*). Also decreases the intensity of reflections on the right-hand shoulder of the peak at *d* = 2.41 Å. After mechanical activation for 5 min, the amount of impurities falls to the lowest level. Only a weak peak of β-MnO_2 at *d* = 3.11 Å is observed (Fig. 2, curve *3*). Also seen are a number of lines at *d* 3.89, 3.71, 2.83, 2.69, 2.26 Å, which are identified as belonging to ε-MnO_2 (JCPDS, 30–820, 12–141). The shape of the peak at *d* = 1.63 Å, which has the highest intensity for this phase, is changed. Presumably, homogenization and redistribution of water molecules in the dioxide lattice leads to recrys-

tallization of the inactive α- and β-forms into γ-MnO_2. Simultaneously, long ε-MnO_2 channels are formed [3, 4]. Longer activation leads to partial disintegration of the superstructure, which is manifested in diffraction line intensity redistribution in favor of γ-MnO_2 (Fig. 2, curve *4*). No new phase formation is revealed in the given stage.

Thus, XPA shows that the main difference of the phase activated for 5 min from the initial EMD consists in decreased content of α- and β-MnO_2, which are inert in the manganese-zinc power cell, and increased content of ε-MnO_2, which is responsible for discharge duration. The specific capacity of EMD activated under the optimal conditions is as high as 122 A h kg^{-1}, which is 145% of that for the control sample. Such an increase in capacity should be regarded as rather good, since mechanical activation is not labor-consuming and can be done in a short time. It should be noted that the theoretical specific capacity of the EMD active paste is 308 A h kg^{-1} [3]. The increase achieved in this study constitutes only a minor fraction of the maximum possible value.

CONCLUSIONS

(1) Mechanical activation of electrolytic manganese dioxide in a centrifugal-planetary mill, with the system isolated from reducing agents, leads to an increase in the specific capacity of manganese dioxide by 20–45%.

(2) The improvement of parameters of manganese-zinc power cells fabricated from electrolytic manganese dioxide mechanically activated under these conditions is due to partial recrystallization of inert impurities into the electrically active form.

Preparation of Solder Powders and Properties of Low-Temperature Solder Creams Based on a Polyester Resin and Dimethylethylphenylammonium Iodide

N. I. Polezhaeva, I. V. Polezhaeva, V. A. Levdanskii, and B. N. Kuznetsov

Institute of Chemistry and Chemical Technology, Siberian Division, Russian Academy of Sciences, Krasnoyarsk, Russia

Received January 10, 2003

Abstract—Solder powders were prepared, and properties of solder creams based on rosin-modified polyester resin and dimethylethylphenylammonium iodide were studied. The possibility of using dimethylethylphenylammonium iodide as a flux in low-temperature solder creams was examined.

Solder creams consist of a powdered solder and an organic binder containing a flux [1]. Particles of the solder powder should have definite size and shape and should not be oxidized. The best results are obtained with particles 3–25 μm in size [2].

The functioning of a solder cream depends on the size of solder powder particles: The smaller the particles, the higher the probability of their oxidation. Oxidation can occur in the course of cream fabrication, after fabrication (before use), and during application. Oxidation of the solder powder is undesirable, since additional power is required to remove the oxide film.

Procedures for pulverizing solids are numerous [3]. The simplest procedure is mechanical grinding in special installations (mills or crushers). However, this procedure is unsuitable for grinding solders because of their high plasticity. Ultrasonic spraying of a molten solder is performed as follows. A molten solder is slowly poured onto the vibrating end of the concentrator of an ultrasonic atomizer and is sprayed in the form of drops, which are deposited after cooling as a powder in a special collector. The drawback of this procedure is that it requires sophisticated equipment; furthermore, it is difficult to prevent the powder oxidation in the course of the process. Spraying of a molten solder in a special sprayer with compressed gas also requires sophisticated equipment to obtain a high-quality powder.

This work continues our studies aimed at development of formulations of low-temperature corrosion-inactive solder creams with different melting points, using quaternary ammonium salts as fluxes [4–6].

EXPERIMENTAL

The solder powder was prepared as follows. The solder was placed in a glass reaction vessel, and VM-1S industrial oil was added. The mixture was heated to a temperature exceeding by 30–50°C the melting point of the solder, after which the electric stirrer was switched on. The mixture was cooled with stirring to a temperature below the melting point of the solder. Then the stirrer was switched off, and the powder was separated after sedimentation by decanting and washed with benzine and acetone.

From the obtained powders of various compositions, we prepared low-temperature solder creams based on the following solders: POSK 50-18, mp 160–180°C; solder of the composition 45% Sn, 29% Pb, 17% Cd, and 9% In, mp 160–180°C; and POIN-52, mp 120°C [7].

To determine the optimal particle size of the solder, we separated the powder by sieving into fractions with particle size of 1–10, 10–50, and 50–100 μm.

From these powder fractions, we prepared solder formulations applied onto contact areas of test printed-circuit boards. The contact areas were prepared by thick-film technology from Ag-containing and Ag–Pd conductor formulations, and also from thin-film copper conductors with a protective tin or gold coating. No significant catalytic effect of metals entering into

1070-4272/03/7606-1014 $25.00 © 2003 MAIK "Nauka/Interperiodica"

solder powder formulas on thermal oxidative degradation of the polyester resin was detected.

To prepare a solder cream, the chosen solder powder should be mixed with a binder containing a flux. As a flux we chose dimethylethylphenylammonium iodide (DMEPAI). A 2-g portion of DMEPAI was added to 15 g of a polyester resin prepared according to [4], and the components were thoroughly mixed.

The parameters of thermal oxidative degradation of the mechanical mixture of polyester resin with DMEPAI flux were determined by dynamic thermogravimetry [8]. To determine the temperature of the decomposition onset more accurately, we recorded not only TG, but also DTG (Fig. 1a) and DTA (Fig. 1b) curves. Experiments were performed with an MOM Q-1000 derivatograph (Hungary) in the programmed heating mode. A 0.03-g sample was heated in a platinum crucible in air at a rate of 10 deg min^{-1}. The sensitivity parameters were as follows: balance, 50 mg; DTA, 1/3; and DTG, 1/10.

The heat resistance of the polyester resin with DMEPAI was judged from the temperature of degradation onset (T_d^{DTG}, temperature at which the DTG curve starts to deviate from the baseline; T_d^{DTA}, temperature of the onset of the exothermic peak in the DTA curve, corresponding to the start of the oxidation) [9]. The results are listed in the table.

The degradation temperature T_d^{av} of a mixture of the polyester resin with DMEPAI is lower than T_d^{av} of the straight polyester resin; the shift is due to both enhanced chemical activity and increased specific surface area [8].

According to the TG and DTA curves, the DMEPAI flux degrades at 140–200°C. This means that DMEPAI is suitable as a component of solder cream formulations with melting point below 200°C.

To study the properties of solder creams, we prepared three formulations containing 15% polyester resin, 2% DMEPAI, and 83% one of the solder powders.

We found that the powder with particle size of 50 to 100 μm is too coarse; the cream with this powder is applied through templates badly and quickly undergoes phase separation in storage. The cream based on the finest powder (1–10 μm) is well applied through templates but requires increased amount of the organic binder; furthermore, in the course of tinplating, many fine particles remain suspended in the organic binder layer and do not form a continuous solder layer.

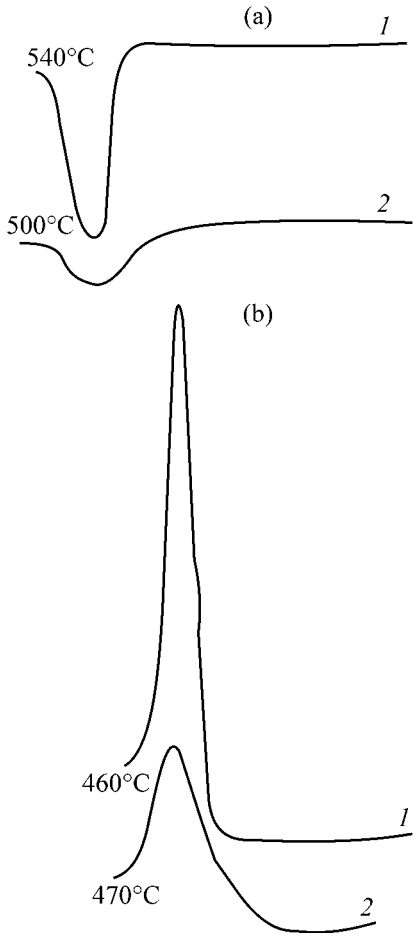

Fig. 1. (a) DTG and (b) DTA curves of (*1*) rosin-modified polyester resin and (*2*) mixture of the polyester resin with DMEPAI.

The optimal particle size is 10 to 50 μm. The solder creams based on this powder are well applied through bimetallic templates and ensure high-quality soldering upon fusion.

The quality of tinplating with solder creams was examined with an MBS-9 microscope at 8–16-fold magnification, following the procedure described in [6].

Parameters of the heat resistance of the samples, according to dynamic thermogravimetry

Sample	T_d^{DTG}	T_d^{DTA}	T_d^{av}
	°C		
Polyester resin	540	460	500
Polyester resin + DMEPAI	500	470	485

* $T_d^{av} = (T_d^{DTG} + T_d^{DTA})/2$ is the degradation temperature defined as the half-sum of the temperatures evaluated from the DTG and DTA data.

The adhesion of the solder cream layers to the contact areas after fusion was evaluated by the procedure involving detachment of the film from the contact area of the test printed-circuit board with an MR-05 tensile-testing machine [6].

With the contact areas prepared by the thick-film technology, the adhesion was no less than 50 kg cm^{-2}, and with those prepared by the thin-film technology, no less than 25 kg cm^{-2}. In most cases, the strength of the solder joint exceeded the adhesion of the contact area to the support.

CONCLUSIONS

(1) A procedure was developed for preparing solder powders for low-temperature solder creams, ensuring the required particle size and protection from oxidation in the course of fabrication.

(2) Formulations of low-temperature solder creams were developed, containing a polyester resin as an organic binder and dimethylethylphenylammonium iodide as a flux.

(3) With respect to the heat resistance, tinplating quality, and adhesion, the formulations developed meet the requirements to solder creams.

INFORMATION

XI Enikolopov Symposium

XI Enikolopov Symposium (March 13, 2003, Moscow) was held at the Enikolopov Institute of Synthetic Polymeric Materials (ISPM) (Moscow), Russian Academy of Sciences (RAS). The symposium was organized by RAS [Department of Chemistry and Materials Science, ISPM, Scientific Council for Macromolecular Compounds, Semenov Institute of Chemical Physics (Moscow), Institute for Problems of Chemical Physics (Chernogolovka, Moscow oblast)] and Moscow Physicotechnical Institute (Dolgoprudnyi, Moscow oblast).

The symposium program included four plenary lectures devoted to further progress of concepts formulated in his time by Academician Enikolopov.

N.Z. Lyakhov (Institute of Solid Fuel Chemistry and Mechanochemistry, Siberian Division, RAS, Novosibirsk) reported in his lecture the mechanism of formation of nanocomposites in mechanical alloying, including data on the initial stages of formation of nanocomposites in metallic systems. The lecturer gave analysis of general features of alloying and specific features of phase interaction in miscible (producing intermetallic compounds) and immiscible systems. It was illustrated by numerous examples that the resulting mechanocomposites are precursors of a new type for subsequent solid-phase reactions occurring in self-propagating high-temperature synthesis and also for synthesis of oversaturated solid solutions, etc.

From the standpoint of synthesis of practically important compounds and materials, an attempt was made to expand the previously developed approaches to systems of different types, including metal–oxide, metal–polymer, and layered systems.

Considerable interest was aroused in the audience by the lecture delivered by S.N. Chvalun (ISPM RAS), devoted to nanostructured polymeric hybrid materials. Nanostructured polymer–inorganic composites constitute one of the most important class of new synthetic hybrid materials. Directed design and manufacture of such materials with preset supramolecular nanostructure is a topical problem of modern science. The lecture covered preparation methods, major properties, and possible application areas of nanocomposites based on various ceramics, polymers, and oligomers. Special emphasis was made on the new class of layered ceramic-polymeric nanocomposites showing promise for practical use. Also, the lecture were considered various methods for preparation of metal–semiconductor–polymer nanomaterials in which inorganic nanoparticles demonstrate unique size-dependent electronic, photophysical, sensor, and catalytic properties.

The lecture given by O.A. Serenko (ISPM RAS) was devoted to composite materials based on plastic matrix and rubber particles. The lecturer considered deformation behavior of elastic particles in a plastic polymer and their effect on the stability of a composite material. He demonstrated that filled composites based on thermoplastics are characterized by definite critical content of rubber particles at which the materials abruptly lose their deformability, failing even at low ultimate elongations. By contrast, composite materials based on a plastic polymer demonstrate deformation without neck propagation and embrittlement.

In composites based on a plastic matrix and rubber particles, raising the filler content leads to successive change of the fracture mechanism, specifically, from neck propagation to brittle fracture and then from brittle fracture to macrouniform deformation. The first transition is accompanied by loss of deformability, and the second, by its increase. The increase in deformability in highly filled materials is due to localization of plastic flow of the matrix polymer in the microzones whose characteristic feature is their orientation. For example, it was demonstrated that the microzones are oriented perpendicularly to the stretching axis.

The fourth lecture given by V.A. Zhorin (Institute of Chemical Physics, RAS) was devoted to the effect of electrical factors on chemical and physical processes occurring in plastic deformation under high pressure. Exposure of solids of varied chemical nature to high pressure leads to a change in their electrical properties. In the case of organic insulators, at pressures of about 2 GPa, 2–3-fold increase in the permittivity was observed, and for some metal oxides this increase was as large as 50-fold. The conductivity of insulators decreases with increasing pressure, and

1070-4272/03/7606-1017 $25.00 © 2003 MAIK "Nauka/Interperiodica"

that of organic semiconductors increases by 3–4 orders of magnitude. Electron injection from a metal of the anvil has a strong effect on the conductivity of insulators. In the course of plastic deformation, the conductivity of different materials may increase 3 to 4–5 orders of magnitude. Applying magnetic and electric fields to compounds under investigation in the course of their high-pressure processing or introducing some functional additives, i.e., changing the electrical conditions of high-pressure experiments, allows control both over the course of chemical reactions and over structuring processes.

The results of the symposium demonstrate that Enikolopov's ideas are being successfully developed by his disciples and other scientists both in Russia and in other FSU countries.

Russian Journal of Applied Chemistry, Vol. 76, No. 6, 2003, pp. 1019–1022. Translated from Zhurnal Prikladnoi Khimii, Vol. 76, No. 6, 2003, pp. 1047–1050.

Nikolai Nikolaevich Kachalov (To 120th Anniversary of His Birthday)

Nikolai Nikolaevich Kachalov, a scientist, engineer, and pedagogue, made an outstanding contribution to the technology of manufacture and processing of glasses for various purposes, to the development of domestic glass industry, and to the science of glass.

N.N. Kachalov was born on June 21, 1883, in a cultured, high-born family of noblemen. His father, also Nikolai Nikolaevich Kachalov (1852–1909), was educated as naval officer and worked at the St. Petersburg Technical College of Telegraph Engineers with three-years education term from the time of its foundation, first as inspector (deputy director) and later, in 1895–1898, as director. He was honored engineer-electrician. It is during these years that the College was reorganized into Institute of Electrical Engineering with five-years education term (1898) and the construction of new building for the Institute was complete. The grandfather of the scientist-to-be, Nikolai Aleksandrovich Kachalov (1818–1891), a naval officer at the beginning of his career, later held high State posts and had a rank of privy councilor. His mother, Ol'ga L'vovna Kachalova (1859–1900), née Blok, was sister of A.L. Blok (1852–1909), professor of state law at Warsaw University, father of poet A.A. Blok (1880–1921). The Kachalov and Blok families were on intimate terms.

In 1900, after finishing secondary school, N.N. Kachalov entered the Mining Institute in St. Petersburg, one of the oldest higher school institutions of Russia (founded in 1773). At the beginning of the XX century, quite a number of prominent Russian scientists were among lecturers at the institute, including a specialist in mining mechanics I.A. Time (1838–1920), chemists I.F. Shreder (1857–1918) and N.S. Kurnakov (1860–1920), metallurgist V.N. Lipin (1858–1930), and electrical engineer M.A. Shatelen (1866–1957). When studying at the institute, N.N. Kachalov worked, in different years, at mining plants of Urals and Donetsk basin. This particularly refers to the period from 1904 till 1907, when studies at the institute were interrupted for a long time.

In 1911, having graduated from the Mining Institute, N.N. Kachalov went to work at the Imperial

Porcelain and Glass Factory at St. Petersburg (later Lomonosov Porcelain Factory) where he successively occupied positions of laboratory assistant, junior technician, and senior technician. In summer of 1910, N.N. Kachalov married Elizaveta Ivanovna Time (1884–1968), younger daughter of I.A. Time, professor of the Mining Institute. N.N. Kachalov's wife was an actor at Aleksandrinskii Theater in St. Petersburg and was already widely popular. For this reason the young family could not move to industrial regions of Russia, where graduates from the Mining Institute traditionally went to work.

N.N. Kachalov's activities at the factory were quite successful, and, in 1916, he became its technical director. World War I (1914–1918) posed a wide variety of important tasks to be accomplished by Russia's industry. To these belonged the necessity for organizing domestic manufacture of optical glass [1]. By N.N. Kachalov's initiative, a special board was created,

1070-4272/03/7606-1019 $25.00 © 2003 MAIK "Nauka/Interperiodica"

N.N. Kachalov. Sculpture (in glass) by V.I. Mukhina.

already in August 1914, for solving this complicated problem. The board included a number of leading scientists from St. Petersburg: academician N.S. Kurnakov and professors V.E. Grum-Grzhimailo, N.A.Pushin, D.S. Rozhdestvenskii, and V.E. Tishchenko [2]. On the suggestion of N.A. Pushin (1875–1947), a professor of the Institute of Electrical Engineering, direct supervision of work on melting was entrusted to his pupil, young lecture at the same institute, I.V. Grebenshchikov (1887–1953, academician since 1932). V.E. Grum-Grzhimailo (1864–1928), a professor of Polytechnic Institute, was charged with furnace design. Professor of physics, D.S. Rozhdestvenskii (1876–1940, academician since 1929) was a known specialist in the field of optics; V.E. Tishchenko (1861–1941, academician since 1935), a professor of St. Petersburg University, was the only member of the academic board who was experienced in glass melting. In 1896–1900, he developed stock formulations for 28 different brands of glass for chemical glassware. The problem of optical glass melting could not be solved in a short time without using the know-how of foreign companies. Pushin was sent to a business trip to London for difficult negotiations with British; N.N. Kachalov also went to Great Britain for completion of the negotiations. Grebenshchikov was the last to visit Great Britain with a group of master craftsmen for ascertaining details of meltings. The vigorous activities of N.N. Kachalov and Grebenshchikov, in which all the members of the academic board took an active part, resulted in that manufacture of optical glass was for the first time started in Russia. By the beginning of 1917, more than 8 tons of glass of satisfactory quality was manufactured [2].

Under N.N. Kachalov's supervision, manufacture of a new brand of porcelain (soft porcelain) was brought to a commercial level at the factory and technical porcelain was started to be produced for the first time. By scientist's initiative, a special building was erected on the territory of the factory for organizing in it a research center for glass and ceramics. During the civil war and the resulting period of collapse of the national economy, the manufacture of optical glass on the territory of the porcelain factory was closed down temporarily. However, an optical glass factory was created on its base already in 1923. N.N. Kachalov was appointed the technical supervisor of this factory, and Grebenshchikov and Rozhdestvenskii became consultants.

In 1918, State Optical Institute (GOI) was organized in Petrograd. Rozhdestvenskii was appointed its director and held this position till 1932. Grebenshchikov organized at this institute a chemical laboratory and headed it till the end of his life. In 1921, Grebenshchikov was sent to a business trip to Germany to purchase necessary materials and equipment and to visit German factories manufacturing optical glass. Later, during the period from 1932 till 1946, N.N. Kachalov also worked at GOI as deputy director, head of laboratory, and (beginning in 1937) consultant.

In 1923, work on refining of technology and improvement of optical glass quality was continued at Leningrad factory of optical glass. Unfortunately, not all members of the original academic board could take part in these activities. It happened so that, in the following years, Grum-Grzhimailo was a professor at Sverdlovsk (Yekaterinburg) University, and Pushin, a professor of the Zagreb University (Yugoslavia). However, Rozhdestvenskii's colleagues from the Optical Institute, known physicists A.A. Lebedev (1893–1969), A.I. Tudorovskii (1875–1963), and I.V. Obreimov (1894–1981), were among the participants. In 1926, a new rapid melting technology was developed, which differed significantly from the original method. Key experiments were performed in June 1926; these experiments were described in detail by journalist Yu.L. Alyanskii in his book devoted to the life and activities of N.N. Kachalov [3]. The duration of each melting was decreased (from 100 to 25 h), the output

capacity of the factory increased by a factor of 2, and the quality of the optical glass obtained conformed to most stringent requirements. The main contribution to the development of the domestic technology for glass manufacture for optical instruments was made by N.N. Kachalov, Grebenshchikov, and Rozhdestvenskii. The import of optical glass to the USSR was completely terminated in 1927 [4, 5].

During many years (from 1918 till 1930), N.N. Kachalov's activities were associated with the State Ceramic Institute. This institute was organized with his participation, and he held there a number of important positions. Under his supervision, extensive studies aimed to improve the technology of manufacture of refractory materials used in glass-making and investigations of the properties of high-quality domestic clays were carried out [4, 6]. The results obtained were summarized in a collective publication "Fireclays" (*Trudy Gos. Issled. Inst.*, 1929, issue 16).

In 1930, N.N. Kachalov was appointed head of the research sector of the All-Union Association of the optical-mechanical industry, where he was engaged in organization of research in the field of manufacture of optical-mechanical instruments. (till 1932) [7].

In 1930, N.N. Kachalov's pedagogical activities commenced at the Leningrad Technological Institute (LTI), where he organized the first chair of glass in the USSR and remained its head till the end of his life. Exceedingly important is N.N. Kachalov's contribution to training of high-skill engineers, many of his pupils became known specialists in the field of technology of inorganic materials and the glassy state. The chair of glass has always been rather popular with students of LTI.

The research activities at the chair developed in three directions: grinding and polishing of glass, manufacture of art glass and enamels, and development of new glass formulations and study of their properties. In 1935, a pilot glass-melting installation was constructed at the chair. This installation served as a basis for practical studies of students, experimental meltings, and execution of orders for manufacture of valuable brands of glass and enamels. At the same year, the laboratory of cold glass processing was organized at the chair. In 1935–1937, an extensive series of investigations carried out under N.N. Kachalov's supervision was devoted to development of a technology for mass production of polished sheet glass. The general theoretical concepts of glass polishing mechanism, developed by Grebenshchikov, served as a basis for extensive experimental studies of the influence exerted by various technological factors on the polishing process. Further, the results obtained in the study, in which a large group of laboratory staff members took part, were summarized by N.N. Kachalov in the monograph *Osnovy protsessov shlifovki i polirovki stekla* (Fundamentals of Glass Grinding and Polishing) (Moscow: Akad. Nauk SSSR, 1946). The monograph was awarded a State Prize in 1947.

In 1948, N.N. Kachalov organized the laboratory of cold processing of silicate materials at the Institute of Silicate Chemistry, Academy of Sciences of the USSR. The equipment of the laboratory with modern high-precision instruments and special devices made it possible to extend the scale of investigations into the physical and physicochemical essence of processes occurring in grinding and polishing of glass and other brittle materials.

A prominent place within the sphere of N.N. Kachalov's scientific interests was occupied by art glass and development of a technology for manufacture of large glass articles. In 1940, he initiated transformation of the Leningrad Mirror Factory into Plant of Art Glass, with an affiliated scientific laboratory. The main part of investigations was transferred from the chair of glass at LTI to the new laboratory and directly to the plant. The artistic supervision of plant was entrusted to a known sculptor, V.I. Mukhina (1889–1953), and the scientific and technological supervision, to the chair of glass at LTI. As plant's consultant was invited professor V.V. Vargin, a specialist in enamel manufacture.

The last N.N. Kachalov's capital work was the unique monograph *Steklo* (Glass) (Moscow: Academy of Sciences of the USSR, 1959), which unveiled the many-century history of glass, technology of its manufacture, and its application in technology, architecture, and art.

Among N.N. Kachalov and E.I. Time's friends were quite a number of prominent writers and artists. They included: A.N. Tolstoy (1882–1945), one of the most prominent Russian writers of the first half of the XX century; L.N. Sobinov (1872–1934), an exceedingly widely known singer; in later time, ballerina G.S. Ulanova (1910–1998). Unfortunately, N.N. Kachalov had no time to write recollections of his life, meetings, and nearest friends. To some extent this is compensated for by the book of E.I. Time's recollections *Dorogi iskusstva* (Avenues of Art) (Moscow: Vses. Teatr. O–vo, 1967), which was written with active participation of Nikolai Nikolaevich.

N.N. Kachalov's scientific, engineering, and pedagogical activities were highly appreciated. Already in 1933, he was elected a corresponding member of the Academy of Sciences of the USSR, Department of Chemical Science; in 1935, he was awarded an honorary title of Honored Scientist and Technologist of the Russian Soviet Federative Socialist Republic. N.N. Kachalov was honored with quite a number of State awards.

Nikolai Nikolaevich Kachalov passed away on June 19, 1961, and was buried in Leningrad at *Literatorskie mostki* (Writers' Footpath) at Volkovo Cemetery. In 1965, one of streets in Leningrad was named after professor N.N. Kachalov. In scientist's memory, memorial boards were mounted on the house where he lived from 1911 till 1961 (Vosstaniya ul., 6), in a hall at the Institute of Silicate Chemistry, and on the building of the Plant of Art Glass. The memory of the scientist is preserved by his numerous pupils.

Russian Journal of Applied Chemistry, Vol. 76, No. 6, 2003, p. 1023. Translated from Zhurnal Prikladnoi Khimii, Vol. 76, No. 6, 2003, p. 1051.

BOOK REVIEWS

Barbin, N.M., Kazantsev, G.F., and Vatolin, N.A., *Pererabotka vtorichnogo svintsovogo syr'ya v ionnykh solevykh rasplavakh* (Processing of Secondary Lead in Ionic Salt Melts), Yekaterinburg: Ur. Otd. Ross. Akad. Nauk, 2002, 178 pp.

The monograph is authored by N.A. Vatolin, academician of the Russian Academy of Sciences, and N.M. Barbin and G.F. Kazantsev, experienced researchers in the field of high-temperature electrochemical technologies. During quite a number of years, all of them have been paying much attention to processing of various technological wastes and, in particular, to utilization of secondary lead and search for ecologically safe technologies.

The book comprises a brief foreword and two parts, each constituted by chapters, conclusion, and bibliographic list. The foreword (pp. 5–6) notes that more than 50% of world's lead is manufactured by processing scrap lead and wastes. The authors point to a number of advantages offered by use of ionic melts in various technological processes.

The first part of the monograph, which comprises five chapters, is devoted to electrometallurgical processing of lead-containing wastes in a carbonate melt. The first chapter (pp. 10–30) briefly characterizes mainly pyrometallurgical methods for processing of lead-containing raw materials. The second chapter (pp. 31–53) describes physicochemical foundations of electrometallurgical processing of lead-containing compounds in a carbonate melt. Much attention is given to thermodynamic modeling of reduction of lead compounds in molten carbonates. The third chapter (pp. 54–80) contains evidence on processing of lead battery scrap and wastes from battery manufacture in a carbonate melt. The process is carried out at temperatures of 800–1050°C in electric furnaces with the use of various reducing agents. The fourth (pp. 81–99) and fifth (pp. 100–130) chapters are devoted to rather specific issues: processing of dust from shaft furnaces of Verkh-Neivinskii plant of secondary nonferrous metals and lead-containing wastes from copper-smelting plants. In the latter case, fine dusts caught by bag filters after shaft furnaces and converters (lead content 24–33 wt %) and products formed in hydrochemical processing of dusts, lead cakes (up to 42 wt % Pb) serve as objects of study. In all cases, molten carbonates are used as the reaction medium.

The second part of the monograph, which is smaller in volume, comprises four chapters considering the physicochemical foundations (pp. 142–160) and technology (pp. 161–172) of electrochemical processing of lead-containing wastes in hydroxide melts.

The bibliographic lists for the first and second parts of the book contain, respectively, 99 and 30 references to publications of mainly domestic authors. About 30% of all the published sources belong to the authors of the monograph.

Unfortunately, the book makes no attempt to analyze the present state of the problem of lead battery scrap, which is the most important, in economic and ecological regards, kind of secondary lead. The processing of battery scrap has nearly escaped the authors' attention. The monograph primarily presents the results of many-year authors' investigations, which are interesting and original, but are mainly devoted to minor kinds of lead-containing raw materials, dusts of shaft furnaces and wastes from battery manufacture.

The book summarizes a vast experimental material, evidence obtained in laboratory and pilot-plant studies, and results of mathematical modeling. All these data may be of interest for scientists, engineers, and technicians working in the field of utilization of secondary lead. The book is well published and contains a large number of tables and figures.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Alloying Elements on the Temperature Dependence of the Rate Constants and on the Activation Energy of Oxidation of Titanium Alloys

V. I. D'yachkov

St. Petersburg State University, St. Petersburg, Russia

Received December 6, 2002

Abstract—The influence exerted by the nature and concentration of alloying elements on the temperature dependence of the rate constants and on the activation energy of oxidation of titanium alloys in air at 823–1473 K was considered.

Available literature on oxidation of titanium alloys contains no systematic data on the effects of alloying elements on such important characteristics of the process as the temperature dependence of the rate constants and the activation energy of oxidation. The authors often restrict the consideration to the estimation of the effect exerted by alloying elements on the heat resistance of alloys, without identification of the oxidation kinetic law. At the same time, the knowledge of these characteristics is useful for comprehensive understanding of the complicated oxidation mechanism.

Such studies are also appropriate in view of the fact that, according to previous data [1–10], in contrast to the data of other authors and partly of [11], the oxidation of titanium and all its alloys indicated below proceeds in a nonstationary (transient) mode in which diffusion and interphase reactions exert comparable effects on the total rate of the process. The validity of the Evans equation supports this conclusion [12]:

$$K_l q^2 + K_p q + K_l K_p \tau = C,$$

where q is weight; τ, time; C, a constant; K_l and K_p, rate constants of the oxidation by the linear and parabolic laws, respectively.

In this study we analyze the effects exerted by the nature and concentration of alloying elements and by the temperatures and duration of tests on the temperature dependence of the rate constants and on the activation energy of oxidation of titanium alloys in air at 823–1473 K.

The corresponding data on the temperature dependence of K_l and K_p were obtained for titanium (purity 99.93%) and alloys with the following contents of alloying elements (wt %): Ti–0.6, 2.2, 3.4, 4.7, 5.9 Al; Ti–1.9, 7.4, 14.2 Zr; Ti–2.0 Al–2.5 Zr (PT-7M); Ti–1.5, 5.0, 10.0 Fe; Ti–0.5, 0.9, 3.0 V; and Ti–5.2 Al–1.2 V–1.1 Mo. The experimental technique and the process for preparing alloys were published earlier [1, 4].

According to [1–10], the Evans equation virtually adequately describes the oxidation rate (3 h) of titanium and its alloys at 923(973)–1373(1473) K. It is valid also in the initial stage of the test at 723–898 K, being replaced then by a cubic or approximately cubic law. When the above-mentioned materials are oxidized (3 h) at $T \geq 973(1023)$ K, two Evans equations with different K_l and K_p values are usually followed sequentially. For reasons given in [10], to increase the descriptiveness of the data on the temperature dependence of these constants, in this work we used their values for the initial and subsequent periods of oxidation, $K_l^{(1)}$, $K_p^{(1)}$ and $K_l^{(2)}$, $K_p^{(2)}$, respectively.

The temperature dependences of $K_l^{(1)}$ and $K_p^{(1)}$ for titanium and some of its alloys are shown in the figure, and the apparent activation energy E of the oxidation calculated by the linear (E_l) and parabolic (E_p) laws for the initial ($E_l^{(1)}$, $E_p^{(1)}$) and the subsequent ($E_l^{(2)}$, $E_p^{(2)}$) stages of the test are given in the table. For each combination of $E_l^{(1)}$, $E_l^{(2)}$ and $E_p^{(1)}$, $E_p^{(2)}$, the corresponding temperature ranges of their validity are indicated. When the boundaries of the temperature ranges for the both periods of oxidation mismatch, their values for the second stage of the test are given in parentheses. The accuracy of the determination of E for titanium is ~(3–5)%, and that for alloys is

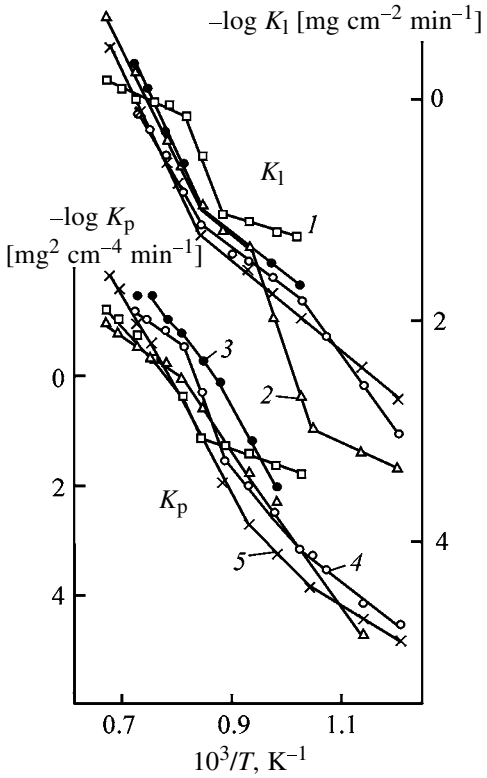
±(3–7)%. The E_l and E_p values were calculated from the slopes of the linear portions of the temperature dependences of therate constants.

It follows from the table and figure that the temperature dependence of K_l and K_p in both stages of oxidation for the majority of compositions is characterized by bends in the range 1123–1173 K, and in the case of titanium, PT-7M, and some alloys of the systems Ti–Al and Ti–Zr, oxidized at 823–1473 K, also in the range 923–973 K. Moreover, for Ti there are two bends in the $\log K_p = f(1/T)$ curve: at 1123(1073) and 1223(1173) K, and in the case of Ti–Fe, also in the $\log K_l = f(1/T)$ curve at 1123(1173) and 1223(1273) K. It should be noted that, in [13], three zones with different values of the activation energy were detected for the oxidation of technical-grade titanium in air in the range 1073–1373 K. At the same time, the Ti–0.5, 0.9 V and Ti–7.4, 14.2 Zr alloys have no bend in the $\log K_p = f(1/T)$ curve in the range 1123–1223 K. Similar trends are observed for PT-7M in the case of $\log K_l = f(1/T)$ and for Ti–5.2 Al–1.2 V–1.1 Mo in the case of both dependences. However, the temperature coefficients of $K_l^{(2)}$ and $K_p^{(2)}$ for all the alloys, except for Ti–5.2 Al–1.2 V–1.1 Mo and for Ti–7.4, 14.2 Zr ($K_p^{(2)}$), undergo the corresponding changes.

For the majority of compositions, the temperature coefficients $K_l^{(1)}$ and $K_l^{(2)}$ increase in going to the region above the temperatures of the bend T_{bend}, in contrast to the PT-7M alloy and partly to the Ti–Fe alloy. On the contrary, the dependence $\log K_p = f(1/T)$ in both stages of oxidation is characterized by a decrease in the slope at the last bend in the range 1023–1473 K, except for the alloys Ti–Zr, Ti–0.5, 0.9 V, and Ti–5.2 Al–1.2 V–1.1 Mo, for which this dependence is linear in the first or in both stages of the test.

The table shows that the T_{bend} values for the $\log K_l = f(1/T)$ and $\log K_p = f(1/T)$ dependences in both stqages of the oxidation ($T_{bend}^{l_1}$, $T_{bend}^{l_2}$ and $T_{bend}^{p_1}$, $T_{bend}^{p_2}$) above 973(1023) K are equal for the majority of compositions within the limits of each dependence. In the first case, the exceptions are Ti–5.9 Al, Ti–5.0 Fe, and PT-7M alloys, whereas in the second case these are Ti and Ti–0.6, 4.7 Al, Ti–1.5 FE, PT-7M, and conventionally Ti–0.5, 0.9 V, owing to a change in the shape of the dependence $\log K_p = f(1/T)$ in going from the initial to the subsequent periods of oxidation. A feature of pure Ti is that, in going from the initial to the subsequent periods of oxidation, the boundaries of the 1123–1223 K range shift by 50 K toward lower temperatures (1073–1173 K), with retention of the dependence type.



Temperature dependence of K_l and K_p for titanium and its alloys. (K_l, K_p) rate constants of the oxidation calculated by the linear and parabolic laws, respectively; (T) temperature. Alloy (wt %): (*1*) Ti–5.0 Fe, (*2*) Ti–4.7 Al, (*3*) Ti–3.0 V, (*4*) Ti and (*5*) Ti–7.4 Zr.

As K_l and K_p characterize mutually dependent processes, it was natural to expect that T_{bend}^{l} and T_{bend}^{p} for both oxidation stages of oxidation will coincide. In fact, in the initial stage of the test of the Ti–2.2, 3.4, 5.9 Al and Ti–Fe alloys, $T_{bend}^{l_1}$ and $T_{bend}^{p_1}$ fully coincided. For the other compositions (Ti–0.6 Al, Ti–1.9 Zr, Ti–V, and PT-7M) $T_{bend}^{l_1}$ is less than $T_{bend}^{p_1}$, and in the case of Ti–4.7A1 and Ti–7.4 Zr, on the contrary, $T_{bend}^{l_1}$ is higher than $T_{bend}^{p_1}$. In the second oxidation stage, titanium and Ti–Al, Ti–Fe alloys have virtually equal values of $T_{bend}^{l_2}$ and $T_{bend}^{p_2}$, whereas for PT-7M and Ti–V $T_{bend}^{l_2}$ is lower than $T_{bend}^{p_2}$. However, the difference between T_{bend}^{l} and T_{bend}^{p} usually do not exceed 50 K, which in many cases is the temperature interval between separate experiments.

The changes in the slope of the dependences $\log K_l = f(1/T)$ and $\log K_p = f(1/T)$ in the range 1123–1223 K, apart from other reasons, are associated with

the effect exerted on the oxidation by the allotropic $\alpha \leftrightarrows \beta$ transition in the metallic phase. This transition takes place in pure titanium at 1155 K. It is accompanied by weakening of interatomic bonds in the metallic lattice, by excitation of atoms, and, therefore, by changing conditions for occurrence of an interphase reaction on the metal–gas boundary and for diffusion. The rate constants K_l and K_p of these processes characterize the nonstationary oxidation at $\tau \to 0$ and $\tau \to \infty$, respectively, since an α-layer with a constant surface concentration of oxygen, close to the equilibrium concentration for pure titanium, is formed in the outer zone of the matrix even in the initial stage of the test [14].

The effect of the $\alpha \to \beta$ transition on the oxidation is manifested not only at the equilibrium temperature, but also in a certain temperature range. In particular, this is due to the fact that the equilibrium temperature of the $\alpha \to \beta$ transition on the metal surface is much lower (by 80 K) than in the bulk metal [15]. A considerable increase in the slope of the dependence $\log K_p = f(1/T)$ in the range 1073–1173 K can be also associated with this phenomenon. Above 1173(1223) K, the surfaces and volumes of matrices of all the materials under consideration have the same β-structure [16]. The corresponding decrease in the temperature coefficient K_p is due, at least partly, to a smaller energy consumption for the diffusion of oxygen in the β-phase compared to the α-modification [17], and, according to [18], the transition to the range of $T > 1173$ K is accompanied by a considerable decrease in the temperature coefficient of the total oxygen uptake by the metal. These features of the temperature dependence of K_p largely result also from changes with temperature in the contributions of bulk and intercrystallite diffusion, scaling, and growth of the diffusion oxygen layer (DOL) to the total oxidation process, and also in the equilibrium of defects in the oxide.

According to the table and figure, the T^{l}_{bend} value (1173 K) remains practically unchanged above 1073 K in going from titanium to the Ti–0.6 Al, Ti–7.4, 14.2 Zr, PT-7M, Ti–1.5, 10.0 Fe, and Ti–V alloys. However, T^{l}_{bend} increases to 1273 K as c_{Al} increases, whereas it tends to decrease as compared to titanium when c_{Fe} increases. To a first approximation, this is attributable to the effect of these elements on the temperature of the $\alpha \to \beta$ transition in the metal. Thus, aluminum as an α-stabilizer increases the temperature of the $\alpha \to \beta$ transition, which is higher by almost 100 K than for pure titanium [16] at c_{Al} = 5.9%, whereas iron, on the contrary, stabilizes the β-phase. The dependence of T^{p1}_{bend} on c_{Al} and c_{Fe} is similar, though it is less pronounced for the Ti–Al alloys. It should also be noted that T^{p1}_{bend} decreases as c_{Zr} increases in alloys at $T > 973$ K.

In most cases, $T^{l1}_{bend} = T^{l2}_{bend}$ and $T^{p1}_{bend} = T^{p2}_{bend}$, except for Ti, PT-7M, Ti–0.6, 4.7 Al, and Ti–1.5, 5.0 Fe.

According to the table, three temperature zones with different E_l and E_p values can be distinguished for titanium in the range 823–1473 K: 823–973, 973–1173(1223), and above 1173(1223) K. In going from the first zone to the second zone, $E_l^{(1)}$ decreases, and $E_p^{(1)}$, on the contrary, increases. Approximately a half of the alloys demonstrate a similar variation of $E_p^{(1)}$ and an opposite variation of $E_l^{(1)}$, whereas in the remaining cases their values within the limits 823–1173(1223) K remain virtually constant. The absence of data for $E_l^{(2)}$ and $E_p^{(2)}$ at 823–973 K in the table results from the fact that the Evans equation is usually valid in this range only in the initial stage of the test. The transition to temperatures higher than 1173(1223) K, as already noted, is accompanied by an increase in E_l and a decrease in E_p in both stages of the oxidation of titanium and majority of the alloys. The exceptions with respect of E_l are mainly Ti–Fe alloys, and in the case of E_p, Ti–Zr and PT-7M alloys.

The values of E_l are lower than the values of E_p for all the compositions in the range 823–1173 K. At the same time, in many cases (Ti–Al and Ti–V) at $T >$ 1223 K, especially in the second stage of the oxidation, the relationship is opposite. It can be treated as growth of the relative contribution of interphase processes to the control of the overall oxidation rate with temperature, which does not contradict the existing theoretical concept of the temperature effect on the energy consumption for diffusion and interphase processes [19].

Let us consider the effect of material composition on E_l and E_p in various temperature ranges. In the range 823–973 K, the alloying of titanium with up to 2.2 wt % aluminum leaves E_l practically unchanged, and at $c_{Al} > 2.2$ wt % it gives rise to its decrease. In this case, as c_{Al} increases, E_l tends to decrease, whereas as c_{Zr} grows, E_l clearly tends to increase. Titanium and Ti–Al alloys with a low Al content have the maximal values of E_l, and Ti–1.9 Zr and PT-7M, the minimal values. In the range 973–1173 K, $E_l^{(1)}$ and $E_l^{(2)}$ for the majority of alloys, except for Ti–Fe, are

higher than those of titanium. As c_M in the Ti–Al alloys increases, $E_l^{(1)}$ and $E_l^{(2)}$ clearly tend to increase, as well as $E_l^{(2)}$ in the case of Ti–Fe, whereas in the case of the Ti–Zr and Ti–V alloys they decrease, as well as $E_l^{(1)}$ in the oxidation of Ti–Fe. The highest values of $E_l^{(1)}$ and $E_l^{(2)}$ in the range 973–1173 K are observed for the Ti–Al ($c_{Al} > 3.4\%$) and PT-7M alloys, and the lowest, for titanium and Ti–Fe. At $T >$ 1173(1223) K, the alloying of titanium with vanadium increases $E_l^{(1)}$, and in most of the remaining cases it is accompanied by its decrease. With respect of $E_l^{(2)}$, a similar behavior is observed for the Ti–Fe, Ti–1.9 Zr and PT-7M alloys, whereas its values for the remaining compositions are higher than for titanium. As c_M in the Ti–Al [c_{Al} = 0.6–2.2%] and Ti–Zr alloys increases, $E_l^{(1)}$ tends to increase, and in the case of Ti–Fe and Ti–V it tends to decrease. The same pattern is observed for $E_l^{(2)}$ in the oxidation of the Ti–Al and Ti–Fe alloys, in contrast to Ti–Zr and Ti–V. At $T >$ 1173(1223) K the most energy-consuming interphase processes occur in both stages of the oxidation of Ti–V and partly of Ti–Al alloys, whereas Ti–5.0, 10.0 Fe has the minimal $E_l^{(1)}$ value and Ti–1.9 Zr and PT-7M, the minimal $E_l^{(2)}$ value.

In the initial stage of the oxidation at 823–973 K, the energy consumption for diffusion processes in Ti–Al alloys is higher, and in the case of Ti–Zr and PT-7M, lower than for titanium, and it tends to decrease as c_{Al} (<4.7 %) and c_{Zr} increase. In the range 973–1123 K, the alloying of titanium with iron (up to 5.0%) decreases $E_p^{(1)}$. For the other compositions, $E_p^{(1)}$ and $E_p^{(2)}$ are mostly higher than for titanium. As C_M in the Ti–Al ($c_{Al} \le 3.4\%$) and Ti–Zr alloys increases, $E_p^{(1)}$ and $E_p^{(2)}$ tend to decrease, and in the case of Ti–Fe and Ti–Al ($c_{Al} > 3.4$ %) they clearly increase. In this case, the PT-7M and Ti–V alloys have the highest $E_p^{(1)}$ and $E_p^{(2)}$ values, and Ti–1.5, 5.0 Fe, the lowest $E_p^{(1)}$ values.

In the range 1123(1073)–1223(1173) K, all the alloys under consideration (except partly Ti–Fe) are characterized by the lower energy consumption for diffusion processes in both stages of oxidation, as compared to titanium. As c_{Al} and c_{Zr} increase within certain limits, $E_p^{(1)}$ and $E_p^{(2)}$ decrease, whereas with increasing c_V and c_{Fe} they tend to grow.

In the range $T >$ 1223 K, the alloying of titanium mostly increases $E_p^{(1)}$. The alloys Ti–Zr and PT-7M have higher $E_p^{(2)}$ values than titanium, whereas in the case of Ti–V, Ti–3.4, 4.7, 5.9 Al, and Ti–5.0 Fe the relationship is reverse. As c_{Al} and c_{Zr} increase, $E_p^{(1)}$ and $E_p^{(2)}$ tend to decrease, and in the case of increasing c_{Fe} they tend to grow. As c_V increases, $E_p^{(1)}$ decreases nonmonotonically, and changes in $E_p^{(2)}$ do not exceed the experimental error. The Ti–Zr alloys are characterized by the greatest energy consumption for diffusion processes in both oxidation stages at $T >$ 1223 K, and the Ti–Al alloys, by the lowest energy consumption.

The comparison of E_l and E_p values for the Ti–2.2 Al and Ti–1.9 Zr alloys with the data for PT-7M (Ti–2.0 Al–2.5 Zr) having the same total atomic concentration of Al and Zr (4.8 at %) shows that zirconium affects the oxidation of the PT-7M alloy to a greater extent than aluminum, though its atomic concentration in the alloy (1.3 at. %) is much lower.

The established dependences of E_l and E_p on the material composition, temperature, and duration of oxidation are associated with the effects of these factors on the composition and structure of metallic and oxide phases. In particular, the alloying of titanium results in a change in the energy of interatomic bonds in the matrix lattice and changes in conditions and, therefore, growth rates of DOL, for example, upon redistribution of alloying elements in oxidation products [20, 21]. It also affects the temperature of $\alpha \leftrightarrows \beta$ transitions in the metal and the type and concentration of point defects, which form on penetration of alloying elements into the rutile lattice and determine the diffusion mechanism of scaling.

The extent of changes in the oxidation mechanism and rate depend on the nature and concentration of alloying elements. The degree and the form of their participation in scaling and DOL growth can change not only with temperature, but also with duration of the oxidation, which is confirmed by the established effects of these factors on E_l and E_p. The Ti–Al and Ti–Fe alloys are remarkable in this respect. For example, aluminum, being an α-stabilizer and having a smaller atomic radius than titanium, enhances the strength of the α-Ti lattice [22]; strengthening of this effect with increasing c_{Al} should result in the growth of E_l. The data in the table for $T >$ 973 K do not contradict this conclusion. When titanium is alloyed with iron stabilizing the β-phase, the strength of interatomic bonds in the matrix lattice decreases, and we can expect that E_l will decrease, which is actually observed in the experiment.

Nonmonotonic and unclear dependence of E_l and E_p on the nature and concentration of alloying elements is attributable, apart from other reasons, to their low content in the alloys and also to inaccuracy of

the experiment. These circumstances and the extraordinary complexity of the oxidation of titanium and its alloys, affected by oppositely acting factors, do not always allow clear interpretation of the effect of these factors on the process parameters.

CONCLUSIONS

(1) The slope of the temperature dependence of K_l for nonstationary oxidation of titanium and the majority of the considered alloys increases, and that of K_p, decreases in going to the range $T >$ (1123–1223) K. The temperatures T^l_{bend} and T^p_{bend} of bends in these dependences remain practically unchanged on alloying of titanium and in going from the initial to the subsequent stages of the oxidation.

(2) In most cases, alloying of titanium results in increase in E_l and E_p in both stages of the test at 973–1373(1473) and 973–1123(1073) K, respectively, and also at temperatures higher than 1223 K. The exceptions are several Ti–Al, Ti–V (E_p), Ti–5.2. Al–1.2 V–1.1 Mo (E_l), and Ti–Fe (E_l, E_p) alloys. The diffusion processes for all the alloys (except partly for Ti–Fe) in the range 1123(1073)–1223(1173) K are less energy-consuming than in the case of titanium.

(3) The growth of c_M in Ti–Al and Ti–Zr alloys is accompanied by the tendency to a nonmonotonic increase in $E_l^{(1)}$ and $E_l^{(2)}$ above 973 K, and in the case of Ti–Fe and Ti–V their decrease is observed. Under these conditions, $E_p^{(1)}$ and $E_p^{(2)}$ tend to decrease with increasing c_{Zr}; for the Ti–Al alloys this is true only with respect to $E_p^{(2)}$. At the same time, when c_{Fe} (outside the 1173–1223 K range) and c_V (≤0.9%) increase, and also (as far as $E_p^{(1)}$ is concerned) when c_{Al} grows, the trend is opposite.

(4) In going to the range 973–1173(1223) K, $E_l^{(1)}$ for titanium decreases and $E_p^{(1)}$ increases. The changes in $E_p^{(1)}$ for the majority of alloys of the systems Ti–Al and Ti–Zr and also for the PT-7M alloy are similar to this pattern, whereas $E_l^{(1)}$ values change in opposite directions, being constant for certain compositions in the range 823–1223 K. In the case of titanium and majority of the alloys, heating above 1173–1223 K results in an increase in E_l and a decrease in E_p.

(5) Passing from the initial to the subsequent periods of titanium oxidation is accompanied by a decrease in E_l at 973–1373 K and a decrease in E_p at 973–1123(1073) K, whereas above 1223(1173) K $E_p^{(1)}$ is equal to $E_p^{(2)}$. For the majority of the alloys, this transition results in the opposite change in E_l (T 1173 K) and E_p (T 1223 K).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Subsolidus Phase Relationships in the Er_2O_3–Rh_2O_3 System

V. N. Skrobot, S. K. Kuchaeva, D. P. Romanov, and R. G. Grebenshchikov

Grebenshchikov Institute of Silicate Chemistry, Russian Academy of Sciences, St. Petersburg, Russia

Received March 18, 2003

Abstract—The Er_2O_3–Rh_2O_3 system was studied by the annealing and quenching method using X-ray phase, thermal, and chemical analyses. A schematic subsolidus diagram of phase relationships was constructed.

In recent decades, there has been a great deal of interest in multicomponent oxide systems [1–3] owing to the fact that phases of various chemical compositions and structures, existing in such systems, have practically important properties. In particular, it was found that complex oxides existing in the systems Ln–M–Rh–O [4–6] (Ln is a rare-earth element and M, an alkaline-earth element) have interesting electrical, magnetic, and catalytic properties. The purposeful search for new mixed oxides in these and even more complicated similar systems should be based on the physicochemical analysis of simpler oxide systems M–Rh–O and Ln–Rh–O along with development of synthetic methods. Of prime importance are the phase diagrams in the subsolidus region.

This work continues the study of phase relationships in systems containing rare-earth and rhodium sesquioxides [7–10]. Our goal was to study in detail the subsolidus phase relationships in the Er_2O_3–Rh_2O_3 system in air at temperatures of up to 1600°C and to construct the corresponding phase diagram.

The fact that the mixed oxide $ErRhO_3$ is formed in the system Er–Rh–O was first reported in 1964 [11]. Later the synthesis and crystal-chemical and certain physicochemical properties of this compound were repeatedly studied [12–15]; however, phase relationships in the Er–Rh–O system were not studied.

EXPERIMENTAL

The initial reagents were erbium oxide Er_2O_3 containing no less than 99.9% main substance and pure-grade rhodium trichloride crystal hydrate $RhCl_3 \cdot 4H_2O$. The prolonged oxidation of the latter compound with atmospheric oxygen in the temperature range 650–700°C yields the metastable polymorph α-Rh_2O_3 with a classic hexagonal corundum-type structure [16]. The high-temperature stable polymorphic form β-Rh_2O_3 [17] was obtained by two following ways. The first method consisted in heat treatment of the metastable form of α-Rh_2O_3 at 800–950°C in air. The second method consisted in the oxidation of finely dispersed metallic rhodium at 950–1000°C in air or in an oxygen flow for no less than 20 h. Finely dispersed rhodium (metallic rhodium black) was obtained by the reduction of rhodium trichloride hydrochloric acid solution with metallic zinc.

The initial compositions for studying phase relationships were prepared from the mixtures of Er_2O_3 and α-Rh_2O_3 in the molar ratios of 9 : 1, 4 : 1, 3 :1, 2 : 1, 3 : 2, 1 : 1, 3 : 5, 1 : 2, 1 : 3, 1 : 4, and 1 : 9. When studying the equimolar composition, we also used a mixture of Er_2O_3 and finely dispersed rhodium. These mixtures were triturated in a jasper mortar with ethanol, dried in air, and then annealed in corundum crucibles at temperatures from 600 to 1600°C at 100°C intervals. In certain cases, e.g., for the equimolar composition, the annealing and quenching were carried out at 10–20°C intervals. The duration of annealing at temperatures of up to 1000°C reached 150 h, and above 1000°C it was up to 75 h. After intermediate annealings for more than 20 h, samples were homogenized by trituration. Up to 1000°C, annealings were performed in a SNOL-I4 electric furnace. In the experiments at higher temperatures, we used an electric furnace with a heater made from a platinum–rhodium, Pt/Rh (30%), wire. Annealing and quenching were performed in air. During the isothermal annealing, the temperature was held constant with an accuracy of no less than ±10°C.

The phase composition of the initial reagents and mixtures and also of samples after annealing and quenching was determined with DRON-3 and Siemens D 500 HS X-ray diffractometers. We used CuK_α radiation with a nickel filter. Scanning was carried

Schematic diagram of phase relationships for the subsolidus region of the system Er_2O_3–Rh_2O_3 in air. (*T*) Temperature. Irreversible polymorphic transition of Rh_2O_3 is shown by a dashed line.

out in the range of 2θ angles 10°–95°, scan rate 2 deg min^{-1}, scanning step 0.02°.

Thermal and chemical analyses, and also some other details of experiments were described earlier [9, 10].

The schematic diagram of phase relationships for the subliquidus region of the system Er_2O_3–Rh_2O_3 is shown in the figure as a combination of diagrams for two pseudo-binary systems Er_2O_3–Rh and Er_2O_3–Rh_2O_3 in the ternary system Er–Rh–O. This way of representation of phase equilibria is characterized by the fact that the reversible dissociation of solid oxide phases is considered conventionally as a phase transition at which a gas phase (oxygen) is not taken into consideration. Then the phase equilibria in a ternary system can be represented using a combination of binary systems, which allows a pictorial schematic diagram of phase relationships to be obtained on a plane. First, such a technique of representation of phase relations was used by Muan [18] when he studied systems involving iron oxides. Later Schneider and Roth applied it to the systems containing other transition metal oxides, including platinum metal oxides [19, 20].

According to the suggested phase diagram (see figure), there are four stable solid phases in the subliquidus region of the system Er_2O_3–Rh_2O_3: Er_2O_3 (C-form of Er_2O_3), β-Rh_2O_3, Rh, $ErRhO_3$, and also one metastable phase α-Rh_2O_3. When three solid phases and a gas phase (oxygen) coexist in equilibrium in the ternary system Er–Rh–O, the system is monovariant. In this case, three condensed phases coexist at a fixed partial pressure of oxygen and a unique value of temperature. Therefore, three-phase equilibria are shown in the phase diagram by horizontal continuous lines. The dashed line in the figure corresponds to the monotropic polymorphic transition

$$\alpha\text{-}Rh_2O_3 \longrightarrow \beta\text{-}Rh_2O_3. \quad (1)$$

In the course of this transition, the metastable polymorph α-Rh_2O_3 with a classic hexagonal corundum-type structure [16] irreversibly transforms to the stable polymorphic form β-Rh_2O_3, the rhombic structure of which is also a derivative of the corundum-type structure [17]. The main features of this monotropic polymorphic transition were studied earlier [15, 21–26]. The temperature range and rate of transformation (1) depend on the composition, structure, and dispersity of the initial α-Rh_2O_3. All these characteristics are determined by the way and conditions of the synthesis of the metastable form α-Rh_2O_3. It is possible to identify unambiguously polymorphic transition (1) of α-Rh_2O_3 synthesized in this work and the formation of β-Rh_2O_3 by X-ray technique after annealing of the initial α-Rh_2O_3 at temperatures above 750°C, but not higher than 1030°C. The reversible thermal dissociation by Eq. (2) is observed above 1030°C:

$$\beta\text{-}Rh_2O_3 = 2Rh + 3/2O_2. \quad (2)$$

Equilibrium (2) and its certain thermodynamic features have been studied fairly well [22–28]. Using the data from [22, 28], we have calculated the dissociation temperature of β-Rh_2O_3 in air at normal atmospheric pressure, i.e., at the partial pressure of oxygen of 0.21 atm. The obtained values of 1034 and 1033°C reasonably agree with the value of 1042°C given in [27]. According to the data from [25, 26], obtained by differential thermal and high-temperature X-ray phase analyses, equilibrium (2) is established in air at 1030 ± 5°C.

Only one phase transition was established also for the binary oxide $ErRhO_3$ at temperatures of up to 1600°C. It is the reversible thermal dissociation by the equation

$$ErRhO_3 = 1/2Er_2O_3 + Rh + 3/4O_2. \quad (3)$$

The thermal dissociation of erbium rhodite is detected in X-ray patterns starting from 1325°C as

an endothermic effect and an abrupt weight loss of 7.42%. This value agrees well with the theoretical value of 7.54% calculated by Eq. (3). In the X-ray patterns of single-phase samples of $ErRhO_3$ after their annealing at temperatures above 1325°C, well-pronounced narrow diffraction peaks appear, which correspond to well-crystallized coarse-grained metallic rhodium and the low-temperature polymorphic form of erbium(III) oxide (so-called C-form of Er_2O_3) crystallizing in the cubic system [29]. These substances do not react with each other and with atmospheric oxygen at 1325–1600°C. But specifically the reaction yielding the double oxide $ErRhO_3$ was detected by the X-ray phase analysis after prolonged calcination (for more than 100 h) of a mixture of Er_2O_3 with finely dispersed rhodium at 1300°C in air. Thus, the results of our annealing–quenching experiments in combination with the data of X-ray and thermal analyses unambiguously prove the validity of Eq. (3) and determine the temperature at which this equilibrium is attained in air, 1325 ± 10°C.

It should be noted that $ErRhO_3$ and β-Rh_2O_3 undergo a similar decomposition by Eqs. (3) and (2), respectively. The reversible dissociation with the formation of metallic rhodium and oxygen is characteristic for these oxides, the decomposition temperature of the double rhodium erbium oxide $ErRhO_3$ being much higher than that of the simple rhodium oxide Rh_2O_3.

Therefore, we have found that only one double oxide $ErRhO_3$ is formed in the system Er_2O_3–Rh_2O_3. The data of the chemical analysis of $ErRhO_3$ agree well with the corresponding calculated values (differences do not exceed 0.2%). The X-ray diffraction study confirmed the data [12–15] on the crystallization of $ErRhO_3$ in the structure of orthorhombically distorted perovskite such as $GdFeO_3$. Single-phase samples of the double oxide $ErRhO_3$ are brown homogeneous polycrystal powders insoluble in water, inorganic acids (hydrochloric, nitric, sulfuric, and phosphoric), and alkalis (NaOH and KOH).

It should be noted that high resistance to the action of acids and alkalis is also characteristic of the simple rhodium(III) oxide.

The offered subsolidus diagram of phase relationships for the system Er_2O_3–Rh_2O_3 is topologically equivalent to the corresponding phase diagrams for the systems Ln_2O_3–Rh_2O_3 (Ln = La, Yb, Lu) studied earlier [7–10]. The phase diagrams of these systems differ only in the dissociation temperatures of $LnRhO_3$ compounds, which decrease from 1450 to 1275°C in going from $LaRhO_3$ to $LuRhO_3$ [7–10]. The offered diagram for the subsolidus region demonstrates phase relationships in air at normal atmospheric pressure, i.e., at the oxygen partial pressure of 0.21 atm. However, variation of the oxygen partial pressure will affect the dissociation temperatures of β-Rh_2O_3 and $ErRhO_3$. According to [22], the increase in the oxygen partial pressure from 0.01 to 0.96 atm results in the increase from 900 to 1126°C in the equilibrium temperature of the dissociation of rhodium(III) oxide. Such experimental studies were not carried out for $ErRhO_3$, but it was found [8] that the dissociation temperature of the similar perovskite-like oxide $LaRhO_3$ increases from 1455 to 1570°C as the partial pressure of oxygen is increased from 0.21 to 1.00 atm. Apparently, the behavior of $ErRhO_3$ will be similar.

Thus, as repeatedly noted earlier [2, 7–10, 22–28], the dissociation temperatures of rhodium oxides in similar systems strongly depend on the partial pressure of oxygen, and its variation will affect the position of the temperature–concentration boundaries of phase fields in the diagrams.

The results of this work confirm certain previous experimental observations and conclusions [2, 7–10, 13–15, 19, 20, 22–28].

CONCLUSIONS

(1) Subliquidus phase relation in binary oxide systems involving oxides of platinum metals are determined mainly by the nature of the corresponding initial simple oxide of a noble metal irrespective of the physicochemical nature of the second component (oxide of a base metal).

(2) The double oxides formed in systems base metal–platinum metal–oxygen inherit physicochemical properties of simple oxides formed in the systems platinum metal–oxygen. In particular, high chemical and thermal stability of simple oxides of platinum metals corresponds to that of the mixed oxides.

(3) The majority of simple and double oxides of platinum metals, when heated, undergo reversible thermal dissociation but not melting. Simple oxides of platinum metals reversibly decompose to give the corresponding platinum metal and oxygen. The dissociation into a platinum metal, oxygen, and a base metal oxide is characteristic, as a rule, for double oxides containing a platinum metal and a base metal. In this case, double oxides dissociate at higher temperatures than the corresponding simple platinum metal oxides.

(4) There is a deep physicochemical analogy between the systems platinum metal–oxygen and base metal–platinum metal–oxygen.

Abstract—The effect of additives introduced into the working solution on the behavior of dispersed aluminum particles obtained in electric erosion was studied.

The electric-spark dispersion of a metal is strongly affected by the conditions under which the electric erosion process is carried out, with formation of various products possible [1–3]. It can be conventionally taken that electric erosion occurs in two stages. The first stage, which occurs in the electric discharge zone characterized by high temperatures, leads to melting of the metal, its partial evaporation, and removal of the liquid–vapor phase in the form of congealed metal particles [4, 5]. In the second stage, which occurs in the sludge-collecting tank, dispersed metal particles enter or do not enter into the reaction with the working solution. The stages under consideration are strongly affected by additives introduced into the working solution. Thermal decomposition of the working solution in the spark discharge zone yields atomic oxygen whose amount largely depends on the nature and concentration of an additive [3]. When present in a sufficient amount, oxygen reacts with dispersed aluminum to form on its surface a protective oxide film which protects the metal from reacting with the working solution. If, however, oxygen is formed in an insufficient amount, surface oxidation of the dispersed metal is only partial, and it reacts with the working solution to form aluminum hydroxides (AH).

This study proceeded with investigations of how additives introduced into the working solution affect the behavior of the forming dispersed aluminum particles; also the dispersity of the products obtained was determined. The experiments were carried out on an installation, and by a procedure, described previously in [1].

Electron-microscopic studies of samples were performed on an EMV-100LM electron microscope with accelerating voltage of 75 kV and beam current of 40 μA. The samples were preliminarily prepared with a UZDN-1 ultrasonic disperser in isopropyl alcohol with subsequent deposition on an organic substrate.

To exclude the influence exerted by the first stage of the electric erosion process and by the resulting change in the concentration of the additive on the nature of processes occurring in the second stage, electric erosion of aluminum was carried out until complete filling of the sludge-collecting tank. Further, 3-l sludge samples were taken from the collecting tank and subjected to thermal treatment at 90°C. The time of thermal treatment of the samples was varied: 3 h for the first sample, 5 h for the second, 7 h for the third, etc. Thus, the initial composition of the sludge was invariable at different times of its thermal treatment.

The influence exerted by the duration of the thermal treatment on the composition of the products obtained with various additives is illustrated in Fig. 1.

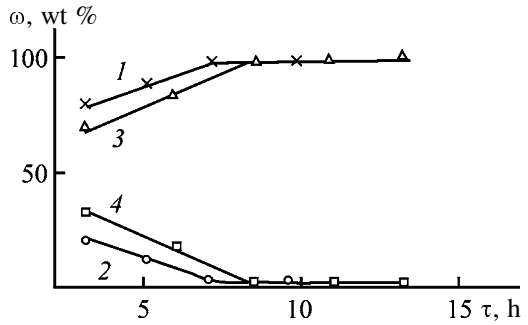

Fig. 1. Content ω of (*1, 3*) boehmite and (*2, 4*) bayerite AH in products of electric-spark dispersion of aluminum in a working solution vs. duration τ of thermal treatment of sludge. Sludge treatment temperature 90°C. Working solution (M): (*1, 2*) 0.039 ammonium acetate and (*3, 4*) 0.22 urea.

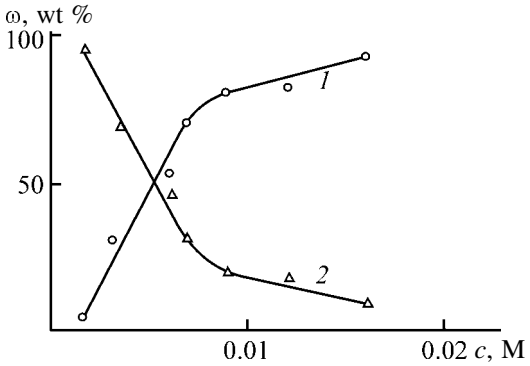

Fig. 2. Content ω of (*1*) aluminum powder and (*2*) AH in electric erosion products vs. concentration *c* of nitric acid in a mixture with 0.025 M working solution of ammonium nitrate. Sludge treatment temperature 25°C, treatment duration 4 h; the same for Fig. 4.

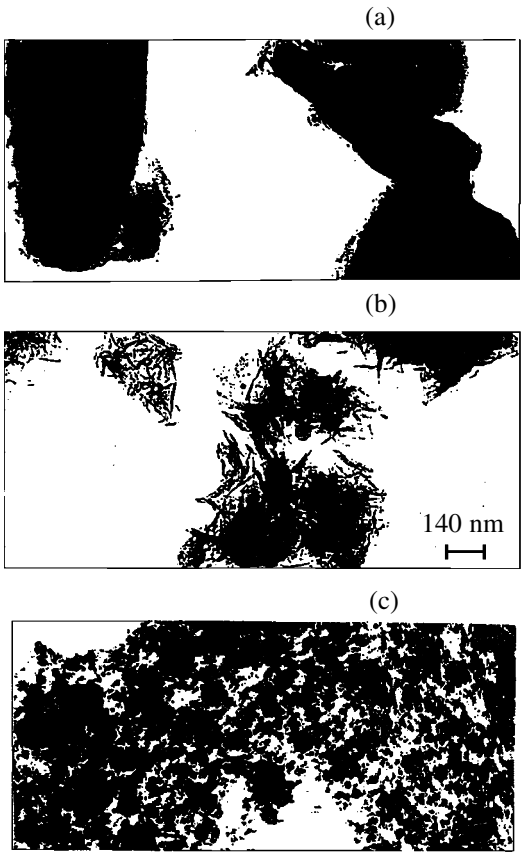

Fig. 3. Electron micrographs of (a) bayerite and (b) boehmite AH and (c) aluminum powder, products formed in electric-spark dispersion of aluminum in a working solution. Working solution (M): (a) distilled water, (b) 0.039 ammonium acetate, and (c) 0.028 nitric acid.

It can be seen that the content of boehmite AH in the erosion product grows and that of bayerite AH decreases with increasing duration of thermal treatment. The observed difference in how the content of boehmite AH grows (and, correspondingly, the content of bayerite AH decreases) in the presence of ammonium acetate and urea in the working solution is probably due to their different adsorption onto the surface of dispersed aluminum. Compared to urea, ammonium acetate presumably forms stronger complexes with oxide areas on the surface of dispersed aluminum particles and shields these areas, thus protecting dispersed aluminum from further hydration. This suggests that an increased amount of less hydrated form, boehmite AH, and decreased amount of bayerite AH are formed. As a result, the initial content of boehmite AH in an ammonium acetate solution exceeds that in an urea solution, and, therefore, the limiting product ratio is reached faster in the presence of ammonium acetate, compared to the case of urea.

Figure 2 shows how nitric acid introduced into a working solution containing ammonium nitrate affects the composition and amount of products obtained in the course of electric erosion. At 0.002 M concentration of nitric acid in an ammonium nitrate solution, the erosion products mainly contain aluminum hydroxide. With increasing concentration of nitric acid in the working solution, the content of powdered aluminum in the product first grows steeply and then varies slowly, approaching a limiting value (curve *1*). Such a behavior of the metal powder content in the product indicates that the amount of atomic oxygen grows in the course of the process. As a result, the fraction of dispersed metal particles with a surface oxide film protecting them from interaction with the working solution increases. Raising further the concentration of nitric acid in the solution affects the amount of forming oxygen only slightly; correspondingly, the fraction of dispersed metal with surface occupied by the oxide film remains nearly constant. As a result, the content of powdered metal in the product grows slowly. Since the working solution contains substances with the same anion, nitrate ion, the effect of the working solution on the composition of the erosion products is largely associated with a change in the concentration of hydrogen (hydroxonium) ions. Thus, the experimental data obtained confirm the previous assumption that the mechanism of aluminum powder formation involves hydroxonium ions.

Electron micrographs of samples obtained in electric-spark dispersion of aluminum under varied conditions are shown in Fig. 3. Three types of products are formed in electric erosion. Figure 3 shows that crystallites of bayerite AH have the shape of parallelepipeds 400 nm and less in size (Fig. 3a), and crystals of boehmite AH are needles about 150 nm long and

Oxalate	0.030	25	5	91	9
Tartrate	0.024	25	5	93	7
Citrate	0.032	25	5	94	6

* *T* and τ are, respectively, the temperature and duration of sludge treatment.

20 nm wide (Fig. 3b). In both cases, the crystallites subsequently coagulate to form secondary aggregates. Crystallites in aluminum powder, which are mostly spherical, also coagulate into secondary aggregates, with only their minor part remaining uncoagulated (Fig. 3c). The size of uncoagulated metal particles varies within 10–50 nm.

Figure 4 shows the results of a morphological analysis of a metal powder obtained in electric erosion of aluminum in a nitric acid solution. Several days after being obtained, dispersed metal particles are mainly represented by secondary aggregates with average size of 3.8 μm and very narrow distribution.

The influence exerted by the concentration of the ammonium acetate and oxalate working solutions on the composition and amount of electric erosion products is illustrated in Fig. 5. With increasing concentration of the working solution, the content of boehmite AH in the product grows (and, correspondingly, the content of bayerite AH falls) (Fig. 5, curves *1* and *2*). Electric erosion of aluminum with ammonium oxalate as the working solution yields AH and metal powder. Raising the concentration of the ammonium oxalate solution leads to a steep rise in the content of aluminum powder, which further becomes slower, with the optimal value reached (Fig. 5, curve 3). Correspondingly, the content of AH in the erosion product decreases (Fig. 5, curve *4*). The observed difference in the composition of products obtained in electric erosion in working solutions containing ammonium acetate or oxalate is due to different types of "primary" processes occurring in the spark-discharge zone. In the first case, thermal decomposition of acetate ions yields an insufficient amount of atomic oxygen, which leads to only partial surface oxidation of the dispersed metal, which further reacts with the working solution to give various forms of AH. In the second case, thermal decomposition of oxalate ions yields atomic oxygen in sufficient amounts, with the result that the fraction of dispersed metal particles having protective oxide film on their surface increases. At the end, the content of metal powder in the erosion product becomes higher. As seen from the table, the increased content of metal powder in the erosion product is also observed in electric-spark dispersion of aluminum in solutions of salts of polybasic carboxylic acids.

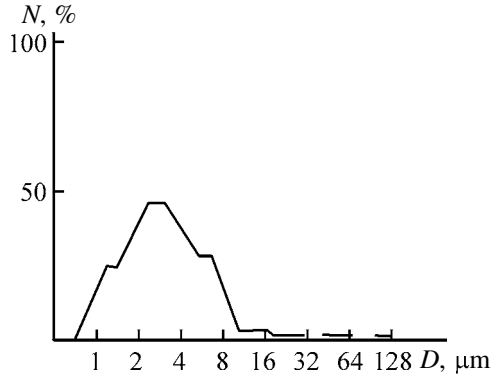

Fig. 4. Content *N* of aluminum particles obtained in electric-spark dispersion of aluminum in a 0.028 M solution of nitric acid vs. their size *D*.

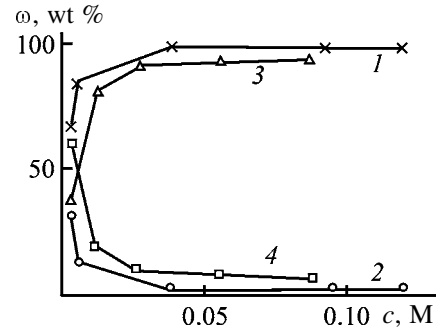

Fig. 5. Content ω of (*1*) boehmite and (*2*) bayerite AH, (*3*) aluminum powder, and (*4*) total AH vs. concentration *c* of the additive in the working solution. Additive: (*1, 2*) ammonium acetate and (*3, 4*) ammonium oxalate. Sludge treatment temperature (°C): (*1, 2*) 90 and (*3, 4*) 25. Sludge treatment duration (h): (*1, 2*) 8 and (*3, 4*) 5.

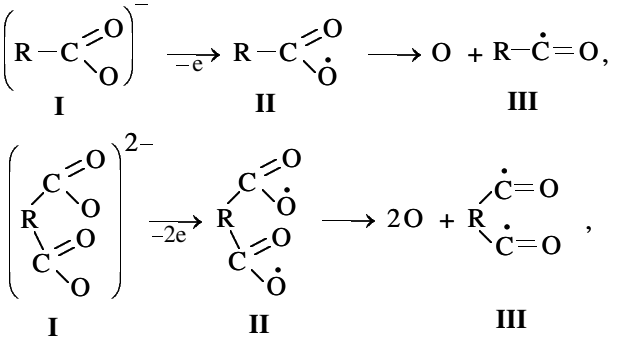
It is known that temperature strongly affects the stability of organic substances [6]. In electric erosion in the spark-discharge zone, in which temperature becomes as high as several thousands of degrees [5], carboxylic acid residues can be broken down. This conclusion is supported by the data of [7, 8]. The formation of atomic oxygen in the spark-discharge zone in thermal decomposition of carboxlic acid residues can be represented as follows:



I **II** **III**

I **II** **III**

where **I** are carboxylic acid residues; **II**, acyloxy radicals; **III**, acyl radicals; and O, atomic oxygen.

In the course of thermal decomposition, acyl radicals may undergo further transformations.

CONCLUSION

Secondary processes occurring in the sludge collector in electric-spark dispersion of aluminum are affected by adsorption of components of the working solution on the surface of dispersed particles of the metal and its oxidized phase. The previously suggested mechanism, which suggests involvement of hydroxonium ions in the formation of a protective oxide film on the surface of dispersed metal, was confirmed experimentally. It was established that most part of dispersed metal particles and products of their reaction with the working solution coagulate to form secondary aggregates. Introduction of ammonium salts of polybasic carboxylic acids promotes formation of aluminum powder in electric erosion.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Formation of Texture Characteristics of SiO_2 Xerogels Prepared from a Spent Film-Forming Formulation

A. N. Murashkevich, V. G. Vashina, and I. M. Zharskii

Received December 27, 2002

Abstract—The possibility of obtaining silica gels with controllable porosity by using various methods for accomplishing a structural transformation in hydrogels was studied.

At present, the sol–gel process with controlled hydrolysis of silicon alkoxides is one of the most promising methods for silica gel preparation [1]. It is important to have, for use in catalysis and chromatography, xerogels with certain physicochemical characteristics. In particular, the highest demand is for silica gels with large sorption volume and prescribed pore size, used as adsorbents and catalyst supports [2]. The structure and properties of a final product obtained by hydrolytic polycondensation of tetraethoxysilane (TEOS) are mainly determined by the initial composition of a mixture being hydrolyzed, conditions under which hydrolysis and polycondensation occur, water : alkoxide molar ratio, presence of catalysts and modifiers in the system, amount and nature of solvents present in the system, and mode of drying of the forming gel [2–8].

The effect of surfactants as active forming agents controlling the pore structure of silica gels obtained from aqueous solutions of sodium silicate was analyzed in [3]. In accordance with the results obtained in [3], surfactants suppress the influence of pH on the particle size and hinder densification of a hydrogel in its drying, which makes it possible to obtain silica gels with large specific surface area and large pore volume: up to 960 $m^2 g^{-1}$ and 2.05 $cm^3 g^{-1}$ for cetylpyridinium chloride, and up to 844 $m^2 g^{-1}$ and 1.71 $cm^3 g^{-1}$ for cetyltrimethylammonium bromide, respectively. However, the largest sorption volumes were obtained at rather high (up to 5 wt %) surfactant concentrations.

The effect of the solvent and water : alkoxide molar ratio was studied in [4, 5]. The dependence of the pore size distribution on the nature and length of the organic radical of the solvent was established. Gels obtained in solvents with shorter organic radicals, which cause weaker steric hindrance, are characterized by smaller pores and narrower pore size distribution. In the presence of methyl ethyl ketone, the maximum sorption volume was 1.68 $cm^3 g^{-1}$ at average effective pore radius of 25 nm and specific surface area of 257 $m^2 g^{-1}$. With ethanol used as a solvent, the samples obtained had specific surface area of 580 $m^2 g^{-1}$ at average effective pore radius of 1.5 nm. The effect of the amount of solvent or solvents introduced remained unclear, although the solvents present affect the particle aggregation and, ultimately, also the internal state of hydrogels, because of the dilution of the formulation.

The drying conditions, which are mainly characterized by kinetics of removal of moisture and solvents present in a hydrogel, also affect the structure of the xerogels obtained. For example, it has been shown [6–8] that, with microwave radiation, the sample drying time can be made considerably shorter. According to [6, 7], the concentration of fluorine-containing ions is a key factor affecting the sorption characteristics of samples prepared under the conditions of microwave drying. With the ammonium hexafluorosilicate concentration raised to 4×10^{-2} M, the pore radius increased to 2.6 nm at specific surface area of 106 $m^2 g^{-1}$. It should be noted that the studies [6–8] were carried out in a rather narrow concentration range at constant water : alkoxide : solvent molar ratio and pore diameters evaluated only approximately from the bulk volume of the powder.

The microporous structure of the samples obtained gives no way of anticipating any significant decrease in diffusion limitations in heterogeneous reactions with a reactant immobilized in a silica gel of this kind: the time of equilibration increases to 47 min when the pore diameter decreases to 1.1 nm [6]. It was noted

1070-4272/03/7607-1039$25.00

that the time of equilibration is independent of the concentration of an immobilized component, being rather diffusion-controlled. Thus, elimination of diffusion limitations, which consists in raising the pore number and volume, is a factor governing the service characteristics of xerogels of this kind. Moreover, of interest is the influence exerted by microwave radiation on the structural-sorption characteristics of xerogels, which have been studied insufficiently.

The aim of this study was to analyze the conditions of formation of the silica gel pore structure by varying the initial conditions of the process and the state of a structure-forming component (tetraethoxysilane), and by introducing modifying additives and subsequent stages of ripening and drying of the hydrogel.

EXPERIMENTAL

Xerogels were synthesized using an organosilicon film-forming formulation based on TEOS. At present, this formulation is employed in manufacture of LCD indicators for depositing protective dielectric layers of SiO_2. The formulation contains, in addition to silicon alkoxide, water in amount necessary for the hydrolysis, HCl catalyst, ethanol, and ethyl acetate. The formula is adapted to obtaining dense nonporous dielectric SiO_2 coatings.

The moderate content of SiO_2 (3 wt %) and the large amount of organic solvents are due to necessity for depositing dielectric films of prescribed thickness. HCl present in the system acts as a catalyst which accelerates TEOS hydrolysis and formulation ripening in the initial stage and as a peptizing agent which prevents coagulation by stabilizing the system. Tetraethoxysilane is present in the formulation in partly hydrolyzed (by 60–70%, on the average) state [9], which specifies a number of characteristic features of the given system, since coatings are deposited using formulations in which the amount of polymeric ethers with large molecular weight and branched 3D structure is not high as yet.

After a certain service time of a formulation, coatings deposited from it no longer satisfy requirements to protective dielectric coatings and the formulation is regarded as spent. At the same time, it is sufficiently stable and remains in this state for several months without introduction of gelation-stimulating additives. Of interest is development of techniques for utilization of the given formulation to obtain high-purity xerogels with developed internal surface.

To obtain xerogels, gelation-accelerating additives were introduced into the formulation in the form of aqueous solutions of prescribed concentration. As these additives served ammonium bifluoride (ABF), ammonium silicofluoride (ASF), diethylamine (DEA), triethanolamine (TEA), ammonia NH_3, hexamethylenetetramine (HMTA), and polyethylene glycol (PEG) with average molecular weight of 6000. Introduction of an additional amount of water may lead to polycondensation and fast gelation with pore closure. Consequently, an additive introduced must promote by itself a change in the ratio of hydrolysis and polycondensation rates, i.e., it must enhance polycondensation.

This requirement is satisfied by fluorine-containing ions which exert a strong catalytic action on the polycondensation rate through formation of a fluorosilicon transition complex [10], are strong coagulants, and favor formation of a developed porous structure. When an above-critical concentration of fluorine-containing ions is used, a precipitated product is obtained [10].

Introduction of a number of organic amines and a cationic surfactant stabilizes particles formed in the sol stage, with their dimensions preserved in the gel structure, i.e., prevents densification of a humid hydrogel precipitate in the course of its drying [3]. Introduction of ammonia and a number of organic amines makes it possible to change the acidity of the medium, since the formulation itself contains HCl originally and an alkaline medium is characterized by a tendency toward formation of silica gels with developed system of pores at a certain decrease in the specific surface area. Thus, choosing the optimal amounts of additives introduced and process conditions may favor formation of a developed porous texture of the gel, which is preserved after drying.

Since the reaction medium plays an important part in hydrolytic polycondensation of alkoxides, changing the composition of this medium is a good method for controlling the porosity. In this study, the substitution of the dispersion medium was done by multiple treatment of hydrogels with aqueous ammonia. This favors deeper extent and more intensive course of the polycondensation through dissolution–reprecipitation reactions and leads to formation of a rigid porous gel skeleton [11].

The large amount of organic solvents in the formulation requires a sufficient time for their removal. Solvents can inhibit polycondensation and affect structure-forming processes because of the formation of hydrogen bonds with silanol groups [4, 5]. Therefore, it is of interest to compare various methods for hydrogel drying. In this study, the recently proposed

drying procedure employing microwave radiation [6–8] was used together with the conventional drying at elevated temperature. The new technique makes it possible to make the drying time as short as several minutes and positively affects formation of mesoporosity in xerogels.

The pore structure parameters of xerogels were determined using the standard procedure from isotherms of adsorption–desorption of benzene vapor and calculated by the BET technique [12]. Also, the sorption volume for benzene under static conditions and the specific surface area for phenol adsorbed from a solution in heptane [13] were determined, which yields more comprehensive information about the real structure of the samples.

The influence exerted by preparation conditions and by the nature of active additives on the structural characteristics of silica gels is illustrated in Table 1 and in the figure. Introduction of fluorine-containing additives yields, in most cases, samples with developed mesoporosity: the largest sorption volume and effective radii were obtained with ABF. Treatment in the hydrogel stage with aqueous ammonia of samples modified with ABF made it possible to raise the sorption volume and pore radius by a factor of 1.5 at invariable specific surface area, which indicates that the given treatment method is promising for modification of the silica gel surface. With ASF, samples with small specific surface area were obtained, but their effective radii indicate that the optimal amount of additive introduced is to be chosen for making larger the specific surface area of the silica gels.

Introducing an additional, compared with that in the initial spent formulation, amount of HCl, i.e., performing the process in a strongly acidic medium with subsequent treatment of the hydrogel with aqueous ammonia yields samples with developed interconnected and accessible surface area: the effective pore radius is 2.9 nm and the sorption capacities in the static and dynamic modes are virtually identical. The isotherms of benzene vapor sorption on the silica gels obtained (see figure) are isotherms of physical sorption of types I and IV according to the IUPAC classification, which points to, respectively, micro- and mesoporous structure of the samples obtained.

With ABF (sample no. 4), ASF, and DEA as active additives, and also with an additional amount of HCl introduced, mesoporous samples could be obtained. The shape of the hysteresis loop of the isotherms is characteristic of cylindrical mesopores or bottle-like

mesopores with very wide entrances into voids [14]. The run of the isotherms is characteristic of agglomerates and globules that are sufficiently uniform in size and are uniformly packed. Samples containing ABF (sample no. 4) and HCl contain a certain amount of very large pores, which are only filled at p/p_0 close to unity (see figure, isotherms *1* and *4*).

With a number of organic amines, silica gels with good sorption characteristics could also be obtained, but, in some cases (HMTA), the amount of the modifier introduced was presumably insufficient for a structural transformation to occur, since HCl is present in the formulation from the very beginning. Introduction of ammonia into the formulation yielded samples with developed microporosity: the sorption volume of the silica gels was 0.32 $cm^3\ g^{-1}$ in the static mode and the pore radius was 1.3 nm at specific surface area of 423 $m^2\ g^{-1}$.

In the case when HMTA or NH_3 are used, the sorption isotherms of the samples belong to a hybrid type I + IV. The samples obtained are composed of mesoporous grains and contain micropores whose total volume gives rise to a plateau in the isotherm. Microporous samples have a rather large external surface area or a pronounced microporosity, or both [12]. It may be assumed that the amount of ammonia additionally introduced into the formulation is insufficient for structural modification and treatment of the hydrogel obtained with ammonia is more promising. With this method of synthesis, the hydrogel formation proceeds in the first stage in a strongly acidic medium with fluorine-containing modifiers, which gives rise to a well-developed surface. Use of a preset excess of ammonia in the second stage leads to roughening of the structure, which makes it possible to obtain samples with controllable porosity.

Treatment with aqueous ammonia of a spontaneously gelated spent formulation yielded samples with large sorption volume and large effective pore radius (sample no. 9). Mention should be made, however, of a too long time of hydrogel ripening and difficult reproducibility of the results obtained. Microwave drying of a spent formulation that gelated spontaneously without introduction of a modifier or treatment with aqueous ammonia yields microporous samples.

Introduction of PEG as modifier did not affect substantially the porosity of silica gels. It is known that PEG introduction in early stages of hydrolysis and condensation affects the morphology of the gels obtained and, in particular, the early development of a gel. Addition of PEG to a formulation in which TEOS is largely hydrolyzed does not cause any significant changes in xerogels.

Table 2 illustrates, for a xerogel modified with ABF as example, the influence exerted by the concentration of an additive introduced and by the conditions of ripening and drying on the sorption volume of the samples obtained. It can be seen that raising the concentration of an additive introduced or making longer the time of hydrogel ripening leads to an increase in the sorption volume of the xerogels obtained. Use of microwave radiation makes it possible to vary, by influencing the liquid evaporation processes, the porous structure of the samples obtained. A large amount of solvents present in the spent and initial

formulations is removed rapidly and simultaneously from the gel bulk, which gives rise to a well-developed surface of the silica gels. The structural rearrangement occurring in the course of prolonged ripening results in formation of a rather loose structure in which the intraand intermolecular condensation proceeds to the greatest extent because of the presence of fluorine-containing ions. The open porosity does not prevent removal of solvents from the bulk of the matrix, and the gel skeleton has enough time in the course of ripening to acquire a rigidity sufficient to withstand shrinkage.

The sorption volumes of the xerogels obtained with or without their treatment in the hydrogel stage with aqueous ammonia and subjected to drying in different ways are compared in Table 3. It can be seen that the sorption volumes of the samples upon microwave drying coincide with, or, in some cases, even exceed the values obtained after drying at elevated temperature. This indicates that a skeleton not subject to further shrinkage is formed in the course of gel ripening, processes of relaxation, condensation, and collapse of pores are complete, and pores in the gels are large enough for free removal of large amounts of organic solvents.

Changing the nature of the reaction medium by replacing the intrapore liquid in the course of synthesis is one more way to control the porosity of xerogels. Treatment of hydrogels with aqueous ammonia actually provides two-stage catalysis in the system, i.e., enables finer, compared with that in a single-stage process, control over gelation stages.

It is known that silica is rather well soluble in the presence of considerable amounts of hydroxide ions, and the originally poorly cross-linked macromolecules may dissolve and repeatedly precipitate at highly condensed surface centers. As a result, the gel skeleton is transformed to take the form of large clusters and relatively large pores in between. Moreover, the aqueous solution itself favors more complete course of the hydrolysis of ethoxy groups, which also promotes formation of a high porosity. The excess of aqueous ammonia results in that the clusters grow rather rapidly and have enough time to become sufficiently large to form a coarsely porous structure after drying.

The strongest influence (Table 3) on the sorption volume is exerted (within a factor of 3–3.5) by ammonia treatment of samples obtained in the presence of an additional amount of HCl, i.e., performing the process in the two-stage catalysis mode strongly affects the porosity formation. In the case of a partly hydrolyzed TEOS, when the initial formation of the gel skeleton is already initiated by introduction of fluorine-containing ions, the condensation proceeds to the greatest extent in the first stage and further treatment with aqueous ammonia raises the porosity to a lesser extent.

CONCLUSIONS

(1) Spent film-forming formulation can be used to obtain mesoporous SiO_2 xerogels by intensive technology.

(2) An important part in formation of structural features is played by organic solvents and methods of their removal in xerogel drying. Raising the concentration of a fluorine-containing additive, making longer the ripening time, and using microwave drying favor formation of a well-developed surface in the samples obtained. Replacing the dispersion medium by treatment in the hydrogel stage makes a greater contribution to porosity formation than use of a number of modifiers introduced into the initial formulation.

(3) The rapidity of the microwave drying, leading to local disintegration and shrinkage of the silica gel skeleton, puts in the forefront the problems associated with the skeleton strengthening. These problems can be resolved by making longer the ripening time and choosing the optimal amounts of modifying additives.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Thermal Stability of Limestone

A. A. Kabanov

Krasnoyarsk Pedagogical State University, Krasnoyarsk, Russia

Received November 4, 2002; in final form, February 2003

Abstract—Thermal stability of limestones and effects of various impurities on their stability were discussed.

The thermal stability of limestones and factors affecting it are of scientific and applied interest, because limestones are widely used in various industries. A number of interesting effects of impurities on the thermal stability of $CaCO_3 \cdot 17H_2O$ samples was established earlier [1–3], and testing natural limestones with respect to these effects has become urgent.

In this work, we used limestone from the Solomensk deposit (Kemerovo oblast). Its –0.08-mm fraction was sifted after dispersion and kept over P_2O_5 for 10 days. Then the sample was degassed at 200°C for 6 h and again kept over P_2O_5 for no less than 10 days. The limestone sample thus pretreated was considered as the starting sample.

The quantitative analysis of the samples was carried according to GOSTs (State Standards) 4530–76 and 5382–91. The X-ray analysis was performed on a DRON-3 diffractometer. The mass spectra were obtained on an MI-1305 ionization spectrometer. Thermal measurements were performed in air on a Q-1500D derivatograph. Magnetic susceptibility was measured on a pendular magnetic balance with automatic equilibration. The sensitivity of measuring specific magnetic susceptibility was 10^{-7} $cm^3\ g^{-1}$. The Mössbauer spectra were obtained on an electrodynamic spectrometer based on an AI-5006-3M-V100 analyzer operating in the constant acceleration mode. The spectra were processed on an ES-1022 computer. γ-Radiation was emitted by a ^{57}Co source of 0.5 GBq activity in a chromium matrix.

Analytical data for limestone (wt %): main substance $CaCO_3$ 95.08, Fe 0.81, (K + Na) 0.08, Si 0.52, Al 0.70, and others 2.81. The X-ray phase analysis (Fig. 1) shows that the starting sample contained $CaCO_3$ in the form of calcite, α-Fe_2O_3, and ferrigaluasite $(Fe^{III}, Al_4)(OH)_8(Si_4O_{10}) \cdot 1.74H_2O$. It is known that the X-ray diffraction patterns of α-Fe_2O_3 and α-$Fe_2O_3 \cdot xH_2O$ are identical. Taking into account the signal intensity and sensitivity of the X-ray diffractometer, we can conclude that the concentration of both iron(III) compounds in limestone is 0.10%.

Thermogravimetric analysis shows (Fig. 2) that the weight of the limestone sample starts to change noticeably in air at 130°C. The highest rate of the sample

decomposition is observed at 852 ± 2°C, and the sample weight gets stabilized at about 900°C. According to the mass-spectrometric data (Fig. 3), the maximal decomposition rate of limestone in a vacuum of 10^{-6} torr is observed at 580 ± 2°C. A significant difference between the maximal decomposition rates in air and in a vacuum is typical for calcite [1].

Three experimental maxima of limestone dehydration rate (Fig. 3) are indicative of the presence of at least three centers of water localization in limestone. It is known [5] that the hydrohematite dehydration starts at 136°C. Therefore, the first maximum (140°C) in curve *1* (Fig. 3) can be assigned to this process. By analogy with $CaCO_3 \cdot 0.17H_2O$ [1, 2], the third maximum (580°C) probably originates from the presence of calcite. Then the second maximum (410°C) is caused by the dehydration of ferrigaluasite. In contrast to $CaCO_3 \cdot 0.17H_2O$ [1], a small maximum of the rate of CO_2 evolution was found for limestone near 410°C, which agrees with an increase in the pressure in the reactor (Fig. 3, curve *3*). It suggests a certain correlation between the dehydration of ferrigaluasite and the partial decomposition of calcite, which seems to result from the bonds in the crystalline calcite phase through polarized H_2O dipoles.

Limestone and $CaCO_3 \cdot 0.17H_2O$ on heating and cooling show principally different temperature dependences of the specific magnetic susceptibility (Fig. 4). On heating, the magnetic susceptibilities are determined for limestone, by ferrigaluasite (it seems to be ferrimagnetic), and for $CaCO_3 \cdot 0.17H_2O$, by van Vleck paramagnetism [1]. On cooling, the magnetic susceptibility seems to be determined in both cases by hematite, which is completely separated from the calcite phase upon dehydration. In all the cases (Fig. 4), we deal with paramagnetism and possibly with ferrimagnetism (for the initial state of ferrigaluasite).

According to the mass-spectrometric data [1] for $CaCO_3 \cdot 0.17H_2O$, its dehydration rate has a small temperature maximum at 235°C, which is not yet understood. In [6], its origin was specially studied by quantitative analysis, mass spectrometry, and Mössbauer spectrometry. It was found that the analytically pure grade reagent $CaCO_3 \cdot 0.17H_2O$ contains about 0.014% α-$Fe_2O_3 \cdot 0.04H_2O$ (which does not contradict the requirements of GOST 4530–76 to the reagent purity). Consequently, the calcite binds only 0.13 mol, but not 0.17 mol of H_2O [1, 2]. The results of this work allow us to supplement the conclusions of [6] by an assumption that the α-$Fe_2O_3 \cdot 0.04H_2O$ phase is linked to the calcite phase through H_2O molecules. The difference between the temperatures of maximal dehydration rate of α-$Fe_2O_3 \cdot 0.38H_2O$ in limestone (Fig. 3, 140°C) and of α-$Fe_2O_3 \cdot 0.04H_2O$ in the $CaCO_3 \cdot 0.17H_2O$ can be explained by different (by nearly an order of magnitde) H_2O content.

According to our data, the iron(III) content in limestone is 0.81%. To make a rough estimate of the iron(III) fractions in hydrohematite and ferrigaluasite, we recorded the Mössbauer spectrum of the starting limestone (Fig. 5). It contained six bands typical for

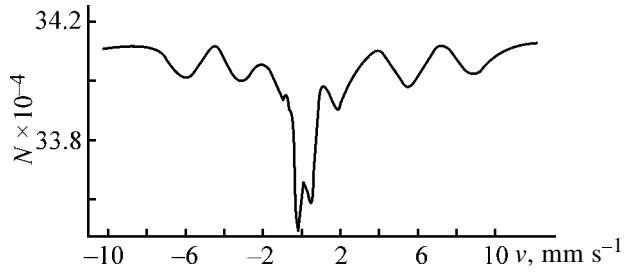

Fig. 5. Mössbauer spectrum of the starting limestone: (*N*) Counts per channel and (*v*) velocity of the γ-source.

hematite [7]. Hydrohematite should have the same spectrum (because of similarity of their X-ray diffraction patterns [4]). The isomer shift $\delta E = 0.2 \pm 0.1$ mm s^{-1} and the quadrupole splitting $\Delta E_Q = 0.5 \pm 0.1$ mm·s^{-1} were calculated from the spectrum. Their values confirm the presence of hematite (or hydrohematite). The absence of ferrigaluasite signals from the Mössbauer spectrum suggests [7] that the concentration of this impurity is at the least by an order of magnitude lower than that of hematite. Therefore, the iron(III) content can be divided into fractions of hematite (0.73%) and ferrigaluasite (0.08%). Let us then calculate the total concentration of H_2O in limestone and its three components (corresponding to three localization centers [1]) on the basis of Figs. 2 and 3 with the calibration of H_2O bands (Fig. 3) by the TG curve (Fig. 2) for 500°C. Under vacuum conditions, it corresponds to the temperature of 250°C [1] at which there is no CO_2 interference (Fig. 3).

Calculations based on the gravimetric calibration of the first band area (Fig. 3, curve *1*; up to 5°C) allow us to make the following conclusions. After thermal treatment at 200°C, the total content of water in the starting limestone sample is 7.52%. The fractions of H_2O in calcite, hydrohematite, and ferrigaluasite are 1.12, 2.50, and 3.90%, respectively. It corresponds to the following formulas of the compounds: $CaCO_3 \cdot 0.06H_2O$, α-$Fe_2O_3 \cdot 0.38H_2O$, and $(Fe^{III}, Al_4)(OH)_8 \cdot (Si_4O_{10}) \cdot 1.74H_2O$. The concentrations of iron-containing impurities can be calculated taking into account the iron(III) content in them. The content of ferrigaluasite and hydrohematite in limestone is 1.47 and 1.06%, respectively. These values are within the framework of the sensitivity of the X-ray diffractometer in use and, consequently, they agree with the X-ray diffraction data (Fig. 1).

CONCLUSIONS

(1) Water in limestone (7.52%) is in three states: in the base substance (calcite) and in hematite and ferrigaluasite impurities.

(2) The chemical composition of limestone is as follows (%): $CaCO_3 \cdot 0.06H_2O$ 96.20, α-$Fe_2O_3 \cdot 0.38H_2O$ 1.06, $(Fe^{III}, Al_4)(OH)_8(Si_4O_{10}) \cdot 1.74H_2O$ 1.47, and impurities 1.17.

(3) The impurity of H_2O in calcite enhances the limestone thermal stability, whereas impurities of iron(III) compounds reduce it.

(4) The available data suggest that calcite is bound to impurities of iron(III) compounds in limestone through H_2O molecules.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Determination of Solid-Phase Composition in Alcohol–Water–Salt Systems from Data on Vapor–Saturated Solution Equilibrium

A. N. Marinichev

St. Petersburg State University, St. Petersburg, Russia

Received January 30, 2003

Abstract—A thermodynamic method is proposed for calculating the composition of the solid phase crystallizing from a three-component saturated solution occurring in equilibrium with a two-component vapor phase. The method is illustrated by an example of the methanol–water–salt systems under the isothermal and isobaric conditions.

Systems of inorganic salts in aqueous–organic solvents are widely used in chemical technology for salt extraction and distillation, which are suitable for separation and purification of substances. Recently, much attention has been given to the interaction of ions in a solution with solvent molecules, salting-in and salting-out phenomena. Various multiparametric models describing solvation and hydration in mixed solvent are described in the literature. At the same time, if the vapor phase is assumed to be an ideal gas mixture, it becomes possible to obtain in a comparatively simple form a number of thermodynamic relations for calculating the composition of the coexisting one-, two-, or three-component solid phase from the data on two-phase equilibrium (for example, between two-component vapor and three-component saturated solution). This was the subject of our study. Note also that the treatment of experimental data to reveal how the temperature or pressure at which the phases coexist depends on the vapor phase composition was made previously in [1] to predict the composition of the liquid phase (or liquid phases) in systems consisting of volatile components only.

Let us present the fundamental equation describing under isothermal conditions (T = const) a change in the state of a salt-saturated solution in the form

$$V_l dP = x_1 d\mu_2 + x_2 d\mu_2 + x_3 d\mu_3, \qquad (1)$$

where V_l is the molar volume of a solution; P, pressure at which the phases coexist; x_i and μ_i, mole fraction and the chemical potential of the ith component in solution.

Let alcohol be the first component, water, the second, and salt, the third. If the solid phase in equilibrium with a three-component solution is a compound of constant composition containing ν_1 alcohol molecules and ν_2 water molecules per salt formula unit, then the isothermal variations of the chemical potentials of components are related as

$$0 = \nu_1 d\mu_1 + \nu_2 d\mu_2 + d\mu_3. \qquad (2)$$

Let us consider how ν_1 and ν_2 can be calculated from data on the saturated solution–vapor equilibrium, and thus how the actual composition of the solid phase can be determined without additional experimental study.

If the vapor phase containing solely volatile components (alcohol and water) is assumed to be an ideal gas mixture, then for isothermal conditions the following relationship is valid:

$$d\mu_i = RT\ln(Py_i), \qquad i = 1,2, \qquad (3)$$

where y_i is the mole fraction of the ith component in the vapor phase (hereafter, $y \equiv y_1$).

Since $PV_l/RT \ll 1$, the expression in the left-hand side of the inequality can be neglected compared to unity. After simple transformations of (1)–(3) are performed, the final relationship becomes as follows:

$$\tilde{x} \equiv \frac{x_1 - \nu_1 x_3}{1 - (1 + \nu_1 + \nu_2)x_3} = y\left[1 - (1 - y)\frac{d\ln P}{dy}\right]. \qquad (4)$$

Let us illustrate the applicability of (4) to analysis of the isothermal data on the solid salt–salt-

* Additional data from [3] are printed italic.

saturated solution–vapor equilibrium in the system methanol–water–calcium chloride at 25°C. Fairly extensive data are available for this system [2, 3]; these data show that the solubility line contains four branches of crystallization of solid phases: $CaCl_2 \cdot 6H_2O$, $CaCl_2 \cdot 4H_2O$, $CaCl_2 \cdot 2CH_3OH$, and $CaCl_2 \cdot 4CH_3OH$. The saturated vapor pressures and compositions of the coexisting phases for the crystallization branch of the hexahydrate are presented in Table 1. The calculated values of the saturated vapor pressure $\tilde{P}$ as a function of composition can be determined with a high correlation coefficient (0.996) by treatment of the experimental data by the correlation equation (hereafter, the standard deviations of the left-hand side values are given with the ± sign in parentheses).

$$\tilde{P} = \exp[1.918(\pm 0.010) + 1.060(\pm 0.021)y]. \quad (5)$$

After the $\tilde{x}$ values were calculated from Eqs. (4) and (5), ν_1 and ν_2 were determined from the evident linear relationship easily derived from (4):

$$Z = \nu_1 + (1 + \nu_1 + \nu_2)\tilde{x}, \text{ where } Z \equiv \frac{\tilde{x} - x_1}{x_3}. \quad (6)$$

The values of the required coefficients [obtained from linear regression using Eq. (6) with the correlation coefficient of 0.979] are as follows: $\nu_1 = 0.28(\pm 0.08)$ and $1 + \nu_1 + \nu_2 = 6.9(\pm 0.3)$. Because the dispersion of the sum of the coefficients approached the ν_1 value, it can be accepted with assurance that $\nu_1 = 0$ and $\nu_2 = 5.9 \approx 6$, which is confirmed by the results obtained by the Schreinemaker's method of wet residues, as applied to the experimental data on the gross compositions of the prepared mixture and on the composition of the saturated solution. The proposed method using the dependence of the saturated vapor pressure on the vapor composition and Eqs. (4) and (6) for determining the liquid-phase composition has also been successfully applied to other crystallization branches of solid phases in the system considered.

Data on the vapor–saturated solution equilibrium for a large number of alcohol–water–salt ternary systems under isobaric conditions (P = const) are presented in a handbook [4]. As in [1], for these cases relationship (4) can be presented in the form

$$\tilde{x} = y\left\{1 + (1 - y)\frac{[L_1 y + L_2(1 - y)]}{R}\frac{\mathrm{d}(1/T)}{\mathrm{d}y}\right\}, \quad (7)$$

where T is the boiling point of the solution saturated with the corresponding salt; L_1 and L_2, molar heats of vaporization (J mol^{-1}) of the first and second components (methanol and water, respectively; L_1 = 35300 and L_2 = 40680 [5]); R, gas constant (8.31451 J mol^{-1} K^{-1}).

The data on the boiling points and compositions of the coexisting phases in the system methanol–water–potassium chloride at normal pressure are presented in Table 2. The calculated values of the boiling point $\tilde{t}$ (°C) as a functions of the vapor composition y were determined with a high correlation coefficient (0.998) by treatment of the experimental data (run nos. 1–7) using the correlation equation

13	0.004	0.905	65.3	0.963	65.4	0.898	–0.749
14	0.003	1	63.8	1	63.6	1	1

$$\tilde{t} = 10^3[2.62(\pm0.005) + 0.213(\pm0.026)y + 0.117(\pm0.029)y^2]^{-1} - 273.2. \quad (8)$$

After $\tilde{x}$ was calculated from Eqs. (7) and (8), ν_1 and ν_2 were determined, as previously, from linear equation (6). The values of these parameters appeared to be $\nu_1 = 0.11(\pm0.07)$ and $1 + \nu_1 + \nu_2 = 6.99(\pm0.26)$. Consequently, we can consider that $\nu_1 = 0$ and $\nu_2 = 5.99 \approx 6$. For run nos. 8–14, the following correlation equation is valid (with the correlation coefficient of 0.998):

$$\tilde{t} = 10^3[2.544(\pm0.008) + 0.425(\pm0.009)y]^{-1} - 273.2. \quad (9)$$

It should be noted that the $\tilde{x}$ values calculated using Eq. (9) for run nos. 9–14 are close to the relative mole fractions $x_1/(1 - x_3)$. This fact shows that, for this range of solution concentrations, the solid phase is KCl. The similar cases have been considered previously [6]. Run nos. 8 and 9 (Table 2) can be assigned to the transition region in which anhydrous KCl starts to crystallize instead of KCl hexahydrate.

Table 3 presents the experimental data and results of their treatment by relationship (7) for the system ethanol–water–mercury iodide at a pressure of 755 ± 3 mm Hg. Unfortunately, for this system the mole fractions of the salt in a saturated solution are not reported. Therefore, relationship (6) cannot be used. At the same time, the crystallization regions of various solid phases can be qualitatively predicted using relationship (7). In contrast to the previous system, the dependence of the boiling point t (°C) on the vapor composition y was derived using the orthogonal Chebyshev polynomials of the first kind [7]. The equation for calculating the boiling points with the correlation coefficient of 0.994 has the form

$$\tilde{t} = 10^3[2.86(\pm0.06) - 0.11(\pm0.09)y + 0.18(\pm0.05)T(2,y) + 0.08(\pm0.02)T(3,y)]^{-1} - 273.2,$$

where $T(2,y) = 2y^2 - 1$ and $T(3,y) = 4y^3 - 3y$ are the Chebyshev polynomials (higher polynomials did not noticeably improve the interpolation equation). The value of 34 000 J mol^{-1} [5] was taken for the molar heat of vaporization of ethanol.

As follows from Table 3, the differences between the experimental and calculated relative mole fractions of alcohol in solution reflect four concentration ranges: the first range covers run nos. 1–3; the second, run nos. 4 and 5; the third, run nos. 7–10; and the fourth, run nos. 11–13. In the first concentration range, crystallization of anhydrous mercury iodide can be assumed, whereas the second, third, and fourth ranges must correspond to solid phases containing different amounts of crystallization molecules of water and (or) alcohol. Therefore, in the concentration triangle the line of the saturated salt solutions would have four crystallization intervals corresponding to different solid phases.

CONCLUSIONS

The thermodynamic relations for calculating the composition of a solid phase crystallizing from a

SORPTION AND ION-EXCHANGE PROCESSES

Synthesis and Properties of Expandable Residual Graphite Hydrosulfate Obtained in the System CrO_3–H_2SO_4

A. P. Yaroshenko, M. V. Savos'kin, A. N. Magazinskii, and G. E. Vaiman

Litvinenko Institute of Physical Organic and Coal Chemistry, National Academy of Sciences of Ukraine, Donetsk, Ukraine

Received July 24, 2002; in final form, March 2003

Abstract—The fundamental aspects of synthesis of expandable residual graphite hydrosulfate with the use of an oxidizing system CrO_3–H_2SO_4 at ultralow consumption of the reagents and their separate introduction into the reaction mass were studied. The dependence of the expansion ratio of the samples obtained on the content of intercalant and expansion temperature was analyzed.

It has been shown previously that successive treatment of natural graphite with a concentrated aqueous solution of chromium(VI) oxide, sulfuric acid, and water yields expandable residual graphite hydrosulfates (RGH) of high quality [1–7]. The products obtained are characterized by high expansion ratios at relatively low expansion temperature (500°C), stability of properties in prolonged storage, and convenient use.

The method developed differs from the conventional techniques in that the graphite oxidation stage is carried out at ultralow consumption of the oxidizing agent and acid and the components of the intercalating solution are introduced into the reaction mass separately. The mass ratio of the total amount of liquid components and graphite does not exceed unity. Interaction of the liquid components to give active species executing the intercalation process occurs *in situ* in the adsorption layer on the surface of graphite particles. This study is concerned with the effect of synthesis conditions on the properties of the RGH obtained.

Natural flaked graphite of the GT-1 brand from the Zaval'evskoe deposit (Ukraine) with ash content of 5.68 wt % was subjected to oxidation. The graphite is mainly composed of two fractions: 74.3 wt % 0.630–0.315-mm particles and 22.1 wt % 0.315–0.200-mm particles. A 50% aqueous solution of chromium(VI) oxide (ρ = 1.501 g cm^{-3}) and concentrated (95%) sulfuric acid of chemically pure grade (ρ = 1.835 g cm^{-3}) were used.

Graphite was oxidized in a cylindrical glass reactor equipped with a T-shaped stainless still rabble. The reaction mass was stirred at room temperature without forced heating or cooling. The reactor was charged with 25 g of graphite, stirring was switched on, and the aqueous solution of chromium(VI) was added. After 10 min of stirring, sulfuric acid was introduced into the mixture and stirring was continued for an additional 10 min. Then 750 cm^3 of water was added to the oxidized graphite, and the resulting mixture was allowed to stand for 24 h for the hydrolysis to occur. During this period of time, continuous evolution of fine gas bubbles from the solid-phase layer was observed. Then the solid phase was filtered off in a water-jet-pump vacuum and washed on the filter with water to pH 5–6. The washed product was dried at 100–110°C to constant weight (moisture content not exceeding 1.0 wt %).

The consumption of the aqueous solution of CrO_3 was varied from 2 to 20 cm^3 per 100 g of graphite, and that of H_2SO_4, from 20 to 48 cm^3 per 100 g of graphite. For all of the 80 RGH samples obtained, the yield, expansion ratio in impact heating mode in the range 400–900°C, and weight loss in expansion at temperatures of 500–900°C were determined. The data on product yield were used to calculate the intercalant content m_i (wt %) in a compound obtained with account of the fact that the contribution from the phase oxidation of graphite under the synthesis conditions was negligible [8, 9].

The expansion ratio of the products obtained was determined as follows. A weighed portion of the product (m = 0.2–0.3 g) was placed in a stainless steel cell preliminarily mounted in a muffle furnace heated to a required temperature. The expansion was done for

1070-4272/03/7607-1052$25.00

5 min at 400–600°C and for 2 min at 700–900°C. The cell with expanded graphite was extracted from the furnace, its contents were carefully transferred to a glass volumetric vessel, and the volume V (cm^3) occupied by the expanded graphite was measured. The expansion ratio was found using the relationship $K_e = V/m$ as arithmetic mean of three replicate measurements.

The process involves graphite oxidation with chromium(VI) oxide and intercalation of the resulting positively charged graphite matrix with hydrosulfate anions solvated by sulfuric acid molecules to give graphite hydrosulfate. In the reagent consumption range used in this study, a compound of the second intercalation stage, $C_{48}^{+}\cdot HSO_4^{-}\cdot(2.0–2.5)H_2SO_4$, is formed.[1] Hydrolysis of this compound gives residual graphite hydrosulfate, in which sulfuric acid molecules solvating hydrosulfate anions in the interlayer space of the graphite matrix are replaced by water molecules.

We found that, with the reagent consumption in the graphite oxidation stage raised, the content of the intercalant in the final product grows. The RGH expansion ratio grows with increasing intercalant content and expansion temperature. The mass loss by RGH samples in their expansion in the temperature range 500–900°C depends linearly on the intercalant content m_i in the initial samples. A typical example of a dependence of this kind is shown for an expansion temperature of 500°C in Fig. 1. The dependences for the other temperatures are similar. For all these dependences, the intercept is virtually zero and the slope is close to unity. This indicates that the expansion in the specified temperature range occurs without burnout of the carbon matrix and is accompanied by virtually total removal of intercalant species.

It was found unexpectedly that, whereas the dependences of the weight loss on the intercalant content in RGH are linear for all the expansion temperatures, the dependences of the expansion ratio on the intercalant content are exponential. For all the expansion temperatures studied, these dependences are expressed by an equation of the type

$$K_e = A\exp(bm_i), \quad (1)$$

where A and b are constants.

A typical semilog plot of the expansion ratio at 500°C vs. the intercalant content m_i in RGH is shown in Fig. 2.

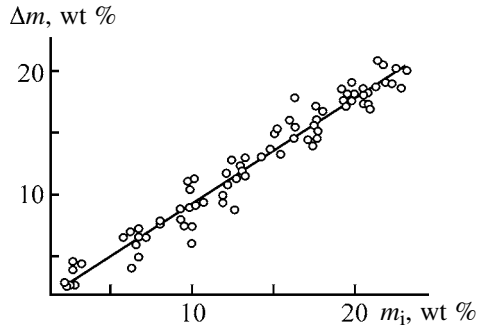

Fig. 1. Weight loss Δm from RGH samples in their expansion at 500°C vs. intercalant content m_i in the samples. $Y = 0.86x + 0.63$; $R^2 = 0.96$.

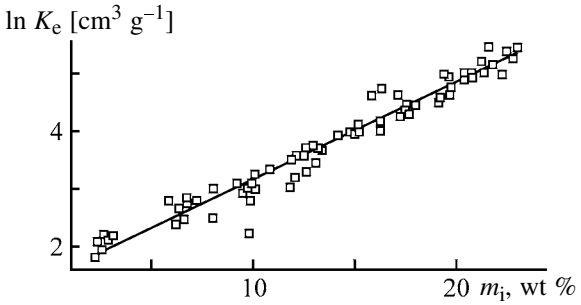

Fig. 2. Semilog plot of the expansion ratio K_e of RGH samples at 500°C vs. intercalant content m_i in the samples. $Y = 0.17x + 1.49$; $R^2 = 0.96$.

The dependences obtained at other expansion temperatures are similar and can also be described by Eq. (1). The parameters of Eq. (1) for expansion of RGH samples at 400–900°C are listed in the table.

It can be seen that, for all the expansion temperatures, parameter b remains virtually invariable, whereas parameter A grows linearly with increasing expansion temperature (Fig. 3).

Figure 4 shows the dependences of the expansion ratio of RGH samples on the content of the intercalant in them and on the expansion temperature. The entire

Parameters of Eq. (1) in relation to expansion temperature T of RGH samples

T, °C	A	b
400	2.36	0.136
500	4.44	0.167
600	7.48	0.156
700	9.17	0.158
800	10.75	0.160
900	14.47	0.146

[1] The general formula of graphite hydrosulfate is $C_{24n}^{+}\cdot HSO_4^{-}\cdot mH_2SO_4$, where n is the stage number of a graphite intercalation compound, designating the number of graphite layers between the two nearest layers of the intercalant.

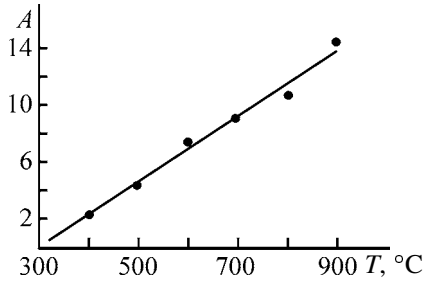

Fig. 3. Parameter A in Eq. (1) vs. expansion temperature. $Y = 0.0232x - 6.97$; $R^2 = 0.985$.

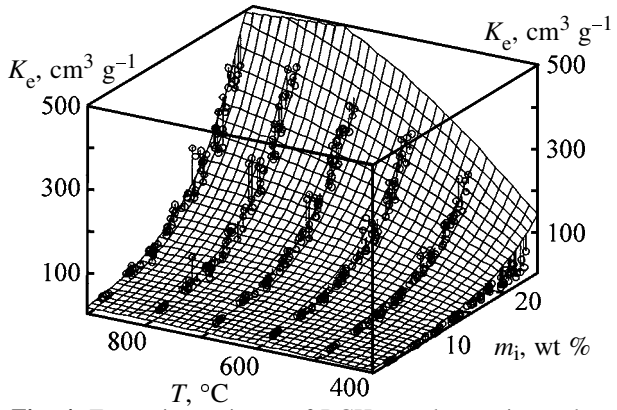

Fig. 4. Expansion ratio K_e of RGH samples vs. intercalant content m_i in the samples and expansion temperature T.

body of data is fairly well described ($R^2 = 0.94$) by the following two-parameter equation:

$$\ln K_e = a + bm_i + c/t^2, \quad (2)$$

where $a = 3.150$, $b = 0.143$, and $c = -285\,600$.

Analysis of the response surface shows that its sections parallel to the temperature axis are near linear at small m_i and take the form of flat, leveling-off curves at higher values of this parameter. The sections parallel to the axis of intercalant content m_i, which are described by the bm_i term in Eq. (2), are exponential dependences, in agreement with a description by a single-parameter equation (1).

The observed exponential dependence of the expansion ratio on the intercalant content is unconventional, since a linear relationship between these parameters is observed for graphite nitrate and other compounds obtained on the basis of graphite hydrosulfate with nitric acid as oxidizing agent [10]. Indeed, the linear dependence can be readily accounted for assuming that the chemical nature and composition of the intercalant remain unchanged when its content grows. In this case raising the intercalant content at constant expansion temperature must lead, in accordance with the Mendeleev–Clapeyron equation, to a linear rise in K_e, and this behavior is indeed observed experimentally [10].

As compared to graphite intercalation compounds, which exhibit a linear relationship between K_e and m_i, with RGH the pattern is different. In all probability, the chemical nature of the intercalant changes with its increasing content in RGH. Species having higher efficiency in RGH expansion are accumulated in the layer introduced. It may be assumed that structural fragments similar to those in the case of graphite oxide act as species of this kind. Such structural fragments may be accumulated as a result of oxidative-hydrolytic processes occurring in the stage of hydrolysis of graphite hydrosulfate [9, 11].

The products obtained under the optimal synthesis conditions are characterized by expansion ratios of 300–400 cm^3 g^{-1} at 900°C and 200 cm^3 g^{-1} at 500°C.

CONCLUSIONS

(1) It was found that the expansion ratio of a product at a given temperature is determined by the content of intercalant in it.

(2) An exponential dependence of the expansion ratio on the intercalant content was observed for the first time for the products obtained.

(3) An assumption was made that the possible reason for such an unusual behavior is a change of the chemical nature of intercalant species.

SORPTION AND ION-EXCHANGE PROCESSES

Synthesis and Sorption Properties of Filled Fibrous Sorbents with Immobilized Hetarylformazan Groups

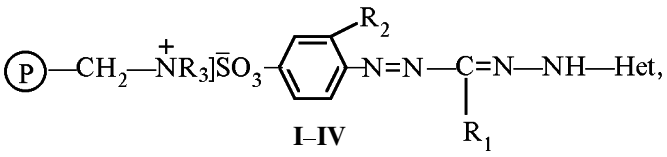
Abstract—New sorbents were prepared by immobilization of structurally different sulfur-containing hetarylformazans on nonwoven polyacrylonitrile fiber filled with AV-17 anion exchanger. Sorption of some heavy metals on these materials was studied as influenced by various factors. Sorbents for selective recovery of copper(II) in the presence of nickel(II), zinc(II), and cadmium(II) cations were found.

Fibrous ion-exchange sorbents widely used for recovering metal ions from solutions attract growing attention [1, 2]. Introduction of complexing groups into fibrous materials increases their selectivity with respect to some metals. These modified sorbents are used for selective recovery of valuable elements of multicomponents solutions and for removal of toxic metals from natural waters [3, 4]. Filled fibrous materials are the most promising [5] since they exhibit good sorption and kinetic properties and can be used for recovery of metals under dynamic conditions. A finely divided complexing sorbent is used as a filler.

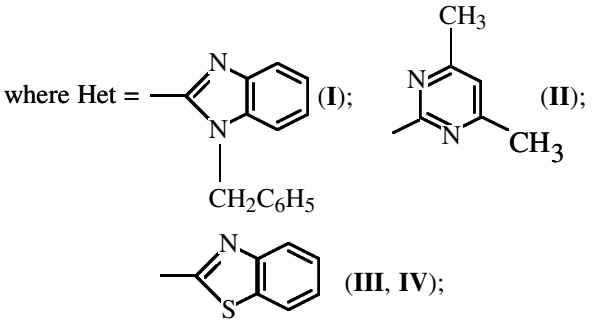
Previously we showed [6–8] that immobilization of complexing formazan groups on AN-20, AN-18, and AV-17 anion exchangers substantially improved their sorption activity and selectivity with respect to some metals. In this work, sulfur-containing hetarylformazans were immobilized on nonwoven polyacrylonitrile fiber filled with AV-17 anion exchanger, and the properties of the resulting sorbents were studied.

EXPERIMENTAL

Nonwoven polyacrylonitrile fiber filled with AV-17 anion exchanger was prepared by the special procedure (Russian Research Institute of Manmade Fibers, Tver). The thickens of a swollen fiber thread was 30–100 μm; the filler content was 50%. The fiber was modified with various formazans with different heterocyclic fragments containing different substituents at the aromatic ring (Table 1). The possible structure of the resulting sorbents is shown below:



I–IV



where Het = (**I**); (**II**);

(**III**, **IV**);

$R_1 = CH_3$ (**I, II**), C_2H_5 (**III, IV**); R_2 = H (**I**–**III**), OH (**IV**).

The content of formazans (*A*) in **I** and **II** was 0.15 and 0.09 mmol g^{-1}, respectively, and that in **III** and **IV** was 0.10 mmol g^{-1}.

The formazan groups were immobilized by the following ion-exchange procedure. To a weighed portion of the fiber filled with AV-17 anion exchanger in the OH^- form (0.4 g), an aqueous–ethanolic solution (1 : 1) (100 ml) of formazan (0.05 g) was added. The mixture was stirred with a vibrator for 4–6 h. The sorbent was filtered off, washed with distilled water, and dried in air. The residual formazan concentration

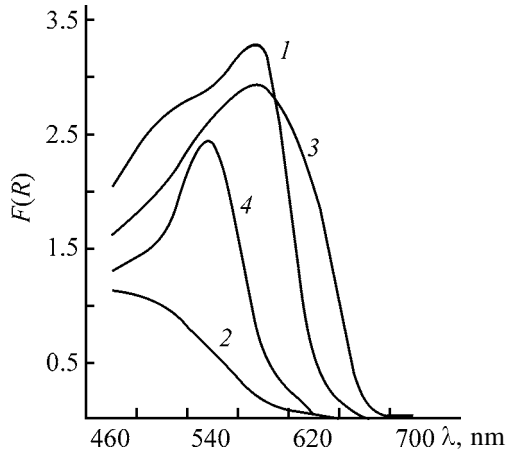

Fig. 1. Diffuse reflectance spectra of modified fibrous sorbents (*1*) **I**, (*2*) **II**, (*3*) **III**, and (*4*) **IV** filled with AV-17. (λ) Wavelength.

in the filtrate was determined photocolorimetrically. Immobilization of formazan was indicated by a change in the fiber color from colorless to yellow or red-violet depending on the formazan structure. Diffuse reflectance spectra of modified sorbents **I**–**IV** are shown in Fig. 1. As seen from Fig. 1, sorbents **I, III**, and **IV** strongly absorb in the range 530–640 nm. In the spectrum of sorbent **II** containing pyrimidinylformazan, a hypsochromic shift of λ_{max} to 500 nm is observed. The content of formazan groups A in modified fibers **I**–**IV** was 0.09-0.15 mmol g^{-1}.

We studied sorption of Cu(II), Ni(II), Zn(II), and Cd(II) cations on the initial and modified fibers. The sorption under static conditions was performed for 3 days by intermittent stirring of a mixture of aqueous solutions of copper(II) sulfate, nickel(II) nitrate, zinc(II) chloride, and cadmium(II) chloride with the sorbent at the solution volume–sorbent weight ratio of 500 : 1. The metal concentration in the electrolytes was 100 and 1000 mg l^{-1}; pH was 3.5 and 6.9. The contact time in the sorption kinetic experiments varied from 10 to 90 min.

Sorption capacity of modified fibrous sorbents. Contact time 3 days, $V : m = 500$

Fiber	c_M, mg l^{-1}	pH	SC, mg-equiv g^{-1}			
			Cu(II)	Ni(II)	Zn(II)	Cd(II)
Initial	100	6.9	0	0.09	0.25	0
I	100	6.9	0.32	0.10	0.13	0
II	100	6.9	0.91	0.10	0.08	0
III	100	6.9	0	0	0.59	0.60
IV	100	6.9	0	0.08	0.69	0.60
I	1000	6.9	0.62	0	0.39	0.90
II	1000	6.9	0.50	0	0.39	0.90
I	1000	3.5	1.09	0.31	0.47	0.78
II	1000	3.5	0	1.38	0.60	1.00

The sorption under dynamic conditions was performed by passing an electrolyte solution at a 0.5 ml min^{-1} flow rate through a 50-mm sorbent bed packed in a glass column 10 mm in diameter.

The metal concentration in model solutions of pure salts, solutions after the sorption, and eluates was determined photocolorimetrically, and in mixed electrolyte solutions, by atomic absorption analysis.

To determine the sorption capacity of the fibers (SC), we measured sorption of heavy metal cations from 100 mg l^{-1} aqueous solutions of their salts at pH 6.9 (see table).

The sorption capacities for Cu(II) of fibers filled with AV-17 anion exchanger and modified with benzimidazolyl and pyrimidinylformazan groups (sorbents **I** and **II**, SC 0.32 and 0.91 mg-equiv g^{-1}, respectively) are higher than those of the initial fiber.

Fibers modified with benzothiazolylformazans (sorbents **III** and **IV**) have high sorption capacity for Zn(II) and Cd(II) and do not sorb Cu(II) and Ni(II).

Not only Cu(II) but also Zn(II) and Cd(II) are sorbed on **I** and **II** from 1000 mg l^{-1} solutions of salts of these metals at neutral pH. In acidic solutions (pH 3.5) the sorption of all the examined metals on **I** and **II** increases [except for sorption of Cu(II) on **II**] as compared to that at pH 6.9. In acidic solutions sorbent **II** sorbs Ni(II), Zn(II), and Cd(II), and its sorption capacity for Cu(II) and Cd(II) is lower than that of **I**.

The study of sorption of heavy metal ions on the modified fibrous sorbents filled with AV-17 anion exchanger showed that immobilization of hetarylformazans on the fiber enhances not only the sorption capacity but also selectivity with respect to some metals.

Thus, sorbent **II** can be used for concentration and recovery of Cu(II) from neutral solutions containing Ni(II), Zn(II), and Cd(II) at the total metal concentration of up to 100 mg l^{-1}, and sorbents **III** and **IV**, for joint recovery of Zn(II) and Cd(II) in the presence of Cu(II) and Ni(II) under the same conditions.

With polyacrylonitrile fiber **I** filled with AV-17 anion exchanger and modified with formazan with benzylbenzimidazole groups was example, we studied in more detail how the sorption of heavy metal ions

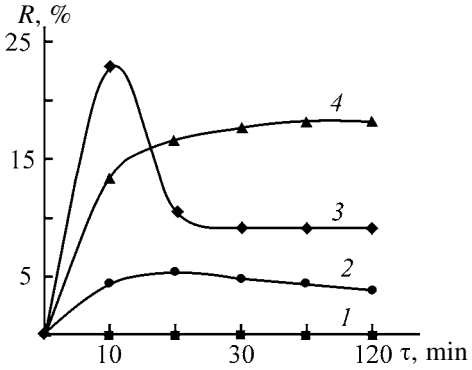

Fig. 2. Degree of sorption R of (*1*) Cd^{2+}, (*2*) Ni^{2+}, (*3*) Zn^{2+}, and (*4*) Cu^{2+} (the same for Fig. 3) on fiber **I** from model solutions of their pure salts under static conditions as a function of the phase contact time. Concentration c_M, mg l^{-1}: Ni^{2+} 25; Cd^{2+}, Cu^{2+}, and Zn^{2+} 75; pH 5.5–6.9; $V : m$ = 500; the same for Fig. 3.

depends on the phase contact time. The sorption kinetics on this sorbents was studied under the static conditions (R is the degree of sorption of metal ions) on the sorbent. The kinetic curves of sorption of Cd(II), Ni(II), Zn(II), and Cu(II) ions from model solutions of pure salts of these metals are shown in Fig. 2. Sorption of Zn(II) and Cu(II) cations on fiber **I** is characterized by good kinetic parameters favorable for recovery of these metals from multicomponent solutions.

Selective sorption on **I** of Zn(II) in the presence of Ni(II) and Cd(II) (Fig. 3a) and Cu(II) in the presence of Ni(II) and Cd(II) (Fig. 3b) confirms the good kinetic properties.

To find whether Zn(II) and Cu(II) cations can be selectively recovered under dynamic conditions, we compared the dynamics of sorption of these cations on fiber **I**.

As seen from the outlet curves for Zn(II) and Cu(II) (Fig. 4), Cu(II) can be completely recovered from Zn(II)-containing aqueous solutions under dynamic conditions. The time during which a filter based on sorbent **I** ensures protective effect with respect to Cu(II) cations is longer than that with respect to Zn(II) cations.

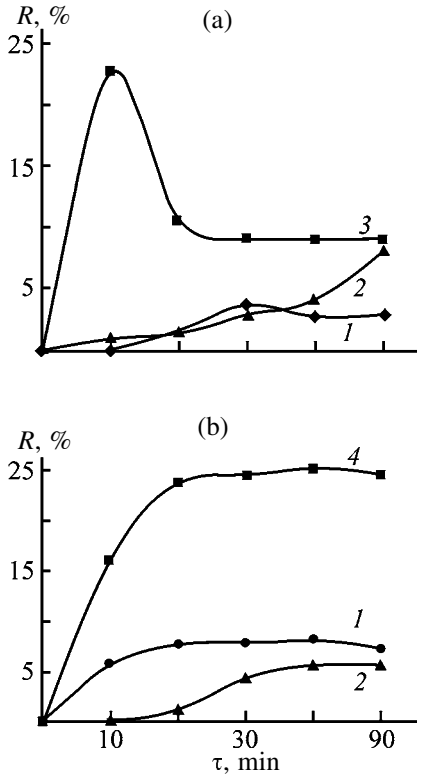

Fig. 3. Degree of sorption of the metal ions R on fiber **I** from model solutions containing a mixture of (a) Cd^{2+}, Ni^{2+}, and Zn^{2+} and (b) Cd^{2+}, Ni^{2+}, and Cu^{2+} ions under static conditions as a function of phase contact time.

CONCLUSIONS

(1) The prepared fibrous polymers with hetarylformazan groups are promising sorbents for recovering Cu(II) cations from solutions containing nickel(II), zinc(II), and cadmium(II) cations.

(2) Sorbents modified with fragments of benzothiazolylformazans can be used for concentrating Zn(II) and Cd(II) cations from dilute solutions and for separating these cations from Cu(II) and Ni(II); sorbents modified with pyrimidinylformazan, for concentrating and separating Cu(II) from solutions containing Ni(II), Zn(II), and Cd(II); and sorbents modified with benzylbenzimidazolylformazans, for concentrating Cu(II) from dilute solutions and for separating Cu(II) from Ni(II) and Cd(II).

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Manganese-Containing Anodic Layers on Titanium

Abstract—Data on formation of anodic layers containing $MnTiO_3$, β-Mn_2TiO_4, Mn_2O_3, Mn_3O_4, and $Mn_3(BO_3)_2$ on titanium from aqueous electrolytes at sparking voltages are presented.

Transition metals oxides and, in particular, manganese oxides are used in catalysis because of their thermal stability and relatively high activity [1, 2]. A conventional method for fabrication of oxide catalysts is thermal decomposition of salts or hydroxides of the corresponding metals on the surface of pretreated supports [3]. Salts or hydroxides are deposited on a substrate by impregnation or precipitation from solutions, by solution spraying, deposition from the gas phase, etc.

Certain opportunities in synthesis of various high-temperature oxide structures, including those promising for catalysis [4–6], on metal surfaces are furnished by anodic-spark deposition. It could be expected that coatings formed on the surface of rectifying metals from aqueous electrolytes with manganese salts should contain manganese oxides, manganese-containing oxide solid solutions, or spinels [7]. For example, coatings containing $MnTiO_3$ spinel [7, 8] have been obtained on titanium from an electrolyte containing Na_2SO_4 and $Mn(CH_3COO)_2$.

It is practically important that, in this technique, high-temperature oxides are synthesized at the surface of the metallic anode in the bulk of the aqueous electrolyte at an average temperature not exceeding 100°C. As additional advantages of the technique can be regarded the following: (i) formation, between the metal and the active layer, of a sublayer composed of the oxide of a metal being anodized, which can serve as a support; (ii) possibility of processing articles with complex geometric shape; and (iii) restoration of the catalyst properties by repeated treatment of an article. However, insufficient attention has been given to application of this technique for preparing oxide catalyst supports on metals and catalytically active structures [4–6].

It has been shown previously that anodic layers containing a thermally stable rutile modification of TiO_2 are formed on titanium in an aqueous tetraborate electrolyte [9]. The aim of this study was to analyze the influence exerted by addition of manganese-containing salts on the formation and the elemental and phase composition of anodic-spark layers on titanium.

EXPERIMENTAL

For surface standardization, samples ($25 \times 5 \times 1$ mm) of VT1-0 titanium were ground mechanically, polished chemically in a 1 : 3 mixture of concentrated HF and HNO_3 at 60–80°C for 2–3 s [10], washed with distilled water, and dried in air.

Electrolytes were prepared from distilled water and commercial reagents $Na_2B_4O_7 \cdot 10H_2O$, $Na_3PO_4 \cdot 12H_2O$, $KMnO_4$, $Mn(CH_3COO)_2 \cdot 4H_2O$, $MnSO_4 \cdot 5H_2O$, and 96% C_2H_5OH, all of chemically pure grade. Electrolytes containing $KMnO_4$ were prepared by adding the required weighed portions of the salt to a 0.1 M solution of $Na_2B_4O_7$. The remaining electrolytes were prepared by combining solutions of sodium tetraborate or orthophosphate and an appropriate manganese(II) salt. Ethanol was added either to a mixture of solutions or to an $Mn(CH_3COO)_2$ solution.

Anodic films were formed in the mode of spark and microarc electric breakdowns. As power source served a TEP4-100/46OH thyristor converter generating pulsed unipolar current. The treatment was done both in the galvanostatic mode at i = 0.2 A cm^{-2} and

1070-4272/03/7607-1059$25.00

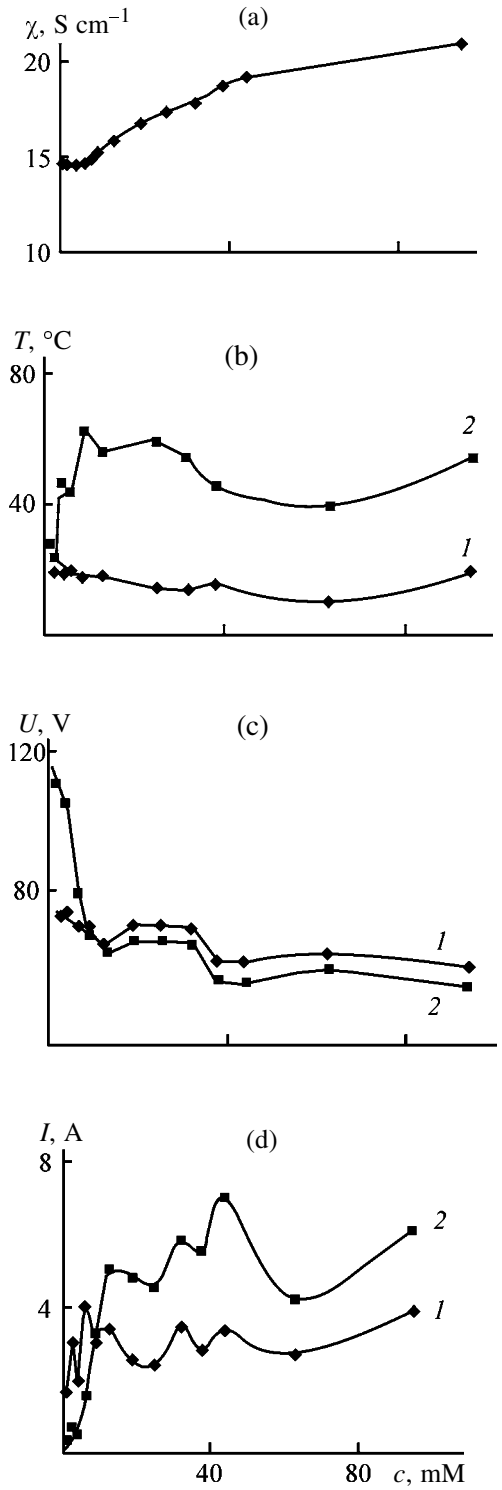

Fig. 1. Effect of the concentration c of $KMnO_4$ additive in 0.1 M tetraborate aqueous electrolyte on (a) electrical conductivity χ of the solution, (b) temperature T of the electrolyte, (c) voltage U across the electrodes, and (d) current I flowing through the cell. Coatings formed in the falling-power mode, U_s = 450 V, treatment duration 4 min. Parameter values: (*1*) initial and (*2*) final.

in the falling-power mode. In the latter case, voltage was set to U_s = 450 or 500 V in the open-circuit mode and then the power source was connected to the electrochemical cell.

Anodic-spark deposition was carried out in a 500-ml vessel made of heat-resistant glass. As cathode served a pipe coil made of Cr18Ni9Ti stainless steel and cooled with tap water. The cooling conditions (flow rate and temperature of water) were the same in all the experiments. The initial temperature of the electrolytes was 13–18°C. Oxidized samples were washed with distilled water and dried in air.

The phase composition of the coatings was determined on a DRON-2.0 X-ray diffractometer (CuK_α radiation), and the elemental composition, on a JXA-5A X-ray fluorescence microanalyzer which gave no way of determining light elements, including boron and oxygen. Electron-microscopic studies were performed on an LEO 430 microscope.

Data on the influence of $KMnO_4$ additive on the electrical conductivity of the tetraborate electrolyte, formation parameters (voltage across the electrodes, current flowing through the cell, temperature in the solution bulk), and elemental and phase composition of the anodic layers formed are shown in Figs. 1 and 2. The results obtained make it possible to distinguish three $KMnO_4$ concentration ranges in which variations of the process parameters under study, electrolyte characteristics, and composition of the surface layers formed are observed (M): $c < 9 \times 10^{-3}$ (I), $9 \times 10^{-3} < c < 40 \times 10^{-3}$ (II), and $c > 40 \times 10^{-3}$ (III).

In region I, the content of titanium in the coatings formed decreases and that of manganese increases with growing $KMnO_4$ concentration. The content of sodium is 0.1–0.2 wt %. The oxide layers contain crystalline TiO_2 phases (rutile, anatase). In the course of time, as films are formed in the falling-power mode, the final voltage across the electrodes increases and the current flowing through the cell decreases.

In contrast to the situation in region I, the voltage across the electrodes decreases and the current flowing through the cell increases in the course of oxide layer formation in regions II and III. Also, the electrolyte warms up to a much greater extent. The films obtained contain 1–2 wt % sodium. In region II, the content of titanium in the anodic layers increases (up to 60 wt %) and that of manganese decreases. The layers contain, together with titanium oxides, crystalline $TiBO_3$. In region III, as also in region I, the content of manganese in the surface part of the films, which is analyzed, increases and that of titanium decreases.

The films formed contain crystalline phases $MnTiO_3$ and β-Mn_2TiO_4. Raising the treatment duration and the initial voltage across the electrodes leads to higher crystallinity of the oxide structures obtained (Fig. 2).

The experimental data indicate that, in the above-considered ranges of $KMnO_4$ concentration in the tetraborate electrolyte, the processes of solution component incorporation into the anodic-spark coatings are different.

As $KMnO_4$ is added to the tetraborate electrolyte, the solution becomes dark violet (a coloration typical of permanganate ions), and the color intensity grows. Before carrying out the oxidation process, no precipitates are formed in the solutions, and the pH value of the solutions under study is independent of the $KMnO_4$ concentration and equals 9.48–9.52. A change in the electrical conductivity of the electrolytes is observed in concentration range II (Fig. 1a). This is due to a change in the charge, number, and mobility of charge carriers, i.e., to a change in the ionic composition of the electrolyte. In the course of electrolysis, a dark brown MnO_2 precipitate is gradually accumulated in the cell, and metallic manganese is deposited at the cathode.

Reasoning from the results described above, known concepts of the mechanism of anodic-spark deposition [11–14], and chemistry of boron and manganese, the processes associated with the influence exerted by the components of the tetraborate–permanganate electrolyte on the formation parameters and composition of oxide layers can be represented schematically as follows. The composition of an anodic-spark layer is determined by two basic concurrent processes: (a) electrochemical oxidation of the anode metal on parts free of the influence of electric breakdowns and (b) interaction between the electrolyte components and the substrate, thermolysis and partial melting of the precipitate formed from the electrolyte, and phase transitions near electric breakdown channels. In a single-component tetraborate electrolyte, anodic-spark layers formed at the titanium anode contain TiO_2 in the rutile modification [9]. Being an oxidant, $KMnO_4$ presumably additionally initiates in the tetraborate electrolyte oxidation of the titanium substrate in areas free of breakdowns. This assumption is confirmed by the presence of a low-temperature anatase modification of TiO_2 in coatings formed in concentration ranges I and II. At the same time, formation of MnO_2 via redox reactions at the anode, in the near-anode region, and in the solution bulk and through permanganate decomposition near the breakdown channels under the action of elevated temperature leads to incorporation of manganese compounds into coatings and to formation of an MnO_2 precipitate in the electrolyte. The reducing medium at the anode and in the near-anode region is created by thermolysis of water under the action of electric breakdowns [15, 16]. Areas of frozen melt, separated by cracks, are

Falling-power mode; U = 450 V, (a, c) τ = 4 min and (d) 10 min; (b, e) U_s = 500 V, τ = 4 min. Elemental content: (*1*) Mn and (*2*) Ti.

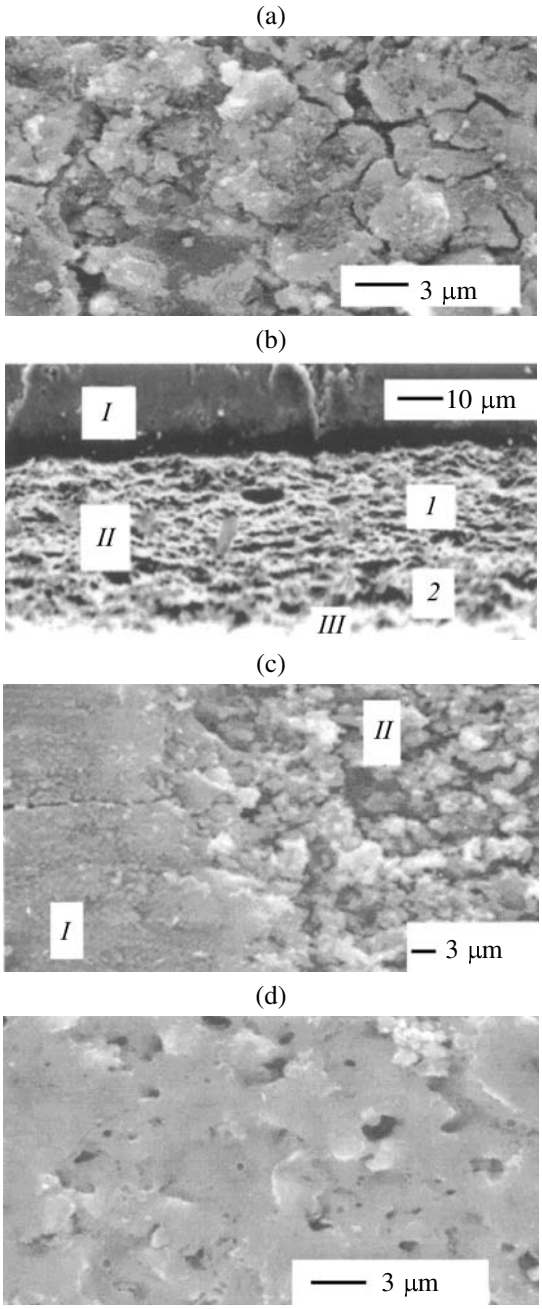

Fig. 3. (a, c, d) Plan-view and (b) cross-sectional electron micrographs of a sample with coating. Coatings contain the following phases: (a) $MnTiO_3$, β-Mn_2TiO_4; (b, c) Mn_2O_3, Mn_3O_4; and (d) $Mn_3(BO_3)_2$. (b) (*I*) Titanium and (*II*) anodic layer; (*1*) inner and (*2*) outer part; (c) (*I*) dense part and (*II*) part containing loosely packed particles.

seen on the surface of coatings formed in region III (Fig. 3a). Presumably, $MnTiO_3$ and β-Mn_2TiO_4 are formed by interaction of titanium and manganese oxides in the melt with its subsequent crystallization.

The scheme described is in agreement with the composition of anodic layers formed in concentration ranges I and III, i.e., at low and high $KMnO_4$ concentrations in the tetraborate electrolyte. In the intermediate region II, the content of manganese in the anodic layers formed is insignificant and the coatings contain titanium borate. This means that, in region II, a change in the ionic composition of the electrolyte near the breakdown channels results in that boron-containing compounds are mainly deposited, undergo thermolysis, and interact with titanium oxide.

The warming-up of electrolytes, decrease in the voltage across the electrodes, and increase in the current flowing through the electrochemical cell in the course of anodic-spark deposition of oxide layers in concentration ranges II and III are interrelated phenomena. They may be due to occurrence of exothermic reactions at the anode, formation of structures with low electrical resistance in the oxide, or changes in energy-related parameters of separate electric breakdowns.

On combining aqueous solutions of 0.1 M $Na_2B_4O_7$ and $Mn(CH_3COO)_2$ (with the concentration in the range 18.1×10^{-3}–90.5×10^{-3} M), a jelly-like pinkish white precipitate was formed. The pH value changed from 8.89 to 8.68. When coatings were formed with stirring by a magnetic stirrer, the precipitate was in the electrolyte bulk in the form of a suspension.

The elemental and phase composition of the coatings formed in these electrolytes are listed in Table 1. In contrast to the previously considered processes in an electrolyte with $KMnO_4$, a decrease in the current flowing through the cell and increase in the voltage across the electrodes is observed in coating formation for all the $Mn(CH_3COO)_2$ concentrations studied. With increasing $Mn(CH_3COO)_2$ concentration in the electrolyte, the content of manganese in the surface part of the anodic layers formed grows, and that of titanium falls, to 60–70 and 2–6 wt %, respectively. At $c > 45 \times 10^{-1}$ M, the crystalline phases of Mn_2O_3 and Mn_3O_4 are present in the coatings formed. The surface of the coatings is colored dark brown. Figure 3b shows a cross-sectional electron micrograph of a titanium sample with coating no. 11 (Table 1). The coating has nonuniform thickness, varying from 50 to 60 μm. A 10–20-μm-thick layer with relatively poor adhesion lies on the outer part of the coating. On its surface, dense areas alternate with areas composed of loosely packed particles 9 μm and less in size (Fig. 3c). It is noteworthy that films obtained in the galvanostatic mode are denser and show better adhesion to the substrate than films formed in the falling-power mode.

* τ is the coating formation duration.
** X/a, X-ray-amorphous; r, rutile; ?, possible presence of a phase.

The effect of the precipitate in the bulk of the tetraborate–acetate electrolyte on the formation and the elemental and phase composition of coatings was analyzed. For this purpose, the precipitate from electrolyte no. 4 (Table 1) was filtered off. In the surface layers formed under the same conditions in an electrolyte with the precipitate removed, the content of manganese decreased to 10 wt %, and that of titanium increased to 50 wt %. In their elemental and phase composition and outward appearance, these layers correspond to coatings no. 1 (Table 1).

As follows from the data obtained, coatings containing crystalline manganese oxides can be formed, in the systems and conditions under study, in a colloid electrolyte. It could be expected that the precipitate formed in a tetraborate–acetate aqueous electrolyte at pH 9 should contain manganese hydroxides [17] and manganese borates [18] simultaneously. In addition, borate ions are coprecipitated, together with metal hydroxides, from solutions of this kind at pH 8–10 [19]. Apparently, particles containing manganese hydroxides and borates are deposited at the anode in the experimental conditions under the action of spark and microarc electric breakdowns. The high temperature in the vicinity of breakdown channels causes decomposition of manganese hydroxides to manganese oxides. At temperatures of 600–800°C, metal borates undergo a "borate rearrangement," crystallization and decomposition with partial liberation of B_2O_3 [18]. Since no crystalline boron-containing compounds were found in the layers formed, the precipitate deposited at the anode is presumably mainly composed of manganese hydroxide with minor amount of manganese and sodium borates.

An assumption was made that addition of organic compounds, e.g., ethanol, to an electrolyte will favor formation of coatings containing oxides with varied degree of manganese oxidation. Ethanol was added either to a colloid electrolyte containing 0.1 M solution of $Na_2B_4O_7$ and $Mn(CH_3COO)_2$ (scheme 1, Table 2, coating nos. 1–4) or to a solution with manganese acetate before combining it with an $Na_2B_4O_7$ solution (scheme 2, Table 2, coating nos. 7 and 8). Adding ethanol in accordance with scheme 1 affects the composition of the coatings obtained (Table 2, nos. 1–6; Table 1, nos. 4 and 5), with the manganese content decreasing substantially. Raising the amount of alcohol or the treatment duration leads to crystallization of boron-containing compounds, including Mn(II) borate, in the coatings. Partly melted glassy formations can be seen on the coating surface around breakdown craters (Fig. 3d). Addition of ethanol to an $Mn(CH_3COO)_2$ solution before combining it with a 0.1 M $Na_2B_4O_7$ solution (scheme 1) has no effect on the composition of the coatings obtained (Table 1, no. 5; Table 2, nos. 7 and 8).

composition of anodic layers can be accounted for as follows. It was established experimentally that addition of ethanol to a 0.1 M solution of $Na_2B_4O_7$ leads to salting-out of borates from the solution. Presumably, addition of C_2H_5OH in deposition of coatings from electrolytes prepared by scheme 1 makes higher the concentration of poorly soluble boron-containing compounds in the deposit formed at the anode. High temperatures in the vicinity of breakdown channels lead to a reaction between manganese oxides and boron-containing compounds to give titanium or manganese borates.

Addition of C_2H_5OH to an $Mn(CH_3COO)_2$ solution leads to formation of manganese(II) alcoholates [17]. When such a solution is combined with an aqueous solution of $Na_2B_4O_7$ (scheme 2), ethanol presumably has no effect on the state of $Na_2B_4O_7$ in solution, i.e., it does not affect the amount of boron-containing compounds arriving at the anode in the course of any particular breakdown.

Partial replacement of $Mn(CH_3COO)_2$ in a tetraborate electrolyte with $MnSO_4$ leads to lower content of manganese in the coatings formed and to synthesis of the $MnTiO_3$ spinel (Table 3). Previously, films with $MnTiO_3$ have been obtained in an electrolyte containing Na_2SO_4 together with $Mn(CH_3COO)_2$ [7, 8]. Apparently, the formation of spinels in the presence of the SO_4^{2-} ion in the electrolyte is determined by occurrence of redox reactions in the solution bulk, near the anode, and at the electrodes. The pH value of the solutions under study, which contain $Na_2B_4O_7$, $Mn(CH_3COO)_2$, and $MnSO_4$, is, depending on the relative concentrations of Mn(II) salts, within the range 8.7–9.3. The solutions give a jelly-like precipitate. With increasing concentration of $MnSO_4$, the precipitate changes its color from pinkish white to dark brown. Presumably, the content of manganese oxides or borates in the precipitate grows. Possibly, the formation of a spinel in the coatings is due, as in the case of tetraborate electrolytes with $KMnO_4$, to the influence of boron compounds. It is known that molten boron(III) oxide (mp 450°C [20]) can dissolve many metal oxides, transferring them to the active state. Molten boron oxide makes looser the lattices of titanium and manganese oxides, favors defect formation in these lattices, and intensifies solid-phase reactions at lower temperatures [21].

Table 4. Elemental composition of anodic layers formed in the electrolyte containing 0.1 M Na_3PO_4 and $Mn(CH_3COO)_2$. The coatings were prepared in the falling-power mode, U_s = 450 V; phase composition TiO_2(a)

* $Mn(CH_3COO)_2$ concentration.

The influence exerted by replacing $Na_2B_4O_7$ with Na_3PO_4 in an electrolyte on the composition of the anodic layers formed was also studied. On adding $Mn(CH_3COO)_2$ to an Na_3PO_4 solution, the solution turns dark brown and a brown flaky precipitate is formed, which is presumably composed of manganese phosphates [19, 22] with impurity of Mn(II) and Mn(IV) oxides and hydroxides; the solution pH is 10. In contrast to tetraborate electrolytes, an insignificant amount of manganese is incorporated into the coatings in the given case on the background of a high content of phosphorus(V) (Table 4). The latter is generally observed in anodic-spark treatment of titanium in phosphate electrolytes [7, 8, 13]. PO_4^{3-} anions are incorporated into anodic titanium oxide to form complexes of the type $(TiO)_x(PO_4)_y$ [23]. Under the action of high temperature in the vicinity of breakdown channels, complexes of this kind may be converted into titanium phosphates and interact, similarly to titanium oxide, with manganese-containing compounds. However, an X-ray phase analysis did not reveal crystalline compounds of titanium or manganese with phosphorus. Possibly, the forming anodic layers contain, similarly to coatings obtained in aqueous electrolytes with sodium polyphosphates and $Mn(CH_3COO)_2$ [24], X-ray amorphous manganese titanophosphates.

CONCLUSIONS

(1) Aqueous electrolytes based on sodium tetraborate are promising for obtaining anodic-spark layers containing various manganese compounds on titanium.

(2) The elemental and phase compositions of the coatings and their surface structure depend on the nature and concentration of a manganese(II) salt introduced into solution and on addition of ethanol.

(3) In aqueous electrolytes containing 0.1 M $Na_2B_4O_7$ and more than 18×10^{-3} M of $Mn(CH_3COO)_2$, anodic films with Mn_2O_3 and Mn_3O_4 in the surface layer can be obtained.

Abstract—The possibility of cycling of thin (8–10 μm) films of chromium oxide compounds was studied. The charging–discharge conditions were optimized.

In the recent decade, much attention has been given to thin-film materials for primary and secondary chemical power sources (CPS) [1, 2]. Such materials are promising electrodes for unconventional (flexible) CPS. Flat CPS are used in laptops, credit cards, optical displays, solar batteries, etc. Also, thin-film electrodes have aroused specific interest for rechargeable power sources. In such sources, protons or ions diffuse for a short distance, and the charging–discharge processes are short compared to pelletized electrodes.

Many materials are used as CPS electrodes: metal oxides, chalcogenides, and some polymers. Among them, the oxide materials are the most environmentally acceptable and convenient in use; they also have high specific electrical characteristics [3].

When choosing the oxide compound for CPS electrode, it should be taken into account that the incorporation of the corresponding ion (Li^+, Na^+, or H^+) must change the unit cell volume of the oxide by no more than approximately 20%. If this value exceeds 20% (as, e.g., 38% for CrO_2 and 33% for MnO_2), then the ion incorporation is irreversible [4] (this also refers to lithium ion).

A cathode material for secondary CPS must be capable of recovery, i.e., discharge in the cathodic cycle and charging in the anodic cycle. Thus, in the ideal case, the lithium ion incorporation into, and removal from the crystal lattice must be reversible to the extent as maximal as possible. As shown in [5], the higher the diffusion rate, the easier are the charging–discharge processes in the system. The mass-transfer rate is considerably higher in oxide compounds with the disordered structure [4–7]. For this reason, nonstoichiometric oxide compounds are of undoubted interest [6, 7]. It was shown that, in such compounds, the rate of electrochemical processes is considerably higher (sometimes by several orders of magnitude) than in stoichiometric compounds. For example, stoichiometric chromium oxide CrO_2 is unsuitable for secondary power sources [4], whereas the nonstoichiometric oxide is a promising electrode material [8].

Powders and films of nonstoichiometric oxide compounds of a series of transition metals can be prepared by an electrochemical procedure developed previously [9]. Use of such compounds as a cathode of primary CPS increases the rate of electrochemical processes, which is manifested as a considerable increase in the current density of pelletized electrodes [5].

The goal of the work was to examine the possibility of using thin-film chromium oxide compounds as cathodes and to find how the extent of reversibility of the charging–discharge process depends on the compound composition (degree of nonstoichiometry).

EXPERIMENTAL

The test objects were chromium oxide compounds differing in the degree of nonstoichiometry. Films of chromium oxide compounds were prepared from an electrolyte containing 2.5 M CrO_3. To vary the compound composition, 0.1, 0.2, 0.3, or 0.4 M fluoride ions were introduced as ligands. The electrolyte temperature did not exceed 30 ± 0.1°C, and the current density was 50 A dm^{-2}.

Films of different compositions were deposited onto electrodes made of 1Cr18Ni10Ti stainless steel. The electrode area was 0.25 cm^2. The film thickness was 8–10 μm depending on the electrolysis time. A film more than 4 μm thick is nonporous, which excludes the contact of the support with the electrolyte.

As electrolyte, we used 1 M KOH. The tests were performed at room temperature. Platinum (surface

3	0.3	75.0	4.5	4.0	9.5	10.7	1.05	0.92
4	0.4	83.0	4.0	4.0	7.0	10.2	1.03	0.89

area 4 cm^2) was the counterelectrode, and saturated calomel electrode was the reference electrode. The cyclovoltammograms (CVA) and charging–discharge curves were recorded on a PI-50-1 potentiostat (potential scanning rate 2 mV s^{-1}) with an LKD-4 recorder.

The ionic component of the conductivity and the composition of the chromium samples were determined by the procedures described previously [9]. Table 1 presents the composition of the samples of the chromium oxide compounds obtained at various concentrations of fluoride ions in the electrolyte.

The reversibility of the process can be judged from the CVA. Figure 1 shows the typical CVAs for a sample of a chromium oxide compound. As seen, both

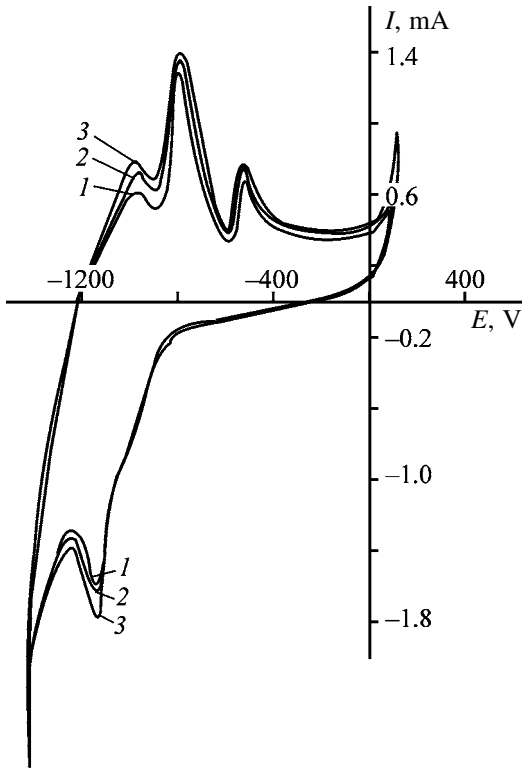

Fig. 1. Cyclovoltammogram of the chromium oxide compound (sample no. 1). Scanning rate 2 mV s^{-1}. (*I*) Current and (*E*) potential. Curve numbers are cycle numbers.

direct and reverse processes occur. The extent of reversibility of the given process can be determined from CVA as the ratio of the current peaks in the second cycle to that in the first cycle [8]. The results are given in Table 2.

Table 2 shows that the extent of reversibility I_{p2}/I_{p1} of the process depends on the sample composition and increases as the deviation from the stoichiometric composition grows.

It should be noted that the degree of conversion in the system is higher in the second cycle. The same is true for the process rate, as seen from the currents of the direct and reverse processes. In both the anodic and the cathodic cycles, the samples are ranked in the following order with respect to the current values: no. 1 > no. 2 > no. 3 > no. 4. In going from sample no. 1 to sample no. 4, the content of total chromium grows, and the content of oxygen, water, and hydroxy groups decreases (Table 1).

It should be noted that the ionic conductivity of the samples correlates with the ratio of the peak currents in the second (I_{p2}) and first (I_{p1}) cycles (Fig. 2). The extent of reversibility of the electrochemical process increases with increasing ionic conductivity (Table 2).

The charging–discharge curves of the chromium samples studied are shown in Fig. 3. They allow evaluation of the reversibility of the charging–discharge processes. The first and the last charging–discharge curves are similar (to the 10th cycle inclusive), indicating that the proton incorporation is fairly reversible and fast.

The values of the given capacity correlate with the total content of chromium in the samples. The voltage efficiency for sample nos. 1 and 2 is 81 and 76%, respectively. The efficiency (discharge-to-charging capacity ratio) is about 97–98%. The specific capacities are fairly high (Table 2); in this respect, nonstoichiometric chromium oxide compounds are comparable with other oxides, e.g., manganese dioxide [10].

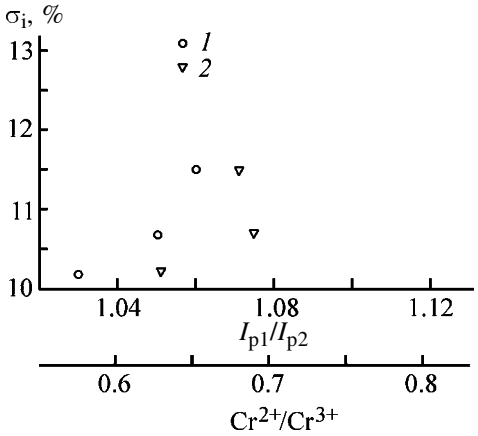

Fig. 2. Dependence of the ionic conductivity σ_i of the chromium oxide compounds on the (*1*) extent of reversibility of the charging–discharge process I_{p2}/I_{p1} and (*2*) Cr^{2+}/Cr^{3+} ratio.

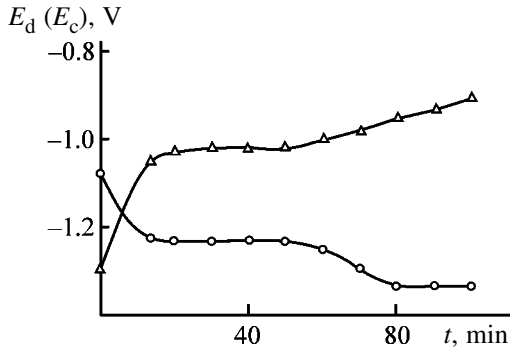

Fig. 3. Charging–discharge curves (sample no. 2). Current 0.7 mA, active paste weight 5 mg. (E_d, E_c) Potential and (*t*) time.

At the same time, the main advantage of chromium oxide compounds is the possibility of depositing then as thin (8–10 μm) films with high adhesion onto virtually any structural material intended for flexible cathode.

It was shown [9, 11] that the ionic conductivity characterizes the amount of defects in the compound; their increase can considerably accelerate electrode processes. This effect was also observed previously [5] on pelletized samples, in line with the published data [6, 7, 12] on the role of structural defects in electrochemical processes. Compared to stoichiometric compounds, nonstoichiometric compounds, including the chromium compounds under consideration, contain a large number of defects and have more disordered structure. They contain M^{n+}/M^{n+1} pairs differing in charges [12, 13] and OH^- groups binding structural defects.

Table 2. Extent of reversibility of charging–discharge processes C_d/C_c, capacity C_{sp}, and ionic conductivity σ_i of the samples of chromium oxide compounds

Sample no.	C_d/C_c	C_{sp}, mA h g^{-1}	σ_i, %	I_{p2}/I_{p1} in indicated region	
				cathodic	anodic
1	0.985	276	13.1	1.12	0.96
2	0.981	268	11.5	1.06	0.93
3	0.964	217	10.7	1.05	0.92
4	0.959	210	10.2	1.03	0,89

CONCLUSION

The possibility of cycling of chromium oxide compounds was demonstrated. These compounds show promise for thin-film batteries with aprotic electrolytes. The optimal charging–discharge conditions are realized on samples (nos. 1 and 2) having the strongest deviation from the stoichiometry.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Kinetics of Hydrogen Peroxide Accumulation in Electrosynthesis from Oxygen in Gas-Diffusion Electrode in Acidic and Alkaline Solutions

G. A. Kolyagin and V. L. Kornienko

Institute of Chemistry and Chemical Technology, Siberian Division, Russian Academy of Sciences, Krasnoyarsk, Russia

Received February 13, 2003

Abstract—Accumulation of H_2O_2 in aqueous solutions with various pH values in electroreduction of oxygen in carbon-black gas-diffusion hydrophobized electrodes was studied. The effect of various parameters of the process on its electrochemical component and decomposition rate of the H_2O_2 formed was analyzed.

In the last 20 years, much interest has been shown in indirect oxidation of organic and inorganic substances with hydrogen peroxide generated electrochemically from oxygen [1–3]. This interest stems from the wide use by modern chemical industries of principles of conjugated processes [4] involving environmentally safe reagents, such as electric current and chemically bound forms of oxygen (O_3, H_2O_2, ROOH, etc.).

Hydrogen peroxide as oxidizing agent has a number of unique properties. It is well soluble in water and is nontoxic. Use of hydrogen peroxide does not yield dangerous wastes, only water and oxygen being products of its decomposition. Hydrogen peroxide shows a pronounced oxidizing power and allows oxidation of various organic and inorganic compounds both in alkaline and in acidic media. The range of its applicability is exceedingly wide: aqueous H_2O_2 solutions are used in pulp-and-paper industry, in manufacture of detergents, in hydrometallurgy, in wastewater purification, and in many other industries requiring an environmentally safe oxidizing agent [5, 6].

It is known that hydrogen peroxide can be comparatively easily obtained by cathodic reduction of oxygen on graphitic carbon electrodes in alkaline solutions. Since the solubility of oxygen in aqueous electrolyte solutions is low, hydrophobized gas-diffusion electrodes are presently used for intensifying its reduction process. This method is waste-free and enables production of H_2O_2 at its consumption site in the form of aqueous solutions and use of these solutions as a commercial product without preliminary isolation of H_2O_2, which makes the cost of hydrogen peroxide much lower [7, 8].

It is known that the rate of H_2O_2 accumulation in the electrolyte in electroreduction of oxygen is described by the equation [9]

$$V_a = dc/d\tau = V_s - V_d = A\gamma I/v - V_d, \quad (1)$$

where V_a is the rate of H_2O_2 accumulation (mol l^{-1} h^{-1}); V_s, rate of H_2O_2 electrosynthesis; V_d, rate of H_2O_2 decomposition; A, electrochemical equivalent of H_2O_2 (mol A^{-1} h^{-1}); I, electrolysis current (A); v, catholyte volume (l); γ, fraction of current consumed for O_2 reduction to H_2O_2; c, H_2O_2 concentration in the catholyte (M); and τ, electrolysis time (h).

Decomposition of hydrogen peroxide is a complex process which depends on numerous factors, including the degree of dissociation in aqueous solutions. In acidic solutions, H_2O_2 molecules are little dissociated and the decomposition process follows the equation [5, 6]

$$2H_2O_2 = 2H_2O + O_2. \quad (2)$$

In alkaline solutions, H_2O_2 is largely dissociated [10, 11]:

$$H_2O_2 + OH^- = HO_2^- + H_2O. \quad (3)$$

When perhydroxide ions appear in considerable amounts, decomposition of H_2O_2 may involve these ions [7, 11, 12]:

$$2HO_2^- = 2OH^- + O_2, \quad (4)$$

$$HO_2^- + H_2O_2 = H_2O + OH^- + O_2. \quad (5)$$

** Experiments carried out with electrodes fabricated from paste heated at 340°C.

Among the factors affecting the rate of H_2O_2 decomposition [3, 5, 6, 10–20], the composition and pH value of solutions are among those most important [5, 10–12, 19, 20]. The rate of decomposition in alkaline solutions can be formally described using various equations:

$$V_d = kc_{H_2O_2} \text{ [9]}, \quad (6)$$

$$V_d = kc^{ud}_{H_2O_2}c_{HO_2^-} \text{ [12]}, \quad (7)$$

$$V_d = kc^{ud}_{H_2O_2} + k_0 \text{ [11]}, \quad (8)$$

where $c_{H_2O_2}$ is the total concentration of H_2O_2; $c^{ud}_{H_2O_2}$, concentration of the undissociated H_2O_2 species; $c_{HO_2^-}$, concentration of perhydroxide anions; and k and k_0, constants.

In acidic solutions, the decomposition rate is commonly described by Eq. (6) [8], whereas in alkaline solutions, each particular case should be considered separately.

The known studies concerned with H_2O_2 electrosynthesis from O_2 paid little attention to kinetics of H_2O_2 accumulation and did not consider as a whole the wide variety of factors affecting the process simultaneously. Revealing the fundamental aspects of the process of H_2O_2 accumulation is an important and necessary stage as regards practical application of the electrochemical method for obtaining H_2O_2 in solutions with varied pH value.

This study is concerned with the effect of the composition, concentration, and pH of the electrolyte on the kinetics of accumulation of H_2O_2 in its synthesis from O_2 in gas-diffusion electrodes.

EXPERIMENTAL

The experimental conditions and the electrolyzer design were similar to those described in [4, 7, 8]. Preparative electrolysis was carried out in the galvanostatic mode at 20°C for 7 h at a current density of 50 mA cm^{-2}, as calculated per unit apparent frontal surface area (5 cm^2). The catholyte volume was 0.023 l. Oxygen was fed into the electrode from its back surface under atmospheric pressure. To reveal the influence exerted by the mass transfer of substances involved in the process, the catholyte was agitated by bubbling of argon through a tube 1.5 mm in diameter at a rate of 10 ml min^{-1} continuously (agitation mode I) or at a rate of 38 ml min^{-1} for 1 min before sampling a solution to determine the content of H_2O_2 every hour (agitation mode II).

The catholyte and anolyte were separated by an MF-4SK-100 cation-exchange membrane. The electrodes were prepared from A-437E acetylene carbon black containing 40 wt % Ftoroplast-4D (Teflon), with 65 vol % porosity, and sintered in air at 360°C for 10 min [17]. The electrode paste was preliminarily heated at a temperature of up to 300°C. Part of electrodes were prepared from a paste heated at 340°C. The results obtained with these electrodes are listed in Table 1 and shown in Fig. 1, curves *3* and *4*.

The fraction of current consumed for synthesis of H_2O_2 was determined by gasometry, or, when possible, calculated from experimental data [16]. The rate of H_2O_2 decomposition was found using Eq. (1) by differentiating graphically the curves of H_2O_2 accumulation. The electrode potential was measured relative to a silver chloride reference electrode. In acidic and alkaline solutions, oxygen is reduced to H_2O_2 in the same range of potentials 0.4–0.6 V,

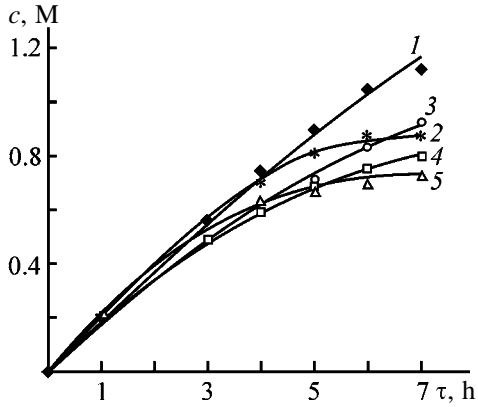

Fig. 1. Curves of hydrogen peroxide accumulation in alkaline electrolytes. (*c*) H_2O_2 concentration and (τ) time; the same for Figs. 4 and 5. Electrolyte (M): (*1*) 1.0 NaOH + 0.017 Na_2SiO_3, (*2*) 1.0 NaOH, (*3, 4*) 0.25 NaOH, and (*5*) 0.5 NaOH. Agitation mode (*1–3, 5*) I and (*4*) II. Points, experiment; lines, calculation.

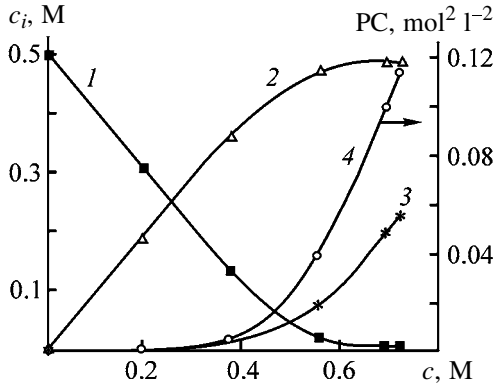

Fig. 2. Concentrations c_i of (*1*) OH^- and (*2*) HO_2^- ions, (*3*) undissociated H_2O_2, and (*4*) product of concentrations PC, $c^{ud}_{H_2O_2} c_{HO_2^-}$, vs. hydrogen peroxide concentration *c* in 0.5 M NaOH solution.

despite that the zero-current potential is about –0.2 V in alkaline solutions and is shifted to the anodic region in acidic solutions. As in [21], the potential is independent of $c_{H_2O_2}$. For example, the potential remained within 0.56–0.58 V at H_2O_2 concentrations in the range from 0.54 to 0.024 M at pH 0.9 (0.05 M K_2SO_4 + 0.15 M H_2SO_4) and shifted in the negative direction to 0.53 V with pH increasing to 2.1. The overvoltage of O_2 reduction to H_2O_2 in acidic solutions much exceeds that in alkaline solutions. No evolution of hydrogen occurs under the given conditions because of the high overvoltage of its reduction on carbon black.

Figure 1 shows curves of H_2O_2 accumulation in the cathode chamber in solutions with various NaOH concentrations and with sodium silicate added as H_2O_2 stabilizer. Table 1 lists constants *k* for Eqs. (6), (7), and (9), current efficiencies by H_2O_2, and its concentrations after 7 h of electrolysis. Also listed for comparison are rates of H_2O_2 decomposition at a concentration of 0.6 M.

As seen from Fig. 1 (curves *1, 2, 5*) and Table 1 (run nos. 4–6), raising the concentration of alkali and adding sodium silicate to the solution make higher the H_2O_2 concentration and the current efficiency by H_2O_2, which can be accounted for by a decrease in the rate of H_2O_2 decomposition [12, 19, 20]. At $c_{H_2O_2}$ = 0.6 M, the action of the stabilizing agent is not manifested yet; when, however, the content of H_2O_2 is raised further, the decomposition rate decreases.

The accumulation rate is strongly affected by the technology of electrode fabrication (Table 1, run nos. 2 and 3). Raising the temperature to which the electrode paste is heated leads to a change of the run of the $V_d = f(c_{H_2O_2})$ dependence, presumably owing to more complete removal of surfactants and other adsorbed substances [18] and to partial oxidation of the carbon black [16]. These electrodes have lower electrolyte porosity (0.5 vol %). The potential of these electrodes in electrolysis is shifted, compared with the other electrodes, to the cathodic region by 0.2–0.3 V. In experiments with electrodes fabricated from a paste heated at 340°C, the rate of H_2O_2 decomposition is described by Eq. (6). With the other electrodes, the rate of H_2O_2 decomposition in 0.5 and 1.0 M NaOH solutions is described by Eq. (7), that in a solution with addition of sodium silicate, by Eq. (6), and that in a 0.25 M NaOH solution, by the equation

$$V_d = k(c_{H_2O_2})^2. \quad (9)$$

Figure 2 shows as an example the influence of $c_{H_2O_2}$ in a 0.5 M NaOH solution on the values of $c^{ud}_{H_2O_2}$, $c_{HO_2^-}$, and c_{OH^-}, calculated using equations taken from [10]. The equilibrium constant of reaction (3) at 20°C is 261.4 [10]. Despite the fact that concentrations were taken instead of activities in the calculations, the resulting products of $c_{HO_2^-}$ and c_{OH^-} were in good agreement with the values reported in [12].

As seen from Fig. 2, the concentration of hydroxide ions decreases and the concentrations of perhydroxide ions and undissociated H_2O_2, and the product of these, grow with increasing total concentration of H_2O_2. In a 0.5 M NaOH solution, at $c_{H_2O_2}$ of up to approximately 0.5 M, when H_2O_2 is mainly in the

form of perhydroxide ions, the decomposition rate can be described using Eq. (6) with $k = 0.05$ h^{-1}. This value is equal to that for a solution with sodium silicate, which must be the case, since the accumulation curves coincide up to 0.5 M of H_2O_2 at equal γ. When a considerable amount of undissociated H_2O_2 is additionally present in the solution, the decomposition rate is described by Eq. (7) in the whole concentration range.

Figure 3 shows the dependence of the H_2O_2 decomposition rate in 0.5 and 1.0 M NaOH solution on the product $c^{ud}_{H_2O_2} c_{HO_2^-}$. The slope of the straight line, i.e., the value of k, grows with increasing alkali concentration, but the product decreases, as also does the decomposition rate.

Figure 1 (curves *2, 5*) shows the accumulation curves calculated using Eqs. (1) and (7) and values of k and γ from Table 1. These curves are in good agreement with experimental data.

Depending on the type of the equations $V_d = f(c_{H_2O_2})$ and $\gamma = f(c_{H_2O_2})$, solutions to Eq. (1) are also different:

$$c = g[\exp(2gk\tau) - 1][1 + \exp(2gk\tau)]^{-1},$$
$$g = [A\gamma I/(kv)]^{1/2} \quad (10)$$

at $V_d = k(c_{H_2O_2})^2$ and γ = const;

$$c = AI\gamma[1 - \exp(-k\tau)]/(kv) \quad (11)$$

at $V_d = kc_{H_2O_2}$ and γ = const [8];

$$c = \frac{AIb\{\exp[(AIa/v - k)\tau] - 1\}}{[AIa/v - k]v} \quad (12)$$

at $V_d = kc_{H_2O_2}$ and $\gamma = b - ac_{H_2O_2}$ [4].

Equation (12) was used to calculate curves *1, 3*, and *4* in Fig. 1.

In alkaline electrolytes, γ is large and virtually independent of $c_{H_2O_2}$ and other electrolysis parameters, even though it tends to decrease somewhat (linearly) with increasing H_2O_2 concentration, as is also the case in [22]. For example, $\gamma = 1 - 0.085c_{H_2O_2}$ in a 0.25 M NaOH solution (Table 1, run no. 1). In acidic solutions, γ depends on the solution composition, but also is a linear function of $c_{H_2O_2}$ [8]. For example, $\gamma = 1 - 0.39c_{H_2O_2}$ in a solution containing 0.05 M K_2SO_4 + 0.15 M H_2SO_4.

In alkaline and acidic solutions, changes in γ are associated both with H_2O_2 decomposition in the electrode, when the appearing oxygen undergoes repeated reduction, and with further reduction of H_2O_2. In alkaline solutions, H_2O_2 is reduced on graphitic carbon materials at high overvoltage, whereas in acidic solutions this process is markedly facilitated. Therefore, the insignificant decrease in γ in alkaline solutions is only due to a rise in the rate of H_2O_2 decomposition in the electrode with increasing H_2O_2 concentration, whereas in acidic solutions the decrease in γ is mainly due to an increase in the rate of H_2O_2 reduction.

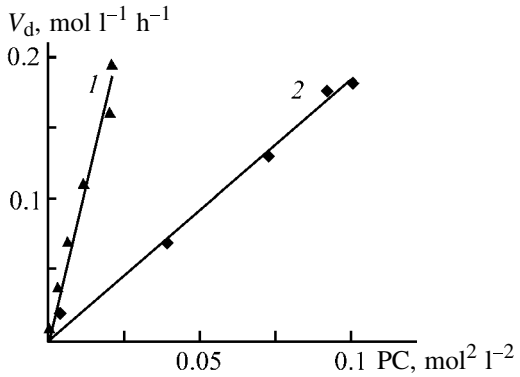

Fig. 3. Effect of the product of concentrations, PC, $c^{ud}_{H_2O_2} \times c_{HO_2^-}$, on the decomposition rate V_d of H_2O_2 in (*1*) 1.0 M NaOH solution and (*2*) 0.5 M NaOH. Agitation mode I; the same for Fig. 5.

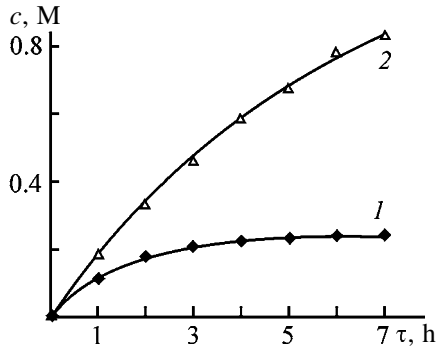

Fig. 4. Curves of H_2O_2 accumulation in solutions with pH 0.9. Electrolyte (M): (*1*) 0.1 H_2SO_4 and (*2*) 0.05 K_2SO_4 + 0.15 H_2SO_4. Points, experiment; lines, calculation by Eq. (2).

Thus, the process occurring in an electrode are strongly affected by H_2O_2 removal from the electrode and by the activity of hydrogen ions, which depends on the electrolyte composition and electrolysis conditions [8], within the electrode. Compared to acidic solutions, removal of H_2O_2 from the pore volume of the electrode is somewhat facilitated in alkaline solutions, since perhydroxide ions are removed not only by diffusion, but also via migration under the action of the electric field. Figure 4 illustrates the influence of the composition of an acidic solution by the exam-

Table 2. Electrolysis parameters* used to calculate curves of H_2O_2 accumulation, shown in Fig. 6

Curve no.	I, A	Catholyte volume, l	b	a, l mol^{-1}	k, h^{-1}	τ, h	η
1	0.25	0.023	1	0	0	2.47	1.00
2	0.25	0.01	1	0.5	0.1	1.33	0.81
3	0.50	0.023	1	0.5	0.1	1.55	0.80

6	0.25	0.023	1	0.5	0.1	3.43	0.72
7	0.25	0.023	0.6	0.5	0.1	8.78	0.28

* τ and η are the time of electrolysis, necessary for the H_2O_2 concentration of 0.5 M to be reached, and the resulting current efficiency, respectively.

ple of the curves of H_2O_2 accumulation in solutions with pH 0.9 (Table 1, run nos. 7 and 8).

The aforesaid is also confirmed by the fact that the agitation mode affects differently the values of γ and $c_{H_2O_2}$ in acidic and alkaline solutions. Raising the intensity of agitation in alkaline solutions leads to a decrease in the rate of decomposition because of the change in $c_{H_2O_2}$ in the near-electrode space (Table 1, run nos. 1 and 2) and has virtually no effect on γ, whereas in acidic solutions, a decrease in γ is observed because of the increasing supply to the electrode of hydrogen ions involved in H_2O_2 reduction to water. For example, in a solution containing 0.05 M K_2SO_4 + 0.15 M H_2SO_4, γ decreases by a factor of nearly 2 in going from agitation mode I to mode II, whereas already at pH 3.2 (0.495 M K_2SO_4 + 0.005 M H_2SO_4) the agitation mode has virtually no effect, since the activity of hydrogen ions decreases by a factor of more than 100.

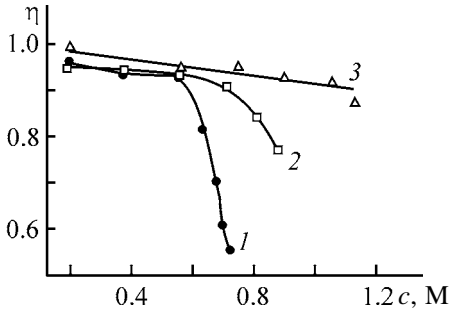

Fig. 5. Current efficiency η vs. H_2O_2 concentration c in various electrolytes. Electrolyte (M): (*1*) 0.5 NaOH, (*2*) 1.0 NaOH, and (*3*) 1.0 NaOH + 0.017 Na_2SiO_3.

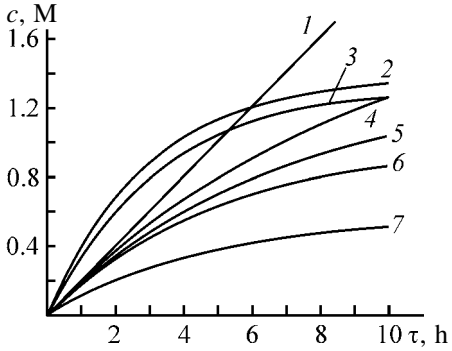

Fig. 6. Effect of electrolysis parameters (Table 2) on the run of curves of H_2O_2 accumulation, calculated by Eq. (2).

The linear dependence of the current efficiency η on $c_{H_2O_2}$ (Fig. 5) is preserved at higher H_2O_2 concentrations on raising the concentration of alkali and on introducing a stabilizer, i.e., in the case when the decomposition rate depends on $c_{H_2O_2}$ linearly [23]; further, the current efficiency falls dramatically because of an increase in the rate of H_2O_2 decomposition. In acidic electrolytes, in contrast to alkaline solutions, the type of the equation $V_d = f(c_{H_2O_2})$ is independent of the electrolyte composition and the dependence $\eta = f(c_{H_2O_2})$ is linear during the whole time of electrolysis [4]. For example, $\eta = 0.97 - 0.37c_{H_2O_2}$ for a solution containing 0.05 M K_2SO_4 + 0.15 M H_2SO_4 (Table 1, run no. 8).

To evaluate the influence exerted by the electrolysis parameters on the run of an accumulation curve and to predict the current efficiency, which is one of the most important electrosynthesis parameters, it is necessary to analyze Eq. (12), which turns into Eq. (11) at $a = 0$ ($\gamma = b$). Figure 6 shows curves of H_2O_2 accumulation for various values of the electrolysis parameters (Table 2). Table 2 also lists for comparison the times required for solutions with $c_{H_2O_2}$ = 0.5 M to be obtained and the resulting current efficiencies. For clarity, the values of the parameters are chosen so that curves do not overlap. All the comparisons are made relative to curve *6* (Fig. 6). Curve *1* is calculated using the equation $c_{H_2O_2} = A\gamma I\tau/v$.

As seen from Fig. 6 and Eq. (12), the multiplier

AIb/v determines the initial slope of an accumulation curve, i.e., the rate of H_2O_2 accumulation, which decreases with increasing H_2O_2 concentration because of a decrease in γ and rise in the decomposition rate. The highest H_2O_2 concentration is obtained when the accumulation rate becomes equal to the rate of H_2O_2 decomposition. When the decomposition rate is described by Eq. (6), the maximum concentration is given by the expression $c_{H_2O_2} = A\gamma I/(kv)$.

The rate of H_2O_2 accumulation is strongly affected by coefficient b (Fig. 6, curve *7*). The decrease in k and a starts to affect the accumulation rate at higher H_2O_2 concentrations (curves *4* and *5*). The quantity I/v is the volume current density and, consequently, the rate of H_2O_2 accumulation may become higher with increasing current density or decreasing catholyte volume (Fig. 6, curves *2* and *3*). This may give, during the first hours of electrolysis, an H_2O_2 concentration exceeding the concentration that would be observed at a decomposition rate close to zero and $\gamma = 1$ (Fig. 6, curve *1*).

CONCLUSIONS

(1) The rate of subsequent electroreduction of H_2O_2 to water in an alkaline electrolyte in hydrophobized carbon black electrodes is low. The accumulation rate of hydrogen peroxide is determined under these conditions by the rate of its chemical decomposition in the cathode chamber.

(2) In acidic solutions, the rate of hydrogen peroxide accumulation is mainly determined by the rate of subsequent H_2O_2 reduction to water, which depends on the concentration of H_2O_2 and hydrogen ions in the volume of the gas-diffusion electrode.

(3) The equations relating $c_{H_2O_2}$ and electrolysis duration, presented in the communication, well describe experimental curves of H_2O_2 accumulation. All the other parameters being the same, the initial rate of H_2O_2 accumulation is determined by the volume current density; with increasing electrolysis duration and H_2O_2 concentration, the rate of hydrogen peroxide decomposition in an alkaline medium and reduction to water in an acidic medium starts to exert steadily increasing influence on the accumulation rate.

Abstract—A procedure was proposed for electrochemical reduction of 2,5-dichloronitrobenzene to 2,5-dichloroaniline in aqueous-ethanolic solution of sulfuric acid. The procedure for preparing 2,5-dichloroanilinium sulfate was optimized. The influence exerted by the cathode material, nature and amount of the organic solvent, sulfuric acid concentration, and electrolysis temperature on the yield and quality of the target product was discussed.

2,5-Dichloroaniline (2,5-DCA) is an intermediate in synthesis of pesticides. The existing methods of reduction of nitro compounds with metals do not meet modern environmental requirements, because the arising wastes are difficult to utilize. Therefore, electrochemical reduction of aromatic nitro compounds attracts much attention [1–5]. However, we found no data on cathodic reduction of 2,5-dichloronitrobenzene (2,5-DCNB) to 2,5-DCA. This process was the subject of the present study.

We tested two procedres for electrochemical reduction of 2,5-DCNB: a classical procedure based on electroreduction of the nitro compound in a sulfuric acid medium, yielding the amine in the salt form, and a recently suggested procedure of reduction in a two-phase system [5] involving the use of a solvent immiscible with water and a buffer solution with the pH close to pK of the forming amine. The second procedure allows preparation of the free amine in one step.

Classical reduction was performed in aqueous solfuric acid with addition of an organic solvent miscible with water to obtain a homogeneous solution.

The first series of experiments on choosing the optimal cathode material was performed in an aqueous-alcoholic solution of sulfuric acid at a cathodic current density of 750 A m^{-2} and temperature of 48–50°C. The catholyte had the following composition (wt %): 2,5-DNCB 7.6, H_2SO_4 7.0, and C_2H_5OH 50.

Table 1 shows that the chemical yield of reduction of 2,5-DCNB to 2,5-DCA on copper is low (69%). The reduction on brass and nickel is also inefficient. Addition of an Sn(II) salt has no appreciable effect on the 2,5-DCA yield, whereas in the presence of zinc sulfate the yield of 2,5-DCA based on 2,5-DCNB increases to 87%. Reproducibly high yield of 2,5-DCA (up to 88%) was obtained on a lead cathode in an aqueous-ethanolic solution of sulfuric acid.

Then, using the lead cathode, we examined how the 2,5-DCA yield depends on the nature and amount of the organic solvent and on the concentrations of 2,5-DCNB and sulfuric acd. We found (Table 2) that such solvents as acetone and acetonitrile affect the reaction negatively. This is manifested in the decreased yield of 2,5-DCA (3.6–6.0%) as compared to reduction in water without organic solvent added (39%). Apparently, these solvents prevent adsorption of 2,5-DCNB on the cathode. Addition of about 50 wt % of aliphatic alcohol increases the yield of 2,5-DCA to 88.4–88.9%.

Variation of the 2,5-DCNB concentration in the reaction mixture from 5.5 to 10% has virtually no

	80	5.4	6.8	66.0
	30	5.2	6.9	58.0
No organic solvent	–	5.5	7.0	39.0

effect on the process (Table 3). When the 2,5-DCNB content is increased to 10%, the target product starts to crystallize on the cathode, which may disturb the process. Therefore, to ensure the homogeneous medium, it is not advisable to increase the 2,5-DCNB concentration above 8%.

An increase in the sulfuric acid concentration in the reaction mixture above 13% favors the Gattermann rearrangement, and the yield of 2,5-DCA decreases. At the H_2SO_4 concentration of 6.8–10.3%, the yield of 2,5-DCA is 86.3–88.3%, whereas at 20.7 wt % concentration of H_2SO_4 it is as low as 61%.

The optimal reaction temperature is 48–50°C. At lower temperatures, the solubility of 2,5-DCNB in the catholyte decreases; above 50°C, by-products are formed. In particular, the Gattermann rearrangement occurs, yielding dichloro-*p*-aminophenol.

The 2,5-DCNB molecule contains reducible functional substituents, chlorine atoms. Therefore, it seemed appropriate to study how the 2,5-DCA yield based on 2,5-DCNB depends on the amount of the electricity passed. We found that the highest yield of 2,5-DCA is attained after passing 150% amount of electricity relative to the amount required by the stoichiometry. At longer electrolysis, the 2,5-DCA yield based on 2,5-DCNB does not decrease, i.e., the product is resistant to further electrochemical reduction.

Thus, the optimal conditions for electrochemical synthesis of 2,5-DCA sulfate in the cathodic chamber of a diaphragm electrolyzer are as follows. Catholyte composition, wt %: 7.7 2,5-DCNB, 6.8–8.7 sulfuric acid, and 50 aliphatic alcohol; lead cathode; current density 750 A m^{-2}; 48–50°C; amount of the electricity passed 150%. Under these conditions, the 2,5-DCA yield based on 2,5-DCNB is 88.6–88.7%, and the current efficiency is 59.1%. Reuse of the electrolyte solution after adjustment of its composition does not impair the process but considerably reduces the amount of wastes and the consumption of auxiliary materials.

Our next goal was to examine the feasibility of preparing free 2,5-DCA directly from 2,5-DCNB by electrolysis in a two-phase system with a cadmium cathode [5]. The catholyte was a phosphate buffer solution (pH 5.0). Toluene was taken as a solvent immiscible with water. After electrolysis, the organic layer of the catholyte was separated, and the solvent was distilled off. Yield of 2,5-DCA 80%.

Thus, 2,5-DCNB can be electrochemically reduced both in an acid solution to obtain the 2,5-DCA salt and in a weakly acidic medium to obtain the free base. In both procedures, the yield of the target product based on 2,5-DCNB exceeds 80%.

EXPERIMENTAL

2,5-DCNB was prepared from 2,5-dichlorobenzene by nitration with a mixture of sulfuric and nitric acids.

Table 3. Influence of the concentrations of 2,5-DCNB and sulfuric acid in the catholyte on the 2,5-DCA yield. Lead cathode, 48–50°C, cathodic current density 750 A m^{-2}, ethanol content 50 wt %

Loaded, wt %		H_2SO_4 : 2,5-DCNB molar ratio	2,5-DCA yield based on 2,5-DCNB, %
2,5-DCNB	H_2SO_4		
5.8	5.0	1.7 : 1	87.1
5.8	7.5	2.4 : 1	88.7
7.7	6.8	1.7 : 1	88.3
7.0	8.6	2.4 : 1	88.5
10.0	8.7	1.7 : 1	88.0
7.0	10.3	3.0 : 1	86.3
7.0	13.1	3.6 : 1	73.0
7.0	20.7	6.8 : 1	61.0

The main substance content was 90%. Potassium phosphate, sulfuric acid, phosphoric acid, and other chemicals (pure or analytically pure grade) were used without additional purification.

Electrolysis was performed in the galvanostatic mode in a 150-ml temperature-controlled cell equipped with a reflux condenser, a ceramic diaphragm, and a platinum spiral anode. The cathode (several materials were tested) was treated with an acid solution and washed with a large amount of water before the experiment.

Reduction in an aqueous-ethanolic solution of sulfuric acid was performed as follows. The cathode compartment (with a lead cylinder as cathode) was charged with 100 ml of a solution containing 7.5 wt % sulfuric acid and 50 wt % ethanol. Then 7.9 g (0.0402 mol) of 2,5-DCNB was added. The anolyte was 25% aqueous H_2SO_4.

The mixture was heated to 50°C, and reduction with a current of 6.5 A (cathodic current density 750 A m^{-2}) was performed for 1 h 29 min with vigorous stirring. After electrolysis completion, the mixture was unloaded and kept for 30–40 min at 3–5°C. The precipitate of 2,5-DCA sulfate was filtered off and dried at room temperature; 9.2 g of 2,5-DCA sulfate was obtained. The product contained about 62.8% DCA and 34% sulfate ions. Yield based on 2,5-DCNB 88.7%, current efficiency 59.1%.

Reduction in the two-phase system was performed with a cadmium cathode (working surface area 87 cm^2). The cathodic compartment was charged with 70 ml of a 1 N potassium phosphate solution (pH 5), 10 g (0.052 mol) of 2,5-DCNB, and 30 ml of toluene. The anolyte was 20% aqueous H_3PO_4. Electrolysis was performed with a current of 6 A (cathodic current density 700 A m^{-2}) for 1 h 20 min and then with a current of 3 A for an additional 1 h 20 min. In the course of the electrolysis, the mixture in the cathodic compartment was vigorously stirred; pH 5.0 was adjusted at regular intervals by dropwise addition of phosphoric acid. The temperature was kept in the range 50–52°C. Yield of 2,5-DCA 7.3 g (main substance content 92%, yield based on 2,5-DCNB 80%, current efficiency 56%).

The content of 2,5-DCNB and 2,5-DCA in the reaction mixtures and isolated products was determined by GLC. The content of sulfate anions was determined by a standard procedure (titration with a $BaCl_2$ solution). The structure of the product was proved by ^{13}C NMR spectroscopy.

Abstract—The possibility is considered of using probe molecules to estimate the effect exerted by addition of phosphorus to supported Mo-containing catalysts on the dispersion of the active component and the support coverage.

Phosphorus modification of Mo-containing catalysts, which are widely used in hydrosupply of oil fractions, is one of the most common methods to enhance the process efficiency [1]. The addition of P to the catalyst strongly affects the physicochemical and service characteristics, such as dispersion of the active component, its reducibility and susceptibility to sulfiding, phase composition, surface acidity, activity in target reaction, the ratio of different types of activities, resistance to coking, and service life of a catalyst.

To understand such a complex effect of P, it is necessary to study in detail all aspects of its action on the catalytic system, including such important parameter as the dispersion of Mo-containing particles. Raman, IR, and X-ray photoelectron spectroscopic studies revealed an increase in the degree of dispersion of Al–Mo [1–4] and Al–Ni(Co)–Mo [3, 5, 6] catalysts at a certain concentration of P, irrespective of the sequence of deposition of components onto Al_2O_3.

To perform a more accurate quantitative estimation of the active component dispersion and to ascertain how P influences it in catalysts of different compositions, it is reasonable to use selective adsorption of probe molecules along with the above methods. This method can yield additional information on the dispersion, active surface area, and coverage of the support. Molecular oxygen, which is not noticeably adsorbed by the support, is a common probe molecule for studying Al_2O_3-supported Mo-containing oxide catalysts. The adsorption is performed on preliminarily reduced samples.

The fact that the amount of chemisorbed O_2 depends on the degree of the Mo reduction makes the use of this sorbate insufficiently reliable. Therefore, it is appropriate to use some additional probe reacting solely with the free surface of the support. The fact that the catalyst additives can appreciably affect the reducibility of the active component makes the use of such a procedure still more necessary.

Carbon dioxide, which interacts with the basic OH groups of Al_2O_3 to form $(CO_3H)^-$-like structures [7, 8], is not adsorbed on Mo-containing catalyst particles.

No data are available on simultaneous adsorption of O_2 and CO_2 on modified Mo-containing catalysts.

In this work, the results of the CO_2 and O_2 chemisorption were used to estimate the effect exerted by P additive on the coverage of the support by the active component and its dispersion in catalysts differing in the composition and sequence of the Mo and P deposition onto Al_2O_3.

EXPERIMENTAL

The test objects were samples of A-64 γ-Al_2O_3 catalysts, aluminum–molybdenum and aluminum–molybdenum–nickel, phosphorus-free (Al_2O_3, Al–Mo, and Al–Ni–Mo) and containing various amounts (0–0.8 mmol g^{-1}) of P (Al–P, Al–P–Mo, and Al–Ni–Mo–P).

P was introduced into Al_2O_3 by impregnation with a solution of ammonium dihydrogen phosphate. The Al–P–Mo catalysts were prepared by impregnating Al–P samples with a solution of ammonium paramolybdate. The Mo concentration in the catalyst was 0.7 mmol g^{-1}. To ensure introduction of the pre-

1070-4272/03/7607-1079$25.00

Al–Ni–Mo–P	0.57	1.0	–	1.0	–	1.0	0.75	–	0.70	–	0.70

scribed amounts of P and Mo, the impregnation was performed under saturation conditions. To synthesize the Al–Ni–Mo–P samples, P was introduced by the above method into the commercial Al–Ni–Mo catalyst ready for use, which contained 0.5 mmol g^{-1} Ni and 0.9 mmol g^{-1} Mo.

The catalytic mass was air-dried for 24 h, then dried at 110–120°C, and calcined at 400°C for 6 h in air after each impregnation.

The amount of the chemisorbed CO_2 and O_2 was determined on a pulsed chromatographic installation. The preparation of samples to chemisorption included oxidation in an O_2 flow at 500°C for 1 h, reduction in an H_2 flow at 500°C for 3 h, blowing at 300°C for 15 min, and cooling to room temperature in an He flow. Then, CO_2 or O_2 was fed to complete saturation. The above conditions for the preliminary treatment ensured reproducible results.

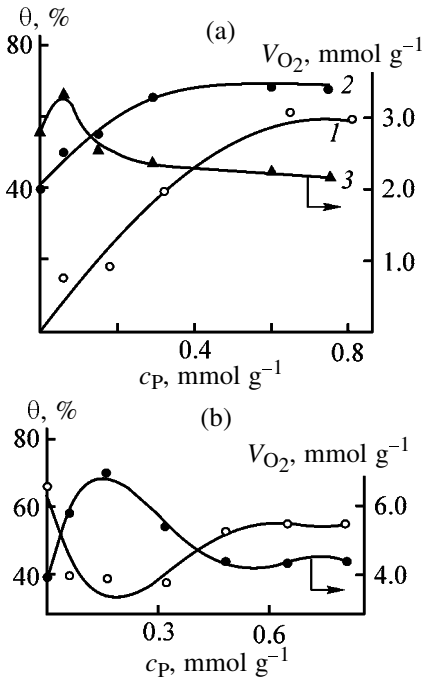

Fig. 1. Degree of exchange of basic OH groups for phosphate anions θ and amount of the chemisorbed oxygen V_{O_2} vs. phosphorus concentration c_P. Sample: (a) (*1*) Al–P and (*2, 3*) Al–P–Mo; (b) Al–Ni–Mo–P.

The amounts of chemisorbed gases were determined, and the coverage of the Al_2O_3 surface with the components was estimated by the formula [7]

$$\theta = n/mf,$$

where n is the CO_2 amount adsorbed on Al_2O_3 containing deposited components; m, CO_2 amount adsorbed on free Al_2O_3; and f, weight fraction of Al_2O_3 in the sample.

The results for the Al_2O_3, Al–P, Al–Mo, and Al–P–Mo samples are presented in the table and in Fig. 1a.

As P is introduced into Al_2O_3 and its concentration is increased, the amount of the chemisorbed CO_2 decreases and, correspondingly, θ grows (table, Fig. 1a). This phenomenon is primarily due to the fact that the phosphate anions interact with the basic OH groups at the surface to form an $AlPO_4$ layer [3, 9–13]. At a P concentration of about 0.6 mmol g^{-1}, the replacement of such OH groups reaches approximately 60% (Fig. 1a). The remaining OH groups (40%) are inactive in exchange for phosphate anions. Thus, with growing P concentration, a considerable portion of P can be attached to the surface by another mechanism. It is possible that phosphate anions interact with other sites of the Al_2O_3 surface. Also, agglomeration of phosphate structures in an impregnating solution or on the Al_2O_3 surface at higher concentrations as well as migration of certain its amount into the bulk should not be ruled out.

Fixation of molybdenum on the Al_2O_3 surface is also a result of its exchange interaction, mostly with basic OH groups [2, 13–15]. According to the results obtained, in the Al–Mo catalyst containing 0.7 mmol g^{-1} Mo, θ is about 40% (Fig. 1a). Such a coverage in the Al–P system is attained even at 0.3 mmol g^{-1} P (Fig. 1a). This confirms the greater aggregation of Mo-containing particles and weaker

adsorption of molybdate anions compared to phosphate anions, which is in line with the data of [16].

In the case of Al–P–Mo catalysts containing a small amount of the deposited P (0.06 and 0.16 mmol g^{-1}), θ is virtually equal to the sum of the θ values in the Al–P sample with the same P concentration and in the Al–Mo catalyst (Fig. 1a). Evidently, at low P concentrations, a sufficient amount of OH groups capable of exchanging for molybdate anion remains in Al–P. As a result, in the weakly phosphated Al–P–Mo system, θ is an additive quantity.

With an increase in the P content, the extent to which θ in Al–P–Mo exceeds that in Al–P decreases, reaching a minimum at 0.6–0.8 mmol g^{-1} P; at a higher P content, θ flattens out at a level of about 70% (Fig. 1a). After Mo is deposited onto Al_2O_3, 40% of OH groups interacting with CO_2 disappear. At the same time, when Mo is deposited onto Al_2O_3 containing 0.6 mmol g^{-1} P, the loss is smaller, only 10%. Apparently, certain amount of OH groups detected by CO_2 chemisorption are incapable of exchanging with molybdate anions.

Thus, only a part of basic OH groups can exchange for phosphate and molybdate anions. Gishti *et al*. [17] discussed their competition in adsorption onto Al_2O_3 and a decrease in the chemisorption capacity of the support as the P content in it grows relative to the content of molybdate anions capable of exchanging for OH groups.

The observed fact that θ in the Al–P–Mo samples stops to grow (Fig. 1a) shows that, at a certain P concentration, fixation of a part of Mo ions on the support occurs by a mechanism other than the exchange with basic OH groups, e.g., by interaction of molybdate anions with other sites of the Al_2O_3 surface, polymerization and aggregation of adsorbed anions, or adsorption on Al–O–P structures. The presence of P–OH groups on the surface of phosphated Al_2O_3 was revealed in [12, 13]. At the P concentration of 0.3 mmol g^{-1}, the molybdate anions react not only with Al–OH, but also with P–OH groups [2].

These facts suggest that, in the system containing certain amounts of P and Mo, the P–O–Mo structures must arise even in the stage of the support impregnation. The presence of these structures in calcined Al–P–Mo catalysts has been clearly confirmed in [3].

Let us consider how the amount of O_2 chemisorbed on Al–P–Mo catalysts varies with the P concentration (see Fig. 1a). The maximum at the P concentration of 0.06 mmol g^{-1} suggests an increase in the degree of Mo dispersion after a given amount of P is introduced into the support. With increasing P concentration, the amount of chemisorbed O_2 decreases to a lower level than in the modified sample. This suggests that a decrease in the O_2 chemisorption is due to the suppression of the Mo reducibility under the action of P additives, rather than by a decrease in the degree of its dispersion. The similar effect of P was found in [1, 3].

The data on CO_2 and O_2 chemisorption on samples synthesized by introducing P into the Al–Ni–Mo catalyst, i.e., into the already formed catalytic system, are presented in the table and in Fig. 1b.

In the case of the Al–Ni–Mo system, the character of the dependence of θ on the P concentration differs markedly from that for Al–P–Mo samples. For the Ni-containing catalyst, a pronounced minimum is observed. Apparently, the observed difference is due to the system composition and the sequence of introducing P and active component. Presumably, when P is added into the Al–Ni–Mo catalyst being formed, the structural rearrangement occurs even in the impregnation stage owing to the passage of certain amounts of Ni and Mo into the dissolved state. Since the impregnating solution is acidic and its acidity increases in the course of P addition, the fraction of Ni cations passed into the solution must be larger than that of Mo ions. On the contrary, in the course of the catalytic mass drying, the molybdate anions should "return" to the surface more readily than the Ni cations. Apparently, structural rearangements of the Al–Ni–Mo system may continue in the course of the subsequent thermal treatment. Small (0.35 Å) P ions can be incorporated into tetrahedral voids, replacing Ni ions [18]. Moreover, P impedes the Ni^{2+} diffusion into Al_2O_3 [5]. Its addition into an Ni-containing system hampers formation of $NiAl_2O_4$ spinel and decreases the content of this phase, increasing the content of octahedral Ni^{2+} ions [6, 19–21].

Thus, presumably, introduction of P into the already formed Al–Ni–Mo catalyst results in the breakdown of Al–Ni compounds, hydroxylation of the "released" aluminum oxide structures, and, as a consequence, appearance of OH groups capable of adsorbing CO_2. As a result, θ decreases. Apparently, when the Ni amount in the system is constant and the amount of phosphate anions increases, these anions (as well as molybdate anions) can enter into exchange reaction with the newly formed OH groups, i.e., the effect produced on θ will be opposite. Consequently, it is reasonable to expect that θ would increase after attaining a certain P concentration, which was indeed observed at a P concentration of about 0.4 mmol g^{-1} (Fig. 1b).

On the whole, the trends in variation of the amount of O_2 chemisorbed on Al–Ni–Mo–P and Al–P–Mo samples are similar (Figs. 1a, 1b). With increasing P concentration, an increase and then a decrease were observed. As for the Al–P–Mo system, the decrease may be due to the predominant formation of structures with the difficultly reducible Mo ions [3, 18]. At the same time, the dispersion effect is more pronounced than in the Al–P–Mo system. The maximal increase in the amount of chemisorbed O_2 is about 75% (compared to about 15% in the Al–P–Mo system), and the range of P concentrations at which the chemisorption is enhanced is considerably wider. Moreover, the chemisorption is never lower than that on the initial sample. These differences can result from the rearrangement of the Al–Ni–Mo structure. Apart from the direct influence exerted by P on Mo-containing particles, breakdown of Al–Ni compounds and formation of OH groups, which can interact with Mo oxide structures, can also affect the Mo dispersion. The released Ni ions can also produce an additional dispersion effect on the Mo-containing particles. The validity of this explanation can be indirectly confirmed by the fact that the dependences of θ and the amount of chemisorbed O_2 on the P concentration show opposite trends (Fig. 1b).

CONCLUSIONS

(1) Use of CO_2 and O_2 as probe molecules revealed that the hydroxy groups interacting with CO_2 are nonuniform with respect to activity in exchange with phosphate and molybdate anions.

(2) The addition of P into Al–Mo and Al–Ni–Mo catalysts increases the dispersion of Mo-containing particles.

(3) The extent of the dispersion effect in the above catalysts is different owing to the different compositions and sequences of introducing the components. Evidently, the introduction of P into the already formed Al–Ni–Mo catalyst appreciably affects its structure and produces a stronger dispersing effect.

CATALYSIS

Transformations of Straight-Run Naphthas on Indium-Modified Pentasils

Abstract—The influence exerted by the procedure of introducing indium into high-silica zeolite of the Pentasil type on its acid properties and catalytic activity in transformation of straight-run naphthas into lower olefins and aromatic hydrocarbons was studied.

Catalytic pyrolysis is one of the most promising procedures for commercial production of lower olefins. Zeolite-containing catalysts based on high-silica zeolites (HSZs) of the Pentasil type are widely used in oil refining and petroleum chemistry. It is known [1–3] that the activity and selectivity of HSZs of the Pentasil type in transformations of various classes of hydrocarbons are determined not only by acid properties, but also by unique molecular-sieve properties of these zeolites. It was shown previously [4–8] that the acid properties of any zeolite-containing catalyst correlate with its catalytic activity in transformation of hydrocarbon raw materials into definite target products. One of the possible ways of controlling the acid and catalytic properties, along with appropriate pretreatment, is introduction of modifying elements into the zeolite matrix.

In this work we studied how the procedure of introducing indium affects the acid properties of HSZs of the Pentasil type in transformation of straight-run naphthas into lower olefins and arenes.

EXPERIMENTAL

Experiments were performed with straight-run naphtha (SRN) from the Surgut Gas-Processing Plant. This raw material belongs to the paraffin-naphthenic type (onset of boiling at 131°C, density at 20°C 0.684 $cm^3\ g^{-1}$). The hydrocarbon composition of the SRN is as follows (wt %): *n*-paraffins 29.7, branched paraffins 27.2, and naphthenic hydrocarbons 32.8.

High-silica zeollites of the ZSM-5 type with the silicate ratio $SiO_2/(Al_2O_3 + M_2O_3) = 30$ were prepared by hydrothermal synthesis from alkaline aluminosilica gels by the procedure described in [9]. The substances were identified by IR spectroscopy and X-ray phase analysis (Mo anode, Ni filter).

The modifier, In(III) (1 wt % in terms of the metal), was introduced by the following procedures: impregnation of the zeolite matrix with an indium nitrate solution (In-HSZ-1), ion exchange of H-HSZ with In(III) (In-HSZ-2), mechanical mixing of ultradispersed indium powder with H-HSZ followed by the heat treatment (In-HSZ-3), mechanical mixing of indium nitrate with H-HSZ followed by heat treatment (In-HSZ-4), and hydrothermal crystallization of a mixture containing aluminum and indium nitrates. By the latter method, we prepared Pentasils with the framework Al atoms isomorphously substituted by In(III) to 10 (IAS-10 sample) and 20 wt % (IAS-20 sample).

The acid properties of HSZ samples modified with In(III) were studied by temperature-programmed desorption of ammonia. This method furnishes information about the content and strength distribution of acid centers [10].

The catalytic properties of In(III)-modified HSZs in transformation of straight-run naphthas were studied in a flow-through installation with a fixed catalyst bed (3 cm^3) at atmospheric pressure in the temperature range 500–700°C; the feed space velocity was 3 h^{-1}. The hydrocarbon composition of the starting SRN and reaction products was determined by gas chromatography. The error in gas-chromatographic determination of the yield of SRN transformation products and of the content of acid centers in the catalysts was ±2.5%.

All the HSZ samples synthesized, according to IR

spectra and X-ray diffraction patterns, have 90–95% degree of crystallinity and belong to the ZSM-5 type.

The spectrum of temperature-programmed ammonia desorption from the initial H-HSZ (Fig. 1a) has

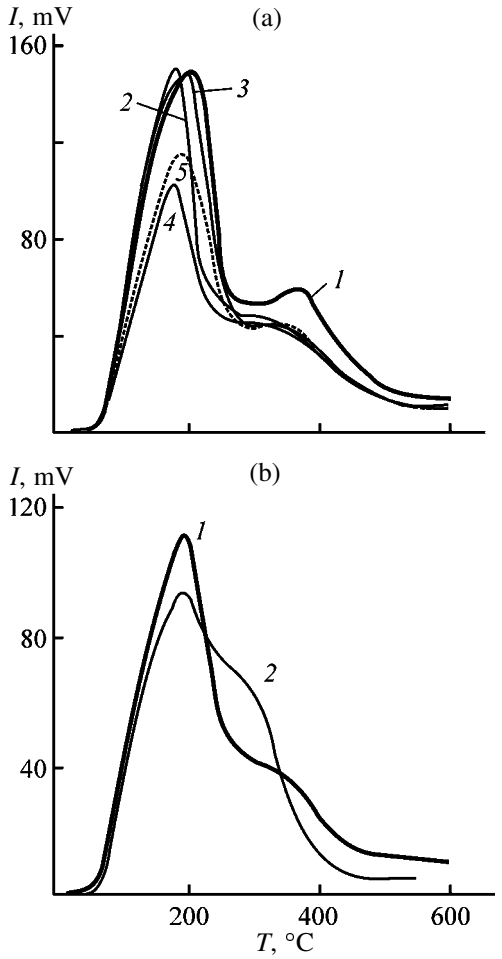

Fig. 1. Spectra of temperature-programmed desorption of ammonia from the surface of zeolites: (*I*) intensity and (*T*) temperature. Sample: (a) (*1*) H-HSZ, (*2*) In-HSZ-1, (*3*) In-HSZ-2, (*4*) I-HSZ-3, and (*5*) I-HSZ-4; (b) (*1*) IAS-10 and (*2*) IAS-20.

two peaks. The low-temperature peak in the range 110–220°C (T_{max} = 203°C) is due to ammonia desorption from weak Lewis acid centers, and the high-temperature peak (310–600°C, T_{max} = 380°C) characterizes the ammonia desorption from strong Brønsted and Lewis acid centers [11, 12]. The concentrations of the weak Lewis acid and strong acid centers in H-HSZ, determined from the amount of the desorbed ammonia, are 530 and 420 μmol g^{-1}, respectively (Table 1).

Modification of H-HSZ with In^{3+} appreciably affects the strength and concentration of acid centers in zeolite-containing catalysts. For example, modification of H-HSZ with 1 wt % In(III) by impregnation of the zeolite matrix with an indium nitrate solution (In-HSZ-1) decreases the strength of both weak (low-temperature) and strong (high-temperature) acid centers. The T_{max} values for the ammonia desorption peaks are shifted to lower temperatures: from 203 to 184 and from 380 to 330°C (Table 1). Modification of H-HSZ with 1 wt % In(III) by impregnation decreases also the concentrations of both weak (from 615 to 563 μmol g^{-1}) and strong (from 343 to 331 μmol g^{-1}) acid centers. Apparently, the In^{3+} ions not only appreciably block the strong acid centers but are also localized in channels and on the external surface of zeolite crystals, forming Lewis acid centers.

Introduction of In^{3+} into H-HSZ by ion exchange (In-HSZ-2) considerably decreases the concentration of strong acid centers (from 343 to 221 μmol g^{-1}), whereas the concentration of the weak acid centers remains virtually unchanged (Table 1). In this catalyst, the concentration ratio of the weak and strong acid centers is the highest, 2.7; in the other catalysts, it varies within a narrow range, 1.7–1.8.

Modification of H-HSZ by mechanical mixing with ultradispersed indium (In-HSZ-3) decreases the strengths and concentrations of both weak and strong

acid centers. For the high-temperature form of ammonia desorption, T_{max} decreases to 330°C. Similar changes in the acid properties are observed upon modification of H-HSZ by mechanical mixing with indium nitrate, followed by a heat treatment. Such a trend in variation of the acid properties of In(III)-modified HSZ are attributable to the fact that indium cations, being arranged on the surface of zeolite crystals, block a part of the active centers, so that the amount of acid centers accessible for the adsorbate molecules decreases.

In modification by ion exchange, impregnation, or dry mixing, the zeolite behaves as a salt of a poly acid in which the macroanion remains unchanged and only the cations compensating the negative charge of the framework are substituted. The anionic part of the Si–O framework can be controlled by adding multicharged M^{n+} cations, in paticular, In^{3+}, into the starting silica gel before its hydrothermal crystallization.

On the IAS-10 catalyst, ammonia is adsorbed in two forms. Form I (low-temperature desorption, T_{max} 194°C) corresponds to weak acid centers and form II (T_{max} 357°C), to strong acid centers (Fig. 1b). Incorporation of the In(III) ions in the stage of the hydrothermal synthesis decreases the total acidity of the catalyst to 825 μmol g^{-1} (IAS-10), with the strength of the weak acid centers remaining virtually unchanged and that of strong acid centers decreasing, as judged from the shift of T_{max} from 380 to 357°C. This is due to the fact that the In(III) ions are weaker acids than the aluminum cations.

As the In(III) concentration in HSZ is increased (IAS-20), the temperature-programmed desorption spectrum changes: There is a single maximum with a high-temperature shoulder, and different types of acid centers are not clearly resolved. The large peak width suggests a fairly broad spectrum of the acid centers, i.e., formation of energetically nonuniform centers. This may be due to the fact that the state of the multicharged M^{n+} ions in the crystallization products may be different, depending both on the composition of the starting mixture and on the nature of M^{n+}, which will affect the acidity of the catalyst and give rise to nonuniform distribution of acid centers with respect to the strength and concentration [3, 13].

Thus, the strength and concentration of acid centers and their distribution in the catalyst are largely influenced by the zeolite modification procedure, state of indium cations, and their arrangement in the zeolite.

The results of experiments on transformation of straight-run naphtha on HSZ samples modified with In(III) by various procedures are listed in Table 2.

High-silica zeolites (H-HSZs) of the ZSM-5 type show high activity in transformation of straight-run naphthas. For example, on the initial H-HSZ sample, the yield of lower (C_2–C_4) olefins increases from 8.1 to 23.6%, and the yield of aromatic hydrocarbons, from 22.3 to 39.9% as the reaction temperature is increased from 500 to 700°C.

Introduction of In^{3+} ions by impregnation of the zeolite matrix (H-HSZ) with an indium nitrate solution (In-HSZ-1) results in a substantial growth of the yield of C_2–C_4 olefins as compared to H-HSZ. The yield of lower olefins on the initial H-HSZ at 650 and 700°C is 16.0 and 23.6%, and on In-HSZ-1, 32.5 and 41.5%, respectively (Table 2). At relatively low temperatures (550–600°C), the yield of aromatic hydrocarbons on In-HSZ-1 is considerably higher (50.7%) than on H-HSZ (22–33%).

Introduction of In^{3+} ions by ion exchange (In-HSZ-2) results in a further increase in the yield of lower olefins as compared to In-HSZ-1. The maximal yield of C_2–C_4 olefins is 47.6% at 700°C. Such a trend may be due to the fact that the ion-exchange procedure ensures more complete substitution of protons in the bridging OH groups of the zeolite by the In^{3+} ions, as suggested by the temperature-programmed desorption spectra.

Modification of HSZ by mechanical mixing of ultradispersed In powder with H-HSZ followed by heat treatment (In-HSZ-3) results in increased conversion of SRN. As the reaction temperature is increased from 550 to 700°C, the yield of lower olefins on the In-HSZ-3 catalyst increases from 4.7 to 33.6 wt %. It should be noted that, at 600–650°C, the yield of aromatic hydrocarbons on this catalyst is maximal (60–61%), especially that of benzene (28–32%) and toluene (24–26%).

Mechanical mixing of indium nitrate with H-HSZ followed by the heat treatment (In-HSZ-4) increases the activity of the catalyst: The yield of aromatic hydrocarbons at 550°C becomes as high as 56.2%, and at higher temperatures the yield of lower olefins increases from 11.7 to 42.5%.

Thus, modification of H-HSZ with indium by dry mixing enhances the activity of the catalyst and increases the selectivity of formation of aromatic hydrocarbons, which may be due to formation on the catalyst surface of additional Lewis acid centers capable of abstracting the hydride ion from a saturated hydrocarbon molecule, and also to fairly high concentration

Table 2. Influence of temperature on the composition of products formed by transformation of straight-run naphtha on indium-modified HSZ

of Brønsted acid centers on which the radical cation can be adsorbed to form aromatic hydrocarbons.

On indioaluminosilicate IAS-10, as the reaction temperature is increased from 550 to 700°C, the yield of C_2–C_4 olefins from SRN increases from 17.6 to 41.6%, whereas the yield of aromatic hydrocarbons decreases from 42.9 to 17.6% (Table 2). Apparently, isomorphous substitution of Al(III) by In(III) in the zeolite gives rise to Lewis acid centers capable of abstracting hydride ions from the initial hydrocarbons of SRN to give radical cations. Their subsequent

transformations occur both on Brønsted acid centers to give aromatic hydrocarbons or in the bulk to give lower olefins. The radical centers Si–O*, Si–O*–Al, and Si–O*–In, as well as the In^{3+} ions occluded on the catalyst surface can act as Lewis acid centers [14].

As the degree of aluminum substitution by indium ions is further increased to 20 wt % (IAS-20 sample), the activity of the catalyst in SRN transformation drastically decreases. As the reaction temperature is increased from 550 to 700°C, the yield of lower olefins from SRN increases from 3.7 to only 26.4%, with the yield of aromatic hydrocarbons being as low as 7–8%. This may be due to fixation of the In^{3+} ions in the framework positions isomorphous with Si^{4+}; according to [13], only a certain part of In^{3+} is fixed in these positions. When the In^{3+} content is increased further, the In^{3+} ions become occluded (in the form of salts and oxides) on the crystal surface and inside the channels and become localized in the vicinity of groups containing oxygen ions with the noncompensated charge (in cationic positions), blocking the Brønsted acid centers.

Also, we studied by DTA the coking of the catalyst surface in the course of SRN transformation. On all the "coked" catalyst samples, a small endothermic effect at 110°C is due to removal of physically adsorbed water. The shift of the peak of the coke deposit combustion in the DTA curve of In(III)-modified HSZ toward higher temperatures (520–740°C) suggests formation of more "condensed" coke on the catalyst surface in the course of SRN transformation (Table 3).

The DTG and DTA curves show that the coke deposits are removed from the zeolite-containing catalyst in the range of burn-out of coke formed from polycondensed aromatic hydrocarbons [15]. In the DTA curves of coked In-HSZ-3 and In-HSZ-4 samples, a second strong maximum appears in the range 520–740°C, suggesting formation of a broader spectrum of coke deposits. The content of coke deposits on these samples is the highest, which is well consistent with their higher activity (maximal yield of aromatic hydrocarbons in transformation of straight-run naphtha).

On the IAS-20 sample, the coke deposits burn out at low temperatures (DTA peak at 420°C), which suggests their nonaromatic nature. This may be due to the absence of strong acid centers in this sample, which results in a low yield of aromatic hydrocarbons from straight-run naphthas.

It is known [16] that the coking in the course of transformation of hydrocarbons on zeolite-containing catalysts follows a consecutive scheme involving polymerization and condensation of alkenes, and also condensation and dehydrocondensation of aromatic hydrocarbons. The consecutive scheme of formation of coke residues from alkenes is as follows [17]: olefins–cycloolefins–benzene–alkylbenzene–condensed polyaromatic hydrocarbons–coke.

Table 3. Differential thermal analysis of coke deposits on indium-modified zeolite-containing catalysts

Catalyst	T of thermal effect, °C	T_{max}, °C	Coke content, %
H-HSZ	500–580	560	7.2
In-HSZ-1	520–710	700	11.0
In-HSZ-2	520–700	680	9.8
In-HSZ-3	520–740	660, 700	19.9
In-HSZ-4	520–710	600, 670	17.9
IAS-10	520–700	670	9.6
IAS-20	300–500	420	4.6

However, the coking may involve, along with polycondensation of aromatic hydrocarbons, also radical polymerization, i.e., a contact of a hydrocarbon with an active center of the catalyst may result in cleavage of aromatic hydrocarbons across the C–C bonds and nonaromatic hydrocarbons across the C–H bonds. The hydrogen atoms generated in the process can react with the carbonaceous deposits on the catalyst surface to give low-molecular-weight hydrocarbon radicals, which behave as active centers effecting propagation of the polymeric chain.

Thus, on zeolite-containing catalysts, the coking can occur by several mechanisms depending on the composition of the hydrocarbon raw material and on the type, strength, and concentration of active centers on the catalyst surface. By varying the procedure for introducing the modifier, in particular, In(III), it is possible to control the ratio of strong and weak acid centers and hence the direction of hydrocarbon transformation toward predominant formation of lower C_2–C_4 olefins or aromatic hydrocarbons. For selective formation of lower olefins, the best procedure for introducing In^{3+} into the zeolite matrix is incorporation of In(III) into the zeolite structure in hydrothermal synthesis, whereas for selective formation of aromatic hydrocarbons from straight-run naphtha it is advisable to introduce In by dry mixing of the zeolite-containing catalyst with an indium salt.

CONCLUSION

A correlation was revealed between the acid properties of In(III)-modified Pentasil-type zeolitic catalysts and their catalytic activity in transformation of straight-run naphtha. For selective production of lower olefins from straight-run naphtha, it is advisable to add In(III) in the stage of the hydrothermal synthesis, whereas for selective production of aromatic hydrocarbons dry mixing of an indium salt with the zeolitic catalyst is preferable.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Water Pretreatment To Remove Organic Impurities and Desalination with Ion Exchangers

G. V. Slavinskaya

Voronezh State University, Voronezh, Russia

Received February 10, 2003

Abstract—Treatment of Neva water to remove organic and mineral impurities on an ion-exchange industrial installation with the resins produced in Russia was studied.

Many of the modern productions use a high-resistivity desalinated water prepared by treatment of natural water [1–5]. The most urgent problem in water treatment is removal of organic contaminants. The reason is that natural waters contain a wide variety of both organic and mineral impurities in diverse combinations and ratios. Therefore, the technique suited for preparation of deionized water with the minimal content of organic pollutants must be adapted to features of water to be treated [1].

The aim of this work was to analyze the efficiency of removal of organic pollutants from Neva water in the course of its pretreatment and ion-exchange desalination on an industrial ion-exchange installation.

EXPERIMENTAL

Neva water belongs to low-mineralized natural waters. It has a yellowish color caused by the significant amounts of humic (HA) and fulvic (FA) acids [1–3]. As a rule, the plant facilities use municipal tap water. This water contains variable amounts of humic substances and other undesirable impurities. Karmazinov and Gumen [6] believe that this is due to insufficient efficiency and overload of the head facilities installation and periodical deterioration of the water quality in the Neva–Ladoga water system.

Data on seasonal variations of both the permanganate oxidizability (PO) (hereinafter referred to as oxidizability) of Neva water and the content of several organic compounds averaged throughout three-year period are listed in Table 1. This table shows that, among organic impurities, fulvic acids prevail.

It is known that the most efficient procedure for water treatment [1, 3] is distillation. The laboratory experiments showed (Table 2) that distillation of Neva water removes about 95% of humic acids. However, this power-consuming technique cannot be used for a large-scale industrial water treatment. As a rule, before water desalination it is pretreated by reagent coagulation, sorption, or combination of these techniques [1]. In preparation of desalinated water for semiconductor production, aluminum sulfate is used as the most efficient coagulant [1, 7]. Upon such a treatment, the aluminum content in the purified water does not exceed 3×10^{-7}%.

Table 2 shows that HA is removed by coagulation to a greater extent than FA. Upon coagulation, the content of oxidizable compounds decreases by 40–50% only, and the residual water oxidizability exceeds 5 mg O/l. Thus, Neva water pretreatment by coagulation only does not decrease its oxidizability to 2.5 mg O/l, which is required for preparation of high-resistivity water by ion-exchange methods.

In order to increase the degree of removal of organic impurities, the tap water treated by coagulation was additionally clarified in a mechanical filter and then filtered through weakly basic IA-1 (IA-2, IA-3) polycondensation anion exchangers derived from *m*-phenylenediamine [7]. Since natural waters contain a wide variety of impurities, their ion-exchange decontamination should be performed with resins containing different functional groups [8]. It was found that anion exchangers of IA type in a salt form exhibit the maximal sorption capacity for humic substances and their sorption increases with increasing temperature and decreasing pH [1, 7]. As seen from Table 3, IA-1 resin exhibits high sorption capacity for all the organic substances present in water of different rivers: Neva (Leningrad oblast), Nevezhis and Panevezhis (Lithuania), and Usman (Voronezh oblast). These data show

that all the organic substances except esters are efficiently sorbed on IA resins. Taking into account that esters are not removed from river water by distillation, coagulation, and filtration through anion-exchange resins, a new technique suited for solution of this problem is required.

To evaluate the contribution of coagulation, sorption, and desalination steps to the total purification of Neva water to remove organic impurities, their concentrations at the inlet and outlet of the corresponding units of an industrial ion-exchange installation with the performance of 6.5 $m^3 h^{-1}$ were monitored during 20 labor shifts (160 h). These experiments were carried out in the spring flood.

In water treatment, the following sequential procedures were performed: heating of the initial water to 20–25°C, coagulation treatment with aluminum sulfate (0.5 mg-equiv l^{-1}), clarification with a mechanical filter packed with quartz sand and anthracite, filtration through strongly acidic KU-2 cation exchanger in the H form, decarbonation, filtration through an adsorber packed with IA-1 anion exchanger in the Cl form, filtration through AN-31 weakly basic anion exchanger in the OH form, and filtration through a combined sorbent (CS) consisting of KU-2-8 strongly acidic cation exchanger in the H form and AV-17-8 strongly basic anion exchanger in the OH form at their volume ratio of 1 : 1.4 and the filtration velocity of 6–7 m h^{-1}.

Under such conditions, one volume of IA-1 resin purifies up to 900–1000 volumes of Neva water. The variations of water characteristics at the inlet of the

desalinating device were as follows: oxidizability from 8.6 to 11.2 mg O l^{-1}, HA content from 0.30 to 1.50, and FA content from 8.10 to 11.5 mg l^{-1}. Taking into account that these variations are appreciable, we determined not only the mean-shift water composition (Table 4) but also water composition in separate treatment stages (Figs. 1a–1c).

Table 4 shows that the degree of HA removal from Neva water by coagulation (60%) considerably exceeds that of FA removal (25%). At the same time,

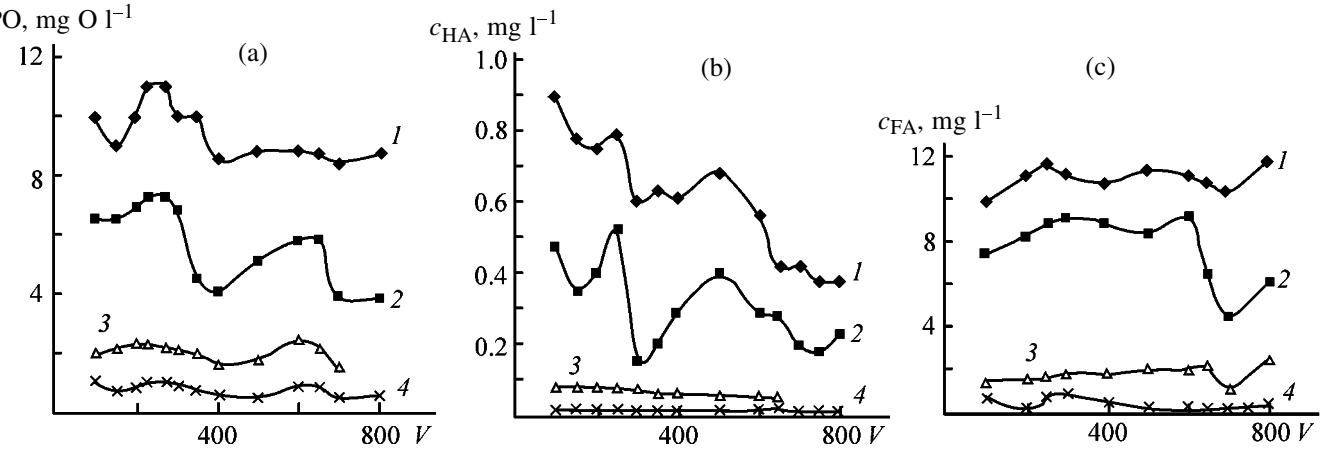

Fig. 1. Variation of the (a) permanganate oxidizability, (b) HA content c_{HA}, and (c) FA content c_{FA} (*1*) in the initial Neva water, (*2*) after coagulation treatment, (*3*) after filtration through IA-1 porous anion exchanger, and (*4*) after filtration through the combined sorbent throughout the process period. (*V*) Volume of purified water (number of IA-1 volumes); the same for Fig. 2.

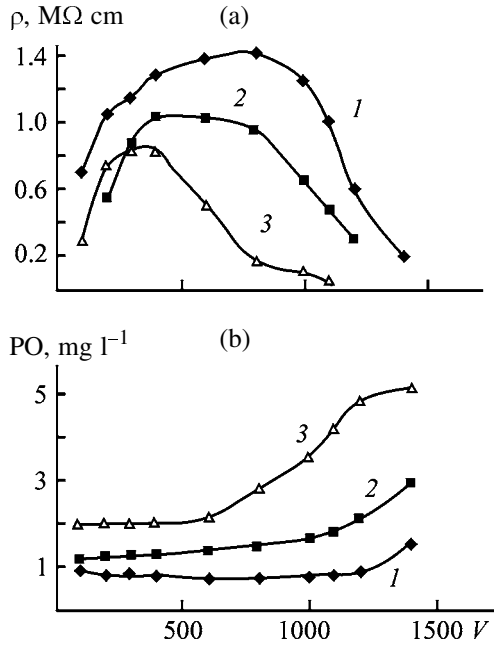

Fig. 2. (a) Specific electrical resistivity ρ and (b) water oxidizability PO as functions of the water volume filtered through the ion exchanger. Figures at curves are numbers of the filtration cycles.

the water oxidizability reflecting the total content of organics in water decreases by 40% only. Upon filtration through the porous anion exchanger, the HA and FA content decreases, on the average, by 90% and 80%, respectively. In the subsequent filtration through AN-31 and CS anion exchangers, a additional amount of organic impurities (13–15%) is removed from water. We found that, after completion of water treatment, humic acids (3–4%) and the organic matter oxidizable with $KMnO_4$ (about 10%) remain in water.

Figures 1a–1c show variations in the content of organic substances in Neva water (single samples) at different stages of its treatment (in the initial water, after coagulation treatment, and after filtration through IA-1 and CS ion exchanger). It is seen that, irrespective of the treatment procedure, the variations in the oxidizability (Fig. 1a) have similar wave-like shape. At the same time, the humic acid content remains virtually constant (Fig. 1b), and the fulvic acid breakthrough gradually increases (Fig. 1c). These facts show that Neva water contains some amount of easily oxidizable nonhumic impurities which are not removed in the course of water treatment. These impurities do not affect the electrical resistivity of deionized water ρ, i.e. they are nonelectrolytes.

We found that, during a three-year process period, the porous anion exchanger retains high sorption power and levels out the variations in the HA and FA content in the clarified water (Figs. 1b, 1c). These figures show also that the FA breakthrough exceeds that of HA. However, we failed to determine a time when IA-1 exhausts its sorption capacity for HA and FA by measuring the filtrate oxidizability, because the oxidizability characterizes the total content of easily oxidizable impurities and is insensitive to a breakthrough of difficultly oxidizable HA and FA.

This is confirmed by Fig. 2 in which the specific electrical resistivity and oxidizability of the filtrate are plotted vs. the water volume sequentially passed through IA-1 anion exchanger and desalinating filters containing KU-2-8 cation exchanger and AV-17-8 anion exchanger (total volume of the ion exchangers 1000 cm^3, filtration velocity through the adsorber and ion exchangers 7 and 20 m h^{-1}, respectively, the performance of the ion-exchange installation 100 l h^{-1}).

Figure 2 shows that a breakthrough of the organic electrolytes (HA and FA) is detected by the electrical resistivity at the smaller filtrate volume than it is detected by the oxidizability. Since the quantitative determination of HA and FA requiring their preconcentration is a prolonged procedure [9], it is difficult to unambiguously determine the time when an adsorber is exhausted and must be replaced by a fresh one.

Based on the fact that HA and FA absorb UV radiation [10], their breakthrough into filtrate was detected by measuring the optical density at 205 nm D_{205}. In order to increase the detection sensitivity, a long optical cell (100 mm) was used. In developing this technique, we found that there is an inverse correlation between the optical density D_{205} (i.e., HA and FA breakthrough into filtrate) and the electrical resistivity of the desalinated filtrate ρ.

A sharp decrease in the specific electrical resistivity of a filtrate flowing out of an adsorber packed with the CS combined deionizing sorbent shows that this sorbent is saturated with mineral ions. At this point, the adsorber must be put out of operation and replaced by a fresh one. However, the electrical resistivity of the filtrate can decrease owing to breakthrough of not only mineral but also organic electrolytes. Among them the FAs contribute maximally into the electrical conductivity, since fulvic acids of Neva water are characterized by a fairly high ionization constant, pK_a 4.3 [11]. If this is the case, the porous anion exchanger rather than the CS combined sorbent must be replaced or regenerated. In practice, upon replacing

the adsorber, the electrical resistivity of the filtrate increased to the initial level.

To meet the growing requirements of certain productions to the quality of deionized water, water treatment to remove organic impurities must be more efficient. In order to develop such an efficient technique, a wide variety of approaches should be tested: sorption treatment with synthetic sorbents selectively removing organic contaminants from natural water, sorption on combined anion–cation exchangers, oxidation under UV irradiation, with ozone, hydrogen peroxide, with combination of these, etc. [12].

CONCLUSIONS

(1) The seasonal variations in the content of organic substances in Neva water were studied. Fulvic acids were found to prevail in all the seasons.

(2) Long-term operation of an ion-exchange installation showed that Neva water pretreatment (reagent coagulation, sorption of organic impurities on porous polycondensation anion exchangers derived from *m*-phenylenediamine in the salt form, preheating of water to 20–25°C, acidification to pH 3–4) followed by desalination on a combined sorbent allows preparation of the deionized water with the specific electrical resistivity of up to 18 MΩ cm and the permanganate oxidizability lower than 1.0 mg O/l.

(3) The combined desalinating sorbent is exhausted and must be replaced by a fresh one when the optical absorption of the final filtrate at 205 nm (a 100-mm cell) caused by breakthrough of the organic impurities starts to grow.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Effect of Design Parameters of the Centrifuge Rotor on Separation of Supensions

N. V. Pavlova, F. F. Spiridonov, S. A. Svetlov, I. N. Pavlov, and Yu. P. Volkov

Biisk Technological Institute, Altai State Technical University, Biisk, Altai krai, Russia

Received September 16, 2002

Abstract—Centrifugal separation of low-concentration suspension in a biconical rotor of a centrifuge was modeled numerically. A system of equations describing the motion of solid particles in a fluid flow was constructed and solved. The effect of geometric parameters of the centrifuge rotor on the separation efficiency was demonstrated.

Centrifugation is rather frequently used for separating low-concentration suspensions containing a finely dispersed solid phase. The choice of the type of a centrifuge and its design features is governed by physical characteristics of the media being separated: size and shape of particles, difference between the densities of the dispersed and continuous phases, and viscosity of the continuous phase.

Despite the sufficiently good understanding of methods used for separating suspensions and wide variety of centrifuges employed in practice, developing a theory of settling of the finely dispersed phase and precise methods for calculating the equipment to be involved is an important task. The data necessary for calculating centrifugation of a particular suspension or emulsion can be obtained from experiments concerned with separation on an experimental centrifuge modeling the design of the centrifuge to be calculated. However, this approach is not always justified.

By now, basic patterns characterizing centrifugal separation and yielding information about the optimal conditions of centrifuge operation have been established [1]. In view of the wide application of numerical methods to solution of various technical problems and simulation of industrial processes, it is possible to pass from formal approximation of experimental operation characteristics of equipment and apparatus for centrifugal separation to mathematical simulation that takes into account the hydrodynamic and kinetic characteristics of the process. In settling centrifugation, two processes occur simultaneously [2]: fluid flow within the rotor (internal problem) and motion of settling particles relative to the fluid (external problem).

Specific features of the distribution of fluid flows in a centrifuge and type of their motion within the rotor largely determine the true time of particle residence in different zones of the field of centrifugal forces, i.e., the actual output capacity of a centrifuge at a given sinking velocity of particles to be separated. In a turbulent flow of a suspension, the settling of solid particles may be strongly affected by turbulent pulsations of the fluid. In addition, the particles in the flow acquire rotatory motion. The transverse forces arising because of the rotation of particles exert influence on the nature of their motion and, consequently, on the settling rate. This rate is also affected by the lagging of the fluid behind the rotor motion. The factors mentioned above result in that a certain amount of particles with size exceeding the separation size is lost with the centrifugate.

The centrifugation of suspensions involves simultaneously occurring processes of fluid flow within the rotor, motion of settling particles relative to the fluid and to the rotor walls, formation of a sediment layer, and its densification.

The results obtained in studying the separation of suspensions in a cylindrical settling centrifuge and a centrifuge with a biconical rotor demonstrated a higher efficiency of separation of low-concentration suspensions in a biconical rotor (Fig. 1) at relatively high centrifugate output capacity of the centrifuge [3].

When describing the motion of a fluid within the rotor with account of the complexity of solution of a system of flow continuity equations and hydrodynam-

1070-4272/03/7607-1094$25.00

ic equations, the vortex strength ω and flow function ψ are introduced as main dependent variables:

$$rw = \partial\psi/\partial r, \quad rv = -\partial\psi/\partial z, \tag{1}$$

$$\omega = \partial v/\partial z - \partial w/\partial r, \tag{2}$$

where w and v are the fluid velocity components along the z and r axes, respectively. The following assumptions are made: the fluid is incompressible; effective viscosity is invariable; gravitational, electric, magnetic, and other fields are weak.

Equations for variables (1) and (2) are reduced to the form [3]

$$a_\phi\left[\frac{\partial}{\partial z}\left(\phi\frac{\partial\psi}{\partial r}\right) - \frac{\partial}{\partial r}\left(\frac{\partial\psi}{\partial z}\right)\right] - \frac{\partial}{\partial z}\left[b_\phi\frac{\partial}{\partial z}(c_\phi\phi)\right]$$

$$- \frac{\partial}{\partial r}\left[b_\phi\frac{\partial}{\partial r}(c_\phi\phi)\right] + rd_\phi = 0, \tag{3}$$

where ϕ is a dependent variable; a_ϕ, b_ϕ, c_ϕ, and d_ϕ are functions.

The values of a_ϕ, b_ϕ, c_ϕ, and d_ϕ were given, depending on the type of a function used, in [4].

The system of equations under study was solved by the finite-difference method, with a finite number of points chosen so that they are distributed in accordance with a certain pattern in the flow field; these points being mesh nodes. The values of the variables were calculated at the nodes and found by interpolation at intermediate points.

An iteration method of successive shifts was developed for solving the system of nonlinear algebraic equations. This method takes into account the specificity of the following boundary conditions for fluid flow within the centrifuge rotor.

Boundary conditions at the inlet cross section. The parameters of the flowing-in fluid are known, the streamlines are considered to be parallel to the symmetry axis in this region. This condition also determines the distribution of the vortex strength. The processes occurring within the centrifuge affect the distribution of quantities over the inlet cross section only slightly.

Boundary conditions at the wall. The wall is impermeable to the fluid and, consequently, the flow function is constant all over the wall. The circumferential velocity of the fluid in the immediate vicinity of the solid wall is equal to the velocity of the wall at any of its points.

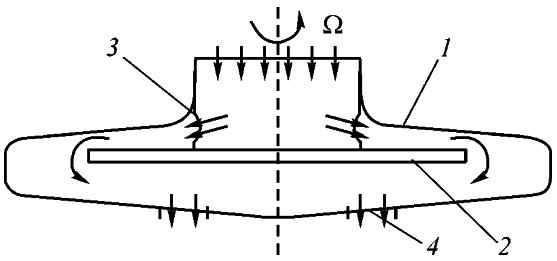

Fig. 1. Schematic of the centrifuge rotor: (*1*) rotor, (*2*) disc, (*3*) inlet opening, and (*4*) discharge opening.

Boundary conditions at the outlet cross section. The boundary conditions at the outlet cross section are set by extrapolation of the values of the sought-for variables from the flow.

Boundary conditions at the symmetry axis. The radial component of velocity at the symmetry axis is zero.

The calculation algorithm of the chosen solution method was implemented using the Maple 6 software package including procedures for data input, mesh construction, solution of the system of equation, and output of the information obtained. Numerical simulation of the flow of a fluid containing the solid phase was done for the example of separation of a suspension of microcrystalline cellulose (MCC) in water, with solid phase content of less than 5%. In doing so, the solid phase was taken to be monodisperse and to contain spherical particles of a certain size. In simulating the separation of an aqueous suspension of MCC, the average particle size d_p was chosen, which varies within the range 1–120 μm in the pulverized product. The preset parameters in studying the process of centrifugal separation were the solid phase particle diameter and the angular rotational velocity Ω of the centrifuge rotor.

Differential equations for finding the trajectory of particle motion in the centrifuge rotor were derived on the assumption that a low-concentration suspension is being separated. The particle motion in a field of centrifugal forces is described by the general law of the drag force [5]

$$m_p = \mathrm{d}w_p/\mathrm{d}t = F_d, \quad m_p = \mathrm{d}v_p/\mathrm{d}t = F_c + F_d, \tag{4}$$

where F_d is the drag force (N); F_c, centrifugal force (N); m_p, particle mass (kg); w_p and v_p, horizontal and vertical components of the particle velocity, respectively (m s^{-1}); and t, time (s).

The z and r components of the drag force F_d are given by

$$F_z = 0.5\rho(\Delta w)^2\xi(\pi d_p^2/4), \quad F_y = 0.5\rho(\Delta v)^2\xi(\pi d_p^2/4), \tag{5}$$

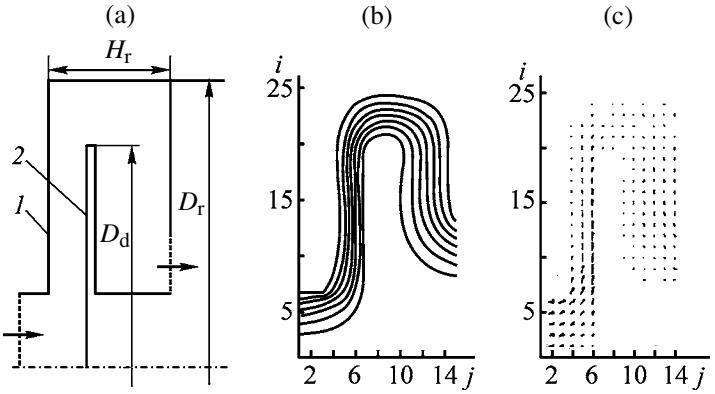

Fig. 2. Suspension flow structure in the contour. (a) Schematic of the contour: (*1*) rotor and (*2*) disc; (b) streamlines; and (c) vector filed of velocities. (D_r) Rotor diameter (m), (D_d) disc diameter (m), and (H_r) rotor height.

where ρ is the fluid density (kg m^{-3}); $\Delta w = w - w_p$, $\Delta v = v - v_p$, the differences of longitudinal and transverse components of the velocities of the fluid and dispersed phases (m s^{-1}); and ξ, the drag coefficient.

The centrifugal force can be found using the formula

$$F_c = m_p \Omega^2 r, \tag{6}$$

where r is the radius of the particle trajectory (m).

Finally, Eqs. (4) of particle motion, supplemented with kinetic relations, are represented as

$$\left.\begin{aligned} S(\mathrm{d}w_p/\mathrm{d}t) &= w - w_p, \\ S[(\mathrm{d}v_p/\mathrm{d}t) - \Omega^2 r] &= v - v_p, \\ \mathrm{d}z/\mathrm{d}t &= w_p, \\ \mathrm{d}r/\mathrm{d}t &= v_p, \end{aligned}\right\} \tag{7}$$

where S is the Stokes number, $S = \rho_p d_p^2/18\mu$ (s); ρ_p, particle density (kg m^{-3}); and μ, fluid viscosity (Pa s).

The system (7) of equations describing the motion of solid particles in the centrifugal filed of the centrifuge was solved by the single-step Gear method. The flow velocity of the fluid was determined by finding numerically the velocity profile in the centrifuge at varied geometric parameters of the centrifuge rotor. The particle velocity at the entry into the centrifuge rotor was taken to be equal to the fluid flow velocity, which is well justified for small particles. In solving the equations, the maximum rate of rotor rotation at which all particles reach the rotor wall was determined.

To study the process in more detail, the separation was simulated at varied geometric characteristics of the contour of the centrifuge rotor. The presented model of the suspension flow in the centrifuge rotor and its numerical solution were used to obtain data on the flow structure of the fluid and particles in various contours of the rotor under consideration.

Figure 2 shows streamlines and vector field of velocities in a contour with rectangular cross section, which has parameters close to those of a laboratory centrifuge with a biconical rotor.

Numerical simulation yielded data on the suspension flow structure in various contours of the centrifuge in question. These data were analyzed in studying the influence exerted by the main operation parameters of the centrifuge on the separation efficiency. In doing so, the extent to which the suspension was separated, amount of particles contained in the centrifugate, and fraction of particles settling in the centrifuge were evaluated from the trajectories of particle motion within the rotor. Therefore, to estimate the data obtained more accurately, the spectrum of particle motion trajectories was considered.

Analysis of the fluid flow structure and trajectories of particle motion in contours of different sizes shows that, at a constant rate of rotor rotation, the structure of particle motion depends on the radius of particle entry into the inlet cross section of the rotor. The influence exerted by the rate of rotor rotation on the degree of suspension separation was studied for contours with rectangular cross sections. The results obtained are shown in Fig. 3. The rate n of centrifuge rotor rotation should be noted as the basic parameter affecting the efficiency of suspension separation. The content of solid particles in the centrifugate, c_ϕ, markedly decreases when the rate of rotor rotation is raised at constant initial concentration c_{in} of the suspension and its flow rate Q.

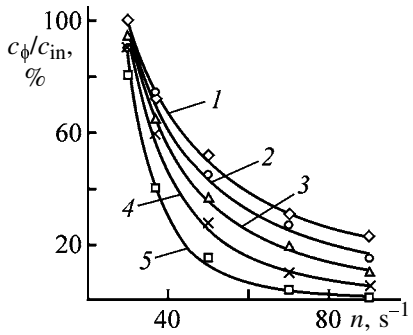

Fig. 3. Relative fraction of particles in the centrifugate, c_ϕ/c_{in}, vs. rate n of rotor rotation. Q = 9000 l h^{-1}, H = 0.045 m, D_r = 0.16 m. Particle diameter d_p (μm): (*1*) 5, (*2*) 10, (*3*) 15, (*4*) 20, and (*5*) 25.

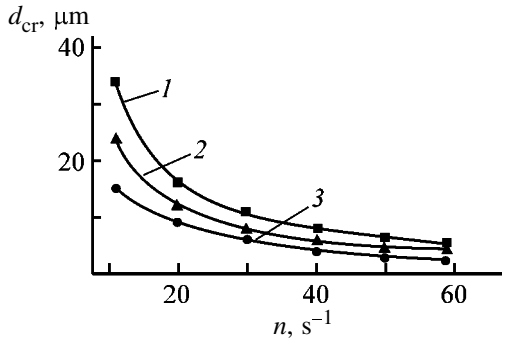

Fig. 4. Maximum particle diameter d_{cr} in the centrifugate vs. rate n of rotor rotation. Suspension flow rate Q (l h^{-1}): (*1*) 300, (*2*) 150, and (*3*) 70.

In the next stage of the study, suspension separation in the rotor of an experimental centrifuge was simulated numerically. For this purpose, the calculation algorithm was applied to the biconical rotor of the centrifuge. The trajectories of motion of solid particles within the rotor largely depend on the flow rate of the initial suspension.

The results obtained in the theoretical analysis were compared with the data furnished by experimental studies of suspension separation in a centrifuge with a biconical rotor at the same process and design parameters. The comparison demonstrated that the results of numerical and experimental studies at identical modes of centrifuge operation (flow rate of the initial suspension, rate of rotor rotation, particle diameter, concentration of the solid phase) are in reasonable agreement.

For a contour with dimensions corresponding to those of the biconical rotor, we examined the influence exerted by the rate of rotor rotation and suspension flow velocity at the centrifuge inlet on the maximum diameter of solid particles in the centrifugate. In the case of separation of a suspension with polydisperse composition of the solid phase, the maximum size d_{cr} of solid particles in the centrifugate decreases with increasing rate of centrifuge rotor rotation and decreasing rate of suspension supply into the rotor (Fig. 4).

The model of the process, presented here, was also used to study the efficiency of particle settling at varied geometric parameters of the centrifuge. The main variable parameters were rotor height, disc thickness, and rotor and disc diameters.

The influence exerted by the height of the rotor on the efficiency of suspension separation was considered with all other design parameters of the centrifuge fixed. In this case, the optimal height of the centrifuge rotor, at which particles of a certain diameter settle onto the inner surface of the rotor, was determined. Figure 5a shows the dependence of the degree of separation $\eta = (c_{in} - c_\phi)/c_{in}$ on the height H of the centrifuge rotor at different diameters of particles of the dispersed phase in the suspension at constant suspension flow rate and rate of rotor rotation. As seen from Fig. 5a, settling of particles with smaller diameters requires that the distance traversed by the fluid in the field of centrifugal forces should increase sub-

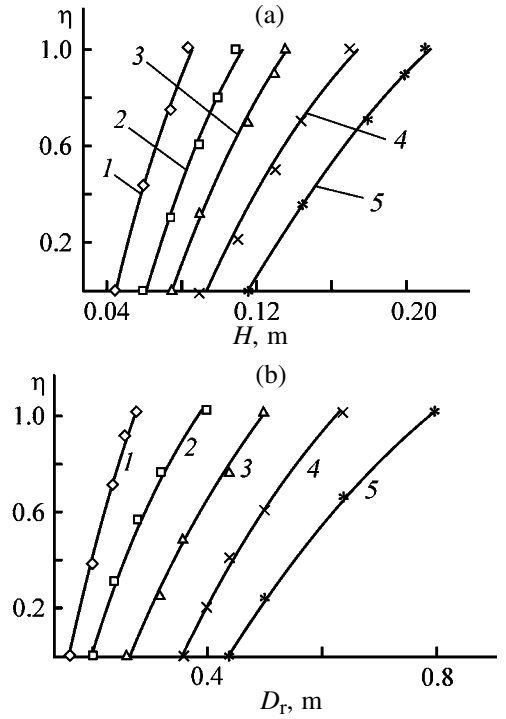

Fig. 5. Degree of suspension separation, η, vs. (a) height H and (b) diameter D_r of the rotor. n = 50 s^{-1}, Q = 9000 l h^{-1}. (a) D_d = 0.115 and D_r = 0.16 m; (b) D_d/D_r = 0.7 and H = 0.045 m. Particle diameter d_p (μm): (*1*) 25, (*2*) 20, (*3*) 15, (*4*) 10, and (*5*) 5.

stantially, which ensures finer separation of the suspension.

Since the separation is affected not only by the rotor height, but also, possibly, by other parameters, their influence was considered with other design parameters of the centrifuge rotor fixed. The influence of the rotor diameter on the efficiency of settling of solid particles was studied. It was found that, when only the rotor diameter is raised at invariable disc diameter, the separation is insufficiently efficient. This may be due to the following: particles move around an obstacle in those regions where the centrifugal force is weak; as a result, they have not enough time to settle on the rotor and find their way into the centrifugate. If the disc diameter is changed in proportion to the rotor diameter, the efficiency of the process increases substantially. Increasing the rotor diameter at constant disc diameter affects the efficiency of settling of solid particles to a lesser extent, which requires that the rotor diameter and, consequently, the overall dimensions of the centrifuge should be made much larger.

The plot representing the dependence of the degree η of suspension separation on the rotor diameter in the case of a proportional increase in the rotor and disc diameters is shown in Fig. 5b.
