an intermediate value between the cases of particle burning and carbon oxidation in a bed [12]. In this case, the values of K_0 (Table 2) do not correspond to those calculated using the particle burning equations. Because the rate of noncatalytic oxidation of carbon is, on the whole, lower, the combustion parameters are strongly affected by reactions that occur at the internal surface of particles, which require an internal diffusion of oxygen and back transport of oxidation products, in accordance with the equation derived by L.N. Khitrin [12]:

$$K_S^C = \beta c_0 (1/K_1 + R/D)^{-1}, \quad (4)$$

where c_0 is the ambient oxygen concentration; *D*, the

* Calculated by equations [16] suggested by (*1*) L.A. Vulis, $\log K_0 = 1.75 \times 10^{-4}E - 0.5$; (*2*) G.F. Knorre, I.I. Paleev, and K.M. Aref'ev, $\log K_0 = 0.991 \times 10^{-4}E + 0.398$; and (*3*) S.M. Shestakov, $\log K_0 = 0.838 \times 10^{-4}E + 2$.

diffusion coefficient; K_1, the overall reaction rate constant; and R, the particle radius.

Here, we should take into account the factor β, which is the stoichiometric coefficient (mass ratio of reacted carbon to spent oxygen) determined by relative yields of CO and CO_2 in oxidation of carbon:

$$\beta = \frac{12}{32}(1 - \xi), \quad (5)$$

where $\xi = 1$ for yield of only CO, $\xi = 0$ for yield of CO_2, and $\xi = 0.33$ at $CO/CO_2 = 1$; 12 and 32 are the molecular weights of carbon and oxygen.

The value of β in the presence of catalysts is, probably, substantially higher. The catalysts can affect both the reaction of carbon with atmospheric oxygen [reaction (6)] and the oxidation of CO formed in the process [reaction (7)]:

$$C + 1/2O_2 \rightarrow CO, \quad (6)$$

$$CO + 1/2O_2 \rightarrow CO_2. \quad (7)$$

Both the reactions are rather complex. Depending on the influence exerted by a catalyst on processes (6) and (7), the overall oxidation mechanism may also vary. In the absence of a promoter or at its low content, it may be assumed, by virtue of the limited area of contact between carbon and the catalyst, that CO oxidation (7) predominates. This leads to a higher value of factor β. In the presence of a catalyst, reaction (7) is, probably, localized at the surface of the complex oxide. In this case, the effective activation energy is comparable with the values of E for CO oxidation on complex oxide catalysts (64 to 132 kJ mol^{-1}) [17], which confirms the assumption made. Estimating the specific rate of oxidation at the catalyst surface

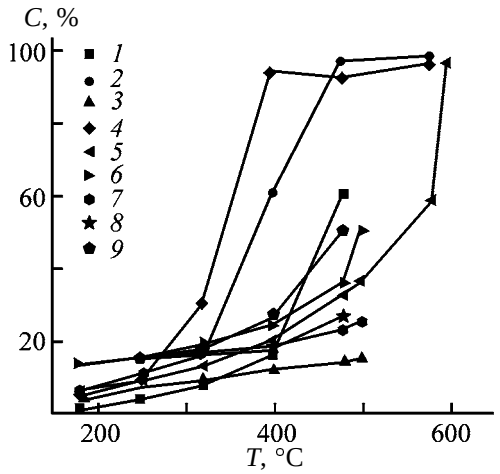

Fig. 2. Extent C of carbon removal at a 20-min exposure in oxidation with (*1, 2, 4*) atmospheric oxygen and (*3, 5–9*) nitrogen oxide vs. temperature T. Sample: (*1* [9], *3*) carbon without catalyst, (*6*) carbon with catalyst without promoter, (*7*) carbon with catalyst containing 1 wt % promoter, (*8*) the same with 5 wt % promoter, (*4, 9*) the same with 10 wt % promoter, and (*2, 5*) carbon with promoter.

of CO formed in the combustion of carbon gives values that are close to the rate of catalytic CO oxidation proper [17]. In oxidation of carbon in the presence of catalysts in the temperature interval 300–400°C, the amount of burning CO is within the range $(1.3–6.1) \times 10^{17}$ molecules/(m^2 s). According to [17], $2.12 \times 10^{17}–3.44 \times 10^{18}$ CO molecules/(m^2 s) burns at 240°C on complex oxide catalysts. This also confirms the hypothesis formulated here. The possible elementary event determining the rate of the overall process is interaction of adsorbed CO with dissociatively adsorbed oxygen at the surface of the complex oxide. Intermediate species of the carbonate type are formed in the course of the reaction, and decomposition of these species is facilitated by transfer of an electron from a cation of the *d* metal of the complex oxide to the oxygen molecule. Thus, a local reduction of the surface of the catalyst, which contains ions with variable oxidation state, occurs in the course of the reaction. Vanadium can change its oxidation state as follows: $V^{5+} \rightleftarrows V^{4+}$. In addition, an intrinsic nonstoichiometry may exist in the compound $Cs_xLa_{1-x} \cdot VO_{4 \pm y}$, and, therefore, oxygen incorporated into the structure of the vanadate may be partly involved in the reactions at elevated temperatures. It can be seen from the previously obtained gravimetric curves [21] that reversible changes in the mass of complex oxide samples occur at the working temperatures in the presence of a carbon residue. After local reduction, the catalyst surface is again oxidized with oxygen, and the next cycle of CO oxidation occurs. However, the described factor affecting the oxidation is hardly the only factor, because catalysts based on manganites (Table 2) and cuprates are somewhat inferior to vanadate catalysts in their activity in oxidation of carbon, although the bonding energy of oxygen, which commonly determines the catalytic activity in CO oxidation [22, 23], is substantially lower than that in the vanadium compounds.

The aforesaid suggests that there should exist a direct influence of the catalyst on the primary oxidation reaction (6) in the zone of contact with carbon, which may be particularly strongly manifested in the presence of a considerable amount of a promoter. This is confirmed by the fact that the catalytic activity of the compounds under study in the given reaction depends on the atomic mass of the dopant cation. At places of contact between the catalyst and carbon, the alkali metal ion can form surface salt complexes of the carbonate type [8]. In addition, raising the amount of promoter makes lower the melting point of the catalytic formulation, and it gains the capacity to envelop carbon particles, thereby increasing the extent of contact. In this case, it becomes understandable why the effective *E* for sample no. 5 (Table 2) strongly decreases and the process passes into the diffusion-controlled mode, in which the overall rate of carbon oxidation is limited by the supply of the oxidizing agent from air into the reaction zone or by removal of gaseous products. Here, as also for sample no. 1, a discrepancy is observed between the experimental values of K_0 and those calculated using the particle combustion equations. It was shown in special-purpose experiments (Fig. 2) that the promoter itself also affects the carbon oxidation. Technical-grade Cs_2SO_4 shows an acid reaction and contains $CsHSO_4$ impurities. It may be assumed that the oxidation reaction is initiated by interaction with this impurity contained in the promoter, e.g.:

$$4CsHSO_4 + C \rightarrow 2H_2O + CO_2 + 2Cs_2SO_4 + 2SO_2, \quad (8)$$

or

$$2CsHSO_4 + C \rightarrow Cs_2CO_3 + H_2O + 2SO_2, \quad (9)$$

$$2CsHSO_4 + C \rightarrow Cs_2SO_4 + H_2O + SO_2 + CO. \quad (10)$$

Reactions of this kind give rise to carbon burning, and they are complete after the acid part of the promoter is exhausted and no considerable amounts of SO_2 are evolved. A thermodynamic estimation of reactions of this type, with compounds of alkali metals involved, demonstrated that they can be performed at low temperatures. The probability of occurrence of reaction (8) is the highest, and that of reaction (10), the lowest. Some promoter samples contained admixtures of $CsNO_3$, which has a melting point of 417°C and can act as a carbon-oxidizing agent, especially in a melt. However, when a promoter containing no impurities of the above kind was used, the type of its influence on the carbon oxidation remained unchanged. It should be assumed in this case that the promoter has a catalytic effect, which is determined by the fact that Cs_2SO_4 is an alkali metal salt. As already mentioned, alkali metal compounds exhibit a catalytic activity in heterogeneous reactions with carbon [8]. It may be stated that cesium lanthanum vanadate and, if present in a considerable amount, Cs_2SO_4 are cocatalysts.

The carbon oxidation with nitrogen oxide NO is also accelerated in the presence of a catalyst. At relatively low temperatures (Figs. 1, 2), the rates of oxidation with nitrogen oxides and atmospheric oxygen are comparable or the rate of the former process is somewhat higher. On raising the temperature, the oxi-

Table 3. Exponent b in the kinetic equation $k\tau = a\alpha^b$ for carbon oxidation with nitrogen oxide

2	Carbon+ catalyst	0.37	0.36	0.45
	Carbon + catalyst +promoter, wt %:			
3	1	0.34	0.39	0.33
4	5	0.43	0.41	0.69
5	10	0.24	0.23	0.44

dation with nitrogen oxides is slower than that with O_2. The complete oxidation of carbon includes two main stages:

$$C + NO \rightarrow CO + 1/2N_2, \quad (11)$$

$$CO + NO \rightarrow CO_2 + 1/2N_2. \quad (12)$$

There is published evidence that the oxidizing capacity of nitrogen oxides NO [23] and N_2O [9] toward CO is lower than that of O_2. This is accounted for, in particular, by the strong difference between the sorption properties of nitrogen oxides and O_2 on the surface of complex oxide catalysts. A possible rate-determining stage of the overall process of carbon oxidation with nitrogen oxide is reaction (12), which is localized at the surface of the complex oxide. To verify this assumption, it is important to study the influence exerted by the promoter on the interaction of carbon with NO. Addition of Cs_2SO_4 plays a less positive role in reactions with NO, compared with the effect of the promoter Cs_2SO_4 on the carbon oxidation with oxygen (Figs. 1, 2). This, probably, occurs because of the change in the sorption capacity of the catalyst surface in the presence of Cs_2SO_4. To evaluate the nominal ignition temperatures, experiments were performed with catalyst–carbon mixtures kept at prescribed temperatures for 20 min (Table 1; Figs. 2, 3). As also in the case of carbon oxidation with O_2, introduction of 1 wt % Cs_2SO_4 markedly changes the properties of the catalyst.

In the temperature range studied, it was more difficult to estimate the effective activation energy of carbon oxidation with nitrogen oxide NO, compared to oxidation with atmospheric oxygen, because the activation energy is temperature-dependent. This points to a significant change in the reaction mechanism with increasing temperature. It is known for carbon that the mechanism of formation of a surface oxide changes in the range 300–550°C [18]. Processing of experimental data by Eqs. (1)–(3) failed to produce any satisfactory result. It was established using the Table Curve 2D v2.0 program by AISN Software Inc. that the experimental data are better described by power-law equations. This software made it possible to find the exponent b in an equation of the type $k\tau = a\alpha^b$ (Table 3). The most pronounced change in the reaction mechanism is observed for noncatalytic oxidation and for catalysts containing 5 and 10 wt % Cs_2SO_4. The trends exhibited by the exponent b for different samples are the opposite. For sample no. 1, E increases as the temperature is raised, and for sample nos. 4 and 5, contrariwise, decreases.

These facts may point to an oxidation mechanism in which direct chemical interaction is not the key factor. It is known [9] that carbon oxidation with nitrogen oxide NO can be hindered at relatively low temperatures by formation of N_2O, whose catalytic decomposition rate is low. In the temperature range studied, formation of N_2O is hardly possible. This is also indicated by effective values of E for samples with the weakest temperature dependence of the exponent b. These values are markedly lower than those for the carbon oxidation with O_2 and N_2O (146 kJ mol^{-1}) [9], being equal to 6–20 kJ mol^{-1}, which is characteristic of sorption or diffusion processes. The decrease in the activation energy for the reaction of carbon oxidation with nitrogen oxide NO, compared to that with atmospheric oxygen, can be attributed to differences between the heats of O_2 and NO sorption on the catalyst surface. Moreover, the oxidation of carbon with nitrogen oxide is more thermodynamically feasible than that with oxygen: the enthalpy of formation of nitrogen oxides is positive. The low effective activation energy of carbon oxidation with nitrogen oxide results in that the oxidation can occur in this case at lower temperatures, compared to the reaction in air (Fig. 2), with only stage (11) probable. At the same time, oxidation of CO with nitrogen oxide NO [reac-

tion (12)] occurs at the catalyst surface. The rate of reaction (12) is considerably lower than that of the CO oxidation with oxygen [reaction (7)], even in the presence of catalysts.

Thus, specific features of the course of practically important reactions were studied. The results obtained in testing of pilot neutralizers of exhaust gases produced by the engine of a ChMZ-3 diesel locomotive and engine of a ZIL-157K truck, operating on natural gas, demonstrated the high performance of combined complex oxide catalysts, including afterburners of carbon black [21, 25, 26]. Catalysts of the composition $Cs_{0.3}La_{0.7}VO_{4+y}$ (with a promoter) and $Ag_{0.25} \cdot La_{0.75}MnO_{3\pm y}$ were fabricated on foamed-nickel supports with an intermediate layer of aluminum oxide stabilized with lanthanum oxide. Catalytic elements of different compositions were assembled in a single unit. The exhaust smoke emission (content of carbon black particles) by the diesel locomotive decreased, on the average, by 50–60%, the decrease in the level of nitrogen oxides was also as large as 60%. As carbon black accumulated in the neutralizer of the ZIL-157K engine because of the burning of oil entrained by pistons, the degree of exhaust purification to remove nitrogen oxides increased by 30–40%. The total decrease in the concentration of CO was 60–80%. Consequently, the reactions studied can, indeed, be carried out under real conditions.

CONCLUSION

A study of some kinetic features of the reactions of carbon oxidation with nitrogen oxide NO and atmospheric oxygen demonstrated that lanthanum–cesium vanadate $Cs_xLa_{1-x}VO_{4\pm y}$ is an effective catalyst in the temperature range studied. Its activity in the reaction with oxygen increases in the presence of a promoting additive Cs_2SO_4, whose effect on the reaction with NO is considerably weaker. The carbon oxidation occurs in the working temperature range of the catalysts by different mechanisms, whose changeover is associated with, e.g., such a factor as the quantitative content of the promoter.

Abstract—Transformations of inert cyclohexane into dimethyldecalins under mild conditions in the presence of a simple catalytic system consisting of aluminum metal and halomethanes were studied.

The catalytic activation of C–H bonds in cyclic and acyclic alkanes with transition metal complexes or electrophilic agents such as Friedel–Crafts catalysts is a promising field of research. As a rule, the catalysts used for activating hydrocarbons are aprotic Lewis acids based on salts of transition and main-group metals in combination with active additives.

Superelectrophilic complexes $RCOX \cdot 2AlX_3$ and $CX_4 \cdot 2AlX_3$ (X = Cl, Br) are the most effective in transformations of saturated hydrocarbons under mild conditions [1–3]. It was shown recently [4] that the reaction system consisting of an organoaluminum compound (OAC) and halomethane in the presence of catalytic amounts of transition metal complexes exhibits similar activity toward cycloalkanes. The activity of this system was tentatively explained by generation of $AlCl_3$ in the reaction of OAC with halomethane, catalyzed with a transition metal, which is followed by formation of a superelectrophilic complex with the starting halomethane, similar to $CX_4 \cdot 2AlX_3$. If this is true, then it will be possible to generate a similar complex *in situ* using a simpler and more available agent, aluminum metal [5]:

$$2Al + 6CCl_4 \rightarrow 2AlCl_3 + 3C_2Cl_6. \quad (1)$$

This work is the first study of chemical transformations of cyclohexane under the action of aluminum halides generated *in situ* by the reaction of halomethanes (CCl_4, $CHCl_3$, $CHBr_3$, CH_2Cl_2, CH_2Br_2) with aluminum metal preliminarily activated with iodine or AlR_3.

The choice of cyclohexane as investigation object was governed by the large body of data available on the effect of aluminum halides in combination with various promoters on cyclohexane.

Pure anhydrous $AlCl_3$ is virtually inert toward cyclohexane [6]. However, in the presence of water [6], HCl, and acetyl chloride [7] $AlCl_3$ effects isomerization of cyclohexane into methylcyclopentane. The reaction of cyclohexane with cyclohexyl bromide [8] in the presence of $AlCl_3$ yields a mixture of dimethyldecalins. A similar mixture of dimethyldecalins is formed by dimerization of methylcyclopentane, effect by the reaction system $AlCl_3$ + *t*-BuCl in the HCl [9]. Dimethyldecalins were detected in the reaction of chlorocamphor with $AlBr_3$ in cyclohexane [9]. Heating of cyclohexane with $AlCl_3$ and HCl in an autoclave for 1 day to 140–150°C results not only in isomerization into methylcyclopentane but also in formation of dicyclohexyl and di(methylcyclopentyl) [10]. At 180°C, methylcyclopentane, 1,3-dimethylcyclohexane, dicyclohexyl, and di(methylcyclopentyl) $C_{12}H_{22}$ were detected together with a small amount of isobutane [11]. Formation of dimethyldecalins was also reported in [12]. Transformation of cyclohexane into alkyladamantanes was noted in [13].

Under the action of superelectrophilic systems $RCOX \cdot 2AlBr_3$ [2] and $CH_nX_{4-n} \cdot AlX_3$ (X = Cl, Br) [3], cyclohexane transforms into dimethyldecalins at room temperature or 40°C with 22 and 10% yield based on cyclohexane, respectively. With excess cyclohexane, dimethyldecalins are formed selectively in low yields.

Aluminum metal was activated by a common procedure by heating under argon in the presence of several iodine crystals until iodine sublimed virtually completely and was removed from the reaction vessel. In some cases, to accelerate the start of the reaction of aluminum with halomethane, a small amount (~0.1 ml) of *i*-Bu_3Al and Et_3Al was added to the reaction mixture.

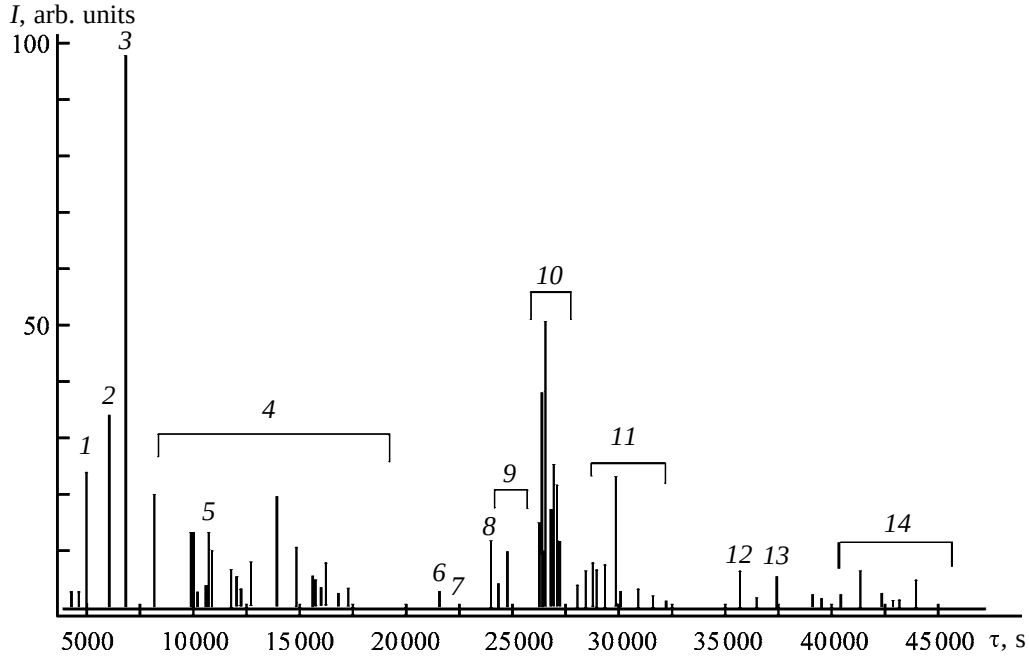
* Some other products (see text for details) were detected in insignificant amounts.
** Yield based on converted cyclohexane.

Transformations of the hydrocarbon start simultaneously with the onset of the reaction of aluminum with halomethane. The exothermic reaction is accompanied by the release of HCl and tarring. The major chlorinated reaction products in the case of CCl_4 are $CHCl_3$ and CH_2Cl_2. In contrast to the reaction of Al with CCl_4 without a solvent, in which the yield of hexachloroethane is virtually quantitative, in the presence of the hydrocarbon the yield of C_2Cl_6 is low. Among other chlorinated prodcts, trace amounts of tetrachloroethylene and tetrachloroethane were detected.

According to GLC and GC/MS, the major products of cyclohexane transformation are isomeric dimethyldecalins (see table). The figure shows as example the



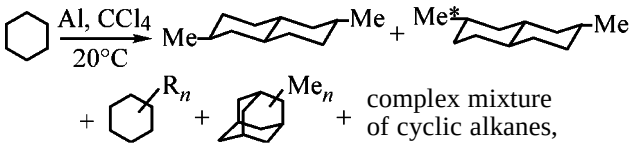
Chromatogram of a mixture of products obtained in run no. 4 (see table) and their identification. (*I*) Intensity and (τ) retention time. (*1*) Methylene chloride, (*2*) methylcyclopentane, (*3*) cyclohexane, (*4*) alkylcyclohexanes, (*5*) perchloroethylene, (*6*) decalin, (*7*) hexachloroethane, (*8*) methyldecalin, (*9*) methyl-substituted adamantanes, (*10*) isomeric dimethyldecalins, (*11*) trimethyldecalins, (*12*, *13*) tricyclanes with $[M]^+$ 192, and (*14*) tricyclanes with $[M]^+$ 248.

chromatogram of a mixture of products obtained in run no. 4 (see table). The mass spectrum of each isomer contains a fairly strong molecular peak ($[M]^+$ 166) and the same set of fragment peaks characteristic of dimethyldecalins (*m*/*z* 151, 137, 124, 123, 110, 109, 96, 82, etc.), corresponding to elimination of alkyl radicals [14] from CH_3 to C_6H_{12} from the moleclar ion. The isomeric mixture mainly consists of the most thermodynamically stable [15] *E*3,*E*8-dimethyl-*trans*-bicyclo[4.4.0]decane and *E*3,*E*9-dimethyl-*trans*-bicyclo[4.4.0]decane. The structures of these isomers were determined from the ^{13}C NMR spectra by comparison with the reference data [16] after isolation of the group of compounds corresponding to *M* 166 from the product mixture by preparative chromatography. As seen from the chromatogram (see figure), other isomers of dimethyldecalin are also present.

Among other products, we detected alkyl-substituted cyclohexanes whose total yields are also given in the table. For example, in run no. 4 we detected methylcyclohexane ($[M]^+$ 98, 2.5%), dimethyl- ($[M]^+$ 112, 4%), trimethyl- ($[M]^+$ 126, 2.4%), tetramethyl- ($[M]^+$ 140, 5.8%), ethyl- ($[M]^+$ 112, traces), methylethyl- ($[M]^+$ 126, 0.15%), and dimethylethylcyclohexanes ($[M]^+$ 140, 1.5%). Also, in the same experiment we detected methylcyclopentane ($[M]^+$ 84, 5%), decalin ($[M]^+$ 138, 0.3%), methyldecalin ($[M]^+$ 152, 1.3%), and trimethyldecalin ($[M]^+$ 180, 5.5%). These compounds were identified by GC/MS. The mass spectra obtained by us coincided with the reference data (NBS library) to 90–96%.

In the mixture of products, we also detected small amounts of methyl-substituted adamantanes: dimethyladamantane ($[M]^+$ 164, 0.5%), trimethyladamantane ($[M]^+$ 178, 1.4%), and tetramethyladamantane ($[M]^+$ 192, 1,1%). The assignment was based on comparison with published data [17].

Peaks *12* and *13* in the chromatogram (see figure) correspond to hydrocarbons with $[M]^+$ 192 and 206, respectively. Group of peaks *14* mainly belongs to hydrocarbons with $[M]^+$ 248. The mass spectra of compounds giving the strongest chromatographic peaks in this group are characterized by the base peak at *m*/*z* 233 [$M^+ - CH_3$] and medium-intensity peaks at *m*/*z* 177, 163, 123, and 109. Some of them contain ions with *m*/*z* 219 [$M^+ - C_2H_5$]. The products of oxidative dimerization of cyclohexane formed under the action of the superelectrophilic complex [3] $CBr_4 \cdot 2AlBr_3$ contain hydrocarbons with $[M]^+$ 248 giving similar mass spectra. Apparently, in our case these compounds can also be identified as alkylated tricyclanes $C_{18}H_{32}$ with methyl and, possibly, ethyl substituents. In addition, compounds with molecular weights of 206, 220, 234, and 262 were identified in trace amounts:



where R = Me, Et; *n* = 1, 2, 3, 4.

The relative yields of all the heavy products are listed in the table.

As in [2], in experiments with excess cyclohexane alkylcyclohexanes and tricyclanes are not formed, and the reaction products contain dimethyldecalins and methylcyclopentane. As the content of halomethane and aluminum in the starting mixture is increased, the content of methylcyclopentane in the reaction products decreases simultaneously with an increase in the content of dimethyldecalin, alkylcyclohexanes, and tricyclanes. Analysis of the reaction products in various steps showed a similar dependence of the product concentrations on the reaction time. The content of methylcyclopentane grows in the initial steps and then decreases. This fact indicates that cyclohexane first isomerizes into methylcyclopentane, transforming then into dimethyldecalin and other products. This result is consistent with the available data [6, 7] on equilibrium isomerization of cyclohexane into methylcyclopentane under the action of $AlCl_3$ with additions of various promoters and on dimerization of methylcyclopentane under the action of $AlCl_3$ and *t*-BuCl [9].

Cyclohexane is successfully involved in transformations also on replacement of CCl_4 by other halomethanes. Data obtained with chloroform, bromoform, methylene bromide, methylene iodide, and butyl chloride are given in the table.

It should be noted that the order of adding reagents [successively (see table, run no. 4), with CCl_4 added to activated Al first and cyclohexane added after the reaction completion, or simultaneously (run no. 3)] have no noticeable effect on the yield of the major products.

As it is difficult to isolate $AlCl_3$ from the reaction mixture and determine its content, we determined the residual content of active aluminum in the reaction mixture after the reaction completion. We found that, after activation of Al with iodine, the amount of Al^{3+} did not exceed 0.5% of the initial amount; after treatment with CCl_4, it was ~42%, and after the reaction

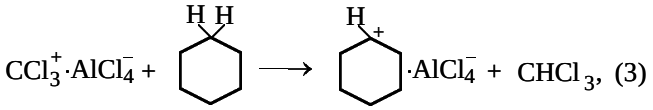
with cyclohexane, ~64%. Carbon tetrachloride was taken in 3 : 1 ratio relative to Al. A noticeable increase in the Al^{3+} content in the presence of cyclohexane can be accounted for as follows. In the reaction of Al with CCl_4 in the absence of the hydrocarbon, the main reaction products are C_2Cl_6 and $AlCl_3$ in the complex with CCl_4, and also tars. On adding cyclohexane, the complex $AlCl_4^- \cdot CCl_3^+$ reacts with the hydrocarbon to form $CHCl_3$ and cyclohexyl carbocation. Chloroform subsequently reacts with a new portion of Al to give $AlCl_3$. $AlCl_3$ effects transformations of cyclohexane. Thus, $AlCl_3$ is formed not only in the initial step of the reaction, but also directly in the course of transformations of the hydrocarbon.

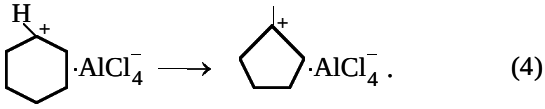
It should be noted that oxidative dimerization of cyclohexane to dimethyldecalin under the action of the system Al–CCl_4 occurs selectively when cyclohexane is in excess.

Our results and published data suggest the following reaction mechanism. In the first step, aluminum metal reacts with CCl_4 to give $AlCl_3$ which forms the complex $AlCl_4^- \cdot CCl_3^+$ with the starting halomethane:

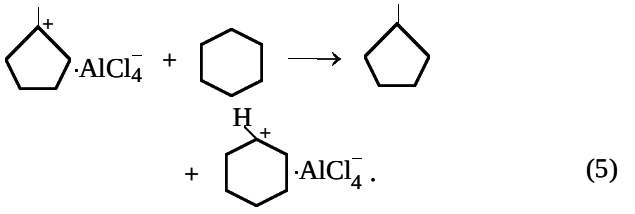
$$AlCl_3 + CCl_4 \rightarrow AlCl_4^- \cdot CCl_3^+. \quad (2)$$

Then formation of dimethyldecalins follows the known scheme [9] according to which CCl_3^+ abstracts the hydride ion from a cyclohexane molecule to give cyclohexyl cation and chloroform. Cyclohexyl carbenium ion isomerizes into more stable methylcyclopentyl carbenium ion:

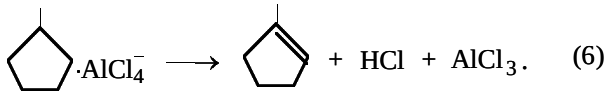




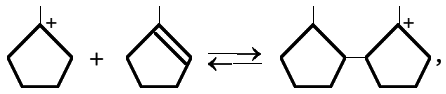
The latter transfers the charge to the cyclohexane molecule to give methylcyclopentane:

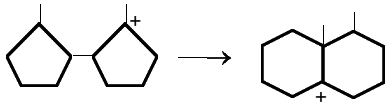


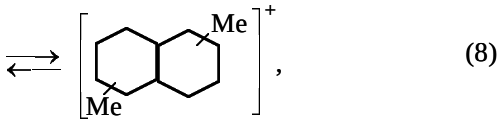
Alternatively, proton abstraction yields methylcyclopentene, $AlCl_3$, and HCl (HCl evolution is indeed observed in the course of the reaction):

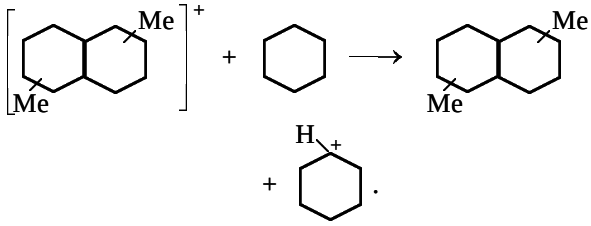


Addition of the olefin to methylcyclopentyl carbenium ion yields dicycloalkylcarbenium ion, whose rearrangement yields thermodynamically stable dimethyldecalinium ion. The subsequent charge transfer from the cyclohexane molecule to the dimethyldecalinium ion results in formation of dimethyldecalin and generation of cyclohexyl cation:









According to [3], the activity of the complex $CCl_4 \cdot 2AlBr_3$ toward cyclohexane is noticeably higher than that of the complex $CCl_4 \cdot 2AlCl_3$. In our case, the complex based on *in situ* generated $AlCl_3$ shows high activity, comparable with that of the superelectrophilic complex $CCl_4 \cdot 2AlBr_3$ which is today one of the most effective initiators of alkane activation under mild conditions, along with the system $RCOX \cdot 2AlBr_3$.

EXPERIMENTAL

CCl_4, $CHCl_3$, $CHBr_3$, CH_2Br_2, CH_2I_2, *t*-BuBr, and cyclohexane (chemically pure grade) were dried and distilled from P_2O_5. Aluminum (chemically pure grade) was used as powder. For comparison, we tested preliminarily ground granulated aluminum (analytically pure grade) and aluminum wire. The results were identical. The ^{13}C NMR spectra were recorded on a JEOL-FX90Q spectrometer. The products were analyzed on a Chrom-5 chromatograph with a capillary column (25 m, SE-30). The GC/MS analysis was performed on a VG TRIO 1000 device (the United King-

dom). We used a JZW Scientific DB-5 capillary column (60 m × 0.25 mm × 0.2 μm) (the Unted States) in the linear heating mode and the NBS library of mass spectra (the United States) containing 75000 mass spectra.

To perform the reaction of cyclohexane with the system Al–CCl_4, a 50-ml glass reactor was charged under Ar with 0.348 g (13 g-at) of Al and several crystals of iodine. The mixture was heated on an alcohol burner until the iodine completely sublimed and was removed from the reactor. The reactor was placed on a magnetic stirrer, and 7 ml (65 mmol) of cyclohexane and 2 ml (19 mmol) of CCl_4 were added. Stirring was continued at room temperature for 2 h. The reaction was accompanied by HCl evolution. After reaction completion, two layers formed: a transparent upper layer and a dark brown viscous lower layer containing aluminum chloride and residual aluminum metal. The upper layer was separated and filtered through Al_2O_3. Determination of the bromine number showed the absence of unsaturated bonds in the products. A GLC analysis of the resulting transparent liquid revealed the presence of dimethyldecalins (39%) nd unchanged cyclohexane (19.6%). The products giving a group of peaks with $[M]^+$ 166 (GC/MS) were isolated by preparative chromatography. Their ^{13}C NMR analysis showed that the samples contained 45% *E*3,*E*8-dimethyl-*trans*-bicyclo-[4.4.0]decane, 41% *E*3,*E*9-dimethyl-*trans*-bicyclo-[4.4.0]decane, four unidentified isomers of dimethyldecalin with $[M]^+$ 166 (2–3% each), and five other isomers with $[M]^+$ 166 (0.2–0.3% each).

Trimethyldecalin. Experiment: *rt* 29.25; 180 $[M]^+$ (74), 165 (98), 138 (3), 137 (4), 123 (15), 109 (94), 95 (100), 83 (34), 82 (18), 81 (67), 69 (30), 67 (37), 55 (55); published data [18] (3,4,8-trimethyldecalin): 180 $[M]^+$ (74), 165 (97), 138 (5), 137 (6), 123 (21), 109 (94), 95 (100), 83 (40), 82 (21), 81 (70), 69 (30), 67 (39), 55 (68).

Dimethyladamantane. Experiment: *rt* 24.30; 164 $[M]^+$ (10), 150 (13), 149 (100), 107 (18), 95 (6), 93 (31), 91 (9), 81 (7), 79 (9), 77 (7), 67 (6), 55 (6); published data [17] (1,4-dimethyladamantane): 164 $[M]^+$ (14), 150 (13), 149 (100), 107 (18), 95 (11), 93 (35), 91 (11), 81 (17), 79 (16), 77 (11), 67 (13), 55 (14).

Trimethyladamantane. Experiment: *rt* 24.67; 178

$[M]^+$ (8), 164 (13), 163 (100), 150 (1), 149 (2), 135 (3), 121 (8), 107 (48), 93 (10), 91 (9), 79 (7), 77 (6), 55 (8); published data [17] (1,3,5-trimethyladamantane): 178 $[M]^+$ (8), 164 (12), 163 (100), 150 (11), 121 (16), 107 (62), 93 (17), 91 (12), 81 (8), 79 (10), 77 (8), 67 (6), 55 (8).

Tetramethyladamantane. Experiment: *rt* 24.80; 192 $[M]^+$ (5), 178 (14), 177 (100), 163 (2), 135 (3), 121 (42), 107 (13), 95 (6), 93 (5), 91 (7), 81 (3), 79 (5), 77 (5), 67 (4), 55 (9); published data [17] (1,3,5,6-tetramethyladamantane): 192 $[M]^+$ (7), 178 (16), 177 (100), 163 (4), 135 (5), 121 (37), 107 (25), 95 (9), 93 (8), 91 (10), 81 (6), 79 (7), 77 (6), 67 (6), 55 (13).

Tricyclane (see figure, peak *12*). Experiment: *rt* 35.59; 192 $[M]^+$ (100), 177 (62), 151 (33), 149 (22), 135 (27), 121 (22), 109 (20), 107 (16), 95 (85), 93 (25), 81 (49), 79 (29), 77 (13), 67 (35), 55 (24).

Tricyclane (see figure, peak *13*). Experiment: *rt* 37.32; 206 $[M]^+$ (100), 191 (70), 165 (15), 149 (18), 135 (44), 121 (19), 109 (61), 107 (17), 95 (72), 91 (16), 81 (43), 79 (26), 67 (34), 55 (33).

To determine active aluminum, a three-necked flask was charged under Ar with 100 mg of Al. Several crystals of iodine were added, and the flask was heated until the iodine completely sublimed and was removed from the vessel. To the resulting activated Al, 50 ml of distilled water was added, and the mixture was analyzed according to [19].

Two three-necked flasks were charged under Ar with 100 mg of Al each. After actvation with iodine, the reaction with 2 ml of CCl_4 was performed in both flasks, and then the reaction with 5 ml of cyclohexane was performed in one of them. After the reaction completion, the resulting mixtures were hydrolyzed with 50 ml of water. The subsequent analysis was performed similarly.

CONCLUSION

The readily available reaction system consisting of activated aluminum metal and halomethane efficiently induces chemical transformations of cyclohexane at 20–60°C and atmospheric pressure. The major product is an equilibrium mixture of dimethyldecalin isomers; methyl-substituted cyclohexanes and tricyclic compounds are formed in smaller amounts.

CATALYSIS

Influence of Activation (Reduction) Conditions on the Catalytic Activity of Copper–Zinc Catalysts of NTK-10 Series

P. D. Androsov, I. A. Mamaeva, and E. Z. Golosman

Novomoskovsk Institute of Nitrogen Industries, Open Joint-Stock Company, Novomoskovsk, Tula oblast, Russia

Received December 26, 2003

Abstract—X-ray phase analysis and the temperature-programmed reduction method were applied to study the activation (reduction) of copper–zinc catalysts of the NTK-10 series. The catalytic activity of catalysts reduced under various conditions in steam conversion of carbon monoxide was determined.

Copper–zinc catalysts are widely used in various processes of chemical, petrochemical, and metallurgical industries. To these belong, in particular, the following: steam conversion of carbon monoxide; synthesis of methanol, butyl alcohols, and aniline; and purification of waste gases to remove organic compounds. In recent years, copper–zinc–alumina–calcium catalysts, which are distinguished by high service parameters, such as activity and mechanical strength, have exhibited good performance. The main distinctive feature of catalysts of the NTK-10 series from most of analogs is that they are manufactured in an uncalcined form [1, 2].

The active surface of both calcined and uncalcined catalysts is formed in the course of activation, i.e., heating in a reducing atmosphere. Activation of calcined copper–zinc catalysts (NTK-4) is sufficiently well understood, and it is noted that lowering the activation temperature affects positively the formation of the active surface of the catalysts and their catalytic activity [3–5].

The activation of NTK-10 catalysts is accompanied by two parallel processes: decomposition of copper-containing compounds contained in the catalyst and reduction of copper. The decomposition of copper-containing compounds is accompanied by heat absorption, whereas the reduction of copper is characterized by an exothermic effect; thus, the overall heat effect of activation is virtually zero. This makes it possible to prevent undesirable overheating in the course of reduction of the catalyst and, thereby, to use a gas with a higher content of a reducing agent, which markedly shortens the activation time. According to the recommendations developed for charging and activation of catalysts of the NTK-10 series, a catalyst is to be heated to 210–230°C and then a gas with the content of the reducing agent increasing from 0 to 20–30% is to be supplied [2]. However, the equipment used in some processes, such as synthesis of aniline and conversion of carbon monoxide on installation for obtaining hydrogen in metallurgical and electrochemical industries does not allow activation at temperatures higher than 200°C, which makes markedly narrower the field of application of NTK-10 catalysts. In this context, it was necessary to study the activation of NTK-10 catalysts in order to assess the possibility of their activation at lowered temperatures and reveal the influence exerted by various parameters of the activation process on the catalytic activity of these catalysts.

For this purpose, the following samples of NTK-10 catalysts were studied: NTK-10-2FM catalyst for low-temperature conversion of CO; NTK-10-7F catalyst, containing manganese oxide, for treatment of waste gases to remove organic compounds; and NTK-10-2FA catalyst for synthesis of aniline.

For comparison was studied NTK-4 catalyst, which is also used in synthesis of aniline [6].

X-ray studies were performed on a DRON-2 diffractometer with monochromatized copper radiation (graphite monochromator in the path of the diffracted beam). The data obtained were used to identify the phase composition of catalysts and determine the dispersity (size of coherent domains) of copper.

The catalyst activation was studied by the method of temperature-programmed reduction. A sample was heated in a flow of H_2, with the temperature raised

* $CaO \cdot 2Al_2O_3$.

linearly at the prescribed rate of 2.5 deg min^{-1}. The amount of products released in activation was determined with a katharometer.

The activities of the catalysts were determined in the steam conversion of CO. The test were performed on a flow-through laboratory installation under the following conditions: gas composition 10.9% CO, 89.1% He; steam/gas ratio 0.2–0.25; space velocity 15000 h^{-1}. The activity of a catalyst was judged from the reaction rate constant calculated using the first-order equation with respect to carbon monoxide:

$$k_v = \ln[1/(1 - x)]W(1 + S/G),$$

where k_v is the reaction rate constant (s^{-1}); x, average CO conversion; W, space velocity of dry gas (s^{-1}); and S/G, steam/gas ratio.

Prior to a test, a sample was activated.

The chemical and phase compositions of the samples studied are listed in Table 1. The catalysts of the NTK-10 series contain copper in the form of various compounds that are precursors of the active component of the catalyst. The main phases are the following: rosasite (R), which is a solid solution of zinc ions in the structure of $(CuOH)_2CO_3$; aurichalcite (A), a solid solution of copper(II) ions in the structure of $(ZnOH)_2CO_3$; and hydroxoaluminate (HA) of copper and zinc.

The catalyst activation leads to thermal decomposition and reduction of these compounds to form a solid solution of copper in an anion-modified zinc oxide; and it is this solid solution that ensures the high activity of a catalyst [2].

The profiles of temperature-programmed reduction of NTK-10-series and NTK-4 catalysts are shown in Fig. 1.

The activation of NTK-10 catalysts is accompanied by two processes: decomposition of copper-containing compounds and reduction of copper. The first stage in the range 170–175°C refers to the process of decomposition–reduction of a copper-containing compound with a rosasite structure, reduction of copper oxide, and removal of interlayer water from hydroxoaluminate of copper and zinc. At 195–205°C, copper from a compound with a structure of aurichalcite and from hydroxoaluminate of copper and zinc is reduced [2, 7] (Fig. 1).

The sample activation is accompanied by release of considerable amounts of H_2O and CO_2. The temperatures at which their release has the maximum intensity coincide with the reduction temperatures of copper-containing compounds contained in catalysts of the NTK-10 series (Fig. 2). The total weight loss in activation is approximately 25%, of which 60–70% is H_2O and 30–40% CO_2.

In contrast to uncalcined NTK-10 catalysts, the activation of a calcined NTK-4 sample occurs in a single stage, and the activation profile of this sample contains the only peak at 160–170°C. The activation consists in this case in reduction of copper from its oxide [3–5].

NTK-10-7F	Cu, ZnO, $CaCO_3$, CA_2, A, HA, gibbsite, aragonite, R, $MnCO_3$	Cu, ZnO, $CaCO_3$, CA_2, A, HA, gibbsite, aragonite, $MnCO_3$	Cu, ZnO, $CaCO_3$, CA_2 A, HA, gibbsite, aragonite, $MnCO_3$	Cu, ZnO, $CaCO_3$, CA_2, $MnCO_3$, aragonite, boehmite, CA
NTK-4	Cu, $ZnCr_2O_4$, boehmite, ZnO, Cu_2O	Cu, $ZnCr_2O_4$, boehmite, ZnO, Cu_2O	Cu, $ZnCr_2O_4$, boehmite, ZnO, Cu_2O	Cu, $ZnCr_2O_4$, boehmite, ZnO, Cu_2O

In the first set of experiments, the catalysts were activated in a flow of 100% H_2 at temperatures of 160, 170, 180, and 250°C for 1.5 h.

The completeness of reduction of the samples was judged from the decrease in the intensity of the lines in the X-ray diffraction patterns, associated with the initial copper-containing compounds. The results of an X-ray phase analysis of samples activated under these conditions are listed in Table 2. Figure 3 shows how the intensity of the aurichalcite lines in the X-ray diffraction patterns depends on the temperature T_r at which the sample was reduced.

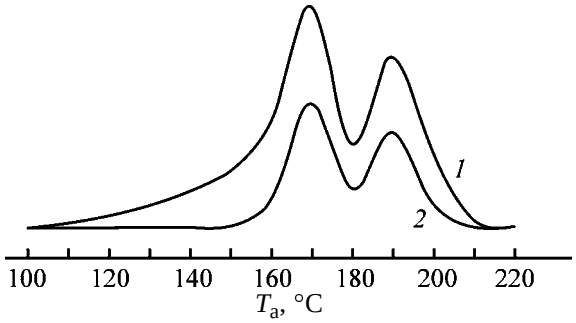

Fig. 2. Intensity of release of (*1*) water and (*2*) CO_2 in activation of catalysts of NTK-10 series.

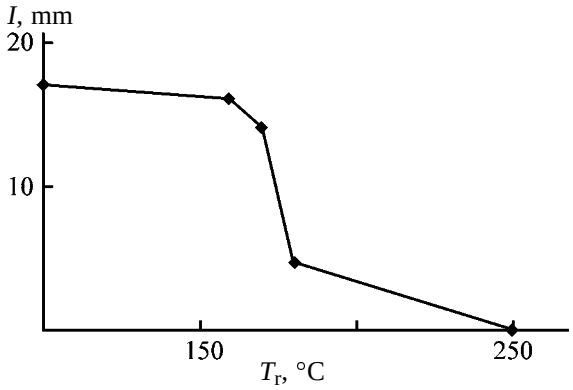

Fig. 3. Intensity *I* of the line associated with aurichalcite in X-ray diffraction patterns vs. the reduction temperature T_r.

Table 2 and Fig. 3 show that the reduction of copper-containing compounds contained in catalysts of the NTK-10 series at 160°C is incomplete. The phase composition of the sample contains insignificant amounts of rosasite. The intensity of the aurichalcite lines remained virtually unchanged, compared to the initial sample. Activation with hydrogen at 170°C leads to complete reduction of copper contained in the structure of rosasite, whereas aurichalcite is reduced only partly (the intensity of lines in the X-ray diffraction patterns decreases only slightly). As the activation temperature is raised to 180°C, there occurs intensive reduction of copper from the aurichalcite structure, which is indicated by a pronounced decrease in the intensity of its lines in the X-ray diffraction patterns. And finally, reduction at 250°C leads to complete reduction of copper from its compounds.

Figures 4a and 4b show how the dispersity of reduced copper (judged from the results of an X-ray phase analysis) and intensities of copper lines vary with the activation temperature.

The intensity of copper lines increases dramatically as the activation temperature increases from 160 to 180°C, which points to intensive reduction of copper in this temperature range. When the temperature is elevated further from 180 to 250°C, the intensity of copper lines increases only slightly, i.e., additional

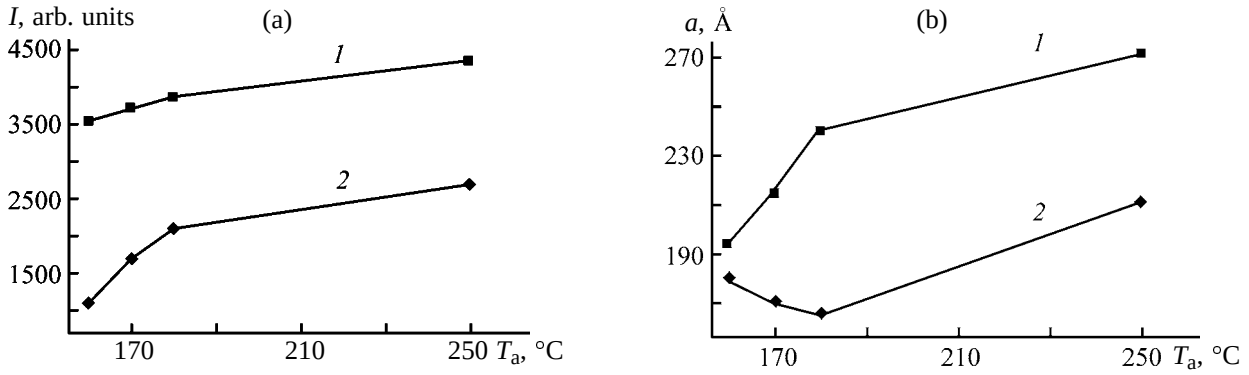

Fig. 4. (a) Intensity *I* of copper lines in X-ray diffraction patterns and (b) sizes a of crystallites of reduced copper vs. the activation temperature T_a. (*1*) NTK-4 and (*2*) NTK-10.

reduction of copper compounds and crystallization of X-ray amorphous copper occurs at these temperatures.

The dependence of the dispersity of reduced copper on the activation temperature shows an extremum. Raising the reduction temperature from 160 to 180°C leads to a gradual decrease in the size of copper crystallites from 180 to 165 Å, because the most finely dispersed part of copper is reduced just from the structure of aurichalcite, which is mostly reduced just in this temperature range, As the activation temperature is elevated to 250°C, the size of copper crystallites increases to 210°C, which is due to agglomeration of copper.

The activities of the samples were determined at three temperatures: 160, 180, and 200°C. The results obtained (Table 3) are in good agreement with the data furnished by X-ray phase analysis.

The activity of samples reduced at 160°C is low, because considerable part of copper remains unreduced. Raising the activation temperature to 170°C leads to a certain increase in the activity of the samples; however, as the copper-containing compounds are reduced to an insignificant extent, the reaction rate constant grows only slightly. When the reduction temperature is elevated to 180°C, copper is reduced virtually completely, which leads to a high activity of the samples. Further increase in the activation temperature to 250°C makes the activity lower, which can be attributed to agglomeration of copper in the course of reduction.

With NTK-4 catalyst, the influence of the activation temperature on formation of the active surface and on the activity is somewhat different.

It can be seen that complete reduction of the copper component of this catalysts occurs even at 160°C. Raising the activation temperature (Figs. 4a, 4b) leads to a minor increase in the intensity of copper lines in the X-ray diffraction patterns, which is due to crystallization of X-ray amorphous copper. The size of crystallites of metallic copper increases in this case from 195 to 270 Å because of copper agglomeration. Accordingly, the activity of the samples decreases as the activation temperature is elevated.

A clearly observable feature is that the thermal stability of NTK-4 catalyst is considerably lower than that of NTK-10 catalysts: the size of copper crystallites in NTK-4 increases by more than 40% as the activation temperature is elevated to 250°C, with the resulting substantial loss of activity.

Thus, the study performed shows that an activation temperature of 180°C not only ensures sufficient reduction of NTK-10 catalysts, but also leads to an

Table 3. Activities of catalysts reduced at different temperatures

increase in their initial activity because of the formation of a more finely dispersed copper.

In the next stage of the study, it was necessary to evaluate the influence exerted by the concentration of H_2 in the reducing gas on the activity of NTK-10 catalysts, obtained at an activation temperature of 180°C.

Table 4. Activities of catalysts reduced at different contents of H_2 in the reducing gas

c_{H_2}, vol %	T_r, °C	Activity, s^{-1}		
		NTK-10-2FM	NTK-10-7F	NTK-10-2FA
20	160	1.2	1.5	1.2
	180	4.3	4.7	4.2
	200	6.9	7.1	6.9
30	160	4.2	4.3	4.2
	180	7.1	7.2	7.2
	200	11.8	11.9	11.8
50	160	4.0	4.1	4.0
	180	7.0	7.0	7.0
	200	11.5	11.4	11.6
75	160	3.9	3.9	3.7
	180	6.9	6.8	6.8
	200	11.3	11.0	11.4

Figures 5a and 5b show how the intensities of lines of reduced copper and the dispersity of copper depend on the content of H_2.

It can be seen that the intensity of copper lines in the X-ray diffraction patterns grows as the content of H_2 in the gas becomes higher. The steepest increase is observed in the range from 20 to 30 vol %. This is due to intensive reduction of copper from the aurichalcite structure, which is also indicated by the decrease in the size of copper crystallites in this range of H_2 contents. As the content of H_2 in the gas increases further, the intensity of copper lines increases only slightly, i.e., the hydrogen content of 30 vol % ensures virtually complete reduction of copper.

The copper particle size grows from 135 to 165 Å as the content of H_2 in the reducing gas becomes higher than 30 vol %.

The highest activity was observed (Table 4) for samples reduced with a gas containing 30 vol % hydrogen. Thus, the hydrogen content of 20–25 vol % is insufficient for complete reduction of copper compounds. Further increase in the content of H_2 in the gas leads to formation of coarser copper crystallites, which adversely affects the activity of the catalysts.

Thus, lowering the activation temperature to 180°C at a sufficient content of the reducing agent in the gas positively affects the formation of the active surface in NTK-120 catalysts, which leads to an increase in their activity, compared with the initial value. At the same time, the activation conditions should ensure complete reduction of copper from its compounds. It is critically important for NTK-10 catalysts that aurichalcite, which contains the most active copper, should be completely reduced. Therefore, lowering the reduction temperature to an even greater extent and diminishing the content of hydrogen are undesirable.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Neutralization and Clarification of Strongly Alkaline Wastewater from Silicate Production, Based on Microflotation with Chemical Agents

N. B. Mel'nikova, V. G. Sokolov, and L. I. Molvina

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received December 2, 2003; in final form, April 2004

Abstract—A study was made of neutralization and clarification of wastewater from silicate production, which exhibits buffer properties. The promise of a two-stage procedure involving the primary thickening of the dispersed phase, followed by separation of the dispersed phase and water by flotation, was elucidated. The choice of the polymeric reagent and its concentration was substantiated.

Wastewater from production of silicate building materials, including cement, brick, etc., cause significant damage to soils via cementation, alkalization, and pollution with gypsum. Huge areas allocated for burial of wastes from silicate production virtually lose their fertility. This is especially pressing for cities consuming large amounts of building materials. Nowadays, silicate-producing enterprises have settlers for separation of coarse fractions, whereupon wastewater is neutralized with sulfuric acid and then removed from the production process. Such procedures pose environmental problems and are cost-ineffective because of large amounts of sulfuric acid and water they require. This makes urgent water reuse at silicate-producing enterprises.

In this work we studied neutralization of strongly alkaline wastewater from silicate production and developed a procedure for reuse of the purified water.

The subjects of our study were cement suspensions comprising calcium silicates, aluminosilicates, ferrites, and aluminoferrites, as well as various additions [1]. Wastewater from cement production contains not only cement components but also their hydration and hydrolysis products formed by the reactions [1, 2]

$$3CaO \cdot SiO_2 + mH_2O \rightarrow xCaO \cdot SiO_2 \cdot nH_2O + (3 - x)Ca(OH)_2, \quad (1)$$

$$2CaO \cdot SiO_2 + nH_2O \rightarrow 2CaO \cdot SiO_2 \cdot nH_2O, \quad (2)$$

$$3CaO \cdot Al_2O_3 + 6H_2O \rightarrow 3CaO \cdot Al_2O_3 \cdot 6H_2O, \quad (3)$$

$$4CaO \cdot Al_2O_3 \cdot Fe_2O_3 + mH_2O \rightarrow 3CaO \cdot Al_2O_3 \cdot 6H_2O + CaO \cdot Fe_2O_3 \cdot nH_2O, \quad (4)$$

$$3CaO \cdot Al_2O_3 \cdot 6H_2O + 3(CaSO_4 \cdot 2H_2O) + 19H_2O \rightarrow 3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 31H_2O. \quad (5)$$

Analysis of the products of hydrolysis and hydration of the initial ingredients of cement shows that the dispersion medium for the suspensions is, essentially, a solution of calcium hydroxide in equilibrium with the dispersion of solid $Ca(OH)_2$ particles. This strongly complicates sedimentation of the suspension in settlers, as well as neutralization of the wastewater. In this connection, we paid much attention to the choice of flocculants able of efficiently binding the suspended particles at pH above 11, as well as to isolation of the solid dispersed phase by flotation to enable extraction of colloidal impurities from the wastewaters within a not very long time [3].

EXPERIMENTAL

We used M-400 D 20 [GOST (State Standard) 10178–85] Portland cement, pure grade sulfuric acid H_2SO_4 (GOST 4204–77), and pure grade orthophosphoric acid H_3PO_4 (GOST 6552-80).

Polyelectrolytes (flocculants) were prepared from cationic polymers: Praestol 644BC, Praestol 650BC (Moscow–Stockhausen–Perm Closed Joint-Stock Company); Polymin SK, Katiofast SF, Polymin KP (BASF, Germany); Kat-flok-487F (KEM-TRON Inc., Germany).

1070-4272/04/7707-1142 © 2004 MAIK "Nauka/Interperiodica"

The efficiency of thickening and compaction of the sediments was assessed from the velocity of displacement of the interface between the clarified and nonclarified parts of the solution in a volumetric flask with a working volume of 2000 cm^3. The sedimentation was assessed quantitatively using the dimensionless parameter D [4]:

$$D = \gamma/\gamma_0 - 1,$$

where γ and γ_0 are the sedimentation rates of the cement suspension with and without cationic flocculant, respectively.

In all the experiments we estimated γ from attainment of a fixed degree of clarification at identical concentration of the flocculant in the thickening solution (c_f = 0.5%).

The acidity of the medium and of the buffer solutions was monitored with a pH 320 SET (Wissenschaftlich-Technische-Werkstätten GmbH) microprocessor-based pH meter.

The charge density of the cationic flocculants, mg-equiv g^{-1}, was determined by colloidal-chemical titration with a 0.01% solution of the polymer with aqueous potassium polyvinyl sulfate (molecular weight M = 132 000, 60 mg l^{-1}) in the presence of Toluidine Blue as indicator [5]. Flotation isolation of the cement suspension sediment was carried out on a pilot pressure installation. The experiments were run in a cylindrical flotator equipped with a facility providing for tangential motion of the flow. The air pressure in the saturator was 3.5 MPa. In the course of the process, we monitored the size of the air bubbles at the outlet of the reducing valve, as well as the degree of clarification of water and the concentration of the ions of pollutant remaining in water. The size of the bubbles was estimated optically, in an MBP-2 horizontal microscope.

Neutralization of a 1% cement suspension (pH 11.8) was studied under the static (a 5-s single stirring run at the beginning of the process) and dynamic (continuous stirring) conditions.

Under static conditions, upon addition of 60 ml l^{-1} of a 5% H_2SO_4 solution to 1 l of 1% cement suspension, pH of the suspension initially decreased to 7.0 and then slowly increased, virtually regaining the initial value. The experiments under dynamic conditions showed that, upon neutralization, stirring accelerates the growth of pH. In this connection, we studied the dynamics of variation of pH of the cement suspension during its neutralization with a 5% solution of H_2SO_4

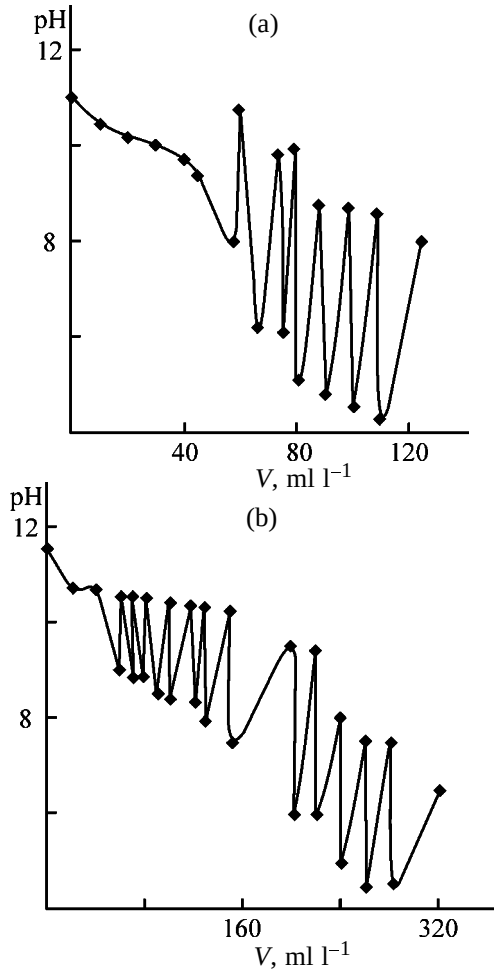

Fig. 1. Variation of pH of a 1% aqueous cement suspension upon introduction of 5% solutions of (a) H_2SO_4 and (b) H_3PO_4 in amount V in portions under stirring.

under continuous stirring. The first 60 ml of the H_2SO_4 solution was introduced into the suspension under stirring in 10-ml portions at 30-s intervals. Next, the acid solution was added in 10-ml portions at 30-min intervals. Figure 1a shows how the acidity varied with the volume of the acid solution introduced; it is seen that pH of the suspension, which strongly decreased under the action of the acid, increased again several minutes later, virtually regaining its initial value. Upon introduction of additional portions of the acid into the solution, this process was reproduced, resulting in a gradual final decrease in the acidity of the solution. The amount of the acid spent is very significant. For example, decreasing pH of the suspension from 11 to 8 requires adding 110 ml of 5% H_2SO_4 to 1 l of the suspension. This also holds for 5% H_3PO_4 (Fig. 1b); neutralization requires a much greater amount of H_3PO_4 and is much slower. Neutralization to pH 6.5 is achieved by introducing

320 ml of 5% H_3PO_4 solution per liter of suspension. Notably, in both cases the solid dispersed phase did not disappear: Instead of solid cement particles, we observed appearance of poorly soluble sulfates, phosphates, and other products of solid-phase reactions and topochemical processes. This is most probably due to the buffer action of the suspended $Ca(OH)_2$ particles.

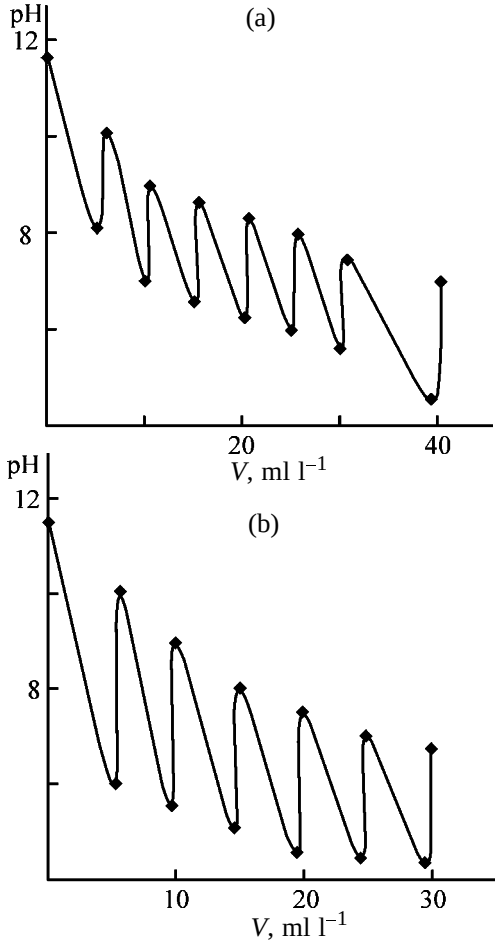

Fig. 2. Variation of pH of a 1% aqueous cement suspension upon introduction of combined flocculants based on Katfloc-487F polymer and (a) H_2SO_4 and (b) H_3PO_4 in amount V in portions under stirring.

Since solutions of acids proved to be inefficient in neutralization of cement suspensions, we studied neutralization of suspensions with combined acid solutions containing a polymeric flocculant.

A preliminary study showed that nonionic polyacylamide (PAA) exerts a very weak flocculation effect on cement suspensions. The same is true of anionic polyelectrolytes like hydrolyzed PAA. Since cement suspensions contain negatively charged particles with a fairly high negative electrokinetic ε potential, it is most probable that, along with "bridging," neutralization of the surface charge by macromolecular compounds is important in flocculation.

In view of the above-said, we studied in this work cationic polyelectrolytes, namely, cationic polymeric flocculants (Table 1). When choosing a polyelectrolyte, we estimated the flocculation effect from the results of the qualitative tests on clarification of the suspension and thickening (compaction) of the sediment. In tests, we added 7 ml of a 0.5% solution of a flocculant to 1 l of a 1% aqueous cement suspension. Among the polymeric flocculants studied, satisfactory results were obtained with Praestol 611BC, Praestol 650BC, Polymin KP, and Kat-floc-487F with a cationic charge of 1–3 mg-equiv g^{-1}.

Neutralization of the suspension with compositions combining aqueous solutions of the above-mentioned flocculants and acids showed that these are more efficient than solutions of acids traditionally used for neutralization. Figures 2a and 2b show how pH varies during neutralization of a suspension with a combined

* Composition no. 3 was prepared according to version no. 2; concentration of Na_2CO_3 was 20 g l^{-1}.

** The composition was prepared by adding concentrated HCl into an aqueous solution of Na_2CO_3 to pH 1.5 (pH 1.5 corresponds to the concentration of excess HCl; concentration of H_2CO_3 is 3.8×10^{-2} M; there are no carbonate ions).

composition based on Kat-floc-487F. In this case, the required amount of the chemicals decreases to 30–40 ml l^{-1}; compositions containing phosphoric acid (Fig. 2b) are more efficient. On the whole, however, the acidity of the suspensions remains unstable during neutralization.

In this connection, we tested neutralization involving removal of the Ca^{2+} ions from solution by converting them into a poorly soluble form. One way of binding Ca^{2+} ions in an alkaline medium is converting them to a poorly soluble carbonate, $CaCO_3$, by the scheme

$$Ca^{2+} + CO_3^{2-} \rightarrow CaCO_3, \quad (6)$$

$$Ca(OH)_2 + CO_2 \rightarrow CaCO_3 + H_2O. \quad (7)$$

Simultaneously, soluble hydrocarbonate can be formed in an acid medium:

$$Ca(OH)_2 + 2HCO_3^- \rightarrow Ca(HCO_3)_2 \rightleftarrows Ca^{2+} + 2HCO_3^-. \quad (8)$$

This assumption was verified experimentally; we found that passing CO_2 through the cement suspension upon isolation of coarse fractions leads to a sharp and, what is essential, irreversible decrease in pH and clarification of the solution.

Our results allowed us to propose compositions including cationic polyelectrolyte and a solution yielded by the reaction of Na_2CO_3 with excess HCl (to pH 1.5) [6].

Figure 3 shows how the flocculation effect *D* varies with the concentration of the combined flocculant

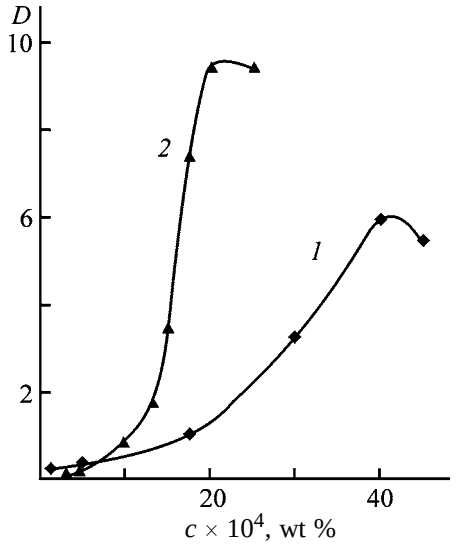

Fig. 3. Flocculation effect *D* as a function of the concentration of the combined flocculant *c*. Formulation no. 1 (Table 2): (*1*) version 3 and (*2*) version 4.

proposed. Curve *2* in Fig. 3 shows that the composition proposed is much more efficient. Thus, the combined flocculants can be regarded as agents favoring neutralization in a strongly alkaline medium containing $Ca(OH)_2$, which makes such compositions suitable for separation of complex dispersed systems.

We separated the suspension into fractions by pressure flotation at the air pressure in the saturator of 3.5 MPa, using a pilot installation proposed in [7, 8]. Table 2 summarizes the results of two-stage purification of the wastewater from cement production, based on separation of the solid and liquid phases by flotation. Stage 1 of removal of the suspension from water involved thickening of the dispersion by combined flocculants (versions 1–4). Neutralization of the wastewater was achieved only with a combined flocculant (version 4). Stage 2 involved flotation with (versions 1–3) and without (version 4) additionally introduced agents. Table 2 suggests high efficiency of purification and neutralization of strongly alkaline wastewater from cement production in a two-stage process involving flotation separation. Water purification was the most efficient in the case of version 4, when a combined flocculant was used in stage 1 of the process (thickening).

CONCLUISONS

(1) Neutralization of strongly alkaline wastewater with H_2SO_4 and H_3PO_4 solutions occurs as an unstable and reversible process, as shown by the example of a 1% cement suspension containing silicates, aluminosilicates, and ferrites.

(2) Efficient neutralizing compositions for wastewater from silicate productions are combined flocculants based on cationic polymers with a cationic charge of 1–33 mg-equiv g^{-1}, including polymers with a molecular weight above 500 000 and the solution yielded by the reaction of sodium carbonate with excess HCl (to pH 1.5).

(3) The combined flocculants proposed allow highly efficient flotation treatment of strongly alkaline wastewater from silicate production.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Acylation of Aromatic Amines with Carboxymethyl Dextran in the Presence of Small Amounts of Water

O. V. Sibikina, A. A. Iozep, and B. V. Passet

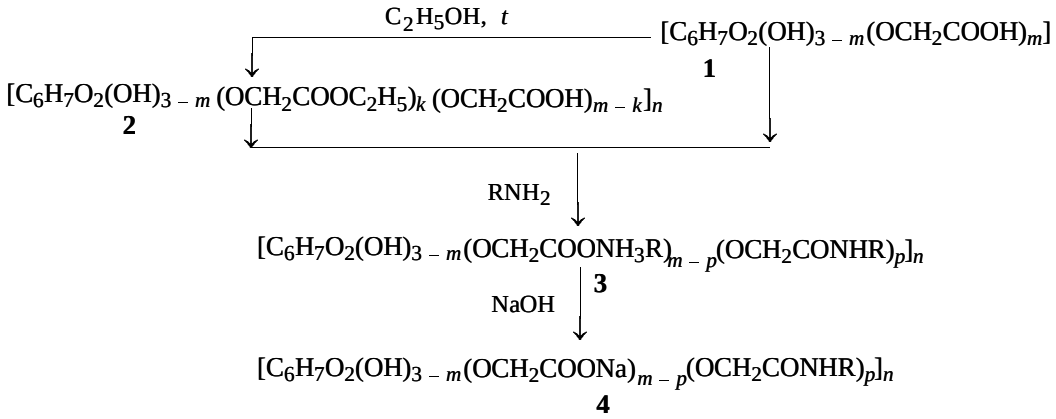
St. Petersburg State Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

Received February 13, 2004

Abstract—Acylation of aromatic amines with carboxymethyl dextran and its ethyl ester in dioxane, ethanol, 1-propanol, and 2-propanol in the presence of small amounts of water was studied.

It was shown previously that esters of polysaccharidecarboxylic acids are convenient agents for acylation of amines in synthesis of physiologically active polymers (PAPs) [1–3]. They can be used for fixation on a polysaccharide matrix of such biologically active substances as antibiotics and enzymes. In this connection, we developed simple procedures for synthesis and analysis of carboxymethyl polysaccharide (CMP) esters and determined conditions of their reactions with various amines in water, dioxane, and DMSO [1–5]. However, difficult isolation of CMP esters from the reaction mixture after their synthesis is a significant drawback of this procedure for PAP preparation. Therefore, we studied the reaction of carboxymethyl dextran (CMD) with aromatic amines in lower alcohols with the aim to eliminate the step of CMD ester isolation and make the modification of dextran less time- and labor-consuming.

Chemical modification of polysaccharides was performed by the following scheme:



Carboxymethyl dextran **1** and its ethyl ester (CMDEE) **2** were prepared as described in [4–6]. The resulting CMD and CMDEE samples were characterized by the degree of carboxymethylation C_{cm} and degree of alkoxycarbonylmethylation C_{acm} (number of carboxymethyl or ester groups per polysaccharide monomeric unit). Acylation of amines with CMD and CMDEE was performed in dioxane [3]. The reaction of CMD with amines in ethanol was performed similarly to the reaction of CMDEE with amines in dioxane but by two procedures: with preliminary esterification of poly acid (procedure 1) and without it (procedure 2). In procedure 1, the H^+ form of CMD was refluxed in excess ethanol for 4–6 h, after which an amine was added to the resulting CMDEE-containing mixture, and refluxing was continued for an additional 4 h. In procedure 2, the reaction mixture containing the H^+ form of CMD, amine, and excess alcohol was refluxed for 4 h. In so doing, it was suggested that first the CMD ester is formed, which is followed by

Table 1. Results of acylation of amines with CMD (C_{cm} = 0.9) and its ethyl ester (C_{cm} = 0.94, C_{acm} = 0.41) in anhydrous dioxane at 100°C [3] and with CMD in ethanol at 78°C. Reaction time 4 h, 5 mol of amine per mole of carboxy groups

Amine	pK_a of amine	C_{am} in dioxane, %		C_{am} of CMD in ethanol, %	
		CMD	CMDEE	procedure 1	procedure 2
p-Nitroaniline	1.02	2	0	0	7
p-Bromoaniline	3.93	–	–	18	32
Aniline	4.61	24	21	29	41
p-Toluidine	5.12	29	26	35	46
p-Phenetidine	5.25	29	27	35	49

acylation, since aromatic amines are not noticeably acylated with the poly acid at 78°C in dioxane [3].

Products **3** were isolated, purified, and analyzed as described in [3].

The number of amide groups in samples of polysaccharides **4** was determined by elemental analysis and UV spectroscopy. Acylation was characterized by the degree of amidation C_{am} (percentage of polysaccharide acyl groups involved in the reaction). The results are given in Table 1.

We found that acylation of aromatic amines in ethanol at 78°C by the suggested procedures gives better results than acylation with CMD and its ethyl ester in dioxane at 100°C. In acylation of amines in dioxane, C_{am} is lower than in acylation of amines in alcohol, on the average, by 20–30 (in procedure 1) and 65–85% (in procedure 2).

With the aim to increase the conversion of CMD carboxy groups into amide groups, we studied the reactions of CMD with aromatic amines in 1- and 2-propanol whose boiling points are higher than that of ethanol (97 and 82°C, respectively). However, despite higher reaction temperature, C_{am} of CMD in these alcohols appeared to be lower than in ethanol.

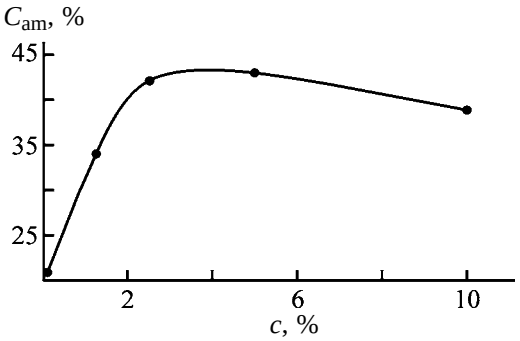

Fig. 1. Degree of amidation C_{am} of CMD (C_{cm} = 1.45) in reaction with aniline as a function of water content *c* in dioxane. Reaction time 4 h, 70°C, 10 ml of amine per mole of monosaccharide units.

This may be due to steric effects associated with longer carbon chain in the alcohol molecule or its branching. A similar trend was observed in acylation of benzylamine with CMD esters in water [4]. However, more detailed examination of the reaction conditions and reagent purity showed that dioxane, 1-propanol, and 2-propanol (chemically pure or pure grade) contained no more than 1% water, whereas rectified ethanol contained 4% water. Therefore, we suggested that water could exert a certain effect on the reaction. Under the conditions of procedure 2, when the H^+ form of CMD and amine are added to the alcohol simultaneously, the carboxylic acid (CMD) rather than CMD ester reacts with the amine, and the acid is a stronger acylating agent. This accounts for the fact that acylation of amines in ethanol by procedure 2 gives the target product in a higher yield compared to preliminary esterification of carboxy groups.

A study of the reaction of CMD with aniline in dioxane containing small amounts of water showed that the efect of water on the reaction is maximal at a water concentration of 2.5–5% (Fig. 1) [7].

In this connection, we suggested that addition of this amount of water to dioxane and 1-propanol will increase the yield of the target product in reactions with the other amines also. The boiling points of dioxane and 1-propanol are approximately equal and higher than that of ethanol; therefore, we expected that the degrees of CMD amidation in acylation of aromatic amines in 1-propanol or dioxane containing 4% water will be the same or even greater, compared to the reaction in ethanol.

Indeed, addition of 4% water to dioxane and 1-propanol increased C_{am} relative to the anhydrous solvent, in some cases by a factor of more than 2 (Table 2). As expected, the yield of CMD amide in 1-propanol was higher than in ethanol (by approximately 30%). Comparison of C_{am} of CMD in water-containing 1-propanol and dioxane is difficult, since

Table 2. Results of acylation of amines with CMD (C_{cm} = 0.9–1.1) in solvents containing 4% water. Reaction temperature 100°C, 4 h, 5 mol of amine per mole of carboxy groups

Amine	C_{am} of CMD, %			
	anhydrous dioxane	dioxane	1-propanol	ethanol*
p-Bromoaniline	26	42	32	
Aniline	24	47	55	41
p-Toluidine	29	57	59	46
p-Phenetidine	29	65	65	49

* At 75°C.

the dependences of the product yield on pK_a of the amine in these solvents are essentially different (Fig. 2).

Thus, addition of 2.5–5% water to dioxane and lower alcohols at temperatures above 70°C allows efficient acylation of aromatic amines with CMD used instead of its ethyl ester, which considerably simplifies the modification of the polysaccharide and increases the yield of the target product by a factor of more than 2.

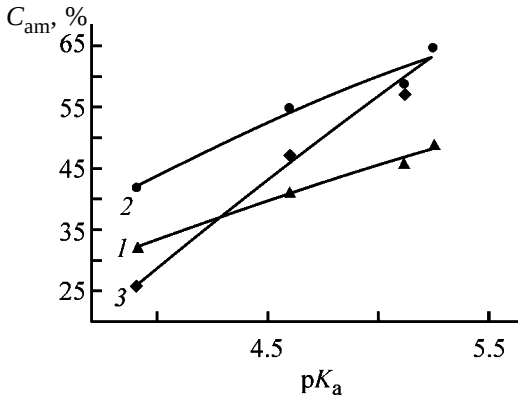

Fig. 2. Degree of amidation C_{am} of CMD in reactions with aromatic amines in (*1*) ethanol, (*2*) propanol, and (*3*) dioxane, containing 4% water, vs. pK_a of the amine. Boiling point of the solvent, 4 h, fivefold excess of the amine.

CONCLUSION

Experiments on acylation of aromatic amines with carboxymethyl dextran and its ethyl ester in wet dioxane, ethanol, 1-propanol, and 2-propanol show that addition of 2.5–3% water to dioxane and lower alcohols allows acylation of aromatic amines at temperatures above 70°C to be performed with carboxymethyl dextran instead of its ethyl ester, which considerably simplifies the modification of the polysaccharide and increases the yield of the target product by a factor of more than 2.

Abstract—A method for determination of catecholamines (adrenaline, noradrenaline, and dopamine) by capillary electrophoresis–electrospray ionization–mass spectrometry is described. The electrospray operating mode is optimized as well as the system for capillary electrophoresis.

Quantitative analysis for the most important neurotransmitters such as adrenaline (A), noradrenaline (NA), and dopamine (DA) is of great significance for diagnostics and treatment of various brain diseases. In this case it is required to determine individual catecholamines, but not their total. Since the concentration of catecholamines in actual objects is extremely low (nano- and picograms), the methods for their determination should be highly sensitive and selective. In recent years, a novel method for separating complex mixtures, capillary electrophoresis (CE), is being actively developed. Its doubtless advantages are very high performance, surpassing that of the chromatographic methods by several orders of magnitude; very small sample volume required for analysis (several nanoliters); small consumption of reagent solutions; and a shorter analysis time than in HPLC.

The most of published works deal with capillary zone electrophoresis with UV detection, which is characterized by insufficient concentration sensitivity. The zone CE–mass spectrometry (MS) combines the high efficiency of separation of components with highly sensitive and selective detection. A great advantage of an MS detector is the possibility of identifying unknown components in matrices of complex samples.

A liquid chromatograph or a CE system can be connected to a MS detector via ESI (electrospray ionization) interface. In the case of CE, such a hybrid mode of determination is known as CE–ESI–MS (capillary electrophoresis–electrospray ionization–mass spectrometry). The method is based on separation of components of a sample in a quartz capillary under the action of an applied potential, electrospray of an electrolyte and the sample followed by ionization in an electrosprayer of a mass analyzer, and recording of an analytical signal from ions in a quadrupole MS detector. Electrospray is electrokinetic injection of the solution to be analyzed to a mass spectrometer under the action of a high potential difference applied to the ends of the quartz capillary, and under a voltage applied between the capillary outlet and MS inlet.

Three major engineering solutions of the ESI interface, to connect a CE block to a mass analyzer are currently used: employment of a quartz capillary with a metal sputtered on its pointed end through which spraying occurs; the use of a gold wire microelectrode arranged into the capillary outlet; and the use of a three-layer metallic needle.

The study was carried out on an Agilent instrument with an ESI interface using a three-layer metallic needle. Three flows are coaxially fed into the needle serving as an electrosprayer: a drying gas (external coating) ensuring transfer of the solvent into the vapor phase; coating liquid [through a high-pressure isocratic pump used in HPLC to ensure liquid contact of the needle (serving also as an electrode) with the liquid flowing from the capillary]; and, finally, a flow of a liquid from the quartz capillary. Particles of the aerosol, formed in the electrosprayer cell under the action of high voltage applied between the needle and the electrode of the inlet capillary of the mass spectrometer (~3000–4000 V), start to crush down. As

1070-4272/04/7707-1150 © 2004 MAIK "Nauka/Interperiodica"

a result, the initially high charge density on their surface decreases, and ions, having no solvation shell, i.e., solvent molecules in the gaseous state, are formed.

The goal of this study is to develop a method for determination of the most important catecholamines by capillary electrophoresis–mass spectrometry. In the work we used an Agilent 1100 CE–MS system, Tsvet Yauza liquid chromatograph with an amperometric detector, and MALDI TOF Voyager DE mass spectrometer. The inner and outer diameters of the capillary were 50 and 375 μm, respectively, and the effective length, 80–90 cm. The inner capillary wall was coated with a polymer. The capillary projected from the ESI needle by 0.3 mm. The voltage applied to the capillary ends was 30 kV. A sample was taken from a sampler wheel (hydraulic input 900 mbar s^{-1}). The capillary was conditioned with water (5 min), 10% ammonia (5–10 min), and again with water (5 min) under a pressure of 1 atm. After completion of the analysis, the capillary was washed with a buffer electrolyte for 4 min.

In detecting positive ions in the mass spectrometer, we used an ESI interface with a three-layer metallic needle. Into the needle serving as an electrosprayer, flows of a drying gas and coating liquid were coaxially fed. The ESI voltage was +4 kV. The coating liquid flow rate was 4 μl min^{-1}, and that of the drying gas (nitrogen), 5 l min^{-1}; temperature 200°C. The objects to be analyzed were dry adrenaline, dopamine, and noradrenaline hydrotartrates (Fluka).

Stock buffer solutions were prepared from standard titrants [$Na_2B_2O_4 \cdot 10H_2O$ (pH 9.18), HCl, CH_3COOH, aq. NH_3, diethylamine hydrochloride $(C_2H_5)_2NH \cdot HCl$, and Na_2EDTA]. The effect of an organic solvent as a component of the electrolyte on the parameters of separation of the mixtures was studied with 2-propanol. All the chemicals used were of chemically pure grade. All the solutions were prepared with double-distilled water. The buffer electrolyte was 0.05–0.1 M acetate buffer containing 5×10^{-3} M $(C_2H_5)_2NH \cdot HCl$; pH was adjusted to 4.5 by adding 10% aq. NH_3. The resulting solutions were filtered through a membrane filter (pore size 1.2 μm) and then degassed under vacuum (water-jet pump).

Stock solutions of the catecholamines (1000 mg l^{-1}) were prepared in 0.1 M HCl and stored at –20°C. Under these conditions, the solutions were stable for a year. Working solutions of catecholamines were prepared by dilution of the stock solutions with water. The coating liquid was prepared from a mixture of methanol or 2-propanol and water (40 : 60–95 : 5 v/v) with addition of 0.5 vol % acetic acid.

Table 1. Relative contribution of protonated molecular ions $[M + H]^+$ and daughter ions in the mass spectra of catecholamines

Major species formed in MS	A	NA	DA
$[M + H]^+$, *m*/*e*	184 (100)	170 (100)	154 (100)
Fragment, *m*/*e*	166 (10)	152 (12)	137 (11)
Neutral fragment, *m*	–18 (H_2O)	–17 (NH_3)	–17 (NH_3)
SIM, *m*/*e*	184	170	154

Solid-phase extraction of catecholamines was performed with active alumina. CE separation of components improves the sensitivity of the MS quadrupole detector, which is caused primarily by the fact that, in this case, operation in the SIM mode becomes possible. We have found only a few versions of determination of catecholamines by CE–MS with electrospray ionization [1–3], and about ten versions, by CE [4–7]. It appeared promising to use capillary electrophoresis with MS detection. Prior to CE–MS analysis, we recorded the MS spectra of standard catecholamines. They show two types of ions: a molecular ion and a daughter ion formed by elimination of the H_2O or NH_3 molecule from the protonated molecular ion. By varying the drying gas temperature and pressure under which it is fed to the needle, we made it possible that the mass spectrometer recorded molecular peaks of the components with practically no fragmentation (Table 1). Above 250°C, the catecholamine molecules are fragmented with the loss of NH_3. Therefore, detection of catecholamines is based, primarily, on the corresponding signals of molecular ions.

There are two modes of MS detector. In the SCAN mode, ions from a selected mass range (*m*/*e*) are detected, and the total ion current is recorded as a function of the time. In the SIM mode, signals from the only ion with a fixed mass are integrated. Signals from other ions are not recorded, and that is why it becomes so important to separate components of the sample prior to input into the mass analyzer. In operating in this mode, the sensitivity of analysis increases by several times. In this case, it is important to attain a good reproducibility in the migration time of components (time in which a component passes through the quartz capillary). Therefore, the quality of preparation of the capillary for analysis is of a great significance in the CE–MS method. We registered the MS spectra under the following conditions: SCAN

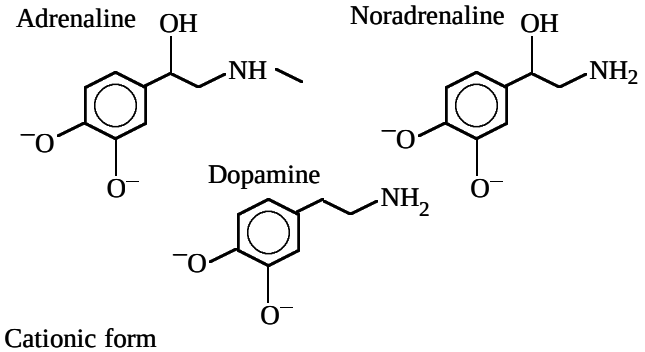
mode: *m*/*e* 150–185 and SIM mode: *m*/*e* 154 (0–11.25 min), 170 (11.25–11.8 min), and 184 (11.8–12.0 min).

In capillary zone electrophoresis, components of a sample are separated as cations or anions, depending on pH.

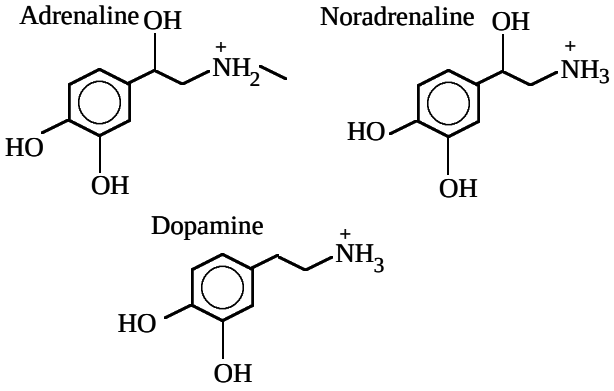
At pH >10, catecholamines occur in the anionic form [3], and at pH <8, in the cationic form (pK_a of catecholamines ~8.5) [2, 6]:

Anionic and cationic forms of catecholamines

Anionic form



Cationic form



We tested both alternatives. We optimized the composition of the sample and buffer electrolyte by varying the concentration, pH, salt additives, and organic modifiers (Table 2). It was demonstrated that the use of buffer solutions with pH > 7 provides better separation, but, in this case, oxidation of catecholamines can occur. Here the requirements to the MS detector should also be taken into account. For example, the use of low-volatile borate buffer makes it impossible to attain stable spraying of the components to be analyzed. Therefore, in the subsequent, all the experiments were carried out in a buffer solution with pH < 7. To increase the solution viscosity and improve the separation, we added 10–20% 2-propanol. However, this resulted in broadening of the peaks and decreased resolution. To overcome these effects through preventing adsorption of the analytes on the capillary wall, we added $(C_2H_5)_2NH \cdot HCl$ in the buffer electrolyte. The optimal conditions were found to be as follows: 0.05 M acetate buffer containing 5×10^{-3} M diethylamine hydrochloride (pH 4.5) and separating voltage +30 kV. Note that, in the CE–MS analysis, the voltage should be higher than in CE–UV, since the ESI voltage applied to the end of the capillary decreases the total electric field in it.

An important step in carrying out this study was optimization of the MS detection conditions. It was necessary to select the ratio of the rates of the drying gas and coating liquid and the coating liquid composition so as to maximize the analytical peaks.

Taking the published data [2, 6, 8] into account, we tested the systems methanol–water and 2-propanol–water (50 : 50 v/v) with addition of an acid. Since acetate buffer was used in separating catecholamines in CE, we selected acetic acid, so as to introduce no additional ions into the system. The maximal intensity of signals of the analytes was observed in the system with 2-propanol, which is consistent with the results of Peterson *et al*. [2] who demonstrated that 2-propanol is the best suited solvent for the coating liquid. Nevertheless, the authors have preferred to use methanol, since, in this case, the signal/noise (S/N) ratio appeared to be higher. Under our experimental conditions, the noise level was higher with methanol. After optimization of the solvent, we selected the system 2-propanol–water (50 : 50 v/v). Additionally, it should be pointed out that the stability of electrospraying decreases as the fraction of the organic solvent in the coating liquid increases. The acetic acid concentration was varied from 0.1 to 1.0%, which had only slight effect on the signal intensity. Thus, the optimal composition of the coating liquid is 2-propanol–water (50 : 50 v/v) + 0.5% acetic acid.

Another significant parameter influencing the response is the coating liquid flow rate. This parameter was optimized over the range of flow rates at which electrospraying is stable (2–8 μl min^{-1}).

According to [8], the coating liquid, being around the capillary and mixing with the outflowing sample, dilutes by half the sample zone when flowing out from the capillary with increasing flow rate from 2 to 8 μl min^{-1}. The highest response and the best separation efficiency were obtained at a flow rate of 4 μl min^{-1}.

To realize stable spraying, it is important to optimize the position of the capillary end relative to the coating liquid outlet. If the end of the capillary projects too much from the ESI needle, there is no way to realize stable spraying. In turn, spraying is also

NA	170.1	58.8–230	100 ± 1	590 ± 3	0.27 ± 0.03

unstable if the end of the capillary is arranged inside the needle. In this case, the eluent is diluted, and the sample can be broken. The best results were obtained in the case when the capillary projected from the ESI needle by 0.3 mm, which is consistent with data of [9].

Under the optimal conditions, using MS detection in the SIM mode, detection limits of 110, 100, and 90 nM were achieved for dopamine, noradrenaline, and adrenaline, respectively (at S/N = 3).

It should be pointed out that an ESI–MS detector is highly sensitive to the sample salinity. At high salt content, the stability of spraying decreases. Therefore, samples should be purified prior to analysis.

Sample preparation procedure was optimized with a model system using solid-phase extraction (SPE) on alumina pretreated with an acid.

Preparation of a sample (2 ml) was carried out as follows. The solution pH was adjusted to 8.5 by adding Na_2CO_3. Alumina (20 mg) was added, and the mixture was stirred for 3 min. After filtration, alumina was washed with water (3 × 2 ml), and the catecholamines were then eluted with 300 μl of 1 M CH_3COOH. Finally, the eluate was analyzed by CE–MS, CE–UV, or reversed-phase HPLC–amperometry.

As eluents we tested 0.6 and 0.1 M $HClO_4$ [7], 0.3 M HCl [6], 0.3 and 1 M CH_3COOH [8], and a mixture of 0.6 M $HClO_4$ with 1 M CH_3COOH

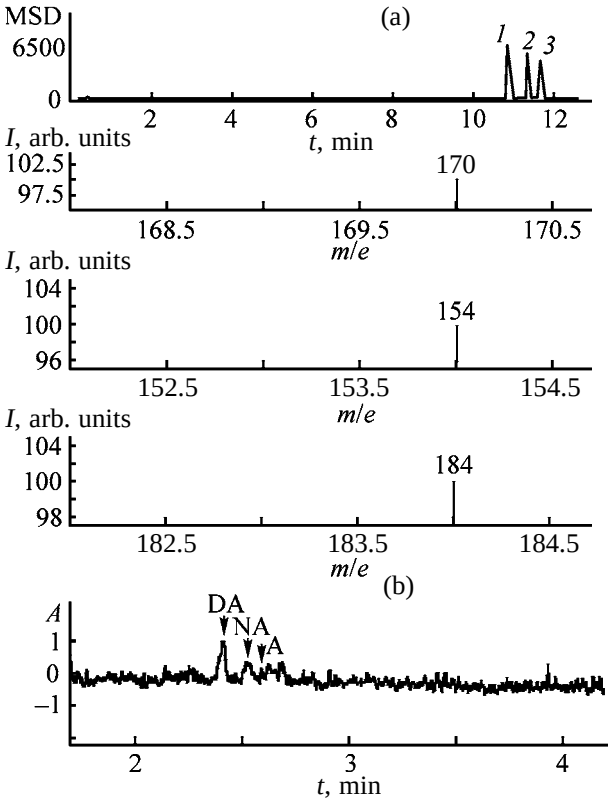

Fig. 1. Electrophoregram of standard samples: (*1*) dopamine, (*2*) noradrenaline, and (*3*) adrenaline. Agilent instrument; sample: 1 mg l^{-1} catecholamine in 1×10^{-2} M HCl; CE conditions: supporting electrolyte acetate buffer (pH 4.45), 0.005 M diethylamine hydrochloride; hydrodynamic injection: 50 mbar × 10 s; separation: 27 kV, 10.5 μA; MS detection: SIM, *m*/*e* 154 (0–11.25 min), 170 (11.25–11.8 min), and 184 (11.8–12.2 min). (*I*) Intensity of MS signal, (*A*) absorbance, (*m*/*e*) mass to charge ratio, and (*t*) migration time. (a) SIM mode (MS detector) and (b) UV detector.

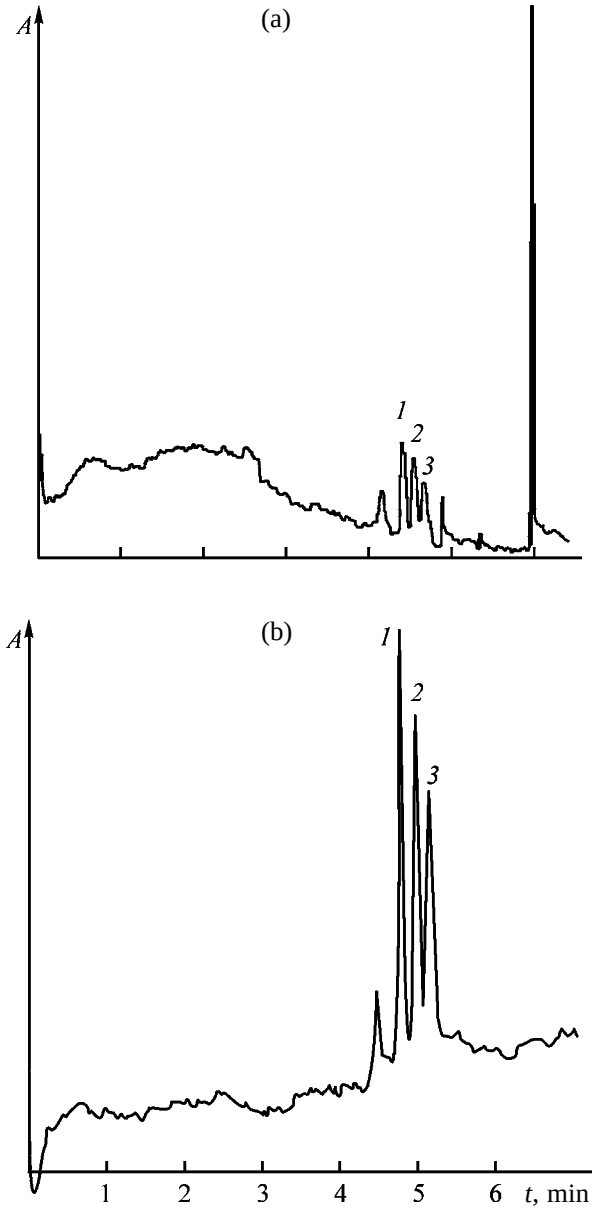

Fig. 2. Electrophoregram of a model mixture of catecholamines after purification by SPE on alumina. (*A*) Absorbance and (*t*) migration time. Kapel' 103 RE instrument; hydrodynamic injection: 10 mbar × 10 s; separation: 25 kV; UV detection at 254 nm. Model mixture: (*1*) dopamine, (*2*) noradrenaline, and (*3*) adrenaline (2 mg l^{-1}). Sample volume (ml): (a) 2 and (b) 5.

(20 : 80). When optimizing the SPE conditions, we varied the amount of alumina from 10 to 100 mg and the eluent concentration from 0.3 to 5 M. The most efficient extraction was obtained with 20 mg of alumina as a sorbent and 1 M CH_3COOH as an eluent. The extract was then analyzed by CE–MS. The recoveries of dopamine, noradrenaline, and adrenaline with 1 M CH_3COOH were 90 ± 2, 104 ± 2, and 82 ± 2%, respectively. The results of analysis of the model mixtures by CE with MS detection (SIM) are presented in Fig. 1, and with UV detection, in Fig. 2 (10- and 25-fold preconcentration).

Table 3 shows that the CE–MS method is inferior to HPLC–amperometry in the sensitivity, the total analysis time being well comparable for both methods. As a conclusion, thanks to the high efficiency of CE and versatility of MS detection, CE–MS can be used also for determination of neurotransmitters other than those described in this work as well as of various organic compounds with an amino group in complex mixtures.

CONCLUSIONS

(1) A method for electrophoretic determination of catecholamines (adrenaline, noradrenaline, and dop-

amine) with mass-spectrometric detection wss developed on simulated mixtures, and the detection limits for the analytes were determined. The supporting electrolyte was 0.05 M acetate buffer containing 0.05 M diethylamine hydrochloride. The electrospray operation mode was optimized to improve the sensitivity of mass-spectrometric detection. The optimal conditions are as follows: drying gas flow rate 5 l min^{-1}, temperature 200°C, pressure 14 kPa, composition of the coating liquid for the inner capillary 2-propanol–H_2O = 1 :1 + 0.5% CH_3COOH, and flow rate 4 μl min^{-1}.

(2) A comparative study was made of the methods of capillary electrophoresis–UV spectrometry, capillary electrophoresis–mass spectrometry, and reversed-phase HPLC–amperometry, as applied to determination of catecholamines. It was demonstrated that adrenaline, noradrenaline, and dopamine can be determined in a biological object by capillary electrophoresis–UV spectrometry and HPLC–amperometry without preconcentration. Capillary electrophoresis surpasses HPLC–amperometry in the performance by an order of magnitude, being inferior to it in the sensitivity.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Specific Features of Synthesis of Poly(Methyl Methacrylate) in the Presence of Bis(isopropylcyclopentadienyl)tungsten Dichloride

E. V. Telegina, L. L. Semenycheva, and D. F. Grishin

Research Institute of Chemistry, Lobachevsky Nizhni Novgorod State University, Nizhni Novgorod, Russia

Received January 26, 2004

Abstract—Synthesis of poly(methyl methacrylate) in the bulk and in dimethylformamide under conditions of radical initiation in the presence of bis(isopropylcyclopentadienyl)tungsten dichloride was studied.

Radical polymerization of methyl methacrylate (MMA), initiated with azobis(isobutyronitrile) (AIBN) in the presence of bis(isopropylcyclopentadienyl)tungsten dichloride (**I**) in the bulk and in dimethylformamide (DMF), is characterized by uniform course with significant reduction of the gel effect and its shift toward higher conversions; the viscosity-average and number-average molecular weights (MW) of the resulting polymer linearly grow with conversion, and the molecular-weight distribution (MWD) curves shift toward higher molecular weights.

Radical polymerization by the mechanism involving a change in the metal atom valence (atom transfer radical polymerization, ATRP) with participation of organometallic compounds as chain-transfer agents is a promising line in controlled polymerization under conditions of radical initiation [1, 2].

A specific feature of ATRP is its applicability to a wide range of monomers, including acrylic monomers [1]. In particular, poly(methyl methacrylate) (PMMA), one of the most important large-tonnage polymeric products, was prepared by the ATRP mechanism in the presence of various complexes of transition metals, in particular, Mo(III) [3], Cu(I) [1, 4, 5], Ru(II) [6, 7], Fe(II) [1, 8–11], etc. It was shown [3] that oxidation of a transition metal by the reversible Kharasch reaction [12] with alkyl halide RX in the medium of a vinyl monomer allows fragment-by-fragment chain propagation:

$$RX + M^nY_mL_x \rightleftarrows R^{\cdot} + X\text{–}M^{n+1}Y_mL_x, \quad (1)$$

$$R^{\cdot} + M \rightarrow RM^{\cdot}, \quad (2)$$

where M^n is the metal atom in oxidation state n; L, ligand; Y and X, halogen atoms; and M, monomer.

This method, however, has signficant drawbacks: toxicity of some organic halides RX, instability of many organometallic compounds in air [10], and relatively low reaction rate. To solve this problem, so-called "reverse" or "alternative" polymerization by the ATRP mechanism was suggested [4, 8, 10, 11]; in the process, standard radical initiators, e.g., azo compounds [4, 10], are used in combination with organic compounds of transition metals in higher oxidation state. In this case, after decomposition of the initiator into radicals, the reversible Kharasch reaction formally "starts" from the left side of Eq. (1) (Reverse Atom Transfer Radical Polymerization, RATRP).

In this study, we examined the prospects for using compound **I** [hereinafter, $W(IV)L_2X_2$, L = *i*-PrC_5H_4] for controlled synthesis of PMMA under conditions of radical initiation in the bulk and in DMF.

EXPERIMENTAL

$W(IV)L_2X_2$ was purchased from Aldrich. AIBN (polymerization initiator) [13], MMA (monomer) [14], and organic solvents [15] were purified by standard procedures.

The calculated amounts of $W(IV)L_2X_2$ and AIBN were dissolved in MMA and DMF (for the process in the solvent), and PMMA was prepared in evacuated ampules at a residual pressure of 1.3 Pa. The kinetics of MMA polymerization in solution was studied gravimetrically and thermographically [16]. The molecular-weight characteristics of PMMA were determined viscometrically [17] and by gel permeation chromatography (GPC) on an installation equipped with a set of five Styrogel columns with pore diameters of 10^5, 3×10^4, 10^4, 10^3, and 250 Å (Waters, the United

States). An R-403 differential refractometer (Waters) was used as detector. The eluent was THF. Calibration was done with close-cut polystyrene references [18].

The kinetic data on MMA polymerization initiated with AIBN in the presence of 0.1 mol % $W(IV)L_2X_2$ in the bulk at 70°C show that the gel effect at the equimolar content of $W(IV)L_2X_2$ relative to AIBN (0.1 mol %) considerably decreases. Figure 1a shows typical kinetic curves for MMA polymerization with the W(IV) complex as the chain-transfer agent. The possible concentration of the organometallic complex for the reaction in the bulk is restricted by its solubility in MMA. Therefore, radical polymerization of MMA with additions of $W(IV)L_2X_2$ was performed in a solvent, DMF. The kinetic data on polymerization of MMA at 70°C in the presence of $W(IV)L_2X_2$ dissolved in DMF ([MMA] : [DMF] = 5 : 1, [AIBN] = 0.1 mol %) indicate that the autoacceleration is suppressed to a significantly greater extent compared to the process in the bulk; with increasing concentration of $W(IV)L_2X_2$, the controlling effect becomes more pronounced (Fig. 1b).

Study of the molecular-weight characteristics of the polymers prepared in the presence of $W(IV)L_2X_2$ confirms a significant effect of the organotungsten compound on the chain propagation step in MMA polymerization both in the bulk and in DMF (see table). As seen from the table, and also from Figs. 2a and 2b, the viscosity-average (M_η) and number-average (M_n) molecular weights linearly grow with the monomer conversion γ in MMA polymerization both in the bulk and in the solvent. The MWD curves of PMMA samples show a shift toward higher MW, typical of controlled polymerization (Fig. 3). The polydispersity coefficients M_w/M_n (see table) of the polymers prepared in polymerization of MMA in DMF are considerably lower as compared to the polymer prepared in the bulk, although in this case the growth of M_w/M_n at high conversions is observed also. Such a phenom-

enon is observed fairly frequently in polymerization in the presence of other organometallic compounds as chain-transfer agents [4, 5, 11]. The growth of the polydispersity coefficients is apparently due to simultaneous occurrence both of the controlled synthesis and of common radical polymerization with bimolecular chain termination, and also of other side reactions [2]. In particular, in the presence of organometallic compounds the growth of the polydispersity coefficients is often associated with the catalytic chain transfer [3].

Thus, polymerization of MMA in the presence of $W(IV)L_2X_2$ in the amount comparable with that of the initiator has features of a controlled process. The strongest controlling effect is observed at the 1 : 5 ratio of the initiator and additive (polymerization in a solvent). In particular, at the 0.5 mol % concentration of the organometallic compound, the gel effect is virtually suppressed, the number-average molecular weight linearly grows with conversion, and M_w/M_n is considerably lower than in the case of the polymer prepared under comparable conditions but without additive.

By analogy with data on polymerization of vinyl monomers in the presence of organomolybdenum complexes $[C_5H_5Mo(PH_3)_2BrCl_2$ and $C_5H_5MoCl_3L$, where L = $P(CH_3)_3$, PCH_3Ph_2, etc.] by the ATRP mechanism [3], we can assume that, in the case of $W(IV)L_2X_2$, whose electronic structure is similar to that of the Mo(IV) complex, the control of the polymeric chain is also accomplished by the ATRP mechanism. Since in the system under consideration the source of primary initiating radicals is AIBN and not the organic halide, the overall reaction scheme will somewhat differ from the usual ATRP mechanism [4, 8, 10, 11]. In particular, in contrast to the ATRP mechanism [reactions (1), (2)], in our case the initiating radicals R$^\bullet$ are generated by homolytic cleavage of AIBN:

$$\text{AIBN} \rightarrow 2R^\bullet, \quad (3)$$

$$R^\bullet + n\text{M} \rightarrow \text{RM}_n^\bullet. \quad (4)$$

Then the arising propagation radicals $RM_n^\bullet$ react with the organometallic compound to give the adduct RM_nX with chlorine abstraction from $W(IV)L_2X_2$. In the process, the oxidation state of the metal decreases:

$$\text{RM}_n^\bullet + W(IV)L_2X_2 \rightleftarrows \text{RM}_n\text{X} + W(III)L_2X, \quad (5)$$

where X is the halogen atom.

The organic halide formed in the reaction can reversibly react with $W(III)L_2X$ [schemes (1), (5)]. This results in regeneration of radicals which can react with the monomer to form propagating chains [scheme (2)]. Taking into account the kinetic features of MMA polymerization in the presence of $W(IV)L_2X_2$ in DMF, and also the molecular-weight characteristics of the synthesized polymers, we can conclude that this chain-transfer agent takes a direct part in the step of chain propagation by the RATRP mechanism.

CONCLUSIONS

(1) Bis(isopropylcyclopentadienyl)tungsten dichloride exerts a significant effect on the kinetic param-

eters of methyl methacrylate polymerization and molecular-weight characteristics of polymethyl methacrylate at temperatures similar to those of commercial synthesis of this polymer (70°C).

(2) The controlling effect of the organotungsten compound is associated with a reversible change in the oxidation state of the metal in the course of the polymer synthesis.

Abstract—The possibility of preparing polymers based on *N*,*N*-diallylhydrazine derivatives by allylation of carboxylic acid hydrazides was considered.

The range of nitrogen-containing allyl compounds from which linear macromolecular polymers can be produced by radical homo- and copolymerization is very limited. Actually, only quaternary diallylammonium salts are widely used as monomers for synthesis of polyfunctional polymers [1–3]. At the same time, such polymers exhibit unique properties [4–6], which makes it urgent to search for and study nitrogen-containing allyl monomers of new structural types. In this respect, promising monomers are *N*-allylated derivatives of carboxylic acid hydrazides. Hydrazides of aliphatic acids have flotation properties [7], and hydrazides of naphthenic acids are selective extracting agents for copper [8, 9].

Preparation of derivatives of *N*,*N*-diallylhydrazines (DAHs) is the way not only to produce new polyfunctional polymers but also to impart to them certain physicochemical and biological characteristics typical for the initial compounds. The first stage on this way is to establish the possibility of involving these derivatives in radical polymerization.

Here we attempted to prepare polymers based on DAHs, in particular, *N*,*N*-diallyl-*N*′-acylhydrazine (DAAH), *N*,*N*-diallyl-*N*′-propanoylhydrazine (DAPH), and *N*,*N*-diallyl-*N*′-benzoylhydrazine (DABH).

EXPERIMENTAL

N,*N*-Diallylhydrazines were synthesized by the reaction of hydrazides of aliphatic and aromatic acids with allyl halides (AllHlg):

$$R–CO–NH–NH_2 + 2AllHlg \rightarrow R–CO–NH–N(All)_2 + 2HHlg,$$

where R is CH_3, C_3H_7, or C_6H_5.

The monomers used for the synthesis of copolymers were acrylonitrile (AN), acrylamide (AA), methyl methacrylate (MMA), vinyl acetate (VA), *N*-vinylpyrrolidone (VP); the initiators were azobis(isobutyronitrile) (AIBN), potassium persulfate (PP), and benzoyl peroxide (BP); the solvents were methanol, chloroform, and dimethyl sulfoxide. After purification by common procedures, the characteristics of all chemicals were in good agreement with published data. Sulfur dioxide was dried by passing through concentrated H_2SO_4 and freshly calcined $CaCl_2$.

Copolymerization of DAHs with vinyl monomers (VMs) was carried out in a vacuum in the bulk and in a solution in the presence of radical initiators (for polymerization conditions, see Table 1).

Copolymerization of DAHs with sulfur dioxide was carried out in a glass reactor by the procedure described in [10] (for polymerization conditions, see Table 2). The polymers were dried by twofold reprecipitation from a solvent to a precipitant chosen individually for each system. The purified polymers were dried in a vacuum at 50°C to constant weight. The compositions of copolymers were evaluated from the results of elemental analysis. The ^{13}C NMR spectra were recorded on a Bruker AM-300 spectrometer operating at 75.46 MHz. DMSO-d_6 and D_2O were used as solvents, and tetramethylsilane and DSS, respectively, as internal references. The UV spectra were recorded on a Shimadzu UV-VIS-NIR 3100 spectrophotometer. The composition of the complex was determined by the method of isomolar series [11].

Under usual conditions, DAHs practically do not enter into homopolymerization by a free-radical mech-

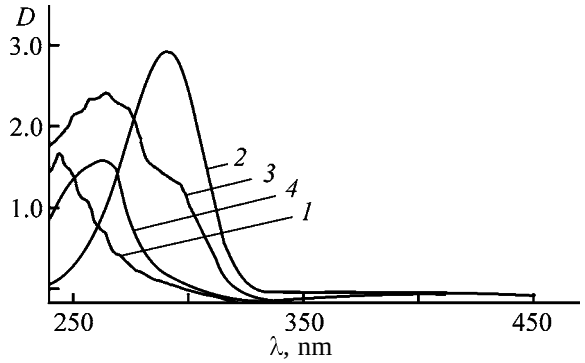
anism. The activity of DAHs somewhat increases on adding protic and aprotic acids, which is a well-known procedure for activation of allyl monomers. However, in this case, e.g., in polymerization of DAAH in the presence of HCl, H_3PO_4, and $ZnCl_2$ at the ratio DAH : acid = 1 : 1.2 (T = 90°C, initiator AIBN, 30 h), the yield of the homopolymer did not exceed 6–10%.

The use of DAHs in radical copolymerization with VMs containing both electron-acceptor (AA, AN, and methacrylic acid) and electron-donor (VA and VP) substituents is significantly more efficient. Copolymerization of DAHs (M_1) with vinyl monomers (M_2) proceeds at a noticeable rate at a temperature above 80°C and initiator concentration of no less than 2.5 wt %. DAHs are less active than vinyl monomers.



Electronic absorption spectra of solutions in chloroform. (*D*) Optical density and (λ) wavelength. (*1*) DAAH ([DAAH] 1×10^{-1} M), (*2*) SO_2 ([SO_2] 1×10^{-3} M), (*3*) a mixture of DAAH and SO_2 ([DAAH] 5×10^{-3} M, [SO_2] 5×10^{-4} M), and (*4*) difference of spectrum *3* and half-sum of spectra *1* and *2*.

Copolymers of all the monomer pairs are enriched with VM units as compared to the composition of the initial mixture (Table 1). At the equimolar ratio of the monomers in the initial mixture, the content of DAHs in the copolymers (excluding the copolymer with VA) does not exceed 20 mol %.

In spite of high temperature (90°C) and high initiator concentration (3 wt %), the rate of copolymerization of DAHs with VM is low, especially at the content of M_1 in the reaction mixture exceeding 50 mol %.

DAHs are significantly more active in copolymerization with sulfur dioxide having high electron-acceptor power. All the DAHs copolymerize with SO_2 to form alternating copolymers with equimolar composition, irrespective of the ratio of the monomers in the initial mixture, solvent and initiator nature, and reaction temperature (Table 2). The constancy of the composition of the copolymers, irrespective of the ratio of the monomers in the reaction mixture, suggests that copolymerization of DAHs with SO_2 proceeds with formation of complexes [DAH···SO_2]. The UV spectra of a mixture of DAAH with SO_2 in chloroform contain a new band of charge transfer with λ_{max} = 263 nm (for SO_2, λ_{max} = 275.9 nm), suggesting formation of a donor–acceptor complex (see figure).

The reaction conditions do not affect the composition of copolymers but significantly affect the copolymer yield (Table 2). In particular, higher yields of copolymers of DAH with SO_2 were obtained with AIBN and PP as an initiator; with BP, there was virtually no copolymerization.

In the systems under consideration, the yields of polymers in copolymerization in the bulk do not exceed 50% even at extremely long reaction time (up to 10 h). In copolymerization in a solution, the yield of copolymer depends on the solvent. In particular, in chloroform the yields of DAPH copolymers are higher than those in the bulk and can reach 70%.

The structure of the copolymers was determined by ^{13}C NMR. In the spectra of copolymers (Table 3) of derivatives of DAHs with SO_2 (nos. 6–8), along with the signals of substituent atoms at the –NHR group, where R is CH_3, C_3H_7, and C_6H_5, there are only three pairs of signals corresponding to two methylene and one methine groups of the polymer chain, which are stereoisomeric. This suggests the structural homogeneity of the copolymers. Two pairs of low-field triplets correspond to *cis*/*trans* stereoisomeric carbon atoms $C^1C^{1'}$ and $C^3C^{3'}$; two doublet signals correspond to stereoisomeric C^2 and $C^{2'}$ atoms of the heterocycle. The relative content of *cis*/*trans* stereoisomeric units of DAH was estimated from the ^{13}C NMR spectrum to be approximately 4/1. The chemical shifts of the above carbon atoms, considering the additive effect of substituents, $–SO_2–$ and NH–R groups, are close to the chemical shifts of the corresponding atoms of the copolymer of *N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride with SO_2 [10]. The chemical shifts of VM units in the spectra of the copolymers are practically the same as those for the corresponding carbon atoms of their homopolymers [12–16]. In the spectra of the copolymers with broad-band proton decoupling, similarly to the spectra of VM homopolymers, there are configuration multiplets belonging to pseudo-asymmetric C^7 atom and adjacent α and β carbon nuclei. These data suggest that the copolymer contains VM blocks alternating with separate DAH units.

The resulting copolymers are soluble in polar solvents such as DMSO and DMF. Copolymers of DAAH with SO_2, AA, and VP are also soluble in water. Preliminary tests showed that copolymers of DAAH with SO_2 have flocculation properties, in particular, in precipitation of $Cu(OH)_2$.

CONCLUSIONS

(1) Derivatives of diallylhydrazines are a new structural type of *N*-allylated monomers promising for production of polyfunctional polymers, among them water-soluble, in radical polymerization.

(2) Diallylhydrazines enter into copolymerization reactions with participation of both double bonds to

Abstract—Thermal transformations of sodium 2-acrylamido-2-methylpropanesulfonate–*N*-vinylpyrrolidone copolymers of various chemical compositions were studied by thermogravimetric, differential thermal, and thermomechanical analyses within 20–600°C in air. The thermal degradation parameters in various temperature ranges were estimated, as well as the heat resistance of the copolymers.

Random copolymers of sodium 2-acrylamido-2-methylpropanesulfonate (Na-AMS) with *N*-vinylpyrrolidone (VP) are of great technical and medical importance owing to high flocculation [1] and adhesion and antistatic [2], as well as thickening and complexing powers. During preparation, dissolution, and application, these copolymers can be subjected to various thermal impacts, but thermal properties of the copolymers are studied inadequately. Only thermal degradation of poly-2-acrylamido-2-methylpropanesulfonic acid (H-PAMS) [3, 4] and its salts with single- and double-charged cations [5], as well as of poly-*N*-vinylpyrrolidone (PVP) [6, 7], was reported.

In this work, we characterize the thermal properties of Na-AMS–VP copolymers of various compositions in the temperature range 20–600°C and compare them with those for homopolymers, Na-PAMS and PVP.

EXPERIMENTAL

Copolymers of Na-AMS with VP, as well as Na-PAMS, were prepared by radical (co)polymerization in aqueous solutions at pH 9 and 50°C, initiated with potassium persulfonate, and PVP, by bulk polymerization at 60°C, initiated with azobis(isobutyronitrile). The procedure of synthesis of (co)polymers was identical to that described in [8]. The resulting (co)polymers were precipitated into acetone, washed with acetone, and vacuum-dried at 50°C to constant weight. Table 1 presents the molecular characteristics of the (co)polymers.

The content of the Na-AMS units in the Na-AMS–VP copolymers was estimated from the sulfur content determined by elemental analysis [9]. The molecular weight MW of the copolymers was estimated from the intrinsic viscosity [η], for which the Mark–Houwink equation [η] ~ MW holds. The intrinsic viscosity [η] was measured in 0.5 M NaCl at 25°C in a VPZh-3 capillary viscometer (capillary diameter 0.56 mm). The intrinsic viscosity [η] was determined from the

linear plot of (η_{sp}/c_p) vs. c_p, where c_p is the copolymer concentration, and $[\eta] = \lim(\eta_{sp}/c_p)$ at $c_p \to 0$.

The differential thermal (DTA) and thermogravimetric (TG) analyses were carried out on an MOM derivatograph (heating rate 3 deg min^{-1} in air; 20-mg weighed portion).

Thermomechanical analysis (TMA) was carried out on a modified Kargin balance at a load of 100 g mm^{-2} and a heating rate of 3 deg min^{-1} in air. The (co)polymer samples were 2-mm-thick films.

The qualitative and quantitative transformations of the (co)polymers in air at 20–600°C were determined from analysis of the DTA and TG curves (see Figs. 1a and 1b for copolymers of Na-AMS with VP and Figs. 2a and 2b for Na-PAMS and VP homopolymers). Table 2 presents the temperature ranges and the mass loss percentages for thermal degradation of the polymer samples. Figures 1 and 2 and Table 2 suggest that thermal transformations of Na-AMS–VP copolymers and PVP include two, and those of Na-PAMS, three stages. According to the TG curves (Figs. 1a and 2a) and to Table 2, heating of the polymer and copolymer samples is accompanied by gradual mass loss from 40–50 to 150°C, followed by a plateau extending to 295–350°C, depending on the specific polymer sample.

The mass loss recorded in the first stage of degradation for all the polymer samples can, evidently, be due to release of water and volatiles, as well as to partial thermal and (possible in air) thermooxidative degradation of the (co)copolymers. These assumptions were confirmed by identification of the products of thermal degradation of H-PAMS [3, 4] and of depolymerization of PVP within 230–270°C [6]. Also, we did not rule out release of ammonia, yielded by imidization, in the first stage of degradation. This assumption was confirmed by identification of the products of thermal degradation of H-PAMS [3] and polyacrylamide [10].

Further heating leads to the second stage of degradation, when the DTA curves for all the copoly-

		2	350–560	100			

* T_{10}, T_{50} are temperatures corresponding to 10 and 50% mass loss, respectively; T_{soft} is the softening point.

meric (Fig. 1b) and polymeric samples (Fig. 2b) exhibit clear endothermic peaks with maxima at various temperatures within 300–405°C, depending on the specific sample. This results in substantial acceleration of the mass loss by copolymers (Fig. 1a) and polymers (Fig. 2a). Above 310–435°C, depending on the specific sample, the mass loss by Na-AMS–VP copolymers and PVP tends to decelerate. At the same time, for Na-PAMS, the third stage of degradation began above 500°C, and the mass loss accelerated again.

More profound, compared to the first stage, transformations of the (co)polymers in the second stage of thermal degradation suggest intensified thermal and thermooxidative degradation, as seen from the DTA and TG curves. This process involves cleavage of the main chains of the macromolecules and imide rings formed in the first stage of degradation. This is accompanied by release of various liquid and gaseous products, in accordance with the published data on thermal degradation of H-PAMS [3, 4] and its salts [5], as well as of PVP [6, 7]. At 500–600°C we observed formation of an insoluble carbon-like powder in all cases.

From the TG curves (Figs. 1a and 2a), we determined the temperatures corresponding to 10 (T_{10}) and 50% (T_{50}) mass loss as the characteristics of the heat resistance of the (co)polymers. The T_{10} and T_{50} parameters are listed in Table 2. Comparison of the T_{10} parameters shows that, at low degradation temperatures, sample nos. 2 and 3 of Na-AMS–3VP copolymers are the most thermally stable among the (co)polymer samples studied by us. Evidently, enhanced thermal stability of sample nos. 2 and 3 having approximately equimolar composition is due to the donor–acceptor interactions between the Na-AMS and VP units in the macromolecules (Na-AMS has a medium electron-acceptor, and VP, a medium electron-donor power). At higher temperatures, as judged from the T_{50} parameters (Table 2), the copolymers become less stable than the homopolymers [except for sample no. 2 having the highest MW among the samples studied by us (Table 1), which is responsible for its slightly higher T_{50} compared to Na-PAMS]. A decrease in the thermal stability of the copolymers at high temperatures is, evidently, due to degradation of the donor–acceptor complexes between the Na-AMS and VP units in the macromolecules.

Figure 3 shows the TMA curves recorded at 20–200°C. It is seen that the strain tends to increase in the course of heating for all the samples. This is due to "defrosting" of the segmental activity of the macromolecules, when softening occurs at the softening point and co(polymer) converts from the glassy to hyperelastic state. Further heating does not change the strain, and the polymer degradation temperature corresponds to the upper limit of the hyperelastic state. Based on Fig. 3, we estimated the softening points (Table 2), which proved to be slightly higher for the copolymers than for the polymers. The highest

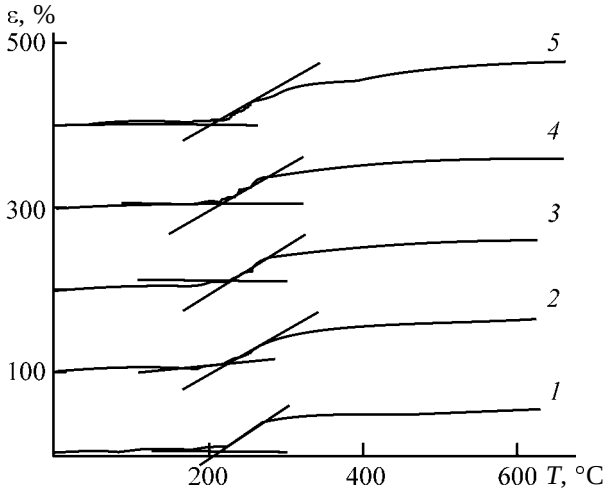

Fig. 3. TMA curves for (*1*) Na-PAMS, (*2*–*4*) Na-AMS–VP copolymers, and (*5*) PVP. (ε) Strain and (*T*) temperature. Sample no.: (*1*) 1, (*2*) 2, (*3*) 3, (*4*) 4, and (*5*) 6.

softening points were recorded for copolymeric sample no. 2. This can be due to formation of donor–acceptor complexes between the Na-AMS and VP units in the macromolecules. However, it is difficult to derive a correlation between the softening point and the chemical composition of the copolymer macromolecules because of the difference in the MWs of the samples (Table 1).

CONCLUSION

The differential thermal, thermogravimetric, and thermomechanical analyses of the copolymers of sodium 2-acrylamido-2-methylpropanesulfonate with *N*-vinylpyrrolidone and of the corresponding polymers in air at 20–600°C showed that, at low temperatures, the thermal stabilities and softening points of the copolymers with approximately equimolar compositions are higher than for the other samples studied, but at high temperatures this trend is lost.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Optimization of Polymer-Analogous Transformations in Grafted Chains of Polycaproamide–Polyglycidyl Methacrylate Copolymers

I. V. Lavnikova, V. F. Zheltobryukhov, and A. E. Godenko

Volgograd State Technical University, Volgograd, Russia

Received December 17, 2003; in final form, April 2004

Abstract—Mathematical simulation and optimization of graft polymerization and polymer-analogous transformations in grafted chains of polycaproamide–polyglycidyl methacrylate copolymers were carried out.

A great number of ion-exchange fibers based on graft polycaproamide–glycidyl methacrylate (PCA–GMA) copolymers were developed. Preparation of ion-exchange fibers involves two stages: (1) graft polymerization of PCA and PGMA and (2) polymer-analogous transformations (namely, phosphorylation) of grafted polyglycidyl methacrylate (PGMA) chains.

Polymer-analogous transformations in grafted chains of PGMA are an efficient way to introduce new functional groups into the side chain. In particular, phosphorylation of graft copolymers of PCA with introduction of phosphorus into the side chains of the macromolecule not only improves the characteristics of the initial fiber but also makes the polymer materials capable of ion exchange and sorption of transition metal ions from solutions [1–3].

Previous studies [4, 5] allowed determination of the main kinetic parameters affecting the yield of grafted PGMA and the efficiency of heterophase graft polymerization and polymer-analogous transformations of grafted PGMA chains with 1-hydroxyethylidenediphosphonic acid (HEDP) $C_2H_3(OH)_5(P{=}O)_2$. The kinetic parameters affecting the phosphorus content in the graft copolymer and transformation of α-oxide groups were found.

The aim of this work was to develop a mathematical model of synthesis of PCA–PGMA graft copolymers and subsequent polymer-analogous transformations in grafted chains of a certain composition (PGMA content 43–48%, phosphorus content in PCA–PGMA 2.8–3%). For this purpose, a mathematical model of the process was developed from the experimental data. This model was used for determination of the process parameters to obtain the required amount of PGMA and phosphorus in the graft copolymer. It was found that the main parameters affecting the yield of the graft polymer are concentration of Cu^{2+} X_1, concentration of H_2O_2 X_2, initiation time X_3, temperature of PCA initiation X_4, concentration of GMA X_5, concentration of emulsifying agent X_6, grafting temperature X_7, and duration of graft polymerization X_8. The process was evaluated by such an output parameter as the amount of grafted PGMA Y_1, since this parameter governs the content of α-oxide groups. Among the main parameters characterizing the second stage of the process in hand are concentration of HEDP in the solution X_9, reaction temperature X_{10}, and reaction duration X_{11}. The output parameter for the second stage of the process was the amount of phosphorus in graft copolymer Y_2, since this parameter governs the amount of sorption-active groups in the fiber.

To develop a mathematical model, we used the experimental data on the process. The initial data were brought to the dimensionless form using the parameter values averaged over the sample. In the subsequent discussion, by the process parameters X_i we will mean the normalized values of the variables.

We suggest to describe graft polymerization process by the product of polynomials and exponential functions of the above process parameters:

$$Y_1 = a_2 \exp(b_0 X_{11}^b)(b_2 X_2^2 + b_{21} X_2 + b_{31}) \exp(b_{30} X_3^b) \times (b_4 X_4^2 + b_{41} X_4 + b_{42})(b_5 X_5^2 + b_{51} X_5 + b_{52})(b_6 X_6^2 + b_{61} X_6 + b_{62})(b_7 X_7^2 + b_{71} X_7 + b_{72})[1 - \exp(d_1 X_8^2 + d_2 X_8)]. \quad (1)$$

The coefficients a_j, b_j, and d_j were selected so as to attain the best agreement between the calculated and

experimental data. For this purpose we minimized by the modified Newton method the standard deviation $(Y_1^{exp} - Y_1^{calc})^2$, where Y_1^{exp} are experimental data and Y_1^{calc} are the corresponding estimated parameters [formula (1)].

In a similar manner, for phosphorylation of graft chains of PGMA, the dependence was searched for in the form

$$Y_2 = a_0(a_1X_9^2 + a_2X_9 + a_3)(b_1X_{10}^2 + b_2X_{10} + b_3) \times [1 - \exp(d_1X_{11}^2 + d_2X_{11})]. \quad (2)$$

The same procedure was used for choosing the coefficients.

It should be noted that the standard deviation obeys the Gauss law and does not exceed 20%. This fact allows conclusion that data obtained by formulas (1) and (2) are in satisfactory agreement with experimental data.

The best quality of modified PCA is obtained at the amount of the grafted component of 43–48% and phosphorus amount in the graft copolymer of 2.8–3%. In this case, it is evident that material and power consumption will be characterized by the process parameters X_i, i = 1, 11, and a decrease in these parameters will result in a decrease in the above expenditures in production of modified PCA. Thus, the problem of optimization involves choice of the process parameters so that

$$X_i \rightarrow \min(i = 1, 11),$$
$$Y_i \rightarrow \max(i = 1, 2). \quad (3)$$

To realize the computation procedure of choosing the optimal process parameters, we introduced Q-criterion of quality, which is an integral parameter characterizing to what extent the specific set of parameters and the results obtained correspond to our views on the process quality. The maximum value of the quality criterion is obtained when all parameters reach maximum and minimum, respectively [formula (3)]. If one of the parameters lies out of the tolerable interval $[X_i^0, X_j^{\#}]$, the quality criterion Q abruptly decreases.

For each of the parameters (3), in turn, we determined the local quality criterion g_i, where i = 1, 13 (partial qualities) are numerical characteristics, which increase to 1 when conditions (3) are obeyed and decrease to 0 when these conditions are not obeyed.

The total quality of the process is defined as the exponential mean of its partial qualities [6]:

$$Q = -\ln\left\{\left[\sum_{i=1}^{13}\exp(-g_i)\right]/13\right\}. \quad (4)$$

Thus, the optimization problem is reduced to the search for the maximum of the function Q, which depends only on the process parameters X_i (i = 1, 11), since the parameters Y_i (i = 1, 2) are related to X_i by (1) and (2).

Let us consider that partial qualities g_i (i = 1, 11) are polynomial functions of the corresponding process parameters:

$$g_i = 1 - \left(\frac{X_i - X_i^{\#}}{X_i^{\#} - X_i^0}\right)^k, \quad (5)$$

where X_i^0 and $X_i^\#$ are so-called "mediocre" and "excellent" values of parameter X_i, governing the interval of desirable values.

For qualities corresponding to the amount of the resulting product in the first and in the second stage, respectively, we take the following functions of partial qualities:

$$g_{12} = \frac{X_{12} - X_0}{X_{12}^\# - X_0},$$

$$g_{13} = \frac{X_{13} - X_0}{X_{13}^\# - X_0}. \quad (6)$$

The "mediocre" and "excellent" values taken for optimization of the process are listed in the table.

The problem of searching the maximum of the target function Q is by far extremal in the range specified by the boundaries of possible values of process parameters. To solve the extremal task, we used the method of gradient descent.

As a result of the calculations we obtained the optimal values of process parameters in the framework of the considered model (see table), which provide preparation of high-quality product with the minimal expenditures.

EXPERIMENTAL

PCA was modified by graft polymerization in GMA monomer emulsion (2.35 M) for 60 min at 70°C with the Cu^{2+}–H_2O_2 redox initiating system. The graft copolymer was modified by treatment with HEDP (4.86 M) in a flask with a reflux condenser for 300 min at 90°C.

CONCLUSIONS

(1) The constructed mathematical model provides good agreement between the calculated and experimental data.

(2) The mathematical model allows determination of the process parameters providing preparation of polycaproamide–polyglycidyl methacrylate graft copolymers with specified characteristics.

(3) The optimization of the process allows determination of the process parameters providing the value of the target function close to 1 (0.972).

Russian National Library, St. Petersburg, Russia

Received January 12, 2004

Abstract—Molecular characteristics of cellulose during accelerated aging were studied over wide temperature and time ranges. Also studied were mechanical properties of model samples of paper made of cotton, sulfate, and sulfite cellulose. Interrelation of the molecular characteristics of cellulose and strength properties of paper was investigated.

In the recent 20 years, nonpaper information carriers such as compact disks and microfilms found wide use in storage and use of reference, information, and bibliographical literature in libraries and archives. At the same time, there are contradictory published data concerning the lifetime of the information stored on these carriers (from 5 to 100 years). Thus, preparation of high-strength acid-free paper suitable for long-term (up to 500 years) storage of information is still urgent.

In this work, we studied the trends in variation of the molecular characteristics of cellulose and strength properties of paper thereof under accelerated thermal aging.

EXPERIMENTAL

We studied model paper samples manufactured under pilot conditions at the Goznak factory on a 38-cm-wide planar-grid paper-making machine. Cotton (C), sulfate (SFA), and sulfite (SFI) celluloses served as semifinished products. The paper was made without use of sizing and bleaching substances and fillers; therefore, model paper samples were all-cellulose (sulfate bleached, sulfite bleached, or cotton) fiber compositions. After conditioning, the paper samples were placed into hermetically sealed glass tubes and kept in an air thermostat at 80, 100, 120, 150, and 180°C for 3, 9, 12, 18, and 30 days.

The molecular weight M of cellulose was determined from the intrinsic viscosity $[\eta]$ measured in a Cadoxen solution at 25°C, by the formula [1]

$$[\eta] = 3.85 \times 10^{-4} M^{0.76}.$$

The functional groups in the cellulose samples before and after accelerated aging were determined photocolorimetrically (carbonyl groups, by the Subolx technique, and carboxy groups, by the Weber technique) [2]. The mechanical characteristics of paper were determined according to appropriate GOSTs (State Standards), namely, the folding resistance at a tension of 4.9 N according to GOST 13525–80, and the breaking force according to GOST 13525.1–79.

It is essential to study how molecular characteristics of cellulose paper vary during aging, since the molecular weight M and the chemical composition of cellulose affect the process characteristics of the resulting paper.

Table 1 presents the calculated intrinsic viscosities $[\eta]$ and molecular weights M of the cellulose samples, calculated from the relative viscosities of solutions η_{rel} measured in the chosen modes of accelerated thermal aging of the paper samples in the tubes. In the case of the SFI samples, we failed to measure the relative viscosity under accelerated aging because of a low velocity of the solution outflow, close to that of the solvent outflow. Table 1 suggests that the initial molecular weights M of the cellulose samples tend to decrease during accelerated aging, most rapidly in the case of C cellulose. As known, polymers with high molecular weights degrade more rapidly that those with lower molecular weights under identical conditions, which is true of cellulose as well. The specific pattern of decrease in the molecular weight of the samples studied was explained by the fact that the supramolecular structure of cellulose comprises various ordered domains (amorphous and crystalline).

* τ is aging time.

For example, a sharp decrease in *M* in the initial stage of depolymerization occurs initially in amorphous domains, which are more sensitive to thermal impact than crystalline domains.

Using the data from Table 1, we constructed the log[η] vs. log*M* plots (Fig. 1). For cellulose types studied in this work (C, SFA, and SFI), these plots are linear for *M* within 15–540 kDa (for the relative viscosity determined accurately to within 10%). The viscometrically estimated molecular weights of cellulose agree well with the published data. For example, a number of researchers [3–5] reported similar [η] vs. *M* dependences recorded in Cadoxen for both nonfractionated samples of cellulose and their close-cut fractions; these plots were also linear for molecular weights of up to ~600 kDa. However, for cotton cellulose and cotton linter samples with higher molecular weights ($M \approx 1000$ kDa) the log[η] vs. log*M* plot tended to deviate from linearity, which was explained in [5] by deteriorated thermodynamic quality of the solvent.

As known, natural aging of paper in air involves slow oxidation with oxygen, which somewhat weakens the 1–4 glycoside bonds without rapid degradation and significant decrease in the molecular weight of cellulose. Accelerated thermal aging can be run in several ways: in air thermostats under natural air circulation at 102°C (TAPPI standard), at 100°C [6, 7], in hermetically sealed glass tubes (sealed am-

* The degrees of polymerization *P* determined in this work during aging in tubes.

pules) [8], and in climatic chambers with controllable temperature and relative air humidity [9].

Paper aging conditions predetermine the physicochemical reactions of degradation of cellulose macromolecules. When the temperature in an air thermostat exceeds 100°C, the paper rapidly loses moisture. Therefore, this procedure is regarded as "dry" aging, and degradation mechanism is conventionallytreated as thermoooxidative. In a climatic chamber, the material is exposed simultaneously to two factors, heat and moisture (modern chambers are additionally supplied with UV radiation sources). Under these conditions, aging follows two mechanisms, thermooxidative and hydrolytic. From the chemical viewpoint, thermal degradation involves cleavage of the 1–4 glycoside bonds and oxidation of the hydroxy groups in the cellulose macrochains. Both reactions proceed simultaneously and are accelerated with rising temperature and increasing exposure time, thus decreasing *M* (or the degree of polymerization *P*).

Various authors showed that the extent of degradation depends not only on the temperature, time of heat treatment, and initial degree of polymerization of cellulose, but also on the composition and nature of the medium in which degradation occurs. Aging of paper made of C, SFA, and SFI cellulose, which is free from fillers and sizing agents, was studied by Belen'kaya and Alekseeva [10] and by Perl'shtein [11, 12] by the dry aging technique at 100°C in thermostats under natural air circulation.

Table 2 compares the data on variation of the degree of polymerization *P* of the samples in air, reported in [10–12], and during aging in tubes at identical temperatures (100°C). It is seen that *P* tends to decrease more rapidly under thermal aging in tubes than in air. The extent of degradation of C and SFA cellulose is greater (see the limiting *P* for 30-day aging). Therefore, paper in tubes ages (or suffers damage) more rapidly than in air. A possible reason is a decrease in the free oxygen concentration and simultaneous accumulation of thermal degradation products in the reaction medium in a closed space of tubes, which accelerates oxidative and hydrolytic degradation of the macromolecules. This effect is less pronounced in the case of SFI cellulose having a lower molecular weight; the limiting $P = 690$ for SFI cellulose agrees well with the published data.

Three hydroxy groups in the unit of cellulose make it very susceptible to oxidation, which modifies the chemical composition of the macromolecules via formation of carbonyl CHO– and carboxy COOH– groups at the C1, C2, C3, C4, and C6 atoms during natural aging of cellulose materials in air [13]. Oxidation is significantly accelerated under artificial thermal aging, which increases the content of the above-mentioned groups in the samples [7–14]. It should be noted that the contents of the CHO– and COOH– groups, reported by different authors, differ significantly depending on the specific analytical method [10, 13–15].

Table 3 lists the contents of the CHO– groups in cellulose for the samples of paper made of C, SFA, and SFI cellulose after thermal aging in tubes. The content of CHO– groups in the samples before and

after heat treatment tends to vary as C < SFA < SFI. These data agree with the available published data [7, 10, 13, 14, 16]. For example, Alekseeva and Belen'kaya [16] found a minimal content of the CHO– groups in cotton cellulose samples, and a maximal, in SFI cellulose samples. As the temperature increases to 100–120°C, oxidation is accelerated due to accumulation of the degradation products in tubes. This increases the content of the CHO– groups in cellulose for each aging time fixed. The scatter of data is the greatest for high temperatures (150–180°C), possibly due to release and accumulation of volatile degradation products. On the whole, our results agree with the published evidence of increase in the content of the functional groups in cellulose macromolecules under thermal aging.

Because of easy oxidation, virtually all cellulose materials contain a small amount of carboxy groups, along with the carbonyl groups. For example, C, SFA, and SFI celluloses contain 0.005, 0.047, and 0.053 mg g^{-1} COOH– groups, respectively [13]. Table 4 lists the contents of the COOH– groups of cellulose for the paper samples subjected to accelerated thermal aging in tubes. These results still remain to be interpreted, but it is seen that the content of the COOH groups of cellulose in the paper samples before and after aging is the lowest for the cotton paper and tends to vary as C < SFA < SFI. As the heating time increased from 3 to 30 days, the content of the COOH– groups either decreased or remained unchanged at all the temperatures.

A similar trend was revealed by Belen'kaya and Alekseeva [10], who attributed it to deceleration of oxidation and domination of decarboxylation reactions at high temperatures (above 100°C). Thus, our data suggest a change in the molecular characteristics and chemical composition (*M* and content of the functional groups) in macromolecules of C, SFA, and SFI cellulose upon degradation. In view of the fact that no other chemicals were applied in preparation of the model samples, we could trace the trends in variation of the estimated strength properties of the paper with the molecular weight *M* of cellulose. In this work, we estimated two indicators of the mechanical strength, namely, folding resistance *N* (*N* is the number of double folds at a load of 4.9 N) and breaking force *F*, N. Our mechanical tests showed the following. For the samples of paper from the C cellulose, *N* remained within 2400–2700 as the initial *M* decreased from 543 to 175 kDa. Similarly, as *M* decreased from 543 to 66 kDa, *F* remained virtually unchanged (75–80 N). Further decrease of *M* from 175 to 57 kDa caused *N* to sharply decrease to 1; *F* also decreased (from 80 to 15 N) as *M* decreased from 66 to 30 kDa.

* Content of carboxy groups before aging, mg g^{-1}: 0.005 for C, 0.034 for SFA, and 0.065 for SFI cellulose.

sharply decrease to 1; *F* also decreased from 95 to 38 N as *M* decreased from 120 to 33 kDa.

In the case of the samples of paper made of SFI cellulose with a lower molecular weight, a decrease in *M* from 220 to 70 kDa resulted in regular decreases in both strength indicators, namely, from 170 to 1 for *N* and from 75 to 56 N for *F*.

Figures 2 and 3 represent our results as the $\log N = f(\log M)$ and $F = f(\log M)$ plots. It is seen that, with decreasing molecular weight of cellulose due to degradation, the strength of the paper tends to decrease. For the C and SFA cellulose samples, whose molecular weights exceed that of SFI cellulose, we revealed the ranges of the molecular weights *M* within which *N* and *F* remained virtually unchanged. For example, the "limiting" molecular weight above which the mechanical strength was independent of *M* was estimated at ca. 175 kDa ($P \approx 1100$) for C cellulose and at ca. 140 kDa ($P \approx 860$) for SFA cellulose. An inflection in the $\log N$ vs. $\log M$ and *F* vs. $\log M$ plots can be due to degradation of various types of structural bonds (intra- and interfibrillar) during mechanical tests of the samples and to the morphological differences in their structure (length and flexibility of fibers). Belen'kaya *et al.* [6] and Sadovskaya and Blank [8] carried out a comparative study of the

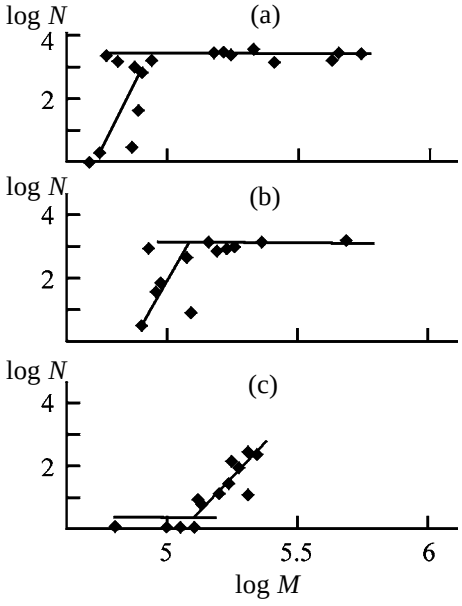

Fig. 2. Variation of the number of double folds *N* with the viscosity-average molecular weight *M* for model samples of paper made of (a) C, (b) SFA, and (c) SFI cellulose under thermal aging in tubes.

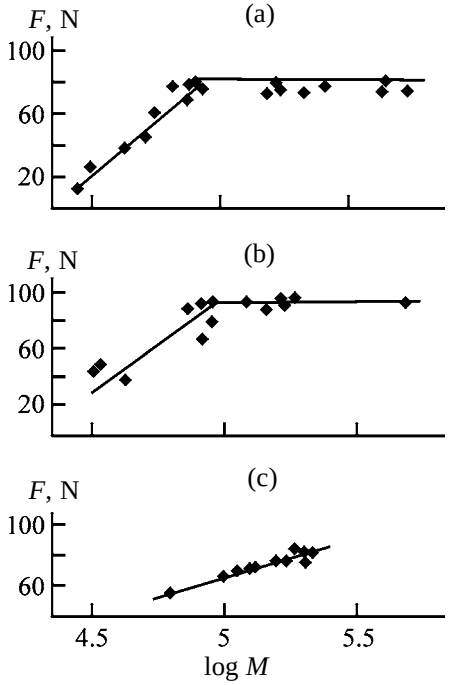

Fig. 3. Variation of the breaking force *F* with the viscosity-average molecular weight *M* for model samples of paper made of (a) C, (b) SFA, and (c) SFI cellulose under chemical aging in tubes.

mechanical properties of the paper made of C, SFA, and SFI cellulose under pilot conditions when subjected to accelerated thermal aging in closed tubes and in air. Despite certain differences in the procedures for determining the molecular weight of cellulose and strength of paper, we can also postulate, on the whole, a similar trend, namely, a thermal degradation-induced decrease in the mechanical strength of the paper samples; this trend is the most pronounced in the case of aging in tubes. Thus, our results supplement the previously revealed trends in variations of the chemical composition and the degree of polymerization of cellulose, as well as of the mechanical properties of paper, upon heat treatment.

CONCLUSIONS

(1) Accelerated thermal aging decreases the molecular weight M and modifies the chemical composition of the macromolecules of cotton, sulfate, and sulfite cellulose. Thermal degradation of the samples in tubes is faster than in air.

(2) At molecular weights above 100 kDa, the strength properties of the paper made of cotton and sulfate cellulose remain unchanged and tend to decrease with decreasing molecular weight of cellulose below this limit.

Abstract—The content, structure, and monosaccharide composition of polysaccharides recovered by sequential extraction with water, ammonium oxalate solution, and sodium hydroxide solution from wastes from production of a series of buckwheat strains were studied. Data characterizing the raw material (ash residue), aqueous, oxalate, and alkaline extracts (list of metals and their concentration in solution), polysaccharides (structure, content of metals absorbed from solution), and insoluble residue of the raw material (weight of the residue) are presented.

In the course of growing and cleaning buckwheat grains, large amounts of wastes are formed (straw, husk, fine particles of grains). These wastes can be considered as valuable renewable raw materials for chemical, food, and pharmacological industries, suitable for production of polysaccharides [1–3], cellulose [4], dyes and food additives [5, 6], furfural [1], and drugs [7]. To develop a scheme for integrated processing of buckwheat production wastes, it is necessary to know the compositions of the raw materials depending on the plant strain and on the site of its growth. Available data on this matter are insufficient.

In this work, we studied the composition and content of carbohydrates from husk and straw of a series of buckwheat strains grown in Primorskii and Krasnoyarsk krais.

EXPERIMENTAL

Polysaccharides (PSs) were recovered from buckwheat husk (BH) and straw (BS) by sequential extraction with water, ammonium oxalate solution, and sodium hydroxide solution; their qualitative and quantitative monosaccharide compositions were determined. Husk and straw samples (particle size ≥2 and ≤10 mm, respectively) were washed with water and dried in air to constant weight.

Samples (70 g) of BH and BS were sequentially treated with water and 0.5 N solutions of ammonium oxalate and sodium hydroxide. Water was added to a raw material sample to S : L = 1 : 10 by weight, and the mixture was heated on a boiling water bath for 3 h. The solution was filtered, concentrated on a rotary evaporator, and centrifuged (4500–5000 rpm, 20–25 min) to remove the residual raw material; polysaccharides were precipitated with a fourfold volume of acetone. The resulting precipitate was separated by centrifugation, dissolved in water, and lyophilically dried to obtain water-extractable PSs.

To the solid residue after extraction with water, a 0.5 N solution of ammonium oxalate was added to S : L = 1 : 10, and the mixture was heated on a water bath under the same conditions as described above. The solution was filtered and dialyzed against running water for 2–3 days and against distilled water for 1–2 days, after which it was concentrated on a rotary evaporator, and a fourfold volume of acetone was added. The precipitate was separated by centrifugation, dissolved in water, and lyophilically dried to obtained oxalate-extractable PSs.

The solid residue after extraction with water and ammonium oxalate was suspended in a 0.5 N NaOH solution and heated on a water bath for 2 h. The solution was separated by centrifugation and worked up as described above to obtain alkali-extractable PSs.

The qualitative and quantitative monosaccharide compositions of the isolated PSs were determined after their acid hydrolysis, which was performed with 1 N trifluoroacetic acid (TFA) at 100°C for 4–5 h. Analysis was performed by paper chromatography

* Monosaccharides: (Rha) rhamnose, (Ara) arabinose, (Xyl) xylose, (Man) mannose, (Glc) glycose, (Gal) galactose, and (Int) inositol; uronic acids: (GalA) galacturonic and (GlcA) glucuronic; structure: (a) amorphous and (c) crystalline.
** Soluble + insoluble PS.

(PC), gas–liquid chromatography (GLC), and gas chromatography–mass spectrometry (GC–MS), after conversion of the polyols to acetates. The descending PC was performed on Filtrak FN-12 paper in the solvent system 2-butanol–pyridine–water (6 : 4 : 3 by volume). The monosaccharides were detected by treatment with an alkaline solution of silver. Uronic acids were detected by GLC in the form of methyl glycoside acetates after methanolysis of PSs (acetyl chloride : methanol 1 : 10 by volume, 100°C, 7–8 h) followed by acetylation. Gas–liquid chromatography was performed with an Agilent 6850 chromatograph (the United States) equipped with a flame-ionization detector; an HP 5MS capillary column (30 m × 250 μm) was coated with 0.25 μm of 5% phenylmethylsiloxane; the temperature schedule was as follows: 150°C, 1 min; heating to 230°C, 3 deg min^{-1}; 230°C, 10 min. The GC–MS analysis was performed with a Hewlett–Packard 6890 chromatograph (the United States) connected to a Hewlett–Packard 5973 mass spectrometer (the United States). The column and temperature schedule were the same as in the GLC analysis.

Data on the PS structure were obtained by X-ray phase analysis (XPA) on a DRON-2.0 diffractometer (CuK_a radiation) by the standard procedure.

Data on PSs recovered by sequential extraction in stepwise hydrolysis of the raw material from buckwheat production wastes are listed in Table 1.

It should be noted that, when recovering alkali-extractable PSs from the raw mateiral and water-extractable PSs from BS-7, the PS precipitate formed on adding a fourfold volume of acetone to the extract did not fully dissolve in water again; therefore, the soluble PSs (supernatant) and PSs insoluble in water (precipitate) were lyophilically dried separately. The total yield of these polysaccharides is given in Table 1, with the monosaccharide composition given only for the soluble fraction.

The PS content depends on the raw material (husk or straw) and plant strain. The total yield of PSs from buckwheat husk varies from 3.2 (BH-10) to 6.3 wt % (BH-6) based on the raw material, and that from buckwheat straw, from 7.6 (BS-4) to 12.2 wt % (BS-7).

The highest yield of PSs from buckwheat wastes in all the cases is attained in the first extraction (with water) (Table 1). The product color depends on the raw material and extractant, being white, light brown,

Cu^{2+}	$(0.4–2.8)\times10^{-4}$	$(0.2–0.5)\times10^{-4}$	3.5×10^{-5}–4.1×10^{-4}	$(3.1–5.1)\times10^{-5}$

or dark. According to XPA, the polysaccharides have an amorphous or crystalline structure, and the majority of PSs extractable with oxalate have mixed amorphous-crystalline structure.

Polysaccharides extractable with water and oxalate from all the BH samples and from BS-4 have increased glucose content. All the PSs extractable with alkali have a more complex monosaccharide composition and contain residues of rhamnose, arabinose, xylose, mannose, glucose, and galactose. Water-extractable straw PSs (BS-4 and BS-7) contain a significant amount of inositol (17 and 31 mol %, respectively). In some other polysaccharides studied, it was detected on the trace level.

All the recovered PSs were analyzed for the presence of uronic acids (Table 1). The major component among uronic acids is galacturonic acid (GalA). Glucuronic acid (GlcA) was detected in trace amounts and not in all the PSs studied. All the water-extractable PSs, from both husk and straw, have a low content of uronic acid, except BS-7 in which the content of galacturonic acid is comparable with that of hexoses. On the contrary, oxalate-extractable PSs from buckwheat husk and straw are characterized by a high content of uronic acids, and in BH-6, BS-4, and BS-7 polysaccharides the GalA content substantially (by a factor of 2–4) exceeds the total content of hexoses. In soluble alkali-extractable PSs, as in water-extractable PSs, the content of uronic acids (GalA and GlcA, with GalA apparently prevailing) is lower than in the oxalate-extractable PSs from the same sources. Insoluble alkali-extractable PSs, like oxalate-extractable PSs, contain a large amount of galacturonic acid, especially straw PSs.

Available data on properties of PSs from buckwheat processing wastes are extremely scarce. Dudkin and Ozolina [2] reported on synthesis of carboxymethyl cellulose from buckwheat husk; this product has already found use in medicine [7]. It is also known that many PSs from higher plants exhibit a wide spectrum of biological activity: immunomodulating, antiphlogistic, antiviral, antitumor, anticomplementary, and wound-healing [8].

The insoluble BH and BS residue after three successive extractions is cellolignin, which can be used as a secondary raw material for production of various materials from plant fibers [9–13].

Data on the content of soluble substances recovered by sequential extraction from buckwheat husk and straw, on the weight of the insoluble residue, and on the ash residue after oxidative calcination of the raw material at 600°C are listed in Table 2. Oxidative calcination of the raw material and analysis of elements in the ash and extracts were performed according to [13].

The results show that the ash residue from BH is lower than from BS. The ash contained K, Ca, Mg, Na, Si, Zn, Mn, Fe, Al, Cu, Ni, Cr, and Ag; their content depended on the plant strain and kind of the waste (husk or straw). Potassium, magnesium, and calcium compounds prevailed in all the ash samples.

In extraction, metals are recovered to some extent along with organic substances. The list of the metals detected in the extracts and their concentrations are given in Table 3. The polysaccharides recovered from the extracts in the solid state take up some metals present in solution, as seen from Table 3. The insoluble residue after the extraction gives virtually no ash.

CONCLUSIONS

(1) The content of polysaccharides recovered from buckwheat processing wastes and their monosaccharide composition (qualitative and quantitative) depend on the kind of the raw material (husk or straw) and recovery procedure. The total yield of polysaccharides from buckwheat husk varies within 3.2–6.3 wt % based on the dry raw material, and that from buckwheat straw, within 7.6–12.2%.

(2) Polysaccharides extractable with water and oxalate from buckwheat husk and straw have increased glucose content. Polysaccharides extractable with alkali have a more complex monosaccharide composition and contain residues of rhamnose, arabinose, xylose, mannose, glucose, and galactose in different ratios depending on the raw material source.

(3) The inositol content in aqueous extracts from buckwheat straw is substantially higher (17–31 mol %) than in those from buckwheat husk, in which inositol was detected in trace amounts.

(4) Uronic acids are present in all the polysaccharides obtained, and their content is the highest in oxalate-extractable and insoluble alkali-extractable polysaccharides, especially in those recovered from buckwheat straw. The major component among uronic acids is galacturonic acid.

(5) In extraction of buckwheat husk and straw, metals are also recovered into solution and are then taken up by polysaccharides; the insoluble residue of the raw material gives virtually no ash.

CHEMISTRY OF FOSSIL FUEL

A Study of the Composition of Water Vapor Saturated Natural Gas, as Applied to Elucidation of the Nature of Vapor–Gas Thermal Phenomena

G. R. Anpilogova, R. A. Khisamutdinov, Yu. I. Murinov, R. M. Kharasov, I. Sh. Khuramshin, and E. G. Galkin

Received January 9, 2004

Abstract—The composition of water vapor saturated gases of various temperatures from reserve wells of Yangantau health resort was studied. The dependence of the concentration and composition of organic substances from the vapor condensate and of the extent of thermal oxidative degradation of the shale organic matter on the rock temperature in the heating zone was examined.

Unique vapor–gas thermal phenomena of the Yangantau mountain attract researchers' attention for more than two centuries. A number of hypotheses associating the origin of the thermal anomaly with exo- and endogenic factors were put forward; however, there is still no common opinion on the origin and evolution of this phenomenon [1, 2]. The component composition of the organic matter (OM) of Yangantau bituminous shales has not been studied. According to the elemental composition {C 78.35, H 6.84, (S + N + O) 14.51% [3]}, the OM of shales can be classed with asphaltites [4].

In this work, we studied the composition of water vapor saturated gas from wells by a set of spectral methods to elucidate the physicochemical processes occurring in the bulk of bituminous rocks of the mountain; also, we examined how the temperature conditions in a well affect the composition of the organic components of the vapor condensate (VC).

EXPERIMENTAL

We studied the gas and vapor (vapor condensate) components of water vapor saturated gases from reserve wells 22 and 27 (Yangantau health resort, Yangantau mountain, Salavat raion, Bashkortostan, Russia), differing in the maximal temperature of rocks along the well shaft (temperature in the heating zone T_{max} 81–86 and 140–150°C at a depth of 70.0 and 65.7 m, respectively [1, 5]). The gas phase was studied with a Varian MAT CH-5 mass spectrometer.

The concentration of nonferrous and ferrous metal ions in VC was determined by atomic absorption spectrophotometry on a Hitachi 508 device (acetylene–air flame). The pH values of the condensate were measured on an OP-211/1 pH meter with a combined glass electrode.

Moderately and slightly volatile organic components of the vapor condensates were isolated by sequential extraction from acidic (concentrate I), alkaline (concentrate II), and neutral (concentrate III) solutions [6]. The isolated extracts of organic substances are greasy yellow-brown substances with specific odor. Each concentrate was examined by spectroscopy and elemental analysis. The gas chromatographic–mass spectrometric (GC–MS) analysis of the concentrates was performed with an HP 5890 chromatograph equipped with an HP 5972A mass-selective detector and a 50 m × 0.20 mm capillary column with the grafted phase 5% methylphenylsilicone–95% methylsilicone rubber. The column was heated from 40 to 250°C at a rate of 10 deg min^{-1}. The data were processed on an HP ChemStation computer. The solvent was CCl_4. The spectra were identified using the artificial intellect program included in the HP ChemStation software. The index of agreement between the experimental mass spectra and published data in most cases was no less than 75%. At lower indices, the methods of spectrum–structure correlations [7] were used. The presence of the main classes of compounds identified by GC–MS was confirmed by the electronic absorption (Specord M40, acetonitrile, cell thickness

0.2 cm) and IR (300–4000 cm^{-1}, Specord M80, liquid film, KRS5 windows, assignment according to [8–10]) spectra.

The gas phase of water vapor saturated gases from wells 22 and 27 contains, along with air components, also methane + ethane (>0.5 vol % relative to the total gas sample volume) and increased amount of CO_2. The gas sample from well no. 27 also contained small amounts of CO and H_2 (0.052 and 0.028 vol %, respectively [5]). According to the observations, the content of CO_2, CO, and O_2 and the temperature of the water vapor saturated gas appreciably vary depending on the season and wind rose. In summer, the concentration of CO_2 grows, and that of O_2 decreases [11]. The increased content of CO_2 in water vapor saturated gases cannot be attributed to thermal decomposition of the inorganic components of bituminous rocks, $CaCO_3$ and $MgCO_3$ [3], since the maximal temperature of the heated rocks, 380°C [5], is considerably lower than the decomposition temperatures of $CaCO_3$ and $MgCO_3$ (825 and 500°C, respectively [12]). It is known that oxidation of petroleum residues with atmospheric oxygen is characterized by an increase in the oxygen uptake with temperature and by formation of CO_2 in the amount exceeding that of the forming CO [13]. Thus, the presence of CO and of increased amounts of CO_2 and the absence of hydrogen in the sample of the burned out rock (results of elemental analysis), taken on the southern slope of the mountain at the site of the outcrop of thermally altered rocks to the diurnal surface, confirms the hypothesis about thermal oxidative degradation of the organic matter of shale. On the southern steep slope of the Yangantau mountain, there are a lot of cracks arising from slope deformations and providing natural ventilation of the mountain with prevailing SW winds [11]. This provides the oxygen access to the heating sites to sustain the exothermic thermal oxidative reactions of the organic matter of shales.

The vapor condensates from wells 22 and 27 have pH 7.43 and 7.34, respectively. We found that, as T_{max} grows, the total content of organic matter in VC (46.3 and >124.5 mg l^{-1} for wells 22 and 27, respectively) and the content of phenols (0.8 and 25 mg l^{-1} for wells 22 and 27, respectively) increases. The unsuitability of vapor from well 27 for balneological purposes [14] is due to the high content of phenols.

The C : H atomic ratio in concentrates I (1 : 1.84 and 1 : 1.03 in wells 22 and 27, respectively), obtained under the conditions of predominant concentration of neutral substances, acids, and phenols [6], suggests lower content of aromatic substances in the concentrate from well 22.

The results of GC–MS analysis of concentrate I from well 27 show that its major organic component is phenol (21.2%); the other components are thiobenzoic acid (6.91%), *o*-, *p*-, and *m*-cresols (1.8%), 3-ethylphenol (<1%), and benzoic (0.6%), α-naphthoic (<1%), and octenoic acids (<1%). The IR spectrum of the concentrate confirms the presence of aromatic compounds [ν(CH) 3080 cm^{-1}; ν(C=C) 1600, 1580, 1496 cm^{-1}; δ(CH) 1176 cm^{-1} for mono- and 1,3-disubstituted rings, 808 cm^{-1} for 1,3- and 1,4-disubstituted rings and α-naphthoic acid] and thiobenzoic acid [ν(C=S) 1324 cm^{-1}]. The spectrum contains the bands ν(OH) at 3360, 3180 cm^{-1} of phenols and carboxylic acids; strong ν(C=O) bands of aliphatic carboxylic acids (1704 cm^{-1}) and carbonyl groups conjugated with an aromatic ring (1690 cm^{-1}, benzoic acid, aryl alkyl ketones); ν(COC) at 1288 and 1128 cm^{-1} belonging to carboxylic acid esters; δ(CH) at 936 cm^{-1} of unsaturated compounds of the type *trans*-$R^1CH{=}CHR^2$. The electronic absorption spectrum of this substance contains bands at 228 (s, sh) and 277 nm (w), assignable to the $\pi \rightarrow \pi^*$ electronic transitions in phenol and cresols (E_2 and *B* bands, respectively) and in benzoic acid (bands *K* and *B*, respectively) [8]. The presence of weak bands at 302 (sh) and 310 nm (sh) suggests the presence of compounds with a thiocarbonyl group ($\pi \rightarrow \pi^*$ and $n \rightarrow \sigma^*$ in the range 250–320 nm [8]) and of the naphthalene core (221, 286, 312 nm [8]).

The previous [5] study of the composition of organic microimpurities in VC from well 27 revealed also the presence of aliphatic (29 kinds) and aromatic carboxylic acids, nitrogen bases (quinolines, benzothiazoles, indoles, carbazoles), sulfur compounds (benzothiophenes, dibenzothiophenes), and hydrocarbons of the naphthalene and anthracene series. Among volatile organic compounds, toluene, ethylbenzene, chlorobenzene, xylene, carbon disulfide, and thiophene were detected in the vapor condensate.

In the organic matter isolated from vapor condensate from well 22 in the form of three concentrates, we identified by GC–MS the following compounds (% of total organics): *n*-alkanes C_{10}–C_{25} 7.20 (with even C_{16} and C_{18} homologs prevailing, odd/even coefficient 0.54); branched alkanes 3.51 (including isoprenanes 2.37); naphthenes 1.41; alkenes 2.19; aliphatic saturated (13.45) and unsaturated (13.28) carboxylic acids; phenols 1.71; aromatic ketones 2.98; α-hydroxyphenylacetic acid and/or 2-hydroxy-1,2-diphenylethanone 12.84; aliphatic and aromatic alde-

Table 1. Alkanes and aliphatic acids detected by gas chromatography–mass spectrometry in the vapor condensate from well 22

Compound	Formula	Content, % of OM of vapor condensate	T_m	T_b
			°C [12, 15, 16]	
n-Alkanes:				
decane	$C_{10}H_{22}$	0.02	–29.8	174.0

hexadec-9-enoic	$C_{15}H_{29}COOH$	0.90		
octadec-9-enoic (oleic)	$C_{17}H_{33}COOH$	12.22	16.0	
eicosa-8,11,14-trienoic	$C_{19}H_{33}COOH$	0.16		

hydes 0.58; aliphatic primary alcohols 0.46 and ketones 0.20; unsaturated oxidized cyclohexane derivatives 1.34; carboxylic acid esters 2.25; oxidized compounds of the naphthalene series 0.17; furan derivatives (isobenzofuran-1,3-dione, 2-pentylfuran) 0.12; S,N-containing compounds (4-methylthiazole, 4-methylisothiazole, benzothiazole) 0.60; nitrogen compounds (3-benzylquinoline, quinoline *N*-oxide, 2,5-diphenyloxazole) 0.50 (Tables 1, 2).

The electronic absorption spectra of the concentrates contain three absorption bands at 222 (s, sh), 272–273 (m), and 278 nm (m, sh) of the substituted aromatic ring. The intensity ratio of these bands in the spectrum of concentrate I A_{222}/A_{272} = 4.6 and A_{222}/A_{278} = 3.9 allows their assignment to the $\pi \rightarrow \pi^*$ electronic transitions in phenols and substituted phenols (for phenol, $\varepsilon_{210}/\varepsilon_{270}$ = 4.3). The *R* band ($n \rightarrow \pi^*$) makes, apparently, a certain contribution to the band at 278 nm. In the spectra of concentrates II and III, the band at 222 nm is considerably more intense, probably owing to the contribution from nonconjugated alkenes. The presence of a very weak broad band at 370–455 and 382–434 nm in the spectra of concentrates II and III, respectively, suggests the presence of small amounts of compounds of the anthracene and naphthacene series [8].

The IR spectra of the concentrates contain the absorption bands of the following structures (cm^{-1}): alkanes and cycloalkanes [ν(CH) 3008–3010; $\nu(CH)_{as}$ 2960 (CH_3), 2928 (CH_2); $\nu(CH)_s$ 2856 (CH_2, CH_3); $\delta(CH_3)_{as}$, $\delta(CH_2)_s$ 1464–1456; $\delta(CH_3)_s$ 1376; $\rho(CH_2)$ 720–736]; alkenes $R^1HC{=}CHR^2$ of the *cis* [ν(C=C) 1660] and *trans* configurations [ν(C=C) 1680, δ(CH) 960–965], $RHC{=}CH_2$ [ν(C=C) 1645–1648, δ(CH) 908–916]; substituted aromatics [ν(CH) 3072–3080; ν(C=C) 1600–1624, 1576, 1500–1495]. Also present are vibration bands of oxygen-containing compounds (cm^{-1}): ν(OH) 3472–3336, 3220 of carboxylic acids, phenols, alcohols; ν(C=O) of alkanoic acid esters and aliphatic aldehydes at 1740–1744, of carboxylic acids and ketones at 1720–1728, of conjugated aromatic acids and aryl alkyl ketones at 1696, of diaryl ketones at 1680; ν_{as}(COC) 1272–1288 and ν_s(COC) 1120 of esters; ν(C–O) 1145 of phenols and aliphatic ethers.

The C (70.4%) and H (10.9%) content in OM recovered from well 22 suggests lower content of aromatic compounds, compared to OM from shales, and the C : H ratio of 1 : 1.85 is close to that in nonoxidized bitumenoids [17].

Among branched alkanes, biomarkers of the isoprenoid structure (Table 1), in particular, phytane and pristane, prevail. The detected naphthenes are mainly monocyclic. On the whole, the composition of alkanes and naphthenes suggests that they belong to nonoxidized bitumenoids or oil component of OM of shales [15, 18–20].

The detected olefins are mainly *n*-alkenes corresponding to the prevailing *n*-alkanes (Tables 1, 2). The presence of olefins is untypical of OM of shales [20]. It is known that intrastratal burning of bituminous shales is accompanied by thermal, catalytic, and oxidative cracking of OM of shales, with formation of unsaturated hydrocarbons [20, 21]. Inorganic components of the rocks (clay, silica, minerals containing oxides and salts of transition metals Cu, Ni, Co, Mn, Fe, REE) catalyze this process [15, 21, 22]. The bituminous rocks of Yangantau contain clay, quartz sand, and fairly large amount of pyrite (up to 2–3%) [3]. The increased H_2 concentration in the vapor from Yangantau [5] suggests that the presence of alkanes in the vapor from well 22 is due to thermocatalytic dehydrogenation of oil alkanes.

Among the eleven fatty acids detected (Table 1), hexadecanoic acid prevails; also present, in smaller amounts, are C_{18}, C_{14}, and C_9 acids, and one isoprenoid C_{20} acid. The composition of the acids and the prevalence of the even homologs are typical of bitumenoids from shales of the algal origin [18, 23]. The maximal temperature of the rocks along well 22 T_{max} is insufficient for efficient and intense thermocatalytic oxidation of paraffins and alkanoic acids of oil in the presence of transition metal compounds from the rock (100–120°C [16, 24]).

Therefore, all the fatty alkanoic and unsaturated acids are mainly oil acids and acids released by hydrolysis. As T_{max} increases (well 27), the composition of the alkanoic acids changes substantially: the number of the detected acids and the total content of low-molecular-weight acids C_5–C_{10} increase. Among fatty acids, isopentanoic acid prevails [5]. This suggests higher extent of thermal oxidative degradation of oil alkanes and acids, and also of eliminated side alkane and acid groups of asphaltenes. Oxidation of saturated monocarboxylic acids in the presence of initiators (oxidizable oil hydrocarbons and eliminated side alkane groups of resin–asphaltene substances of OM of shales) mainly occurs at the α- or β-CH_2 group and is accompanied by conjugated decarboxylation [24]:

$$RCH_2CH_2COOH \xrightarrow{O_2} \begin{cases} \rightarrow RCH_2COOH + CO_2 + H_2O, \\ \rightarrow RC(=O)CH_3 + CO_2 + H_2O. \end{cases}$$

3-methylbenzophenone	$CH_3C_6H_4C(O)C_6H_5$	0.36
1-naphthyl-1-ethanone	$C_{10}H_7C(O)CH_3$	0.08
benzaldehyde	C_6H_5CHO	0.03

The rate of the conjugated decarboxylation grows with an increase in the molecular weight of the monocarboxylic acid and temperature (from 120 to 145°C). Under similar conditions, C_6–C_9 fatty acids are more resistant to oxidation than C_{10}–C_{20} acids [24].

In VC from well 22, we identified two monounsaturated and one trienoic acids, among which oleic acid prevailed (Table 1). The high content of natural unsaturated acids C_{18} and C_{16} suggests the algal origin of OM os Yangantgau shales [18]. Thermocatalytic oxidation of oleic acid is possible at 70–100°C. The process yields aldehydes and aldehydo acids with 6–12 carbon atoms, which are readily oxidized to the corresponding carboxylic and dicarboxylic acids at temperatures less than 60°C [24]. Therefore, decanedioic acid (present as ester), nonanal (Table 2), and a part of C_6–C_{11} alkanoic acids can be considered as products of thermocatalytic oxidation of oleic acid.

Primary alkanols present in small amounts (Table 2) may originate from elimination of side groups of resins and asphaltenes by hydrolytic cleavage of ether and ester bonds; they may also be components of oil (*n*-alcohols) [18]. Aliphatic esters, ketones, phenols, furan derivatives, S,N-containing compounds, and nitrogen bases have the composition typical of bitumenoids [15, 18, 23] or are oxidized bitumenoids (isobenzofuran-1,3-dione, quinoline *N*-oxide). Unsaturated oxidized cyclohexane derivatives are probably products of thermal oxidative elimination of cyclohexane cores from resins and asphaltenes. The presence of metal ions (Pb [5], Fe 0.4, Cu 0.5, Zn 2.1–6.3 mg l^{-1}) in the vapor condensates is due to steam distillation of their complexes with methylthiazoles, benzothiazole, benzoquinoline, and other low-molecular-weight complexing agents from OM of shales [15, 20].

Identified (alkylphenyl)ethanones, benzophenones, and 2-hydroxy-1,2-diphenylethanone are apparently products of thermocatalytic oxidation of the corresponding aromatic components of bitumen oil: (alkylphenyl)ethanes and bridged diphenylalkanes [15] which are less resistant to oxidation than alkanes [24]. Significant content of 2-hydroxy-1,2-diphenylethanone (or α-hydroxyphenylacetic acid) in VC from well 22 is probably due to oxiative elimination of peripheral groups from bitumen resins. Bitumen resins are unstable to oxidation with atmospheric oxygen even at low temperature [15]. It is known that, in oxidation of hydrocarbons, the hydroperoxy radical attacks the least stable C–H bond. In the aromatic bitumenoids under consideration, this is the C–H bond in the methylene group in the α-position to the benzene ring [24]. Oxidation of a part of 2-hydroxy-1,2-diphenylethanone yields benzaldehyde and benzoic acid. Benzaldehyde is oxidized to benzoic acid even at moderate temperatures (<60°C) [24].

Oxidation of asphaltenes with atmospheric oxygen is accompanied by formation of arenes, ketones, and acids (mainly benzenecarboxylic) and by a decrease in the number of aromatic and aliphatic rings and long alkyl chains [15]. Therefore, high content of aromatic compounds in vapor condensate from well 27 is attributable to thermal oxidative degradation of resin–asphaltene components of OM of shales. Relatively high content of phenol in VC from well 27 may be due to thermocatalytic oxidation of benzoic acid in the presence of atmospheric oxygen, water vapor, $MgCO_3$, and transition metal ions (Cu [3]) from the rock at a relatively high temperature. It is known that catalytic decarboxylation of aromatic acids (benzoic, toluic) in the liquid phase in the presence of Cu(II) compounds or Mg(II) and Cu(II) benzoates at 200–300°C, conjugated with oxidation with atmospheric oxygen, yields phenols with the release of CO_2 [15,

24]. Thus, an increase in the total content of organic impurities and phenols in the vapor condensate with increasing T_{max} suggests greater extent of thermal oxidative degradation of OM of shales, involving oxidation of condensed compounds of resins and asphaltenes.

The bulk of bituminous shales of the Yangantau mountain is considerably heated above and below the heating sites. Regions heated to 50°C sometimes reach the external surface and groundwater [2]. The melting points of oil alkanes, fatty acids, phenols, and unsaturated acids detected in VC from well 22 do not exceed 70°C (Table 1) [12]. Hence, the majority of components of bitumen oils and unsaturated acids occur in the molten state in a wide region of heated rocks and can migrate in the bulk of the mountain as melts, solutions, and colloids under the influence of temperature, concentration, and pressure gradients; in the regions of elevated temperatures, they can also be steam-distilled in the native form or as products of thermal oxidative degradation. The mobile components of OM, when appearing in heating sites with temperatures $T \geq 100$°C, undergo intense exothermic thermocatalytic oxidation with atmospheric oxygen [16, 24]. This provides supply of hydrocarbons to the heating sites and maintenance of high temperatures required for thermal oxidative degradation of resin–asphaltene components of bitumen. Thermal oxidative degradation of polymeric components of bitumen is also exothermic [20, 23]. Local accumulation of heat and slow progress of the combustion front to the depth of the mountain are favored by the low thermal conductivity of the rocks [21] (~1 $W\,m^{-1}\,K^{-1}$ for Green River dolomite marls [18]).

The presence of methane and ethane in water vapor saturated gases from Yangantau suggests supply of the combustion sites with light oil and gas hydrocarbons migrating along natural cracks from deep oil- and gas-bearing strata. The Yangantau mountain is located on the Yuryuzan–Aya depression of the Yuryuzan–Sylva region of South Cis-Ural oil and gas fields [25, 26]; it is located in the zone of oil and gas collectors widely occurring in carbonate deposites of early Carboniferous–early Permian periods [27]. The seismic and tectonic activity in the region of the Yangantau mountain [2] may facilitate distortion of rocks covering deep oil- and gas-bearing strata [28].

CONCLUSIONS

(1) Water vapor saturated gases of the Yangantau mountain contain products of therma oxidative degradation of organic matter of shales, unsaturated hydrocarbons, CO, and increased amounts of CO_2 and H_2, which suggests the occurrence of thermal and thermocatalytic degradation of the organic matter of shales with atmospheric oxygen in the presence of inorganic components of the rock [pyrite, Cu(II), silica].

(2) With increasing T_{max}, the extent of thermal oxidative degradation of the organic matter of shales and the concentration of organic matter (and, in particular, phenol) in the vapor condensate increase.

(3) The presence of moderately and slightly volatile organic (in particular, resin) substances and of metal ions in water vapor saturated gases is due to steam distillation of mobile components and products of thermal oxidative degradation of the organic matter of shales, and also of complexes of rock metal ions with complexing compounds of the organic matter of shales.

(4) The heat release in the Yangantau mountain is due to the occurrence of exothermic thermal and thermocatalytic oxidation of the organic matter of shales with atmospheric oxygen. The local accumulation of heat is favored by low thermal conductivity of the carbonate rocks. The supply of organic matter to the combustion sites and slow progress of the combustion front to the depth of the mountain are provided by migration of molten components of the organic matter of shales from the heated adjacent rocks and, possibly, of light hydrocarbons of oil and gas from deep oil- and gas-bearing strata along natural cracks.

Abstract—Decomposition of cyclohexyl hydroperoxide in the presence of 3*d*-metal acetylacetonates was studied by mathematical simulation.

Previously [1] we considered the kinetic features of the catalytic decomposition of secondary and tertiary naphthene hydrocarbon hydroperoxides and showed that the complexing power of 3*d* metal acetylacetonates with respect to cyclohexyl hydroperoxide (CHP) correlates with the metal electronegativity and increases in the order V(II) ≈ Cr(III) < Mn(III) ≈ Fe(III) < Co(III) < Ni(II) < Cu(II). The activation energy of hydroperoxide decomposition increases in the same order.

CHP decomposes homolytically at the 3*d*-metal acetylacetonate concentrations of 6×10^{-5}–6×10^{-4} M and, in addition, heterolytically at 8.8×10^{-4}–8.8×10^{-3} M [1]; the catalysts studied and CHP [2] exist not only as monomers but also as self-associates. 3*d*-Metal acetylacetonates catalyzing CHP decomposition can be subdivided into three groups. Compounds of first group do not change the metal oxidation state in the reaction event [$Fe(acac)_3$, $Zn(acac)_2$]; compounds of the second group undergo one-electron transition and alternately transfer during the reaction with CHP into oxidized and reduced states (Co, Mn, Cu); and in compounds of the third group the metal oxidation state partially changes (V, Cr).

In this work, we developed a mathematical model of the CHP catalytic decomposition in the presence of 3*d*-metal acetylacetonates. The methods were described previously [1, 3].

The typical kinetic curves of CHP (ROOH) decomposition (Fig. 1a) in the presence of the catalysts studied and of accumulation of the reaction products [cyclohexanol (ROH), cyclohexanone (R=O), isomeric decanols] show that, in the overall process of CHP decomposition, these products are formed in comparable amounts and that catalyst occurs in the free state (in the heterogeneous form) and as a complex with CHP. The content of the catalyst heterogeneous form monotonically increases with time from the start of the CHP decomposition, whereas the contents of the free and complexed forms decrease. The whole set of our experimental and published data [1, 2] suggests the following scheme of the CHP decomposition, where HS is decane (diluent); SOH, isomeric decanols; ROH, cyclohexanol; $RO^{\bullet}$, cyclohexylalkoxy radical; $S^{\bullet}$, secondary isomeric alkyl radicals; k_h, constant of catalyst heterogenization; and k_d, constant of CHP dimerization.

(a) Catalysts in which the metal oxidation state is preserved [$Fe(acac)_3$, $Zn(acac)_2$]:

$$m\mathrm{M(acac)}_n \underset{}{\overset{K_1 = 38.5\ \mathrm{M}^{-1}}{\rightleftharpoons}} [\mathrm{M(acac)}_n]_m, \quad (1)$$

$$\mathrm{M(acac)}_n + \mathrm{ROOH} \overset{K_2 = 4.6\ \mathrm{M}^{-1}}{\rightleftharpoons} \mathrm{ROOH \cdot M(acac)}_n, \quad (2)$$

$$\mathrm{ROOH \cdot M(acac)}_n \xrightarrow[k_1 = 5\ \mathrm{min}^{-1}]{} \begin{cases} \xrightarrow{\alpha = 0.41} \mathrm{RO^{\bullet} + {\cdot}OH + M(acac)}_n, \\ \xrightarrow{\beta = 0.59} \mathrm{H_2O + R{=}O + M(acac)}_n, \end{cases} \quad (3)$$

$$\mathrm{HS^{\bullet} + {\cdot}OH} \xrightarrow{k_2} \mathrm{H_2O + S^{\bullet}}, \quad (4)$$

$$\mathrm{S^{\bullet} + {\cdot}OH} \xrightarrow{k_3} \mathrm{SOH}, \quad (5)$$

$$\mathrm{RO^{\bullet} + HS} \xrightarrow{k_4} \mathrm{ROH + S^{\bullet}}, \quad (6)$$

$$M(acac)_n \cdot ROOH + HS \xrightleftharpoons{k_5 = 0.06\ l\ mol^{-1}\ min^{-1}} HOS + ROH + M(acac)_n, \quad (7)$$

$$ROH + M(acac)_n \xrightleftharpoons{K_3 = 20.3\ M^{-1}} M(acac)_n \cdot ROH, \quad (8)$$

$$M(acac)_n + H_2O \xrightleftharpoons{K_4 = 163\ M^{-1}} M(acac)_n \cdot H_2O, \quad (9)$$

$$2ROOH \xrightleftharpoons{K_d = 0.26\ M^{-1}} (ROOH)_2, \quad (10)$$

$$(ROOH)_2^* \xrightarrow{k_6 = 0.425\ min^{-1}} \begin{cases} \xrightarrow{\gamma} ROH + RO_2^{\cdot} + OH, \\ \xrightarrow{\delta} RO^{\cdot} + RO_2^{\cdot} + H_2O, \end{cases} \quad (11)$$

$$RO_2^{\cdot} + RO_2^{\cdot} \longrightarrow O_2 + ROH + R{=}O, \quad (12)$$

$$M(acac)_n(hom) \xrightarrow{k_h = 0.01\ min^{-1}} M(acac)_n(het), \quad (13)$$

$$M(acac)_n(het) + ROOH \xrightarrow{k_8 = 0.2\ M^{-1}} R{=}O + H_2O. \quad (14)$$

Let us consider the above scheme of the CHP decomposition in the presence of $Fe(acac)_3$ quantitatively. The rate of the overall process of CHP decomposition v is described by the equation

$$v = (1.95 \pm 0.2)[ROOH]^{1 \pm 0.08}[(Fe(acac)_3)_0]^{0.6 \pm 0.02}. \quad (I)$$

At [ROOH] = 0.1 M and $[Fe(acac)_3] = 8.8 \times 10^{-3}$ M, $v = 12.5 \times 10^{-3}$ mol l^{-1} min^{-1}.

The following system of differential equations corresponds to the above mechanism:

$$-d[ROOH]/d\tau = (k_1 + k_5[HS])K_2[Fe(acac)_3]_{fr}[ROOH]_{fr} + 2k_6K_d[ROOH]^2 + k_8[ROOH][Fe(acac)_3](het), \quad (II)$$

$$Fe(acac)_3(het) = [Fe(acac)_3]_{fr}(hom)(e^{k\tau} - 1), \quad (III)$$

$$d[R{=}O]/d\tau = d[H_2O]/d\tau = \beta k_1K_2[Fe(acac)_3)]_{fr}[ROOH]_{fr} + k_6K_d[ROOH]^2 + k_8[ROOH][Fe(acac)_3)](het), \quad (IV)$$

$$d[ROH]/d\tau = (\alpha k_1 + k_5[HS])K_2[ROOH]_{fr}[Fe(acac)_3]_{fr} + 2k_6K_d[ROOH]^2, \quad (V)$$

$$d[SOH]/d\tau = (\alpha k_1 + K_5[HS])K_2[Fe(acac)_3]_{fr}[ROOH]_{fr} + k_6K_d[ROOH]^2. \quad (VI)$$

* Association via α- and β-oxygen atoms of CHP is presumed.

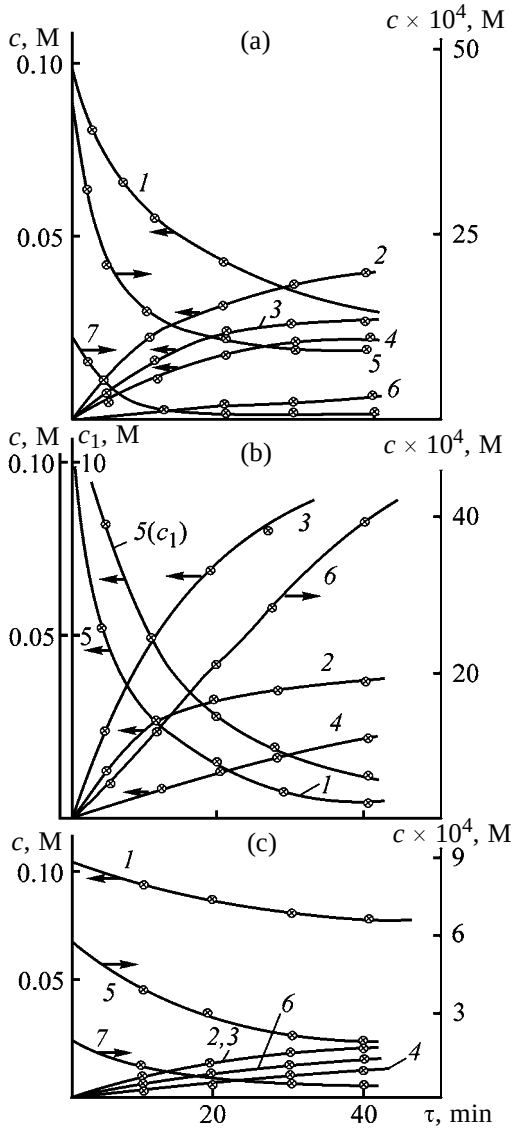

Fig. 1. Consumption and accumulation of (*1*) CHP, (*2*) cyclohexanone, (*3*) cyclohexanol, (*4*) isomeric decanols, (*5*) (a, b) $[Fe(acac)_3]_{fr}$ and (c) $[Co(acac)_2]_{fr}$, (*6*) (a, b) $[Fe(acac)_3]$(het) and (c) $Co(acac)_2$(het), and (*7*) (a, b) $[Fe(acac)_3 \cdot ROOH]$ and (c) $Co(acac)_2OH$ at 95°C. $[Fe(acac)_3]_0$: (a) 8.8×10^{-3} and (b) 8.8×10^{-4} M; $[Co(acac)_2]_0$: (c) 8.8×10^{-3} M. (c, c_1) concentration and (τ) time. Points; experiment; curves: calculation.

The initial concentrations of free CHP and catalyst ([ROH] = $[H_2O]$ = 0) were found from the material balance:

$$[ROOH]_0 = [ROOH]_{fr} = [ROOH][Fe(acac)_3] + [(ROOH)_2] \approx [(ROOH)]_{fr}, \quad (VII)$$

$$[Fe(acac)_3]_0 = [Fe(acac)_3]_{fr} + [Fe(acac)_3]_m + [Fe(acac)_3] \cdot ROOH. \quad (VIII)$$

The stoichiometric coefficient in Eq. (1) allows calculation of the concentration of the free catalyst $[Fe(acac)_3]_{fr} = 5.3 \times 10^{-3}$ M at $[Fe(acac)_3]_0 = 8.8 \times 10^{-3}$ M.

The equilibrium constant of $ROOH \cdot Fe(acac)_3$ complex formation was found from the CHP decomposition kinetics as a slope of the $1/K_{eff}$–1/[ROOH] dependence; it is equal to 4.6 l mol^{-1} (95°C). Knowing K_2, $[ROOH]_{fr}$, and $[M(acac)_3]$, we can calculate K_1 from Eq. (VII). $K_1 = 38.5$ l mol^{-1} for $Fe(acac)_3$ dimer and 0.54×10^4 l^2 mol^{-2} for the trimer. Taking into account the ratio of the yields and initial rates of formation of alcohol, ketone, and isomeric decanols (Fig. 1) and assuming dimerization of the catalyst, we can find k_1, k_5, and k_6 from the above system of differential equations.

The CHP dimerization constant k_d and the constant of $RO_2^{\bullet}$ recombination were taken from the literature [4, 5]. Calculations show that the initial rates of the CHP consumption and of accumulation of the reaction products in the whole range of ROOH (0.02–0.1 M) and catalyst (8.8×10^{-4}–8.8×10^{-3} M) concentrations are satisfactorily described by the system of differential equations with the found values of the corresponding rate constants. However, during the CHP decomposition, heterogenization of the catalyst occurs concurrently with formation of complexes with the reaction products (alcohol and water). At the further optimization of the CHP decomposition, we refined the equilibrium constants K_3 and K_4 and determined k_5 and k_8. The concentration of the free catalyst with regard to formation of all the above complexes and partial transformation into heterogeneous form was found from the condition of the material balance

$$[Fe(acac)_3]_0 = [Fe(acac)_3]_{fr} + [Fe(acac)_3](het) + [Fe(acac)_3]_m + [Fe(acac)_3] \cdot ROOH + [Fe(acac)_3 \cdot ROH] + [Fe(acac)_3 \cdot H_2O. \quad (IX)$$

(b) Catalysts in the lower oxidation state $[Co(acac)_2]$, in which the metal oxidation state changes during the hydroperoxide decomposition:

$$2Co(acac)_2 \xrightleftharpoons{K_1 = 226\ M^{-1}} (Co(acac)_2)_2, \quad (15)$$

$$2Co(acac)_2 + ROOH \xrightleftharpoons{K_2 = 8.62\ M^{-1}} Co(acac)_2 \cdot ROOH, \quad (16)$$

$$Co(acac)_2 \cdot ROOH + ROOH \xrightleftharpoons{k_1 = 67\ l\ mol\ min^{-1}} ROOH + H_2O + Co(acac)_2OH, \quad (17)$$

$$Co(acac)_2OH + ROOH \xrightarrow{k_2 = 36.9\ l\ mol\ min^{-1}} RO_2^{\bullet} + H_2O + Co(acac)_2, \quad (18)$$

$$Co(acac)_2 \cdot ROOH + HS \xrightarrow{k_3 = 0.07\ l\ mol\ min^{-1}} SOH + ROH + Co(acac)_2, \quad (19)$$

$$RO_2^{\bullet} + RO_2^{\bullet} \xrightarrow{k_4} ROH + R{=}O + O_2, \quad (20)$$

$$ROH + Co(acac)_2 \xrightleftharpoons{K_3 = 80.3\ M^{-1}} ROH \cdot Co(acac)_2, \quad (21)$$

$$H_2O + Co(acac)_2 \xrightleftharpoons{K_4 = 363\ M^{-1}} H_2O \cdot Co(acac)_2, \quad (22)$$

$$Co(acac)_2 + RO_2^{\bullet} \xrightarrow{k_5} Co(acac)_2OH + R{=}O, \quad (23)$$

$$ROH + Co(acac)_2OH \xrightarrow{k_6 = 7.55 \times 10^{-4}\ l\ mol\ min^{-1}} Co(acac)_2 + R{=}O + H_2O, \quad (24)$$

$$RO_2^{\bullet} + Co(acac)_2 \xrightarrow{k_7} ROO \cdot Co(acac)_2, \quad (25)$$

$$ROO \cdot Co(acac)_2 \xrightarrow{k_8} RO^{\bullet} + O^{\bullet}Co(acac)_2, \quad (26)$$

$$O^{\bullet}Co(acac)_2 + SH \xrightarrow{k_9} S^{\bullet} + Co(acac)_2OH, \quad (27)$$

$$RO^{\bullet} + SH \xrightarrow{k_{10}} ROH + S^{\bullet}, \quad (28)$$

$$S^{\bullet} + OH \xrightarrow{k_{11}} SOH, \quad (29)$$

$$Co(acac)_2(hom) \xrightarrow{k_{12} = k_h = 0.02\ M^{-1}} Co(acac)_2(het), \quad (30)$$

$$Co(acac)_2(het) + ROOH \xrightleftharpoons{K_5 = 9.1\ M^{-1}} ROOH \cdot Co(acac)_2(het), \quad (31)$$

$$ROOH \cdot Co(acac)_2(het) \xrightleftharpoons{k_{13} = 5\ M^{-1}} Co(acac)_2(het) + HO^{\bullet} + RO^{\bullet}, \quad (32)$$

$$2\mathrm{ROOH} \xrightleftharpoons[]{K_d = 0.26\ \mathrm{M}^{-1}} (\mathrm{ROOH})_2, \quad (33)$$

$$(\mathrm{ROOH})_2^* \xrightarrow{k_{14} = 0.425\ \mathrm{min}^{-1}} \begin{cases} \xrightarrow{\alpha = 0.95} \mathrm{ROH} + \mathrm{RO}_2^{\bullet} + \mathrm{OH}^{\bullet}\ \text{(a)}, \\ \xrightarrow{\beta = 0.05} \mathrm{RO}^{\bullet} + \mathrm{RO}_2^{\bullet} + \mathrm{H_2O}\ \text{(b)}. \end{cases} \quad (34)$$

The scheme of the above mechanism of CHP decomposition considers dimerization of both CHP and catalyst, formation of complexes of the catalyst with CHP and reaction products (alcohols, water), and the observed heterogenization of the catalyst proceeding as a first-order reaction. This scheme corresponds to the total order of approximately 2 with respect to CHP and 0.5 with respect to the catalyst. The reactions of formation of the alcohol and ketone from CHP radical reacting with the reduced form of the catalyst [6] and oxidation of the alcohol with cobalt(III) were also considered. It is known that the rate constants of reactions (9) and (11) in the case of the Co catalyst differ by a factor of 2.

The following system of differential equations corresponds to the mechanism considered:

$$-\mathrm{d[ROOH]}/\mathrm{d}\tau = 2k_1[\mathrm{Co(acac)_2 \cdot ROOH}][\mathrm{ROOH}] + k_2[\mathrm{Co(acac)_2OH}][\mathrm{ROOH}] + k_3[\mathrm{HS}][\mathrm{Co(acac)_2 \cdot ROOH}] + k_{13}[\mathrm{ROOH \cdot Co(acac)_2(het)}] + k_{14}[(\mathrm{ROOH})_2], \quad (X)$$

$$\mathrm{d[ROH]}/\mathrm{d}\tau = 2k_1[\mathrm{ROOH}][\mathrm{Co(acac)_2 \cdot ROOH}] + k_3[\mathrm{HS}] \times [\mathrm{Co(acac)_2 \cdot ROOH}] + k_{13}[\mathrm{ROOH \cdot Co(acac)_2(het)}] - k_6[\mathrm{ROH}][\mathrm{Co(acac)_2OH}] + (1.5 + 0.5\alpha - 0.5\beta)k_{14}[(\mathrm{ROOH})_2], \quad (XI)$$

$$\mathrm{d[R{=}O]}/\mathrm{d}\tau = k_1[\mathrm{ROOH}][\mathrm{Co(acac)_2 \cdot ROOH}] + 0.25(2 + \alpha - \beta)k_{14}[(\mathrm{ROOH})_2] + k_6[\mathrm{ROH}][\mathrm{Co(acac)_2OH}], \quad (XII)$$

$$\mathrm{d[H_2O]}/\mathrm{d}\tau = k_2[\mathrm{ROOH}][\mathrm{Co(acac)_2OH}] + k_6[\mathrm{ROH}][\mathrm{Co(acac)_2OH}] + \beta k_{14}[(\mathrm{ROOH})_2], \quad (XIII)$$

$$\mathrm{d[SOH]}/\mathrm{d}\tau = k_3[\mathrm{HS}][\mathrm{Co(acac)_2 \cdot ROOH}] + k_{13}[\mathrm{ROOH \cdot Co(acac)_2(het)}] + \alpha k_{14}[(\mathrm{ROOH})_2], \quad (XIV)$$

$$[\mathrm{Co(acac)_2}]_{fr} = [(B_2 + 4K_1C - B)/2K_1]^{0.5}, \quad (XV)$$

$$B = K_2[\mathrm{ROOH}] + k_1/k_2K_2[\mathrm{ROOH}] + K_3[\mathrm{ROH}] + K_4[\mathrm{H_2O}] + (e^{k\tau} - 1)(1 + K_5[\mathrm{ROOH}]), \quad (XVI)$$

$$C = [\mathrm{Co(acac)_2}]_0 - 0.5D/k_8 - 0.5D/k_9[\mathrm{SH}] - 0.75D/k_2[\mathrm{ROOH}] \approx [\mathrm{Co(acac)_2}]_0, \quad (XVII)$$

$$D = (\alpha - \beta)k_{14}[(\mathrm{ROOH})_2],$$

$$[\mathrm{Co(acac)_2}](\mathrm{het}) = [\mathrm{Co(acac)_2}]_{fr}(e^{k\tau} - 1), \quad (XVIII)$$

$$[\mathrm{RO_2}] = \{k_1[\mathrm{ROOH}][\mathrm{Co(acac)_2 \cdot ROOH}] + 0.5k_{14}[(\mathrm{ROOH})_2]/k_4]^{0.5}, \quad (XIX)$$

$$[\mathrm{Co(acac)_2OH}] = (k_1[\mathrm{ROOH}][\mathrm{Co(acac)_2 \cdot ROOH}] + 0.75D)/(k_2[\mathrm{ROOH}] + k_6[\mathrm{ROH}] \approx (k_1[\mathrm{ROOH}][\mathrm{Co(acac)_2 \cdot ROOH}] + 0.75D)/k_2[\mathrm{ROOH}]. \quad (XX)$$

The rate of the overall process of CHP decomposition v in the presence of $\mathrm{Co(acac)_2}$, expressed by the equation $v = 32.5[\mathrm{ROOH}]_0^{1.8\pm0.15}[\mathrm{MeL}_n]_0^{0.5\pm0.35}$, is equal to 5×10^{-2} mol l^{-1} min^{-1}. At [ROOH] = 0.1 M and $[\mathrm{Co(acac)_2}] = 8.8 \times 10^{-3}$ M, we found K_1 = 226 l mol^{-1} (95°C) from the equation of the material balance with respect to the catalyst at the initial time of the reaction (Fig. 1b). Taking into account that the initial process is steady-state with respect to $\mathrm{RO_2^{\bullet}}$, $\mathrm{S^{\bullet}}$, $^{\bullet}\mathrm{OH}$, $^{\bullet}\mathrm{OCo(acac)_2}$, and $\mathrm{Co(acac)_2OH}$, from the content of Co(II) and Co(III) (in the absence of the heterogeneous form of the catalysts) and of complexes with alcohol and water, we calculated k_1–k_3 and coefficients α and β from the system of differential equations (X)–(XX). The equilibrium constant was determined previously [1]; the constants k_4–k_7 are given in [5, 7–9]. The initial stage of the decomposition is well described with the rate constants found [scheme (15)–(34)]. In the developed reaction, the concurrent formation of the CHP complexes with reaction products (alcohol and water) and the catalyst heterogenization should be considered. The subsequent optimization allows selection of the equilibrium constants K_3–K_5 and determination of k_{13}. The constant of the catalyst heterogenization k_h was determined in the special experiments. The system of differential equations (X)–(XX) integrated with the rate constants obtained adequately describes the CHP decomposition (Fig. 1c) {[ROOH] = 0.02–0.1 M, $[\mathrm{Co(acac)_2}]_0 = 8.8 \times 10^{-4}$–$8.8 \times 10^{-3}$ M}.

* Association via α- and β-oxygen atoms of CHP is presumed.

In accordance with the calculated coefficients α and β, the association with respect to β-atom of CHP is preferable, which agrees with data of [10] and contradicts the results of [4]. The contribution of this reaction to the overall process of the CHP decomposition is small.

(c) For catalysts in which the metal is in the higher oxidation state [$Co(acac)_3$, $Cu(acac)_2$, $Mn(acac)_3$] and is partially reduced during the CHP decomposition, the scheme of the reaction mechanism should be supplemented by the reactions of one-electron transfer and substitution of acetylacetone with CHP in the coordination sphere of the metal ion. The observed high order of the reaction with respect to ROOH [in the presence of $Co(acac)_2$] indirectly suggests the possibility of two-sphere coordination of CHP.

From the data obtained, we can conclude that the lower catalytic activity of 3*d*-metal acetylacetonates as compared to 3*d*-metal stearates is caused by the different electron density on the metal ion, which affects the strength of the CHP O–O bond because of the change in the degree of delocalization of the unpaired electron to the ligand. The system of conjugated atoms in the chelates provides the enhanced stability of the complex. Increase in the ligand bonding with 3*d*-metal ion decreases its acceptor power; as a result, the rate constant is lower than with the corresponding carboxylates [11, 12].

The catalytic power of 3*d*-metal acetylacetonates and carboxylates in decomposition of hydroperoxides depends on a number of factors: catalyst tendency to self-association and heterogenization, hydroperoxide association, and catalyst complexing power with respect to hydroperoxides and products of their transformation ($RO_2^{\bullet}$, alcohol, water). As a rule, the equilibrium constants of the catalyst complex formation with hydroxyperoxides and alcohols and the relative contribution of the ROOH radical decomposition increase as the 3*d*-metal electronegativity increases.

CONCLUSIONS

(1) A mathematical model of cyclohexyl hydroperoxide decomposition in the presence of 3*d*-metal acetylacetonates was developed.

(2) Along with the mechanism involving one-electron transfer (change in the metal oxidation state in the catalyst), cyclohexyl hydroperoxide can decompose without changes in the oxidation state of the 3*d* metal [Fe(III), Zn(II) acetylacetonates], as it takes place in the presence of alkali and alkaline-earth (*s* metals) metal ions. The catalyst controlling function is manifested in the step of the cyclohexyl hydroperoxide decomposition.

Solubility of Iodine in the System Water–Nitric Acid

A. I. Lutsyk, S. Yu. Suikov, V. S. Chuprina, and V. Yu. Portnyanskii

Litvinenko Insitute of Physical Organic and Coal Chemistry, National Academy of Sciences of Ukraine, Donetsk, Ukraine

Received October 29, 2002; in final form, November 2003

Abstract—The solubility of iodine in 30–55% nitric acid at 25°C was measured. Particular attention was given to the control of equilibration in the system. An equation was suggested for estimating the iodine solubility in nitric acid in the concentration range 0–70 wt % HNO_3.

Iodine solutions in concentrated nitric acid are of great practical importance. They found wide application as relatively cheap strong oxidants. Recently, the interest in solubility of iodine in nitric acid increased in the context of utilization of substandard concentrated solutions of nitric acid.

Experimental measurement of the iodine solubility in nitric acid and data interpretation is a complex problem, despite availability of high-sensitivity methods and pronounced absorption of iodine solutions in the visible and UV ranges. Iodine is relatively poorly soluble in polar solvents and forms solutions with considerable deviation from ideality [1]. In oxidative systems, iodine can enter numerous reactions. For example, in concentrated fuming nitric acid it can be oxidized to iodates in preparative yield [2].

Carter [3] measured the iodine solubility in 3.3–72.6% HNO_3 at 10, 25, and 35°C. According to these data, at all the temperatures studied the iodine solubility grows over the entire examined range of the acid concentrations.

Sozontov *et al*. [4] measured the iodine solubility in 20–100% HNO_3 in the range 0–80°C. They found that, at all the temperatures studied, the iodine solubility decreased as the acid concentration increased to 60–80 wt % (depending on temperature), reached a minimum (lower by a factor of 4–5 compared to water), and then, at higher concentrations up to 100% HNO_3, increased slowly to the value remaining, however, lower than that in water. Sozontov *et al*. [4] explained a decrease in the I_2 solubility with HNO_3 concentration increasing from 0 to 60% by binding of water molecules to the molecules of nitric acid, and the subsequent growth of the solubility, by the reaction of iodine with HNO_3 to form more soluble iodic acid. However, it seems incorrect to consider this process in terms of the solubility (and the solubility models), since formation of iodic acid in concentrated nitric acid is irreversible. The iodine compound formed in 100% HNO_3 is also sparingly soluble, as can be observed visually as transformation of violet iodine crystals into the orange precipitate.

The experimental data [3, 4] at 25°C are compared in Fig. 1. As seen, the difference in the numerical solubility values reaches an order of magnitude and more. It should be noted that, according to [4], the iodine solubility in 100% nitric acid is lower than that in water, which is rather unusual for a nonelectrolyte.

Carter's results [3] were obtained by iodometric titration of saturated iodine solutions, whereas Sozontov *et al*. [4] used the dynamic method with gravimetric determination of the solute amount. In these studies, the mechanism by which the equilibrium was attained was not considered.

Here we tried to reveal the causes of the discrepancy of the iodine solubility values reported by various authors and to determine the values suitable for practical use.

EXPERIMENTAL

The equilibration in the system in the course of the iodine dissolution was monitored spectrophotometrically. The iodine electronic spectrum in acid (H_2SO_4) solutions was described in [5], and a long-wave shift (by 50 nm in going from 0 to 94.9% H_2SO_4) of the absorption maximum and slight variation of the extinction with increasing acid concentration were reported.

In this study, the total spectra of iodine in nitric acid were obtained with a Specord-2000 spectropho-

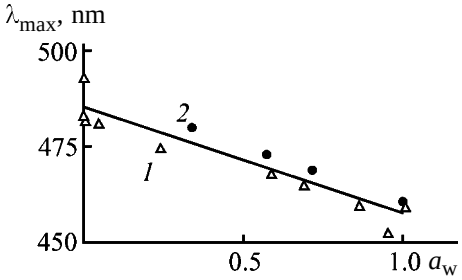

Fig. 2. Position of the absorption maximum λ_{max} for the iodine solutions in (*1*) H_2SO_4 [5] and (*2*) HNO_3 vs. water activity a_w [6] at 25°C.

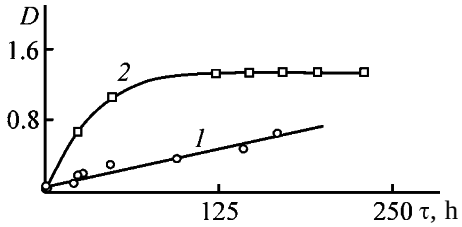

Fig. 3. Solution optical density D vs. time τ for the system I_2–30% HNO_3 (*1*) kept without stirring and (*2*) stirred 3–5 times daily. λ = 465 nm (SF-46), 25°C.

tometer (Fig. 2). As in the case of H_2SO_4, the maximum shifts to the long-wave region with decreasing water activity, without changes in the line shape. In this case, the data for both sulfuric and nitric acids are fitted by the same straight line (Fig. 2).

As seen from Fig. 3, without stirring the equilibrium in the iodine–water–nitric acid system is not attained even in more than 160 h (line *1*). If the vessel for dissolving iodine is shaken at regular intervals (3–5 times daily), then the equilibrium can be attained in 5–6 days (line *2*). Therefore, the solutions were prepared by saturating nitric acid with iodine for 7–8 days in an air thermostat at 25°C with regular shaking. The dissolved iodine was extracted with carbon tetrachloride, and its concentration was determined by iodometric titration. The titer of the thiosulfate solution was determined using chemically pure grade $K_2Cr_2O_7$ and ultrapure grade KI. The reproducibility was within 0.3%.

Unfortunately, none of the methods considered is suitable for measuring the iodine solubility in concentrated nitric acid, since observations at 25°C show that, under these conditions, iodine is completely oxidized within several minutes.

It was found previously [7] that, over the entire composition range, from 0 to 100%, the solubility of saturated hydrocarbons in the water–nitric acid system is adequately described by the equation

$$(\log\alpha)^E \equiv \log\alpha - x_w\log\alpha_w - x_a\log\alpha_a = L(V^E/V), \quad (1)$$

which relates the excess $(\log\alpha)^E$ value, expressed in terms of mole fractions of water and acid, x_w and x_a, to the excess volume $V^E = V - x_wV_w - x_aV_a$ (compression) of a water–acid two-component solvent; α_w, α_a, V_w, and V_a refer to pure components; α is the equilibrium coefficient of distribution of the substrate between the gas phase and the solution, $\alpha = \lim(c_{gas}/c_{liq})$ at $c_{gas} \to 0$; α^{-1} is equal to the substrate solubility (M etc.) at its given concentration in the gas phase. Among the forms accepted in the literature for describing the solubility of gases and volatile compounds (molarity, mole and weight fractions and percents, Henry and Bunsen constants, solvomolality, etc.), it is reasonable to use just the distribution coefficient, because it is equal to the activity coefficient of the substrate in a solution if ideal gas is chosen as the standard system [8].

Taking into account that Eq. (1) quantitatively describes the salting-out effects in concentrated electrolyte solutions, including water–acid (sulfuric, nitric, phosphoric, and other acids) systems, and in a variety of nonelectrolytes [9–11], we suggest that the solubility of such a typical nonelectrolyte as iodine in the water–nitric acid system can be adequately described by this equation. In calculation by Eq. (1), we used the value of 1.32×10^{-3} M for iodine solubility in water [5]. The solubility in M was converted to α using the value of 0.309 mm Hg for the iodine saturated vapor pressure at 25°C from [12], according to which the concentration of saturated iodine vapor is equal to 1.66×10^{-5} M: $\alpha = (1.66\times10^{-5}\ \text{M})/(1.32\times10^{-3}\ \text{M}) = 1.3\times10^{-2}$.

The α coefficient for the iodine solution in 100% HNO_3 (α_a = 0.00073) and the L (L = –2.2) parameter were calculated from the dependences presented in [7]:

$$L = -5.2 + 0.054\bar{V}_s^0,$$

$$\log(\alpha_a/\alpha_w) = 0.37 - 0.029\bar{V}_s^0,$$

where $\bar{V}_s^0$ is the partial molal volume of the nonelectrolyte in water.

We used the value $\bar{V}_{iod}^0 = 56$ cm^3 mol^{-1}, as estimated from data of [13]. The excess volume of the solvent V^E was calculated using the density of HNO_3 solutions [14]. The calculated curve of the iodine solubility in the water–nitric acid system (line in Fig. 1) at $[HNO_3] < 70$ wt % adequately describes the experimental data of [3] and those obtained in this study. The fact that the experimentally measured solubility exceeded the calculated value at $[HNO_3] > 70$ wt % may be due to the contribution of iodine oxidation under these conditions.

BRIEF COMMUNICATIONS

Quantitative Representation of Tananaev's Effect

A. Pigaga and O. Timofeeva

Institute of Chemistry, Vilnius, Lithuania

Received February 25, 2004

Abstract—Average concentrations of Ni(II) in suspended hydroxide and basic salts precipitated with NaOH from $NiSO_4$ solutions and the degree of concentration of Ni(II) as functions of the initial concentration of Ni(II) salt in solution were studied.

Precipitation methods have long been in use in chemical technology and chemical analysis for concentrating, separating, and purifying various substances.

Much attention is given now to secondary use of both precious and non-ferrous metals (zinc, chromium, nickel, and copper), which are lost in electroplating industry when washing workpieces. A reliable method of nickel regeneration is its precipitation as poorly soluble salts and hydroxide using such cheap precipitants as NaOH and Na_2CO_3.

The precipitates obtained should have favorable technological characteristics: high filtration factor, high sedimentation rate, and small volume of the final sediment.

The kinetics of precipitation of poorly soluble nickel(II) compounds with sodium hydroxide and sodium carbonate solutions from dilute Limed NB-I electrolyte with nickel(II) concentration of 0.2–20 g l^{-1} was studied previously. It is believed that, when nickel(II) is precipitated with sodium hydroxide from $NiSO_4$ solutions (of concentration less than 1 M), two basic salts, $NiSO_4 \cdot 9Ni(OH)_2$ and $NiSO_4 \cdot 4Ni(OH)_2$, or $Ni(OH)_2$ is precipitated depending on the concentration [1]. The self-compaction of the precipitates practically stopped after the lapse of 1.5–4 h, though a slight volume reduction was observed within a few days.

The results obtained show that the average concentration c_{Ni} of nickel in the precipitate depends on its initial concentration c^0_{Ni}.

It is known that, when some metals hydroxides are precipitated from solutions of their salts, the density of pseudo-amorphous precipitates increases with increasing concentrations of the salts (Tananaev's effect) [2]. There are no quantitative relationships for this effect; therefore, we decided to study this phenomenon in more detail.

EXPERIMENTAL

The experiments were carried out at room temperature (17–20°C) with solutions of $NiSO_4$ in which the nickel(II) concentration was varied from 0.1 to 20.0 g l^{-1}. The solutions were prepared by dilution of the starting solution with c^0_{Ni} = 30 g l^{-1}. The precipitant (20% aqueous solution of NaOH) was added dropwise with stirring to 25 ml of the starting solution until the required pH was reached (8.0, 9.0, 10.0, and 11.0), as monitored with a pH-340 pH-meter. After the precipitation, the resulting suspensions of insoluble compounds were poured in calibrated test tubes and allowed to settle for 24 h.

The average concentration of nickel(II) in suspensions c_{Ni} (g l^{-1}) was calculated by the formula

$$c_{Ni} = c^0_{Ni} V_0 / V_n,$$

where V^0 is the initial volume of $NiSO_4$ solution (ml), and V_n, the volume of the precipitate (ml).

The degree of concentration ε was expressed as

$$\varepsilon = c_{Ni} / c^0_{Ni}.$$

In the calculations, we did not take into account the concentration of nickel(II) in an aqueous phase above a precipitate, as it is less than the initial concentration by more than two orders of magnitude and thus can be neglected. The pH of solutions above the precipitate gradually decreases (after four days, ΔpH is 0.2–1.5 depending on initial pH and c^0_{Ni}), which seems to be due to the hydrolysis of Ni(II) basic salts [1, 2].

It should be noted that the results obtained are well reproducible. In two series of five parallel experi-

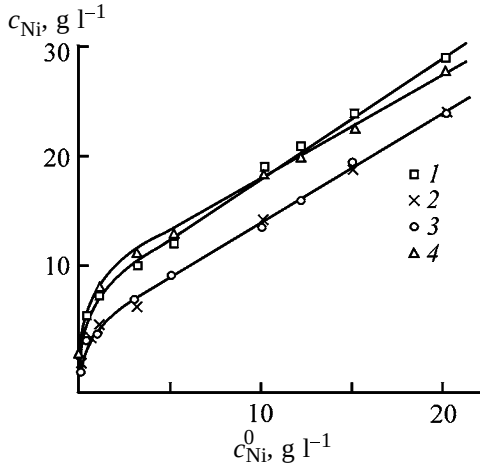

Fig. 1. Average nickel(II) concentration in the precipitate c_{Ni} as a function of its initial concentration in solution c^0_{Ni}. Precipitation with 20% NaOH solution up to the following final pH values: (*1*) 8.0, (*2*) 9.0, (*3*) 10.0, and (*4*) 11.0; the same for Fig. 2.

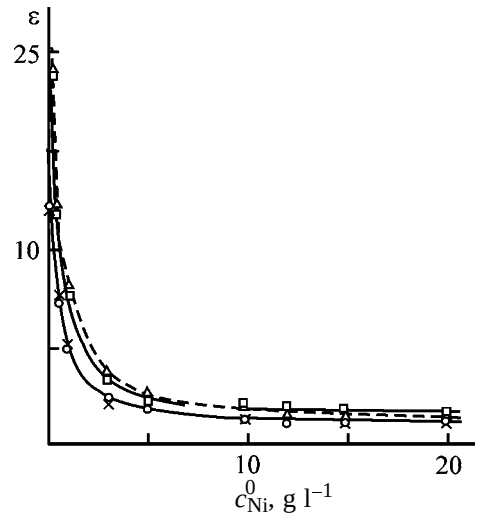

Fig. 2. Degree of concentration ε as a function of the initial nickel(II) concentration c^0_{Ni}.

ments, the deviation from the average c_{Ni} and ε values does not exceed 5%.

The experimental results are given in Fig. 1, which shows that the dependences of c_{Ni} on c^0_{Ni} in the pH range under study are similar and can be described by the equation

$$c_{Ni} = c^0_{Ni}/(ac_{Ni} + b) + cc_{Ni}, \quad (1)$$

where *a*, *b*, and *c* are empirical coefficients. At pH 8.0, $a = 0.14$, $b = 0.02$, and $c = 1.14$; at pH 9.0 and 10.0, $a = 0.24$, $b = 0.06$, and $c = 1.00$; and at pH 11.0, $a = 0.098$, $b = 0.09$, and $c = 0.98$. It is interesting that the curves obtained at pH 9.0 and 10.0 practically coincide (all the three coefficients are identical), and the curves obtained at pH 8.0 and 11.0 are close to each other. At pH 8.0 and 11.0, c_{Ni} is much higher than that at pH 9.0 and 10.0.

The initial steep ascent of the curves is attributable to the fact that, as c^0_{Ni} increases, the composition of the precipitate changes from less dense $Ni(OH)_2$ to more dense basic salts. The further increase in the density of the precipitates is explained by the effect of coagulating ions [nickel(II)] at their increased concentration [2].

Furthermore, we have found that the volume of the precipitate is independent of the concentration of sodium hydroxide used for the precipitation (concentration range 2–20% NaOH).

The density of the forming precipitates is important for the technology. Denser precipitates have more perfect structure; they are better filtered and contain less impurities.

The degree of concentration of Ni(II) is plotted in Fig. 2 vs. the initial nickel(II) concentration in solution. It is seen that the precipitation of nickel(II) as poorly soluble compounds with an NaOH solution is an efficient concentrating method at moderate initial concentrations ($c^0_{Ni} \le 3$ g l^{-1}). At higher nickel concentrations ($c^0_{Ni} > 3$ g l^{-1}), the degree of concentration approaches unity, i.e. the volume of the precipitate approaches the volume of the initial solution. In the industry such precipitates are subsequently compacted (dehydrated) using press-filters, vacuum filters, or centrifuges.

CONCLUSIONS

(1) At pH 8–11, the dependence of the average nickel(II) concentration c_{Ni} in the precipitate on its initial concentration c^0_{Ni} in the solution can be described by Eq. (1) with empirical coefficients *a*, *b*, and *c*.

(2) The precipitation of nickel(II) as poorly soluble compounds with NaOH solutions as an efficient concentrating method at moderate initial concentrations ($c^0_{Ni} \le 3$ g l^{-1}).

Bismuth(V) Oxide and Silver Bismuthate as Oxidizing Agents for Gas-Chromatographic Elemental Microanalysis

A. Yu. Shvykin, V. V. Platonov, V. P. Proskuryakov, K. B. Chilachava, E. M. Khmarin, and I. V. Kovtun

Tolstoy State Pedagogical University, Tula, Russia

Received June 24, 2003; in final form, April 2004

Abstract—Bismuth(V) oxide, silver bismuthate, and a mixture of bismuth(V) oxide with fine silver powder were studied as oxidizing additives in gas-chromatographic elemental microanalysis of readily combustible organic substances and coal.

Gas-chromatographic elemental analysis (GCEA) is one of fast and automated methods for analyzing organic compounds. The accuracy and reproducibility of this method are comparable with, and sometimes, exceed those of conventional elemental analysis.

One of serious problems of GCEA is efficient and almost instantaneous oxidative thermolysis of an organic sample to form products suitable for chromatographic analysis. To provide compete oxidation of a sample, appropriate oxidizing agents or their mixtures with combustion catalysts are added to the sample, and oxidation is performed in a carrier gas (usually helium) containing oxygen. A wide range of oxidizing agents and combustion catalysts providing reliable and complete oxidation of a sample are used in modern GCEA. However, frequently samples of organoboron, organosilicon, and organogermanium compounds, salts of polybasic carboxylic acids, salts of sulfonic acids, various solid caustobioliths, and their derivatives (lignite, coal, peat, sapropels, humic acids, and their extracts) are incompletely burnt in the presence of these oxidizing agents. This is due to high content of mineral fraction (up to 95%) in these materials. Therefore, a search for new effective oxidizing agents and combustion catalysts for difficultly oxidizable organoelemental compounds and solid caustobioliths is an urgent problem.

Diverse inorganic compounds and their mixtures were studied as oxidizing additives to samples to be burnt up [1–4]. Some of them such as PbO_2 and MnO_2 are oxygen donors. Other compounds, e.g., NiO, Cr_2O_3, WO_3, and CeO_2 are surface combustion catalysts. Compounds of the third groups (V_2O_5, Ag_2O, $AgMnO_4$, $AgVO_3$, $Ag_2Cr_2O_7$, and Ag_2O_2) are both oxygen donors and oxidation catalysts. Among compounds of the third group, silver-containing substances $AgMnO_4$ and Ag_2O_2 are the most effective. Metallic silver formed in their thermolysis is a very active catalyst for surface oxidation of the organic component of organoelemental compounds as well as high-ash and high-carbon caustobioliths. These oxidizing agents are suitable for highly effective and complete combustion of difficultly combustible samples in GCEA. The procedure of GCEA of solid caustobioliths, with coals as example, using a Carlo Erba-1100 elemental analyzer was developed and optimized in [4]. $AgMnO_4$, PbO_2, $Ar_2Cr_2O_7$, and Ag_2O_2 were studied as oxidizing catalysts for sample combustion. The most effective were $AgMnO_4$, PbO_2, and Ag_2O_2. In addition, the procedures for weighing and pretreatment of the samples were substantially modified, and mathematical treatment of the chromatrograpms was improved. As a result, the accuracy and reproducibility of the analysis sharply increased.

Bismuth(V) compounds, Bi_2O_5, and $AgBiO_3$, have not been used as oxidizing agents for GCEA. We suggest that bismuth(V) oxide should be an active oxygen donor; $AgBiO_3$ should be both an oxygen donor and a catalyst of surface oxidation owing to the presence of silver in its composition. The influence of catalytic additives of fine metallic silver powder on the oxidizing power of inorganic compounds that are used in modern GCEA as oxygen donors but are not oxidation catalysts was not fully understood. In this work we studied synthesis of bismuth(V) oxide and silver bismuthate and tested these compounds as oxidizing agents for GCEA. We

also studied the influence of catalytic additives of fine metallic silver powder on the oxidizing properties of these compounds in combustion of microamounts of difficultly combustible samples.

EXPERIMENTAL

γ-Bi_2O_5 was prepared by treatment of $NaBiO_3 \cdot 2H_2O$ with a large excess of 68% HNO_3 at –15°C for 1 h [5–7]:

$$2NaBiO_3 \cdot 2H_2O + 2HNO_3 + (n - 5)H_2O \rightarrow Bi_2O_5 \cdot nH_2O\downarrow + 2NaNO_3.$$

After reaction completion, excess HNO_3 was neutralized to pH 7 with an $NaHCO_3$ solution cooled to 0°C. The $Bi_2O_5 \cdot nH_2O$ precipitate was filtered off, washed many times with water, and predried at 20°C for 48 h over freshly calcined $CaCl_2$. Anhydrous bismuth(V) oxide was prepared by drying $Bi_2O_5 \cdot nH_2O$ at 105°C for 10 h in a drying oven:

$$Bi_2O_5 \cdot nH_2O \rightarrow Bi_2O_5 + nH_2O.$$

$AgBiO_3$ was prepared by reaction of 28-fold excess of $AgNO_3$ with $NaBiO_3 \cdot 2H_2O$ in an aqueous solution at 20°C for 1 h [5]:

$$NaBiO_3 \cdot 2H_2O + AgNO_3 \rightarrow AgBiO_3\downarrow + NaNO_3 + 2H_2O.$$

The $AgBiO_3$ precipitate was filtered off, washed many times with distilled water, and predried at 20°C for 48 h over freshly calcined $CaCl_2$. Anhydrous $AgBiO_3$ was obtained by heating at 60°C for 24 h in a drying oven.

To study the influence of catalytic amounts of silver on the oxidation power of Bi_2O_5, bismuth oxide was mixed with fine silver powder prepared by reduction of $[Ag(NH_3)_2]Cl$ with $N_2H_4 \cdot HCl$ in excess NH_4OH. The resulting mixture was thoroughly ground in an agate mortar and stored without air access. The weight fraction of Ag(0) in the mixture was 22.56 wt %.

Bi_2O_5, $AgBiO_3$, and Bi_2O_5 + Ag(0) were studied as oxidizing additives to samples for GCEA. We also studied $AgMnO_4$ as reference effective oxidizing agent. The organic compound to be analyzed was *p*-nitrophenol. Coal of Yakutiya basin was used as the sample of difficultly combustible high-carbon caustobiolith. The average rounded weight (mg) of Bi_2O_5, $AgBiO_3$, Bi_2O_5 + Ag(0), and $AgMnO_4$ added to the sample was 9.6, 11.4, 28.5, and 43.7, respectively, with their volume being approximately the same. The chromatographic analysis and mathematical treatment of the results were performed by the procedure in [4]. The results of the elemental analysis are summarized in the table.

Since Bi_2O_5 and $AgBiO_3$ are loose powders, their bulk density is minimal among the examined oxidizing agents. $AgMnO_4$ has the highest bulk density. The bulk density of Bi_2O_5 increases by a factor of approximately 3 after addition of Ag(0), i.e., addition of Ag(0) increases the Bi_2O_5 amount in the sample, on the average, by a factor of 2.3. Hence, the amount of "active" oxygen liberated in thermolysis of Bi_2O_5 increases by the same factor, which should make oxidation of the sample more complete. Thus, the increase in the bulk density of Bi_2O_5 after grinding with fine Ag(0) powder should increase the completeness of sample combustion owing to an increase in the amount of the oxidizing agent added to the sample, even if there were no catalytic effect of Ag(0).

As seen from the table, the results of elemental analysis of *p*-nitrophenol, performed with all the tested oxidizing agents, agree with each other and with the calculated values. Hence, all these oxidizing agents can be used in GCEA of readily combustible organic compounds like *p*-nitrophenol (or their mix-

tures). On the contrary, the carbon contents in coal determined in the presence of these compounds strongly differ. Only nitrogen and hydrogen contents are consistent. The carbon content determined with Bi_2O_5 (54.01% C) is lower by 14.36% than that determined with $AgMnO_4$ (68.37% C). The carbon content determined in the presence of $AgBiO_3$ (57.08% C) is underestimated by 11.29%. The results obtained with a Bi_2O_5 + Ag (68.24% C) mixture are close to those obtained with $AgMnO_4$. Hence, addition of fine Ag(0) powder sharply increases the oxidizing power of Bi_2O_5 under GCEA conditions. This mixture can be used to analyze difficultly combustible materials like caustobioliths. Probably, Ag(0) can also enhance the oxidizing power of $AgBiO_3$ and other compounds.

CONCLUSIONS

(1) Bismuth(V) oxide, its mixture with fine silver powder, and sliver bismuthate can be used as effective oxidizing agents for combustion of readily combustible organic compounds in chromatographic elemental microanalysis.

(2) The nitrogen and hydrogen contents determined in coal samples by gas-chromatographic elemental microanalysis in the presence of the tested Bi(V) compounds and their mixtures are consistent. The carbon content in coal, determined with bismuth(V) oxide and silver bismuthate, is lower than that determined in the presence of $AgMnO_4$. The carbon content determined with Bi_2O_5 + Ag(0) mixture is close to that determined with $AgMnO_4$. This mixture can be used as oxidizing additive in gas-chromatographic analysis of solid caustobioliths.

Combinatorial-Multiplicative Method of Calculating the Limiting Filling of Composites with Solid Dispersed Components

A. S. Ermilov and A. M. Fedoseev

Perm State Technical University, Perm, Russia

Received October 21, 2003

Abstract—A new method for engineering calculation of the limiting volume filling of various composites with particles of solid components with arbitrary granulometric composition is presented. A calculation of the density of random packing of dispersed fillers is described, including an algorithm for calculating the porosity of two fractions. The precision of the method is evaluated.

The limiting degree of volume filling, φ_m, with dispersed components of binder matrices of various composites (asphalts, concretes, polymeric composites, blended solid propellants) is the most important characteristic of the aggregate parameter φ/φ_m (φ is the volume fraction of the filler). It has been shown for rubbers that φ_m depends on the shape and granulometric composition of filler particles, as well as on their physicochemical interaction with binders [1]. The parameter φ/φ_m invariantly determines the strengthening of composites in, e.g., the dynamic viscosity coefficient or the initial modulus of viscoelasticity. The strongest influence on the strengthening of composites (at φ = const) is exerted by the density of random packing of filler particles in the original bulk form.

This communication suggests, in contrast to [2, 3], a more precise combinatorial-multiplicative method for engineering calculations of the limiting volume filling of composites with solid dispersed fillers with an arbitrary number of fractions and particle size distribution by determining the density of random packing of particles of a loose material.

The algorithm for calculating φ_m is based on determining the porosity of, first, a mixture of two fractions and then replacing this mixture with a single fraction with equivalent particle size. After that, the porosity is calculated for a mixture of the equivalent and next fraction and so on to *n*th fraction (*n* is the number of fractions in the filler). The $(n - 1)$th iteration yields the volume fraction of pores in a mixture of *n* fractions, equal to φ_p, with the density of random packing equal to $\varphi_m = 1 - \varphi_p$. A method for calculating the porosity of a mixture of two fractions from the known porosity and mass-average particle size (diameter) is described below. The input information for calculating φ_p for an arbitrary mixture of filler fractions are the factor vector $\mathbf{D} = (d_1, d_2, d_3,..., d_n)$, with fraction particle sizes arranged in increasing (or decreasing) order, and the corresponding vectors of fraction porosities $\mathbf{Q} = (q_1, q_2, q_3,..., q_n)$ and volume shares of fractions $\Phi = (\varphi_1, \varphi_2, \varphi_3,..., \varphi_n)$. Then follows a calculation of φ_p by the algorithm. Let the porosity of a mixture of *i*th ($i = 1, 2, 3,..., n - 1$) and *j*th ($j = i + 1$) fractions be q_z (for the last iteration, the porosity $q_z = \varphi_p$). Then the result of the first iteration ($i = 1$) is a fraction that is equivalent to a mixture of the first and second fractions, whose characteristics are the following:

$$q^{(i+1)} = q_z = F_z(d^{(i)}, d_j, q^{(i)}, q_j, \varphi^{(i)}, \varphi_j), \quad (1)$$

$$d^{(i+1)} = (\varphi^{(i)} + \varphi_j)/(\varphi^{(i)}/d^{(i)} + \varphi_j/d_j), \quad (2)$$

$$\varphi^{(i+1)} = (\varphi^{(i)} + \varphi_j), \quad (3)$$

where $q^{(i+1)}$, $d^{(i+1)}$, $\varphi^{(i+1)}$ are the porosity, particle size, and volume share of the equivalent fraction, which are calculated as a result of $(i + 1)$th iteration; F_z, the function determining the dependence of the porosity of a mixture of two fractions on their characteristic parameters and volume shares; $q^{(i)}$, $d^{(i)}$, $\varphi^{(i)}$, the porosity, particle size, and volume share of the equivalent fraction in the *i*th iteration ($q^{(1)} = q_1$, $d^{(1)} = d_1$, $\varphi^{(1)} = \varphi_1$); and q_j, d_j, φ_j, the porosity, particle size, and volume share of *j*th fraction.

1070-4272/04/7707-1203 © 2004 MAIK "Nauka/Interperiodica"

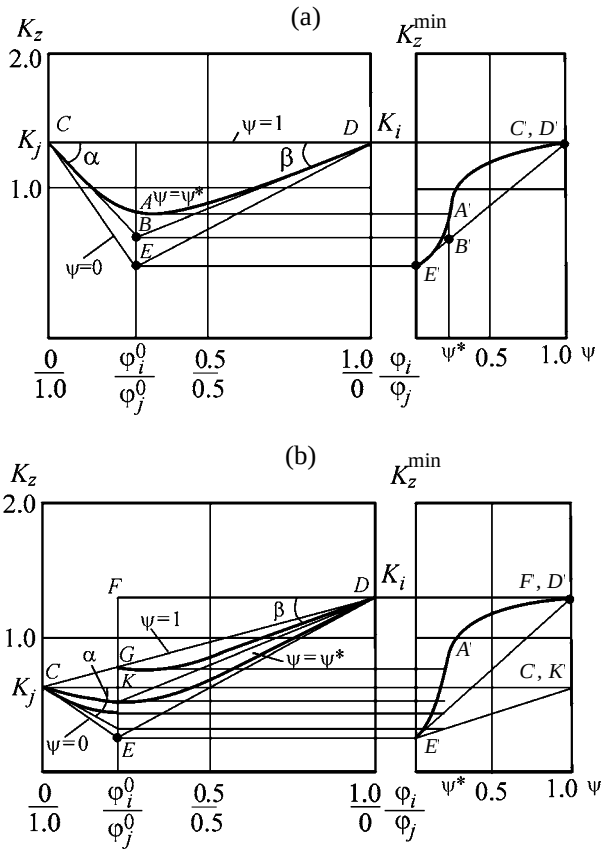

Fig. 1. Dependence $K_z(\varphi_{i(j)}, \psi_{ij})$ at (a) $K_i = K_j$ and (b) $K_i \neq K_j$.

In the second iteration ($i = 2$), the equivalent fraction is "mixed" with the third ($j = 3$). As a result, the parameters of a fraction equivalent to a mixture of the first, second, and third fractions are calculated, with the characteristics determined by formulas (1)–(3), etc.

The particle size ratio ψ_{ij} ($i < j$), the porosity coefficients K_i and K_j of ith and jth fractions, their additive porosity coefficient K_a, and the optimal volume share φ_i^0 of ith fraction in a mixture ($\varphi_j^0 = 1 - \varphi_i^0$) are given by the expressions

$$\psi_{ij} = d_i/d_j \text{ at } d_i < d_j; \quad (4)$$

$$K_i = q_i/(1 - q_i),\ K_j = q_j/(1 - q_j); \quad (5)$$

$$K_a = K_i\varphi_{zi} + K_j\varphi_{zj} \text{ at } \varphi_{zi} = \varphi_i/(\varphi_i + \varphi_j) \text{ and } \varphi_{zj} = \varphi_j/(\varphi_i + \varphi_j); \quad (6)$$

$$\varphi_i^0 = K_j/(1 + K_i + K_j),\quad \varphi_j^0 = (1 + K_i)/(1 + K_i + K_j). \quad (7)$$

These expressions are derived from the obvious relation

$$\varphi_i^0/\varphi_j^0 = \varphi_i^0/(1 - \varphi_i^0) = [(1 - \varphi_{mj})\varphi_{mi}]/\varphi_{mj}, \quad (8)$$

which is valid at $\psi \to 0$. Here φ_{mi} and φ_{mj} are the packing densities of ith and jth fractions. The geometric interpretation of the algorithm for identifying how the porosity coefficient of a mixture depends on volume shares of fractions for known porosity coefficients of the fractions and a prescribed particle size ratio is shown in Fig. 1a for $K_i = K_j$ and Fig. 1b for $K_i \neq K_j$. The dependence $K_z(\varphi_{i(j)})$ is determined by two branches (*CA* and *AD*), each of which is described by a third-degree polynomial (Fig. 1a):

$$K_z = a_i + b_i\varphi_i + c_i\varphi_i^2/2 + d_i\varphi_i^3/3 \quad \text{at } \varphi_i \le \varphi_i^0, \quad (9)$$

$$K_z = a_j + b_j\varphi_j + c_j\varphi_j^2/2 + d_i\varphi_i^3/3 \quad \text{at } \varphi_i \ge \varphi_i^0. \quad (10)$$

The polynomial coefficients $a_{i(j)}$, $b_{i(j)}$, $c_{i(j)}$, $d_{i(j)}$ are found by solving a system of four equations written with account of the boundary conditions and the key dependence $W(\psi)$ (e.g., curve E', B', K', C', D' in Fig. 1a) of the minimum normalized porosity coefficient $K_z^{min}(\psi)$ on the particle size ratio ($\psi = \psi^*$ is an arbitrary value):

$$W(\psi) = [K_z^{min}(\psi) - K_z^{min}(0)]/[K_z^{min}(1) - K_z^{min}(0)] = \exp(-1.818\log^2\psi), \quad (11)$$

which is obtained by summarizing experimental data obtained by different authors. The system of equations has the form

$$K_z = a_{i(j)} + b_{i(j)}\times 0 + c_{i(j)}\times 0/2 + d_{i(j)}\times 0/3 = K_{j(i)} \quad \text{at } \varphi_{i(j)} = 0, \quad (12)$$

$$K_z = a_{i(j)} + b_{i(j)}\varphi_{i(j)}^0 + c_{i(j)}(\varphi_{i(j)}^0)^2/2 + d_{i(j)}(\varphi_{i(j)}^0)^3/3 = K_{j(i)}^4 \quad \text{at } \varphi_{i(j)} = \varphi_{i(j)}^0, \quad (13)$$

$$dK_z/d\varphi_{i(j)} = b_{i(j)} + c_{i(j)}\times 0 + d_{i(j)}\times 0 = \tan\alpha(\beta) = (K_{i(j)} - K_{i(j)}^B)/\varphi_{i(j)}^0 \text{ at } \varphi_{i(j)} = 0, \quad (14)$$

$$dK_z/d\varphi_{i(j)} = b_{i(j)} + c_{i(j)}\varphi_{i(j)}^0 + d_{i(j)}(\varphi_{i(j)}^0)^2 = 0 \quad \text{at } \varphi_{i(j)} = \varphi_{i(j)}^0. \quad (15)$$

At $K_i \neq K_j$ (see Fig. 1b), e.g., for a mixture of particles of spherical and arbitrary shape, the scheme of calculation for each branch of the sought-for dependence is first similar to that in the case $K_i = K_j$, i.e., the parameters of the left and right branches are found to be imaginary. Further, the branches (equations) are matched to form a common smooth curve *CD* via a transformation performed in accordance with the

congruence rule (ΔCKE is extended to ΔCGE, and ΔDFE is contracted to ΔDGE; the line CGD corresponds to the additive porosity coefficient of the mixture).

The table lists experimental values of the porosity coefficients for four-fraction mixtures of packing elements of a catalyst for reactions columns, which have different shapes and sizes [3], and values of K_z, calculated using a software for the method suggested here (MCM), in comparison with those furnished by the method developed by Polish engineers Wienckowsky and Strek (MWS) [2, 3]. The sizes of fraction elements, arranged in decreasing order, are as follows: d_1 = 25.4, d_2 = 12.7, d_3 = 6.35, d_4 = 3.18 mm. The porosity coefficients of the fractions: K_1 = 0.765, K_2 = 0.680, K_3 = 0.623, K_4 = 0.610. Comparison of the results obtained shows better, on the average, agreement of the calculated and experimental data for the method suggested here, compared to the MWS method. This is due to taking into account the nonlinearity of the dependence $K_z(\varphi_{i(j)})$ in the optimal range of volume ratios of the fractions in the calculation by MCM. The precision of this method for calculation of the porosity or density of random packing of particles of granulated materials is about 7%.

A transition from a loose state of the filler to a composite is done by using as input data the porosity coefficients of the fractions determined via $\varphi_{m\,i}$ viscometrically, with account taken of the physicochemical interaction at the filler–binder interface [1]. The MCM technique is recommended for optimization of the granulometric composition of a solid dispersed filler by the criterion of the limiting volume filling of a binder in a composite.

CONCLUSIONS

(1) A procedure for calculating the density of random packing of particles in loose form is described. This procedure employs the combinatorial-multiplicative method, suggested by the authors, for calculating the limiting filling of composites with solid dispersed components.

(2) The algorithm for calculating the porosity of a mixture of two fractions of a solid dispersed filler is described and the approach used is illustrated graphically.

(3) Comparison of the calculated and experimental data shows that the precision of the method suggested is about 7%.

BRIEF COMMUNICATIONS

Inhibition of Polymerization of Poly-bis-maleimides in Solution

D. M. Mognonov and V. V. Khakhinov

Baikal Institute of Nature Management, Siberian Division, Russian Academy of Sciences, Ulan-Ude, Buryatia, Russia
Buryat State University, Ulan-Ude, Buryatia, Russia

Received April 8, 2004

Abstract—The influence of inhibitors on the rate of polymerization of poly-bis-maleimide in organic solvents at various temperatures was studied.

One of the most important problems of applied chemistry of macromolecular compounds is production of thermostable composite polymeric materials reinforced with continuous fibers [1, 2]. In this case, the main requirement to the binder is high stability of viscous characteristics of polymer solutions for a long time; in so doing, the impregnation solution is usually heated to decrease its viscosity. This problem can be solved using appropriate inhibitors of thermal polymerization. The criterion for the choice of these inhibitors is high solubility in organic solvents and high performance in a wide temperature range.

Polymerization of unsaturated monomers and oligomers can be decelerated or inhibited almost completely with relatively small amounts of an inhibitor. Previous studies of inhibition of polymerization with molybdenum, tungsten, and vanadium compounds by the example of poly-bis-maleimide (PBMI) [3, 4] showed their high performance.

In this work we studied the inhibiting effect of heteropoly compounds (HPCs) in thermal polymerization of PBMI in organic solvents. The specific viscosity of oligomer in a solvent (η_{sp}), which increases in high-temperature impregnation of the filler or in prolonged storage, was selected as a parameter defining the inhibition efficiency. The specific viscosity was determined on an Ostwald–Pinkevich viscometer in the range 25–140°C. The temperature gradient in the heat-carrier bulk did not exceed ±0.5°C.

As inhibitors we took HPCs recrystallized from aqueous solutions and readily soluble in organic media: $H_3PMo_{12}O_{40}\cdot nH_2O$ (PMO_{12}) and $H_3PW_{12}O_{40}\cdot nH_2O$ (PW_{12}), where n = 6–14. Poly-bis-maleimide produced by the Karbolit RPA [TU (Technical Specifications) 00-06-173–73] was used without additional purification. The UV spectra of aqueous solutions were recorded on an SF-46 spectrophotometer. Typical dependences of the specific viscosity of PBMI in DMF and *N*-methylpyrrolidone (*N*-MP) solutions with added HPCs on time at various temperatures and inhibitor concentrations are shown in Figs. 1a and 1b. With increasing temperature, the viscosity of the solutions regularly increases. The curves of variation of the specific viscosity of PBMI solution in the presence of the inhibitor show that the polymerization rate significantly decreases. As seen from Fig. 1, the dependence of the specific viscosity on time is characteristic of a zero-order reaction independent of the concentration of the initial reactants. The curves of viscosity variation in time, obtained at various temperatures, are unambiguously related to the presence of multiple bonds, since polymerization of PBMI though double bonds results in gelation and an increase in the solution viscosity. Therefore, the polymerization rates obtained are relative quantities, and in this stage they allow us to choose only an inhibitor and its concentration.

The time dependences of the viscosity of PBMI solutions and also the relative rates of PBMI polymerization in the presence of various HPCs confirm higher inhibiting power of PMo_{12}, whose oxidation potential is higher than that of PW_{12}. The assumption that the mechanism of inhibition with HPCs is caused by reduction of heteropoly anion is confirmed by the electronic spectrum of an aqueous extract of a mixture of PBMI and HPC, preheated at 200°C for 30 min, considering this fact that the polymer is insoluble in water. A broad absorption band in the range 660–750 nm, characteristic of transitions in reduced HPC species, appears in the spectrum. Preservation of the band with a maximum at 750 nm suggests that the structure of the heteropoly anion remains the same

1070-4272/04/7707-1206 © 2004 MAIK "Nauka/Interperiodica"

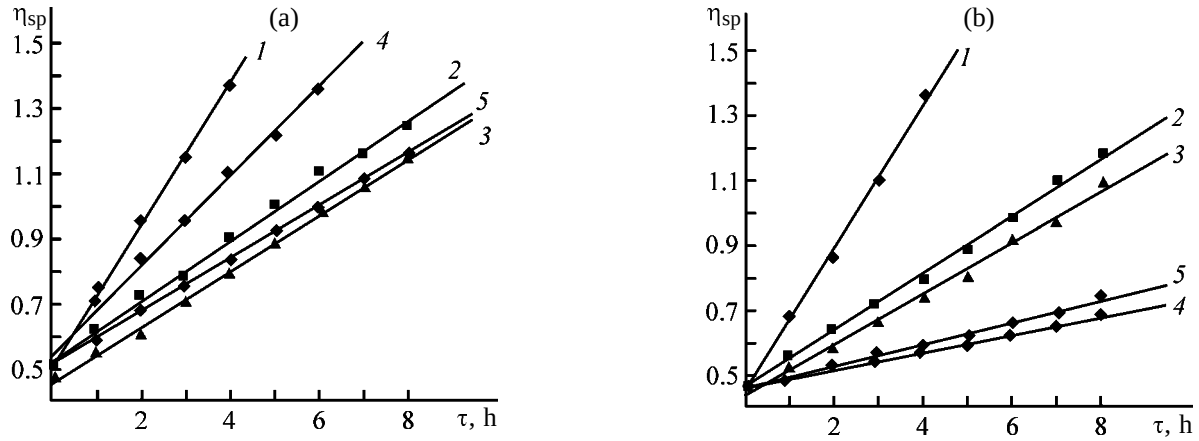

Fig. 1. Specific viscosity η_{sp} of PBMI solutions containing inhibitors as a function of time τ at (a) 140 and (b) 120°C. (a) Inhibitor concentration 2 wt %; (*1*) PBMI in DMF (no inhibitor), (*2*) PBMI with PW_{12} in N-MP, (*3*) PBMI with PMo_{12} in N-MP, (*4*) PBMOI with PW_{12} in DMF, and (*5*) PBMI with PMo_{12} in DMF. (b) PBMI solution in *N*-MP, inhibitor PMo_{12}; inhibitor concentration, wt %: (*1*) 0, (*2*) 2, (*3*) 5, (*4*) 10, and (*5*) 20.

[5, 6]. The relative rate of thermal polymerization of PBMI decreases with increase in concentration from 2 to 10 wt % (Fig. 1b); however, further increase in the HPC content in the solution does not significantly affect the inhibition process but deteriorates the final technical characteristics of polymer.

Since inhibition of the polymerization was monitored by variation of the specific viscosity of the polymer solution, the effective activation energy of the process was determined from the coefficients of transformation of the kinetic curves. This made it unnecessary to determine the absolute values of the reaction rate and know of the analytical equation of the kinetic curve. The effective activation energy of thermal polymerization of PMBI in the *N*-MP solution is 12.2 kJ mol^{-1}, and in the presence of 10 wt % PMo_{12}, 44.9 kJ mol^{-1}, which suggests that addition of HPC significantly increases the activation barrier of PBMI polymerization.

Thus, HPCs can be used as polymerization inhibitors in organic solvents. The process mechanism involves reduction of the heteropoly anion and is in good agreement with previous data on inhibition of polymerization in melt.

ANNIVERSARIES

Mikhail Mikhailovich Shul'ts (to 85th Anniversary of His Birthday)

On July 1, 2004, Mikhail Mikhailovich Shul'ts, Academician of the Russian Academy of Sciences, Hero of Socialist Labor, and a known Russian scientist in the field of physical chemistry, thermodynamics, chemistry and electrochemistry of glass, and membrane electrochemistry, was 85.

M.M. Shul'ts is the head of one of the best known Russian scientific schools. Under his supervision, 45 scientists defended their candidate's dissertations and five scientists became doctors of science (and one of these, a corresponding member of the Russian Academy of Sciences).

Shul'ts entered the chemical department of the Leningrad State University in 1937, volunteered to the front line in the Great Patriotic War, and graduated from the University in 1947, to become a postgraduate student. His supervisor was an outstanding scientist, later an academician, Boris Petrovich Nikol'skii. In his scientific activities, Shul'ts became the main continuer of Nikol'skii's researches.

Most part of the scientific life and activities of Shul'ts was associated with the St. Petersburg (Leningrad) University, where he successively occupied positions of an assistant researcher, docent, head of a laboratory at the Research Institute of Chemistry, and professor of the Chair of Physical Chemistry. In 1967–1972, he was dean of the Chemical Department. The main scientific achievements of Shul'ts are associated with investigations of the electrode properties of glasses, solution of a wide variety of theoretical and applied problems of ionometry, and especially pH-metry. Shul'ts suggested a rigorous proof of the metallic function of a glass electrode and studied the mechanism of ion transport in membranes of varied nature. Under his supervision, a set of glasses for pH-metry, glasses with metallic electrode functions, and glass redox-metric electrodes were developed. The results of studies in this area found exceedingly wide use in many fields of industry, in agriculture, in medicine, and in research.

Another important study by Shul'ts at the University is that of fundamental problems of the thermodynamic theory of heterogeneous systems, performed together with Professor A.V. Storonkin. Here, a separate mention should be made of the following: the Le Chatelier–Braun principle was refined, fundamental thermodynamic aspects of phase and chemical transformations in closed systems were established, and methods for investigation of complex systems forming solid solutions were developed.

In 1972, after he started to work at the Grebenshchikov Institute of Silicate Chemistry as director of this institute (till 1998), Shul'ts continued intensive research work in a third field: he studied the structure and thermodynamic properties of glasses and oxide melts. He created a leading scientific school "Thermodynamics and Chemical Structure of Glasses and Oxide Melts," which now efficiently works under his supervision. Papers by Shul'ts and co-workers, devoted to this subject and published in *Fizika i Khimiya Stekla* (Glass Physics and Chemistry) journal, were distinguished in 1996 and 2000 by an award established by Interperiodica publishing house. Shul'ts was twice awarded for his studies State Prizes of the USSR (1973 and 1986), twice he received the First University Prize. He was awarded the Grebenshchikov Prize of the Russian Academy of Sciences (1999). In 2003, he received Mendeleev Prize in

1070-4272/04/7707-1208 © 2004 MAIK "Nauka/Interperiodica"

Chemical Sciences, established by the Government of St. Petersburg and by the St. Petersburg Scientific Center of the Russian Academy of Sciences.

Shul'ts combined intensive research with pedagogical activities: he delivered a general course of lectures "Physical Chemistry" and special courses of lectures. At St. Petersburg State University and Institute of Silicate Chemistry, he supervised the work of postgraduate students and consulted those who prepared doctoral dissertations. His disciples include known scientists and doctors and candidates of science. The list of his scientific works contains more than 350 titles, including four monographs, textbooks, and subject collections of works, edited by him.

Shul'ts is engaged in intensive scientific-organizational activities, being a member of many interbranch and academic councils, chairman of the scientific council of the Russian Academy of Sciences for ceramic materials, and a member of scientific and dissertation councils at St. Petersburg State University and Institute of Silicate Chemistry, and a chairman or member of organizing committees of Russian and international conferences.

During the days of the remarkable jubilee, 85th birthday, numerous disciples, friends, and colleagues of Mikhail Mikhailovich wish him sound health, preservation of his inherent good spirits, creative activity, and joy of life.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Professor Nikolai Ivanovich Stepanov (to 125th Anniversary of His Birthday)

At the very beginning of the XX century, a scientific school of inorganic chemistry, the largest in Russia and known worldwide, was formed on the basis of chemical laboratories of three higher-school institutions of St. Petersburg, Mining, Polytechnic, and Electrotechnical Institutes, under the supervision of N.S. Kurnakov (1860–1941, Academician since 1913). One of its most prominent representatives was N.I. Stepanov, Corresponding Member of the USSR Academy of Sciences and Professor of the Mining Institute.

Nikolai Ivanovich Stepanov was born on July 6, 1879, in the town of Tara, uezd center of Tobol'sk province (now Omsk oblast), into the family of a doctor at Altai okrug. In spring of 1888, the family moved to Tomsk, where Stepanov, owing to his good home training and natural abilities, was accepted directly in IV form. He finished his secondary education at one of the best nonclassical secondary schools of St. Petersburg, where the Stepanov family moved in 1895. In 1897, he successfully passed a competition and entered the Mining Institute. Founded in 1773 by the empress Catherine II, the Mining Institute was one of the oldest and best higher-school institutes of Russia at the end of the XX century. Its lecturers included in those years such known scientists as chemists I.F. Schroeder (1858–1918) and Kurnakov, crystallographer E.S. Fedorov (1853–1919), mathematicians I.P. Dolbnya (1853–1912) and G.A. Thieme (1831–1910), and electrical engineer M.A. Shatelen (1866–1957). Already when being a fifth-year student, Stepanov carried out, under Kurnakov's supervision, a complex experimental study: he analyzed the phase diagrams of the magnesium–tin and magnesium–lead systems and found intermetallic compounds in these systems. In 1903, he finished, the best among the graduates of that year, the Mining Institute and was left as assistant researcher at the Chair of Analytical Chemistry. Simultaneously, he continued his investigations of metallic alloys with strong interaction between the components and intermetallic compounds formed. Together with using thermal analysis as a method for studying the nature of alloys in the solid state, Stepanov employed the method of measurement

of the electrical conductivity, having improved the experimental procedure. The investigations of the young scientist were honored by a minor Mendeleev Prize, awarded by the Russian Physicochemical Society in February 1910.

The whole set of experimental studies, whose results were published in *Zhurnal Russkogo Fiziko-Khimicheskogo Obshchestva* in 1905–1910 under the general title "On Electrical Conductivity of Metal Alloys in the Context of the Electronic Theory," was submitted by Stepanov as a dissertation for the degree of an associate professor at the Chair of Chemistry. The author, in particular, noted that the method of electrical conductivity measurements proved to be very sensitive to the boundaries of formation of solid solutions. All the results were explained in terms of the electronic theory existing at that time. The study was highly appreciated by Kurnakov and P.I. Walden (1863–1957, academician since 1910). The dissertation was successfully defended at the Mining Institute on December 11, 1911. In accordance with the regulations existing at that time, Stepanov delivered on December 14 of the same year two trial lectures: "On the Rule of Phases" and "Extraction of Salts from

1070-4272/04/7707-1210 © 2004 MAIK "Nauka/Interperiodica"

Seawater, According to Studies by van't Hoff." After the degree of an associate professor was conferred on him, Stepanov was sent to a business trip to Germany and Switzerland to familiarize himself with the methodology of teaching of chemistry and to visit laboratories of higher-school institutions. The scientist had a perfect command of German and French from childhood. During the trip, Stepanov made acquaintance with the following prominent chemists of that time; G. Tammann (1861–1938), who left Russia in 1903 and occupied the position of a professor at Goettingen University (Germany); S.A. Arrhenius (1859–1927), Swedish physical chemist and 1903 Nobel Prize winner; and Swiss chemist A. Werner (1866–1919, 1913 Nobel Prize in chemistry), founder of the coordination chemistry.

In 1912–1914, Stepanov published a series of papers devoted to electrochemistry of aqueous solutions. Beginning in 1913, he studied, on a commission from the Mining Department, together with a professor of the Mining Institute A.A. Skochinskii (1876–1960), the explosive properties of the coal dust at mines of the Donets basin. This work continued for a number of years. In 1916, Stepanov was elected an extraordinary professor at the Chair of Chemistry. In 1918, he was charged with delivery of all the main chemical courses of lectures at the Mining Institute. Stepanov's lectures enjoyed a considerable and well-deserved success with students.

In 1918, Stepanov commenced, simultaneously with his pedagogical activities, work at the Institute for Studies of Platinum and Other Noble Metals, organized on the initiative of Professor L.A. Chugaev (1873–1922). However, already in 1920 he went to the Institute of Physicochemical Analysis, headed by Kurnakov. Stepanov carried out interesting studies in the field of kinetics of transformations in metals and alloys. The main results of these studies were reported at the III Mendeleev Congress in May 1922. In those same years, the scientist started a series of his most important studies devoted to the theory of physicochemical analysis. This new research area was named the chemical metrics of equilibrium systems. The success in this area was achieved because Stepanov showed great abilities in mathematics and had a perfect command of the necessary mathematical apparatus. Spacious publications by Stepanov in *Izvestiya Instituta Fiziko-Khimicheskogo Analiza* in 1928–1933 and in *Uspekhi Khimii* journal (1936, vol. 5, nos. 7–8) were devoted to the new field of physicochemical analysis.

In October 1933, at the First All-Union Conference

Stepanov's dissertation "On Electrical Conductivity of Metal Alloys in the Context of the Electronic Theory."

of Physicochemical Analysis, Stepanov made three reports at plenary sessions. One of these considered the relationship between the law of mass action and the equilibrium composition–property diagram, and the two others discussed the run of the solubility isotherm in ternary systems. At the Jubilee Mendeleev Congress in Leningrad, in September 1934, Stepanov summarized the main results of the series of his investigations in the report "The Critical Points of Mendeleev's Theory of Solutions and the Metrics of a Chemical Diagram."

On March 28, 1934, the general meeting of the USSR Academy of Sciences made a decision to unite the Institute of Physicochemical Analysis, Institute for Study of Platinum and Other Noble Metals, and Laboratory of General Chemistry into the Institute of General and Inorganic Chemistry, Academy of Sciences of the USSR. Academician Kurnakov was elected director of the Institute. On June 14, 1934, the Government of the country included the institute into the list of institutions transferred from Leningrad to Moscow [1]. As a closest Kurnakov's associate and aide, Stepanov took a rather active part in the organization of a new scientific institution, in which the

basic areas of inorganic chemistry were to be represented. In 1936, Stepanov headed the sector of physicochemical analysis at this institute.

The scientific interests of Stepanov were rather diverse; a complete list of his scientific works can be found in [2]. Two scientist's publications were devoted to the history of chemistry: "Biographic Evidence Concerning Some Personalities in the Field of Russian Platinum Industries" (*Izv. Inst. Platiny*, 1927, vol. 5) and "Chemistry at the Mining Institute during the Last 150 Years" (*Izv. Inst. Fiz.-Khim. Anal*., 1927, vol. 3). Professors A.T. Grigor'ev [2] and S.V. Lipin, who were closely acquainted with Stepanov, noted in the articles devoted to the life and scientific activities of their colleague the breadth of his interests, his intimate knowledge of literature, painting, and sculpture, and his talent for music.

In the last years of his life, Stepanov suffered from a heart illness, but continued intensive work. Nikolai Ivanovich Stepanov died on May 19, 1938. Kurnakov characterized his disciple as follows: "Nikolai Ivanovich Stepanov is one of the most prominent and outstanding alumni of the Mining Institute, who studied at our chemical laboratory. He combined the capacity for a fine experimental study and a profound mathematical erudition... The studies of dear Nikolai Ivanovich Stepanov will erect an eternal monument to him, which will serve as a guiding source in the wide world of the chemical metrics of equilibrium systems" [4].

BOOK REVIEWS

Kovenskii, I.M. and Povetkin, V.V., *Elektrolitricheskie splavy* (Electrolytic Alloys)

Moscow: Internet Inzhiniring, 2003, 288 pp.

Electroplated coatings find exceedingly wide use in various fields of technology. Coatings composed of individual metals are the subject of a vast body of industrial-technological and reference literature, textbooks, and scientific monographs. A much smaller number of publications and lesser evidence are devoted to electrolytic alloys. At the same time, use of electrolytic alloys makes it possible to obtain coatings more completely satisfying the necessary operational requirements. The monograph by I.M. Kovenskii and V.V. Povetkin summarizes the presently available results of investigations of electrolytic alloys, carried out by the authors and devoted to preparation, properties, thermal treatment, and amorphization of these alloys. The primary attention is given by the authors to electrolytic alloys in the form of single-phase solid solutions. The book comprises six chapters, each with its own bibliographic list.

Chapter 1 (pp. 3–19) describes methods for determining the properties of electrolytic coatings. The whole set of techniques for evaluating the mechanical, physical, and chemical properties and service characteristics is briefly considered. Microscopic and X-ray diffraction analyses, electron spectroscopy, and resonance methods are described.

Chapter 2 (pp. 20–44) is devoted to thermodynamic and kinetic aspects of alloy formation processes. Also considered are the influence exerted by electrolysis parameters on the chemical composition of alloys and the mechanism by which impurities pass into the deposit. Chapter 3 (pp. 45–136), which occupies the central position in the monograph, discusses how the structure of alloys is formed in the course of electrocrystallization.

Chapter 4 (pp. 137–179) considers the whole set of the properties of the alloys: hardness; internal stresses; electrical, magnetic, and optical properties; wear resistance; solderability; corrosion resistance; and catalytic activity. The application fields of electrolytic alloys are briefly discussed. Chapter 5 (pp. 180–243) is devoted to various kinds of thermal treatment of electrolytic deposits. Chapter 6 (pp. 244–286) presents evidence concerning amorphous alloys: amorphization conditions, structure, thermal stability, and properties.

The monograph contains a total of 281 references, and many of these, to publications by the authors themselves. A rather positive impression is created by the section in which the structure of the alloys and its formation are considered (Chapter 3). Chapter 1 is written too concisely, the physical methods of investigation could be described in more detail. There are debatable critical remarks concerning the description of the thermodynamic characteristics of alloying processes.

The monograph is intended for researchers, engineers, and technicians working in the field of deposition of coatings with special properties and corrosion protection of metals; it can also be of use for post- and undergraduate students specialized in the corresponding branches of chemical technology and metallurgy.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of the Kinetics of Conversion of Natural Langbeinit Mixed with Carnallite

I. Yu. Kostiv and O. M. Khatsevich

Precarpathian Vasyl Stefanyk University, Ivano-Frankivsk, Ukraine
State Research Institute of Mineral-Salt Technology, Kalush, Ukraine

Received March 22, 2004

Abstract—The dependence of the process of conversion of natural langbeinite with carnallite in the presence of a carnallite solution on the process duration, temperature, and particle size was studied. The mechanism and kinetics of the process were analyzed.

The most valuable component of Precarpathian polymineral potassium ores is a sulfate mineral, langbeinite, whose content in the ore may be as high as 20–30%. In the mineral-salt technology of ore processing, used in practice, only 20–23% of the difficultly soluble langbeinite passes into solution, with the rest remaining in the halitelangbeinite residue, which is the waste. Because of the low solubility of langbeinite, the recovery of K^+ into fertilizer does not exceed 60%, and the content of chloride ions in the finished product is not higher than 25% [1]. Therefore, a study of how the solubility of langbeinite components can be raised is a matter of current interest.

A method for processing of langbeinite ores is known. This method consists in washing-out with water of well-soluble salts to give a langbeinite concentrate. Drying of the concentrate yields a compound that contains 18 wt % MgO, 22 wt % K_2O, and ≤2.5 wt % Cl^- [2]. Polymineral ores are also processed using electrostatic separation [3]. However, these methods are not applicable to processing of Precarpathian polymineral ores because of the high content of readily soluble potassium–magnesium minerals kainite, sylvine (20–30%), and clayey admixtures (up to 20%) [2].

Also known is a method for processing of polymineral ores with preliminary conversion of langbeinite into schoenite [4] by the reaction

$$K_2SO_4 \cdot 2MgSO_4 + 13H_2O \rightleftarrows K_2SO_4 \cdot MgSO_4 \cdot 6H_2O + MgSO_4 \cdot 7H_2O. \quad (1)$$

The recovery of components of the polymineral ore into fertilizer is 80–82%. This technique cannot provide a >85% conversion of langbeinite into solution, because an increase in the concentration of the reaction product, $MgSO_4$, in the liquid phase leads to a shift of the point corresponding to the solution composition into the region of langbeinite crystallization. Kainite present in the polymineral potassium ore also enters into the conversion reaction to give schoenite [3]:

$$2[KCl \cdot MgSO_4 \cdot 3H_2O] \rightleftarrows K_2SO_4 \cdot MgSO_4 \cdot 6H_2O + MgCl_2. \quad (2)$$

The forming $MgCl_2$ hinders the course of reaction (2). The negative effect of kainite on the conversion of langbeinite into schoenite was noted in [5]. In addition, conversion of langbeinite into schoenite requires a large amount of water, which is bound into crystal hydrates, and soluble salts crystallize entrapping particles of the ore. In dissolution of a schoenite-containing ore, there occurs crystallization of secondary leonite, which gives no way of achieving a high saturation of the solution with sulfate potassium–magnesium salts.

Also, a method for conversion of langbeinite with a magnesium chloride solution into kainite has been developed [1]. The process occurs in a suspension and can be represented as

$$K_2SO_4 \cdot 2MgSO_4 + 9H_2O + MgCl_2 + KCl \rightleftarrows 3[KCl \cdot MgSO_4 \cdot 3H_2O]. \quad (3)$$

The reaction of $MgCl_2$ with langbeinite terminates already at its concentration in solution equal to 16 wt %. The figurative point of the system shifts from the field of kainite into the field of crystallization of langbeinite, where the conversion terminates.

1070-4272/04/7708-1215 © 2004 MAIK "Nauka/Interperiodica"

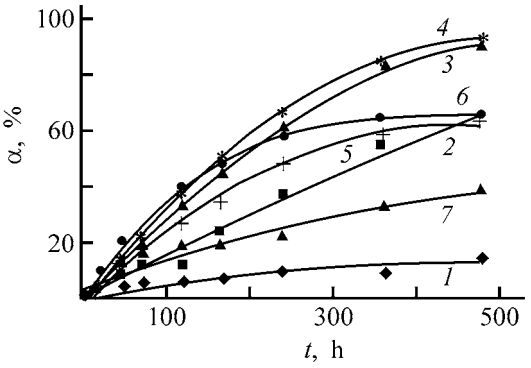

Fig. 1. Langbeinite conversion α vs. the process duration *t*. *T* (°C): (*1*) 20, (*2*) 30, (*3*) 40, (*4*) 50, (*5*) 60, (*6*) 70, and (*7*) 80.

A complete conversion of langbeinite into kainite requires an excess amount of $MgCl_2$. In the subsequent dissolution of the converted ore, the excess $MgCl_2$ makes lower the dissolution rate and solubility of potassium–magnesium minerals.

A method for conversion of langbeinite into kainite with the use of carnalite is suggested. The process can be described by the equation

$$K_2SO_4 \cdot 2MgSO_4 + 3H_2O + KCl \cdot MgCl_2 \cdot 6H_2O \rightleftarrows 3[KCl \cdot MgSO_4 \cdot 3H_2O]. \quad (4)$$

The process occurs at the interface between solid phases and the minimum amount of a liquid phase; $MgCl_2$ passes from carnallite crystals into the liquid phase on their surface and, simultaneously, enters into the reaction with langbeinite. A limited amount of the liquid phase acts as a transport medium for transfer of $MgCl_2$ and as a source of water necessary for the reaction to occur. By the end of the process, the reaction mass becomes nearly dry, and, consequently, the remaining amount of free $MgCl_2$ is small. Therefore, the dissolution of potassium–magnesium minerals is not decelerated in the stage of ore dissolution.

EXPERIMENTAL

The influence exerted by various factors on the conversion of langbeinite mixed with carnallite into kainite was studied under laboratory conditions. A langbeinite rock from the presently used potassium mine was crushed to particle size of less than 3 mm, washed to remove admixtures of soluble salts with a plentiful of tap water under stirring, and filtered. The remaining intercrystallite moisture was removed with acetone. The washed langbeinite was dried at 50°C for three days and the 1–3-mm fraction was separated by sieving on wire sieves. The resulting product had the following composition (wt %): K^+ 19.12, Mg^{2+} 11.44, Ca^{2+} 0.16, Na^+ 0.05, Cl^- 0.12, SO_4^{2-} 69.01 (or 97.3% langbeinite, 0.1 anhydrite, 0.9 polyhalite, 0.12 halite, 0.08 sylvine, 1.4 arcanite).

Carnallite was prepared from chloride–magnesium solutions formed in processing of polymineral potassium ores by synthesis with crystalline KCl. The composition of the solid phase of carnallite was as follows (wt %): K^+ 13.04, Mg^{2+} 8.15, Ca^{2+} 0.16, Na^+ 1.5, Cl^- 38.28, SO_4^{2-} 0.2, H_2O 38.67. Also, a carnallite solution obtained by filtering-off carnallite was used (wt %): K^+ 0.33, Mg^{2+} 7.52, Ca^{2+} 0.45, Na^+ 0.26, Cl^- 23.42, SO_4^{2-} 0.02, H_2O 68.0.

The prepared weighed portions of langbeinite, carnallite, and carnallite solution were kept separately in thermostats for 24 h for heating to the temperature of the experiment. Then they were mixed together and a sample was taken for a blank run. The langbeinite samples and the carnallite solution contain soluble sulfate impurities, which leads to experimental errors.

The reaction mixtures were kept under isothermal conditions for 480 h, with agitation and sampling at regular intervals. Samples of mass 100 g were dissolved in 400 g of distilled water at 20 ± 1.0°C in the course of 10 min in a thermostated reactor. The resulting suspension was filtered on a preliminarily weighed Buchner funnel under reduced pressure. The filtrate was weighed and analyzed for the content of K^+ and Na^+ by flame photometry, Mg^{2+} and Ca^{2+} by complexonometry, Cl^- by mercurimetry, and SO_4^{2-} by gravimetry [6]. The conversion of langbeinite, α, was calculated by the formula

$$\alpha = [m(SO_4^{2-})_{sol} - m_0(SO_4^{2-})]/[m(SO_4^{2-})_{lang} - m_0(SO_4^{2-})],$$

where $m(SO_4^{2-})_{sol}$ is the mass of sulfate ions in the resulting solution; $m_0(SO_4^{2-})$, the mass of sulfate ions in the solution from the blank run; and $m(SO_4^{2-})_{lang}$, the mass of sulfate ions in the weighed portion of the ore.

Also, the effect of temperature on the conversion process was studied. The conversion of langbeinite into kainite is accompanied by heat release and warming-up of the reaction mass. In addition, the carnallite used for the conversion is formed in evaporation of solutions obtained in ore processing and has a temperature of 40–70°C. Therefore, the temperature of the conversion process can be varied.

The results of the study show (Fig. 1) that the reaction is the slowest at 20°C, with the conversion in

20 days being as low as 15%. The conversion is also low at 80°C, which can be attributed to stabilization of langbeinite at elevated temperatures. At 40°C, the conversion in 20 days is 89.7%. The maximum conversion of langbeinite into kainite is achieved at 50°C (93% in 20 days).

The conversion of langbeinite into kainite is a topochemical reaction, whose kinetics is commonly studied using the Erofeev equations [7, 8]

$$\alpha = 1 - \exp(-kt^n), \quad (5)$$

where α is the conversion; k, the reaction rate constant; t, time; and n, the reaction order.

The correctness of choosing Eq. (5) for describing the kinetics of langbeinite conversion into kainite is confirmed by the plot of the dependence $\alpha = f(t)$ in the coordinates $[1 - (1 - \alpha)^{1/3}]$–t (Fig. 2). The kinetic dependences of the conversion α on the process duration t are plotted as straight lines in these coordinates, which indicates that the zone of the conversion reaction is close to the surface of spherical langbeinite particles. A rearrangement of Eq. (5) yielded

$$n\log t = \log(1/k) + \log[-\ln(1 - \alpha)]. \quad (6)$$

Figure 3 shows the dependence of the conversion of langbeinite into kainite, which is linear when plotted in the coordinates $\log[-\ln(1 - \alpha)]$–$\log t$. The rate constant of the reaction can be determined graphically from the condition

$$k = -\ln(1 - \alpha_{t=1}). \quad (7)$$

The results obtained are listed in the table.

The plot of the rate constant of the reaction of langbeinite conversion into kainite against temperature in the coordinates $1/T$–$\ln k$ (Fig. 4) was used to determine the activation energy, which was equal to 39.08 kJ mol^{-1} in the temperature range 40–70°C. This means that the heterogeneous reaction is governed both by diffusion and by the chemical process at the interface. The activation energy of langbeinite conversion at 20–40°C is 53.2 kJ mol^{-1}, which corresponds to the kinetic region of the heterogeneous process. The temperature at which the conversion rate is the highest was determined graphically (Fig. 4) to be 39.5°C.

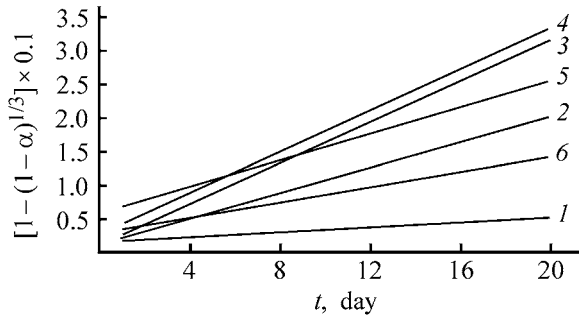

Fig. 2. Graphical verification of the occurrence of langbeinite conversion into kainite by the mechanism of a contracting sphere. (*t*) Time. *T* (°S): (*1*) 20, (*2*) 30, (*3*) 40, (*4*) 50, (*5*) 70, and (*6*) 80.

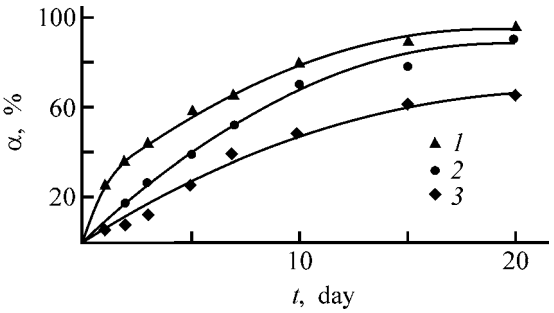

Fig. 5. Conversion α vs. the process duration for different langbeinite fractions. Fraction (mm): (*1*) 0.5–1, (*2*) 1–3, and (*3*) 3–5.

points to a complex nature of the processes accompanied by formation of intermediate compounds.

The conversion of langbeinite mixed with carnallite into kainite in a carnallite solution is a heterogeneous process whose kinetics is affected by the area of the phase boundary. Therefore, the influence exerted by the particle size of langbeinite on the conversion was studied at 50°C with 3–5-, 1–3-, and 0.5–1-mm langbeinite fractions. The results obtained are shown in Fig. 5. It can be seen that the conversion in 10 days is 48.9% for the 3–5-mm fraction and 70.4% for the 1–3-mm fraction. For the 0.5–1-mm fraction, the conversion in 10 days is 79.6%. Consequently, the smaller the langbeinite particles, the faster and the more complete its conversion into kainite. For the 0.5–1-mm fraction, a 96.8% conversion was achieved in 20 days.

The data obtained can be used in developing a technique for processing of polymineral potassium ores. The conversion of langbeinite mixed with carnallite into kainite in a carnallite solution makes it possible to raise the recovery of K^+ into a fertilizer to 85% and diminish the content of Cl^- ions in the fertilizer to 3%.

This method can be applied not only to Precarpathian polymineral potassium ores, but also to langbeinite ores from the United States by adding KCl, which forms with $MgCl_2$, in the course of solution evaporation, carnallite necessary for the reaction of conversion with langbeinite.

CONCLUSIONS

(1) The highest conversion of langbeinite into kainite in the temperature range 20–70°C is achieved at 50°C, and the fastest reaction rate, at 39.5°C.

(2) The activation energy is 53.2 kJ mol^{-1} in the temperature range 20–39.5°C, which points to the kinetic region, and 39.08 kJ mol^{-1} at 40–70°C, which corresponds to the transition region of the heterogeneous process.

(3) The reaction order *n* is 1.41 at 40°C, 1.25 at 50°C, and 0.65 at 80°C. As the langbeinite particles become smaller, the conversion grows and exceeds 96.8% in 20 days at a particle size of less than 1–0.5 mm.

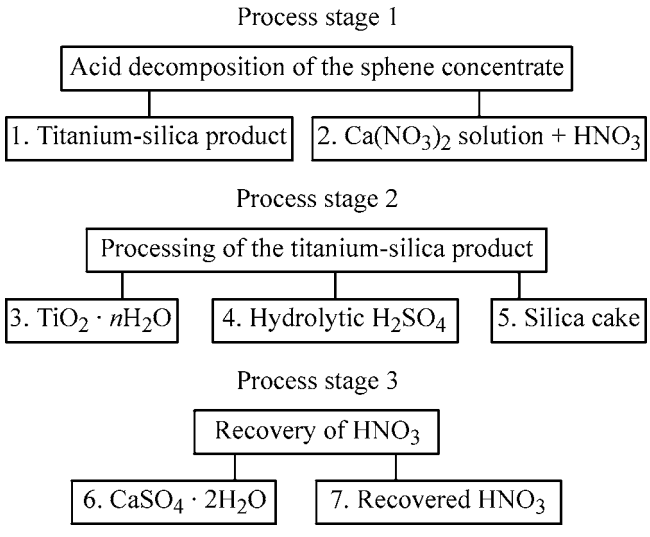
Received July 1, 2003; in final form, February 2004

Abstract—The distribution of natural nuclides and of the effective specific radioactivity in processing of the sphene concentrate was studied.

The total specific radioactivity ΣA of the sphene concentrate obtained in dressing of Khibiny ores varies within the range 10–15 kBq kg^{-1} [1]. In conformity with the regulations concerning the radiation safety [2–4], the content of natural radionuclides and the effective specific radioactivity A_{eff} (Bq kg^{-1}) in the starting concentrate and in the products obtained from this concentrate in three main process stages [5] was determined in developing a technology for processing of the sphene concentrate: titanium-silica product, nitric acid solution of $Ca(NO_3)_2$, meta-titanic acid $TiO_2 \cdot nH_2O$, hydrolytic H_2SO_4, silica cake, $CaSO_4 \cdot 2H_2O$, and recovered HNO_3.

EXPERIMENTAL

The study was carried out on the certified equipment of an accredited laboratory for radiation monitoring: Progress-AG gamma spectrometer with a 63 × 63 mm NaJ/Tl scintillation detector and a Sputnik alpha-beta radiometer. Freshly prepared technological products (see Scheme), kept for 1–45 days for restoration of the radioactive equilibrium in the uranium-238 and thorium-232 series, were analyzed by two methods under different conditions. It was necessary to use different methods because of the possible disturbance of the radioactive equilibrium in radioactive series in chemical treatment of the concentrate.



Scheme of the main process stages in processing of the sphene concentrate.

Gamma spectrometry was applied to analysis of solid and liquid products. The measurements were performed in the "Marinelli" (volume 1 l) and "Petri dish" (80 × 35 and 90 × 90 mm) configurations at an exposure duration of 1800–5400 s. Radiometry was used to analyze powder samples with weighed portions of 3–15 g and exposure duration of 3 × 600 s.

The significance of the results was confirmed by using control and reference sources of ionizing radiation (OSGI, ^{90}Sr, ^{238}Pu), a reference source of natural radionuclides (bulk measure of activity), State standard samples SG-1, SVT-16, OSO-6, and other references certified for the content of uranium and thorium in the range 2×10^{-4}–9×10^{-1} wt % (with varied U/Th ratio and chemical composition). Control sources were used to calibrate the gamma spectrometer in energy and to verify the invariability of parameters of the spectrometric installation and radiometers. The determination error for a confidence probability of 0.95 was 19–25 rel. % for ^{238}U and ^{226}Ra and 15–18 rel. % for ^{232}Th. A good agreement between the results obtained by different methods was observed. The precision and sensitivity of analysis ensured that the radionuclides could be determined at the level required by NRB-99 (Radiation Safety Standard) and GOST (State Standard) 30 108–94.

0.013 wt % ^{232}Th and 0.002 wt % ^{238}U. The experiments performed demonstrated that the radioactive equilibrium in the processing products is disturbed only slightly. The disturbed equilibrium, especially that in liquid products, was restored during the time of the experiments, specified above, and was taken into account when calculating the content of uranium and thorium.

The ratios of the amounts of alpha- and beta-emitting substances (α/β) in the final products are close to those in sphene. In the intermediate titanium-silica product, α/β increases to 2.9 because of the redistribution of radionuclides (Th/U = 68.6).

In leaching of the sphene concentrate with a HNO_3 solution, with addition of fluorine compounds, most part of the radioactivity (up to 65–70%, process stage 1) passes into the nitric acid solution, which contains 0.06 g l^{-1} of ^{232}Th and 0.007 g l^{-1} of ^{238}U (Tables 2, 3). In process stage 1, the distribution of ^{238}U, ^{226}Ra, and ^{232}Th among the solid and liquid phases is the same and approximately equal to 1 : 2.

In separating titanium from silicon in process stage 2, there occurs partial separation of the radionuclides. Uranium-238, radium-226, and thorium-232 are virtually evenly distributed among TiO_2 and SiO_2, with approximately 15% of these radionuclides remaining in the filtrate. A greater amount of uranium and radium, compared with that of thorium, coprecipitates with TiO_2. SiO_2 contains the largest amount of radioactivity: 35% relative to that in the titanium-silica precipitate. The amount of thorium in the filtrate after hydrolysis is 46.5% relative to that in TiO_2 + SiO_2, which is 2.8 times the amount of uranium and radium.

In precipitation of $CaSO_4$ in process stage 3, 84% of radium and 15% of thorium passes into solution. Up to 60–88% of thorium and 16% of uranium and radium [relative to the intermediate product, $Ca(NO_3)_2$

solution] passes into the filtrate containing nitrates of rare-earth elements. Thus, partial separation of radionuclides occurs in this stage, too.

On the whole, the unbalance of radioactivity in the process stages and in the entire scheme is within the errors of the methods used.

It follows from the results obtained that the effective specific activity of the sphene concentrate, $A_{eff} = 880 \pm 140$ Bq kg^{-1}, i.e., the concentrate belongs to Class-II materials with increased content of natural radionuclides ($0.74 < A_{eff} < 1.5$ Bq kg^{-1}) [2].

The processing of the concentrate by the technique developed yields products, both intermediate and final, whose total specific radioactivity is a factor of 1.6–3.6 lower than the initial radioactivity; no concentration of radioactivity in a separate product occurs. The effective specific activity of natural radionuclides in the titanium-silica product, silica cake, gypsum, and metatitanic acid is within 50–420 Bq kg^{-1}. According to NRB-99 and OSPORB-99 (Basic Sanitary Regulations Concerning Radiation Safety), working with the products under study is radiation-safe and the products are not radioactive. The effective specific activity of TiO_2 and SiO_2, as well as that of $CaSO_4 \cdot 2H_2O$, is less than 370 Bq kg^{-1}. According to NRB-99 [2], these products belong to Class-I building materials and can be used in manufacture of building materials without any radiation-related restrictions.

The filtrate obtained after separation of TiO_2, which contains 300 g l^{-1} of H_2SO_4, is used, upon an approximately 3-fold dilution, for chemical purification of the sphene concentrate and after that can be discharged into a tailing dump [6]. Recovered HNO_3 is recycled into the stage of decomposition of further batches of the sphene concentrate.

CONCLUSIONS

(1) In radioecological studies, the distribution of natural radionuclides in products formed in processing of the sphene concentrate was examined and it was shown that the total specific radioactivity of both intermediate and final products is a factor of 1.6–3.6 lower than its initial value and no concentration of radioactivity in a separate product occurs.

(2) It was established that the effective specific activity of natural radionuclides in the final products of processing: metatitanic acid, gypsum, and silica cake, is less than 370 Bq kg^{-1}. These products belong to Class-I building materials and can be used without any radiation-related restrictions.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Methods for $MgSiN_2$ Synthesis

F. F. Grekov and B. V. Chernovets

State Polytechnic University, St. Petersburg, Russia

Received June 8, 2004

Abstract—Direct synthesis of $MgSiN_2$ from simple substances was performed in a flow-through system. The sequence of transformations that occur on heating mixed magnesium and silicon powders in flow of nitrogen was determined by X-ray phase analysis.

Owing to the increasing interest in semiconductor nitrides, works on synthesis and study of $A^2B^4N_2$ compounds (A^2, Mg or Zn; B^4, Si or Ge) have been resumed recently [1–4]. These compounds inherit the structure of a double prototype compound A^3B^5 (wurtzite or a derivative orthorhombic structure) and, as established by approximate calculations and experiments, must have electronic and optical characteristics closely similar to those of double nitrides.

Aluminum nitride can not only be used as a wide-bandgap semiconductor, but is also regarded now as one of the best materials for substrates of integrated circuits. It has a higher thermal conductivity than the traditionally used aluminum oxide, which makes it possible to raise substantially the degree of integration and speed of response of integrated circuits. Similar applications are possible for a direct analogue of aluminum nitride, $MgSiN_2$.

The best known methods for synthesis of $MgSiN_2$ in the form of a powder are based on sintering of mixtures of double nitrides or on nitration of magnesium silicide [4]. The necessity for a preliminary synthesis of double half-products makes process more complex and is a potential source of impurities. This is especially true for the insufficiently chemically stable magnesium nitride.

This study was aimed to carry out a direct synthesis of $MgSiN_2$ from simple substances: Mg, Si, and N_2. The second goal was to perform a gas-phase synthesis of $MgSiN_2$, using volatile Si compounds as a source and relying upon the volatility of Mg.

The direct synthesis was performed in a tubular porcelain reactor connected to a gas-distributing system in such a way that a rarefaction, a flow of N_2 or Ar, or a static atmosphere of N_2 could be obtained in it. We used containers made of sintered corundum and inserts for collection of sublimates. The heating was performed in a resistance furnace. The temperature was monitored and controlled using platinum to platinum–rhodium thermocouples. The flow rates of high-purity gases {nitrogen [GOST (State Standard) 9293–74] and argon (GOST 101 157–79)} was dosed and monitored using valve floating rotameters.

The starting mixture was prepared by a thorough dry mixing of powders obtained by mechanical grinding of high-purity ingots of Mg (GOST 6001–79) and Si (semiconductor-grade purity, GOST 19 658–81). The particle size was 100–200 μm for the magnesium powder and <10 μm for the silicon powder.

The mass of the starting substances, reaction products, and, in some cases, sublimates was measured on an analytical balance. X-ray diffraction patterns were obtained with Fe_{K_α} radiation at angles $2\theta = 20$–$120°C$. The processing of the results relied upon the PDF-2 database [5].

The Mg : Si ratio in the starting mixture was varied within the range 1–1.8 to compensate for the unavoidable loss of Mg in the flow-through system. The process was performed with an excess of N_2 delivered from an external source, with the temperature gradually elevated. To reveal the sequence of the occurring transformations, the experiment was interrupted at one or another stage, the products were cooled in a flow of N_2 and subjected to analysis.

The results of the experiments are presented in Fig. 1. The phase composition is shown in the form of a diagram constructed on the basis the results of a qualitative XPA of the products formed in the course

1070-4272/04/7708-1223 © 2004 MAIK "Nauka/Interperiodica"

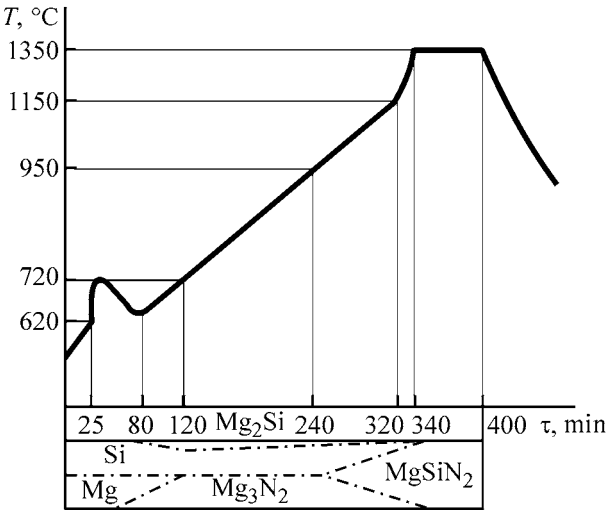

Fig. 1. Direct synthesis of $MgSiN_2$ and variation of the phase composition of the mixture in the course of the reaction. (T) Temperature and (τ) time.

of the experiments interrupted at different stages of synthesis. When constructing the diagram, points of appearance or disappearance of the reflections of the corresponding phase were used. Connecting these points, we obtained the conditional boundaries of phase coexistence at different stages of the process, which gives notion of the most probable scheme of the transformations resulting in the synthesis of a single-phase product.

After a temperature of 620°C is reached, indications of a reaction appear. Magnesium starts to be transformed into nitride:

$$3Mg + N_2 = Mg_3N_2,\ \Delta H^0_{298} = -461.8\ \text{kJ mol}^{-1}.$$

Simultaneously, a minor part of magnesium is bound with silicon into a silicide:

$$2Mg + Si = Mg_2Si,\ \Delta H^0_{298} = -79.5\ \text{kJ mol}^{-1}.$$

The first reaction is strongly exothermic, and for a certain time the synthesis proceeds in the self-ignition mode, which is manifested, in particular, in a dramatic increase in the N_2 absorption at the inlet of the reactor, at its outlet closed and the heater switched off. During this period of time, local warming-up leads to difficultly controllable loss of Mg, indicated by the appearance of sublimates. After this stage is complete, i.e., intense absorption of N_2 stops, the amount of free Mg in the reaction mixture is insignificant.

On further heating, $MgSiN_2$ starts to be formed, probably, with partly dissociating Mg_3N_2 involved. The appearance of $MgSiN_2$ was observed at those same temperatures (>900°C) at which the sublimation of Mg_3N_2 in a flow-through reactor was intensified. Since no indications of silicon nitration were observed, the most probable schemes of the final transformations do not involve Si_3N_4 and can be presumably represented as

$$Mg_3N_2 + Si = MgSiN_2 + 2Mg\uparrow,$$
$$Mg_2Si + N_2 = MgSiN_2 + Mg\uparrow.$$

The equations of these reactions include magnesium compounds, which are unstable with respect to dissociation at the experimental temperatures, on the left-hand side, and a volatile product (Mg vapor), which facilitates both the thermodynamic and kinetic aspects of the process, on the right-hand side.

The final annealing at about 1350°C ensures the completion of the reaction and improves the crystallinity of the product. The excess amount of Mg condenses in the cool part of the reactor in the form of Mg_3N_2.

The material obtained is a light gray powder, which is, according to X-ray analysis, a single-phase $MgSiN_2$ [6].

The reaction yield by silicon approaches 100%. In the preliminary experiments, compaction of the powder synthesized under RF heating in a mixture N_2–H_2 produced compact ceramic samples. However, the sintering process was sufficiently successful only with oxide additives introduced.

The possibility of codeposition of $MgSiN_2$ from the gas phase is not reflected in the literature, although this process has been performed previously in a chloride system for an analogue of this compound, $ZnGeN_2$ [7]. The fact that $MgCl_2$ has a relatively low volatility (T_{boil} = 1420°C) and readily undergoes hydrolysis gives no way of applying the above method directly to the system studied.

To make control of the process simpler and to diminish the possible contamination, the following reaction of hydride synthesis was chosen as the main reaction

$$Mg + SiH_4 + 2NH_3 = MgSiN_2 + 5H_2.$$

The involvement of two metastable hydrides in the process ensures a complete irreversibility of the deposition of the ternary nitride. At the same time, there appears a risk of development of a side reaction, pyrolysis of silane. Magnesium (T_{boil} = 1120°C)

is considerably more volatile than its chloride $MgCl_2$, but certain difficulties are caused by the corrosiveness of the Mg vapor with respect to the container materials.

We used an axially symmetric vertical reactor with a graphite reactor unit (Fig. 2). Graphite was covered with a Si_3N_4 layer from the inside. A uniaxial feeding of the reagents and the upper, with respect to the gas-flow inlet, position of the substrate were used. The position of the substrate was adjusted in the vertical direction. The design of the reactor unit ensured the minimum time of contact between SiH_4 and heated surfaces to prevent its decomposition. The Mg vaporizer was fabricated in the form of an annular cavity connected with the main channel via effusion orifices. Within a vaporizer of this type, the Mg vapor pressure is mainly temperature-controlled and the rate of vapor outflow from it is rather stable. As the carrier gas served Ar, the silane–argon mixture or NH_3 was fed through separate pipes. The sealing was ensured by ground-quartz joints and an upper annular ring-shaped seal. A two-zone resistance furnace allowed independent variation, within certain limits, of the temperatures of the substrate and Mg vaporizer.

Magnesium with less than 0.08 wt % impurities, a silane–argon mixture containing 96 vol % high-purity Ar and 4 vol % SiH_4, and NH_3 with a content of H_2O vapor less than 0.04 vol % were used as starting substances. The consumption of Mg was controlled by varying the temperature within the zone of its evaporation and monitored by the change in its mass during the experiment. The partial pressures in the deposition zone were calculated from the molar consumption of the reagents.

The deposition was done onto polished leucosapphire substrates etched in a mixture of H_2SO_4 and H_3PO_4. The duration of the experiment was about 60 min, and the deposition rate did not exceed 3 $\mu m\ h^{-1}$.

All the experiments were performed at a deposition temperature of 1050°C. At higher temperatures, the process is complicated by pyrolysis of SiH_4, and at lower temperature, it is difficul to ensure a sufficient flow rate of Mg vapor. The ratio of the partial pressures of Mg and SiH_4 in the mixture was maintained close to equimolar value, whereas the excess of NH_3 was overwhelming (about 200).

The position of a substrate in the gas flow is an important parameter [8], because homogeneous transformations, which dramatically affect the result of deposition, may develop in a thermodynamically unstable gas mixture. At different total flow rates in the

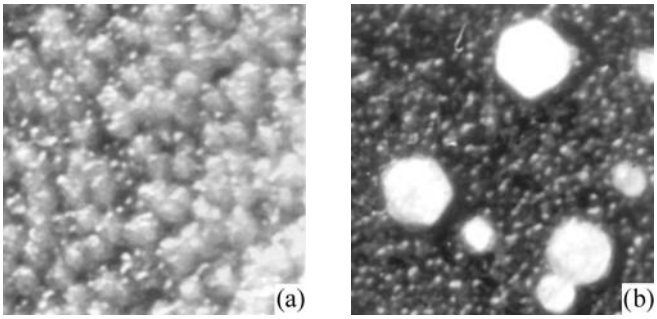

Fig. 3. $MgSiN_2$ layers obtained in different zones of the reaction volume. (a) Spherulitic structure of $MgSiN_2$, (b) spherulitic structure of $MgSiN_2$ in combination with Mg_3N_2 crystals.

reactor, zonal patterns of the same type were observed for the variation of the composition of the layers being deposited with the distance between the nozzle end and the substrate.

In the first, nearest to the nozzle, position on the substrate, Mg_3Ni_2 is formed as druses of well-faceted crystals, which constitute a solid layer at a sufficiently long duration of the experiment. At longer distances, a mixture of Mg_3N_2 and spherulitic $MgSiN_2$ is formed on the substrate (Fig. 3b). A dense $MgSiN_2$ layer composed of white spherulitic grains 100–200 μm in size can be obtained as the distance from the mixing zone increases further (Fig. 3a). When the distance from the substrate to the nozzle is too long, the rate

of layer growth decreases considerably and the film losses its crystalline structure.

At the optimal position of the substrate, found under the above conditions, deviations of the vapor composition from the magnesium-to-silane equimolar ratio strongly change the deposit properties. In these experiments, the molar consumption of Mg with respect to SiH_4 was varied from 0.5 to 2.0 (at a constant consumption of SiH_4). At a deficit of Mg, the growth rate of the layer decreases, but its morphology and phase composition correspond to the pattern shown in Fig. 3a. At an excess of Mg, the mass of the deposit increases and the growth pattern corresponds to a two-phase mixture $MgSiN_2$ + Mg_3N_2.

In some experiments, the $MgSiN_2$ film peeled-off in storage of samples under laboratory conditions. Most probably, this is due to formation of a Mg_3N_2 sublayer at the interface with the substrate. Probably, this phenomenon can be used as a method for separating thick layers of the ternary nitride. At the same time, it is necessary to have an opportunity to ensure a sufficient adhesion of the film to the substrate.

A transition mode precluding formation of a Mg_3N_2 sublayer may consist in such a sequence of reagent supply at which the interaction of Mg and NH_3 vapors would be impossible in the first stage of growth. Special experiments performed under the same conditions, but in the absence of NH_3, showed that the growth rate of Mg_2Si films is negligible, compared with that of $MgSiN_2$ films. This circumstance was used as follows. Delay in the delivery of NH_3 by 180–200 s (time in which a silicide sublayer can be formed, but its thickness is apparently negligible) with respect to that of Mg and SiH_4 did eliminate the peeling-off even in the case of a subsequent storage in a water vapor of the sample obtained.

An X-ray analysis of the $MgSiN_2$ deposits obtained did not reveal any reproducible texture. This may be due to the presence of a sublayer, which eliminates the orienting influence of the substrate. The reflections observed were identified using published data [6], which yielded, after processing with a UNITCELL software [9], the following constants of the rhombic lattice (Å): $a = 5.26 \pm 0.03$, $b = 6.52 \pm 0.02$, and $c = 5.04 \pm 0.01$.

CONCLUSIONS

(1) On heating mixtures of Mg and Si powders in a flow of N_2, there occurs an exothermic reaction of Mg_3N_2 formation, which makes it difficult to control the process. By choosing the composition of the starting mixture, the rate at which the temperature is elevated, and the rate of the N_2 flow, it is possible to optimize the process mode and perform a direct synthesis of $MgSiN_2$.

(2) $MgSiN_2$ is deposited in the hydride system at 1050°C onto sapphire substrates in the form of spherulitic polycrystalline layers at the equimolar ratio of Mg and SiH_4 vapors and an overwhelming excess of NH_3.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis and *in situ* Gravimetric Monitoring of Formation of Titanium-Oxide Layer on Silica Surface

A. A. Malkov, E. A. Sosnov, and A. A. Malygin

St. Petersburg Technological Institute, St. Petersburg, Russia

Received April 9, 2004

Abstract—Stages of formation of a titanium oxide monolayer in a flow reactor combined with a McBain balance were studied *in situ* in successive treatment of porous silica with a $TiCl_4$ vapor, dried inert gas, water vapor, and again dried inert gas. The chemical composition of the resulting products, calculated using the data obtained in gravimetric monitoring, is in agreement with the results of a chemical analysis.

Gravimetric methods for studying heterogeneous processes find wide application owing to the possibility of *in situ* monitoring of separate stages of synthesis, high precision of measurements, and conveniently obtained kinetic dependences in varied technological modes [1–7]. Synthesis of element-oxide surface structures by molecular layering (ML) is based on performing chemical reactions between active reagents, e.g., between chlorides of an element and functional groups on the surface of oxide solid matrices [8–9]

$$m(\equiv M\text{–}OH) + ECl_n \rightarrow (\equiv M\text{–}O\text{–})_m ECl_{n-m} + m HCl, \quad (1)$$

followed by a vapor-phase hydrolysis of element-oxide groups

$$(\equiv M\text{–}O\text{–})_m ECl_{n-m} + (n - m)H_2O \rightarrow (\equiv M\text{–}O\text{–})_m E(OH)_{n-m} + (n - m)HCl. \quad (2)$$

The sample weight may change in the course of reaction (1) because of the replacement of, first, OH groups with element-oxochloride groups and then chloride groups with hydroxide groups [reaction (2)]. Comparing the observed weight changes with the chemical composition of surface groups, we can gain insight into the nature of the occurring conversions on the basis of the material balance. However, only a linear weight change in relation to the number of ML cycles has been established and discussed in the available reports on gravimetric studies of ML reactions [10–12]. This weight change is determined after the completion of a separate synthesis cycle, which gives no way of regarding the thermogravimetric method as a tool for an *in situ* study of separate synthesis stages and mechanisms of reactions occurring on the matrix surface.

The purpose of this study was to examine separate ML stages for the example of synthesis of a titanium oxide monolayer on the surface of porous silica on a thermogravimetric installation equipped with a McBain balance.

The experiments were carried out with a silica gel of ShSKG brand, purified to remove admixtures (0.2–0.4-mm fraction, average pore diameter 15.6 nm, specific surface area by BET [13] 235 $m^2 g^{-1}$) [14]. The thermogravimetric installation used in the study (Fig. 1) includes a flow reactor *1* with an indirect

electric heater *2* and a spring balance in the reactor. A quartz spring *3* with a constant of 3.25 mg mm^{-1} was used in the experiments. Estimating the relative spring extension with a KM-6 cathetometer *4* ensured that changes in the sample weight were measured with an accuracy of ±0.03 mg. With a weighed sample of about 0.1 g, placed in pan *5*, the change in the sample weight was measured with an accuracy of ±(0.3–0.4) mg g^{-1}. Reagents were transported by an inert gas, air or high-purity nitrogen from a cylinder *6*, with a residual oxygen content less than 0.0001 vol %. After being passed through a unit *7*, which ensured a residual moisture content corresponding to a dew-point temperature not higher than –60°C (4.5 mg H_2O/m^3), the dry gas was saturated with $TiCl_4$ vapors in batcher *8* at room temperature and fed into the reactor. The vapor-phase hydrolysis of titanium chloride surface groups was carried out with a humid air passed through a bubbler *10* with distilled water at room temperature and fed into the reactor by a microcompressor *9*. The excess amount of reactants and gaseous reaction products was absorbed in the bubbler *11*. The temperature in the reaction zone was maintained constant to within ±5°C by a potentiometer *12*. The products synthesized were analyzed for the content of titanium(IV) and chloride ions [15, 16]. To compare the chemical compositions of samples obtained at different temperature, the concentrations of Ti(IV) and chloride ions in these samples were recalculated to 1 g of an anhydrous matrix (g_0) [17–19].

Based on the assumed schemes of occurrence of the surface chemical reactions (1) and (2), we can estimate changes in the product weight in the synthesis of, first, titanium oxochloride and, further, a titanium chloride monolayer. The increase in the sample weight, Δm_{chs} (mg g_0^{-1}), as a result of $TiCl_4$ chemisorption accompanied only by the replacement of the hydrogen ions of the surface OH groups with titanium chloride groups [scheme (1)] can be calculated by the formula

$$\Delta m_{chs} = [Ti]M_{Ti} + [Cl]M_{Cl} - [OH_{used}]M_H. \quad (3)$$

Here [Ti] and [Cl] are the contents of Ti(IV) and Cl^- in the chemisorption product; $[OH_{used}]$, the amount of OH groups (mmol g^{-1} of anhydrous matrix) consumed in the reaction; M_{Ti}, M_{Cl}, and M_H, the atomic weights of titanium, chlorine, and hydrogen, respectively.

The amount of hydroxide groups consumed in the reaction is given by

$$[OH_{used}] = (4 - [Cl]/[Ti])[Ti] = 4[Ti] - [Cl]. \quad (4)$$

Transforming expression (3) and taking (4) into account, we obtain

$$\Delta m_{chs} = (M_{Ti} - 4M_H)[Ti] + (M_{Cl} + M_H)[Cl]. \quad (5)$$

Then the concentration of Ti(IV) in the product of chemisorption can be calculated by the formula

$$[Ti] = \frac{\Delta m_{chs} - (M_{Cl} + M_H)[Cl]}{M_{Ti} - 4M_H}. \quad (6)$$

To determine the number of Cl^- ions in the titanium oxochloride groups, we used the thermogravimetric data obtained in the stage of the vapor-phase hydrolysis and subsequent treatment with a dry gas at the temperature of synthesis. According to reaction (2), the weight change Δm_h (mg g_0^{-1}) in hydrolysis with an equivalent exchange of Cl^- for OH groups can be represented as

$$\Delta m_h = (M_{OH} - M_{Cl})[Cl]. \quad (7)$$

Then we can calculate the amount of chlorine:

$$[Cl] = \frac{\Delta m_h}{M_{OH} - M_{Cl}}. \quad (8)$$

Typical thermogravimetric curves obtained in different stages of synthesis of a titanium oxide monolayer are shown in Fig. 2: (*I*) $TiCl_4$ chemisorption,

(*II*) removal of the excess amount of a reagent with a flow of a carrier gas, (*III*) vapor-phase hydrolysis, and (*IV*) drying of the product in a carrier-gas flow at the temperature of synthesis. The reproducibility of the experimental data after the completion of stage *IV* of synthesis at different temperatures (according to the results of 3–5 experiments) is illustrated in Table 1.

The results of a chemical analysis and sample weight changes in synthesis on a thermogravimetric installation are listed in Table 2. It can be seen that the experimental weight changes in chemisorption and desorption (stages *I* and *II*) coincide, within the experimental error (Table 1), with similar values calculated from the chemical analysis data. At the same time, the weight changes for samples (Fig. 2) after hydrolysis of titanium chloride structures (stage *III*) and after removal of the excess amount of the low-molecular reagent (stage *IV*) are greater than those calculated from the chemical analysis data by 8–13%, which exceeds the corresponding errors of determination (Table 1). These differences can be associated with occurrence of additional, with respect to reaction (2), transformations in the composition of titanium-containing groups in stages *III* and *IV*.

It is known that OH groups are present on the surface of TiO_2, with their maximum content being as high as 6.6 and 15.4–15.6 μmol m^{-2} for crystalline and amorphous TiO_2, respectively [20]. The heat treatment of TiO_2 at $T_0 > 15$°C is accompanied by a significant dehydroxylation of the surface, with the complete removal of OH groups from a surface attained, according to different publications, even at $T_0 = 450-600$°C [21]. As follows from Fig. 2, a significant amount of silanols (7.1 μmol m^{-2} [22]) that can enter into chemical reactions still remains on the silica gel surface under the same conditions ($T_0 = 600$°C). As the thermal stability of titanols is much lower than that of Si–OH groups, the most probable reason for the discrepancies indicated in Table 2 may be partial dehydroxylation of Ti–OH groups formed in the stage of the vapor-phase hydrolysis, which is accompanied by the formation of bridging Ti–O–Ti bonds. This should result in an additional decrease in weight in the hydrolysis stage and in the subsequent drying:

$$\Delta m_{\Sigma h} = \Delta m_h + \Delta m_{dh}. \quad (9)$$

Here Δm_{dh} is the weight change associated with the dehydroxylation of surface groups.

$$\Delta m_{dh} = \frac{M_{H_2O}}{2}[OH_{dh}], \quad (10)$$

where $[OH_{dh}]$ is the amount of dehydroxylated titanols.

Then, with account of (7), we obtain

$$[OH_{dh}] = \frac{\Delta m_{\Sigma h} - (M_{Cl} - M_{OH})[Cl]}{M_{H_2O}/2}. \quad (11)$$

Using the derived expression (11) and thermogravimetric data obtained in the stage of hydrolysis and subsequent thermal treatment, we can estimate the

Table 3. Composition of titanium oxide structures on silica

Curve in Fig. 2	Content, mmol g_0^{-1}				$\frac{[OH_{res}]}{[OH_{calc}]}$	Distance l_{Ti-Ti}, nm
	Ti	OH_{calc}	OH_{dh}	OH_{res}		
1	1.08	2.35	0.39	1.96	0.83	0.60
2	0.79	1.29	0.36	0.93	0.72	0.70
3	0.49	0.84	0.13	0.71	0.84	0.89

thermal stability of titanium hydroxide groups on the surface of the dispersed support. The calculations for the samples represented in Fig. 2 demonstrated that, in the synthesis conditions under consideration, Ti–OH groups are partly dehydroxylated in the stages of hydrolysis and drying immediately after their formation, with the degree of dehydroxylation equal to 0.39, 0.36, and 0.13 mmol g_0^{-1} at 200, 400, and 600°C, respectively (Table 3). In this case, 70 to 85% of the hydroxo groups forming by reaction (2) in vapor-phase hydrolysis of titanium chloride groups remains on the surface of the samples (Table 3). This is in a good agreement with the results of a chemical analysis of multilayer titanium oxide coatings synthesized at the same temperatures, because the remaining amount of hydroxide groups is sufficient for further growth of the titanium oxide layer [18].

At the same time, no complete dehydroxylation of surface titanium-containing structures on silica at 600°C (as differentiated from the surface of pure TiO_2) is observed. The enhanced thermal stability of titanols on silica may be due to the stabilizing effect of the silica matrix [23]. By contrast, the amount of removed hydroxo groups even decreases in comparison with the samples synthesized at 200 and 400°C, which is presumably due to the topography of active sites on the surface of the starting matrix. The rise in the T_0 of silica results in a substantial increase in the average distance between the groups synthesized (Table 3), which hinders interfunction interactions because of the spatial remoteness of the structures synthesized on the matrix surface.

CONCLUSION

The use of gravimetric measurements makes it possible to monitor *in situ* separate stages of molecular layering of element-oxide surface structures, to calculate the chemical composition of the groups synthesized, and to analyze the possible processes of dehydroxylation of the newly formed hydroxyl groups.

ACKNOWLEDGMENTS

This study was carried out within the framework of the grant of the President of Russian Federation "Leading Scientific Schools of Russia," "Chemistry of Highly Organized Substances" Program (project NSh 2236.2003.3) and was financially supported in part by the Russian Foundation for Basic Research (project no. 04-03-32048) and Programs of the Ministry of Education of the Russian Federation.

Abstract—Cadmium phosphate $Cd_{0.5}Zr_2(PO_4)_3$ was obtained by precipitation from aqueous solutions and studied by means of X-ray phase analysis and IR spectroscopy. The behavior of powdered and ceramic samples in water, aqueous ammonia solutions, nitric acid, EDTA, and also in gamma-radiation fields (^{60}Co source), was examined. Experimental characteristics of the chemical and radiation stability are presented.

Cadmium compounds are a dangerous component of wastes formed in some industries [1]. At present, methods for conversion of cadmium-containing wastes into an environmentally safe stable form by their solidification are being developed. For this purpose, it has been suggested to use polymers and resins [2], cements [3, 4], glasses, and glassy ceramic [5, 6] and ceramic materials [7]. The method of incorporation of waste products into crystalline (mineral-like) forms is ecologically expedient. These forms can find application for detoxication of highly toxic waste products and for their insulation from the biosphere, and also as new materials with special and practically important properties. One of approaches to the solution of this problem is to convert soluble cadmium compounds into a crystalline phosphate, which is temperature- and radiation-resistant and chemically stable and can be further used as a sorbent in various media, including application in ion-exchange chromatography. When creating such a material, it is necessary to take into account the stability of the phosphate brought in contact with a liquid medium, the rate at which ions pass into solution, and, when in a contact with a radioactive medium, also its radiation stability.

The goal of this study was to obtain cadmium phosphate $Cd_{0.5}Zr_2(PO_4)_3$, characterize it by X-ray phase analysis (XPA) and IR spectroscopy, examine its behavior in chemically aggressive media in the presence of complexing substances, and assess its radiation stability. This compound belongs to the structural type of sodium-dizirconium triphosphate $NaZr_2(PO_4)_3$ [8], or the cosnarite mineral [9], and has a skeleton structure (Fig. 1). The skeleton is built from ZrO_6 octahedra and PO_4^{3-} tetrahedra jointed by

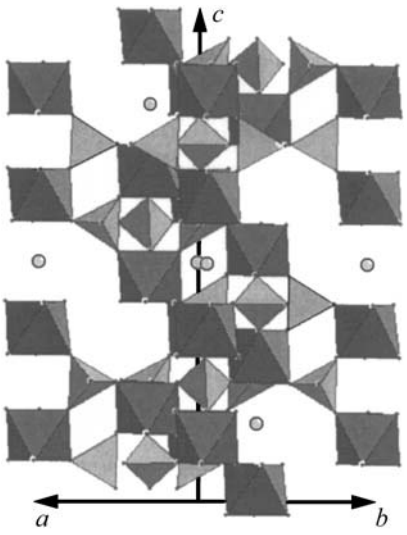

Fig. 1. Structure of the phosphate $Cd_{0.5}Zr_2(PO_4)_3$ (a fragment of the structure is constructed using the data of [10]).

common vertices. Representatives of this family are known to have a high thermal and hydrolytic stability [11, 12]. Some of these, including Cd^{2+} phosphates, have low thermal expansion and ability to withstand multiple thermal shocks [13–16]. The structure of the compounds is favorable for performing an ionic diffusion.

EXPERIMENTAL

Phosphate $Cd_{0.5}Zr_2(PO_4)_3$ was prepared by the sol–gel technique [16, 17]. Chemically pure reagents $Cd(NO_3)_2 \cdot 4H_2O$, $ZrOCl_2 \cdot 8H_2O$, and H_3PO_4 served as starting substances for the synthesis. Stoichiometric amounts of aqueous solutions of $Cd(NO_3)_2$ and $ZrOCl_2$ were poured together at room temperature and then a solution of H_3PO_4 was added dropwise with stirring. The resulting gel was dried at 80°C and subjected to a heat treatment at 600, 800, 1000, and 1100°C for no less than 24 h in each stage. Step-by-step heating was alternated with dispersion.

Ceramic samples were also prepared. For this purpose, a powder of the phosphate was compacted (at a pressure of about 10 MPa) into pellets and annealed at 800–1100°C for 24 h.

A ceramic sample of the phosphate $Cd_{0.5}Zr_2(PO_4)_3$ (diameter 1.13 cm, height 0.45 cm) was subjected to hydrothermal tests.

The hydrolytic stability was studied under dynamic conditions in a Soxhlet apparatus at 95°C, with distilled water (MSS-1 test) as a solvent. The volume of the solvent was 300 ml, the cycle duration of the apparatus was 100–120 min. The experiment duration was 28 days.

The solvent was changed after certain time intervals. The Cd^{2+} content in these solvent portions was determined by inversion voltammetry on a TA-1 analyzer equipped with an IBM-compatible computer.

The rate of Cd^{2+} leaching was calculated by the equation

$$R = m/(c_{sp} S \tau).$$

Here R is the rate of leaching of an element (g cm^{-2} day^{-1}) in a time τ; m, the mass (g) of an element that passed into a solution during a time τ; c_{sp}, the specific concentration of an element in the solid phase (g g^{-1} of a solid phase); S, the surface area of a ceramic sample (cm^2); and τ, the time of leaching (days).

The behavior of the phosphate in aggressive chemical media in the presence of complexing compounds was studied as follows. A weighed portion of a powdered cadmium-zirconium phosphate (0.1 g) was poured over with a solution under study (2 ml) and kept for a certain time.

Aqueous solutions of HNO_3 (10 and 65%), NH_4OH (25%), and EDTA (0.1 M) were used as contacting solutions.

Similar studies were carried out with a phosphate of the same composition in the form of a ceramic pellet (diameter 1.11 cm, height 0.13 cm). In this case, 10% HNO_3 served as a contacting solution.

The analysis of samples (of volume 10 μl) for the content of Cd^{2+} and PO_4^{3-} was carried out on a Tsvet 306 liquid chromatograph in a flow-through-injection mode without a separation column. As detector served an SF-00 spectrophotometer. An ammonia solution (5×10^{-4} M) of cadion-IREA and NH_4OH_{conc} in the ratio 1 : 1 was used as a mobile phase.

Preliminarily, absorption spectra of ammonia solutions of cadion and its complexes with Cd^{2+}, ZrO^{2+}, and PO_4^{3-} were recorded using the detector and wavelengths were selected at which Cd^{2+} and PO_4^{3-} ions do not interfere with determination of each other: 625 nm for Cd^{2+} and 400 nm for PO_4^{3-}. At these wavelengths the spectrum of a ZrO^{2+} complex with the cadion coincides with that of the mobile phase and does not interfere with the determination of Cd^{2+} and PO_4^{3-}.

We have found that the calibration plots of peak areas in output curves vs. weights of ions, used to Cd^{2+} and PO_4^{3-} ions with cadion ammonia solutions, are described by the equations $y_1 = 9.947x_1$ ($R^2 = 0.995$) and $y_2 = 0.1355x_2$ ($R^2 = 0.992$), respectively. Here y_1 and y_2 are the areas under the output curves (mm^2) for Cd^{2+} and PO_4^{3-} ions, and x_1 and x_2 are the weights of Cd^{2+} and PO_4^{3-} ions (μg).

To study the behavior of cadmium-zirconium phosphate under the action of gamma-radiation, we used a ^{60}Co source ($\tau_{1/2} = 5.272$ year, $E_\gamma = 1.17$, 1.33 MeV). The dose rate p at a sample was determined by a Fricke dosimeter, i.e., a ferrosulfate system consisting of a 0.001 M solution of Mohr's salt $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$ in 0.4 M H_2SO_4. The p (Gr s^{-1}) was calculated by the formula

$$p = CN_A/(G\tau \times 6.25 \times 10^{15}).$$

Here c is the experimental concentration of Fe^{3+} ions (M); G, the yield of Fe^{3+}, equal to 15.6 ion/100 eV for ^{60}Co gamma-radiation; N_A, the Avogadro number; and τ, the irradiation time (s).

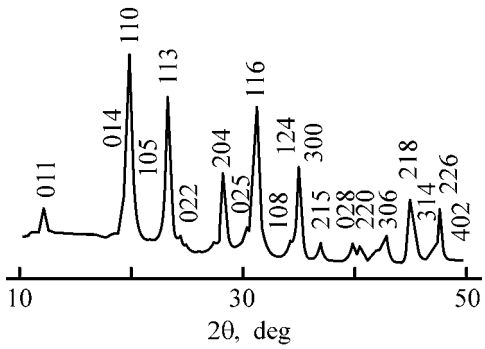

Fig. 3. X-ray diffraction pattern of the phosphate $Cd_{0.5}Zr_2(PO_4)_3$. (2θ) Bragg angle.

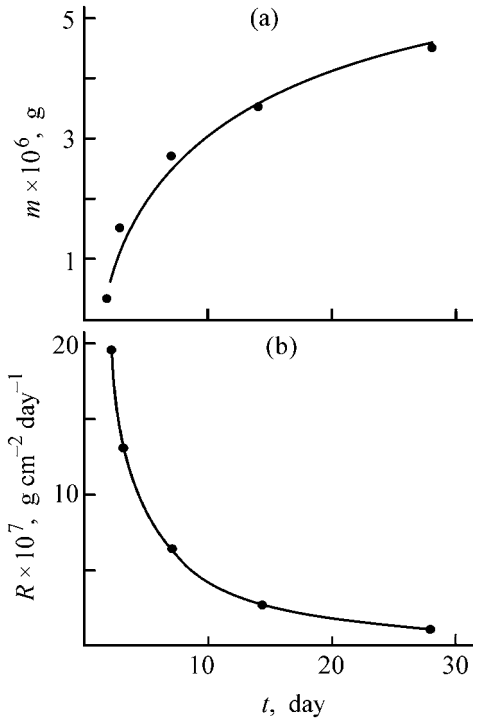

Fig. 4. (a) Mass of Cd^{2+} m that passed into distilled water from the phosphate $Cd_{0.5}Zr_2(PO_4)_3$ and (b) leaching rate R of cadmium vs. time t.

The concentration c of Fe^{3+} ions formed in radiolysis was determined by spectrophotometry on an SF-4A instrument.

The irradiated sample was studied by X-ray phase analysis and IR spectroscopy and compared with an unirradiated control sample.

The gas evolution from a gamma-irradiated sample (powder, $m \approx 30$ g) placed in an ampoule was judged from the composition of the gas and the rate of its evolution. The composition of the gas was determined by chromatography on Shimadzu 3G-AH and LKhM-8M instruments.

The X-ray phase analysis of the phosphates was carried out on a DRON-2.0 diffractometer with filtered Cu_{K_α} radiation. The lattice constants were determined from X-ray diffraction patterns analyzed at $2\theta = 10°–50°$ and refined by the least-squares method.

The IR absorption spectra of samples prepared as finely dispersed films on a KBr substrate were recorded on a Specord-75 IR spectrophotometer at frequencies of 1800–400 cm^{-1}.

The ESR spectra of powdered unirradiated and gamma-irradiated samples were recorded on a Bruker EMX-113 spectrometer (wavelength $\lambda = 3$ cm) at room temperature. The working frequency of the device was 9.5 GHz.

Several samples synthesized were in the form of a white polycrystalline powders.

We found that the synthesis of the phosphates was complete at 800°C. A slight increase in the intensity of diffraction reflections was observed in the X-ray diffraction patterns of substances heated to 1100°C.

The IR spectral data indicate that the phases obtained belong to the class of orthophosphates (Fig. 2). On the whole, the IR spectrum is characteristic of phases with an *NZP* structure and $R\bar{3}$ space group: the bands at 1250–1000 cm^{-1} correspond to the stretching asymmetrical vibrations ν_3; that at ~950 cm^{-1}, to the stretching symmetrical vibrations ν_1; and the bands at 630 and 550 cm^{-1}, to bending vibrations ν_4 of PO_4^{3-} ions. Five bands out of the six allowed by selection rules are observed in the range of stretching asymmetrical vibrations.

In the X-ray diffraction pattern, there were reflections characteristic of $Cd_{0.5}Zr_2(PO_4)_3$ (Fig. 3). The set of the interplanar distances obtained was compared with the data of [18]. The calculated parameters of the rhombohedral cell of the compound

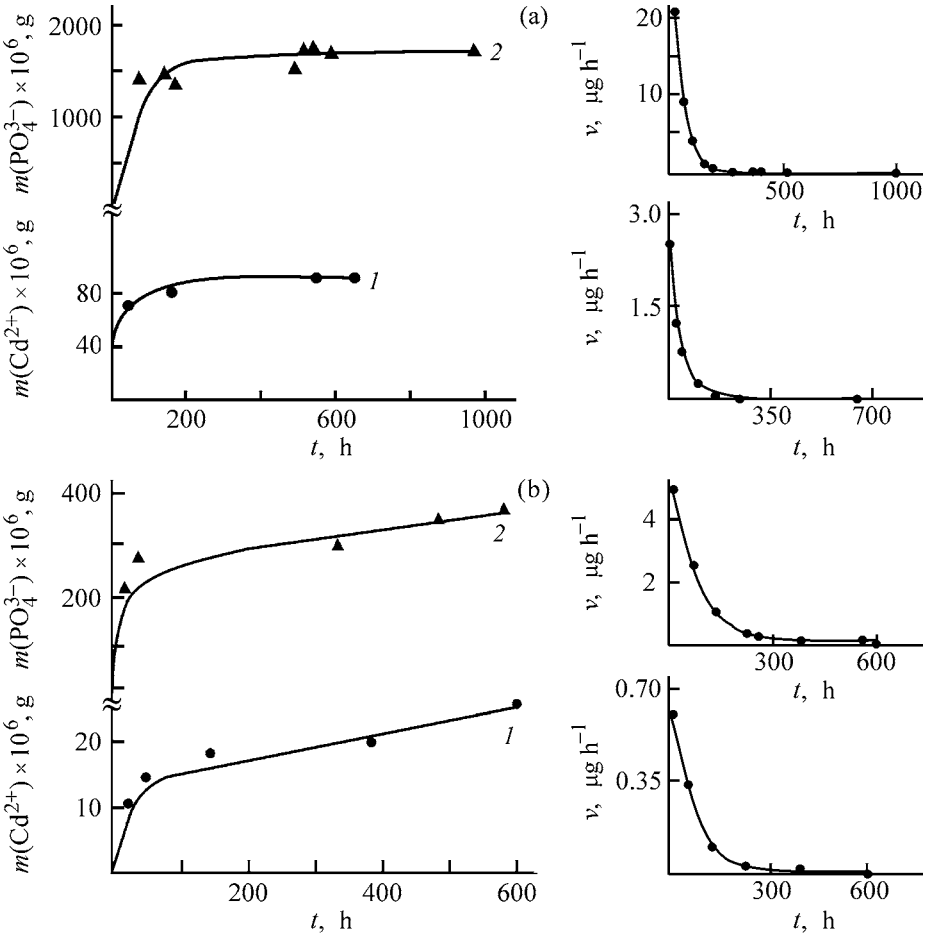

Fig. 5. Mass m of (*1*) Cd^{2+} ions and (*2*) PO_4^{3-}-ions that passed into HNO_3 solutions during the time t of contact and rates v at which these ions passed into solution vs. time t. (a) 65% solution of HNO_3, powdered sample; (b) 10% solution of HNO_3, ceramic sample.

(space group $R\bar{3}$) in a hexagonal positioning were as follows: a = 8.822 Å (1), c = 22.28 Å (1), and V = 1502 Å^3.

The time dependences of the mass of Cd^{2+} that passed into distilled water from the phosphate $Cd_{0.5}Zr_2(PO_4)_3$ and of the leaching rate of Cd^{2+} are shown in Fig. 4.

Within the first three days of contact with water, the leaching rate rapidly decreased with time. The minimum experimental leaching rate was 1.1×10^{-7} g cm^{-2} day^{-1} (by the 28th day).

According to the XPA data, the phase composition of the sample after tests remained unchanged.

The time dependences of the mass of Cd^{2+} and PO_4^{3-}-ions that passed into 10 and 65% HNO_3 solutions and of the rates at which they pass into the solutions are shown in Fig. 5. It can be seen that, when powdered samples are brought in contact with a 65% HNO_3 solution, a quasi-equilibrium state is attained after 200–250 h for both Cd^{2+} and PO_4^{3-}-ions. When ceramic samples are brought in contact with a 10% HNO_3 solution, no equilibrium was attained within more than 600 h of the experiment.

The data obtained allowed us to determine the quasi-equilibrium degree of extraction of Cd^{2+} and PO_4^{3-}-ions from a powdered sample and the degree of extraction of these ions from a ceramic sample in 600 h of contact, and also to calculate the minimum rate D of their transfer from a pellet sample into the contacting medium (Table 1).

The value of D was calculated for a cylindrical sample with a fixed height l from the slope of the linear dependence of M_t/M_∞ on $\sqrt{t}$ [19]:

$$\frac{M_t}{M_\infty} = \frac{4}{\sqrt{\pi}}\sqrt{\frac{D}{l^2}}\sqrt{t}.$$

Here M_t is the mass of ions (Cd^{2+} and PO_4^{3-}) that passed from a pellet into a solution by the instant of

Table 1. Degree of extraction, *c*, and rate *D* at which ions pass into nitric acid

HNO_3, %	*c*, wt %		*D*, $cm^2\ s^{-1}$	
	Cd^{2+}	PO_4^{3-}	Cd^{2+}	PO_4^{3-}
10	0.25	0.7	3×10^{-11}	5×10^{-12}
65	0.82	3.12	–	–

time *t*; M_∞, the masses of Cd^{2+} and PO_4^{3-}-ions that passed into a 65% HNO_3 solution from a powdered sample until an equilibrium was attained (Fig. 5a); *t*, the time of the contact of a pellet with a 10% HNO_3 solution (s); *l*, the height of a pellet (cm); *D*, the rate at which the ions under control pass from a pellet into a 10% HNO_3 solution ($cm^2\ s^{-1}$).

The data listed in Table 1 indicate that Cd^{2+} and PO_4^{3-}-ions pass into nitric acid at rates approaching the rates of diffusion in solids.

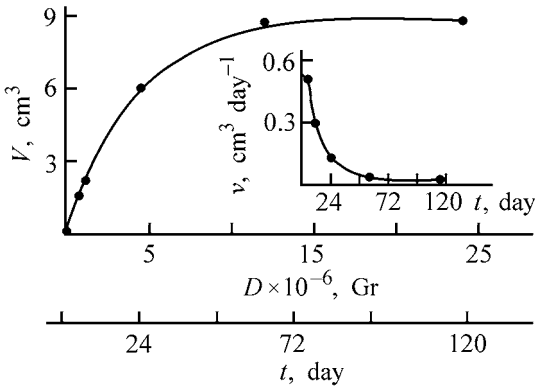

Fig. 6. Volume *V* of the gas evolved in gamma-irradiation of the phosphate $Cd_{0.5}Zr_2(PO_4)_3$ vs. time *t* and absorbed dose *D*. Inset: gas evolution rate *v* vs. time *t*.

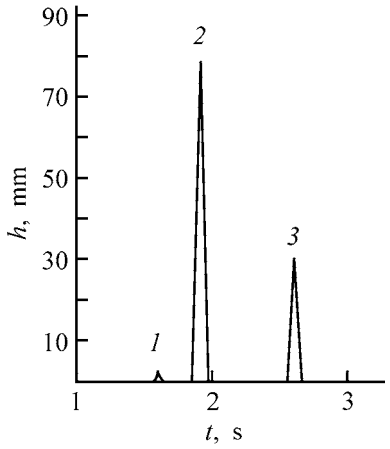

Fig. 7. Chromatogram of the gas mixture. (*h*) Peak height and (*t*) elution time. (*1*) H_2, (*2*) O_2, (*3*) N_2.

It also follows from these data that ratios between Cd^{2+} and PO_4^{3-}-ions in the solid phase and in solution differ from each other. The solution is enriched with Cd^{2+} ions. This seems to be due to different positions of these ions in the phosphate structure: PO_4^{3-} is a skeleton-forming group, whereas Cd^{2+} ions occupy extra-skeleton positions, in which the contribution of the ionic component is more important. This circumstance results in a selective dissolution (leaching).

We also studied the behavior of a powdered $Cd_{0.5}Zr_2(PO_4)_3$ sample in a 0.1 M EDTA solution and a 25% NH_4OH solution. The degree of Cd^{2+} extraction in 600 h is given below:

Contact solution	*c*, wt %
Water	0.003
10% HNO_3	0.2
65% HNO_3	0.8
25% NH_4OH	0.03
0.1 M EDTA	0.01

These values are an order of magnitude higher than those for a sample brought in contact with water and an order of magnitude lower than those for 10 and 65% HNO_3 solutions.

Thus, complexing compounds NH_4OH and EDTA, which form stable complexes with Cd^{2+} ions [20, 21], lead to an only slight disintegration of the structure of the Cd–Zr phosphate.

To assess the radiation resistance, we irradiated a $Cd_{0.5}Zr_2(PO_4)_3$ sample for 4 months, using a ^{60}Co-source. The maximum accumulated dose was $D = 2.5 \times 10^7$ Gr (dose rate $p = 2.4$ Gr s^{-1}). A comparison of the X-ray diffraction patterns of the samples before and after irradiation demonstrated that the structure remains virtually unchanged upon irradiation. An IR spectral analysis of an irradiated sample revealed no changes in the structure of Cd–Zr phosphate, either.

The radiation resistance of the phosphate was also judged from the amount and composition of the gas evolved under the action of gamma-radiation. The dependence of its volume on the irradiation time *t* and on the accordingly accumulated dose of gamma-radiation, *D*, is shown in Fig. 6.

A total of 9 ml of the gas evolved during the test. It was found by chromatography that the main component of the mixture was O_2, with minor amounts of N_2 and H_2 and trace amounts of CO_2 also detected (Fig. 7).

The compositions of the gas mixtures at various doses of irradiation of a $Cd_{0.5}Zr_2(PO_4)_3$ sample are listed in Table 2.

The calculated radiative-chemical yield was 0.058 ± 0.005 molecules/100 eV. The fraction of O_2 evolved from Cd–Zr-phosphate as a result of its radiative-chemical destruction was about 0.0009 of its calculated content in a sample with the formula $Cd_{0.5}Zr_2(PO_4)_3$.

To describe qualitatively the radiation resistance of Cd–Zr phosphate, we also used ESR data, which make it possible to establish the fact of formation of paramagnetic centers in the phosphate structure under the action of radiation. As follows from the experimental data, the ESR spectra of unirradiated and irradiated samples do not differ significantly. In the spectrum of the irradiated phosphate, the signal of Zr^{3+} ions becomes somewhat stronger, and very weak signals of PO_3^- groups appear. These radical anions are presumably formed due to bond rupture in the phosphate structure, which results in the observed evolution of oxygen.

On the whole, the results of XPA of irradiated and unirradiated samples, the low radiative-chemical yield of the gas mixture, and the insignificant difference between the ESR spectra of unirradiated and irradiated samples indicate a high radiation resistance of Cd–Zr phosphate. The rate of gas evolution, which reaches a constant value in approximately 48 days, remains virtually unchanged in further irradiation, even in a long-term test (Fig. 6), and does not exceed the values obtained.

CONCLUSIONS

(1) The possibility of utilization of cadmium(II) from crystalline (ceramic) Cd-containing zirconium phosphate, which belongs to structural analogues of $NaZr_2(PO_4)_3$ and has a skeleton structure, was demonstrated.

(2) An all-round study of the behavior of the phosphate $Cd_{0.5}Zr_2(PO_4)_3$ in water and aqueous solutions of NH_3, HNO_3, and EDTA was carried out, and the parameters of leaching of cadmium(II) and phosphate ions in these media were determined.

(3) It was shown experimentally that the Cd-containing zirconium phosphate $Cd_{0.5}Zr_2(PO_4)_3$ is stable in water and aggressive chemical media, including those containing complexing substances. The occurring radiation-stimulated destruction is insignificant.

Table 2. Composition of gas mixture evolved in gamma-irradiation of a Cd-containing zirconium phosphate at doses $D \le 2.4 \times 10^7$ Gr

D, Gr	Gas mixture component, %			
	H_2	O_2	N_2	CO_2
6.8×10^5	0.8 ± 0.1	88.3 ± 1.5	9.9 ± 1.3	Trace
1.08×10^6	1.4 ± 0.2	92.3 ± 0.9	7.3 ± 0.9	〃
4.5×10^6	1.2 ± 0.4	88.3 ± 1.1	9.1 ± 0.8	1.4
1.2×10^7	1.7 ± 0.3	87.1 ± 1.5	8.8 ± 1.5	1.7
2.4×10^7	1.3 ± 0.2	90.2 ± 1.3	7.9 ± 1.3	0.9

(4) The data obtained and the specific structural features of zirconium-cadmium phosphate make it possible to regard this compound as a form of immobilization of cadmium(II) and a basis for development of new sorbents resistant to aggressive chemical media and radiation. They can be used in ion-exchange chromatography and, taking into account the nuclear properties of cadmium(II), as a basis for neutron-absorbing ceramics.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Nanocomposites by Abrasive-Reactive Wear of Grinding Bodies in a Mechanochemical Reactor

F. H. Urakaev

Received November 28, 2003

Abstract—The possibility of synthesis of various nanocomposites and processing of mineral and technological raw materials with the use of abrasives and the material of grinding bodies of mechanochemical reactors was studied.

As a rule, only the possibility of contamination of mechanical activation (MA) products with substances of frictional wear of the grinding bodies [1–3] is taken into account when considering the direct influence of the material of grinding bodies on the course of mechanochemical processes. As it is impossible to eliminate the wear phenomenon, it is suggested to consider the material of grinding bodies subjected to abrasive wear as one of inherent components of the MA system, the abrasive amorphous substances being the most convenient component as regards interpretation of the results of an X-ray phase analysis (XPA).

In this study, the influence exerted by wear of grinding bodies on the course of mechanical activation of reagent–abrasive systems in a mill with steel accessories is analyzed.

At the same time, finding, studying, and obtaining nanoparticles in natural and model systems with the use of various methods are of primary interest [4]. For example, it has been found that the abrasive-reactive wear of the steel material of grinding bodies in a mechanochemical reactor can be used to modify the surface of quartz particles with an amorphous nanolayer of iron silicates, which have magnetic properties [5]. Of specific interest for extending the potentialities of this method is the use of carbon (in particular, graphite) and sulfur, which have unique physicochemical and mechanical properties [6, 7]. Also of interest is the processing of mineral and technological raw materials.

The use of carbon and sulfur in the method of abrasive-reactive wear can give a new impetus to the development of carbide or sulfide functional nanocomposite materials. This method can also be successfully used in utilization of dust formed in decarbonization and desulfurization of the coke-oven gas formed in cake and by-product industries [8, 9]. The accumulation of sulfur at oil refineries and plants processing natural gas also makes its utilization a matter of current interest.

Analysis, breakdown, enrichment, and processing of mineral and technological raw materials (in particular, complex oxides and sulfides) by mechanochemical methods have also found wide application in recent years [10–19]. This is primarily due to the possibility of directly obtaining metal components and various composite nanocrystalline materials from geological and technological materials by, mechanothermal methods [12, 13], both in progressive [12, 14, 17, 18] and in explosive [12, 13, 16, 19] modes of the exothermic reaction.

EXPERIMENTAL

The mechanical activation was carried out in an AGO-2 double-drum steel-ball water-cooled planetary-centrifugal mill (mill volume 140 cm^3, 400 balls of radius 0.2 cm) at a relative impact veocity of grinding bodies of 11 m s^{-1} [13]. For more effective processing of samples, all the four possible orientations of the mill axis were used: vertical, horizontal and ±15° to the horizontal. The duration of MA was varied from 5 up to 240 min.

MA products were studied by the standard XPA method. Mechanically activated amorphous samples

1070-4272/04/7708-1239 © 2004 MAIK "Nauka/Interperiodica"

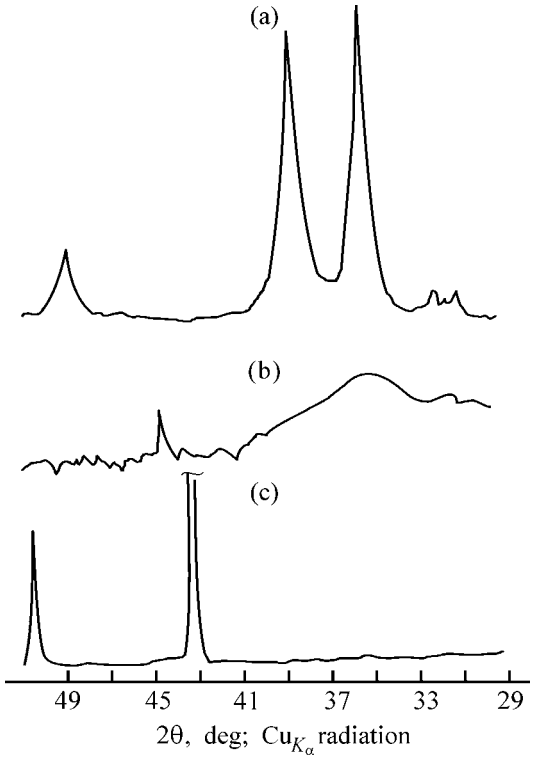

Fig. 1. XPA spectra of the system constituted by fused silica (3 g) and tenorite (1.5 g). (2θ) Bragg angle; the same for Figs. 2–4. (a) Initial tenorite (cf. PDF 48-1548 and 80-1917); (b) MA duration 60 min; and (c) MA duration 60 min, annealing for 2 h in argon at 700°C (PDF 4-836 for copper).

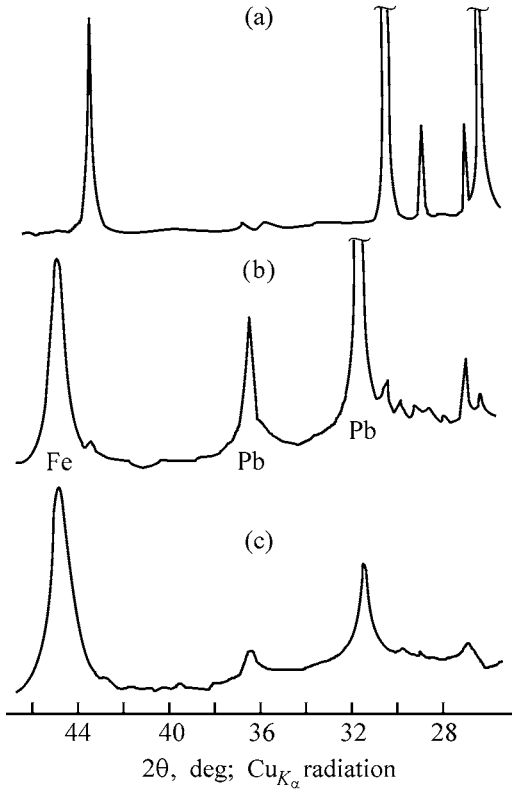

Fig. 2. XPA spectra of the system constituted by fused silica (3 g) and galenite (1.5 g). (a) Initial mixture (PDF 1-880); (b) MA duration 60 min (PDF 4-686 and 6-696); (c) MA duration 210 min.

were also isothermally annealed (2 h) in a flow of argon (~1 cm^3 s^{-1}) in alundum crucibles with graphite plugs and titanium sponge placed before the crucibles in the heated area of the quartz tube to remove the possible oxygen impurity from argon. The chosen annealing temperatures were certainly lower than the temperature of formation of the target products and corresponded to the maximum temperatures used for crystallization of MA products [20].

Graphite, sulfur, galena (PbS), or tenorite (CuO) were introduced in amounts of 0.3–1.6 g into a crushed amorphous (microscopic slide or fused silica) or crystalline (natural α-quartz) abrasive taken in an amount of 3.0 g. The initial tenorite was obtained by thermal decomposition of malachite at ~250°C in the course of 7 h. XPA spectra of this black powder are shown in Fig. 1a. The samples were preliminary crushed and homogenized for 1 h in a Fritsch Pulverisette mill equipped with steel accessories (mortar diameter 9.45 cm + 1 ball of diameter 5.16 cm). The XPA spectrum of a sample of this kind, based on natural galena, is shown in Fig. 2a. It indicates the presence of not only galena, but also some admixtures (mainly crystalline quartz) commonly contained in this mineral. The XPA results for the initial graphite-based samples correspond to PDF 1-640 for graphite in mixtures with an amorphous abrasive. In a mixture with α-quartz, a superposition of reflections (PDF 1-640 and, e.g., PDF 75-443 for α-SiO_2) was observed. The XPA results for the initial sulfur-based samples in mixtures with an amorphous abrasive also point to the presence of only orthorhombic sulfur crystals (PDF 83-2285). According to the data of optical microscopy, the initial average size of abrasive particles was 0.015–0.025 cm for the initial homogenized samples.

Preliminary experiments demonstrated that the mechanochemical processes involving tenorite and galena show both similarity and significant differences. In both the systems, there occurs abrasive wear of steel grinding bodies, which is more pronounced in the system with galena. Even a short-term (5–15 min) MA of the system with tenorite (Fig. 1) results in a self-lining of the grinding bodies with the material being processed. Tenorite starts to change color for green after 1 h of MA, and this color, as well as the

self-lining, is preserved and becomes more intense in the course of MA. By contrast, the self-lining phenomenon is completely absent in the system with galena (Fig. 2), and, after a short time of MA, a black homogeneous "oily" powder of a composite material is formed.

The results obtained in studying the products of MA of the systems under study by XPA and isothermal annealing methods point to the occurrence of various processes. These are the abrasive wear of steel grinding bodies, amorphization, and reduction of copper from tenorite and lead from galena. There are no crystalline phases of other products (iron oxides and halides) of reduction reactions, e.g., CuO + Fe = Cu + FeO ($\Delta_r G^0$ = –28.0 kcal mol^{-1}).

Figure 1b indicates that an X-ray-amorphous product is formed in the system with tenorite and iron wear occurs (peak at 44°–45°). The degree of amorphization increases as the processing duration becomes longer, even the Fe peak is broadened. Metallic copper is the only product formed in annealing of this sample at ~700°C: reflections of all other products that can be formed in the exchange reaction, iron oxides, are completely absent (Fig. 1c).

Figure 2b illustrates a similar phenomenon of abrasive wear of Fe and reduction of galena by this iron, which occur, in this case, directly in the course of MA. It should be noted here that there are no reflections of other possible products of the reduction-exchange reaction, namely iron sulfides. If the MA duration is raised to 120 min, the spectrum remains virtually unchanged: only the reflections of the α-SiO_2 admixture in natural galena disappear (because of amorphization). Annealing of these products also does not change the situation: only the relative intensities change insignificantly and the corresponding reflections become considerably narrower. If the MA duration is increased further, abrasive wear of Fe starts to prevail over all other processes (Fig. 2c).

The data obtained confirm that the self-lining of grinding bodies prevents their abrasive wear and, as a consequence, hinders the reduction reaction of tenorite with the material of grinding bodies in the course of MA. By contrast, the full absence of self-lining of grinding bodies in the system with galena results in a fast breakdown of galena by iron formed in the abrasive wearing of grinding bodies.

It is difficult to give an unambiguous interpretation of the fact that reflections of iron oxides (sulfides) disappear after reductive breakdown of tenorite (galena) without thoroughly studying the MA of natural quartz with the material of steel grinding bodies [5]. The results of [5] suggest that the surface of quartz particles can be modified not only by amorphous iron silicates (after annealing of mechanically activated tenorite samples), but also by iron sulfides after MA of galena together with amorphous quartz particles. In the case of galena, a nanosize surface layer on quartz particles must be formed of a certain amorphous compound of the system Fe_xS_y–SiO_2. An even more complex compound of green color, which is formed upon MA of tenorite and contains nanosize particles produced by abrasive wear of the steel accessories (Fig. 1b), is the amorphous compound $Cu_xFe_yO_z$–SiO_2 on the surface of quartz particles.

The following aspect is associated with dimensional effects. In the case of the conventional mechanochemical reduction of, e.g., copper sulfides [18] with metallic Fe powders with an initial particles size of about 50 μm, the duration of MA is tens of hours. In the new abrasive-reactive method of breakdown of, e.g., galena, suggested here, the size of initial particles formed in abrasive wear of Fe is close to 10 nm, which is orders of magnitude shorter than that in the conventional mechanochemical exchange reaction. Therefore the rate of the breakdown reaction involving the material of steel grinding bodies is also higher and, as a consequence, the time of MA breakdown of minerals becomes shorter.

The XPA data were used to calculate by the known method [2, 10, 17, 18] the structure of crystalline blocks in metal particles obtained in the course of MA in the system with galena. The parameters of the fine crystal structure were calculated from the halfwidth of diffraction peaks (Figs. 2b and 2c) for MA duration of 60, 210, and 120 min (XPA spectrum is not shown). To determine the instrumental broadening of the lines, we used the profiles of the corresponding reflections after the annealing of these samples. The resulting size of Pb blocks was (nm): 83 (60 min MA), 61 (120 min MA), and 46 (210 min MA); the corresponding data for particles formed in wear of Fe were 24, 19, and 12 nm.

Thus, we obtained metal-oxide–sulfide nanocomposite powders based on the quartz matrix in the course of MA of natural minerals (tenorite and galena) mixed with an abrasive (fused silica) in an AGO-2 mill with steel accessories.

Cementite (Fe_3C) is commonly obtained by MA of mixtures of iron and carbon powders, with subsequent thermal or arc-plasma processing of the MA products [21–23]. Sulfides are, as a rule, obtained from elements on heating. However, the morphology

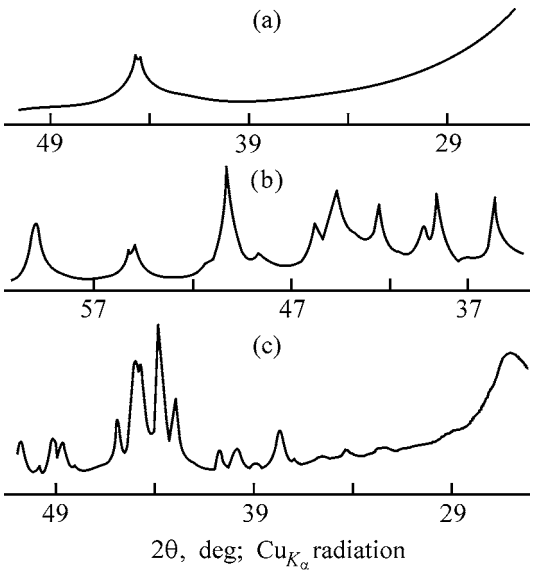

Fig. 3. XPA spectra of the system constituted by quartz (3 g) and graphite (1.5 g). (a) Amorphous quartz, MA duration 90 min; (b) α-quartz, MA duration 90 min; (c) annealing of MA sample (a) for 2 h in argon at 960°C.

and the homogeneity of the target products are not always of the required level. It depends on a number of factors and, in particular, on the area and state of the surface of the starting reagents. The use of a mechanochemical reactor eliminates these drawbacks. At present, iron sulfides, especially those of nanosize [17], are applied in power cells with a high energy density, in photoelectrolysis and solar power engineering, and in synthesis of superconducting, diagnostic, and luminescent materials and chalcogenide glasses.

The results of simulation of mechanochemical reactions involving sulfur [7] show that the most important process for the synthesis of sulfides, e.g., ZnS, is the plastic flow of sulfur. The heat pulse in the shock displacement of molten sulfur is determined by the thickness of layers on the surface of Zn particles lined with softer sulfur. The thinner this layer, the higher the temperature and the faster the amorphization of sulfur (polymerization with a transition to the glassy state). However, the occurrence of this process has not been confirmed experimentally. Therefore, to substantiate the theory [7, 19], it was necessary to choose for MA a system that would contain an inert amorphous component, alongside with crystalline sulfur. Ordinary glass and fused silica are suitable for this purpose. To confirm the mechanochemical amorphization of sulfur, is also the goal of this study.

The XPA spectrum of the system constituted by amorphous quartz and graphite after MA is shown in Fig. 3a. It indicates an amorphization of graphite and wear of steel grinding bodies (α-Fe reflection at $2\theta = 44.68°$ or PDF 6-696).

In the course of MA of the system with α-SiO_2, quartz reflections are preserved, but with significant broadening and decrease in intensity, compared with the initial homogenized sample (cf., e.g., PDF 75-443). Wear of steel grinding bodies also occurs (see a fragment of the spectrum in Fig. 3b at $2\theta = 44°–45°$).

As already noted, MA samples were annealed under the conditions that ruled out thermal synthesis of cementite [24]. In both low (660°C) and high-temperature (960°C, Fig. 3c) annealing, cementite crystallizes (PDF 75-910) from the amorphous phase. However the degree of cementite crystallization from the amorphous phase for samples annealed at 660°C is lower than that for the samples annealed at 960°C. The presence of residual nanosize iron particles in the samples [5] is confirmed by the following: the peak of cementite at $2\theta = 44.72°$ overlaps the base reflection of α-Fe, but not its reflection at $2\theta = 82.4°–82.5°$. In annealing, a partial crystallization of graphite also occurs (halo at $2\theta \approx 26°$ in Fig. 3b). Similar results were obtained for the system with crystalline quartz. It can be stated that the nanocomposite Fe–Fe_3C–C–SiO_2 is formed in the course of MA of quartz–graphite systems.

Experiments on MA of only sulfur crystals (weighed portion 2 g) were carried out under identical conditions. The XPA data for samples of mechanically activated sulfur (MA duration of up to 180 min) show that no structural transformations in sulfur takes place. All the reflections are preserved without any appreciable change in their shape and relative intensity (PDF 83-2285), except for the absence of a halo associated with the presence of amorphous particles of quartz or glass. The situation changes (Fig. 4a) when sulfur is treated in the presence of inert glass particles.

According to the results of a simulation [7], the structural changes in sulfur are due to the attainment of the necessary *t–P–T* conditions in the impact-frictional contact of sulfur-lined glass particles. Although the hardness of glass particles somewhat exceeds that of steel, the abrasive wear of steel accessories is small. Furthermore, the heat pulse in the impact-frictional contact of grinding bodies and particles being processed cannot exceed the glass softening point (~700 K), which also does not favor synthesis of iron sulfides within the activation time specified. We note that the synthesis of iron sulfides

in MA of Fe and S powders [17] requires tens and hundreds of hours of MA.

Fundamental changes occur in activation of samples based on amorphous quartz: pyrite is formed (FeS_2, PDF 71-2219; Fig. 4b). The hardness of quartz particles is considerably higher than that of steel, and its softening point substantially exceeds that of glass. In this case, amorphization of sulfur (absence of reflections of excess sulfur in Fig. 4b) and its chemical reaction with iron nanoparticles (which have already appeared in a significant amount as a result of abrasive-reactive wear of steel accessories) to form pyrite FeS_2 occur simultaneously. The formation of just FeS_2 is due to the excess of sulfur in MA samples.

Using the above-described method and the XPA data, we also calculated the sizes of crystal blocks and the extents of distortion in the structure of the resulting FeS_2 (and Fe particles). The parameters of fine crystal structure were calculated from the half-widths of the diffraction peaks (220) and (440), which are commonly associated with FeS_2 [10]. To determine the instrumental broadening, we used the profile of lines of crystalline FeS_2. The resulting size of blocks in FeS_2 was about 24 nm (~10 nm for iron particles [5]), and the extent of distortion, 1%. Similar results were obtained in [17], but after more than 110 h of MA of a 1 : 2 mixture of powders of Fe (particle size of about 50 μm) and S.

We determined gravimetrically the following absolute and relative values of wear of the material of steel grinding bodies—drum (D) and balls (B), for the systems under study: (1) amorphous quartz (3 g) and graphite (1.5 g), MA duration 90 min, D (0.63 g or 0.077%) and B (0.52 g or 0.50%), total wear 1.15 g; (2) α-quartz (3 g) and graphite (1.5 g), 60 min, D (0.23 g or 0.028%) and B (0.25 g or 0.26%), total wear 0.48 g; (3) amorphous quartz (3 g) and sulfur (1.6 g), 135 min, D (0.21 g or 0.077%) and B (0.47 g or 0.50%), total wear 0.68 g; and (4) glass (3 g) and sulfur (1.6 g), 135 min, D (0.03 g or 0.077%) and B (0.43 g or 0.50%), total wear 0.073 g.

We note that the experiment gives higher abrasive characteristics for fused silica, compared with crystalline α-quartz.

Let us assume that the nanosize particles formed upon abrasive wear of steel grinding bodies are completely consumed for formation of the phase Fe_3C (FeS_2) by the reaction $3Fe + C = Fe_3C$ ($Fe + 2S = FeS_2$). Then we would have the following composition of nanosize MA products: Fe_3C (1.23 g), C (1.42 g), and amorphous quartz (3 g); Fe_3C (0.51 g), C (1.46 g), and α-quartz (3 g); and FeS_2 (1.46 g), S (0.82 g), and amorphous quartz (3 g).

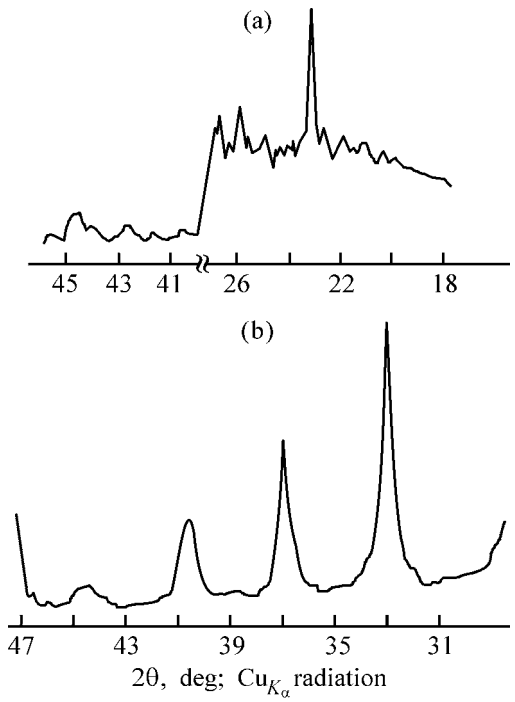

Fig. 4. XPA spectra of systems with sulfur. (a) Glass (3 g) and sulfur (0.4 g), MA duration 135 min; (b) amorphous quartz (3 g) and sulfur (1.6 g), MA duration 135 min.

However, the structure of composites formed may be considerably more complex [5].

CONCLUSIONS

(1) The study performed demonstrated that the steel material of grinding bodies can be involved in direct mechanochemical breakdown of minerals and synthesis of nanocomposites with the use of the abrasive properties of quartz varieties. The mechanical activation of mixtures of quartz and reagents (galena, tenorite, graphite, or sulfur) yielded nanocomposites in a time one to two orders of magnitude shorter than that in the case of activation of mixtures of iron powders with the reagents.

(2) Abrasive-reactive wear of the material of steel grinding bodies in an AGO-2 planetary mill was measured quantitatively under fixed conditions of mechanical activation.

(3) A scrap of any metal and ceramic products can be used as grinding bodies, which makes it possible to extend considerably the potentialities of the method suggested, based on abrasive-reactive wear of the material of grinding bodies in mechanochemical reactors and substances being processed.

Abstract—Tellurite glasses were synthesized on the basis of the binary system composed of 70 mol % TeO_2 and 30 mol % $ZnCl_2$ and doped with Nd^{3+}, Pr^{3+}, Tb^{3+}, Er^{3+}, Yb^{3+}, Ho^{3+}. The physicochemical, luminescent, and magneto-optic properties of these glasses were studied.

Tellurite glasses based on TeO_2 have a wide optical transmission range (0.35–5.5 μm) and good chemical and crystallization resistance. Tellurite glasses doped with ions of rare-earth elements (REE) exhibit interesting magneto-optic and luminescent properties [1–7].

Tellurite glasses of the following composition were synthesized: (1) (100 – *x*)(70 mol % TeO_2–30 mol % $ZnCl_2$)–*x*Ln_2O_3, where *x* = 0.1–3.0 wt %, Ln = Nd^{3+}, Pr^{3+}, Tb^{3+}, Er^{3+}, and Yb^{3+}; (2) 96 wt % (70 mol % TeO_2–30 mol % $ZnCl_2$)–1 wt % Er^{3+}–3 wt % Yb^{3+}; (3) (100 – *x*)(70 mol % TeO_2–30 mol % $ZnCl_2$)–*x*R'F_3, where *x* = 0.1–2.0 wt %, R' = Pr^{3+}, Tb^{3+}, Ho^{3+}; (4) 96 wt % (70 mol % TeO_2–30 mol % $ZnCl_2$)–1 wt % Er^{3+}–3 wt % Yb^{3+}, in order to study their magneto-optic and luminescent properties (Table 1).

EXPERIMENTAL

The glasses were synthesized from analytically pure (TeO_2, $ZnCl_2$) and special-purity (Nd_2O_3, Pr_2O_3, Tb_2O_3, Er_2O_3, Yb_2O_3, PrF_3, TbF_3, HoF_3) reagents in porcelain crucibles in two stages. First, a two-component glass composed of 70 mol % TeO_2 and 30 mol % $ZnCl_2$ was synthesized at 650°C. The glass obtained was cooled and ground, and xenon difluoride XeF_2 was added to the resulting powder. The mixture was kept at 200–250°C for 30 min. Then, weighed portions of oxides and fluorides of the above-mentioned REE were added and the resulting mass was fused at

700–750°C. After the muffle furnace was switched off, the crucible was left inside for 30 min for a homogenization of the melt to occur. The glass obtained was annealed at 250°C. The glass was successively cut, ground, and polished. Glass samples had the shape of 15×30 mm planar polished plates of thickness 3 mm.

To make smaller the content of water, XeF_2 was introduced into the stock. Previously [8], the fluoride method has been specially developed to obtain tellurite glasses with a low content of water. Photoluminescence (PL) spectra of the glasses were recorded on a Jobin–Yvon HR-640 spectrometer. As PL excitation source was used a semiconductor LED (~1 W, 980 nm). Transmission spectra were recorded on a Specord 75 M spectrophotometer in the spectral range 4600–1600 cm^{-1}. The optical quality of the glasses obtained was assessed by means of laser ultramicroscopy.

The IR spectrum of a tellurite glass synthesized in air contains a broad absorption band at 2.8–3.6 μm (3600–2800 cm^{-1}), which is due to the high content of water. Synthesis in the atmosphere of dry nitrogen did not lead to any significant changes in the spectrum, because the glass is inevitably contaminated with water owing to the hygroscopicity of the starting $ZnCl_2$ and it is impossible to obtain a tellurite glass containing no trace amounts of water without taking special measures (use of anhydrous $ZnCl_2$). Therefore, it was decided to remove water from the tellurite glass with the use of dehydrating reagents. As reagent of this kind, which produced a positive effect, was used XeF_2 added to a powdered tellurite glass. A crucible with its contents was placed in a quartz vessel blown-through with nitrogen from a Dewar flask. After a short-term fusion and subsequent cooling to room temperature, the glass was extracted from the crucible and its transmission spectrum was recorded. Figure 1 shows transmission spectra of tellurite glasses synthesized (*1*) with and (*2*) without XeF_2. In the former case, the band associated with H_2O vibration completely disappears. For some of the glasses, optical heterogeneities were analyzed by means of laser ultramicroscopy. Figure 2 shows a typical histogram of particle distributions over sizes and numeric concentrations for a sample of a tellurite glass containing 3 wt % erbium(III). The total content of particles is 3.21×10^4 cm^{-3}. A large fraction of impurity particles (~75%) are 0.07–0.08 μm in size.

The magneto-optic properties of tellurite glasses doped with Nd(III), Pr(III), Tb(III), Er(III), Yb(III), and Ho(III) were studied for compositions with 70 mol % TeO_2, 30 mol % $ZnCl_2$, and 0.1–3.0 wt % dopant. The setup for studying the rotation of the polarization plane of linearly polarized light is shown schematically in Fig. 3. As source of light served helium–neon (λ = 632 nm) and neodymium (λ 534 and 1060 nm) lasers. The exciting light passed through a modulator *2* to eliminate noise and a polarizer *3*. The linearly polarized light was incident onto a polarization beam splitter *6*. The orientation of the incident light determines the relative intensities of the resulting two beams. The beam intensities in both

channels of the double-beam polarizer become equal when the polarization plane of the incident light makes a 45° angle with the polarizing directions of the prism. When the polarization plane is rotated, the intensities of the two beams change in opposite directions; an increase in the intensity of one of these beams leads to an automatic decrease in the intensity of the other. Further, the signals were recorded with two photodiodes *7* and fed into the inputs of a differential amplifier. The difference signal was recorded at the output. This is convenient because the excess noise signals are subtracted simultaneously.

The Verdet constants were measured at three wavelengths: 1060, 632, and 532 nm. The results obtained in studying the effect of rotation of the polarization plane of linearly polarized light are listed in Tables 2, 3.

The rare-earth elements neodymium, praseodymium, erbium, ytterbium, and holmium, which were used as dopants in the tellurite glasses synthesized, exhibit a paramagnetic rotation in the polarization plane. Their Verdet constants are negative. It can be seen from Table 2 that the Verdet constants increase as the wavelength of the probing light decreases. The Verdet constants also grow as the concentration of the doping ion in the glass becomes higher. Fluorine-zirconate glasses also exhibit a rotation effect, but it is very weak. Their Verdet constants are three times smaller than those for tellurite glasses. Phosphate glasses surpass tellurite glasses in the efficiency of the rotation effect when doped with ions of such REE as terbium and praseodymium and are inferior to the tellurite glass in this regard when doped with ions of neodymium and erbium (Table 3).

The luminescent properties were studied for tellurite glasses doped with ions of erbium and neodymium or with the pair erbium–ytterbium. The ions of erbium and ytterbium were excited with a semiconductor laser (emission wavelength 980 nm). The mechanism of pumping of Er^{3+} consists in successive absorption of two exciting photons by an erbium ion, with the result that Er^{3+} is excited to the $^4F_{7/2}$ level. After thermal relaxation to the $^4S_{3/2}$ level there occurs the transition $^4S_{3/2} \rightarrow {}^4I_{15/2}$ (to the ground level), to which corresponds the band peaked at 545 nm. Erbium ions also can give rise to a green ($^2H_{11/2} \rightarrow {}^4I_{15/2}$ transition) and red ($^4F_{7/2} \rightarrow {}^4I_{15/2}$ transition) emission, which is characteristic of, e.g., the fluorine-zirconate glass. However, these peaks are not observed in the PL spectrum of Er^{3+} in the tellurite matrix. This circumstance is associated with the properties of the tellurite matrix and is manifested in the kinetics of the Er^{3+} luminescence. The PL of a tellurite glass doped with a donor–acceptor pair Er^{3+}–Yb^{3+} is markedly different. The ion–ion interaction leads to energy transfer from Yb^{3+} to Er^{3+}. As a result of a cascade transition, an excited ion Er^{3+} goes to the $^4F_{7/2}$ level. As in the case of Er^{3+}, relaxation to the $^4S_{3/2}$ level is followed by the $^4S_{3/2} \rightarrow {}^4I_{15/2}$ transition corresponding to the band peaked at 545 nm (green emission). However, green emission is also observed in this case in the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ transition (PL band peaked at 530 nm). Occupation of the $^4F_{9/2}$ level with depletion of the $^4S_{3/2}$ level (thermal relaxation) leads to a $^4F_{9/2} \rightarrow {}^4I_{15/2}$ transition corresponding to a band peaked at 651 nm, i.e., red emission from Er^{3+} is observed. The intensity of red PL is very low as compared with that of the green emission (545 nm). The intensities of all the above-mentioned transitions in the tellurite glass are lower than that of similar transitions in the fluoride glass. This is due to a higher probability on nonradiative transitions in the tellurite glass. The energy of phonons is ~800 cm^{-1} in the tellurite glass and 600 cm^{-1} in the fluoride glass. For the same reason, the probability of the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ transition, to which corresponds a band peaked at 1.536 μm, is lower in the tellurite glass, compared with the fluoride glass.

Exposure of a tellurite glass doped with Nd^{3+} to light of a mercury lamp gives rise to a green luminescence with λ = 510–540 nm. The Nd^{3+} ion absorbs light with a wavelength of 432 nm, which is present in the spectrum of the mercury lamp. The light with λ = 432 nm, absorbed by the neodymium ion, is reemitted with a wavelength characteristic of the green emission. The UV part of the spectrum (up to λ = 440 nm) was cut off with a UFS-1 filter. In this case, no green luminescence was observed.

CONCLUSIONS

(1) Tellurite glasses with a concentration of impurity particles of 3.21×10^4 cm^{-3} and particle size of 0.07–0.08 μm, doped with neodymium, praseodymium, terbium, erbium, ytterbium, and holmium ions, were synthesized.

(2) A method for lowering the content of water in the tellurite glass is recommended.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of Complexation in the System Constituted by Water, Carbamide, and Sulfur Dioxide at 293 K

R. E. Khoma, M. I. Gavrilenko, and V. I. Nikitin

Mechnikov National University, Odessa, Ukraine

Received October 7, 2003; in final form, March 2004

Abstract—Electronic absorption spectroscopy and potentiometry were applied to study complexation at 293 K in a system constituted by water, carbamide, and sulfur dioxide. The composition and stability of the molecular and ionic complexes formed was determined in relation to the concentration of components in solution.

A study of the complexation of sulfur dioxide with carbamide in water is of theoretical and practical importance [1]. Carbamide, which exhibits properties of a weak base, reacts with mineral acids to give products of salt nature [2–5]; however, only a limited number of publications have been concerned with the chemistry of compounds formed by this ligand and SO_2. Potentiometry has been used to study the reaction of sulfur dioxide with aqueous solutions of carbamide at temperatures in the range from 273 to 313 K [1, 6, 7]. In [8], the interaction in the system constituted by water, carbamide, and sulfur dioxide was studied by means of conductometry at 298–353 K. However, the presently existing interpretations of the mechanism of interaction between SO_2 and aqueous solutions of carbamide are contradictory.

The aim of this study was to examine equilibrium processes in the systems H_2O–SO_2 and H_2O–$CO(NH_2)_2$–SO_2 at 293 K by spectrophotometry and potentiometry.

EXPERIMENTAL

As starting substances were used gaseous sulfur dioxide and analytically pure carbamide (Ur). The water used to prepare all solutions was distilled and deoxygenated by bubbling with nitrogen for 4–6 h. The concentration of Ur in the systems studied was monitored photometrically [9].

Aqueous solutions of SO_2 were prepared by saturating deoxygenated water with gaseous sulfur dioxide purified by the method described in [10] and by diluting the resulting solution to required concentrations. The concentration of sulfur(IV) was determined by iodometry [11] and by Scheniger's procedure [12]. The values yielded by these methods coincided. No sulfate ions were found in the system under study, which contradicts the model suggested in [8].

Electronic absorption spectra were recorded on Specord M400 (230 to 310 nm) and SF-18 (256 and 276 nm) spectrophotometers in 1-cm-thick quartz cuvettes. The potentiometric measurements were performed with a pH-150M pH-meter with an ESK-10601 combined glass electrode.

Published data on physicochemical properties of sulfur(IV) anions [13–15] suggest that sulfur dioxide dissolved in water exists as equilibrium forms $H_2O \cdot SO_2$, HSO_3^-, $S_2O_5^{2-}$, and SO_3^{2-}:

$$H_2O \cdot SO_2 \overset{K_1}{\rightleftarrows} H^+ + HSO_3^-, \quad (1)$$

$$2HSO_3^- \overset{K^*}{\rightleftarrows} S_2O_5^{2-} + H_2O, \quad (2)$$

$$HSO_3^- \overset{K_2}{\rightleftarrows} H^+ + SO_3^{2-}. \quad (3)$$

It is known that the electronic spectra of aqueous solutions of SO_2 show three absorption peaks at λ 276 (A_{276}), 256 (A_{256}), and 210 nm. The peak at 276 nm corresponds to sulfur dioxide hydrate; light absorption at about 256 nm, to the pyrosulfite ion; and the peak at about 210 nm, to the disulfite ion [13, 16, 17].

Published data on ion-molecular equilibria in the H_2O–SO_2 system at 293 K are obtained with account of only reactions (1) and (3), with reaction (2) disregarded [18].

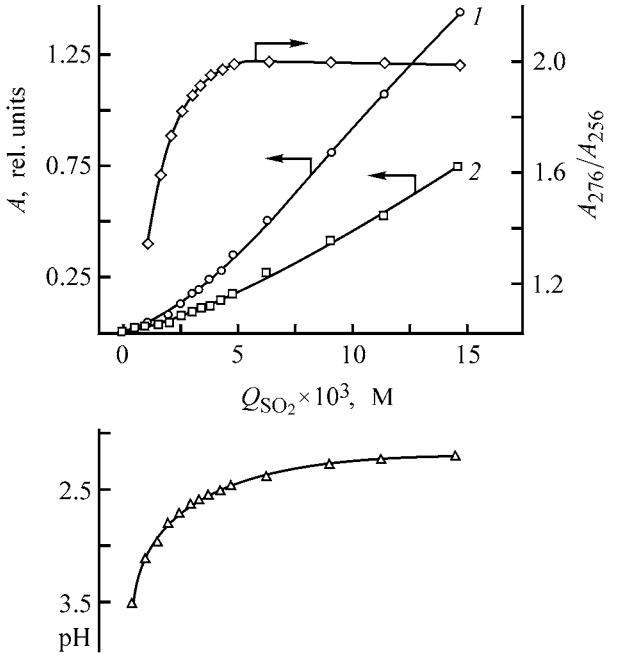

Fig. 1. Spectrophotometric and potentiometric characteristics of aqueous solutions of sulfur dioxide at 293 K. (*A*) Optical density and (Q_{SO_2}) concentration of SO_2 in solution. λ (nm): (*1*) 276 and (*2*) 256.

Spectrophotometric studies of the equilibrium system H_2O–SO_2 at 293 K (Fig. 1) demonstrated that the optical densities A_{276} and A_{256} increase virtually in direct proportion to the total content of SO_2 in the solutions under study (at $Q_{SO_2} \geq 2.5 \times 10^{-3}$ M, where Q_{SO_2} is the total content of SO_2 in solution, M). Consequently, the solutions analyzed are described by the Bouguer–Lambert–Beer law in the concentration range $Q_{SO_2} = (2.5–15.0) \times 10^{-3}$ M. However, $A_{276}/A_{256} \neq \varepsilon_{276}/\varepsilon_{256}$ in this range. This indicates that A_{256} is an additive quantity. Analysis of the data in Fig. 1 shows that, as the total content of sulfur dioxide in water increases, the $A_{276} : A_{256}$ ratio grows and reaches a constant value at $Q_{SO_2} = 4.0 \times 10^{-3}$ M.

Table 1. Comparison of published and experimental data obtained by analysis of electronic absorption spectra of aqueous solutions of sulfur dioxide

Equilibrium form	λ, nm	ε, M^{-1} cm^{-1}
$SO_2 \cdot H_2O$	276	~500 [16, 19], 500*
$S_2O_5^{2-}$	256	2217 [13], 5790 [20], 1940*
$HOSO_2^-$	256	3.8 [13], 2.5*

* Data obtained in the present study.

To find the quantitative relationships between the concentrations of oxo compounds of sulfur in an aqueous solution of SO_2, it is necessary to determine the constants K_1 and K^*, since equilibrium (3) can be disregarded at pH < 4. To calculate the dimerization constant of hydrosulfite ions, K^*, the molar absorption coefficients ε of hydrosulfite and disulfite ions were preliminarily determined. The molar absorption coefficients of HSO_3^- and $S_2O_5^{2-}$ at 256 nm were found by extrapolation of the dependences $A_{256}/Q_{SO_2} = f(Q_{SO_2})$ and $A_{256}/Q_{SO_2} = f(1/\sqrt{Q_{SO_2}})$ to intersection with the ordinate axis [13].

The molar absorption coefficient of sulfur dioxide hydrate was determined at λ = 276 nm in a similar way. Comparison of the resulting values of $\varepsilon_{H_2O \cdot SO_2}$, $\varepsilon_{HSO_3^-}$, and $\varepsilon_{S_2O_5^{2-}}$ with those previosly known (Table 1) shows a good coincidence of these values with the calculated data.

The concentration constants K_1 and K^* were calculated with account of Eqs. (4) and (5) (which reflect the mass action law), the additivity rule (6) and (7), and material balance and electroneutrality conditions (8) and (9):

$$K_1 = \frac{[H^+][HSO_3^-]}{[H_2O \cdot SO_2]}, \quad (4)$$

$$K^* = \frac{[S_2O_5^{2-}]}{[HSO_3^-]^2}, \quad (5)$$

$$A_{276} = \varepsilon^{276}_{H_2O \cdot SO_2}[H_2O \cdot SO_2], \quad (6)$$

$$A_{256} = \varepsilon^{256}_{S_2O_5^{2-}}[S_2O_5^{2-}] + \varepsilon^{256}_{HSO_3^-}[HSO_3^-], \quad (7)$$

$$Q_{SO_2} = [H_2O \cdot SO_2] + 2[S_2O_5^{2-}] + [HSO_3^-], \quad (8)$$

$$[H^+] = 2[S_2O_5^{2-}] + [HSO_3^-]. \quad (9)$$

In processing of the experimental data, a linear dependence of the ionic strength I of the aqueous solutions on the amount of sulfur dioxide dissolved in these solutions was established ($2.5 \times 10^{-3} \leq Q_{SO_2} \leq 15.0 \times 10^{-3}$ M):

$$I = 0.8113Q_{SO_2} + 0.0002, \quad R^2 = 0.99, \quad (10)$$

where R^2 is the statistical significance of approximation.

The dependences of the concentration constants K_1 and K^* on the total concentration of SO_2 ($2.5 \times 10^{-3} \leq$

$Q_{SO_2} \le 15.0 \times 10^{-3}$ M) are shown in Fig. 2. These dependences can also be described by the equation whose parameters are listed in Table 2:

$$pK = A_0 + A_1\sqrt{Q_{SO_2}} + A_2 Q_{SO_2}, \quad (11)$$

where $pK = -\log K$.

Ur can react with sulfur dioxide in water in several ways: (i) via direct addition [Eq. (12)] and (ii) via protonation of Ur [Eq. (13)] [7]:

$$mH_2O \cdot SO_2 + nCO(NH_2)_2 + (h - m)H_2O \rightleftarrows mSO_2 \cdot nCO(NH_2)_2 \cdot hH_2O, \quad (12)$$

$$CO(NH_2)_2 + H^+ \rightleftarrows \{CO(NH_2)_2H\}^+. \quad (13)$$

The equilibrium processes in the system H_2O–Ur–SO_2 were studied spectrophotometrically in the spectral range 230–310 nm. For this purpose, light absorption of 30 solutions was recorded at 16 wavelengths. The number of light-absorbing species was determined by analyzing a matrix with orthogonal rows by the Mark method [21].

Analysis of how the matrix rank depends on the prescribed experimental error (Fig. 3) shows that the number of types of light-absorbing species in the system under study is, in all probability, four. In this case, the error in determining the optical density must fall within the range $0.0018 \le S_A \le 0.004$ units of light absorption. If, however, the error is lowered to 0.00016, and further to 0.00006, the results of calculations point to five forms; if, by contrast, the error is increased to 0.0042–0.0046 light-absorption units, the number obtained is three. A similar tendency was observed in [22] when analyzing the matrix rank for a system constituted by hafnium(IV), perchloric acid, and chloranilic acid.

It should also be noted that the number of different types of light-absorbing species in the system H_2O–SO_2 is three. Then, it is highly probable that the number of types of light-absorbing species in the system H_2O–Ur–SO_2 is greater than three.

It was established that the absorption peaks are not shifted upon complexation, whereas the optical densities of the peaks change significantly. Therefore, all further studies were carried out by analyzing the light absorption at 276 and 256 nm.

The composition of the complexes in solution was determined using the method of molar ratios [22].

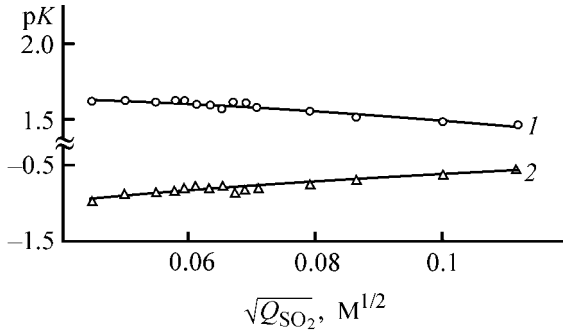

Fig. 2. (*1*) pK_1 and (*2*) pK^* vs. the total content of SO_2, Q_{SO_2}.

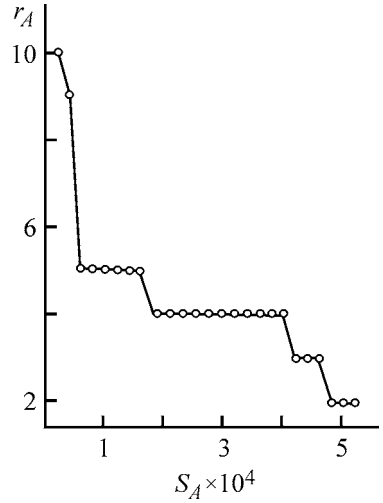

Fig. 3. Matrix rank r_A vs. the prescribed experimental error S_A for the system H_2O–Ur–SO_2.

The calculations were based on deviations of the optical densities from additivity, ΔA ($\Delta A = A_\Sigma - A_{SO_2} - A_{Ur}$, where A_Σ is the total optical density of all the components of a solution; and A_{SO_2} and A_{Ur} are the optical densities of solutions of the components SO_2 and Ur at concentrations equal to those in the series under study). The resulting values of ΔA were used to construct ΔA–composition diagrams for the solution series under study (Fig. 4).

When analyzing the data in Fig. 4 (curves *1*, *2*), it should be noted that compounds of composition

Table 2. Values of parameters in Eq. (11) ($R^2 = 0.91$)

pK	A_0	A_1	A_2
pK_1	1.7917	0.7902	–37.652
pK^*	–1.2925	8.7247	–19.152

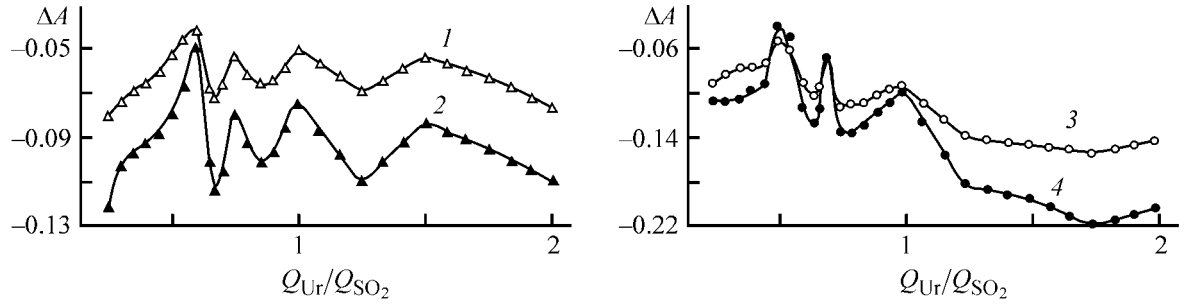

Fig. 4. ΔA vs. the composition of the system constituted by water, carbamide, and sulfur dioxide at 293 K. Q_{SO_2} (M): (*1*, *2*) 5.0×10^{-3} and (*3*, *4*) 7.5×10^{-3}. pH: (*1*, *2*) 2.66 ± 0.02 and (*3*, *4*) 2.42 ± 0.02. λ (nm): (*1*, *3*) 256 and (*2*, *4*) 276.

$[mSO_2 \cdot nCO(NH_2)_2 \cdot hH_2O]$, in which $m : n$ = 5 : 3, 3 : 2, 4 : 3, 6 : 5, 1 : 1, 4 : 5, and 2 : 3, exist in the 5.0×10^{-3} M solution of sulfur dioxide. A 7.5×10^{-3} M solution of SO_2 is characterized by the ratios $m : n$ = 2 : 1, 3 : 2, 4 : 3, 1 : 1, and 4 : 7 (Fig. 4, curves *3* and *4*). Similarly, it was also established that complexes of composition $[SO_2 \cdot CO(NH_2)_2 \cdot hH_2O]$ (I) and $[2SO_2 \cdot CO(NH_2)_2 \cdot hH_2O]$ (II) exist in a 2.5×10^{-3} M solution of sulfur dioxide.

With account of Eqs. (4), (5), (14), and (15) (which reflect the mass action law), the material balance and electroneutrality conditions (16)–(18), the numerical values of the arbitrary complexation constants β_1 and β_2 were calculated for compounds (I) and (II), respectively (Table 3):

$$\beta = \frac{[[mSO_2 \cdot nCO(NH_2)_2 \cdot hH_2O]]}{[H_2O \cdot SO_2]^m [CO(NH_2)_2]^n}, \quad (14)$$

$$K_a = \frac{[CO(NH_2)_2][H^+]}{[\{CO(NH_2)_2H\}^+]}, \quad (15)$$

$$Q_{SO_2} = [H_2O \cdot SO_2] + 2[S_2O_5^{2-}] + [HSO_3^-] + mc_K, \quad (16)$$

$$Q_{Ur} = [CO(NH_2)_2] + [\{CO(NH_2)_2H^+\}] + nc_K, \quad (17)$$

$$[\{CO(NH_2)_2H^+\}] + [H^+] = [HSO_3^-] + 2[S_2O_5^{2-}] + [OH^-], \quad (18)$$

where $c_K = [[mSO_2 \cdot nCO(NH_2)_2 \cdot hH_2O]]$; Q_{SO_2} and Q_{Ur}, the total content of sulfur dioxide and Ur, respectively, in the system under study; $p\beta = -\log \beta$.

In the calculations, the value of pK_a was taken to be 0.18 [23].

The arbitrary constants β_3 and β_4 characterize the acid–base interaction of uronium cations with hydrosulfite and disulfite ions, respectively:

Table 3. Results obtained in spectrophotometric studies of the system H_2O–$CO(NH_2)_2$–SO_2 at 293 K

Parameter	Concentration $Q_{SO_2} \times 10^3$, M		
	2.5	5.0	7.5
$Q_{Ur} \times 10^3$, M	1.85–2.50	4.50–5.00	6.00–7.50
pH	2.90	2.66	2.42
$p\beta_1 \pm \Delta p\beta_1$	-4.03 ± 0.051	-3.74 ± 0.057	-3.28 ± 0.065
$p\beta_3 \pm \Delta p\beta_3$	-5.98 ± 0.051	-5.62 ± 0.057	-5.02 ± 0.065
$p\beta_4 \pm \Delta p\beta_4$	-11.8 ± 0.10	-10.4 ± 0.12	-9.37 ± 0.13
$\log \varepsilon_{K(I)}^{276}$	2.04	1.91	1.95
$\log \varepsilon_{K(I)}^{256}$	1.80	1.56	1.51
$Q_{Ur} \times 10^3$, M	1.25	1.50–2.50	2.25–3.75
pH	2.91	2.66	2.42
$p\beta_2 \pm \Delta p\beta_2$	-8.06 ± 0.042	-7.67 ± 0.268	-6.74 ± 0.182
$\log \varepsilon_{K(II)}^{276}$	2.40	2.20	2.33
$\log \varepsilon_{K(II)}^{256}$	1.98	1.86	1.95

$$\{CO(NH_2)_2H^+\} + HSO_3^- + (h - 1)H_2O \rightleftarrows [SO_2 \cdot CO(NH_2)_2 \cdot hH_2O], \quad (19)$$

$$\beta_3 = \frac{[[SO_2 \cdot CO(NH_2)_2 \cdot hH_2O]]}{[HSO_3^-][\{CO(NH_2)_2H\}^+]}, \quad (20)$$

$$2\{CO(NH_2)_2H^+\} + S_2O_5^{2-} + (2h - 2)H_2O \rightleftarrows 2[SO_2 \cdot CO(NH_2)_2 \cdot hH_2O], \quad (21)$$

$$\beta_4 = \frac{[[SO_2 \cdot CO(NH_2)_2 \cdot hH_2O]]}{[S_2O_5^{2-}][\{CO(NH_2)_2H\}^+]^2}. \quad (22)$$

It was established in the study that compounds (I) and (II) absorb in the UV spectral range:

$$A_{276} = \varepsilon^{276}_{H_2O \cdot SO_2}[H_2O \cdot SO_2] + \varepsilon^{276}_K c_K, \quad (23)$$

$$A_{256} = \varepsilon^{256}_{S_2O_5^{2-}}[S_2O_5^{2-}] + \varepsilon^{256}_{HSO_3^-}[HSO_3^-] + \varepsilon^{256}_K c_K, \quad (24)$$

where ε^{276}_K and ε^{256}_K are the molar absorption coefficients of the forming complexes at 276 and 256 nm, respectively.

The fact that the values of $\varepsilon^{276}_{K(I)}$, $\varepsilon^{256}_{K(I)}$ and $\varepsilon^{276}_{K(II)}$, $\varepsilon^{256}_{K(II)}$ for compounds (I) and (II), respectively (Table 3) depend on the total content of sulfur dioxide and Ur in solution presumably indicates that the composition of complexes (I) and (II) also depends on the concentrations of these components in solution.

Analysis of the data in Table 3 shows that, as the solutions are diluted, the stability of the compounds increases, which would be impossible if hydrolysis dominated over complexation. Hence follows that the complexes are hydrated from the very beginning and a further increase in the concentration of water does not lead to displacement of other species from the compounds.

In all probability, the effects described above are due to selective solvation in aqueous-carbamide solutions of sulfur dioxide.

CONCLUSION

Joint application of spectrophotometric and potentiometric methods enables a conclusion that both molecular and ion complexes can be formed in the system H_2O–$CO(NH_2)_2$–SO_2. The composition and stability of the forming compounds strongly depend on the concentration of components in solution. It is established that the hydration of the complexes dominates over their hydrolysis in the system under study.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Calculation of the Solubility of Solid Hydroxides $M(OH)_2$ in Water and Alkaline Media

E. V. Shkol'nikov

St. Petersburg State Forestry Academy, St. Petersburg, Russia

Received April 15, 2004

Abstract—The influence exerted by the pH value on the molar solubility of a number of amorphous and crystalline hydroxides of Group-II elements in an aqueous alkaline medium was calculated thermodynamically with account of the formation of hydroxo complexes.

Previously, the thermodynamic method has been used to establish the limits of applicability of crystalline sensor membranes in a strongly acidic medium [1]. However, as the hydrogen index of the medium increases, binding of free cations into hydroxo complexes changes the response of Cd- (Hg, Ca, Cu, Pb)-ion-selective electrodes by making narrower the range of admissible pH values in a potentiometric analysis for cations. At the same time, the effect of the pH value on the solubility of metal hydroxides in an aqueous-alkaline medium is of interest in itself in determining the conditions of hydrolysis, virtually complete precipitation, or effective masking of cations in the form of soluble hydroxo complexes [2]. In addition, the amphoteric behavior and the effect of structural-chemical specific features of te hydroxides on their solubility in water have been studied insufficiently [2, 3].

A thermodynamic calculation of the solubility of a number of hydroxides in pure water and in an aqueous-alkaline medium (with addition of NaOH or $HClO_4$) at pH 7–15 and 25°C was performed. As objects of study were chosen hydroxides of Group-II elements, which are used in chemical processing of wood and vegetable waste, forestry and agriculture, medicine, and analytical chemistry.

In an aqueous solution saturated with a sparingly soluble hydroxide $M(OH)_2$, a heterogeneous chemical equilibrium

$$M(OH)_2(\text{cryst}) \rightleftarrows M^{2+}(\text{sol}) + 2OH^-(\text{sol}), \qquad (1)$$

is attained, whose thermodynamic constant is given by the expression

$$K_s^0 = \text{SP}^{\text{th}} = a_{M^{2+}} a_{OH^-}^2 = \text{const}(T), \qquad (2)$$

where $a_{M^{2+}}$ and a_{OH^-} are the activities of the ions M^{2+} and OH^-.

The constant K_s^0 was calculated using the thermodynamic relation [1]

$$\log K_s^0 = -0.175\Delta G_{s,298}^0, \qquad (3)$$

where $\Delta G_{s,298}^0$ is the standard change in the Gibbs energy (kJ mol^{-1}), which was calculated for the dissolution process (1) by the equation

$$\Delta G_s^0 = \Delta G_{f,M^{2+}}^0 + 2\Delta G_{f,OH^-}^0 - \Delta G_{f,M(OH)_2}^0; \qquad (4)$$

The values of ΔG_f^0 for ion formation in aqueous solutions were taken from [4]; those for Zn^{2+}, from the reference book [5]; and values of ΔG_f^0 for formation of amorphous or crystalline modifications of hydroxides at 298 K, from the reference books [5–7] or found by calculation [8]. In the calculation for mercury(II) in a saturated aqueous solution, the following chemical equilibria were taken into account

$$HgO(\text{cryst}) + H_2O(\text{l}) \Leftrightarrow Hg(OH)_2(\text{sol}) \Leftrightarrow Hg^{2+}(\text{sol}) + 2OH^-(\text{sol}). \qquad (5)$$

The molar solubility of $M(OH)_2$ in pure water and in aqueous NaOH solutions was calculated taking into account the ionic strength of the solution and the formation of mononuclear hydroxo complexes [2], using the generalized equation

$$s = c_M \frac{K_s^0}{f_{M^{2+}} + f_{OH^-}^2} \sum_{i=0}^{n} \beta_i [OH^-]^{i-2}, \qquad (6)$$

* Freshly precipitated amorphous.

** Octahydrate.

where c_M is the total molality of all the chemical forms of M(II) in a saturated solution; $f_{M^{2+}}$ and f_{OH^-}, the molar activity coefficients of the ions M^{2+} and OH^-; $\beta_0 = 1$; and β_1, β_2, β_3, and β_4, the total stability constants of the hydroxo complexes MOH^+, $M(OH)_2$, $M(OH)_3^-$, and $M(OH)_4^{2-}$.

The concentration of free anions OH^- and the pH value of saturated hydroxide solutions in pure water were found by solving the system of three equations

$$[M^{2+}][OH^-]^2 = K_s^0, \quad \frac{[MOH^+]}{[M^{2+}][OH^-]} = \beta_1,$$

$$[M^{2+}] + [MOH^+] = [OH^-] \qquad (7)$$

with the use of the Cardano method for a cubic equation.

The results of the calculations are listed in the table ($pK_s^0 = -\log K_s^0$; P_i, the ionicity of the chemical bond M–O in a hydroxide, evaluated using the Pauling curve in relation to the difference of the electronegativities of the elements M and O; A, the amphoterism parameter; and $\bar{n}$, the ligand number).

It can be seen from the table that there is a satisfactory agreement between the pK_s^0 values calculated by Eq. (3) and those taken from the reference book [2]. For a number of hydroxide modifications, K_s^0 was calculated for the first time. For strontium and barium hydroxides, the parameters of dissolution of octahydrates, which are stable in saturated aqueous solutions, were determined.

As the ionicity of the M–O bond increases in the order $Be \rightarrow Mg \rightarrow Ca \rightarrow Sr \rightarrow Ba$, the solubility of the hydroxides $M(OH)_2$ in pure water grows dramatically (see table). The solubility of freshly precipitated amorphous hydroxides of beryllium, magnesium, zinc, and cadmium exceeds that of their crystalline modifications. The solubility of these latter strongly depends on structure and decreases on passing to the stable modifications β-$Be(OH)_2$, ε-$Zn(OH)_2$, and β-HgO.

It can be seen from the table and the figure (curves *2*, *3*) that, as the pH or the active alkalinity of the medium (a_{OH^-}) increases, the molar solubility of the bases $Mg(OH)_2$, $Ca(OH)_2$, $Sr(OH)_2$, and $Ba(OH)_2$ steadily decreases, following the approximate equation $s = K_s/[OH^-]^2$. The effect of a strong decrease in solubility in the presence of the likely charged OH^- ions is not compensated for by a weak positive effect of formation of the unstable hydroxo complexes

MOH^+ and $M(OH)_2$. The solubility of the yellow (α) and red (β) modifications of HgO is nearly independent of pH in the range 7–13, and only at pH ≥ 14 starts to increase noticeably [see table and figure (curve *6*)]. The solubility of amphoteric hydroxides of beryllium, zinc, and cadmium passes through a minimum as the pH value of the medium increases (see figure, curves *1*, *4*, and *5*). Analysis of Eq. (6) shows that the lowest solubility of $M(OH)_2$ precipitates is observed at the optimal concentration of OH^- ions, when neutral complexes $M(OH)_2$ are predominant among the equilibrium species in solution. From the condition for the maximum mole fraction $x_{M(OH)_2}$, the following equation was obtained

$$2\beta_4[OH^-]^4 + \beta_3[OH^-]^3 - \beta_1[OH^-] - 2 = 0. \quad (8)$$

Solving this equation approximately with the use of the Newton method and the constants β_i from the reference book [2] yielded the $[OH^-]_{opt}$ at $x_{M(OH)_2} = \max$ and then s_{min} (see figure). The values of s_{min} (M) at 25°C are 1.5×10^{-7} and 1.3×10^{-8} for freshly precipitated amorphous and β-$Be(OH)_2$, respectively, at pH 8.9; 2×10^{-5} and 5×10^{-6} for α- and ε-$Zn(OH)_2$ at pH 10.2; and 2×10^{-6} and 4×10^{-7} for α- and β-$Cd(OH)_2$ at pH 11.6.

The mole fraction of free cations M^{2+} in saturated aqueous solutions of $M(OH)_2$ was calculated using the equation

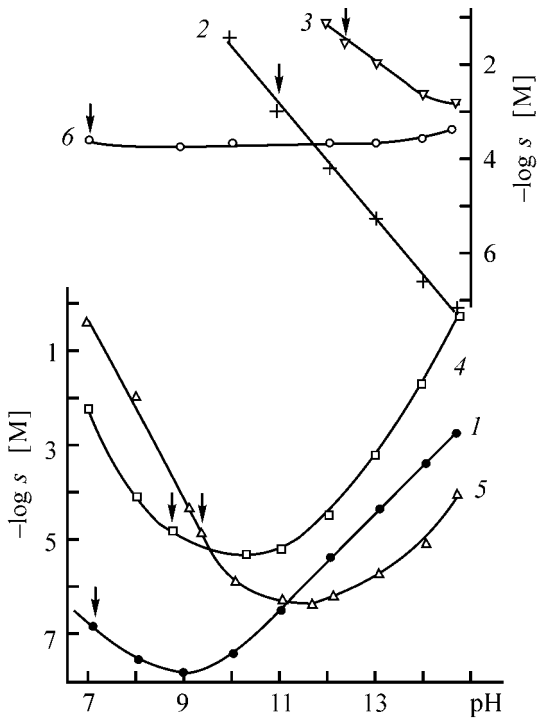
$$x_{M^{2+}} = [M^{2+}]/c_M = \left(1 + \sum_{i=0}^{n} \beta_i [OH^-]^i\right)^{-1}, \quad (9)$$

where $n = 1$ for Mg^{2+} and Sr^{2+}; $n = 2$ for Ca^{2+} and Ba^{2+}, $n = 3$ for Hg^{2+}; and $n = 4$ for Be^{2+}, Zn^{2+}, and Cd^{2+} [2].

Doubly charged cations not bound into hydroxo complexes can be determined potentiometrically in pure aqueous solutions at pH less than 1.5 (Hg), 3.5 (Be), 5.5 (Zn, Cu, Pb), 8.0 (Cd), 9.5 (Mg), and 10.5 (Ca, Sr, Ba).

In purely aqueous saturated solutions of the hydroxides (shown by the arrows in the figure), $BeOH^+$, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, $ZnOH^+$, Cd^{2+}, and $Hg(OH)_2$ predominate. The complexation is the strongest for cations of mercury(II), beryllium, and zinc, which form the least stable and least water-soluble hydroxides.

It can be suggested to evaluate the amphoterism of the hydroxides by ratio ($A > 1$) of their molar solubilities in an alkaline medium with pH 14.7 (5 M NaOH solution) and in pure water. As follows from the table, the amphoterism of the hydroxides decreases in the order $Zn(OH)_2 \rightarrow Be(OH)_2 \rightarrow Cd(OH)_2 \rightarrow HgO$. In approximately the same order decreases the mean ligand number $\bar{n}$ in the hydroxo complexes (Bjorrum function) at $[OH^-] = 10$ M (see table). Hydroxides of magnesium, calcium, strontium, and barium show no amphoterism ($A < 1$, $n < 2$).



Solubility *s* of solid hydroxides vs. the pH value of the aqueous-alkaline medium at 25°C. (*1*) (β-$Be(OH)_2$, (*2*) freshly precipitated $Mg(OH)_2$, (*3*) $Ca(OH)_2$, (*4*) (ε-$Zn(OH)_2$, (*5*) (β-$Cd(OH)_2$, and (*6*) (α-HgO.

CONCLUSIONS

(1) The molar solubility of $M(OH)_2$ hydroxides in water grows as the ionicity of the chemical bond M–O increases in the order $Be \rightarrow Mg \rightarrow Ca \rightarrow Sr \rightarrow Ba$ and depends on their structure, decreasing on passing from the amorphous to the stable crystalline modification.

(2) The thermodynamic method is used to calculate the effect of the pH value on the solubility of the hydroxides $M(OH)_2$ in an aqueous-alkaline medium. A condition for existence of amphoterism in $M(OH)_2$ (mean ligand number in the hydroxo complexes $\bar{n} > 2$) and its estimate (parameter $A > 1$) increasing in the order $HgO \rightarrow Cd(OH)_2 \rightarrow Be(OH)_2 \rightarrow Zn(OH)_2$ are suggested. The pH intervals in which cations of Group-II metals are not bound into hydroxo complexes are determined.

(3) The minimum solubility and the pH values at which the precipitation of amphoteric hydroxides of beryllium, zinc, and cadmium is the most complete are calculated with account of the formation of hydroxo complexes.

SORPTION AND ION-EXCHANGE PROCESSES

Selective Ion-Exchange Sorption of K^+ from Aqueous Solutions Containing Na^+–K^+ Mixture on Sn(IV) Hydrophosphate

G. I. Smirnov, L. M. Dimova, and A. A. Redchenko

Irkutsk State University, Irkutsk, Russia

Received December 23, 2003; in the final form, April 2004

Abstract—Ion-exchange sorption of K^+ and Na^+ from their mixture on X-ray-amorphous and crystalline Sn(IV) hydrophosphates was studied. These sorbents exhibit a high selectivity for K^+. Amorphous Sn(IV) hydrophosphate can be used for efficient purification of aqueous sodium salt solutions to remove potassium impurity.

It is known that metal(IV) hydrophosphates show a high selectivity in the ion-exchange sorption of various metal cations, including chemical analogues. However, the most part of data on this subject concern the sorption of metals from aqueous solutions containing only one kind of cations. Data on ion-exchange sorption of metals from their binary mixtures on Zr(IV) hydrophosphate are scarce [1–3]. A procedure has been developed for purification of sodium iodide to remove potassium cations by sorption treatment of aqueous NaI–KI mixture with Sn(IV) hydrophosphate [4]. However, the physicochemical reasons for the selectivity of sorbents based on Sn(IV) hydrophosphate for K^+ and the effect of their crystalline ordering on selectivity for alkali metals are poorly understood.

In this study, we examined the selectivity of ion-exchange sorption of Na^+ and K^+ from their binary mixture on X-ray-amorphous and crystalline samples of Sn(IV) hydrophosphate.

EXPERIMENTAL

X-ray-amorphous Sn(IV) hydrophosphate was prepared by recrystallization of crude Sn(IV) hydrophosphate (P : Sn ratio 1.4) in 0.5 M aqueous H_3PO_4 for 48 h [5]. Crystalline Sn(IV) hydrophosphate was prepared by precipitation from refluxing 12 M aqueous H_3PO_4 (reaction time 175 h) [6]. The ion-exchange characteristics of both amorphous and crystalline Sn(IV) hydrophosphates were determined by potentiometric titration of their weighed portions with a multicomponent alkaline titrant containing 0.1 M KCl and 0.1 M NaCl, or 0.1 M KOH and 0.1 M NaOH [7].

The content of K^+ and Na^+ ions in solution before and after sorption was determined using the atomic-absorption method. The relevative standard deviation was 0.002.

It has been reported [5, 6] that both crystalline and amorphous ion-exchangers based on Sn(IV) phosphate are composed of Sn(IV) hydrophosphate $Sn(HPO_4)_2$ containing the hydrophosphate anions as the cation-exchange sites. Figure 1 shows the curves of potentiometric titration of amorphous and crystalline Sn(IV) hydrophosphates with the alkaline multicomponent titrant, plotted as pH vs. the amount of hydroxide added. We found that, on addition of the titrant to the initial sorbent–water suspension to pH 9, the concentration of phosphate anions in the liquid phase remains constant (3×10^{-2} g l^{-1}), i.e., the ion-exchange sorption of alkali metals does affect the solubility of Sn(IV) hydrophosphate. Figure 1 shows that, on adding the alkaline titrant to an aqueous suspension of amorphous Sn(IV) hydrophosphate, the pH gradually increases. Such a shape of the sorption titration curve shows that, in sorption of alkali metal cations under consideration, a continuous series of their solid solutions in the amorphous sorbent is formed. By contrast, for crystalline Sn(IV) hydrophosphate, the slope of the titration curve sharply decreases at pH 6.2 due to fundamental changes in the sorption mechanism.

At pH < 6.2, the sorption capacity of the amorphous sorbent for K^+ and Na^+ exceeds that of the crys-

talline sorbent. At the same time, the crystalline Sn(IV) hydrophosphate becomes a stronger sorbent for alkali metal cations at pH > 6.2 (Fig. 1). This difference is caused by features of the amorphous and crystalline sorbents. The amorphous Sn(IV) hydrophosphate (interplanar spacing 0.874 nm) has a more disordered structure than the crystalline sorbent (interplanar spacing 0.785 nm) [5, 6]. Therefore, at pH < 6.2 the sorbing sites of the amorphous sorbent are more accessible to alkali metal cations. As the alkaline titrant is added, the content of protons in Sn(IV) hydrophosphate decreases and excess hydroxide anions are sorbed. As a result, the sorbent matrix becomes negatively charged and the sorbent capacity for charge-compensating alkali cations increases [7, 8]. It is also believed [9] that the sorption of Na^+ on crystalline Sn(IV) hydrophoshate facilitates the sorption of K^+ owing to broadening of the channels and cavities in the sorbent structure and decrease in the sterical hindrance to sorption. Therefore, at pH > 6.2 the total sorption capacity of the crystalline sorbent for K^+ and Na^+ exceeds that of the amorphous sorbent.

The curves in Fig. 2 demonstrate the contribution of $K^+$and Na^+ cations to the total sorption capacity of the sorbents for these cations. These curves show that the sorption capacity of both crystalline and amorphous Sn(IV) hydrophosphates grows with increasing amount of hydroxide anions added. These correlations are consistent with the well-known effect of acidity on the concentration of ionized sorbent sites in the cation exchanger [8]. When the amount of added hydroxide anions exceeds 0.75 mmol g^{-1} of sorbent, the curves describing sorption of K^+ and Na^+ on the crystalline sorbent becomes steeper than the curves for sorption these cations on the amorphous sorbent and, ultimately, both alkali metal cations become more sorbable on the crystalline sorbent.

Figure 2 shows that, in sorption of K^+ and Na^+ from their mixtures on X-ray-amorphous Sn(IV) hydrophosphate, the sorption of K^+ prevails. The stronger sorption of K^+ than Na^+ on Sn(IV) hydrophosphate was also observed in sorption of these cations from aqueous solutions containing only one kind of these cations [5]. Thus, our data show that K^+ and Na^+ do not interfere with each other in their simultaneous sorption on the sorbents under consideration.

It was reported in [6] that, in sorption of K^+ and Na^+ from their aqueous solutions containing either Na^+ or K^+ on crystalline Sn(IV) hydrophosphate, Na^+ cations are more sorbable than K^+. At the same time, Fig. 2 shows that the sorption of K^+ prevails in sorption of K^+ and Na^+ from their binary mixture on the crystalline sorbent. We believe that, in sorp-

tion of K^+ and Na^+ from their mixture on crystalline Sn(IV) hydrophosphate, the sorption of relatively small Na^+ cations facilitates that of larger K^+ cations owing to broadening of the channels and cavities in the sorbent. Similar effects have been reported for crystalline zirconium and titanium hydrophosphates [9].

Figure 3 shows that the plots of the K^+/Na^+ separation factor against pH for crystalline and amorphous Sn(IV) hydrophosphate have similar shapes with a maximum. The greatest K^+/Na^+ separation factors for amorphous and crystalline sorbents, equal to 5.7 and 3.0, are observed at pH 3.2 and 5.8, respectively. Thus, the X-ray-amorphous sorbent is more selective for K^+ than the crystalline sorbent.

The data reported in [5, 6] show that amorphous Sn(IV) hydrophosphate exhibits a higher chemical stability than crystalline Sn(IV) hydrophosphate. For example, in sorption of Na^+ from aqueous NaI on amorphous and crystalline sorbents, the phosphate concentration in the equilibrium sorbate was 13.0 and 20.2 mg l^{-1}, respectively. Since amorphous Sn(IV) hydrophosphate is more chemically stable and more selective to K^+ than the crystalline sorbent, the former is more suitable for practical separation of K^+ from Na^+.

The separation of microamounts of K^+ from similar amounts of Na^+ microamounts is one of important problems in analytical chemistry. In this context, the sorption of K^+ and Na^+ from their mixture on amorphous Sn(IV) hydrophosphate was studied in relation to pH (see table). The sorption was carried out under static conditions from an aqueous NaCl–KCl mixture containing 1 mg l^{-1} of each cation.

The table shows that, with the pH increasing to 3.2, the distribution and separation factors of K^+ first grow and then remain constant. By contrast, the sorption of Na^+ begins at pH 3.2. These data show that the best separation of K^+ from Na^+ is achieved in the case of sorption on amorphous Sn(IV) hydrophosphate at low pH.

Owing to the high selectivity of amorphous Sn(IV) hydrophosphate for K^+, this sorbent can be used for efficient purification of sodium salts to remove K^+. Taking into account that this procedure must ensure efficient separation of potassium from both micro and macroamounts of sodium, the sorption of K^+ on amorphous Sn(IV) hydrophosphate from aqueous solutions containing various NaI amounts was studied at pH 3 (Fig. 4). The K^+ content in all the K^+–Na^+ mixtures tested was 5×10^{-3} wt %.

Figure 4 shows that, with increasing NaI concentration, the efficiency of NaI purification to remove

Sorption of microamounts of K^+ and Na^+ from their mixture on X-ray-amorphous Sn(IV) hydrophosphate*

pH_{eq}	E, %		K_d		K_{K^+/Na^+}
	K^+	Na^+	K^+	Na^+	
1.0	68	0	110	0	–
2.0	94	0	780	0	–
2.9	96	0	1200	0	–
3.2	99	22	4950	14	350
3.2	99	33	4950	25	200

* (E) Degree of sorption (%) and (K_d) distribution factor.

K^+ decreases. Therefore, in order to ensure a high efficiency of NaI purification to remove K^+, the NaI concentration in the NaI–KI mixture should be low. However, we found that even at a NaI content as high as 300–400 g l^{-1}, the separation of potassium from sodium was quite acceptable to ensure an efficient purification of NaI to remove KI under dynamic conditions. The sorptive separation of K^+ from Na^+ on amorphous Sn(IV) hydrophosphate ensures preparation of sodium salts of ultrapure grade, which contain less than 2×10^{-4}% K^+.

CONCLUSIONS

(1) In the pH range below 6.2, the total cation-exchange capacity of X-ray-amorphous Sn(IV) hydrophosphate for a K^+–Na^+ mixture exceeds that of crystalline Sn(IV) hydrophosphate but, at pH > 6.2, the crystalline sorbent becomes more efficient than its amorphous modification.

(2) Owing to its higher selectivity for K^+ and higher chemical stability as compared to the crystal-

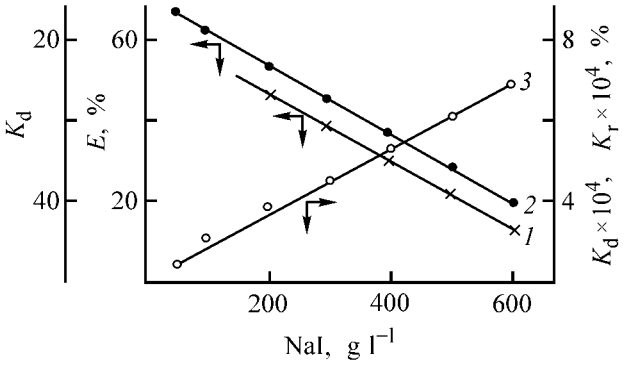

Fig. 4. Characteristics of K^+ sorption on amorphous Sn(IV) hydrophosphate vs. NaI concentration. (*1*) Distribution factor K_d, (*2*) degree of sorption E, and (*3*) residual K^+ content in aqueous solution K_r.

line modification, amorphous Sn(IV) hydrophosphate is more suitable for separation of K^+ from Na^+. The optimal separation is achieved at pH lower than 3.2. Amorphous Sn(IV) hydrophosphate can also be used for efficient purification of concentrated Na-containing solutions to remove K^+ microimpurities.

SORPTION AND ION-EXCHANGE PROCESSES

Acid–Base Characteristics of Carbon Adsorbents, Determined by Potentiometric Titration

A. M. Puzii, O. I. Poddubnaya, and S. S. Stavitskaya

Institute of Sorption and Endoecological Problems, National Academy of Sciences of the Ukraine, Kiev, Ukraine

Received May 12, 2003; in final form, March 2004

Abstract—For initial carbons of varied origin and carbons oxidized with various oxidizing agents, the continuous distribution function of surface groups with respect to the protonation constants was determined by acid–base potentiometric titration.

The surface chemistry of carbon materials is of great importance for their use as adsorbents, catalysts, or supports of catalytically active substances [1–3]. The surface characteristics of carbon adsorbents are governed by heteroatoms, which can substitute carbon atoms in the carbon structure or occur in the form of surface groups.

To determine the surface groups of carbon materials, various methods have been used [3]. The best known and rather simple method is selective neutralization of surface groups with alkaline ($NaHCO_3$, Na_2CO_3, NaOH, NaOEt) or acidic (HCl) solutions [4]. According to this method, the surface groups are classified into several discrete types of acidic (carboxy, lactonic, phenolic, carbonyl) and basic (pyrone, chromene) nature depending on their ability to add or eliminate proton. However, assignment of individual types of surface groups to definite chemical structures is arbitrary. For example, neutralization of carboxy groups with sodium hydrogen carbonate or phenolic groups with sodium hydroxide has been reported to be incomplete [5].

One of the methods for determining acid–base surface groups is potentiometric titration. It was shown that the titration curve of carbon black oxidized with nitric acid suggests the presence of surface groups with the acidity close to that of carboxy groups [6]. Later, a more perfect method was suggested, in which the titration curves obtained in the experiments (dependence of equilibrium solution pH on the volume of titrant added) are transformed into the isotherms of proton sorption (dependence of the amount of sorbed protons on pH) [7]. However, the isotherms are usually characterized in the case of carbon adsorbents by smooth variation of the amount of sorbed protons throughout the entire pH range without any plateaus or inflections. This shape of the isotherm gives no way of distinguishing individual surface groups without using complicated calculation procedures.

A significant progress in the analysis of acid–base characteristics of carbon adsorbents was achieved with the nonuniformity of surface groups analyzed by solving the integral equation of adsorption by approximation of the local isotherm (the Rudzinskii–Jagiello method) [8]. This method allows evaluation of continuous distribution of surface groups with respect to protonation constants. Later the resolution of peaks in the distribution curve was improved by numerical solution of the integral adsorption equation by the SAIEUS method [9, 10]. However, this method disregards the electrostatic interaction of the charged adsorbent surface with ions of the nearsurface layer is not considered.

For carbon adsorbents, the difference in the proton concentrations in the solution and near the surface may be as large as two to three orders of magnitude. Therefore, the constants calculated without taking into account the influence of the charged adsorbent surface on the concentration of ions near surface groups are only apparent.

In this study, we applied the method of a continuous distribution of surface groups with respect to the protonation constants, with account taken of the electrostatic interaction, to analysis of the surface groups of carbon adsorbents on the basis of potentiomentric titration data [11, 12].

(a) (*1*) SKN, (*2*) SKNo-1.6, (*3*) SKN0-2.0, and (*4*) SKNo-2.2; (b) (*1*) KAU, (*2*) KAUo-1.0, (*3*) KAUo-1.7, and (*4*) KAUo-2.2; (c) (*1*) KAU, (*2*) KAUo-0.8, (*3*) KAUo-1.2, (*4*) KAUo-1.8, and (*5*) KAUo-2.6; the same for Fig. 2.

EXPERIMENTAL

Synthetic carbon SKN from vinylpyridine copolymer [13] and carbon KAU from apricot pit [14] with progressive increase in the degree of oxidation were used. The synthetic (SKN) and pit (KAU) carbons were oxidized by hot humid air (300 ml min^{-1}) at 430°C for 2, 6, and 10 h. Pit carbon KAU was also oxidized with boiling 25% nitric acid (carbon : acid = 1 : 3) for 0.5, 2.5, 10, and 15 h.

Potentiometric titration was carried out by the method of separate weighed portions at constant ionic strength (0.1 M NaCl) [11]. The sorption isotherms of protons were calculated from the potentiometric titration data by the formula

$$Q = \frac{V_0 + V_{tit}}{m}\left([H^+]_{in} - [OH^-]_{in} - [H^+]_{eq} + [OH^-]_{eq}\right), \quad (1)$$

where V_0 and V_{tit} are the volumes of the supporting electrolyte and added titrant, respectively; m is the adsorbent weight; $[H^+]$ and $[OH^-]$ are the concentrations of protons and hydroxyl ions, respectively; subscripts "in" and "eq" refer to the initial and equilibrium concentrations.

The distribution functions of surface groups with respect to the protonation constants were calculated by solving the integral adsorption equation by means of the CONTIN procedure [11, 12]:

$$Q_t(\mathrm{pH}) = \int_{\mathrm{p}K_{min}}^{\mathrm{p}K_{max}} Q_l(\mathrm{pH}, \mathrm{p}K)\, f(\mathrm{p}K)\,\mathrm{d}\,\mathrm{p}K + Q_0, \quad (2)$$

where Q_t is the experimental isotherm, Q_l is the local isotherm (Langmuir type) describing the adsorption on a uniform surface group, $f(\mathrm{p}K)$ is unknown distribution function, and Q_0 is a constant that accounts for the adsorption of protons by surface groups with pK values outside the limits of the experimentally determined range.

The distribution function describes the concentration of surface groups as a function of the protonation constant and is a unique characteristic of the adsorbent surface groups. The electrostatic interaction of the charged surface with adsorbed ions was considered in terms of the diffusion model of electric double layer [11, 12].

The isotherms of proton sorption by carbon adsorbents can have both positive and negative values of adsorption Q (Fig. 1). The positive values of sorption mean proton association, and the negative values correspond to passing of protons into solution via dissociation of acidic surface groups. The intersection point of the isotherm with the pH axis corresponds to the zero-charge potential (ZCP) at which the adsorption values of potential-determining ions (protons and hydroxyls) are the same.

The isotherms of proton sorption by unoxidized and weakly oxidized carbons have both positive and negative values of adsorption, and strongly oxidized carbons show negative proton sorption only (Fig. 1). With increasing degree of oxidation, the carbon surface becomes more acidic, which is manifested in an increasing cation-exchange power, decreasing ZCP, and shift of the isotherm to negative values of proton sorption (Fig. 1). The most significant variation of acid–base characteristics of carbons is observed in the initial stages of oxidation; the amount of surface

groups responsible for proton association significantly decreases and the content of acidic groups increases (see table). This effect is the most pronounced for SKN synthetic carbon.

The gradual increase in the degree of oxidation of both SKN synthetic carbon and KAU pit carbon results in an increase in the amount of all types of surface acidic groups. At the same duration of oxidation with air, SKNo synthetic carbon has a more acidic surface than KAUo pit carbon. In addition, at all degrees of oxidation, the surface of KAUo carbon oxidized with air contains a noticeable amount of basic surface groups capable of proton adsorption (see table, Q_0).

The distribution of surface groups with respect to the protonation constants (Fig. 2) suggests that the acid–base characteristics of the carbons studied are nonuniform. The peaks in the distribution curves are relatively broad, the peak width at half-maximum is approximately 2.0 pK units, which suggests a high nonuniformity of individual types of surface groups. The distribution of surface groups with respect to the protonation constants suggests the presence of three types of groups at the surface of weakly oxidized carbons KAUo-1.0 and KAUo-0.8 with pK 3.6–4.3, 7.0, and 9.6–10.5. The pK values of the first two groups are lower than ZCP and therefore correspond to proton association. These groups can be assigned to sorption of protons with by surface groups, or they result from electrochemical reduction of oxygen by the reaction

$$\equiv C + O_2 + 4H^+ \rightarrow \equiv C^+ + 2H_2O. \qquad (3)$$

The release of protons with pK 9.6–10.5 corresponds to dissociation of phenolic groups. It should be noted that unoxidized carbons SKN and KAU have only one group capable of releasing protons, while in oxidized carbons there are two (SKN) or even three (KAU) groups releasing protons into a solution (Fig. 2).

The distribution function of surface groups with respect to the protonation constants for synthetic oxidized carbons SKNo shows the presence of only two types of surface groups capable of releasing protons (Fig. 2a). Contrastingly, oxidized pit carbons KAU contain, irrespective of the oxidation procedure, three types of acidic surface groups (Figs. 2b, 2c). Most likely, the difference in the amount of the types of functional groups at the surface of SKN synthetic carbon and KAU pit carbon is due to the difference in the structure and characteristics of these carbons. In particular, it is well known [13] that synthetic carbons of the SKN type, produced from nitrogen-containing polymeric raw materials (vinylpyridine copolymer), contain 3–5% nitrogen and give in carbonization

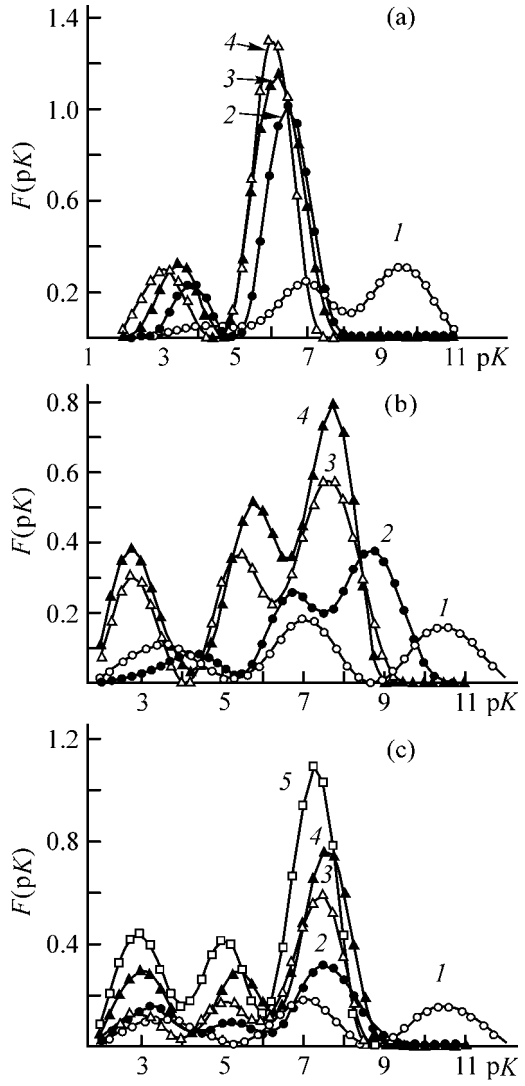

Fig. 2. Distribution of surface groups $F(pK)$ with respect to the protonation constants pK in (a) KAU synthetic carbons oxidized with air and KAU pit carbons oxidized with (b) air and (c) HNO_3.

a fairly dense carbon (d = 1.92–1.96 g cm^{-3}), while the raw material for production of pit carbon is a natural polysaccharide, cellulose, with a high oxygen content. Therefore, carbon with a density lower than that of SKN synthetic carbon (d = 1.83–1.85 g cm^{-3}) is formed in carbonization of fruit pits. This carbon is more active in oxidation.

The nature of surface groups of oxidized carbons can be considered in the framework of the commonly accepted scheme based on the analogy of the dissociation constants of surface groups and the known chemical compounds [3]. When comparing the experimental protonation constants of oxidized carbons with reference data, it should be taken into account that the pK values obtained in this study were measured in a solution with the ionic strength of 0.1 and, therefore, they are only apparent. The thermodynamic pK values of surface groups, corrected for the salt effect, are greater by 0.12–0.60 pK units than the apparent values, depending on the stage of dissociation [11].

According to the above scheme, the most acidic surface groups with pK 2.9–3.6 for oxidized SKNo synthetic carbons and with pK 3.1–3.9 for oxidized KAUo pit carbons can be assigned to carboxy groups. It should be noted that surface carboxy groups are more active than the isolated carboxy group, e.g., in acetic (pK 4.75) or benzoic (pK 4.18) acid. This is accounted for by the mutual influence of two or more adjacent functional groups due to the inductive effect. For example, addition of a hydroxy or a second carboxy group to benzoic acid results in a decrease in pK to 3.0 in salicylic acid and to 2.95 in *o*-phthalic acid. The carboxy group surrounded by two substituents with negative inductive effect, e.g., in 2,6-dihydroxybenzoic acid (pK 1.22) is still more acidic. The nature of the carbon skeleton also affects the characteristics of acidic groups via the resonance effect.

According to the scheme from [3], the less acidic surface groups with pK 6.1–6.5 for oxidized SKNo synthetic carbons and with pK 5.0–6.7 for oxidized KAUo pit carbons can be identified as second carboxy groups in dibasic acid fragments or lactonic groups.

The least acidic surface groups are observed at the surface of oxidized KAUo pit carbons (pK 7.3–8.7); these can be identified, in all probability, as phenolic groups.

CONCLUSIONS

(1) Calculation of the continuous distribution function of surface groups with respect to the protonation constants from the potentiometric titration data shows that unoxidized carbons have two types of surface groups capable of proton adsorption and one type of acidic surface groups. Oxidized SKNo synthetic carbons have two types of acidic surface groups (carboxy and phenolic), and pit carbons, three types of acidic surface groups (carboxy, lactonic, and phenolic).

(2) The composition of the surface groups is affected most significantly by the origin of the initial carbon and, to a lesser extent, by the procedure of oxidation of the carbon surface.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of Lustrous Zinc Coatings from Sulfate Electrolyte

G. I. Medvedev and N.A. Makrushin

Novomoskovsk Institute, Mendeleev Russian University of Chemical Engineering, Novomoskovsk, Tula oblast, Russia

Received November 25, 2003

Abstract—The electrodeposition of lustrous zinc coatings from a sulfate electrolyte containing $ZnSO_4$, Na_2SO_4, buffer additives, and 2-butyne-1,4 diol was studied.

Sulfate zinc-plating electrolytes are now used for coating of articles of a simple shape. To obtain high-quality coatings, various organic substances, such as dextrin, condensation products, and various mixtures, are added to the electrolyte [1]. At present, zinc is electrodeposited using electrolytes with luster-forming additives, which are organic substances of a rather complex composition [2–4].

In this communication, we report the results obtained in a study of Zn electrodeposition from a sulfate electrolyte in the presence of 2-butyne-1,4-diol (BD), which is widely used in deposition of lustrous nickel and zinc coatings [3, 5]. The electrolyte contained (g l^{-1}): $ZnSO_4 \cdot 7H_2O$ 200–250, $Na_2SO_4 \cdot 10H_2O$ 50–100, $Al_2(SO_4)_3 \cdot 18H_2O$, H_3BO_3, and aminoacetic acid 25–30; 2-BD (35 wt % solution) 1–70 ml l^{-1}. A 10–12-μm-thick zinc layer was deposited onto unpolished St.3 steel. The polarization curves were measured in the potentiodynamic mode with a P-5828 potentiostat. The leveling power P of the electrolytes was determined by a direct method involving a profilographic measurement of the sample surface with a sine-shaped microprofile and calculation by the formula [6]

$$P = 2.3\frac{a}{2}\pi h_{av}\log\left(\frac{H_0}{H_i}\right),$$

where a is the amplitude of the wave of the sine-shaped microprofile; h_{av}, the average thickness of the coatings (10 μm); and H_0 and H_i, the initial and final wave amplitudes of the sine-shaped profile, respectively.

The capacitance of a double electric layer was measured in the course of electrolysis with a P-5021 ac bridge at a frequency of 30 kHz in a series equivalent circuit. As the working electrode served a zinc-coated platinum wire situated at the center of a platinum-plated cylinder. The pH value of the near-electrode layer was measured by the method described in [7]. The electrodeposition was performed at 18–25°C with and without agitation of electrolytes with a magnetic stirrer.

The influence exerted by the BD concentration, nature of the buffer solution, and current density i_c on the outward appearance of the coatings is illustrated in Table 1. As can be seen, lustrous coatings are obtained in H_3BO_3- and $Al_2(SO_4)_3$-containing electrolytes at a BD concentration of 30–45 ml l^{-1}, and in an electrolyte containing aminoacetic acid, at 60–70 ml l^{-1}. The i_c range in which lustrous coatings are formed varies with the nature of the buffer solution. It is the widest in a $Al_2(SO_4)_3$-containing electrolyte (i_c = 1–6 A dm^{-2}). It should be noted that high-quality lustrous coatings are obtained solely in an agitated electrolyte, and lusterless and rough coating are formed without agitation.

The pH value of the electrolytes should be within 3–4. At pH < 3, the i_c range in which lustrous coatings are formed is narrower and the current efficiency (CE) is lower. At pH > 4, semilustrous coatings are formed, and the electrolyte operation is unstable. The current efficiency was studied in the electrolytes ensuring formation of lustrous coatings. It was found that, in electrolytes containing BD, $Al_2(SO_4)_3$, and H_3BO_3, CE varies at i_c = 1–6 A dm^{-2} within 93–95%. At the same time, in an electrolyte containing BD and aminoacetic acid at i_c = 4–8 A dm^{-2}, CE decreases from 94 to 89%.

In the zinc-plating electrolytes, cathodic polarization curves were measured on a rotating-disc electrode. It can be seen from Fig. 1 that BD leads to an increase in the cathodic polarization ΔE_c (curves *1*, *2*). As the rate of rotation of the disc electrode is raised from 200 to 2000 rpm in a BD-containing electrolyte, ΔE_c increases (curves *2–4*).

The inhibiting influence exerted by BD on the Zn electrodeposition is due to its adsorption on the electrode surface. This is confirmed by measurements of the capacitance of the double electric layer. In an electrolyte without BD, the dependence of the capacitance on the potential has a minimum (20 μF cm^{-2}) at $E = -0.8$ V (Fig. 1, curve *5*). In the presence of BD, the capacitance of the double electric layer decreases to 9 μF cm^{-2} at $E = -0.8$ V (curve *6*). At more electronegative potentials, an increase in the capacitance is observed owing to desorption of a part of luster-forming additive from the electrode surface [8].

Analysis of the cathodic polarization curves shows that the extent to which the Zn electrodeposition is hindered depends on the rate at which BD is delivered to the cathode surface: the higher the rate of delivery of the additive to the cathode surface, the stronger the hindrance to the process. As is known [6], such a dependence of the polarization curves on the rotation rate of a disc electrode is adopted as a basis for classification of additives with respect to their leveling power. If the polarization increases with rotation rate, then it would be expected that the additive will produce a leveling effect under the given conditions

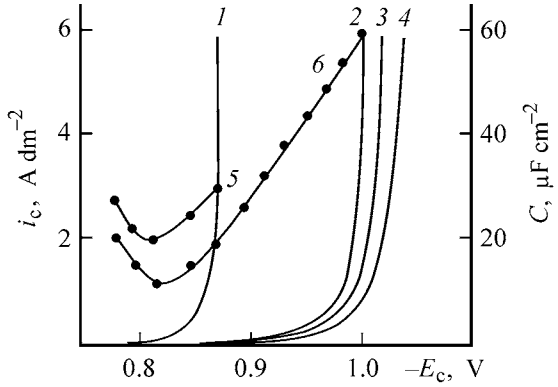

Fig. 1. Current density i_c and capacitance C of the double electric layer vs. the electrode potential relative to a standard hydrogen electrode E in the zinc-plating electrolyte. Electrolyte (g l^{-1}): $ZnSO_4 \cdot 7H_2O$ 200, $Na_2SO_4 \cdot 10H_2O$ 50, $Al_2(SO_4)_3 \cdot 18H_2O$ 30; pH 3; the same for Fig. 2; (*1, 5*) Electrolyte, (*2–4, 6*) electrolyte + BD (35 wt % solution) 35 ml l^{-1}. [6]. Profilographic measurements on a gently sloping sine-shaped profile showed that surface leveling does occur in the course of Zn electrodeposition.

The dependences of P on i_c and BD concentration are shown in Fig. 2. It can be seen that the P–i_c and P–C dependences pass through a maximum at i_c = 4 A dm^{-2} (curves *1*, *2*). The run of these dependences can be understood in terms of the adsorption-diffusion leveling theory [6]. Raising i_c first leads to an increase in the leveling power. Then, at relatively high current densities, the concentration of the additive on the surface and its inhibition effect will decrease even at microprojections owing to the high rate of surface renewal, which must diminish the efficiency of leveling. At a too low concentration of the additive in the electrolyte, when the Zn electrodeposition is inhibited only slightly, the leveling effect cannot be stronger. At the same time, at too high concentrations of the additive, the leveling power decreases because of the termination of the diffusion control over the rate of delivery of the additive and its inhibition effect. Thus, it was established that a luster-forming additive BD to a zinc-plating electrolyte provides a leveling effect because of its being simultaneously a leveling additive.

As is known [3], the formation of lustrous coatings is due to the leveling of submicrometer irregularities on the surface. In this case, it is sufficient that the additive should be adsorbed on the cathode surface, with the overvoltage of electrocrystallization increased, for a lusterless coating to be formed. At the same time, it is necessary that, for lustrous coatings to be obtained, an adsorption layer of a certain composition should be present on the cathode surface. Layers of this kind can be formed from organic substances and products of secondary reactions in the near-cathode layer. In the case of a simultaneous deposition of metal and evolution of hydrogen, the adsorption layer may consist of hydroxides and other basic compounds [3].

The assumption that hydroxo compounds of zinc are formed in the near-cathode space is confirmed by measurements of pH_s in the near-cathode layer. As can be seen from Fig. 3, the pH value varies from 3.5 to 6 at i_c = 1–8 A dm^{-2} (depending on the type of a buffer solution). The pH_s varies to the smallest extent in an electrolyte containing aminoacetic acid (curve *4*). It should be noted that hydrates are formed in a zinc-plating electrolyte at pH 6.4. All these facts suggest that the presence of hydroxo compounds of zinc in the near-cathode layer is not a necessary condition for obtaining lustrous deposits. Apparently, lustrous coatings are formed in the case when a highly dispersed adsorption layer is formed on the electrode surface [3].

Evidently, the dispersity of the adsorption layer is controlled by buffer solutions. In their presence, the adsorption layer can change because of the formation of both $Al(OH)_3$ and sparingly soluble zinc borates in the near-cathode layer. It is not improbable that complex compounds are formed by orthoboric and aminoacetic acids with zinc ions, and intracomplex chelate compounds, by H_3BO_3 with BD and products of its reduction [3].

Of high importance in obtaining lustrous coatings is the hydrodynamic mode in which a luster-forming additive is delivered to the cathode surface and decomposition products are removed from the near-cathode space, as also noted in [9].

It has been shown [10] that, in the course of electrolysis, the luster-forming additive BD undergoes complex transformations, which strongly affects the quality of the coatings obtained. A gas-chromatographic analysis of the BD-containing electrolyte showed that, as the electrolysis duration increases, 2-butene-1,4-diol, 2-butane-1,4-diol, 2.6-octene-1,8-diol, 2-butenol, and butanol are accumulated owing to diol reduction. The influence exerted by luster-forming additives in acid electrolytes may be associated with their reduction in the near-cathode layer [11]. This is accompanied by a deceleration of the hydrogen evolution and the corresponding change in the structure of the adsorption layer, as well as by a decrease in the degree of hydrogen saturation of the metal [12].

To elucidate the mechanism of the influence exerted by BD on the Zn electrodeposition, the system consisting of hydrated ions present in the electrolyte and BD molecules was subjected to a quantum-chemical analysis. The calculation was performed using the semiempirical chemical method PM3 [13, 14]. We calculated the coordination numbers of hydration for ions and BD molecules. According to the calculation performed, these numbers are 5 for Zn^{2+}, 3 for H_3O^+, 8 for SO_4^{2-}, and 9 for BD. Introduction of H_3O^+ and SO_4^{2-} ions into a Zn^{2+}-containing aqueous solution results in their additional interaction. It was shown that each BD molecule displaces two H_2O molecules from the hydration sheaths of Zn^{2+} ions, thus forming stable complexes with the ions. It was established that the interaction of Zn^{2+} ions with BD molecules is energetically more favorable than the formation of the hydration sheath of an ion. It is the most probable, with account of the composition of the zinc-plating sulfate electrolyte, that complex ions $[Zn(H_2O)_x(BD)_y]^{2+}$ (x = 1–5 and y = 1–3) exist in the bulk of the electrolyte.

In the following stage, the structure of BD at the electrode–solution interface was analyzed by the quantum-chemical method. In doing so, the surface of the zinc electrode was modeled by a negatively charged cluster consisting of 49 atoms situated in two layers having a hexagonal shape. The cluster was chosen with account of the recommendations made in [15]. To model the process of Zn^{2+} reduction on the surface of the zinc electrode, a system constituted by a zinc cluster Zn_{49}, Zn^{2+}, and BD was calculated. It was shown that, when approaching the cluster, the BD molecules contained in the complex form a stable system at a distance of 310 pm from the cluster. In this case, the interaction energy is 353 kJ mol^{-1}, which considerably exceeds the energy of interaction of the cluster with a hydrated zinc ion (200 kJ mol^{-1}). It is noteworthy that the BD molecule forms no stable system with the cluster without Zn^{2+} ions.

Table 2. Change in the total energy of the products in comparison with the total energy of the starting substances

Reaction	Reaction equation	ΔE, kJ mol^{-1}
(1)	$Zn(OH)_2 + e = ZnOH + OH^-$	271
(2)	$ZnOH^+ + e = ZnOH$	–897
(3)	$[ZnBD]^{2+} + e = Zn^+ + BD$	–1051
(4)	$[Zn(OH)BD]^+ + e = ZnOH + BD$	–579
(5)	$[Zn(OH)_2BD] + e = ZnOH + OH^- + BD$	337

Alkalization may result in that mixed aqua hydroxo complexes of varied composition with BD are formed in the near-cathode layer. With account taken of the fact that BD molecules displace H_2O molecules from the aqua complexes with Zn^{2+}, the most probable is the formation in the near-cathode layer of the following species: $Zn(OH)_2$, $Zn(OH)^+$, $[ZnBD]^{2+}$, $[Zn(OH)BD]^+$, and $[Zn(OH)_2BD]$. The highest energy of interaction with a Zn_{49} cluster is observed for $Zn(OH)^+$ species. The presence of a BD molecule in a complex species somewhat decreases the energy of such an interaction and increases the distance between the Zn^{2+} ion and the cluster surface. One of the reasons for such a behavior may be the spatial structure of the complexes being formed, which creates steric hindrance to approach of Zn^{2+} ions to the cluster.

The rather wide diversity of complex species in the near-cathode layer suggests a mechanism of their discharge (Table 2). To qualitatively estimate the probabilities of the occurring processes, we calculated the change in the total energy of the presumed reactions in comparison with the total energy of the initial substances (ΔE, Table 2). In doing so, we took into account that the energy necessary for an electron to be involved in each of the above processes is a constant value. In the given case, the reaction was considered with and without BD.

It follows from the data in Table 2 that the most energetically probable are reactions (2)–(4), which yield a ZnOH species and a Zn^+ ion. Apparently, reaction (3) is the first of these three to occur. The Zn^+ ions formed in this case enter into the electrochemical reaction

$$Zn^+ + e \rightarrow Zn,$$

and BD molecules may be reduced electrochemically to give various products [10].

Table 3. Composition of zinc-plating sulfate electrolytes yielding lustrous coatings with leveled surface (T = 18–25°C, pH 3–4, mechanical agitation)

Components and working mode of electrolyte	Component concentration, g l^{-1}		
	1	2	3
$ZnSO_4 \cdot 7H_2O$	200–250		
$Na_2SO_4 \cdot 10H_2O$	50–100		
$Al_2(SO_4)_3 \cdot 18H_2O$	25–30		
H_3BO_3		25–30	
Aminoacetic acid			25–30
BD (35 wt % solution)	30–40	30–40	60–70
Current density, A dm^{-2}	1–6	1–5	4–8
Current efficiency, %	92–95	93–95	89–94

Thus, the quantum-chemical calculation showed that it is the most probable that, in a sulfate zinc-plating electrolyte containing BD, the complex ions $[Zn(H_2O)_x(BD)_y]^{2+}$ are present in the electrolyte bulk and $Zn(OH)^+$, $[ZnBD]^{2+}$, and $[Zn(OH)BD]^+$ are electroactive species in the near-cathode space owing to alkalization.

As a result of the study performed, electrolytes of simple composition were developed for obtaining lustrous zinc coatings with a leveled surface (Table 3). To diminish the contamination of the electrolyte with sludge, it is necessary to place the anodes (of Ts0 or Ts1 brand) into jackets made of a polypropylene fabric. The electrolyte is to be adjusted with respect to the main components on the basis of chemical analysis data [16].

CONCLUSIONS

(1) The study of the electrodeposition of zinc from a sulfate electrolyte containing 2-butyne-1,4-diol and buffer additives $Al_2(SO_4)_3 \cdot 18H_2O$, H_3BO_3, and aminoacetic acid showed that, depending on the type of additive, lustrous coatings are formed in an agitated electrolyte at i_c = 1–8 A dm^{-2}.

(2) The system constituted by hydrated Zn^{2+} ions and 2-butyne-1,4-diol molecules was studied by the quantum-chemical method. It was shown that presence of complexes of the type $[Zn(H_2O)_x(BD)_y]^{2+}$ in the electrolyte bulk is the most probable. In the near-cathode layer, $Zn(OH)^+$, $[ZnBD]^{2+}$, and $[Zn(OH)BD]^+$ are electroactive species owing to alkalization. Sulfate electrolytes for obtaining lustrous zinc coatings with a leveled surface were developed.

Abstract—The electrodeposition of copper(II) and selenium(IV) onto pyrographite and carbon-pyroceramic electrodes in sulfate solutions was studied. The optimal conditions for obtaining a compound of composition Cu_2Se were found.

Copper–indium double selenide $CuInSe_2$ is of interest as a material for high-efficiency solar cells [1]. The possibility of electrodeposition of a thin film of copper-indium double selenide is even more interesting because this compound can be obtained in the polycrystalline state by joint deposition of three components. This procedure for film fabrication is the least expensive among the known methods. The main factor determining the photoelectric properties of semiconductor films is their composition. In crystallization from a melt, $CuInSe_2$ is formed by the solid-phase reaction between Cu_2Se and In_2Se_3 [2].

In electrochemical codeposition under nonequilibrium conditions, another process can take place. Therefore, it is important to study the electrodeposition of each pair of components, especially for such systems as Cu–Se and In–Se, which are distinguished by strong interaction and formation of intermediate phases. Preliminary studies [3] have shown that the electrodeposition of Cu^{2+} and H_2SeO_3 is a diffusion-limited process. Therefore, the relative concentrations of components in the electrolyte will affect the composition of the forming deposit and depend on diffusion coefficients.

The goal of this study was to demonstrate, for the example of the copper–selenium system, how the stoichiometric composition of the forming compounds can be determined from the change in the cathodic and anodic portions of the voltammetric curves upon gradual variation of the concentration of copper(II) or selenium(IV).

EXPERIMENTAL

As working electrodes were used pyrographite and carbon-pyroceramic disc electrodes with a geometric surface area of 0.12 and 0.07 cm^2, respectively. A three-electrode cell contained the electrode under study, an auxiliary platinum electrode with a surface area of 1.5 cm^2, and a silver chloride reference electrode. All the potentials are given relative to this electrode. Prior to each experiment, the working electrodes were trimmed with an Al_2O_3 fine powder and washed with alcohol and water. We used the salts $CuSO_4 \cdot 7H_2O$ and Na_2SeO_3 (both analytically pure). As the supporting electrolyte served a solution 0.05 M H_2SO_4 + 0.45 M Na_2SO_4. The voltammetric curves were measured without agitation. The accumulation of a deposit on the electrode occurred in an electrolyte agitated with a magnetic stirrer. The study was performed at room temperature. An X-ray phase analysis of the copper selenide deposits on 1×1-cm glassy carbon plates was made on a DRON-4 diffractometer (Co_{K_α} radiation). Simultaneously with the X-ray analysis, an electron-microscopic study of the deposits was performed on an EM-125-K instrument, using the method of singlestep replicas.

The reduction of the Cu(II) ions was studied on a pyrographite electrode.

Figure 1 shows reduction voltammograms measured at various potential sweep rates. In reduction of Cu(II) ions, one wave with a peak at a potential of –0.130 V is observed (Fig. 1a). The oxidation of copper in the reverse run of the voltammetric curve

(*I*) Current and (*E*) potential; the same for Figs. 2, 3, 5–7. Sweep rate (mV s^{-1}): (*1*) 2, (*2*) 10, (*3*) 20, and (*4*) 50.

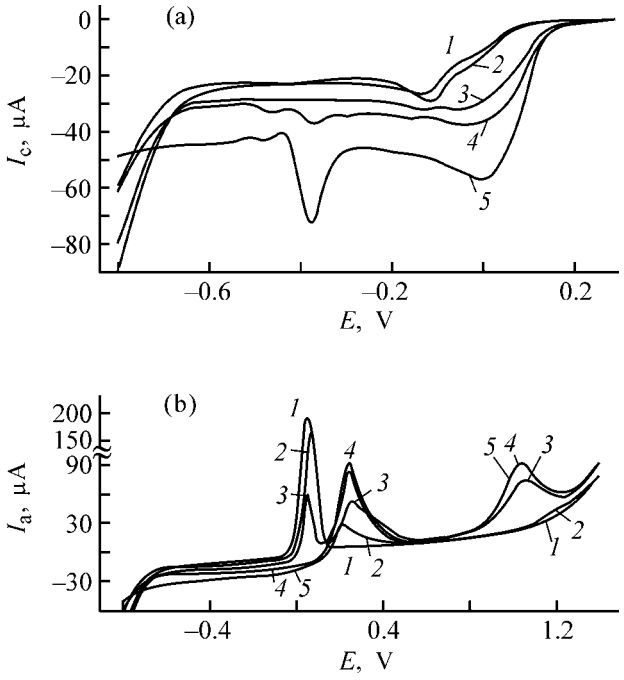

Fig. 2. (a) Cathodic and (b) anodic portions of the voltammetric curves measured in codeposition of Cu(II) and Se(IV) ions on a pyrographite electrode at $c_{Cu(II)} = 1 \times 10^{-3}$ M. Supporting solution 0.05 M H_2SO_4 + 0.45 M Na_2SO_4, V = 20 mV s^{-1}; the same for Figs. 6, 7. $c_{Se(IV)}$ (M): (*1*) 0, (*2*) 1×10^{-4}, (*3*) 3×10^{-4}, (*4*) 5×10^{-4}, and (*5*) 1×10^{-3}.

is accompanied by the appearance of a peak of the anodic current at $E_{ox} = 0.04$ V.

The reduction of Cu(II) is diffusion-controlled and can be described as a classical behavior determined by the mass-transfer rate. The reduction starts at +0.1 V and occurs in accordance with the scheme:

$$Cu^{2+} + 2e \rightarrow Cu^0. \quad (1)$$

When copper(II) and selenium(IV) ions are simultaneously reduced from an electrolyte containing $CuSO_4$ and an excess amount of H_2SeO_3, the reduction onset potential shifts to positive region. In the reduction voltammograms, two, and occasionally three waves are observed in the potential range +0.3… –0.85 V, depending on the relative concentrations of the components.

According to [4, 5], the shift of the first reduction wave in the positive direction may be due to enhanced adsorption of copper and selenium adatoms on the electrode surface. It is necessary to note that desorption of HSO_4^- and SO_4^{2-} anions from the electrode surface occurs in the same range of potentials [6].

The main cathodic wave is observed at potentials of +0.15…–0.2 V. The limiting current of this wave increases in proportion to the Se(IV) concentration (Fig. 2a). At a constant concentration of selenium(IV), the limiting current of this wave does not remain constant, but increases with the Cu(II) concentration. At potentials of +0.15…–0.2 V, the main process of copper and selenium codeposition occurs to give a compound $CuSe_x$:

$$Cu^{2+} + xH_2SeO_3 + 4xH^+ + (2 + 4x)e \rightarrow CuSe_x + 3xH_2O. \quad (2)$$

According to the phase diagram, the compounds Cu_2Se, CuSe, and Cu_3Se_2 can be formed in the system Cu–Se [7].

The higher the Se(IV) concentration, the stronger the shift of the first reduction wave in the positive direction. Thus, it should be concluded that the codeposition of selenium(IV) and copper(II) is facilitated in the presence of large amounts of H_2SeO_3 and proceeds at more positive potentials (Fig. 2a).

At –0.4 V and more negative potentials, one clearly pronounced and one weak peak of cathodic cur-

rent appear in the cathodic curve. The current peak at –0.4 V is the most characteristic feature of the cathodic process of joint reduction of copper and selenium at copper concentrations in the electrolyte lower than selenium concentration, and up to a 1 : 1 ratio. This peak appears even upon addition of a minor amount of copper(II) ions to a 10^{-3} M Se(IV) solution (Fig. 3a).

Comparison of curves *2* and *3* (Fig. 3a) shows that this peak can be assigned to formation of selenide ions. In accordance with the suggestion of [5, 8], curve *3* reflects the occurrence of an electron-addition reaction in which $CuSe_x$ is transformed into a compound Cu_2Se, which is the most stable in this system and has an enthalpy of formation equal to –61 kJ mol^{-1}:

$$2CuSe_x + 2xH^+ + 2xe \rightarrow Cu_2Se + xH_2Se. \quad (3)$$

The appearance of a weakly pronounced current peak in the more negative range of potentials may be due to further reduction elementary selenium formed by reaction (4) or to formation of Cu_2Se by reaction (5) and its further reduction:

$$2H_2Se + H_2SeO_3 \rightarrow 3Se + 3H_2O, \quad (4)$$

$$2Cu^{2+} + H_2Se + 2H^+ + 2e \rightarrow Cu_2Se + 2H_2. \quad (5)$$

Copper selenide Cu_2Se can also be reduced in the region of negative potentials that are close to the potential of hydrogen evolution by the reaction

$$Cu_2Se + 2H^+ + 2e \rightarrow 2Cu + H_2Se. \quad (6)$$

The chemical composition of the compound $CuSe_x$ strongly depends on the delivery of a substance to the electrode. Without agitation of the electrolyte, the mass-transfer process is controlled by the relative concentrations of substances in the electrolyte and by their diffusion coefficients.

According to [5, 9, 10], the diffusion coefficient of Cu^{2+} ions in a 10^{-3} M $CuSO_4$ solution is $D_{Cu(II)} = (6.5 \pm 0.6) \times 10^{-6}$ cm^2 s^{-1}, $D_{Se(IV)} = (9.2 \pm 0.6) \times 10^{-6}$.

The composition parameter x characterizing the compound $CuSe_x$ is determined by the relative concentrations of the components by formula

$$x = \left(\frac{D_{Se}}{D_{Cu}}\right)\frac{c_{H_2SeO_3}}{c_{CuSO_4}} = 1.41\frac{c_{H_2SeO_3}}{c_{CuSO_4}}. \quad (7)$$

To verify the assumptions concerning the composition of copper selenide forming in the joint electrodeposition, the anodic portions of the voltammetric curves were analyzed. As can be seen from Fig. 2b, introduction of a minor amount of Se(IV) (curve *2*) into the 10^{-3} M Cu^{2+} solution does not result in any considerable change in the cathodic portion of the voltammetric curve. An additional peak of anodic current peak appears in the anodic portion. The additional current peak is observed at potentials that are 200 mV more positive than the potential of the current peak of copper oxidation. It is determined by dissolution of copper from copper selenide $CuSe_x$. The current peak becomes the highest at an ion concentration ratio $c_{Cu^{2+}} : c_{Se^{4+}} = 2.2 : 1$, and the potential of the current peak shifts in the positive direction to +0.25 V. Immediately after a peak of cathodic current appears at –0.4 V in the cathodic portion of the voltammetric curve, the current peak corresponding to oxidation of copper selenide starts to decrease in height, which reflects a decrease in its amount on the electrode. This suggests that the decrease in the amount of the deposit is due to its partial decomposition and to evolution of hydrogen selenide by reaction (3). When the greatest amount of the deposit is formed on the electrode, which is indicated by the maximum current of its oxidation, the current peak corresponding to oxidation of free copper (present in an excess

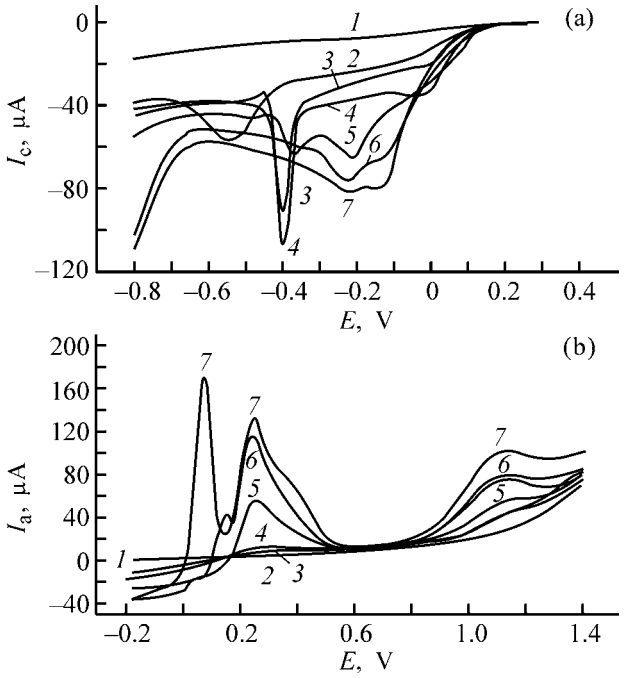

Fig. 3. (a) Cathodic and (b) anodic portions of the voltammetric curves in codeposition of Cu(II) and Se(IV) ions on a pyrographite electrode at $c_{Se(IV)} = 1 \times 10^{-3}$ M. V = 20 mV s^{-1}; Supporting solution 0.05 M H_2SO_4 + 0.45 M Na_2SO_4 (*1*). $c_{Cu(II)}$ (M): (*2*) 0, (*3*) 1×10^{-4}, (*4*) 3×10^{-4}, (*5*) 1×10^{-3}, (*6*) 2×10^{-3}, and (*7*) 3×10^{-3}.

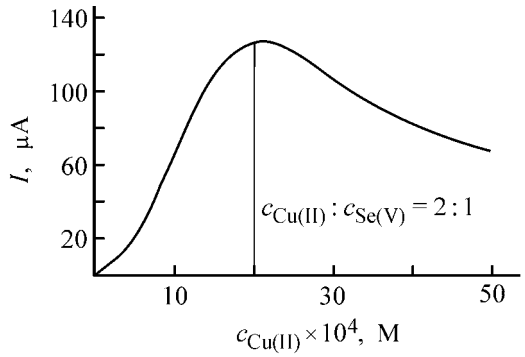

Fig. 4. Peak anodic current I at E_{ox} = 0.25 V vs. the concentration of copper ions, $c_{Cu(II)}$. $c_{Se(IV)} = 1 \times 10^{-3}$ M.

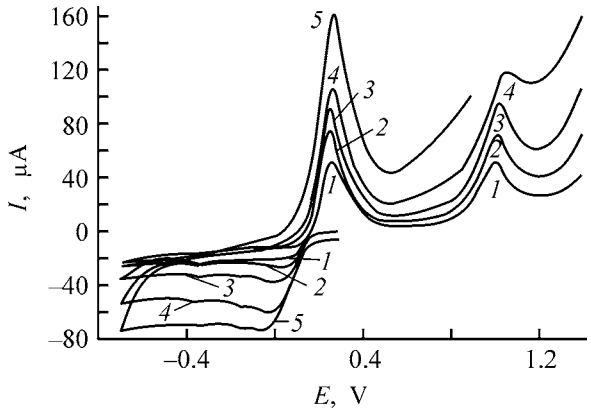

Fig. 5. Voltammetric curves measured in joint electrodeposition of copper and selenium and in electrooxidation of the deposit on a carbon-pyroceramic electrode at various potential sweep rates. $c_{Cu(II)} = 1 \times 10^{-3}$ and $c_{Se(IV)} = 5 \times 10^{-4}$ M. Sweep rate (mV s^{-1}): (*1*) 5, (*2*) 10, (*3*) 20, (*4*) 50, and (*5*) 100.

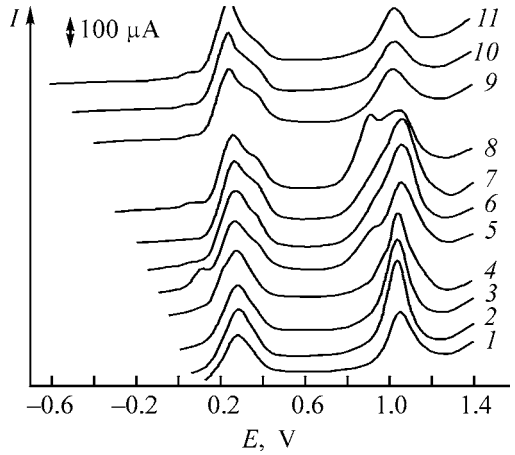

Fig. 6. Anodic portions of the voltammetric curves obtained after keeping the electrode was at various potentials, at $c_{Cu(II)} = 2 \times 10^{-3}$ M. $c_{Se(IV)} = 1 \times 10^{-3}$ M, τ_{keep} = 30 s; the same for Fig. 7. Potential (mV): (*1*) +100, (*2*) +50, (*3*) 0, (*4*) –50, (*5*) –100, (*6*) –150, (*7*) –200, (*8*) –300, (*9*) –400, (*10*) –500, and (*11*) –600.

with respect to the stoichiometric composition Cu_2Se) disappears, whereas that corresponding to oxidation of Se(0) is not shifted markedly and its height increases with the Se(IV) concentration in the electrolyte. When the current peak of oxidation of the compound decreases in height, that corresponding to oxidation of selenium remains unchanged.

It can be seen from Fig. 3a that the first cathodic wave shifts in the positive direction with increasing concentration of copper(II) ions. This may be due to reduction of Se(IV) ions on copper. As already noted, the maximum anodic current of oxidation of the compound is observed at a Cu(II) : Se(IV) concentration ratio in the electrolyte greater than unity. We analyzed how the current peak of oxidation of the compound varies with concentration of a component added. In all cases, the maximum corresponded to the composition with Cu : Se ≈ 2 : 1 (Fig. 4).

In the study, we analyzed the influence exerted by the potential sweep rate on the oxidation potential of a compound. It was found that, as the potential sweep rate increases, the potential of the current peak observed on the carbon-pyroceramic electrode shifts only slightly (by about 30 mV) in the positive direction (Fig. 5).

To analyze in more detail the anodic portions of the voltammetric curves measured in oxidation of the compound $CuSe_x$ in an electrolyte with ion concentrations (M): $c_{Cu^{2+}} = 2 \times 10^{-3}$ and $c_{Se^{4+}} = 1 \times 10^{-3}$, the deposit was accumulated with the electrode kept at different potentials (Fig. 6).

It can be seen that the compound Cu_2Se is formed even at a potential of +0.1 V. The probable mechanism is the reduction of Se(IV) on copper. In codeposition of selenium and copper, only the current peaks corresponding to oxidation of the compound Cu_2Se (E_{ox} = 0.25 V) and of selenium (E_{ox} = 1.1 V) are observed in the anodic curve at all potentials. The additional shoulder observed both at the first and at the second current peaks of oxidation after the deposition in the potential range –0.15…–0.4 V (Fig. 6, curves *6*–*9*) may indicate that different forms of the compound are present and that this is the transition region between two of these. When the deposition is performed at potentials corresponding to the limiting current of reduction (at –0.5 and –0.6 V), only a single form of the compound is present, which is, probably, the most stable Cu_2Se. The voltammetric curve of Cu(II) and Se(IV) codeposition, measured at 80°C and a 2 : 1 concentration ratio, repeats the main features of the curve measured at room temperature. In particular, a partial reduction of copper selenide

occurs at –0.4 V to give H_2Se in accordance with Eq. (3).

The results obtained show that codeposition of copper and selenium occurs even at a potential of +0.10 V via reduction of selenium(IV) on copper, which is confirmed by the rise in the current of the first wave upon gradual addition of selenium (IV) to a solution with a constant Cu^{2+} concentration of 10^{-3} M (Fig. 2a).

If a solution containing a large excess of copper ions ($c_{Cu^{2+}} : c_{Se^{4+}} = 4 : 1$) is taken as the starting solution, then the accumulation of copper deposit at any potential results in the deposition of free copper, which is in excess with respect to the stoichiometric composition Cu_2Se (Fig. 7).

Figure 7 shows voltammetric curves measured in oxidation of a deposit accumulated at various deposition potentials under the conditions of an excess amount of copper ions in the electrolyte. The peak corresponding to oxidation of the excess copper is present in all the curves, along with the peak of oxidation of the compound. This result confirms the conclusion that the copper-to-selenium concentration ratio in the electrolyte not exceeding 2.2 : 1 is the optimal for obtaining a compound of composition Cu_2Se.

The structural properties of the surface of films electrodeposited onto glassy carbon plates at a chosen composition of the electrolyte showed that the structure of the deposit formed at a potential of –0.6 V corresponds to the composition of the compound $Cu_{2-x}Se$.

The main reflections in the X-ray diffraction pattern measured after annealing the film at 300°C correspond to this compound (Fig. 8a). According to the ASTM File, the composition parameter x for the compound is 0.15. An electron-microscopic study with analysis of microdiffraction patterns demonstrated that the structure of the compound Cu_2Se manifests itself in the form of separate reflections related to the coarsely crystalline phase (>200 Å). The clearly pronounced rings correspond to the finely crystalline phase of the same compound (crystallite size 15–25 Å). A micrograph of crystals of this compound, whose size corresponds to the finely crystalline phase, is shown in Fig.8b. For all the samples, the preferred reflections correspond to the [111] directions in the cubic lattice.

CONCLUSIONS

(1) Compounds of various composition are formed in the electrodeposition of copper(II) and selenium(IV), depending on the relative amounts of the components in the electrolyte and on the deposition potential.

(2) The condition for the formation of the compound Cu_2Se is that the Cu(II) : Se(IV) concentration ratio should be 2.2 : 1.

(3) Copper and selenium compounds of any composition give a peak of oxidation current at a potential of $+0.25 \pm 0.02$ V. The peak potential shifts only slightly in the positive direction as the content of copper ions increases.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Behavior of Aluminum–Zirconium Alloys Microalloyed with Strontium and Cerium

Nikitin Institute of Chemistry, Academy of Sciences of the Republic of Tajikistan, Dushanbe, Tajikistan

Received October 21, 2004

Abstract—The potentiodynamic method was used to study in solutions of 3% NaCl and 0.01 N NaOH the corrosion-electrochemical behavior of aluminum alloyed with zirconium, strontium, and cerium.

In choosing alloying elements in the development of aluminum-based conductor alloys and alloys for cable sheaths it is necessary to take into account not only the strength, technological, and electrical properties, but also the corrosion resistance. This refers in full measure to transition, alkaline-earth, and rare-earth metals, which are increasingly used for these purposes. There is published evidence concerning the positive influence of these metals on the corrosion resistance of aluminum [1–6].

The present communication reports the results of a study of the influence exerted by small additions of zirconium, strontium, and cerium on the corrosion resistance of technical-grade aluminum.

EXPERIMENTAL

As the starting material for preparing the alloys under study served aluminum of 99.6% purity, as well as strontium and cerium with a purity of no less than 99.8%. All the alloying components were introduced in the form of the corresponding alloys at a melt temperature of 800–850°C. From each melting, cylindrical samples 8 mm in diameter and 100 mm long were cast into a heated graphite mold.

The study was performed electrochemically in a neutral (3% NaCl) or alkaline (0.01 N NaOH) medium. The electrode potentials were measured with a PI-50-1 potentiostat relative to a silver chloride reference electrode during a month at 1-day intervals. The potentials are given relative to this electrode. The free-corrosion potential was determined from the potential–time dependence. The classical, well-reproducible polarization curves were obtained in the neutral medium by using the potentiodynamic method in combination with a preliminary deep cathodic polarization at a potential of –2.0 V for 5 min [7]. The current corresponding to each potential was recorded with an LKD-4 *X*–*Y* recorder in the potential–current coordinates. In the alkaline medium, polarization curves were measured, after the free-corrosion potential was attained, at a potential sweep rate of 2 mV s^{-1}.

In neutral solutions containing halogen ions, the passive oxide film on aluminum and its alloys ceases to be solid and pitting corrosion occurs. To assess the resistance of the alloys to pitting corrosion, the pitting potential and the corrosion potential under the identical testing conditions were compared.

Tables 1–3 list the results of an electrochemical study of the aluminum alloys. The dependences of the electrode potentials of aluminum–zirconium alloys on the time of keeping demonstrated that addition of zirconium shifts the free-corrosion potential of aluminum to a more negative region (Table 1). When

* Aluminum the rest.

the electrodes are submerged in a 3% NaCl solution, the corrosion potentials of the alloys have a higher negative value, but are shifted in the positive direction during the first 5–10 min. Further keeping for 1 h results in that a virtually stationary potential is attained, which is due to the formation of oxide films on the surfaces under study.

Table 2 lists electrochemical parameters of alloys of the system Al–Zr. Raising the content of zirconium in the alloys shifts the potentials of complete passivation and pitting to more positive values, with the passivation region extended by 40–100 mV. Introduction of up to 0.3% zirconium makes somewhat lower the current densities

of passivation onset (i_{po}) and complete passivation (i_{cp}).

The influence exerted by the alloying of the starting Al + (0.01–0.5%) Zr alloy with strontium or cerium was analyzed using the data for the binary alloys. The alloying shifts the free-corrosion potential to more positive values to –0.675…–0.680 V, and the pitting potential by 40–60 mV. The strongest shift of the potential in the positive direction is observed upon joint introduction of strontium and cerium. Analysis of the potentiodynamic curves measured in a 3% solution of NaCl shows that the free-corrosion potential of the alloys under study lies within the passive region. The irreversibility of the process of formation of passivating layers is confirmed by the hysteresis loop observed when measuring the curve in the reverse sweep. The potentiodynamic curves for the alloys are similar to those for pure aluminum, but the passivation current densities for the alloys with strontium and cerium are lower than those for the starting alloy and pure aluminum, which indicates that the dissolution rate of the alloys under study in a neutral medium is lower (Table 3).

The corrosion resistance of aluminum is largely determined by the nature of a corrosive medium and by the possibility of formation or dissolution of a protective film. It is believed that the medium with pH > 8.5 is the most corrosive for aluminum. According to [8], the process of dissolution of aluminum can be understood as follows. First, after aluminum is submerged in an alkali solution, the natural thin oxide film is chemically dissolved under the action of OH^- ions, and then, after the film is partly removed, there begins the electrochemical dissolution of the metal. The anodic dissolution process is described by the equation

$$Al + 3OH^- = AlOOH + H_2O + 3e.$$

In an alkaline medium, the thickness of the boehmite film increases with time, which leads to partial passivation, shifts the electrode potentials in the positive direction, and makes slower the corrosion rate of aluminum and alloys under study. A pronounced shift of the potentials in the positive direction occurs during the first 10 days. The cathodic and anodic curves for the alloys under study are similar to those for pure aluminum, and the passivation current densities indicate that the corrosion resistance of aluminum alloys containing up to 0.1% strontium and cerium increases. The lowest passivation current density is observed for the alloys with both strontium and cerium. The high corrosion resistance of these alloys is confirmed by gravimetric measurements of the corrosion rate in the same NaOH medium (pH ≈ 11.6).

* Numerator, data for cast alloys; denominator, for annealed alloys.

** Data for annealed alloys.

The nature and amount of the second phase in the alloys affect the pitting potential only slightly, which was demonstrated by tests of the alloys under study before and after thermal treatment (Table 4).

The alloys were homogenized at 500°C for 6 h, with subsequent quenching in cold water. The pitting potentials of these alloys are in the range –600… –700 mV. It can be seen that the thermal treatment strongly affected the passivation current density and the corrosion potential. It follows from the data in Table 4 that a homogenizing thermal treatment can

improve the corrosion resistance of aluminum alloys with strontium and cerium in an alkaline medium, which is indicated by the decrease in the passivation current density.

CONCLUSION

A study by the potentiodynamic method demonstrated the possibility of improving the corrosion resistance of technical-grade aluminum by its microalloying with zirconium, strontium, and cerium.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Fundamental Aspects of Film Formation in Electrochemical Polishing of Silver and Silver–Copper Alloys in Thiosulfate Solutions

Received April 15, 2004

Abstract—The anodic behavior of silver and its alloys with copper in thiosulfate solutions was studied by cycling voltammetry. A scheme of an electrochemical polishing process including the stage of formation of a resistive layer of silver thiosulfate and the chemical stage of its dissolution is suggested.

Electrochemical polishing has found fairly wide use for finishing treatment of plated silver coatings and silver articles [1, 2]. The variety of electrolytes used for this purpose is limited to few solutions with high concentrations of CN^- [3, 4], CNS^- [5], $S_2O_3^{2-}$ [6, 7], and NH_4^+ [8] ions. All these anions form with the Ag^+ cation highly stable complex compounds [9], which ensure that the products of the anodic reactions exist in a soluble form. At the same time, it is known that the electrochemical polishing of silver is accompanied by periodic formation and dissolution of the surface passivating salts films of the corresponding sparingly soluble compounds. The chemical stability of these films in concentrated solutions of like anions is low, which is presumably due to the occurrence of fast reactions of film dissolution to give complex salts.

A nontoxic thiosulfate solution, in which passivating films [7] of sparingly soluble silver thiosulfate [10] can also be formed, is rather promising for electrochemical polishing of silver. The fundamental aspects of the film-forming process in anodic oxidation of silver have been little studied. This leads to higher labor expenditure in choosing the optimal polishing conditions.

The main difficulty in working with thiosulfate solutions is the strong influence exerted by the acidity of the medium on the stability of the $S_2O_3^{2-}$ ion. In an acid medium, this ion decomposes by reaction [11]

$$S_2O_3^{2-} + 2H^+ \rightarrow SO_2 + S\downarrow + H_2O. \quad (1)$$

In addition, the cathodic reduction of the anion to the S^{2-} ion is facilitated [11]:

$$S_2O_3^{2-} + 6H^+ + 8e \rightarrow 2S^{2-} + 3H_2O. \quad (2)$$

In this context, it is appropriate to use in the study a sodium thiosulfate solution combined with an acetate buffer system [6], which maintains the neutral pH value both in the near-electrode layers and in the electrolyte bulk. According to [12], the silver electrode interacts with $S_2O_3^{2-}$ ions at considerably less positive potentials than those in the case of acetate ions [12]. Therefore, acetate ions will not affect the anodic oxidation of the metal under study at the potentials considered.

The aim of this study was to examine the kinetic aspects of the anodic dissolution of silver and silver–copper alloys in a thiosulfate solution for the case of electrochemical polishing.

EXPERIMENTAL

The study is concerned with the electrochemical oxidation of silver (Sr999 brand) and binary single-phase silver–copper alloys (SrM940 and SrM910 brand, containing 94% and 91% silver, respectively, and copper the rest) in 320 g l^{-1} $Na_2S_2O_3$ solutions (in acetate buffer system, pH 6.5) [6] using the methods described in [13] (PI 50-1 potentiostat). Prior to the polarization measurements, the samples of silver and silver alloys were mechanically polished,

degreased, and washed. In some cases, silver was subjected to chemical polishing in a 1 : 1 aqueous solution of HNO_3 for 1 min, instead of mechanical polishing, which made the silver surface white matte, similarly to a plated silver coating. The polarization measurements were performed in the temperature range 20–40°C, with temperature maintained constant to within ±0.1°C, at a potential sweep rate in the interval 5–100 mV s^{-1}.

The quality of the surface was judged from the fractal dimension and the reflectivity of the electrode surface. The fractal dimension D_f, related to the surface roughness, was calculated from a frequency dependence of the electrode impedance, measured with a P5021 ac bridge by the method described in [14, 15]. The surface reflectivity was measured on a specially designed setup [16].

The steady-state potentials of Sr999 silver and silver–copper alloys in thiosulfate solutions strongly depend on the alloy composition and concentration of sodium thiosulfate (Fig. 1). Owing to the high complexing ability of Ag^+ with respect to the $S_2O_3^{2-}$ ion and the low solubility product of $Ag_2S_2O_3$ [10], the steady-state potential of the silver electrode in the solution studied is rather negative and lies within the range –0.360…–0.340 V relative to a saturated silver chloride reference electrode.

The anodic behavior of silver in this solution is described by a polarization curve with a clearly defined peak of the anodic current (Fig. 2a). The height of this peak linearly depends on the square root of the potential sweep rate V (Fig. 3). This is due to the formation, by the electrochemical mechanism, of a resistive porous layer of sparingly soluble products of silver oxidation [17]. The most probable is formation of a salt layer of $Ag_2S_2O_3$, since the potential of the redox process under study, measured as the half-sum of potentials of the anodic and cathodic current peaks, is –0.220 to –0.150 V.

The experimental data in Fig. 2a show the following. As the time of anodic polarization decreases (i.e., the potential sweep rate increases), a peak of cathodic current, gradually increasing in height, is observed in the cathodic portion of the cyclic voltammogram. This peak is conjugate to the anodic peak and reflects the reduction of the salt layer. The electrolyte used shows a high chemical activity with respect to the resistive layer and dissolves it, apparently owing to the occurring complexation. The dissolution rate of the primary product of the electrode process at 20°C, expressed in current density units and determined as the intercept on the current-density axis (Fig. 3) [13],

is 10 mA cm^{-2} and is diffusion-limited (the effective energy of activation of this process, determined by the temperature-kinetic method, is A_{eff} = 12 kJ mol^{-1}). Based on the aforesaid and taking into account the known forms of complex ions [9, 10], we can represent the electrochemical dissolution of silver in a thiosulfate solution as

$$\begin{array}{l} 2Ag + S_2O_3^{2-} \rightarrow Ag_2S_2O_{3(s)} + 2e \\ \qquad\qquad \downarrow +nS_2O_3^{2-} \\ \qquad\qquad Ag(S_2O_3)_{2(sol)}^{3-}, \\ \qquad\qquad Ag(S_2O_3)_{3(sol)}^{5-} \end{array} \qquad (3)$$

The electrochemical polishing of silver was performed in a solution of the above composition in the ac mode, which ensures anodic formation, partial chemical removal, and cathodic reduction of the residual amount of the film substance. The alternation of such actions at a certain frequency results in a pronounced leveling of the surface [fractal dimension D_f decreases, luster appears or is enhanced for both mechanically and chemically treated surfaces (see table)].

The anodic polarization curves of SrM940 and SrM910 alloys, compared with those of silver, show two additional electrochemical responses recorded in the form of waves (Fig. 2b). Such changes in the polarization curve are due to the electrochemical oxidation of the more electronegative component of the alloy, i.e., copper, which proceeds in two single-electron stages [18]. In the process, the half-wave potentials $E_{1/2}$ of Cu $\rightarrow$ Cu(I) and Cu(I) $\rightarrow$ Cu(II) oxidation are strongly different. It may be suggested that, in all probability, the forming compounds of Cu(I) are sparingly soluble, similarly to Ag(I) compounds. Therefore, if the potentials corresponding to the Cu(I) $\rightarrow$ Cu(II) transition, which enables formation of soluble thiosulfate complexes of Cu(II), are not attained in the electrochemical treatment of the alloy, no surface polishing will occur.

A study of the electrochemical polishing of the alloys in a thiosulfate solution with short current pulses (pulse width $t_p = 3.0 \times 10^{-3}$ s at the on-off time ratio g = 2–10) showed that polishing takes place at the electrode polarization in the range ΔE = 0.4–0.75 V, i.e., after the potential of ionization of copper to Cu(II) and that of silver are attained. Another reason why the ΔE interval in which the polishing process occurs is so narrow is that the potentials of processes involving copper

$$2Cu + H_2O = Cu_2O + 2H^+ + 2e, \qquad (4)$$

Characterization of the surface of a silver electrode before and after electrochemical polishing in a thiosulfate solution

Sample preparation	Surface	D_f	Luster, cd m^{-2}
Mechanical	Initial	2.3–2.4	400–450
	Electrochemically polished	2.3–2.4	585–615
Chemical	Initial	2.7–2.75	300–330
	Electrochemically polished	2.3–2.4	400–450

$$Cu_2O + H_2O = 2CuO + 2H^+ + 2e \qquad (5)$$

are attained at a stronger polarization [18].

The reaction of copper oxides with the $S_2O_3^{2-}$ ion is rather slow. Apparently, this is the reason why the optimization of the polishing conditions for silver–copper alloys is very difficult and why copper and alloys containing >9% copper cannot be polished in thiosulfate solutions.

In polarization of silver alloys in the pulsed mode, the kinetic component of the anodic current can be also distinguished (Fig. 3). Extrapolation of the dependence of the average pulsed current density j on the on-off time ratio n to $n \rightarrow 0$ gives the same j_0 value as that found in the potentiodynamic study (Fig. 3). This value is 10 mA cm^{-2} and corresponds to the anodic current density at which the rate of film formation is close to the rate of its dissolution via chemical reaction with thiosulfate ions. The coincidence of the j_0 values obtained in different experiments confirms the physical meaning of this parameter, as well as its effect on the kinetics of anodic dissolution of silver and silver alloys.

CONCLUSIONS

(1) The electrochemical polishing of silver in a thiosulfate solution is accompanied by the formation of a resistive porous layer of silver thiosulfate, whose dissolution rate is 10 mA cm^{-2} under the given conditions. This current density is the optimal for polishing of silver and the alloys studied with short current pulses.

(2) The complex polarization dependence for silver–copper alloys in thiosulfate solutions, which indicates the formation of a number of sparingly soluble copper(I, II) compounds, along with silver oxidation,

predetermines the rather narrow interval of alloy polarization in which electrochemical polishing occurs. To obtain a polishing effect, it is necessary to perform the anodic process at the potentials of occurrence of the reactions $Cu(I) \rightarrow Cu(II)$ and $Ag_2S_2O_{3\,(sol)}$.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Corrosion-Electrochemical Behavior of Aluminum Alloys Low-Alloyed with Magnesium and Alkaline-Earth Metals

I. N. Ganiev, R. O. Barotov, and M. B. Inoyatov

Nikitin Institute of Chemistry, Academy of Sciences of the Republic of Tajikistan, Dushanbe, Tajikistan

Received March 2, 2004

Abstract—In connection with the development of low-alloyed aluminum alloys, their corrosion-electrochemical behavior was studied in various media.

The positive effect of magnesium on the physicochemical properties and corrosion resistance of aluminum is known. Taking into account this fact, series of industrial alloys of AMg6 and AMg8 brands, which contain increased amounts of the alloying element, have been developed [1, 2]. Data on the influence exerted by small amounts of magnesium are contradictory and require refinement. In view of the development of low-alloyed aluminum alloys for electrical engineering purposes, the influence exerted by addition of magnesium in an amount of 0.01–1.0% and of alkaline-earth metals (AEM) on the corrosion-electrochemical behavior of aluminum of A6 brand in a 3% NaCl solution was studied.

EXPERIMENTAL

To obtain classical polarization curves with all the three kinetic regions of active dissolution, active-passive transition, and repassivation, the potentiodynamic method was used in combination with a preliminary deep cathodic polarization at a potential of –2.0 V for 2 min [2]. This technique yields well-reproducible dependences in the case when a potentiodynamic polarization curve is measured at a potential sweep rate of 10–20 mV s^{-1} immediately after the cathodic polarization. The study was carried out with a PI-50-1 potentiostat and an LKD-4 X-Y recorder. The potentials are given relative to a silver chloride reference electrode.

The alloys studied were obtained on a shaft resistance furnace from aluminum, magnesium, and Al + 10% AEM alloys. The melt was cast to give cylindrical samples 10 mm in diameter and 100 mm long. The rods were pressed in Teflon tubes, sand-papered, polished, degreased, etched in a 10% NaOH solution, thoroughly washed with water, and placed in the working solution. The measurements were performed at a temperature of 20°C and potential sweep rate of 10 mV s^{-1}. The main electrochemical parameters of binary alloys of the system Al–Mg, deduced from potentiodynamic polarization curves, are listed in Table 1.

It can be seen that addition of magnesium positively affects the electrochemical parameters of aluminum. For example, a shift of the free-corrosion potential to the negative region has virtually no effect on the potentials of pitting and passivation onset, which, on the whole, extends the passivation interval.

The free-corrosion potentials of all the alloys studied, as well as that of aluminum, lie in the passivation region, which points to their high capacity for spontaneous passivation. Alloying of aluminum with mag-

nesium leads to a decrease in the passivation current density in the entire range of the concentrations studied, especially for the alloy with 0.1% Mg. The resistance to pitting corrosion can be evaluated by a characteristic of the pitting resistance, pitting-resistance basis ΔE_{pt} [4]:

$$\Delta E_{pt} = \Delta E_{pt} - \Delta E_{k}.$$

In this parameter, the alloys markedly surpass pure aluminum, which is indicated by an increase in ΔE_{pt} from 80 mV for aluminum to 260 mV for the alloy containing 1% magnesium.

Table 2 lists the results of an electrochemical study of binary alloys of aluminum with small additions of strontium and barium. Alloying of aluminum with these metals als0 leads to a decrease in the current densities of complete passivation and passivation onset in the potentiodynamic curves. Introduction of strontium and barium in amount of 0.10–0.15 wt % has virtually no effect on the main electrochemical parameters of aluminum. As the content of the alloying element is raised further, the passivation region somewhat narrows and the current densities of passivation onset and complete passivation increase.

With account of previous studies [5, 6], the following concentration ranges were chosen in developing the composition of complex alloys based on ternary systems aluminum–magnesium–AEM (wt %): 0.01–1.0 for magnesium and 0.01–0.05 for AEM.

The results obtained in a study of ternary alloys are listed in Tables 3 and 4. The variation with time of the free-corrosion potential of alloys of the optimal composition in a 0.1 N NaOH solution shows that the corrosion potential in an alkaline medium reaches a constant value in 2–3 h. A strong shift of the potential into the positive region is observed in the first 30 min, and then only a minor shift of the potential is observed till its complete stabilization (Table 3).

At a constant content of AEM and increasing concentration of magnesium, the corrosion potential of the alloys are shifted, as also in the case of binary alloys of the system Al–Mg, into the negative region (Table 4). However, addition of up to 0.5 wt % magnesium has virtually no effect on the electrochemical parameters of aluminum: E_{pt} and E_{rp} change only slightly. The free-corrosion potential lies in the passive region, which points to good passivation characteristics of the ternary alloys. Virtually all of the alloys studied have a lower current density of complete passivation than pure aluminum (Table 4).

The best corrosion resistance is observed for alloys that contain (wt %): magnesium 0.05–0.020, AEM 0.05. The electrochemical data are confirmed by gravimetric measurements of the corrosion rate of a number of alloys in a 3% NaCl solution containing 0.1% H_2O_2 (Table 4). Alloying of aluminum with magnesium and AEM simultaneously can raise its corrosion resistance by 30–50%.

The effect of plastic deformation at an extent of deformation equal to 80% on the corrosion-electrochemical behavior of the alloys was studied for the example

* Numerator, data for cast alloys; denominator, for deformed alloys.

of alloys with varied content of magnesium and constant content of AEM, equal to 0.05% (Table 5).

The electrochemical studies were carried out in a 3% NaCl solution, and gravimetric studies, in a solution of 3% NaCl + 0.1% H_2O_2.

The technological procedure used to fabricate compacted samples consisted in forging of rectangular $20 \times 30 \times 100$-mm cast samples preliminarily heated to 500°C on planar blocks, with their thickness decreasing by 80%, i.e., to 4 mm. Further, the samples were cut to required dimensions.

Comparison of the parameters of the alloys and the starting aluminum before and after deformation shows that the corrosion potential shifts to a more negative region after the deformation. This, on the whole, makes greater the pitting-resistance basis of the alloys. The decrease in the current density of complete passivation leads to an increase in the corrosion resistance of alloys of the optimal composition after their deformation, which is confirmed by gravimetric data. The corrosion rate v_c of the alloys subjected to deformation is 30–50% lower than that of the starting aluminum under the same conditions. This is due to the following: in the case of an oriented structure, the corrosion mainly develops along the surface, i.e., in parallel with the vector of the maximum deformation (compaction) in the fabrication of a semifinished product [7]. In addition, the dissolution rate is also affected by the formation on the surface of a protective passivating film on the defects of the crystal lattice of the surface layer of the metal [8].

According to the phase diagram of ternary alloys of the systems Al–Mg–AEM, all the alloys studied, which contain up to 1% magnesium, form solid solutions, i.e., have a single-phase structure [9]. The anodic potentiodynamic curves of the alloys show only a single peak of the anodic current, which characterizes the active dissolution of the given phase. The presence a peak of this kind in potentiodynamic curves and its nature is explained differently by different authors. All the existing hypotheses consist in the following.

(1) The peak is due to active dissolution of aluminum (or its solid solution) with the subsequent formation of aluminum oxide [3]. The role of the cathodic polarization consists in alkalization of the near-electrode layer, which results in chemical dissolution of the oxide film that passivates aluminum.

(2) Because of the existence of aluminum hydride in aqueous solutions, the presence of an anodic peak in a potentiodynamic curve can be attributed to the decomposition of this compound. The formation of the hydride is favored by the cathodic polarization of the electrode [11]. Timonov *et al*. [10] observed an anodic current peak after keeping the electrode at potentials of –2.5 and –3.0 V, i.e., at those potentials at which Al is stable according to thermodynamic data and no hydride should be formed.

(3) The adherents of the theory of cathodic introduction of an alkaline metal into aluminum to give an intermetallic compound in solutions of alkali metal chlorides attribute the presence of a current peak in the potentiodynamic curve to decomposition of this intermetallic compound, which is formed in the cathodic polarization of the electrode. A study performed in LiCl, NaCl, KCl, NH_4Cl, and $CaCl_2$ [10] demonstrated that the current peak is present in solutions of alkali metal chlorides and absent in solutions of NH_4Cl and $CaCl_2$.

However, analysis of the phase diagrams of the systems Li–Al, Na–Al, K–Al, and Ca–Al shows that intermetallic compounds are formed in the systems Li–Al and Ca–Al. The systems Na–Al and K–Al are characterized by complete absence of interaction between the components and by formation of a monotectic system [14].

Thus, it is possibly necessary to agree with the authors of the theories that attribute the existence of the peak to active dissolution of aluminum with the subsequent formation of aluminum oxide passivating the metal [3].

CONCLUSION

The possibility of improving the corrosion resistance of technical-grade aluminum by its microalloying with magnesium and alkaline-earth metals was demonstrated by means of the potentiodynamic method.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Finding an Effective Way to Inhibit Carbon Dioxide Corrosion of Ferrous Metals in Oil-and-Gas Production Media

L. S. Moiseeva

Scientific-Engineering Center of Lukoil Company, Moscow, Russia

Received December 22, 2003; in final form, June 2004

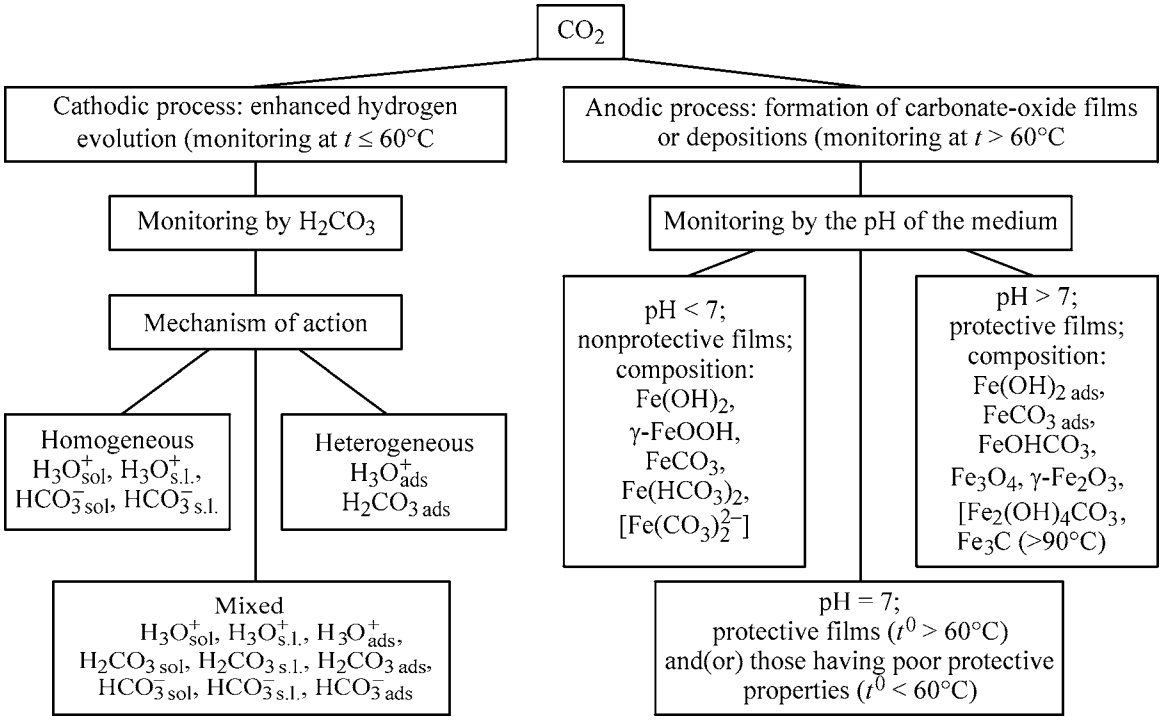
Abstract—Main ways to control the carbon dioxide corrosion, type of inhibitors employed, reasons for choice of the inhibitors, and various factors determining the efficiency of inhibitors of different types in carbon dioxide oil-and-gas production media are considered.

When solving problems related to carbon dioxide corrosion, which are encountered in oil and gas fields, it is particularly important to determine the most effective protective method [1, 2]. Inhibition is an efficient and, in many cases, rational protection technique [1–5]. Previously, mechanisms of carbon dioxide corrosion in single- and double-phase oil-and-gas production media at various pH values have been analyzed [6, 7].

The aim of this study was to continue investigations aimed to choose the most promising ways to control the carbon dioxide corrosion and to consider main types of inhibitors and factors determining their efficiency.

An analysis of the mechanism of action of CO_2 revealed its main specific features (Scheme 1). Primarily, the accelerating effect of CO_2 is due to en-

Scheme 1.
Effect of CO_2 on the corrosion of steel*



* Content of depolarizer in the surface layer (s.l.) and is solution (sol).

hanced evolution of hydrogen and formation of carbonate-oxide films on the metal surface (which may have good or poor protective properties) [8–16]. Hence follows that an effective protection can be achieved, first, by hindering the cathodic process and, second, by forming protective carbonate films on the steel surface [12–14]. These films preclude penetration of depolarizers (H_3O^+, HCO_3^-, H_2CO_3) and activators (Cl^-, SO_4^{2-}) to the metal surface and(or) migration of iron ions across the film [16–19].

The cathodic process can be effectively hindered (1) by lowering the concentration of depolarizers in solution and in the surface layer by their chemical binding with derivatives of aminoformic acid: amides, carbamates, hydrazides, organic carbonates, neutral acyclic carbonates, and carbonic acid esters [20]; (2) by displacing depolarizers with ions or molecules of inhibitors (competing adsorption) with the use of ethylene imine, and ethers or esters (PIK 12, SNPKh-6302, Minkor-2) [20, 21]; and (3) by forming protective oxide-carbonate, inhibiting, or mixed films that preclude migration of depolarizers and activators to the metal surface or that of Fe^{2+} ions across the film by using compounds with an active adsorption group or a long hydrocarbon radical, such as SZhK, OR-2K, GIPKh-3A, SNPKh-6011B, Neftegaz, Tarin, KRTs-3G, or organophosphorus compounds: FAN-403M, F-741, etc. [1–3, 22–24].

In the last case, films or deposits formed on the metal surface can affect both the anodic and cathodic processes. The extent of this influence is determined by the composition and structure of the films and by presence and size of pores in them [12–19]. When a carbonate-oxide film or deposit with poor protective properties is formed on the metal surface, its hindering action can be enhanced by introducing into the medium a specially selected inhibitor, which is not only adsorbed but also can penetrate into the pores in the film.

The hindrance of the anodic process in carbon dioxide corrosion, which is closely associated with the formation of protective siderite films or deposits, can be achieved by raising the pH of the medium (by shifting the pH to the alkaline region) or elevating the temperature (to 40–60°C) [8–19, 23–27].

The pH of the medium can be adjusted by using inhibitors that shift the pH to the alkaline region to 8–10, which favors formation of a protective siderite layer on the metal surface, the so-called neutralization method [12, 15, 18, 28–31].

It should be noted that the pH of water can change with temperature and strength of an external electromagnetic field [32, 33]; thermochemical reactions can be used to maintain the temperature of the medium in a prescribed temperature interval. In particular, the possibility of a thermohydrodynamic adjustment of the pH of water in the range 5.7–8.6 was demonstrated in [32]. It was established that the pH of water grows as the number of cycles of hydrodynamic cavitation becomes greater. After 9 to 10 cycles, pH = 8.6. Adjusting *t* thermochemically and pH by physical methods in systems for production, gathering, and transportation of oil and gas is, presumably, possible only in separate localities.

The main ways to control the carbon dioxide corrosion, including that with the use of inhibitors, are shown in Scheme 2.

Scheme 2.
Main ways to control the carbon dioxide corrosion of steel

As is known, inhibitors are classified by the mechanism of action (anodic, cathodic, or mixed) [4], chemical nature (in accordance with classes of organic and inorganic compounds) [3, 4, 22–24], and the principle of action (neutralizers and film-forming agents) [31, 34]. According to the presently developed concepts concerning the mechanisms of carbon dioxide corrosion, the effective inhibiting effect can be produced by inhibitors of the cathodic or mixed type, with predominant hindrance of the cathodic process [35, 36]. At the same time, inhibitors of the anodic type (KhOSP, OR-2K, GIPKh-3, etc.) are frequently used in practice to control the carbon dioxide corrosion [1, 2, 23].

Traditionally, ferrous metals are protected from the carbon dioxide corrosion at oil and gas fields using N-containing compounds and, in particular, amines, imidazolines, and nitrogen heterocycles (Olazol, Sepacorr 5120, Sepacorr ES-3201, Corexit 7755 and 7798, Norust-9M, Norust RA 23D, XC-320, KW-10, etc.) [1–5, 30, 35–39] despite numerous failures of the equipment. These compounds can act both as neutralizers and as film-forming agents. As is known [4, 5], amines and imidazolines are effective in protection from carbon dioxide corrosion in the presence of hydrogen sulfide. It was shown in [40, 41] that lower primary and secondary amines hinder the carbon dioxide corrosion of steel in the aqueous and gaseous phases at their considerable concentration in solution (20–80 g l^{-1}). Despite their higher, compared with primary amines, basicity, tertiary amines are ineffective in protection from the carbon dioxide corrosion.

In [42], results of a comparative study of the influence exerted by quaternary ammonium salts with alkyl radicals of length from C_1 to C_{16} on the carbon dioxide and hydrogen sulfide corrosion of steel in NaCl solutions were reported, which confirm, to a certain extent, the validity of the concepts described above (Table 1). In particular, it was established that, in a CO_2-containing medium, they are inhibitors of the cathodic type, which shift the corrosion potential into the negative region and lead to a noticeable increase in the Taffel slopes $b_c \approx 300$ mV and $b_a \approx 100$ mV. This is due to the formation on the metal surface of a film that is poorly permeable to the depolarizer. In the presence of H_2S in the medium, these same quaternary ammonium salts act as inhibitors of the anodic type. The observed differences in the shift of the corrosion potentials are due to the formation of corrosion products of some other composition and to their influence on the adsorption of inhibitor molecules. In the case of hydrogen sulfide corrosion, quaternary ammonium compounds are adsorbed on the layer of earlier adsorbed HS^-_{ads} species, i.e., at anodic areas. In CO_2-containing media, no layer of adsorbed $HCO^-_{3(ads)}$ species is formed on the steel surface and quaternary ammonium cations are adsorbed directly at the cathodic areas on the metal surface.

Taking into account the chemical nature of the depolarizers, carbonic acid and hydrocrabonate ions, and the related adsorption activity toward iron, which is due to the presence of both a carboxyl and a carbonyl group in the molecule, it would be expected

that organic substances that contain these groups (carboxylic acids, ketones, and esters) are effective inhibitors of the carbon dioxide corrosion because they can compete for adsorption sites and displace depolarizers from the metal surface. Presumably, it was not a mere chance that the first inhibitors of the carbon dioxide corrosion were the calcium salt of acid tar (IKSG-1), synthetic fatty acids, and wastes containing a mixture of high-molecular-weight carboxylic acids and their salts [4]. Until now, vegetable oils (palm "copra," coconut, burdock, soybean), tall oil, and resin acids (abietic acid derivatives of general formula $C_{20}H_{30}O_2$: levopimaric, neoabietic, dehydrobithienic, and palustric) are used to manufacture many foreing inhibitors [3, 42–4]. It should be noted that publications concerned with the influence exerted by this group of substances on the carbon dioxide corrosion of ferrous metals in oil-and-gas production media are scarce [6, 7, 18, 20, 45], and inhibitors containing these compounds a virtually not used at all in domestic oil and gas fields.

Apart from the organic substances mentioned above, possible effective inhibitors of the carbon dioxide corrosion may be compounds that have, in addition to a high adsorption activity, an ability to create on the metal surface a protective film, the so-called film-forming agents [3, 5, 29, 31, 45–48]. In these compounds, the excess electron density on the heteroatom (N, S, P) or at the unsaturated bond is the prerequisite of their chemisorption [5, 49, 50].

The choice of one or another type of inhibitor of the carbon dioxide corrosion is also governed by the initial state of the metal surface [presence or absence of films and(or) deposits on the surface of a metal being protected and their type] [8, 15].

In media with pH $\geq$ 7, in the presence of films or deposits, it is preferable to use oxygen-containing organic inhibitors {salts of carboxylic acids, some derivatives of carbamic acid (carbamates, amides, hydrazides), and organic derivatives of carbonic acid [19]}, which can, first, be adsorbed on this layer and, second, shift the corrosion potential into the negative region, with the result that the general and local corrosion is hindered.

The inhibitors should be able to penetrate into pores of deposits that are stable in the medium (according to the classification presented in [51]) and reach the metal surface or to enhance the protective properties of deposits unstable in the medium. This ability is determined by the correspondence between the size of inhibitor molecules and that of pores in the film. In the second case, an important role in the effective protection is played by the correspondence between the spatial structure of inhibitor molecules and the crystal structure of the deposit.

By contrast, Crolet [51] related the protective properties of corrosion deposits to the internal mechanism of their control and to the structure of the corresponding diffusion model, rather than to their chemical composition and morphology. In this study, films or deposits composed of siderite, amorphous phase of corrosite $FeCO_3 \cdot FeO$, Fe_3C matrix filled with siderite were classified with stable deposits, and films or deposits composed of oxyhydroxides $FeO_x(OH)_{3-2x}$, intermediate phase of α-FeOOH and lepidocrocite γ-FeOOH, and $Fe_2(OH)_4CO_3$ and $FeOHCO_3$ complexes, with unstable deposits.

In the same pH range, and with unstable deposits that tend to grow intensively, it is preferable to use inhibitors that can bind cations (Ca^{2+}, Fe^{2+}) or exhibit the so-called crystal-disintegration effect [52].

In media with pH < 7, in the absence of films or deposits, it is preferable to use neutralizers that favor a shift of the pH into the alkaline region and formation of deposits on the metal surface. In this case, the choice of a neutralizer is determined by the pH.

The neutralization can be achieved by using both contact-type and volatile corrosion inhibitors (inorganic and organic bases or their salts). With account of the characteristic features of the carbon dioxide corrosion in oil-and-gas production media and the necessity for simultaneous protection of the equipment in liquid and gaseous phases, use of volatile inhibitors-neutralizers is a matter of current interest.

The first attempts to use ammonia and carbonates to adjust the pH failed [31, 53]. With these compounds, the pH value widely fluctuated (8–1). This adversely affected the protective properties of the forming film, and the danger of intensive growth of carbonate deposits was preserved. At present, nitrogen-containing organic compounds and their salts (dimethylamine, ethylenediamine, methoxypropylamine, morpholine, sodium salt of merkaptobenzothiazole MBTNa, etc.) are used to control the pH in CO_2-containing media.

The mechanism of protective action of organic nitrogen-containing bases in media with a large content of dissolved CO_2 is not reduced to only neutralization of a weak acid H_2CO_3, whose solutions have a large buffer capacity. Reacting with dissolved carbon dioxide, nitrogen-containing organic bases maintain the pH value at 9, which favors formation of HCO_3^- [53]:

$$R_2N\text{–}H + H_2CO_3 \rightarrow HCO_3^- + R_2NH_2^+. \quad (1)$$

Further, this leads to formation of CO_3^{2-} ions and protective carbonate films. Reaction (1), which occurs in solution and in a thin electrolyte film, is slow, irreversible, and going to completion [16, 53].

Standard amines (A) used to control the pH are, as a rule, volatile, with an ionization constant on the order of 10^{-11}. A part of amine, as well of that of CO_2 present in the gas, dissolves in drops of the condensation moisture. Two compounds react with each other, with the result that the following equilibrium is established [54]:

$$A + H^+ = AH^+ \quad (2)$$

$$CO_2 + H_2O = HCO_3^- + H^+ \quad (3)$$

$$A + CO_2 + H_2O = AH^+ + HCO_3^- \quad (4)$$

The concentration of the free amine in solution under real conditions can be calculated using the equilibrium constants of reactions (2) and (3), K_A and K^* [54]:

$$K_A = [AH^+]/([A][H^+]),$$

$$K^* = [HCO_3^-][H^+]/P_{CO_2}.$$

The partial pressure of amine over solution, P_A, and the concentration of amine in solution, [A], are related by

$$P_A/P_A^0 = [A]/[A_{sat}], \quad (5)$$

where P_A^0 is the partial pressure over pure amine, and $[A_{sat}]$, the concentration of a saturated amine solution.

According to [54], use of Eq. (5) makes it possible to monitor the efficiency of the corrosion protection with inhibitors of the neutralizing type in the gaseous and aqueous phases.

In [40, 41], the influence exerted by the partial pressure of amine, P_A, in a single reaction series of organic substances on the corrosion of steel was prognosticated. It was established that introduction of minor amounts of such bases as monoethanolamine, cyclohexylamine, and diallylamine into a 0.5% NaCl solution containing 250 mg l^{-1} of acetic acid and saturated with CO_2 (1 atm) stimulates corrosion of carbon steel. The protective effect is observed at considerable concentrations of amines in solution (32–48 g l^{-1}). The stimulating action of these amines is attributed to an increase in the content of carbonate ions in the electrolyte, because the solubility of CO_2 at a constant pressure grows as pH becomes higher.

The efficiency of neutralizers is determined by their neutralizing capacity, which can be evaluated by the basicity (K_b) or acidity (K_a, or pK_a [31]) constants. As a rule, the greater pK_a, the higher the efficiency of a neutralizer. The inhibiting efficiency of organic bases is affected by the length of the hydrocarbon chain and the degree of its branching, configuration of a molecule, and position and number of adsorption centers in the molecule [3, 4].

The efficiency of neutralization is affected to a certain extent by the buffer capacity of the solution [31]. For example, the amount of methoxypropylamine necessary for neutralization of a solution considerably exceeds that of ethylenediamine, and the buffer capacity of the former is negligible compared with that of the latter, so that even a minor decrease in the concentration of methoxypropylamine leads to a considerable change in the pH value and strongly raises the corrosion rate [54, 55].

Another factor determining the efficiency of neutralizers, the distribution of neutralizing amines, is characterized by the distribution factor $K_d = c_g/c_a$, where c_g and c_a are the equilibrium concentrations of amine in the gaseous and aqueous phases under the conditions of a phase transition (in evaporation and condensation). Amine exhibits the strongest neutralizing properties in both the gaseous and aqueous phases at $K_b > 100 \times 10^{-6}$ and $K_d = 1.0$ [31].

An important issue is the correspondence between the chemical types of a neutralizer and an acidic agent present in the corrosive medium [55]. In the general case, the following should be noted: (1) presence, together with H_2CO_3 ($CO_2 \cdot H_2O$), of a strong inorganic acid in the medium requires that a strong, mostly inorganic base ($K_b \times 10^6 > 500$) should be used as a neutralizer; (2) presence of a weak inorganic acid with a high buffer capacity (of the carbonic type) requires that organic neutralizers with a high buffer capacity should be used; and (3) presence, together with H_2CO_3, of corrosive carboxylic acids (lower carboxylic, naphthenic) requires use of organic bases with a high adsorption capacity for the metal, whose molecules can compete for adsorption sites and, in the end, displace molecules of the acid from the metal surface, which favors formation of a protective film.

The state of the metal surface is one more factor determining the efficiency of an inhibitor-neutralizer. In particular, morpholine is more efficient in the case of a clean steel surface, and cyclohexylamine, in the case of steel covered with oxides [54, 55].

It should be noted that some of organic corrosion inhibitors protect a relatively clean steel surface to

a lesser extent, compared with that covered with corrosion products. Such an action, determined by the difference between the adsorption properties of inhibitors on a clean metal surface and on corrosion products, depends on their concentration in the corrosive medium [56, 57]. It was shown in [9, 10, 35, 36] that film-forming inhibitors with a cathodic type of action, which contain a carbonyl or carboxyl group, are universal as applied to the carbon dioxide corrosion. They can be used both on a clean metal surface and on that covered with a carbonate-oxide film or a layer of deposits.

As shown by practical experience, choosing inhibitors among the reagents conventionally used to control the hydrogen sulfide corrosion without taking into account the specific features of the carbon dioxide corrosion frequently yields unsatisfactory results.

A set of corrosion inhibitors of the KRTs brand have been developed specially for inhibition of the carbon dioxide corrosion in oil-and-gas production media. These inhibitors include organic substances containing a carboxyl and a carbonyl groups (cyclic ketones, ethers, and esters) [47, 35, 36]. The efficiency of inhibitors with respect to the carbon dioxide corrosion was studied in a wide range of pH values, 2–10. The behaviors of anodically and cathodically polarized steels in a two-phase medium (pH 2) saturated with CO_2 were compared and the influence exerted on these processes by inhibitors of various types was studied: Neftekhim-3, a product of reaction between fatty acids of light tall oil and polyethylepolyamine with dispersed additives; SNPKh-6302 A and B, a mixture of alkylpyridinium bromide of aminoparaffin, fatty acid, and anionogenic surfactant; OR-2K, a mixture of rhodanic benzylquinolinium and still bottoms produced in monoethanolamine purification of natural gas; and Korreksit, a formulation containing imidazolines, oxyalkylated resins, and esters in a hydrocarbon solvent.

Potentiodynamic polarization curves were measured using the standard procedure [36].

On introducing inhibitors KRTs-3G, KRTs-2, Neftekhim-3, and SNPKh-6302, the stationary potential E_{st} is shifted in the negative direction, and the hindrance to the anodic process dominates over that of the cathodic process (Table 2).

In the presence of inhibitors KRTs-2 and KRTs-3G, the maximum shift of E_{st} is observed. The inhibitors in which the hindrance to the anodic process predominates over that to the cathodic process were found to be inefficient (Table 2).

Table 2. Hindrance factors for the corrosion rate (γ_{cor}) and the cathodic (γ_c) and anodic (γ_a) processes occurring on St.3 steel in a two-phase medium 0.1 N NaCl + kerosene (10 : 1), pH 2, saturated with CO_2, in the presence of 1 g l^{-1} of inhibitors

Inhibitor	E_{st}, V	Hindrance factor		
		γ_c	γ_a	γ_{cor}
Fon	–0.24	–	–	–
KRTs-3	–0.26	5.6	1.4	6.3
KRTs-2	–0.27	22	5.0	25
KRTs-8	–0.19	4.0	6.3	3.2
KRTs-3G	–0.26	5.5	1.3	6.4
Neftekhim-3	–0.25	4.4	2.5	5.1
Corexit 7798	–0.20	3.9	5.8	2.9
SNPKh-6302	–0.24	3.8	4.0	3.8
OR-2K	–0.25	4.3	2.9	4.8

It was established that the adsorption of components of the inhibiting formulations KRTs on the steel surface leads to an increase in the slope of the Taffel portion of the cathodic polarization curve to 130–190 mV, which indicates that the cathodic process is hindered. At the optimal, from the standpoint of adsorption, relative contents of components, the strongest increase in b_c was observed. It has been established that the KRTs reagents are inhibitors of the blocking type [35, 36, 45]. Presumably, the reaction between the components of the formulation in the adsorption layer yields molecular compounds forming a protective film that precludes penetration of depolarizers (HCO_3^-, $CO_2 \cdot H_2O$) to the metal surface. In media with pH > 8, the inhibitors of the KRTs series hinder both the cathodic and anodic process, with the hindrance to the former predominating. Inhibitor-bactericide CNPKh-1002, taken as reference, even stimulates the overall corrosion of steel when present in a low concentration. The effect becomes weaker as the concentration of the inhibitor is raised. This confirms the previously established fact that inhibitors of the anodic type are dangerous when present in solution in an insufficient concentration.

The efficiency of inhibitors of the blocking type, Corexit 7798 and Corexit 6350 (manufactured by Nalco-Exxon) was demonstrated by industrial tests in oil and gas fields of Western Siberia, where the carbon dioxide corrosion is predominant (CO_2 in a water–oil emulsion, 200 mg l^{-1}). The corrosion rate was monitored gravimetrically using witness samples and by the electrostatic method on the basis of the polarization resistance in pipe sections suffering from cor-

Table 3. Efficiency of the protective action of inhibitors in a water-oil emulsion of varied composition*

Inhibitor	Concentration, g m^{-3}	Test duration, months (number of shutdowns)	*Z* (%) in an emulsion of indicated composition

* Emulsion composition: (**I**) [CO_2] = 200 mg l^{-1}, mineralization 93 g l^{-1}, pH 6.4 (Samotlor field); (**II**) [CO_2] = 99 mg l^{-1}, [H_2S] = 55 mg l^{-1}, mineralization 78 mg l^{-1}, pH 6.2 (Chutyra field).

** Numerator, determined by gravimetry; denominator, found electrochemically (from the polarization resistance).

rosion to the greatest extent and subject to replacement once in seven months. Both the inhibitors led to a decrease in the corrosion rate and in the number of pipe accidents (Table 3). The electrostatically determined efficiency of the inhibitors was somewhat lower than that furnished by the gravimetric method.

As regards the end result, lowering the number of accidents and making longer the interrepair life of pipes, the most efficient inhibitors are KRTs-3 and KRTs-3G (Table 3). At the same time, when the efficiency of corrosion inhibitors is evaluated gravimetrically on witness samples placed in a flow of a water-oil emulsion, the most efficient was the Norust RA 2D inhibitor, which diminished the pipe accident rate (monitored during a longer time: a year and more) to a lesser extent. These facts indicates that caution is necessary in evaluating the efficiency of inhibitors by a single method.

Thus, the results of industrial tests of oxygen-containing inhibitors of the cathodic type of action (KRTs) in systems for oil gathering and utilization of wastewater and formation water, in pumping oil, gas-lift, and gas-condensate wells with CO_2 concentration in the product in the range from 43 to 230 g m^{-3} revealed the efficiency of these inhibitors both on a relatively clean metal surface and on that covered with a significant amount of carbonate-oxide deposits and demonstrated that development of efficient inhibitors of the carbon dioxide corrosion on the basis of compounds that contain a carbonyl group is possible and shows promise.

CONCLUSIONS

(1) It is shown that the following inhibitors ensure an effective protection from the carbon dioxide corrosion in oil-and-gas production media: organic compounds containing a carboxyl and a carbonyl groups; nitrogen containing neutralizers, both of contact type and volatile; film-forming agents favoring formation of protective siderite films or forming protective films themselves; all with the cathodic type of action.

(2) The choice of the type of an inhibitor of the carbon dioxide corrosion is governed by the pH of the medium, temperature, partial pressure of CO_2 in the system, and initial state of the metal surface [presence or absence of films and(or) deposits on the metal surface, and their type and structure].

Abstract—Catalytic decomposition of cyclohexyl and 1-methylcyclohexyl peroxides in the presence of 3*d*-metal acetylacetonates was studied.

A cyclohexanol–cyclohexanone mixture is commercially produced on a large scale by oxidation of cyclohexane with atmospheric oxygen on a cobalt catalyst [1]. Cyclohexyl hydroperoxide (CHP, ROOH) is formed in the first step of this process. Kinetic features of the oxidation and the composition of the oxidation products are mainly determined by the course of catalytic decomposition of this intermediate. Previously, we have shown that the selectivity of cyclohexanone formation in the presence of chromium-containing catalysts is higher than that in the presence of industrial cobalt-containing catalysts [2].

The oxidation of methylcyclohexane depends on the catalyst present in the system. The reaction yields either a tertiary alcohol (1-methylcyclohexanol) or a mixture of methylcyclohexanols and methylcyclohexanones, formed by reaction of the secondary C–H bonds with oxygen and peroxy radicals [3]. In the latter case, the reaction kinetics and composition of the oxidation products are determined by the course of transformation of tertiary 1-methylcyclohexyl hydroperoxide (MCHP, ROOH) into secondary methylcyclohexyl hydroperoxides.

In this study, we examined the catalytic decomposition of CHP and MCHP in the presence of 3*d*-metal compounds.

As shown previously [4, 5], *s*- and 3*d*-metal carboxylates form with MCHP complexes $ML_n \times m$ROOH (n, m = 1, 2). This is due to the fact that intermolecular hydrogen bonds in the complexes of *s* elements and the coordination bond between 3*d* metals and the α-O atom of hydroperoxide are stronger than the hydrogen bonds in peroxide self-associates. These complexes catalyze decomposition of the hydroperoxide into radicals and molecular products. The catalytic activity of *s*-metal carboxylates [e.g., stearates (St)] in MCHP decomposition decreases with a decrease in the cation radius in the following order: CsSt > $BaSt_2$ > NaSt ~ Na^1_{pel} > $CaSt_2$ > LiSt [6].

EXPERIMENTAL

Cyclohexyl hydroperoxide was prepared via intermediate trialkyl borates [7] at –78°C, which were oxidized with H_2O_2. MCHP was prepared by the procedure described in [8]. The content of the available oxygen in the hydroperoxides was 100%.

3*d*-Metal acetylacetonates were prepared by the procedure described in [9].

Decomposition of CHP and MCHP at 85–105°C in the presence of catalysts listed in Table 1 was studied in decane and methylcyclohexane solutions, respectively. The catalyst concentration ranged from 3×10^{-5} to 3×10^{-4} and from 6×10^{-4} to 8.8×10^{-3} M; and the concentration of hydroperoxides, from 0.01 to 0.1 M. The first concentration range of the catalysts was chosen so as to minimize their association at 85–105°C.

The representative kinetic curves of overall CHP decomposition are shown in Fig. 1. The fast decomposition in the first steps decelerates with time owing to catalyst deactivation. The limiting degrees of CHP decomposition are determined by the nature and con-

[1] Na pelargonate.

* v_r and v_Σ are the rates of radical and overall decomposition, respectively.

** The hydroperoxide decomposition sharply decelerates at the indicated conversion.

centration of the catalyst (Table 1). The dependence of the initial rate of overall CHP decomposition on the catalyst concentration in the range $(0.3–3) \times 10^{-4}$ M is linear, and that on $[ROOH]_0$ tends to level off (Figs. 2a, 2b). This suggests the of intermediate $ML_n \cdot ROOH$ (n = 2–3) is formed:

$$ROOH + ML_n \overset{K_1}{\rightleftarrows} ML_n \cdot ROOH \overset{k_0}{\rightarrow} \text{decomposition products.}$$

The initial rate of hydroxoperoxide decomposition can be described by the following equation:

$$v_0 = \frac{k_0 K_1 [\mathrm{ML}_n]_0 [\mathrm{ROOH}]^{n_1}}{1 + K_1 [\mathrm{ROOH}]}. \quad (1)$$

3*d*-Metal acetylacetonates react with one ROOH molecule [10]. The rate constants of the decomposition and the equilibrium constants of complexation of these catalysts with the hydroxoperoxide were obtained (Fig. 1, Table 2) by graphical solution of Eq. (2) at $n_1 = 1$ in the coordinates $1/v$-vs.-$1/[\mathrm{ROOH}]$ (Fig. 3)

$$1/v_0 = 1/k_0 K_1 [\mathrm{ML}_n][\mathrm{ROOH}] + 1/k_0 [\mathrm{ML}_n]_0. \quad (2)$$

The catalytic activity estimated from the product $k_0 K_1$ increases in the following order: Ni(II) < Cr(III) < Fe(III) < Mn(III) < Cu(II) < Co(III) < Co(II). The complexing power of 3*d*-metal acetylacetonates grows in the series VO(II) ≈ Cr(III) < Mn(III) ≈ Fe(III) < Co(III) < Ni(II) < Cu(II) and correlates with the electronegativity of the metals [10]. Both oxidized and reduced catalyst species are present in the solution in the course of CHP decomposition. The stability of the complexes of the reduced form with most of oxygen-containing ligands increases in the following order [11]: $Mn^{2+} < Fe^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} < Zn^{2+}$.

The hydroperoxide decomposition in the presence of $Cr(CO)_6$, $Cr(acac)_3$ and at certain concentrations of $Ni(acac)_2$ and $Fe(acac)_3$ occurs with an induction period (Fig. 1). This is due to the relatively slow formation of the catalytically active complex at 85–95°C.

The kinetic data obtained at $[\mathrm{ML}_n] = 8.8 \times 10^{-4}$–$8.8 \times 10^{-3}$ M suggest a complex mechanism of the hydroperoxide decomposition. The dependence of the overall reaction rate on [ROOH] and $[\mathrm{ML}_n]$ cannot be adequately described if only the complexation of the initial reagents is taken into account. The fractional reaction orders with respect to [ROOH] and $[\mathrm{ML}_n]$ (Table 2) suggest that the homogeneous complexation of the hydroxoperoxide with the oxidized form of the catalyst and heterogeneous complexation with the reduced form can be accompanied by reactions of the hydroxoperoxide with the solvent. The formation of isomeric decanols supports this assumption. The fractional reaction orders with respect to the catalyst (from 0.14 to 0.865) are probably due to self-association of the catalysts (Table 3). The com-

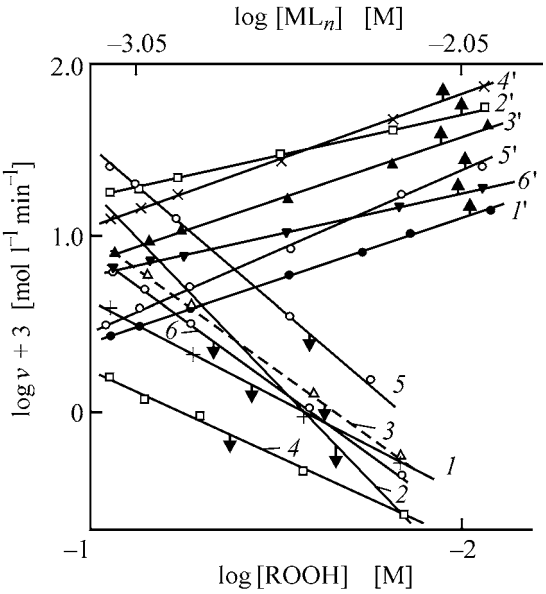

Fig. 4. Rate of overall CHP decomposition v vs. (*1*–6) CHP concentration and (*1*'–6') catalyst concentration, (*1*, *1*') $Fe(acac)_3$, (*2*, *2*') $Co(acac)_2$, (*3*, *3*') $Co(acac)_3$, (*4*, *4*') $Ni(acac)_2$, (*5*, *5*') $Cu(acac)_2$, and (*6*, *6*') $Mn(acac)_3$.

petition of the reaction products (ROH and H_2O) with ROOH for complexation with ML_n makes lower the content of the catalytically active species, thus decelerating the decomposition. The dependences of the rate of overall CHP decomposition on the catalyst concentration and on the initial CHP concentration are linearized in the log–log coordinates (Fig. 4). The overall rate of CHP decomposition in the examined range of the initial CHP and catalyst concentrations is described by the equation

$$v_0 = k_i[\mathrm{ROOH}]_0^{n_{i1}}[\mathrm{ML}_n]_0^{n_{i2}}, \quad (3)$$

where n_{i1} and n_{i2} are the partial reaction orders with respect to the hydroxoperoxide and catalyst, respectively.

The parameters of this equation are listed in Table 3.

The dependence of the activation enthalpy of CHP decomposition on the nature of 3*d*-metal acetylacetonate complexes passes through two extrema, which is characteristic of the stability constants of these complexes. The stability of these complexes depends both on the M(II)/M(III) redox potential and on the number of *d* electrons of the central metal. The dependence of the size of 3*d*-metal cations on the atomic number is not smooth. The dependence of E_{eff} measured in the presence of d^0, d^5, and d^{10} systems having spherical distribution of the electron density is smooth (crystal

* (k_i) Rate constant of overall hydroperoxide decomposition.

field stabilization energy CFSE = 0 [10]). Theoretically, two maxima should be observed in the case of octahedral complexes for d^4 [Cr(III)] and d^9 [Cr(II)] ions. A regular octahedral coordination environment of these ions is impossible. The Jahn–Teller effect results, as a rule, in an underestimation, compared to the experimental values, of the theoretical stabilization energy due to occupation of low-lying *d*-orbitals (CFSE). This is the case when the coordination number of these ions is 4. If the Jahn–Teller stabilization is low and the coordination number is 6, Ni(II) and Cr(III) complexes should be more stable than the Cu(II) and Mn(III) analogs. The enthalpy of complexation of $Cr(acac)_3$ with 1-methylcyclohexane is lower than that of the $Ni(acac)_2$. Since all the acetylacetonate complexes in question are of high-spin type [12], the presence of two maxima in the dependence of E_a on the atomic number of the 3*d* metal indirectly suggests that the CFSE contribution is no less than 5–10% of the total metal–ligand bond energy. Subtraction of the parameter proportional to CFSE from the experimental E_{eff} (taking the *d* configuration of the metal into account) gives a linear dependence of E_a on the number of *d* electrons in the 3*d* metal atom. A similar dependence has been observed for ethylbenzene decomposition [13].

Since the enthalpy of formation of the hydroperoxide–catalyst complex is low (Table 1), E_{eff} characterizes both the decomposition of this complex and other pathways of hydroperoxide decomposition. As determined by NMR spectroscopy, only one hydroperoxide molecule is present in the complexes with 3*d*-metal acetylacetonates. Hydroxoperoxide does not substitute acetlyacetonate ligands in the complexes of Cr(III), Mn(III), Fe(III), and Co(III). In the initial steps of this reaction, only "anisotropic" complexes with intermediate intra-outerspheric coordination of hydroperoxide are formed. The hydroperoxide ligand expands (inflates) the coordination sphere and changes the electronic structure of the catalyst, which affects the reactivity of the catalyst with respect to the substrate. In the case of square planar complexes, the hydroperoxide ligand attacks in the direction normal to the plane of the complex. In the further steps, the acetylacetonate ligand can be substituted by two monodentate or one bidentate ligand. In the case of substitution in $Cu(acac)_2$ and $Co(acac)_2$, octahedral complexes can be formed only after coordination of two ligands.

Catalytic decomposition of CHP and MCHP was studied by UV spectroscopy in the range 240–700 nm. Oxidation of V(III) to V(V) and a partial change in the oxidation state of Co(II), Cr(III), Mn(III), and Cu(II) were observed. Solutions of 3*d*-metal acetylacetonates in ethanol and chloroform absorb in the range 240–400 nm. The absorption bands and the extinction coefficients of these compounds were measured in [14]. The electronic absorption spectra of methylcyclohexane solutions of Mn(II) and Cu(II) stearates and Mn(III), Co(IIII), Cr(III), Cu(II) acetylacetonates have a broad band at 330–350 nm; $Ni(acac)_2$ absorbs at 300 nm; $Fe(acac)_3$ has two bands at 350 and 440 nm. The high-frequency bands in the UV spectra of 3*d* metal acetylacetonates are due to $\pi \rightarrow \pi^*$ transition in the ligand [14]. The weaker band in the visible region (550–700 nm) is assigned to the *d–d* transition in the metal.

The UV spectra of methylcyclohexane solutions of $Co(acac)_2$, $CoSt_2$, $Co(acac)_3$, $Mn(acac)_3$, and $Co(Nf)_3$ (St = stearate and Nf = naphthenate) substantially change upon addition of MCHP. The UV absorption of a $CoSt_2$ solution in methylcyclohexane, initially characterized by a weak band with λ_{max} = 275 nm, substantially increases upon addition of hydroxoperoxide. The spectrum of the mixture is a monotonically decreasing curve with an inflection at 330 nm. This long-wavelength band is due to a charge transfer from the metal to hydroperoxide ligand in the donor–acceptor complex. This pattern cannot be attributed to oxidation of Co(II) in the presence of the hydroperoxide, since Co(III) absorbs in the long-wavelength range. Uncoordinated MCHP has a weak band at 260 nm, which is not overlapped with the spectrum of the complex.

When cobalt(II) acetylacetonate is added to an MCHP solution, a strong band of the $Co(acac)_2$–MHCHP complex appears. The solution color changes from pink [Co(II)] to green [Co(III)]. The *d–d* transition band appears in the visible range. The electronic absorption spectra of reactions mixtures of $Mn(acac)_3$, $Co(acac)_3$, and Co(Nf)3 with the hydroxoperoxide contain the bands of the donor–acceptor complexes of the catalysts with the hydroxoperoxide. Clearly, both the oxidized and reduced forms of the catalyst form these complexes. It should be noted that the band of $Mn(acac)_3$–ROOH complex is weaker than that of free $Mn(acac)_3$, whereas the bands of the complexes $CoSt_2$–ROOH, $Co(acac)_2$–ROOH, $Co(acac)_3$–ROOH, and $Co(Nf)_3$–ROOH are stronger than those of the initial salts. The color of solutions of $Co(acac)_3$ and $Co(Nf)_3$ changes after mixing with the hydroxoperoxide, which suggests the occurrence of the Co(III) $\rightleftarrows$ Co(II) equilibrium. In the spectrum recorded immediately after reagent mixing, the band of free acetylacetone (275 nm) is absent. This band appears in the course of the reaction.

The coordination sphere of Co in anisotropic complexes [$(Co(acac)_3 \cdot ROOH$, $Co(Nf)_3 \cdot ROOH$] rear-

ranges owing to a change in the oxidation state of the central metal in the course of the reaction. The hydroxoperoxide can be coordinated to both Co(II) and Co(III).

It is known that 3*d*-metal stearates are associated in hydrocarbon solvents [15]. We recorded IR spectra of *s*- and 3*d*-metal acetates, stearates, and acetylacetonates in decane. The upper concentration limit of the analyzed solutions was determined by the solubility of these compounds in decane at 25°C. It was possible to obtain 10^{-3} M solutions of all the catalysts examined. The spectra of $CoSt_2$, $CuSt_2$, $Cu(acac)_2$, $VO(acac)_2$, $Zn(acac)_2$ and $Ni(acac)_2$ solutions contained only the bands on nonassociated species (1700–1710 cm^{-1}). In the spectra of 10^{-3} M solutions of $Co(acac)_2$, $Co(acac)_3$, $Mg(acac)_2$, $Fe(acac)_3$, $Cr(acac)_3$, and $Mn(acac)_3$ in decane, the band of associated species (1580 cm^{-1}) are observed along with the bands of the monomeric complexes (1705 cm^{-1}). Addition of ROOH, which exhibits surfactant properties increases the solubility of the catalysts. However, both monomeric and associated complexes are present in 8.8×10^{-4}–8.8×10^{-3} M solutions of acetylacetonates in decane and methylcyclohexane containing CHP and MCHP. The fractional reaction orders with respect to catalysts in CHP decomposition (Table 3) are apparently caused by partial association of the catalysts.

The yield of free radicals released into the bulk of the solution upon homolytic rupture of O–O bonds in the course of thermolysis of CHP at 150°C was found [16] to be 12%. In the presence of chromium-containing catalysts, this yield is 8.3–27.0%. Chromium-containing compounds catalyze the conversion of CHP into cyclohexanone. The solvent is involved in the radical decomposition (isomeric decanols were detected in the reaction mixture). The oxidation state of the central metal atom (Co, Mn, V, Cr, and Cu) changes alternately in the course of reaction with the hydroperoxide. The reaction rate is determined by the difference between the energies of the oxidized and reduced metal species. The heaviest metals of the 3*d* series have a single stable oxidation state [Co(III), Cu(II), Ni(II)]. Hence, the catalytic cycle requires a higher activation enthalpy with an increase in the atomic number of the central metal atom [17]. This assumption was confirmed experimentally. As the electronegativity of metals increases, the stability of their complexes grows.

CONCLUSIONS

(1) The complexing power of 3*d*-metal acetylacetonates with respect to cyclohexyl hydroperoxide correlates with the metal electronegativity and increases in the order: VO(II) ≈ Cr(III) < Mn(III) ≈ Fe(III) < Co(III) < Ni(II) < Cu(II). The activation energy of hydroperoxide decomposition increases in the same order.

(2) Kinetic parameters of cyclohexyl hydroperoxide decomposition (overall rate constants, reaction orders with respect to the hydroperoxide and catalyst) via formation of intermediate complexes with 3*d*-metal acetylacetonates were determined at the catalyst concentration ranging from 8.8×10^{-4} to 8.8×10^{-3} M.

(3) Cyclohexyl hydroxoperoxide decomposition is a homogeneous reaction proceeding by radical and molecular pathways to form not only $ML_n \cdot ROOH$ intermediate at low concentrations of nonassociated catalysts, but also associated and partially heterogeneous catalytic species.

(4) *s*- and 3*d*-Metal carboxylates form $ML_n \times m$ROOH (m = 1, 2) complexes with 1-methylcyclohexyl hydroperoxide, which is due to the fact that the intermolecular hydrogen bonds (*s* metals) and bonds of the metal with α-oxygen atom of hydroperoxide (3*d* metals) are stronger than the hydrogen bonds in associated hydroperoxides. The formation of these complexes catalyzes decomposition of tertiary hydroperoxide into radicals and molecular products.

CATALYSIS

Features of Claus Treatment of Acid Gases with Low Content of Hydrogen Sulfide

O. I. Platonov, A. G. Ryabko, and L. Sh. Tsemekhman

Gipronikel Institute Joint-Stock Company, St. Petersburg, Russia

Received April 5, 2004

Abstract—Changes in the activity of industrial alumina catalysts CR-31 and AO-MK-2, which occur under the real industrial conditions in the last catalytic stage of the Claus process in the coke-oven gas treatment shop of the Magnitogorsk Metallurgical Plant, are analyzed.

More than 30 million tons of sulfur is produced in the world in the course of treatment of natural gas and petroleum products by the procedure described in [1]. This procedure involves partial oxidation of hydrogen sulfide with subsequent catalytic conversion of the reduction products by the Claus reaction:

$$2H_2S + SO_2 = 2H_2O + 3/nS_n, \quad n = 1–8. \quad (1)$$

The known and newly developed procedures for utilization of metallurgical off-gases from melting of sulfide raw materials to obtain elemental sulfur [2] also involve treatment of the products of sulfur dioxide reduction by the Claus procedure (1). Since the efficiency of the multistage Claus treatment is determined by the residual concentrations of sulfur-containing components in the tail gases, optimization of the operation parameters in the last catalytic stage of industrial Claus installations is a problem of current interest.

In this study, we analyzed changes in the activity of alumina catalysts CR-31 (La Roche Chemicals) and AO-MK-2 [GRES-24 (State Regional Power Station)] in a two-sectional Claus reactor at the coke-oven gas treatment shop of the Magnitogorsk Metallurgical Plant (MMP) [3].

The gas treated at 230–270°C contained, vol %: 1.15 ± 0.33 H_2S, 0.47 ± 1.6 SO_2, 0.51 ± 0.08 COS, 4.6 ± 0.8 CO, 26.6 ± 3.3 CO_2, 3.6 ± 1.1 H_2, 62.5 ± 3.5 N_2, elemental sulfur (10–30 g m^{-3}), and water (120 g m^{-3}), which corresponds to the typical gas composition in the last catalytic stage of the Claus process.

The catalyst activity was evaluated from the conversion η_i (where i is the component index) of the main sulfur-containing products (H_2S, COS, and SO_2), using the chromatographic method. For this purpose, the volume concentrations of N_2, O_2, H_2, CH_4, CO_2, CO, H_2S, COS, and SO_2 were determined [4] in dried samples of the process gas at the inlet and outlet of certain stages of the Claus reactor, which were synchronized with an accuracy of 2–5 min by the sampling procedure. For example, the conversion of H_2S was calculated from the initial ($c_0 \equiv [H_2S])_{in}$) and final ($c \equiv [H_2S]_{out}$) concentrations in the process gas at the inlet and outlet of given stage of the Claus reactor as follows

$$\eta_{H_2S} = 1 - [H_2S]_{out}[N_2]_{in}/([H_2S]_{in}[N_2]_{out}) = \{[N_2]_{in} \approx [N_2]_{out}\} \approx 1 - c/c_0. \quad (2)$$

Measurements were carried out twice a day at a 2–3-h interval for the available gas of variable composition [3], which ensured independence of the resulting η_i values.

To reveal the factors of activity and the effects of aging and regeneration, the dynamics of the catalyst activity was studied separately for hydrogen sulfide and carbonyl sulfide. In this case, the conversion η_i for each component was determined as its daily mean value found by averaging two pairs of η_i values, i.e., from four paired measurements timed with an accuracy of no less than ±1.5 h. To determine the general dependences $\eta_i = \eta_i(\tau)$, the experimental η_i values were additionally averaged over the nearest points, which is equivalent to digital filtration [5].

The experimental dependence of the conversion of the sulfur-containing components in the course of treatment, plotted using the daily conversion values η_{H_2S} and η_{COS} recorded during 3 years of operation of the CR-31 catalyst in the first stage of the Claus re-

1070-4272/04/7708-1308 © 2004 MAIK "Nauka/Interperiodica"

actor, are shown in Fig. 1 (points). The corresponding empirical dependences η_i–τ calculated by averaging nine nearest η_i values are represented by curves. Although the first two η_{COS} values are absent[1] in Fig. 1, the generally monotonic empirical dependence of η_{COS} on time τ strongly suggests that the carbonyl sulfide conversion η_{COS} at the beginning of the CR-31 catalyst operation tends to 100%.

As can be seen from Fig. 1, the conversion of hydrogen sulfide on a fresh CR-31 catalyst under given operation conditions (space velocity $W \sim 1000$ h^{-1} and average temperature $T \sim 250.5$°C) is characterized by significant negative values ($\eta_{H_2S} \to -40$ rel %), which suggests generation of H_2S in the initial period of CR-31 catalyst operation. With time, the conversion of H_2S increases and reaches $\eta_{H_2S} = 40-45$% by the second month of operation, and then it gradually decreases to approximately 30% in the subsequent two years (Fig. 1). It should be noted that the current deviations of the empirical daily values of η_{H_2S} and η_{COS} from the general dependences η_{H_2S}–τ and η_{COS}–τ (due to changes in the temperature and composition of the process gas) correlate in antiphase.

The revealed $\eta_{H_2S} = f(\tau)$ and $\eta_{COS} = f(\tau)$ dependences were verified in industrial tests of the AO-MK-2 alumina catalyst supplied by GRES-24 (Mosenergo Joint-Stock Company, Moscow, Russia). For this purpose, 12 m^3 of the CR-31 catalyst after ~2.5 year operation in the first section of the Claus reactor were replaced with 5 t (~7 m^3) of AO-MK-2 catalyst, and its activity characteristics were studied by the procedure given above.

The variation of the conversion of hydrogen sulfide (η_{H_2S}) and carbonyl sulfide (η_{COS}) and of the total conversion η_S during nearly one year of operation of the AO-MK-2 catalyst in the first stage of the Claus reactor is shown in Fig. 2. Since the first values were recorded on heating the reactor to the temperature of the catalyst bed of 189°C, which is lower by 50°C than the working temperature, the conversion η_{COS} is underestimated, whereas η_{H_2S} and η_S are overestimated relative to the values typical of the fresh catalyst.

The empirical dependence of the carbonyl sulfide conversion h_{COS} on AOMK-2 catalyst is qualitatively similar to the kinetic dependence $\eta_{COS} = f(\tau)$ found previously; it gradually decreases in first 6–7 months of operation from the initial $\eta_{COS}(0) = 98$% to minimal $\eta_{COS}(0.3) \sim 40-45$% (Fig. 2). At the same time, the conversion of hydrogen sulfide [$\eta_{H_2S} = f(\tau)$] and the total conversion of sulfur-containing gases [$\eta_S = f(\tau)$] monotonically increase (to a first approximation) up to the maximal values at $\tau = 0.05$ year ($\eta_{H_2S\,max} \sim 60$ and $\eta_{S\,max} \geq 50$ rel %) and then decrease to $\eta_{H_2S\,min} \sim 30$ and $\eta_{S\,min} \sim 40$ rel %, respectively.

The experiment on regeneration of the AO-MK-2 catalyst after 7-month operation consisted in heating of the catalyst bed in the first stage of the Claus reac-

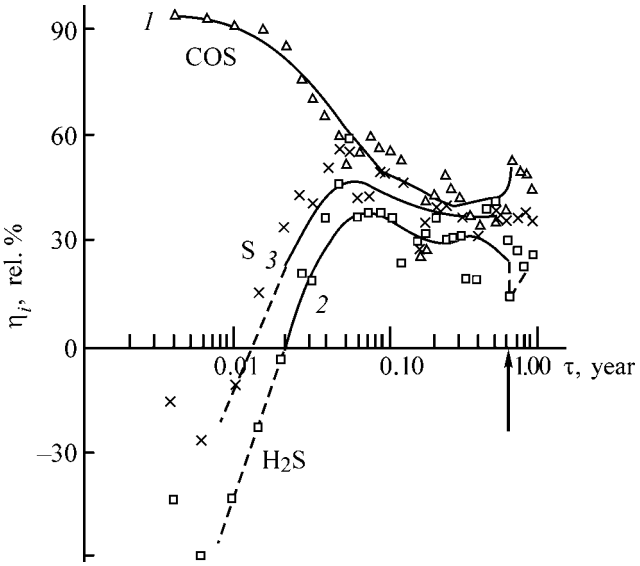

Fig. 2. Conversion η_i of (*1*) carbonyl sulfide, (*2*) hydrogen sulfide, and (*3*) sulfur-containing gases on AO-MK-2 alumina catalyst vs. the operation time (year). Space velocity 2000 h^{-1} and temperature 253 ± 6°C.

[1] Due to the delay in calibration with respect to COS, the content of carbonyl sulfide at the new MMP Claus line put in operation on September 1, 2000 was not recorded till August 4, 2000.

tor to 300°C, which was performed using the in-line bypass of a primary boiler-utilizer without interruption of the line operation and changes in the operation schedule of hydrogen sulfide oxidation in the Claus reactor. As can be seen from Fig. 2, the conversion of carbonyl sulfide η_{COS} first increased at the beginning of the catalyst regeneration (marked by an arrow in Fig. 2) from 39 to 53% and then monotonically decreased; and vice versa, the conversion of hydrogen sulfide η_{H_2S} first sharply decreased and then increased to the initial value.

The qualitative similarity of the dynamic dependences $\eta_{COS} = f(\tau)$, and $\eta_{H_2S} = f(\tau)$ found for different catalysts and space velocities differing by a factor of 2 (Figs. 1 and 2), suggests that the features of conversion of the "depleted" gases (with low content of hydrogen sulfide) on alumina catalysts are similar. Fresh industrial alumina catalysts are characterized by high negative conversion (i.e., generation) of H_2S at a complete (up to 98 rel %) consumption of COS. After the beginning of operation, the COS conversion decreases, whereas the observed conversion of H_2S increases, reaches a maximum in several weeks, and then monotonically decreases with the catalyst aging. The opposite trends are observed in the conversion of H_2S and COS at varying catalyst activity: with an increase in the COS conversion, the conversion of H_2S decreases, and *vice versa*.

Using the Tekhnolog program [6], we performed a thermodynamic analysis of the acid gas of given composition at 250°C and found that the equilibrium concentrations of the gas components ($[H_2S]^{eq}$ = 3.07, $[COS]^{eq}$ = 0.005, $[H_2O]^{eq}$ = 9.6, $[H_2]^{eq}$ = 4.6, $[CO]^{eq}$ = 0.15, $[CO_2]^{eq}$ = 27.6, and $[S]^{eq} \approx 0.0001$ vol %) correspond to a negative conversion of hydrogen sulfide, $\eta_{H_2S}^{eq}$ = –233%, at nearly complete consumption of COS (η_{COS}^{eq} = 99.3%). Thus, the equilibrium conversion of depleted gas is characterized by hydrogen sulfide generation, which is accompanied by hydrolysis and hydrogenation of elemental sulfur and carbonyl sulfide, described by the following reactions

$$2COS + SO_2 = 2CO_2 + 3/nS_n \quad (n = 1–8), \quad (3.1)$$

$$COS + H_2O = H_2S + CO_2, \quad (3.2)$$

$$1/nS_n + H_2 = H_2S. \quad (3.3)$$

The formation of H_2S by reactions (3.2) and (3.3) is opposite to its conversion by the Claus reaction (1). Therefore, the resulting process can be described as a competition of reactions (1) and (3). In this case, negative conversion of hydrogen sulfide on fresh alumina catalysts is thermodynamically expectable. With the catalyst activity decreasing in the course of operation, the conversion of carbonyl sulfide also decreases (Figs. 1 and 2), which, in turn, causes deceleration of the slow hydrolysis reactions (3.2), and, in the course of time, the conversion of hydrogen sulfide by reaction (1) becomes predominant.

Similarly, the effects of nonmonotonic changes (fluctuations) in the catalyst activity under various operation conditions on the conversion of H_2S and COS are also different. For example, a sharp decrease in the activity of the CR-31 catalyst due to its overheating ($T > 500$°C) at the end of the second year of operation was accompanied by a strong decrease in the COS conversion, whereas the hydrogen sulfide conversion increased (Fig. 1).

Along with the hydrolysis of COS and/or elemental sulfur by reaction (3.2), hydrolysis of carbon sulfide is also observed:

$$CS_2 + 2H_2O = 2H_2S + CO_2, \quad (4)$$

providing an increase in the hydrogen sulfide concentration in the initial period of operation of a fresh catalyst.

Our experimental data suggest that the difference between the $\eta_{H_2S} = f(\tau)$ and $\eta_{COS} = f(\tau)$ dependences is due to the difference in the mechanisms of H_2S and COS conversion on the active surface and at the active centers of the catalyst.

The deceleration of hydrolysis and hydrogenation on alumina catalysts can probably account for the increase in the equilibrium yield of elemental sulfur in the course of the Claus conversion [1].

The results of industrial tests show that the conversion of sulfur-containing components of depleted gas is due to the hydrolysis and hydrogenation, causing negative conversion of H_2S with complete consumption of COS at the start of operation of a fresh alumina catalyst. Since the conversion of H_2S in depleted gases on industrial alumina catalysts is provided at the expense of deceleration of carbonyl sulfide hydrolysis, it is necessary to reliably determine the kinetic mode of the catalyst operation in the last stage of the Claus treatment of acid gases.

Our results show that the use of similar-type (even highly active) catalysts in different stages of the Claus process is inefficient. The high total activity of the catalyst bed, frequently determined from the content of products formed in hydrolysis of sulfur-containing

organic compounds (COS, CS_2) [7], in the last conversion stage does not ensure a low residual content of hydrogen sulfide in the tail gases. As we know, this obvious conclusion is frequently ignored in designing and running Claus process lines.

CONCLUSION

Based on experimental data, the thermodynamic principles of treatment of depleted acid gases are refined and ways to optimize kinetic modes of the catalyst operation in the last treatment stage are suggested.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Removal of Ni(II) with Sodium Ferrate(VI) from EDTA-containing Aqueous Solutions

D. Yu. Stupin and M. I. Ozernoi

St. Petersburg State Agricultural University, St. Petersburg, Russia

Received April 26, 2004

Abstract—A procedure was developed for removal of Ni(II) from EDTA-containing aqueous solutions with sodium ferrate(VI) Na_4FeO_5.

Any treatment procedure to remove heavy metal ions from wastewater involves precipitation and coagulation [i.e., addition of Fe(II), Fe(III), or Al(III) salts] at a given pH, with the subsequent removal of hydroxide precipitates. However, precipitation is hindered by complexation of heavy metal ions with organic ligands. This process is frequently used in separation of metal ions by extraction or ion exchange, in metal electroplating, in cleaning of metal surfaces, in antiscale treatment, etc. The resulting complexes can be decomposed with strong oxidants.

For this purpose, alkali metal ferrates(VI) are rather promising. The ferrate ion FeO_4^{2-} acts as an oxidant and coagulant, and no harmful by-products are formed in its reduction to Fe(III) oxides and hydroxides [1]. Its coagulation efficiency is greater as compared with the most widely used inorganic coagulants, such as Fe(II), Fe(III), and Al(III) salts [2].

Ferrates efficiently remove heavy metals from natural and waste water [2–6]. However, such a treatment is occasionally inefficient in the presence of some complexing agents. For example, the results of treatment of a low-level wastewater containing Am and Pu and complexing agents that form chelates with these radionuclides were unsatisfactory. These chelating agents were ethanolamine, 2-butoxyethanol, Triton X100, and of dipropylene glycol methyl ether. As the amount of potassium ferrate added was raised, the degree of radionuclide removal increased to some constant value (about 40%); i.e., removal of radionuclides was incomplete. Moreover, a similar removal of radionuclides from solutions was found upon addition of Fe^{3+} ions to the solutions at the same pH. Obviously, ferrate ions act under given experimental conditions as only a source of iron hydroxide $Fe(OH)_3$ without any oxidizing effect [Fe(VI) → Fe(III)].

In this case, apparently, the rate of water oxidation (decomposition of ferrate ions) strongly exceeds the oxidation rate of chelating ligands. As in the case of the other oxidants, this is probably due to a sharp decrease in the redox potential of the ferrate ion in alkaline medium under the experimental conditions studied (pH 7.2–10.0). At pH < 5, the oxidation rate of ferrate ions should be extremely high.

It is known that Fe(VI) is reduced to Fe(III) step-by-step via short-lived Fe(IV) and Fe(V), which are also rather strong oxidants [7, 8].

Only ozone is a stronger oxidant than the ferrate ion FeO_4^{2-}. Its redox potential depends on pH and varies from 2.07 (pH 0) to 0.9 (alkaline medium) [9]. The stability of ferrate ions is also determined by pH and grows with increasing pH to a maximum at pH ~ 10. At pH < 7, ferrate ions are unstable and are involved in water oxidation with liberation of oxygen. In most cases, Fe(VI) was studied in the form of potassium ferrate K_2FeO_4.

In this study, we used specially prepared sodium ferrate Na_4FeO_5. Upon dissolution in water, the FeO_5^{4-} ion apparently immediately transforms into FeO_4^{2-}; as a result, the absorption spectra of purple potassium and sodium ferrate solutions are identical and exhibit absorption bands at ~515 and ~318 nm, respectively.

EXPERIMENTAL

We used analytically pure reagents. Sodium ferrate(VI) was prepared by the solid-phase reaction $Fe_2O_3 + Na_2O_2$ in an oxygen flow [10]. An X-ray diffraction (XRD) analysis of 20 samples prepared showed the set of reflections similar to those found for Na_4FeO_5 [10]. No additional reflections belong-

1070-4272/04/7708–1312 © 2004 MAIK "Nauka/Interperiodica"

ing to the initial compounds (Fe_2O_3 and Na_2O_2), ferrate(IV), ferrate(III), and Na_2CO_3, which can be formed in the presence of air, were observed. Since the sensitivity of the conventional XRD analysis is about 5%, we believe that the content of Fe(VI) in the sample was no less than 95%.

The reference $[NiEDTA]^{2-}$ solution with pH 3.9 and 2×10^{-4} M concentration was prepared by mixing the corresponding amounts of 0.1 M $Ni(NO_3)_2$ and 0.01 M Na_2EDTA solutions. This reference solution (50 ml) was poured into a three-electrode Teflon cell with a glass electrode for pH measurements of the buffer solutions, a standard reference electrode, and a platinum working electrode for redox measurements. The required amount of iron ions was added to the sample with constant stirring either as a weighed portion of powdered sodium ferrate(VI) or as an aliquot of 0.1 M $Fe(NO_3)_3$ solution. Since the breakdown of Na_4FeO_5 in water with liberation of oxygen is accompanied by the formation of NaOH [pH ~ 12 upon dissolution of a 20–mg portion of sodium ferrate in water (20 ml)], its required amount (30–220 mg) was added in small portions (5–10 mg), and the required solution pH was adjusted using 1 M HNO_3. After the breakdown of ferrate ions in solution, the pH was brought to 6–8 by adding crystalline Na_2CO_3 to provide the optimal conditions for precipitation of Fe(III) compounds. The resulting flakes of iron(III) oxides and hydroxides were allowed to precipitate for 1 h, after which a 5-ml portion of the solution in equilibrium with the precipitate was sampled and filtered through a "blue ribbon" filter.

The residual content of nickel(II) in the solution was determined by measuring its X-ray fluorescence with a spectrophotometer recording the energy dispersion with an accuracy of 210 eV (Mn $K_{\alpha 1}$ line). The sample for X-ray fluorescence measurements was prepared as follows. The sample was evaporated to 0.5 ml, and the residue was placed on a porous disc of chromatographic cardboard (8 mm in diameter) and dried at 343–353 K. The X-ray fluorescence spectrum of nickel(II) was excited by primary gamma-radiation (^{109}Cd source). The content of Ni(II) in the calibration samples was varied within 2–100 μg. The peak area ($K_{\alpha 1}$) was a linear function of the nickel(II) content (μg); the analysis accuracy was ±5%.

In some experiments, we added to the initial sample of the reference $[NiEDTA]^{2-}$ solution before addition of sodium ferrate one of the reagents NaCl, HCl, K_2SO_4, or H_2O_2 + HCl mixture to the 10^{-4}–10^{-2} M concentration in order to study the possibility of promoting the EDTA oxidation.

In the experiments with Fe(III) coagulant, the required amount of 0.1 M solution of $Fe(NO_3)_3$ was added to the solution, the solution pH was adjusted to 1.5 (1 M HNO_3), and the resulting solution was allowed to stand for 20 min; then Na_2CO_3 was added in order to precipitate metal hydroxides. Further procedure of preparation of the solution sample over the precipitate for X-ray fluorescence analysis was similar to those given above.

The data on the effect of Fe(III) and Fe(VI) coagulants on aqueous solutions of $[NiEDTA]^{2-}$ are listed in the table.

Since the difference in the molecular weights of Na_4FeO_5 and $Fe(NO_3)_3$ is relatively small (227.85 and 241.85, respectively), similar portions of these salts contain similar amounts of Fe(III). Our results showed that, with decreasing solution pH, the degree of Ni(II) removal increases simultaneously with an increase in the redox potential of the solution. Upon addition of sodium ferrate (40–50 mg), the removal of nickel(II) changed from 5 at pH 5 to 50–55% at pH 2. The sulfate ions did not affect the removal of nickel from the sample.

However, on replacing HNO_3 with HCl or on adding NaCl to the sample acidified with HNO_3 to pH ~ 2, the degree of Ni(II) removal sharply increased up to 85% at 65-mg portion of sodium ferrate. At pH < 4.5, water immediately decomposed Fe(VI) and chloride ions occurring in solution were partially oxidized to free chlorine Cl_2; the decrease in the Cl^- ions concentration was recorded with a silver chloride electrode. It is apparent that rapid reduction of Fe(VI) in solution yields highly reactive species, which are then involved in oxidation of chloride ions and EDTA.

It should be noted that the complexes of *d* elements with EDTA are very strong, and one of the strongest complexes is $[NiEDTA]^{2-}$. Just in this connection, we studied the possibility of its breakdown with ferrate ions. The reduction of $Fe^{VI}O_4^{2-}$ in aqueous solution to Fe(III) hydroxo compounds occurs via formation of short-lived $Fe^{V}O_4^{3-}$ and $Fe^{IV}O_4^{4-}$ species, which are highly aggressive oxidants. Sharma *et al.* [8] studied the oxidation of CN^- ions with potassium ferrate(VI) in alkaline solutions and found that the rate of this oxidation with Fe(V) and Fe(IV) species is greater by four and two orders of magnitude, respectively, as compared to Fe(VI).

Thus, Cl^- ions are probably also oxidized by ferrate(VI) ions via intermediate species, which oxidize EDTA and cause liberation of gaseous Cl_2 even at a concentration of chloride ions smaller than 10^{-3} M at

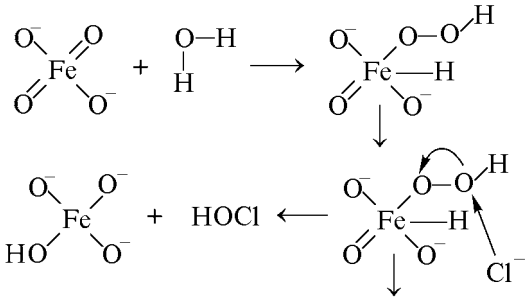
pH ~ 2. The formation of $Fe^{IV}O_4^{4-}$ and hypochlorous acid can proceed by the following scheme.



These reactions are similar to the scheme of formation of $Fe^{IV}O_4^{4-}$ and H_2O_2, suggested in [7]. The other oxidants probably are involved in further processes, including HClO reduction to Cl_2.

The liberation of Cl_2 from the sample was monitored by decrease in the chloride ion concentration. The redox potential observed in a series of solutions (see table) was the highest (+780 mV) in the sample with the concentration of chloride ions of 10^{-2} M. Just in this case the removal of nickel(II) from the sample was the most efficient (85%) upon addition of an "average" (65 mg) weighed portion of sodium ferrate. Separate series of experiments were performed to study the oxidation of Cl^- ions.

Aliquots of a 10^{-3} M NaCl solution were acidified with 1 M HNO_3 to attain the pH values from 1.5 to 4.0. Sodium ferrate Na_4FeO_5 (27–40 mg) was added in small portions to the sample; the solution pH was maintained constant by adding 0.1 M HNO_3. After complete decomposition of Fe(VI), the solution pH was brought to 5–7 by introducing crystalline Na_2CO_3. The concentration of the residual chloride ions was determined with a selective chloride electrode. Under the given experimental conditions, the maximum removal of chloride ions (about 80%) was observed at

pH ~ 2; the analysis accuracy was ±20%. These results and the data listed in the table indicate that the optimal conditions for removing Ni(II) from aqueous solutions containing EDTA are as follows: pH 1.5–2.0 and 100 mg of sodium ferrate per 50 ml. In the presence of 10^{-2} M chloride ions, the removal of Ni(II) becomes more efficient.

In aqueous solutions containing EDTA and metal ions, the degree of their complexation depends on pH. At pH 10, EDTA is completely ionized and, if $c_{Ni^{2+}} = c_{EDTA} = 1 \times 10^{-4}$ M, the NiY^{2-} complex is formed in a concentration of 1×10^{-4} M. With decreasing pH, other EDTA species are formed, namely HY^{3-}, H_2Y^{2-}, H_3Y^{-}, and H_4Y, and, as a result, NiY^{2-} decomposes partially or completely with liberation of Ni^{2+} ions. Calculations based on the stability constant of Ni(II) complex with EDTA ($K_{EDTA} = 4.2 \times 10^{18}$) and the fraction of nondissociated EDTA at a given pH [11] showed that, at pH 2 or 1.5, 22.4 or 82.5% of nickel, respectively, occurs in solution as Ni^{2+} ions. As a result, a certain fraction of nondissociated EDTA (H_4Y) is oxidized under the above optimal conditions for ferrate(VI) reduction at pH < 2. Mediators (chloride ions) promote the oxidation and the amount of ferrate ions to be added can be decreased [removal of Ni(II) is complete upon addition of 100 mg of Na_4FeO_5 per 50 ml of solution]. Addition of $Fe(NO_3)_3$ coagulant did not provide any quantitative removal of nickel(II); even when the portion of Fe(III) was greater than that of Fe(VI) by a factor of 2.5 (other conditions being equal), only 77% of Ni(II) was removed.

CONCLUSION

Complete breakdown of the $[NiEDTA]^{2-}$ complex [~5 mg Ni(II) per liter] with the subsequent removal of Ni(II) from aqueous solution is ensured by treatment of the initial solution with sodium ferrate(VI): 2 g l^{-1} at pH ~ 2. Chloride ions added to the solution decrease the required amount of sodium ferrate.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Corrosion-Protective Properties of Acetylenic Esters of Bicyclo[2.2.1]hept-5-ene-2-carboxylic Acid

E. G. Mamedov

Institute of Petrochemical Processes, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

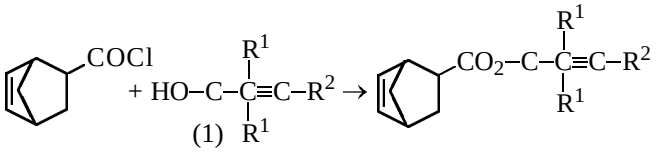
Received March 5, 2004

Abstract—A procedure was developed for preparing acetylenic esters of bicyclo[2.2.1]hept-5-ene-2-carboxylic acid. The structures of the compounds were confirmed by IR and ^{1}H NMR spectroscopy. The Kovats indices of the compounds were determined, and their boiling points were estimated by gas–liquid chromatography. The protective properties of the esters against acid corrosion of steel were studied.

Norbornene derivatives exhibit various useful properties. Thanks to their rigid framework structure, these compounds with fixed substituents are promising models for studying structure–property relationships [1]. Some norbornene derivatives exhibit analgetic, antiseptic, and antiphlogistic properties [2, 3]. Of particular interest are acetylenic esters of norbornenecarboxylic acid. On the one hand, they have valuable properties themselves; on the other hand, they are promising as synthetic precursors of diverse valuable compounds owing to the combination of reactive norbornene and acetylenic fragments [4].

The synthesis of propargyl norbornenecarboxylate by esterification of norbornenecarboxylic acid with propargyl alcohol in the presence of Brønsted acid catalysts was described in [5]. However, the yield (30%) and purity (88%) of the target product were poor.

Proceeding with studies concerned with synthesis of acetylenic esters of norbornenecarboxylic acids [6–8], we developed a convenient synthetic route to these compounds and examined their protective properties against acid corrosion of metals. The compounds were prepared by reactions of bicyclo[2.2.1]hept-5-ene-2-carboxylic acid chloride **I** with acetylenic alcohols **II**–**IV**:



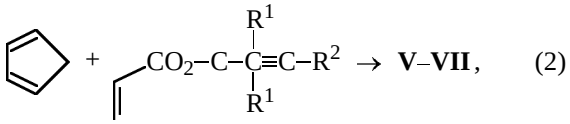
(1)

I **II**–**IV** **V**–**VII**

where $R^1 = R^2 = H$ (**II**, **V**); $R^1 = Me$, $R^2 = H$ (**III**, **VI**); $R^1 = Me$, $R^2 = CH{=}CH_2$ (**IV**, **VII**).

The reaction with primary alcohol **II** occurs at room temperature with heat liberation and is complete in 0.5 h. With tertiary alcohols **III** and **IV**, the reaction is less facile, and the corresponding esters **VI** and **VII** were obtained by heating at 80°C for 5 h. The yield of the target products was 90–96%.

The structure of esters **V**–**VII** was confirmed by independent synthesis. First, we prepared acetylenic acrylates **IX**–**XI** by a reaction of acryloyl chloride with acetylenic alcohols **II**–**IV**. This was followed by the Diels–Alder addition of cyclopentadiene **VII** to acrylates **IX**–**XI** to obtain compounds **V**–**VII**:



(2)

VIII **IX**–**XI**

where $R^1 = R^2 = H$ (**IX**); $R^1 = Me$, $R^2 = H$ (**X**); $R^1 = Me$, $R^2 = CH{=}CH_2$ (**XI**).

The constants of compounds **IV**–**VII** prepared by both procedures are identical; they are listed in Table 1. The compositions and structures of the compounds were also confirmed by elemental analysis and by IR (Table 1) and ^{1}H NMR spectroscopy.

The IR spectra of **V**–**VII** contain the stretching vibration bands (cm^{-1}) of C=O (1730–1740), C–O (1225–1240) and C≡C (2160–2165) groups. The band at 3290 cm^{-1} in the spectrum of **V** is characteristic of the ≡C–H bond. The stereoisomers of **V** and **VII** have similar IR spectra, with the absorption bands of the double bond in the norbornene moiety at 1580–1555 [ν(C=C)] and 730–710 [δ(=C–H)] cm^{-1}. The unusual

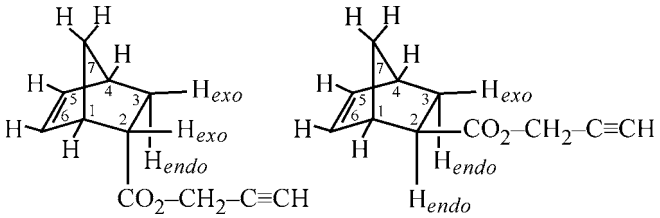
position of the first band may be due to the strained state of the ethylene bond in the bicyclo[2.2.1]heptene moiety [9]. The position of the δ(=C–H) band depends on the orientation of the substituent in the carbon skeleton of **V** (705–700 and 735–720 cm^{-1} for *exo* and *endo* isomers, respectively).

In the ^{1}H NMR spectra, the major differences between stereoisomeric propargyl esters of bicyclo-[2.2.1]hept-5-ene-2-carboxylic acid consist in the positions of the signals of the protons at the C^2, C^5, and C^6 atoms.



The olefinic protons (at C^5, C^6) in the *endo* isomer of **V** are nonequivalent because of the steric proximity of the substituent situated in the rear part of the bicyclic core. Therefore, these protons give relatively widely separated signals: at 6.12 (5-H) and 6.24 (6-H) ppm. The 5-H and 6-H protons in the *exo* isomer of **V**, more weakly influenced by the remote substituent, give closely situated signals. The 2-H proton in *exo*-**V** has an *endo* orientation and gives a signal at 2.97 ppm, whereas the 2-H proton in *endo*-**V** has an *exo* orientation and gives a multiplet at 2.17 ppm.

The coupling constants are as follows (Hz): *endo*-**V**, $^3J_{5,6}$ = 5.62, $^3J_{1,6}$ = 3.66, $^3J_{4,5}$ = 3.00; *exo*-**V**, $^3J_{5,6}$ = 5.60, $^3J_{1,6}$ = $^3J_{4,5}$ = 2.93.

The stereoisomers of **V** were separated by preparative gas–liquid chromatography. The isomeric composition of esters **V**–**VII** was determined by GLC anal-

Prop-2-ynyl benzoate (reference)	3	30	1.36	87.26	7.9**	21.0	90.56	10.56**	No data		

* (K) Corrosion rate, (Z) degree of protection, and (γ) inhibition coefficient.

** Calculated from data for the reference.

ysis. It was found that the isomeric composition fully coincided with that of the starting acid chloride **I**. The fraction of the *exo* isomer in adducts **V**–**VII** is 10%.

The compounds synthesized were studied chromatographically on two stationary liquid phases: polar [5% polyethylene glycol succinate (PEGS) in Dinokhrom P] and nonpolar (5% Apiezon N on Dinokhrom P). The polar PEGS phase appeared to be the best for separation of the *endo* and *exo* isomers of **V**–**VII**. The retention parameters, Kovats indices (procedure from [10]), and boiling points (procedure from [11]) of the compounds were determined (Table 2).

Compounds **V**–**VII** were tested as inhibitors of the acid corrosion of steel. The inhibiting activity was studied in relation to the structure of the alcoholic moiety; the temperature was varied within 25–80°C; the HCl concentration was 1, 3, and 5 N; and the inhibitor concentration was 3, 6, and 12 mM. The results are listed in Table 3.

As can be seen from Table 3, all the compounds **V**–**VII** are effective inhibitors of the acid corrosion of steel. They surpass in inhibiting power the known

structurally related inhibitor, propargyl benzoate. This fact suggests that the certain contribution to the inhibiting effect of **V**–**VII** is made by the norbornene moiety, along with the acetylenic fragment.

Table 3 shows that all the three compounds **V**–**VII** show a better performance than the reference, propargyl benzoate, when added in lower concentrations (3, 6, and 12 mM, against 30 mM for the reference).

The best performance is shown by **V**. This may be due to the steric hindrance produced by two geminal methyl groups in the position adjacent to the triple bond in **VI** and **VII**.

EXPERIMENTAL

The IR spectra were recorded on a UR-20 spectrophotometer (4000 – 400 cm^{-1}, thin films or KBr pellets), and the ^1H NMR spectra, on a Tesla BS-487C spectrometer (80 MHz, CCl_4, internal references HMDS and TMS). The preparative separation was performed on a Varian-Aerograph chromatograph [900 × 0.8-cm column, 5% polyethylene glycol adipate on porous support (Porovina), vaporizer temperature 250°C, column temperature 175°C, carrier gas nitrogen (flow rate 200 $cm^3\ min^{-1}$), sample volume 100 μl, flame ionization detector]. The chromatographic analysis of the compounds, with determination of their purity, was performed on an LKhM-8MD chromatograph [thermal conductivity detector, 300 × 0.3-cm columns, 5% Apiezon or PEGS on Dinokhrom P, carrier gas helium (40 $cm^3\ min^{-1}$, column temperature 150°C, vaporizer temperature 250°C).

The compounds were tested as corrosion inhibitors in HCl solutions with 50 × 20 × 3-mm St.3 steel plates; the test time was 2 h. The HCl concentration was 1, 3, or 5 N, and the temperature was varied within 25–80°C. The corrosion rate and the degree of protection, *Z*, were determined as described in [12].

Acryloyl chloride was prepared by refluxing benzoyl chloride with acrylic acid [13] in a 2 : 1 ratio; bp 75–76°C. Bicyclo[2.2.1]hept-5-ene-2-carboxylic acid chloride **I** was prepared by condensation of acryloyl chloride with freshly distilled cyclopentadiene.

2-(Prop-2-ynyloxycarbonyl)bicyclo[2.2.1]hept-5-ene V. To a stirred solution of 5.6 g (0.1 mol) of prop-2-yn-1-ol **II** (propargyl alcohol) and 10.1 g (0.1 mol) of triethylamine in 30 ml of absolute diethyl ether, we added dropwise 15.5 g of chloride **I**. The reaction was exothermic. The precipitate of triethylammonium chloride was filtered off. The ether from the filtrate was evaporated, and the residue was distilled in a vacuum to give 20 g of **V**; bp 100°C (5 mm Hg), n_D^{20} = 1.4936, d_4^{20} = 1.0836. Published data [2]: bp 72–80°C (0.7 mm Hg).

2-(1,1-Dimethylprop-2-ynyloxycarbonyl)bicyclo-[2.2.1]hept-5-ene VI. To a stirred solution of 8.4 g (0.1 mol) of 1,1-dimethylprop-2-yn-1-ol **III** and 10.1 g (0.1 mol) of triethylamine in 30 ml of absolute benzene, we addded dropwise 15.5 g (0.1 mol) of chloride **I**. The mixture was refluxed with stirring for 5 h. The salt precipitate was filtered off, the solvent was evaporated, and the residue was distilled in a vacuum to give 18.76 g of **VI**. The physicochemical characteristics of **VI** are listed in Table 1.

2-(1,1-Dimethylpent-2-yn-4-enyloxycarbonyl)bicyclo[2.2.1]hept-5-ene VII. To a solution of 11 g (0.1 mol) of 1,1-dimethylpent-2-yn-4-en-1-ol **IV** and 10.1 g (0.1 mol) of triethylamine in 30 ml of absolute benzene, we added dropwise with stirring 15.5 g (0.1 mol) of chloride **I**. The mixture was refluxed with stirring for 5 h and worked up as described above. Yield of **VII** 20.7 g; for constants, see Table 1.

CONCLUSIONS

(1) Acetylenic esters of norbornenecarboxylic acid of high purity were prepared in good yields by reactions of primary and tertiary acetylenic alcohols with norbornenecarboxylic acid chloride in the presence of tertiary amines (pyridine, triethylamine). The primary alcohol reacts with the chloride at room temperature, whereas in the case of tertiary alcohols, elevated temperatures (80°C) and longer reaction times (5 h against 0.5 h) are required.

(2) Chromatographic procedures were developed for separation and analysis of acetylenic esters of norbornenecarboxylic acid; their Kovats indices and boiling points were determined. The esters are mainly *endo* isomers; the content of the *exo* isomer is 10%.

(3) Acetylenic esters of norbornenecarboxylic acid were tested as inhibitors of metal corrosion and showed a good protective performance.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Reactions of Dithiocarbamic Acids Derived from Alkaloids, Morpholine, and Piperidine with Acrylic Acid and Its Derivatices

Institute of Organic Synthesis and Coal Chemistry of the Republic of Kazakhstan, Limited Liability Company, Karaganda, Kazakhstan

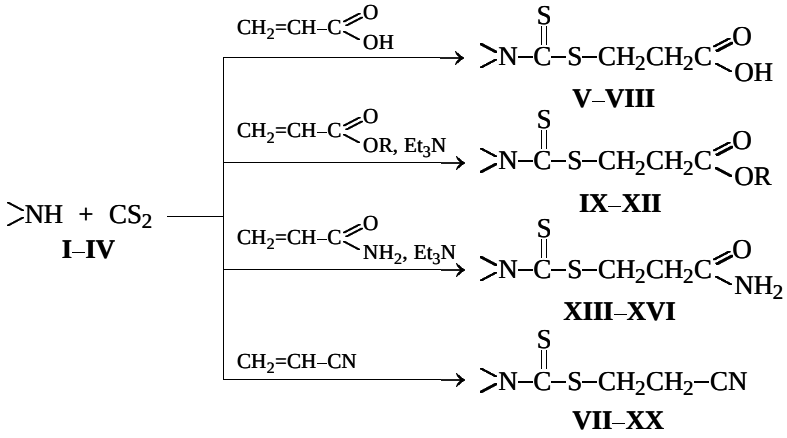
Received April 20, 2004

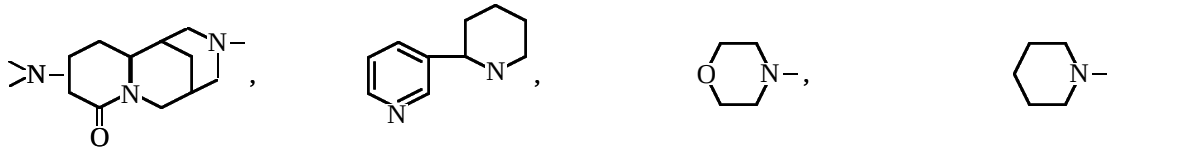
Abstract—β-(Thiocarbamoylthio)propionic acids derived from alkaloids, morpholine, and piperidine and their esters, amides, and nitriles were prepared by reactions of the corresponding dithiocarbamic acids with acrylic acid and its derivatives. Some of the compounds were tested for insecticidal activity.

Dithiocarbamic acids are important synthetic precursors of various antimicrobial [1], fungicidal [2], pesticidal [3], bactericidal [4], and other biologically active agents.

Dithiocarbamic acid esters containing various functional groups in the mercaptan residue can be prepared by reactions of dithiocarbamic acids with unsaturated electrophilic compounds in which the double bond is activated with electron-withdrawing substituents, such as unsaturated acids, their esters and anhydrides, unsaturated ketones, and related compounds.

Proceeding with a search for new biologically active dithiocarbamate derivative of alkaloids and their synthetic structural analogs [5], we performed reactions of dithiocarbamic acids prepared *in situ* from amines **I**–**IV** and CS_2 (with or without the base catalyst, triethylamine) with acrylic acid and its derivatives:





I, V, IX, XIII, XVII **II, VI, X, XIV, XVIII** **III, VII, XI, XV, XIX** **IV, VIII, XII, XVI, XX**

R = CH_3 (**a**), *i*-C_3H_7 (**b**), and C_4H_9 (**c**).

In view of the high physiological activity of dithiocarbamates and alkaloids, it seemed interesting to combine, in a single molecule, alkaloid and dithiocarbamate fragments and to study the biological properties of such compounds.

Acrylic acid contains a double bond conjugated with the carboxy group. The withdrawing effect of the carbonyl oxygen on the π electrons of the double bond facilitates its attack by nucleophilic agents. Therefore, dithiocarbamic acids react with acrylic acid under mild conditions to form the corresponding β-[alkaloido(amino)thiocarbonylthio]propionic acids **V**–**VIII** in high yields, 86–93% (Table 1).

The alkyl groups in alkyl acrylate exhibit a positive inductive effect and noticeably decrease the conjugation between the carbonyl oxygen atom and C=C bond of the acrylate; as a result, the rate of reaction of dithiocarbamic acids with alkyl acrylates somewhat decreases. Compounds **I**–**IV** react with alkyl acrylates under more severe conditions, in the presence of triethylamine, apparently via formation of an ammonium salt. The length of the carbon chain and the degree of substitution of the α-C atom in the alcoholic residue exert no significant effect on the yield of β-[alkaloido(amino)thiocarbonylthio]propionic acid esters **IX**–**XII**. The yield of esters **IX**–**XII** derived from methyl (**a**), isopropyl (**b**) and butyl (**c**) acrylates ranges from 57 to 77% (Table 2).

The reaction with acrylamide also occurs in the presence of triethylamine; the yields of β-[alkaloido(amino)thiocarbonylthio]propionic acid amides **XIII**–**XVI** range from 74 to 91% (Table 3). In the absence of triethylamine, the reaction takes somewhat more time and requires heating; the yield of amides **XIII**–**XVI** appreciably decreases. This may be caused by thermal instability of dithiocarbamates and by consumption of the amine or alkaloid as a base for the salt formation. The product of direct

* Eluent benzene–acetone, 1 : 1.

addition of the amine to acrylamide is formed as a by-product.

The reactivity of acrylonitrile toward **I**–**IV** is similar to the reactivity of acrylic acid, which is due to the high electron-withdrawing power of the nitrile group, facilitating nucleophilic attack of the C=C bond by the carbamate anion. The reactions of *in situ* prepared diethyldithiocarbamic acids with acrylonitrile are performed with a small excess of CS_2; β-[alkaloido(amino)thiocarbonylthio]propionitriles **XVII**–**XX** are obtained in high yields, 78–91% (Table 4).

The nucleophilic addition of the dithiocarbamates to acrylic acid and its derivatives occurs against the Markownikoff rule [scheme (1)].

β-[Alkaloido(amino)thiocarbonylthio]propionic acids **V**–**VIII** are crystalline substances insoluble in organic solvents, but readily soluble in alkalis with the formation of the corresponding salts. Esters **IX**–**XII**, amides **XIII**–**XVI**, and nitriles **XVII**–**XX** were isolated as crystalline substances or light yellow oils, soluble in the majority of organic solvents.

Some of compounds **V**–**XX** and alkali metal salts of **V**–**VIII** were tested for insecticidal activity with respect to *Lepidosaphes ulmi* (Diaspididae family), *Capitophorus ribis* (Aphididae family), and *Abrahas grossulariata* (Geometridae family). The insecticidal activity was compared to that of a reference agent, Sumi-alpha (Sumito Chemical Co., Ltd, Japan).

We found that salts of **V** and **VIII**, sodium β-[cytisinothiocarbonylthio]propionate and potassium β-[cytisinothiocarbonylthio]propionate, exhibit pronounced insecticidal activity with respect to all of the examined pests, exceeding that of Sumi-alpha by a factor of 1.5–2.

The results were confirmed by the results of biological tests; compounds **V** and **VIII** were recommended for further comprehensive studies with the aim to assess the possibility of their use in agriculture as pesticides.

EXPERIMENTAL

The compositions and structures of the compounds were confirmed by elemental analysis and IR spectroscopy.

The IR spectra were recorded on a UR-20 spectrometer (KBr pellets, mulls in mineral oil, or solutions in $CHCl_3$ and CCl_4).

β-(Cytisinothiocarbonylthio)propionic acid V. A solution of 1.90 g (0.01 mol) of cytisine in ethanol was added to a solution of 0.76 g (0.01 mol) of CS_2 and 0.72 g (0.01 mol) of acrylic acid in ethanol.

The mixture was stirred for 5–6 h. After the removal of the solvent, a white precipitate formed. Recrystallization from alcohol gave 3.04 g (89.0%) of **V**, mp 252–253°C. IR spectrum, ν, cm^{-1}: 700–600 (C–S), 1500–1470 (N–C=S), 1320–1210 (COOH).

Found, %: C 52.61, H 6.46, N 8.32.

$C_{15}H_{22}N_2O_3S_2$.

Calculated, %: C 52.63, H 6.43, N 8.19.

Compounds **VI**–**VIII** were prepared similarly.

Methyl β-(cytisinothiocarbonylthio)propionate IXa. A solution of 1.90 g (0.01 mol) of cytisine and 1.01 g (0.01 mol) of triethylamine in ethanol was slowly added dropwise with stirring to a solution of 0.86 g (0.01 mol) of methyl acrylate and 0.76 g (0.01 mol) of CS_2 in ethanol. The mixture was heated for 1 h at 60–70°C. After the removal of the solvent, a white precipitate formed. Its recrystallization from alcohol gave 2.5 g (70.0%) of **IXa**, mp 94–95°C. IR spectrum, ν, cm^{-1}: 700–610 (C–S), 1500–1470 (N–C=S), 1410–1300 (COO^-).

Found, %: C 53.96, H 6.70, N 7.90.

$C_{16}H_{24}N_2O_3S_2$.

Calculated, %: C 53.93, H 6.74, N 7.87.

Compounds **Xa**–**XIIa**, **IXb**–**XIIb**, and **IXc**–**XIIc** were prepared similarly.

β-(Cytisinothiocarbonylthio)propionamide XIII. A solution of 1.9 g (0.01 mol) of cytisine and 1.01 g (0.01 mol) of triethylamine in ethanol was slowly added dropwise with stirring to a solution of 0.71 g (0.01 mol) of acrylamide and 0.76 g (0.01 mol) of CS_2 in absolute ethanol. The mixture was heated for 4–5 h. After the removal of the solvent, a white precipitate formed. Its recrystallization from alcohol gave 2.9 g (87.0%) of **XIII**, mp 148–150°C. IR spectrum, ν, cm^{-1}: 710–610 (C–S), 1520–1480 (N–C=S), 1140–1070 ($CONH_2$).

Found, %: C 52.81, H 6.70, N 12.38.

$C_{15}H_{23}N_3O_2S_2$.

Calculated, %: C 52.79, H 6.74, N 12.32.

Compounds **XIV**–**XVI** were prepared similarly.

β-(Cytisinothiocarbonylthio)propionitrile XVII. A solution of 1.9 g (0.01 mol) of cytisine in ethanol was slowly added dropwise to a solution of 0.53 g (0.01 mol) of acrylonitrile and 1.14 g (0.015 mol) of CS_2 in ethanol. The mixture was stirred at 40–50°C for 2–3 h. After the removal of the solvent, a light yellow oil crystallizing on storage was obtained. Its recrystallization from alcohol gave 2.75 g (85.0%) of **XVII**, mp 41–42°C. IR spectrum, ν, cm^{-1}: 700–610 (C–S), 1510–1460 (N–C=S), 2260–2240 (C≡N).

Found, %: C 55.77, H 6.46, N 13.02.

$C_{15}H_{21}N_3OS_2$.

Calculated, %: C 55.73, H 6.50, N 13.00.

Compounds **XVIII**–**XX** were prepared similarly.

CONCLUSIONS

(1) β-[Alkaloido(amino)thiocarbonylthio]propionic acids and their esters, amides, and nitriles were prepared by reactions of dithiocarbamic acids derived from alkaloids, morpholine, and piperidine with acrylic acid and its derivatives.

(2) Alkali metal β-(aminothiocarbonylthio)propionates derived from cytisine and piperidine exhibit a pronounced insecticidal activity.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Spectral-Luminescent and Generation Properties of Rhodamine Dyes in Thin Polymer Films under Optical Excitation

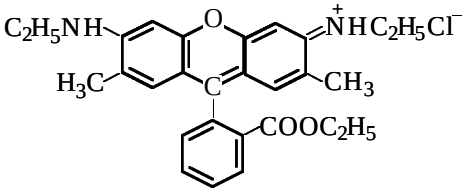
Abstract—A study was made of the absorption, fluorescence, and emission spectra of organic dyes Rhodamine 6Zh and Rhodamine C in thin (0.6–1.0 μm) layers based on methyl methacrylate–methacrylic acid copolymers formed by centrifugation on optically transparent glasses. The influence of a terbium salt on the properties of laser dyes in acrylic films was elucidated.

Xanthene dyes rhodamine 6Zh (R6Zh) and rhodamine C (RC), classic representatives of laser dyes, have unique optical properties and find wide application as laser-active substances operating in liquid and solid polymer solutions. The spectral-luminescent properties of these dyes in liquid media and, in particular, in methyl methacrylate (MMA), and in a solid medium based on poly(methyl methacrylate) and a copolymer of MMA with methacrylic acid (MAA) were studied in [1, 2]. Solid solutions of dyes in polymer matrices are mainly prepared by bulk radical polymerization of solutions of dyes in a monomer in the presence of initiator in special molds. At the same time, the preparation of such solutions as thin polymer films and, especially, the energy transformations by rhodamine dyes in them are little studied, despite great scientific and technical importance of these processes.

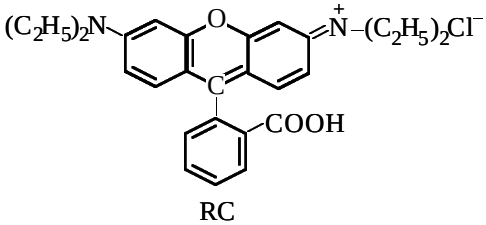
In this study, we examined the spectral-luminescent properties (absorption and fluorescence spectra) of rhodamine dyes (R6Zh and RC), as influenced by their chemical structure in thin polymer layers based on MMA–MAA copolymers under optical excitation. We determined the generation power of the dyes and their photostability in polymer films. Also, we studied how the characteristics of rhodamines in acrylic films are influenced by addition of terbium trifluoroacetate and analyzed theoretically the processes occurring in the polymer–dye–salt system.

EXPERIMENTAL

Xanthene dyes R6Zh and RC exhibit luminescent properties and, thus, are promising for application in luminescent devices. The chemical structure of rhodamines can be varied within one structural type of the dyes, which makes them suitable for studies of the photoluminescent properties of dyed polymers. The substances studied in the form of films have the following structural formulas:



R6Zh



RC

As polymer base we used commercial solutions of MMA–MAA copolymers in organic solvents, known as electronic resists ELP-9 and ERP-40. The content

of carboxy groups in the copolymers and their structural features were determined by IR spectroscopy. The films for IR-spectroscopic studies were prepared by applying a polymer solution onto transparent KBr plates. The IR spectra were recorded on a Specord M80 spectrophotometer at 4000–400 cm^{-1}. The spectra were interpreted using the reference data from [3–5]. The modifying additives were introduced into the resists by homogeneous dissolution. The content of the dyes in the initial solutions was 1×10^{-3} M. In parallel, we studied solutions of the xanthene dyes in the resists with terbium(III) trifluoroacetate (TFA-Tb) added in the amount of 2.5×10^{-2} M. A more complete dissolution of the modifying additives was achieved via stirring on a WU-4 vibrating mixer and ultrasonic treatment. Mechanical inclusions were removed from the solutions by filtration through a polyamide filter with a pore diameter of 0.5 μm. The polymer films were formed by centrifugation (at 2500–3000 rpm) on preliminarily degreased substrates made of an optically transparent glass, with diameters of 20 and 35 mm. After application, the films were dried for 30 min at 165 ± 5°C. The thickness of the films, mostly under 1 μm, was determined with an MII-4 interference microscope. To measure the film thickness more precisely (to improve the reflection), a 0.1-μm aluminum layer was deposited on their surface in a UVN-71P3 vacuum sputtering setup. To prepare thicker (≥1 μm) films, we increased the viscosity of the initial solutions by evaporating the solvents at room temperature. Next, we studied the spectral-luminescent characteristics, generation properties, and photostability of the resulting samples. The electronic spectra were recorded on a Specord M40 (200–900 nm) spectrophotometer. The luminescent properties were studied on an upgraded KSVU-23 spectral complex and on a Hitachi 850 spectrofluorimeter. Laser-induced fluorescence excited by $XeCl^-$ or YAG–Nd^{3+} lasers was recorded by a Real spectrometer.

The generation powers of the rhodamines in films were studied in a transverse excitation scheme. Laser radiation was focused into a 18 × 0.8 mm band, at which the radiation intensity was about 30 MW cm^{-2}. The induced radiation was formed without an external resonator.

The generation photostability $P_{0.5}$ was estimated as the number of excitation pulses upon which the generation efficiency decreased by half due to degradation of the dye.

The molecular photostability of the dyes was studied by irradiating the films with unfocused radiation from a YAG–Nd^{3+} laser (532 nm). The quantum yield of degradation was determined by the formula $\gamma = N_{phot}/N_{abs}$, where N_{phot} is the number of the molecules that underwent phototransformations in the irradiation zone, and N_{abs}, the number of the photons absorbed. We estimated N_{phot} spectrophotometrically, from the variation of the optical density at the absorption band maximum during irradiation.

We found that the compositions with dye additives exhibited good film-forming power and adhesion to the substrate surface. The films based on these compositions have no defects and are equal in thickness, except at the substrate edge, where a thicker polymer layer (compaction) was formed. The initial polymer compositions without modifiers had a high light transmission (up to 97%) at wavelengths over 280–300 nm. Upon introduction of the dyes into the polymer formulations, the corresponding absorption bands appeared in the electronic absorption spectra. In the spectra of the rhodamines in the MMA–MAA copolymer, the absorption peak is observed at the same wavelength as in solutions in MMA, this peak being almost identical in position to that of the dyes in ethanol. Table 1 presents the spectral properties of the dyes studied. The optical density D_{max} of R6Zh is

several times that of RC in identically prepared films, while the molar extinction coefficients ε of these dyes in ethanol are close (~10^5 l cm^{-1} mol^{-1}). When calculating the molar extinction of the rhodamines in films, we assumed that the content of the dye after removal of the solvent in the course of drying increased to 5×10^{-3} M.

Introduction of a terbium(III) salt into the initial compositions increases the absorption band intensities of the dyes in films by 30–45% (Table 1). The spectral properties of the rhodamines are intensified due to an increase in polarity of the polymer solutions upon introduction of trifluoroacetate and terbium ions and to the reaction of the dye molecules with the metal salt. In the case of RC, stronger bonds (hydrogen, donor–acceptor) can be formed via the carboxy groups occurring in its structure. The strengthening of the cohesion forces in the polymeric medium upon introduction of a terbium salt is also suggested by the measured thicknesses of the films of various compositions. The films with TFA-Tb are, on the average, 15–20% thicker than those without the Tb(III) salt. In the case of R6Zh, the thin and thick films differed in thickness (as estimated from the optical densities and measured microscopically) by 40–50%, and those in the case of RC, by 300–400% (as estimated from the optical densities).

The luminescence spectra of the dyed films contained one band; the contour of the fluorescence curve was the mirror image of that of the absorption band. In the presence of the Tb(III) ions, the luminescence intensity of the rhodamines substantially increases due to a rise in the intensity of the absorption bands. The fluorescence spectra of the rhodamine dyes in methacrylic films and in ethanolic solutions are virtually identical, probably due to the influence of polar (carboxy) groups of the polymer chain. The luminescence intensity of R6Zh in methacrylic films is 6–9 times that of RC, which is also due to a higher optical density of R6Zh in films (Table 1).

The generation properties of the xanthene dyes in films are presented in Table 2. In the case of R6Zh, lasing was observed in all the samples studied, excited both by $XeCl^{-}$ and YAG–Nd^{3+} lasers. Under excitation at λ = 308 nm, generation is recorded spectrally; the generation energy is small; the efficiency is under 1%. Under excitation at 532 nm, the efficiency is 10–17%. Lasing develops in the long-wave branch of the fluorescence band (Fig. 1a). The emission band is separated by ca. 20 nm from the fluorescence band maximum. Such a large shift is due to the loss caused by the reabsorption of emitted light by the dye. Notably, the generation photostability $P_{0.5}$ of R6Zh in film is fairly high. At the pumping power density of ca. 30 MW cm^{-2} for the YAG–Nd^{3+} laser, the working life of the active medium is about 2000 pulses. Terbium(III) salt noticeably affects the photostability of the active medium, predominantly under UV irradiation. Table 2 shows that the working life $P_{0.5}$ remained virtually unchanged upon introduction of

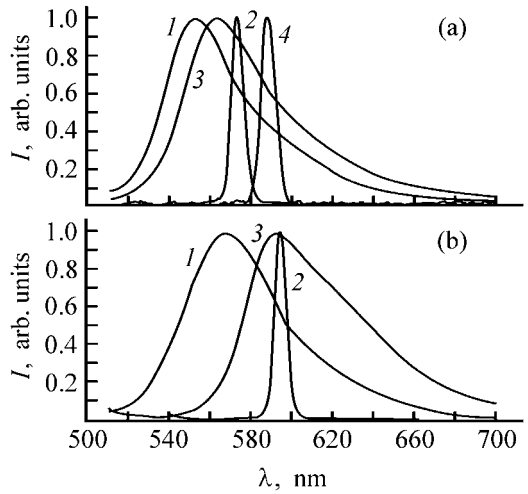

Fig. 1. Emission spectra of (a) R6Zh and (b) RC in films (*1*, *2*) with and (*3*, *4*) without Tb(III). (*I*) Intensity and (λ) wavelength.

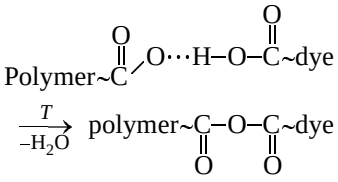
a Tb(III) salt under excitation at λ = 532 nm and increased 2–3-fold under excitation at λ = 308 nm.

In the case of RC, generation was observed only in one sample whose optical density was 0.32 in the absorption band maximum under pumping with both $XeCl^-$ and YAG–Nd^{3+} lasers (Fig. 2). Under excitation at λ = 308 nm, the generation efficiency was low, while under pumping at λ = 532 nm, the generation efficiency for this sample was 22%, and the working life, over 5000 pulses. In the case of other samples with thinner films, no generation developed because of the very low optical density, which was probably due to chemical binding of the dye to the polymer molecules via carboxy groups in the course of drying of the samples:



As is known, the generation efficiency of RC chemically bound to the polymer is lower that of the dye in a free state [6]. Upon dissolution of the dye and the metal salt in the copolymer, the modifier competes with the dye for formation with the MAA molecules of hydrogen or other, e.g., donor–acceptor, bonds, and these compositions exhibit in thick layers generation of RC unbound with the polymer.

We estimated the molecular photostability of the rhodamine molecules in films, γ, at ca. 10^{-6} and 5×10^{-6} for R6Zh and RC, respectively. These data agree with those for ethanolic solutions of the dyes under excitation at λ = 532 nm. Thus, the photostability of the rhodamines in films is not poorer than that in solutions.

In the presence of the ions of rare-earth elements in the films, the effect exerted on the luminescence intensity by external factors, namely, light, UV radiation, moisture, and low temperature, was significantly weaker. The samples were irradiated with the full spectrum of a DRL-400 mercury lamp for 120 h, kept for 30 days in the light, in a moisture chamber (relative humidity 95%), and in a freezing chamber (–15°C). As a criterion of resistance to radiation, light, and moisture, we took the relative change in the luminescence intensity $I_{rel} = (I_0 - I_t)/I_0 \times 100\%$ after exposure (Table 1).

Table 3. Influence of various factors on the luminescence intensity of R6Zh and RC in acrylic films

Film composition	I_{rel}, %, after effect of			
	UV radiation	light	moisture	temperature
ELP-9 + RC	49	61	34	30
ELP-9 + RC + TFA-Tb	28	36	18	13
ELP-9 + R6Zh	27	48	23	17
ELP-9 + R6Zh + TFA-Tb	14	22	9	2

Table 3 shows that the terbium salt noticeably improves the resistance of the dyes to all the external factors. The fact that the Tb(III) salt containing active groups enhances the resistance of the dye to irradiation and illumination is, evidently, due to formation of intermolecular bonds (hydrogen, van der Waals, etc.)

with polymer macromolecules, yielding a three-dimensional network in the polymer. Dyes are known to exhibit enhanced photostability in a more photostable (modified) matrix characterized by a smaller number of macrochain breaks [7]. Also, metal ions in the system can diminish the concentration of free radicals forming in the polymer during irradiation (illumination). This decreases the probability of reactions between the radicals and the dye molecules, which are accompanied by photoinduced degradation of the dye. The decelerating effect of terbium(III) ions on the degradation of a dye molecule may also be due to deactivation of the excited states via increasing dye–cation coordination. The moisture-protecting action of terbium trifluoroacetate is evidently due to the presence of highly active centers (metal cation, fluoride ions, carbonyl oxygen) able to form fairly strong bonds with water molecules, thus preventing the diffusion of water molecules deep inside the polymer film. The intermolecular attraction due to forces of varied nature in the polymer–dye–salt system can exert another favorable effect, namely, prevent the diffusion of the dye dissolved in the polymer and, in particular, the transfer of dye molecules into the environment (the so-called exudation).

A change from the ELP-9 to ERP-40 polymer matrix does not significantly affect the position of the absorption and fluorescence bands, but their intensities in the case of EPR-40 are 1.5–2 times lower than those in the case of ELP-9, whatever the composition. This can be due to the high content of carboxy groups in ERP-40, which interact with reactive groups in R6Zh and RC molecules during film preparation, thus deteriorating the spectral-luminescent characteristics of the dyes. The content of the carboxy groups in the polymers was estimated from the optical density ratio of the absorption band at 3400–3100 cm^{-1}, I_1, corresponding to stretching vibrations of OH groups, to that near 1300–1100 cm^{-1}, I_0, which are characteristic of the 3CO–O– acrylate moiety. In the IR spectra of the films with ERP-40, the intensity of the bands near 3400–3100 cm^{-1} is more than 2 times that of the films with ELP-9 (Fig. 2). The optical density was estimated by plotting the baseline [8]. As the I_1/I_0 ratio served the ratio of the areas confined in the IR spectrum by the baseline and the corresponding absorption band. A larger content of methacrylic acid in the case of the films with ERP-40 is also evidenced by a broader, compared to ELP-9, absorption band with a fine structure at 1730 cm^{-1}, corresponding to vibrations of the C=O group.

The higher content of carboxy groups in the case of the films with ERP-40 is also evidenced by lithographic data, namely, by the fact that the exposure time in which elements with identical size can be formed in the polymer films of equal thickness is 10–15 s longer in the case of the films with ERP-40 compared to those based on ELP-9. This can be caused by a denser three-dimensional network in the film with ERP-40 due to formation of hydrogen bonds between the COOH groups, whose cleavage requires more energy. The lithographic studies employed the procedure described in [9].

CONCLUSIONS

(1) The feasibility of preparing thin luminescent layers of organic molecules (film thickness $\leq 1\mu m$) was demonstrated.

(2) The absorption and emission intensity of the xanthene dyes in films can be raised by introducing a terbium(III) salt into copolymers: In the case of R6Zh, the absorption band intensity increases by 30–40%, and in the case of RC, the increment is an order of magnitude larger. The luminescence intensity of R6Zh in the films increases 6–9-fold. This is accompanied by an increase in the resistance of the material to aggressive external factors, namely, moisture, temperature, and UV radiation.

(3) The molecular photostability of the xanthene dyes in films is comparable with that in ethanolic solutions.

(4) Generation of laser radiation in the xanthene dyes in films under excitation with an YAG–Nd^{3+} laser is efficient (up to 22%) and photostable (working life up to 5000 pulses), which makes the materials prepared suitable for creation of microlasers.

Abstract—A gas-chromatographic method was developed for determining deuterium in organic compounds at its atomic fraction of 1 to 99%. The accuracy of the method is 0.1–0.5%.

Deuterium-labeled organic compounds are widely used in various branches of science and technology [1, 2]. As a rule, the isotopic composition of hydrogen in such compounds is determined by ^{1}H NMR spectroscopy [1] and mass spectrometry [2, 3]. The choice of the analytical method depends on the structure and properties of a compound to be studied. The cheapest and the most versatile is the method for determining the isotope composition of hydrogen directly in organic compounds using commercial class-II mass spectrometers [2]. The method involves solution of a system of 2m equations with $m + 1$ unknowns, taking into account the probability of formation of all the possible molecular fragments. The method can be used for proximate analysis of the isotopic composition of hydrogen in simple organic compounds, e.g., in deuteroacetone. The atomic fraction of deuterium is determined in the range 1–99% with an accuracy of 0.2–3%. With compounds exhibiting a complex fragmentation pattern under electron impact, it is necessary to take into account various empirical factors and to use a computer, which considerably complicates the analysis and impairs its accuracy [2].

We developed a procedure for determining the isotope composition of hydrogen in organic compounds of various classes, using elemental analysis on standard equipment. The accuracy of determination of the deuterium atomic fraction is 0.1–0.5%.

The elemental analysis of deuterated organic compounds was performed on a Carlo Erba 1100 gas-chromatographic elemental analyzer as follows. The organic compound being analyzed was subjected to oxidative pyrolysis. After separation of water and its deuterium analogues, a mixture of gaseous N_2 and CO_2 was analyzed by chromatography, and desorbed water containing the deuterium label was converted to a mixture of H_2, HD, and D_2; its composition was determined by gas-adsorption chromatography. The oxidative pyrolysis was performed in the C,H,N channel of the device by the standard procedure at 1050°C. The charge of the combustion reactor, recommended by the producer, was changed: Over a bed of CuO wire (10 cm), we placed a bed of Cr_2O_3 (9 cm) and then a bed of quartz crumb (1 cm). This allowed efficient after-oxidation of the pyrolysis products and fully eliminated the danger of reactor plugging with fused reduced metallic copper.

The analysis was performed in the dynamic mode. The flow rate of the carrier gas (Ar containing 80 vol % O_2) was 30 ml min^{-1} in the C,H,N channel and 20 ml min^{-1} in the reference channel. A sample (0.5 mg) was placed in an aluminum container. The oxidant was $AgMnO_4$, which showed high performance in previous studies [4]. As references we used both cyclohexanone 2,4-dinitrophenylhydrazone (recommended by the producer of the device) and nonlabeled analogs of the organic compounds to be analyzed. For example, in analysis of toluene-α-*D*, we used toluene as reference. Samples were fed into the combustion reactor from a ring-shaped automatic

1070-4272/04/7708-1331 © 2004 MAIK "Nauka/Interperiodica"

dosing unit with 23 sample cells in the manual or automatic mode. Samples were arranged in this unit in the following order: container with reference sample and oxidant, container with oxidant, three containers with the compound being analyzed and oxidant, again container with the reference sample and oxidant, container with oxidant, three containers with the compound being analyzed and oxidant, container with reference sample and oxidant, container with oxidant, and four containers with the compound being analyzed. Such an arrangement allows accurate determination of the zero signal for the given element and ensures the best reproducibility of the results.

The mixture obtained by oxidative pyrolysis was analyzed for the content of N_2, CO_2, H_2O, HOD, and D_2O.

No direct method is known today for analysis of this gas mixture. Determination of N_2 and CO_2 by gas chromatography involves no problems; numerous sorbents are suitable for this purpose [5, 6]. Water is determined by this method relatively poorly and, as a rule, is converted with appropriate reagents into other chemical forms convenient for chromatographic determination [6, 7]. Therefore, the mixture was analyzed after separation of water and its deuterium analogues. For this purpose, the gas mixture was passed at room temperature through two columns made of transparent quartz (l = 0.2 m, d = 6 mm), packed with the water absorbent and appropriate reagent, after which the mixture of N_2 and CO_2 was analyzed using an aluminum column (l = 4 m, d = 3 mm) packed with alumina-supported Chromosorb-102. The column temperature was 120°C. A thermal conductivity detector was used. After determination of N_2 and CO_2 in the gas mixture, a tubular furnace preheated to 120°C was moved on the column with the water absorbent.

Commercial units for adsorption drying of gases use silica gels ASK and ASKM [8]. However, silanol groups present on the surface of these adsorbents distort the results of analysis because of the isotope exchange. It is known that silanol groups transform into siloxane groups on heating [9]. Therefore, for qualitative and semiquantitative analysis, we calcined the silica gels of the above brands for 3 h at 400°C in a vacuum (1 mm Hg) and then modified them with trimethylchlorosilane [9]. In this case, however, the error was relatively large and the reproducibility was poor, which does not allow use of silica gel for determining deuterium in organic compounds by our procedure. With Carbowax-550 (methoxy polyethylene glycol) supported (30%) on quartz crumb (0.25–0.5 mm) as water sorbent, it appeared possible to decrease the temperature of water desorption to 120°C and considerably accelerate its release. At 120°C, water was desorbed rapidly and quantitatively; the amount and isotopic composition of the desorbed water were determined by reaction gas chromatography.

This method is widely used for quantitative determination of nonlabeled water [6, 7, 10, 11]. In this method, water vapor in a carrier gas flow is fed into a column with an appropriate reagent that quantitatively converts water into another chemical form convenient for gas-chromatographic determination. To convert nonlabeled water into H_2, the following reagents meeting the requirements of reaction gas chromatography are used: CaH_2 [12, 13], $LiAlH_4$ [14], $NaAlH_4$ [15], and sodium metal [13]. These reagents, however, are unsuitable for quantitative determination of the isotope composition of deuterium-labeled water, because the hydrogen formed in the reaction will differ in the isotope composition from the initial water sample.

To convert deuterium-labeled water into a mixture of H_2, HD, and D_2, we performed its reaction with activated magnesium (Khlorvinil Production Association, Ukraine, MRSh-1 brand, 0.25–0.5-mm fraction) at 500°C [16]. Magnesium was activated with iodine directly in the column (l = 0.2 m, d = 6 mm) or in a quartz test tube at 500°C [16]. Five grams of activated magnesium is sufficient for more than 100 experiments on water conversion. The absence of the chromatographic peak of water and its deuterium analogues confirms the 100% conversion. The detection of water indicates that the reagent has lost its activity and requires replacement. Similar results have been obtained in water conversion with reduced iron powder (Reakhim Production Association, Russia) at 650°C [17].

Determination of the isotope composition of the released hydrogen by gas-adsorption chromatography involves no problems; the procedure has been well developed [5, 6].

In the present study, the isotope composition of the released hydrogen was determined with a Tsvet-570 gas chromatograph [18] following the procedure suggested in [19], which allows determination of the content of HD, D_2, and H_2 within 3 min with a <1% error on a column (l = 4 m, d = 3 mm) packed with zeolite 13X at 40°C, using a thermal conductivity detector. Isimura and Kaetsu [19] used high-purity helium as carrier gas. However, the thermal conductivity detector has a low sensitivity to hydrogen with this carrier gas

because of the small difference in the thermal conductivities of these gases [10]. With zeolite 5A, which separates hydrogen isotopes more efficiently than to 13X, used as adsorbent and with dry argon as carrier gas [5, 10], we were able to decrease the determination error to 0.1–0.2%.

Since there were no reference gas mixtures containing deuterium among the reference samples produced in Russia, we tested our installation with D_2O reference samples produced by Aldrich (the United States).

A reference sample of D_2O was analyzed as described above with the only difference that the D_2O sample (0.25 μl) was introduced directly into the absorption column preliminarily purged with dry argon. The error of determination of the isotope composition of hydrogen was calculated from the results of ten analyses of D_2O reference samples. The results are listed in Table 1.

From the results of the analysis, we calculated the following characteristics: content of elements x (%); arithmetic mean content of elements; standard deviation of single determination for each element, s (%); estimated variance of the mean content of each element, s^2; and confidence intervals $\langle x\rangle \pm st_{0.95,9}$, where $t_{0.95,9}$ is the Student coefficient for the con-

** Oxygen was determined in the O channel of the Carlo Erba 1100 gas-chromatographic elemental analyzer.

fidence level $P = 0.95$ and significance level $f = 0$, $l = 9$, which is equal to 2.26.

An independent determination of oxygen was performed in the O channel of the Carlo Erba 1100 gas-chromatographic elemental analyzer in the form of CO, after reductive pyrolysis of the sample over activated carbon. The pyrolysis was performed in a quartz tube with the following packing (cm): quartz wool, 1; thin twisted silver wire, 4; activated carbon, 15; and quartz crumb, 1. The temperature of the quartz tube in the pyrolysis zone and in the upper part of the reduction zone was 1120 ± 5°C. The carrier gas was He or Ar. The flow rate of the carrier gas in the O channel was 20 ml min^{-1}. Pyrolysis of organic compounds yields oxygen in the form of CO, CO_2, H_2O, D_2O, HOD, and molecular oxygen. After passing through a bed of activated carbon, the gas mixture mainly consists of He (or Ar), CO, and CO_2, with minor impurities of H_2 and CH_4. The mixture was analyzed by gas-adsorption chromatography on a column (l = 2.5 m, d = 3 mm) packed with zeolite 5A at 118 ± 2°C, using a thermal-conductivity detector (carrier gas He or Ar). As reference channel we used the C, H channel of the same device.

The results of elemental analysis of samples of organic compounds with different atomic fractions of deuterium are listed in Table 2.

Our results show that, in contrast to the results of [2], the atomic fraction of deuterium can be determined in the range 1–99% with a 0.1–0.5% accuracy. Furthermore, the method suggested in [2] involves additional problems (determination of empirical coefficients) and is applicable to a limited group of organic compounds.

CONCLUSION

The developed gas-chromatographic method for quantitative determination of deuterium has no limitations with respect to structure of organic compounds and ensures a high accuracy (0.1–0.5%) in a wide range of deuterium content (1–99%).

Received February 5, 2004

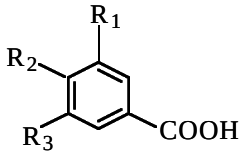
Abstract—A study was made of the chemiluminescence in the course of initiated oxidation of sunflower oil with a luminescence activator in the presence of natural phenols. The kinetic parameters $k_2/\sqrt{k_1}$ were determined, which take into account the appearance of chemiluminescence and characterize the antioxidative activity of the phenols.

Antioxidative stabilization of fats, oils, fat-containing foodstuff, and pharmaceuticals is practical problem of current interest, which can be solved by using natural phenolic antioxidants [1]. Application of plant phenols as inhibitors of radical-chain oxidation in vegetable oils requires that the antioxidative activity (AOA) of these phenols should be estimated and their action in complex substrates be taken into account.

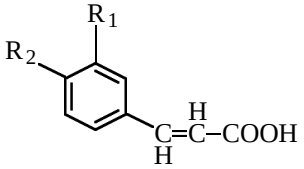
In this study, we examined the antioxidative activity of natural phenols in sunflower oil and revealed the specific features of chemiluminescence (CL) in the course of inhibited oxidation of the oil.

EXPERIMENTAL

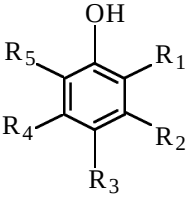
Commercial oil produced from sunflower seeds, whose initial physicochemical characteristics were specified by GOST (State Standard) 1129–93, was used without further purification. Pure-grade ethylbenzene (ETB) and chlorobenzene were purified by the standard procedure [2]. As the source of free radicals served pure-grade azobis(isobutyronitrile) (AIBN) double-recrystallized from absolute ethanol and benzoyl peroxide purified by the procedure from [3]. We used 9,10-dibromoanthracene (DBA) and 1,10-phenanthroline complex of europium thenoyltrifluoroacetonate (Eu chelate) as CL activators. Synthesis and purification of DBA and Eu chelate were described in [4, 5]. Plant phenols and p.a.-grade Ionol (Merck) were used without further purification. The CL kinetics in the course of inhibited oxidation was followed using a setup whose schematic was described in [6]. The formulas of the phenols studied are presented below:



$R_1 = R_2 = R_3 = OH$, gallic acid
$R_1 = R_2 = OH$, $R_3 = H$, pyrocatechic acid
$R_1 = R_3 = OCH_3$, $R_2 = OH$, syringic acid
$R_1 = OCH_3$, $R_2 = OH$, $R_3 = H$, vanillic acid
$R_2 = OH$, $R_1 = R_3 = H$, *p*-hydroxybenzoic acid



$R_1 = R_2 = OH$, caffeic acid
$R_1 = OCH_3$, $R_2 = OH$, ferulic acid



$R_2 = R_4 = OH$, $R_1 = R_3 = R_5 = H$, phloroglucinol
$R_3 = CH_3$, $R_1 = R_5 = C(CH_3)_3$, $R_2 = R_4 = H$, Ionol
$R_2 = OH$, $R_1 = R_3 = R_4 = R_5 = H$, resorcinol

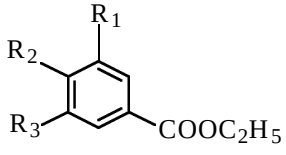
alizarine



ethyl gallate

We estimated the kinetic parameters of the antioxidative action of phenols PhOH in the course of oxidation of the oil by the CL method based on measuring the luminescence (I_0) arising during homolytic oxidation of organic substances with oxygen [7]. Electronically excited products of this reaction are typically yielded by recombination of peroxy radicals ROO•:

$$ROO^{\bullet} + ROO^{\bullet} \xrightarrow{k_1} [ROOOOR] \rightarrow R{=}O^{*} \rightarrow R{=}O + h\nu. \quad (1)$$

In the presence of inhibitors, the reaction between peroxy radicals is suppressed, and the CL decays (*I*) or completely disappears:

$$ROO^{\bullet} + PhOH \xrightarrow{k_2} ROOH + PhO^{\bullet}. \quad (2)$$

AIBN-initiated oxidation of sunflower oil with or without DBA activator was carried out in a 1 : 1 oil : chlorobenzene mixture. The phenolic antioxidant was introduced into the system after all the natural antixodants of oil, tocoferols, were spent and the CL intensity attained saturation, I_0. Figure 1a shows three types of kinetic curves describing variation of I/I_0 upon introduction of the phenols into the oil. It is seen that only Ionol and syringic acid exhibit classical patterns [the luminescence intensity decreases upon introduction of inhibitor (*I*), whereupon it regains the initial value of I_0 as the antioxidant is consumed]. The second type of kinetic curves is characteristic of phloroglucinol, resorcinol, pyrocatechic acid, gallic acid, and ethyl gallate: Upon introducing these phenols into the oil, the luminescence intensity increases, rather than decreases. On introducing into the oil the remaining phenols (quercetin, caffeic, syringic, ferulic, vanillic, and *p*-hydroxybenzoic acids, rutin, and alizarine) the CL intensity initially decreases and then increases, exceeding I_0 (Fig. 1a). Evidently, the final products of transformation of the phenols do not affect the CL, since all the kinetic curves of CL tend to $I/I_0 - 1$, which corresponds to the time at which the phenolic antioxidant is fully exhausted.

The nonclassical influence of the phenols on the CL of the oil being oxidized could seemingly be accounted for by the lack of antioxidative properties of these

Table 1. Induction periods for initiated oxidation and high-temperature autooxidation of ethylbenzene and sunflower oil in the presence of the phenols*

* The phenol concentration is 5×10^{-4} in initiated oxidation and 5×10^{-5} M in high-temperature autooxidation.

substances in oil. However, a parallel gas-volumetric study showed that all the phenols inhibit to a certain extent the oxidation of the oil, by reacting with peroxy radicals with chain termination (Table 1). We compared the induction periods τ for initiated oxidation of the oil and a model hydrocarbon substrate ethylbenzene and found that, on going from saturated (ethylbenzene) to a more complex unsaturated (oil) substrate, the phenols preserved the AOA. Also preserved were the trends in variation of this activity along the series of phenols differing in the structure. The most efficient inhibitors of the oil oxidation are *ortho* polyphenols: gallic acid and ethyl gallate, caffeic acid, and quercetin. Notably, the AOA of the phenols in the oils most prominently decreases relative to ethylbenzene in the case of high-temperature oxidation (Table 1). A decrease in the activity of the phenols in the oil may be due to a number of factors, among which the chain propagation via phenoxy radicals seems to be the most essential.

Special experiments on the CL in phenol-inhibited oxidation of the oil showed that the phenols and their transformation products are not common photosensitizers. Without luminescence activators, the CL intensity during the oil oxidation is very weak and lies below the detection limit of the CL setup. Therefore, we studied CL in the oil in the presence of activators only. We found that, on going from DBA activator to Eu chelate, the degree of enhancement of CL by the phenols remains unchanged during the induction period of oxidation; the enhancement of luminescence on introducing the phenols into the oil is preserved upon changing to another initiator; without initiator and upon termination of the oxygen supply no CL is observed. With increasing initiation rate V_i (at [PhOH] = const), I_{max} tends to linearly grow, and at a constant AIBN concentration I_{max} tends to increase with increasing phenol concentration and reaches a constant value at a certain concentration of the phenol. These data agree with our earlier conclusions [8] that the factor responsible for the additional luminescence in the substrates being oxidized (ethylbenzene, cumene, methyl ethyl ketone) is the reaction between the phenoxy $PhO^\bullet$ and peroxy radicals, yielding a phenol transformation product (quinone) in an electronically excited state, capable of light emission during transition to the ground state:

$$PhO^\bullet + ROO^\bullet \xrightarrow{k_3} \text{products}. \qquad (3)$$

Thus, the CL intensity in the induction period in inhibited oxidation of the oil will depend on the contributions from all the reactions giving rise to [reactions (1) and (3)] and quenching [reaction (2)] the luminescence and will be described by the expression

$$I = k_1\varphi_1[ROO^\bullet]^2 + k_3\varphi_3[ROO^\bullet][PhO^\bullet]. \qquad (4)$$

Here, k_1, k_3, φ_1, and φ_3 are the rate constants and quantum yields of reactions (1) and (3), respectively.

If [PhOH] = 0, $[PhO^\bullet] = 0$, then $I = I_0 = k_1\varphi_1[ROO^\bullet]^2 = \varphi_1 V_i$. With increasing [PhOH], $[PhO^\bullet]$ tends to grow, and at a high phenol concentration $[PhP^\bullet] \gg [ROO^\bullet]$; hence, $I = I_{max} = k_3\varphi_3[ROO^\bullet][PhO^\bullet] = \text{const}$.

In contrast to the case of ethylbenzene [8], the CL in the oil is enhanced during the induction period of inhibited oxidation in the presence of activator. This can be associated with the influence exerted by the polarity of the substrate on the CL in reaction (3). To elucidate how the polarity of the medium affects I_{max}, we studied CL of the oil in the presence of the phenols upon introduction into the oil of a nonpolar solvent, benzene. The results are presented in Fig. 2a; it is seen that I_{max} tends to decrease with increasing benzene content in the system. This supports our earlier conclusions [8] that, in polar media, the energy levels of the forming excited product get higher; also, the probability of transition of quinone from the excited singlet state Q_{S_1} to the excited triplet state Q_{T_1} increases. A portion of the excited triplet molecules have time to transfer the excitation energy to the activator A:

$$ROO^{\cdot} + PhO^{\cdot} \xrightarrow{k_3} Q_{S_1} \xrightarrow{\text{Polar nolecule}} Q_{T_1} \xrightarrow{A} Q + A^{*}. \quad (5)$$

The intensity of CL in reaction (3) in the oil varies with the structure of the phenol and activity of the corresponding radical. This luminescence is characteristic only of the phenols capable of forming quinones by reaction (3). We characterized the activity of the phenoxy radicals in this reaction by the electron affinity E_A, which was calculated by the AM1 quantum-chemical semiempirical method in the software package [9] by the formula

$$E_A = H^0_{Ph^{\cdot}} - H^0_{PhO^{\cdot}}.$$

Here, E_A is the adiabatic electron affinity, and $H^0_{Ph^{\cdot}}$ and $H^0_{PhO^{\cdot}}$, the standard heats of formation of phenoxy radical anion and radical, respectively.

Figure 2b shows that, with increasing electron affinity of the phenoxy radical, CL in the induction period of oil oxidation inhibited by the corresponding phenol tends to increase in intensity. This supports the suggested mechanism of occurrence of an additional luminescence in the reaction involving phenoxy radical.

Since the introduction of the phenols into the oil being oxidized enhances CL, the rate constants k_2 of the reactions of these phenols with peroxy radicals of the oil cannot be calculated by the conventional procedure [7]. We calculated these constants by the procedure taking into account the CL by reaction (5) as well [10]. According to this procedure, the luminescence intensity in the presence of a phenol is described by Eq. (4). Based on the kinetic scheme of inhibited oxidation [1] and taking into account the steady-state

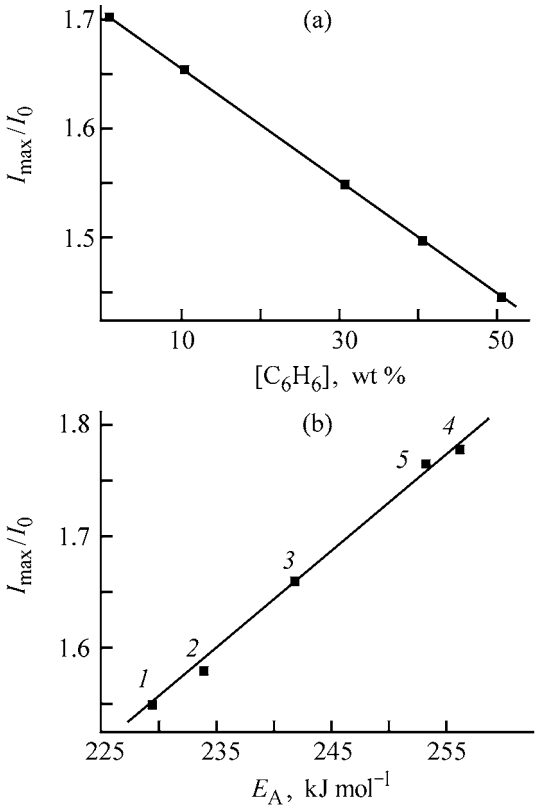

Fig. 2. I_{max}/I_0 vs. (a) benzene concentration $[C_6H_6]$ in a 1 : 1 oil : chlorobenzene mixture in the presence of pyrocatechic acid ($c = 4 \times 10^{-4}$ M) and (b) calculated electron affinity E_A of phenoxy radicals. (a) [AIBN] = 2×10^{-2}, [DBA] = 2×10^{-3} M, T = 343 K; (b) [PhOH] = 5×10^{-4} M. (*1*) phloroglucinol, (*2*) ethyl gallate, (*3*) gallic acid, (*4*) pyrocatechic acid, and (*5*) resorcinol.

concentration in the system of $ROO^{\cdot}$ and $PhO^{\cdot}$ radicals, we can write

$$\frac{d[ROO^{\cdot}]}{dt} = V_i - k_1[ROO^{\cdot}]^2 - k_2[ROO^{\cdot}][PhOH] = 0,$$

$$\frac{d[PhO^{\cdot}]}{dt} = k_2[ROO^{\cdot}][PhOH] - k_3[ROO^{\cdot}][PhO^{\cdot}] = 0.$$

By substituting $[ROO^{\cdot}]$ and $[PhO^{\cdot}]$ into Eq. (4), we obtain

$$\Delta I = (\eta_3 - 2\eta_1)\frac{k_2^2[PhOH]^2}{k_1}\left[\left(1 + \frac{V_i k_1}{k_2^2[PhOH]^2}\right)^{1/2} - 1\right]. \quad (6)$$

Equation (6) is mathematically transformed into

$$\Delta I = \frac{\varphi_3 - 2\varphi_1}{2} V_i - \frac{k_1}{2(\varphi_3 - 2\varphi_1)k_2^2}\frac{\Delta I^2}{[PhOH]^2}, \quad (7)$$

where $\Delta I = I_{max} - I_0$ and φ_1 and φ_3 are the quantum yields of CL for reactions (1) and (3), respectively.

Table 2. Calculated parameters $k_2/\sqrt{k_1}$ of selected phenols in initiated (AIBN) oxidation of ethylbenzene ($V_i = 4.9 \times 10^{-7}$ mol l^{-1} s^{-1}) at $T = 343$ K

Phenol	$k_2/\sqrt{k_1}$, l$^{1/2}$ mol$^{-1/2}$ s$^{-1/2}$		Phenol	$k_2/\sqrt{k_1}$, l$^{1/2}$ mol$^{-1/2}$ s$^{-1/2}$	
	oil : chlorobenzene = 1 : 1	ethylbenzene		oil : chlorobenzene = 1 : 1	ethylbenzene
Ethyl gallate	$(9.9 \pm 0.2) \times 10^1$	$(1.5 \pm 0.1) \times 10^2$	Pyrocatechic acid	8.0 ± 0.2	$(2.0 \pm 0.1) \times 10^1$
Gallic acid	$(6.9 \pm 0.2) \times 10^1$	$(1.30 \pm 0.09) \times 10^2$	Phloroglucinol	1.10 ± 0.04	2.6 ± 0.1

* The initiation rate V_i for sunflower oil was estimated as $V_i = f[\mathrm{PhOH}]/\tau$ with Ionol (inhibition coefficient $f = 2$ [11]) as reference inhibitor.

To calculate $k_2/\sqrt{k_1}$, we constructed the ΔI-vs.-[PhOH] plots (Fig. 1b), which were then linearized in the coordinates of Eq. (7). The $\eta_1 - 2\eta_2$ parameters were estimated from the intercepts on the ordinate, and $k_2/\sqrt{k_1}$, from the slope of the corresponding straight lines (Fig. 1b). Table 2 lists the $k_2/\sqrt{k_1}$ parameters calculated by this procedure for selected phenols in the oil against those in ethylbenzene. It is seen that these parameters exhibit similar trends in the series of the phenols studied and that the $k_2/\sqrt{k_1}$ parameters for the oil are lower, which is also a reason for the decrease in AOAs of the phenols in the oil.

CONCLUSION

In the course of inhibited oxidation of sunflower oil with luminescence activator in the presence of natural phenols, chemiluminescence is prominently enhanced in the induction period due to the influence exerted by the substrate (oil) on the luminescence arising in the reaction between phenoxy and peroxy radicals. The chemiluminescence intensity measured depends on the total contribution from the reactions responsible for the generation and quenching of luminescence in the system. The kinetic parameters for the oil oxidation, characterizing the antioxidative activity of the phenols, suggest a higher reactivity of natural *ortho* polyphenols (gallic acid and ethyl gallate, caffeic acid, and quercetin), compared to other phenols studied. At the same time, the antioxidative activity of the phenols in the oil is, on the whole, much lower than that in the case of ethylbenzene.

Abstract—A graft copolymer simulating glycoprotein was prepared by reaction of poly-*N*-methacryloylaminodeoxyglucose containing terminal amino group with a copolymer of *N*-vinylpyrrolidone and acrylic acid *N*-hydroxysuccinimide ester.

Synthetic glycopolymers attract growing researchers' interest as polymeric carriers for biologically active substances, immunomodulators, and as objects for studying molecular biorecognition mechanisms [1–5]. The molecular recognition is based on a specific interaction of macromolecular systems containing, in particular, carbohydrate and peptide fragments. Detailed understanding of the mechanisms of this interaction in natural polymeric systems is difficult because of their complex chemical and supramolecular structure. In this context, it is appropriate to study model systems with controllable chemical structures. Suitable objects are synthetic water-soluble polymers that contain recognizing fragments: carbohydrates, oligosaccharides, oligopeptides, or proteins. In this study, we developed a method for preparing a model system, graft copolymer with poly-*N*-vinylpyrrolidone (PVP) backbone (a model of peptide chains) and polyvinyl saccharide (namely, poly-*N*-methacryloylaminodeoxyglucose, PMAG) side chains.

Linear and cross-linked random copolymers of *N*-vinylpyrrolidone (VP) and other vinylamides with vinyl saccharides were described in [6–8]. Graft copolymers based on these monomers have been unknown previously.

The desired graft copolymers were prepared by reaction of a copolymer of *N*-vinylpyrrolidone and acrylic acid *N*-hydroxysuccinimide ester (VP–AA HSIE) with PMAG containing terminal primary amino group (PMAG-NH_2):

EXPERIMENTAL

The procedures for purifying *N*-vinylpyrrolidone and preparing AA HSIE were described in [9]. The VP–AA HSIE copolymer (88 : 12 mol %) was prepared by radical copolymerization of the corresponding monomers; after isolation, its composition was determined [9, 10]. PMAG-NH_2 was prepared by radical polymerization of the monomer in the presence of a chain-transfer agent, amino-containing mercaptan; it was characterized according to [11, 12]. To study the hydrodynamic characteristics of VP–AA HSIE copolymer and of a mechanical blend of the starting polymers with VP–AA HSIE copolymer, the reactive groups were removed with *n*-butylamine.

Exclusion chromatography of the polymers was performed on a KhZh-1309 gel microchromatograph (Scientific and Technical Society, USSR Academy of Sciences) equipped with a refractometric detector [13]. A 0.5 × 367-mm column was packed with TSK G3000PW sorbent (Japan); the eluent was 0.05 M sodium trifluoroacetate in water.

The centrifugal sedimentation of polymers was studied in 0.2 M NaCl on a Beckman XLI analytical ultracentrifuge in two-sector cells (12 mm) with titanium inserts at 57000 rpm. Rayleigh interference optics served as an optical recording system. Solutions of a concentration $c = 0.15 \times 10^{-2}$ g cm^{-3}, corresponding to strong dilution ($c[\eta] \ll 1$), were studied. The sedimentograms were processed using the Sedfit program [14]. The program allows the choice of the best numerical solution of the general Lamm sedimentation equation [14] for a set of noninteracting particles (molecules). The set of such solutions gives the total calculated interferograms that fit the experimental interferograms to the maximum possible extent. By this procedure we obtain the sample distribution with respect to sedimentation coefficients, which may be multimodal (multipeak) in the general case. The program allows determination of the weight fraction of each distribution; the sum of all the fractions is unity. The floatability factor $1 - \nu\rho_0$ of the system was determined from the measured densities of solutions of various concentrations (DMA Kratky densimeter [15], Anton Paar, Graz, Austria).

The high reactivity of polymeric AA HSIE [16] allows its reaction with amines to be performed at room temperature. The reaction between the starting polymers was performed in dimethylformamide for 24 h at room temperature. Then *n*-butylamine was added to remove unchanged AA HSIE groups. The reaction product was isolated by precipitation into ethanol, in which PMAG is insoluble [12], but PVP is soluble.

The molecular weights M_η of the starting polymers, PMAG-NH_2 and VP–AA HSIE copolymer containing 12.0 mol % AA HSIE units, were calculated from the intrinsic viscosity, using the Kuhn–Mark–Houwink–Sakurada (KMHS) relationships [10, 12] (see table). Since the content of AA HSIE units was low, M_η of VP–AA HSIE copolymer was calculated with the equation obtained for PVP [10].

A sedimentation analysis showed that the starting VP–AA HSIE copolymer has a unimodal distribution, whereas PMAG-NH_2 is bimodal. When estimating M_s from the sedimentation coefficients, we used the following relationships: $s_0 = 3.55 \times 10^{-15} M^{0.44}$ (for PMAG) [12] and $s_0 = 1.28 \times 10^{-15} M^{0.47}$ (for PBP) [10]. The *M* values calculated from the intrinsic viscosity and sedimentation coefficient are reasonably consistent (see table).

In the distribution of the reaction product with respect to the sedimentation coefficient, there is a fraction with the sedimentation coefficient of 2.3 Svedberg units, close to that found for the starting polymers (see table). At the same time, another fraction appears, with the sedimentation coefficients distributed in a wider range: $3.9 < s < 5.0$ Svedberg units. This fact suggests the presence of heavier macromolecules of the graft copolymer. It is known that the sedimentation coefficient *s* is directly proportional to *M* and inversely proportional to the size of a moving molecule [17]. Therefore, we can generally determine from the sedimentation coefficient only the ratio *M*/*R*,

where R is the hydrodynamic size of the molecule in friction. Estimation of the molecular weight of the graft copolymer from a single hydrodynamic characteristic seems to be impossible, because KMHS-type correlations for it are unknown.

Comparison of the chromatograms (see figure) of the starting VP–AA HSIE and PMAG–NH_2 copolymers, their mechanical blend, and reaction product shows that, in contrast to the blend of the starting polymers, the chromatogram of the reaction product contains new peaks with small retention volumes. These peaks suggest the formation of graft copolymers of higher molecular weight, compared to the starting polymers, which is consistent with centrifugal sedimentation data.

In independent experiments, we obtained the density increment $\Delta\rho/\Delta c$ of the reaction product, from which we determined its specific partial volume: $\nu = 0.707$ cm^3 g^{-1}. From this value, it is possible to estimate, to a first approximation, the composition of the reaction product. This was done as follows. First, we determined [10, 12] ν for PVP and PMAG: $\nu_{PVP} = 0.778$ and $\nu_{PMAG} = 0.669$ cm^3 g^{-1}. The reaction product was isolated by precipitation into ethanol, in which PVP is soluble, but PMAG is not and precipitates. If the low-molecular-weight peak in the sedimentogram is due to the presence in the unchanged form of only one of the starting polymers, PMAG, then the specific partial volume corresponding to the graft copolymer can be calculated from the following relationship (assuming the additivity of the specific partial volumes):

$$\nu_{product} = \nu_{graft} x + \nu_{PMAG}(1 - x),$$

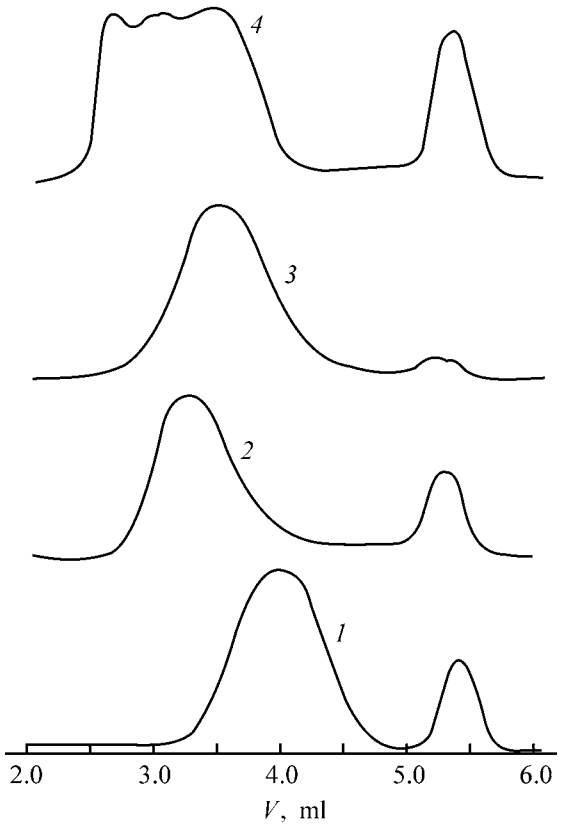
where x is the fraction of the graft copolymer in the reaction product.

We obtain $\nu_{graft} = 0.764$ cm^3 g^{-1}, which can be used for estimating the composition of the graft copolymer:

$$\nu_{graft} = \nu_{PVP} y + \nu_{PMAG}(1 - y),$$

where y is the PVP fraction in the graft copolymer; we obtained $y = 0.35$.

Thus, using two independent methods, we proved the possibility of preparing graft copolymers by the reaction of two polymers containing mutually reactive activated ester and amino groups in the side chain and at the end of the macromolecule, respectively.



Chromatograms of the polymers. Eluent 0.05 M sodium trifluoroacetate in water, elution rate 3 μl min^{-1}, 25°C. (V) Retention volume. (*1*) PMAG-NH_2, (*2*) VP–AA HSIE copolymer, (*3*) mechanical blend of the starting polymers, and (*4*) reaction product.

CONCLUSIONS

(1) A graft copolymer with polyvinylpyrrolidone backbone and poly-*N*-methacryloylaminodeoxyglucose side chains was prepared by the reaction of poly-*N*-methacryloylaminodeoxyglucose with a copolymer of *N*-vinylpyrrolidone and acrylic acid *N*-hydroxysuccinimide ester.

(2) The hydrodynamic parameters of the copolymer obtained were calculated.

Abstract—Mechanical properties, optical transmission, surface topography, and dielectric loss are studied for films formed by blends of polymers of vinyl chloride and methyl methacrylate with their copolymers.

The development of new polymeric materials based on blends of large-scale polymers is one of the most promising areas of research on the way to modification of properties of polymers. In this context, a major interest was focused on the system poly(methyl methacrylate) (PMMA)–poly(vinyl chloride) (PVC), which has been studied in detail by 2D NMR spectroscopy, differential scanning calorimetry, X-ray diffraction [1], electron microscopy [2], and microcalorimetry [3, 4]. It was concluded in most studies that PMMA and PVC are incompatible [1, 5–7]. In particular, Li *et al.* [7] have drawn such a conclusion on the basis of the fact that two glass transition temperatures were found over the entire composition range of the blends. Our thought is that the compatibility of this pair of polymers can be improved by introducing a third component, vinyl chloride (VC)/methyl methacrylate (MMA) copolymer, into the system. Therefore, the goal of this study was to examine in detail blends of VC and MMA homopolymers with VC/MMA copolymer.

EXPERIMENTAL

Homopolymerization of VC and MMA and copolymerization of these monomers were carried out by the suspension method in a specially designed 3.5-l laboratory autoclave equipped with a 200-rpm impeller agitator, a doser, a sampler, and a cooling jacket. The MMA and VC monomers met the requirements of GOST (State Standard) 20 370–74 and TU (Technical Specifications) 6-01-14–90. The content of the main component in both cases was no less than 99.9%. In synthesis of PVC and VC-rich copolymers, we used as an emulsifier F-50 hydroxypropyl methyl cellulose (HPMC) containing 28.5 wt % methoxy groups and 7.0 wt % hydroxypropyl groups. In preparation of PMMA and MMA-rich copolymers, we used the saponification product of the copolymer of methacrylic acid (78.8 wt %) and MMA (21.2 wt %). As initiators we used di-2-ethylhexyl peroxydicarbonate (EHPC) and lauryl peroxide (LP), and as chain-terminating agents, 0.2 wt % lauryl mercaptans (in preparation of MMA-rich copolymers) and 0.75 wt % trichloroethylene (TCE) (in preparation of VC-rich copolymers). The liquor ratio (water to monomer ratio) was 2 : 1 and 5 : 1 in VC- and MMA-rich systems, respectively. The synthesis of PMMA with low (<10 wt %) VC content was carried out at 80°C. In this case, the reaction mass was rapidly cooled after 1–3 h. The synthesis of PVC and VC-rich copolymers was performed at 66°C until the pressure in the autoclave decreased by 0.5 atm, which corresponded to a 75% consumption of VC. Copolymers with increased degree of homogeneity (DH) were obtained by stepwise addition of the more reactive monomer, MMA, under nitrogen pressure. To the initial mixture of VC (800 g) and MMA (40 g), three 40-g portions of MMA were added at 3.5-h intervals. The polymers were separated from the mother liquor on a Buchner funnel, washed with distilled water, and dried in an oven at 60°C. The conversion was determined gravimetrically. The composition of the VC/MMA copolymers was determined

from the chlorine content according to GOST 25303–92. The method is based on complete burning of a sample in an oxygen flow, followed by chlorine determination by titration with mercury nitrate. The molecular weight (MW) of PVC and VC-rich copolymers was determined viscometrically in cyclohexanone at 25°C, using the Mark–Kuhn–Houwink equation:

$$[\eta] = KM^{\alpha} \quad (K = 1.37 \times 10^{-4},\ \alpha = 0.78).$$

For PMMA and MMA-rich copolymers, $K = 5.91 \times 10^{-4}$ and $\alpha = 0.57$ (solvent methyl ethyl ketone; temperature 30°C) [8]. The films were obtained by casting organic solutions of the mixtures in hand onto a glass support. The film thickness ranged within 0.15 ± 0.01 mm. The transmittance was determined using a KF-77 photoelectric colorimeter. The films with a transmittance of 100–80, 80–30, and <30% were classified as transparent, semitransparent, and opaque, respectively. The mechanical tests were performed on an RMI-5 tensile-testing machine.

* Conversion 36.5%.

** Copolymer with increased compositional homogeneity.

Copolymerization of VC with MMA is complicated by the more rapid exhaustion of the more reactive monomer. Figure 1 shows the conversion dependences of the instantaneous composition of the copolymer, estimated from the relative reactivity of the monomers $r_1 = 0.11$ and $r_2 = 12.73$ (here and hereinafter, indices 1 and 2 refer to VC and MMA, respectively). It is significant that these values were obtained from data on copolymerization [9]. It is seen from Fig. 1 that, in copolymerization of the mixtures enriched with VC to a considerable extent, PVC homopolymer is formed even at intermediate conversions. Therefore, to obtain the copolymer as the only product, the process should be completed on reaching relatively low (30–40%) conversions. This is cost-inefficient, and, moreover, makes no sense if the goal is to prepare PVC–PMMA copolymer blends. Therefore, copolymerization of VC-rich VC–MMA mixtures was performed until reaching the maximal conversions. In this case, the product was a blend of PVC with VC/MMA copolymer. The composition of such blends was determined as follows. First, the conversion corresponding to the onset of PVC formation (conventionally defined as that corresponding to 99 mol % VC + 1 mol % MMA) was estimated from the theoretical dependence of the instantaneous composition of the copolymer on the conversion. Second, the bulk composition of the copolymer was determined as

$$q_o' \bar{m}_1 = M_{10} - M_1(1 - q_o'),$$

where q_o' is the conversion corresponding to the onset of PVC formation (wt %); $\bar{m}_1$, bulk composition of the copolymer; and M_{10} and M_1 are the initial and instantaneous mole fractions of the monomer in the mixtures.

Then we determined the PVC content (wt %) in the copolymerization product:

$$\text{PVC} = q_{\text{lim}} - q_o',$$

where q_{lim} is the experimental limiting conversion (wt %).

Characteristics of the copolymerization products are listed in Table 1. At [VC]/[MMA] < 1, they are copolymers, and at [VC]/[MMA] > 1, a blend of the

Fig. 2. (*I*) Optical transmission and (*c*) PMMA content; the same for Fig. 3.

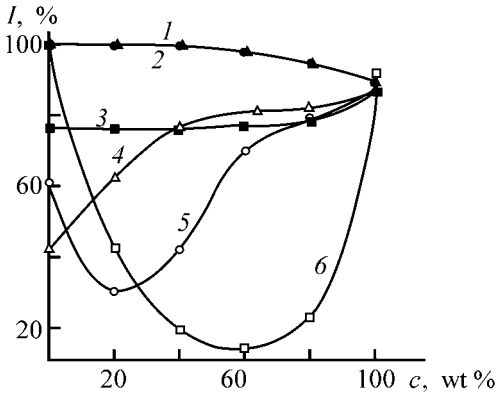

Fig. 3. Optical transmission of mixed films from PVC blends: (*1*) PVC1–MMA/VC copolymer (10.1 wt % VC); (*2*) PVC1–MMA/VC copolymer of high compositional homogeneity (74 wt % VC); (*3*, *4*, *5*) PVC1–MMA/PC copolymerization products containing (*3*) 94.1, (*4*) 89, and (*5*) 84 wt % VC; and (*6*) PVC2–MMA/VC copolymer (10.1 wt % VC). Molecular weight: PVC1 4.7×10^4 and PVC2 9.0×10^4.

copolymer with PVC is formed. The relative contents of the products, estimated by the above-described procedure, are listed in Table 2.

Figures 2 and 3 show the most typical dependences illustrating how the composition of blends of MMA and VC homopolymers with products of their copolymerization affects the optical transmission of the resulting films. The films from PVC–PMMA (Fig. 2, curve *4*) and PMMA–MMA/VC copolymer (curve *3*) blends are opaque at a low MMA contents (minimal optical transmission is observed for the compositions with 20–30 wt % MMA).

The copolymers with a considerable MMA content (4.5, 10.1, 29.5, and 46.5 wt % VC) form transparent films when taken in combination with both PMMA and PVC over the entire composition ranges. Typical examples are given in Figs. 2 and 3 (curves *1*). This is also true for the copolymer with a lower MMA content (26 wt %), but with increased compositional homogeneity (Figs. 2 and 3, curves *2*).

The blends of the VC-rich copolymerization products (78.9, 84.9, 89.0, and 94.1 wt % VC) form opaque films with PMMA and semitransparent films with PVC (Fig. 2, curve *5*; Fig. 3, curves *3*–*5*).

For the blends containing VC/MMA copolymer (10.1 wt % VC, 89.9 wt % MMA), the changing molecular weight of PMMA from 4.2×10^4 to 1.16×10^5 had no effect on the optical transmission of the film, which was close to 100%, while increasing the molecular weight of PVC from 4.7×10^4 to 9.0×10^4 resulted in that the films became opaque (Fig. 3, curves *1* and *6*).

PVC–PMMA–copolymer (or copolymerization product) ternary blends were characterized by the Gibbs diagrams. We measured the optical transmission of the films over the entire composition range. The optical transmission of ternary films mostly correlated with that of the binary films containing common components. If some copolymer or VC/MMA copolymer-

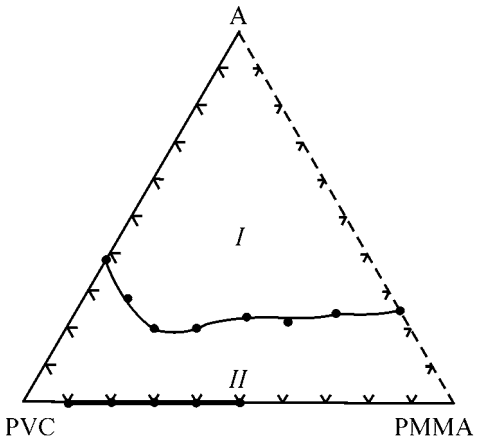

Fig. 4. Fields of compositions forming (*I*) opaque and (*II*) transparent films in the system PVC–PMMA–copolymerization product (89 wt % VC, 11 wt % MMA), composed by PVC and copolymer A (79.1 wt % VC, 20.9 wt % MMA).

ization product forms transparent films, being taken in combination with both PVC and PMMA, then, with rare exception, ternary films are transparent also. For example, the ternary films containing MMA-rich copolymers are mostly transparent. The ternary films with copolymerization products with high VC content form both transparent and opaque films. Let us consider, for example, copolymerization product no. 11 (89 wt % VC–11 wt % MMA) (Table 1). It follows from the results of a theoretical estimation by the above-described procedure that this product is a mixture of PVC (26.4 wt %) and VC/MMA copolymer (79.1 wt % VC). Figure 4 shows the Gibbs diagram with this copolymer as a separate component, but not the copolymerization product as a whole. Its another fraction, PVC, is summed with the corresponding component added to the mixture.

Field *II* corresponds to the compositions of transparent films, and field *I*, of opaque films. Binary blends copolymer–PMMA cannot be obtained, as the copolymer is initially mixed with PVC, and, therefore, the corresponding axis is given as a dashed line. In the PVC–PMMA axis, we distinguish a segment corresponding to PVC–PMMA blends forming opaque films.

The use of VC/MMA copolymers with comparable VC and MMA contents (31.9% MMA–68.1% VC; 42.3% MMA–57.7% VC) as the third component provides formation of films with an optical transmission of 80%. In both cases, the most transparent films are formed from blends containing 20% of the copolymer, PVC (70–50%), and PMMA (10–30%). It was interesting to analyze the correlations between the optical transmission of the films and their structural and mechanical characteristics. Data for films of close compositions, containing from 80 to 83.6% VC, are listed in Table 3. The lowest strength was observed for opaque PMMA– PVC binary films, and the highest strength, for transparent PMMA–PVC–copolymer ternary films. With close total relative content of the monomeric units, the increase in the strength appeared to be rather significant (by a factor of about 2), with the relative elongation remaining practically unchanged (within 16–20%). The compositions selected for comparison contain large amounts of the VC units. Such a decision was made taking into account such factors as the low cost of the base monomer and the incombustibility of PVC and PVC-based materials, which is significant from the practical standpoint.

To elucidate the features characteristic of the transparent and opaque films formed by PVC–PMMA blend compositions, we performed dielcometric and scanning electron microscopic experiments. Figure 5 shows the surface topography at side illumination of the opaque film composed by a blend of 80% PVC and 20% PMMA and also of the transparent film (*I* = 80%, Fig. 3) consisting of 70% PVC and 30% copolymer (89% VC, 11% MMA). As seen, the surface of the opaque film is more developed, with grains 2,5–3 μm in size. On the surface of the opaque film, the intergrain boundaries are more diffuse, and the grains are considerably smaller, being about 1 μm in size. Data on the surface topography of the films at normal illumination show considerable differences in the surface roughness (1.66 and 0.14 μm for opaque and transparent films, respectively), also suggesting that the surface of the opaque films is more developed.

Since formation of a highly developed rough surface is thermodynamically unfavorable because of

Table 3. Strength and optical transmission of binary and ternary mixtures of MMA and VC copolymers

Composition, wt %	Total VC and MMA contents, wt %	σ, MPa	*I*, %
20 PMMA–80 PVC	20 PMMA–80 PVC	1.34	5
20 copolymer (89.9 MMA–10.1 VC)–80 PVC	18 PMMA–82 PVC	2.08	100
20 copolymer (31.9 MMA–68.1 VC)–10 PMMA–70 PVC	16.4 PMMA–83.6 PVC	2.90	80
20 copolymer (42.3 MMA–57.7 VC)–10 PMMA–70 PVC	18.5 PMMA–81.5 PVC	2.46	80

the higher surface free energy as compared to a smooth surface, it may be concluded that formation of a smooth surface is impeded by the incompatibility of the components. The surface of the transparent film is considerably less rough, suggesting better compatibility of the components in this case.

Figure 6 shows the temperature dependence of the dielectric loss tangent for the films formed by PVC, PMMA, a blend of 80% PVC and 20% PMMA, and binary and ternary blends containing the copolymerization product (89% VC, 11% MMA). For the blend polymer (curve *1*), a characteristic plateau is observed, while the curves of the homopolymers pass through a maximum corresponding to the glass transition (75 and 110°C for PVC and PMMA, respectively). It may be suggested that the weakly pronounced plateau in curve *3* (Fig. 6) is a result of superposition of the peaks characteristic of the components of an incompatible or partly compatible polymer blend. In all the cases of the binary and ternary blends of the copolymers with the homopolymers, only one peak is observed.

The results show that the properties of the films formed by blends of PVC and PMMA and VC/MMA copolymers depend on the extent of compatibility of the components. The dielcometric data obtained for the blends containing the copolymers suggest a higher level of compatibility of the components as compared to PMMA–PVC blends, which is also supported by the SEM data. Therefore, it may be concluded that the effect of interpenetration of the polymer networks in PVC–PMMA mixtures is considerably enhanced in the presence of VC/MMA copolymers. As a result, the polymer blend becomes more homogeneous, which is reflected, in particular, in erosion of the phase boundaries as a result of formation of a transition layer consisting of segments of all the components.

CONCLUSIONS

(1) Suspension copolymerization of vinyl chloride with methyl methacrylate can be performed to high conversions over a wide range of compositions of monomer mixtures. In PVC-rich systems, poly(vinyl chloride) is formed in the final stage of the process, as a result of strongly different copolymerization constants.

(2) Poly(vinyl chloride)–poly(methyl methacrylate) blends enriched in PVC form opaque films. The use of PVC/MMA copolymers as a component of the blends allows preparation of transparent films from blends of any composition.

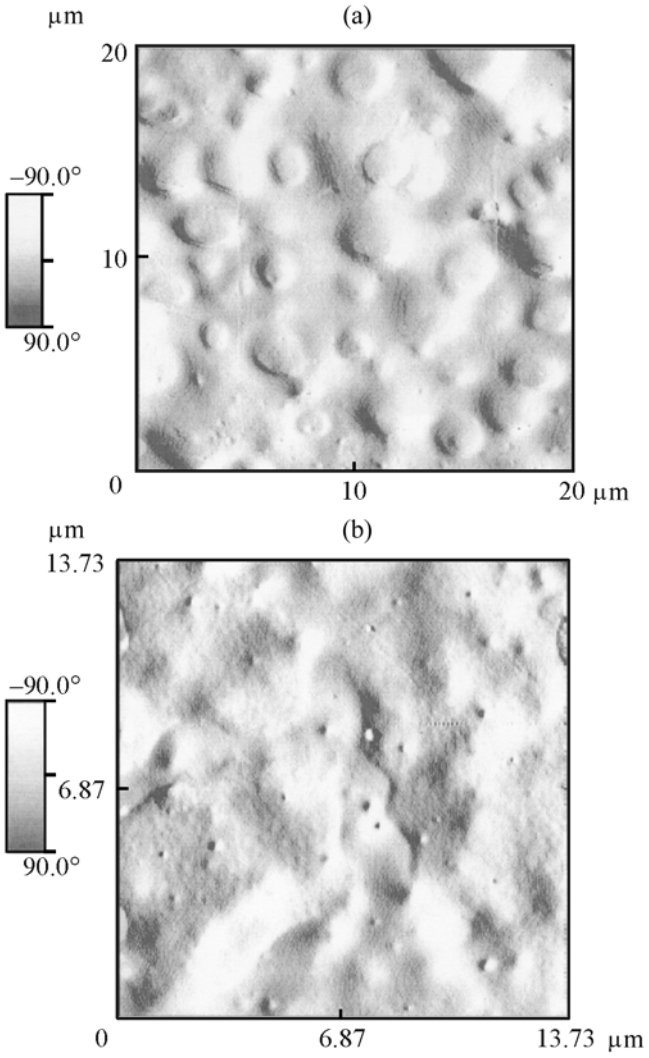

Fig. 5. Surface topography of the films: (a) 80% PVC–20% PMMA and (b) 70% PVC–30% copolymerization product (89% VC, 11% MMA).

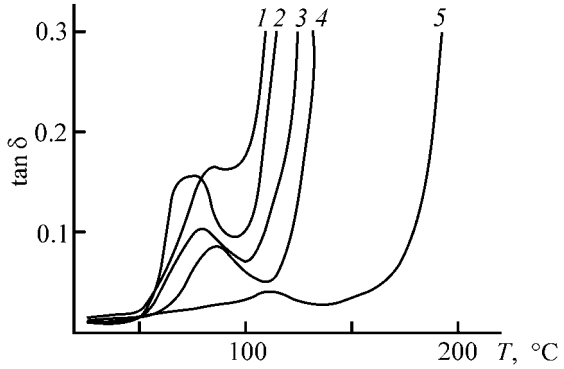

Fig. 6. Dielectric loss tangent tan δ vs. the temperature *T*. Film composition (%): (*1*) PVC + PMMA, (*2*) PVC, (*3*) 70 PVC–30 copolymerization product (89 VC), (*4*) 20 copolymerization product 89 VC–60 PVC–20 PMMA, and (*5*) PMMA.

(3) Transparent films formed by blends of the polymers and PVC/MMA copolymers demonstrate a higher strength as compared to opaque films of similar compositions. This can be attributed to better compatibility of components, as demonstrated by the dielcometric and scanning electron microscopic data.

Abstract—Low-temperature carbonization of hydroxyethyl, allyloxyethyl, and allylcarboxymethyl cellulose ethers and their copolymers with polyacrylonitrile was studied. The quantitative relationships between the degree of carbonization, on the one hand, and the degree of substitution of cellulose hydroxy groups and chemical structure of the substituents, on the other, were established. The dependence of the carbon residue on the amount of grafted polyacrylonitrile chains tends to a certain limit. The carbon residue depends on the atmosphere in which the carbonization is performed.

Graft copolymers of cellulose and polyacrylonitrile (PAN) simulate the structure of precarbonizates obtained by joint thermolysis of cellulose and its nitrogen-containing derivatives with PAN [1].

In this study, we examined the behavior of cellulose ethers (hydroxyethyl, HOEC; allyloxyethyl, AOEC; allylcarboxymethyl, ACMC) and their graft copolymers with PAN (AOEC–PAN, ACMC–PAN) at heating in the range 20–900°C in a vacuum, in a self-generated atmosphere (SGA) and in CO_2. Our goal was to find synthetic routes to carbon compounds based on cellulose derivatives and to elucidate the influence of nitrogen-containing polymers on the yield of the forming carbonizates.

EXPERIMENTAL

The cellulose ethers and PAN were prepared by published procedures (see references in [1]).

The kinetics of thermochemical transformations in various gas media were studied by thermovolumetric analysis (TVA) with manometric recording [2]. The behavior of the samples in SGA was studied on an MOM C derivatograph [3] with recording of the weight loss and thermal effects. Carbonization of the compounds in a CO_2 atmosphere was studied with an STA 429 device (Netzsch), with recording of the same parameters [4].

In accordance with the principal goal of our study, determination of carbonization conditions ensuring the maximal carbon residue (CR), we performed express analysis of the samples in SGA. As noted previously, carbonization of cellulose ethers and some other cellulose derivatives occurs mainly in three steps; their kinetic features were considered in [1, 5–9]. The most interesting for us, in the context of this study, were the quantitative and specific qualitative characteristics directly related to the carbonization step occurring, as a rule, above 400–500°C.

Comparison of the main parameters characterizing degradation and cross-linking (carbonization) of our samples (Table 1) reveals the following facts. The ethers in hand show relatively poor heat resistance, compared to PAN (the weight loss due to dehydration up to the temperature T_0 is 10–15%), and CR at 800°C is within 0–13%. Thermal degradation and cross-linking, according to TGA (Fig. 1a), occur in two steps. For cellulose ethers, in the first step in the range 200–350°C, degradation occurs with the release of a large amount of volatiles (up to 70% weight loss, depending on the structure of substituents). As seen from the DTA curves (Fig. 1b), degradation is exothermic; it involves several reactions: dehydration, decarboxylation, and formation and release of levoglucosan. The peaks of these reactions lie in the same range, 250 ± 20°C. The sharp exothermic peak

in the DTA curve of PAN, corresponding to the onset of its cyclization [10] (Fig. 1b, curve *4*), lies in the same range. These facts suggest that, in joint thermolysis of cellulose ethers and PAN in the range 200–350°C, reactions involving the reactive products can shift the degradation–cross-linking balance toward cross-linking. To substantiate this assumption, we considered the thermal characteristics of graft AOEC and ACMC copolymers with various degrees of substitution, γ, and various degrees of PAN grafting, *C*. Table 1 shows that grafting of small amounts of PAN to both ethers increases CR by a factor of 3–4 and noticeably enhances the overall heat resistance of the cellulose ethers. As *C* for AOEC–PAN grows, CR increases to 44.5%. For ACMC–PAN samples, the highest CR value was obtained at the highest *C* value, *C* = 670.

The enhancement of the heat resistance and the increase in the carbon residue in carbonization of graft copolymers are apparently due to formation of cross-

* (T_{max}) Temperature of the exothermic peak.

linked structures by reactions of allyl groups with nitrile nitrogen or reactions involving the degradation products (radicals, intermediates). With ACMC–PAN, the first steps of degradation may be accompanied by condensation of carboxy groups with amino groups arising in the course of PAN degradation.

The increased CR of the graft copolymers, compared to CR of pure PAN, indicates that the cellulose ethers are involved in cocarbonization with PAN. This fact shows that it is promising to use PAN for modification of carbonizates of cellulose derivatives under appropriate cocarbonization conditions differing from dynamic heating in SGA.

It is known that the carbon residue in carbonization of cellulose materials in some cases appreciably increases when the carbonization is performed in CO_2 [11]. To find whether this is the case for our system, we performed a combined TG–DSC analysis of the samples under dynamic conditions in a CO_2 atmosphere at temperatures of up to 800°C (Table 2).

Comparison of the thermal characteristics of the samples heat-treated in SGA and CO_2 shows that the balance of thermochemical degradation and cross-linking shifts toward formation of cross-linked carbonized products. Saturation of the surrounding atmosphere with degradation products causes an appreciable increase in CR; this parameter reaches 60% for the copolymers. The heat resistance, especially T_{50}, increases also. Presumably, the changes mainly concern thermolysis of cellulose ethers; their CR increases by almost an order of magnitude when the samples are heat-treated in CO_2. The heat resistance parameters and CR of the graft copolymers increase also, but this trend is less pronounced, compared to the ethers.

Thus, we confirmed once more the previous data [12] that the rate of PAN cyclization in the initial heating steps (250–300°C) is independent of the ambient atmosphere.

Similar features are observed in thermolysis of graft copolymers of PAN with AOEC and ACMC in a vacuum. At any degree of grafting, the TVA curve, similarly to the DTA and DSC curves, contains a very sharp, "bursting" peak corresponding to the onset of PAN cyclization. Even at small C, this peak appears at the same temperature; only its area proportionally changes. At higher temperatures, the effect of PAN on the formation of the cocarbonizate with cellulose ethers varies, depending on the composition of the surrounding gas phase and on the temperature mode. As shown by our experiments, the CR varied under dynamic heating conditions in opposite direction with the heating rate and depended also on the chemical structure of the cellulose ether, values of γ and C, and temperature range of heating; the dependence for all the samples is proportional. For example, the CR of the PAN–AOEC samples, compared to PAN–ACMC samples, is higher if the thermolysis in the range 150–300°C is performed faster. This may be due to competition of degradation through the hydroxy and carboxy groups of the ethers with cross-linking through the allyl groups. Above 300°C, the difference is less pronounced, but the PAN fragments play a more significant role in the thermolysis under these conditions.

In the case of isothermal carbonization mode (expected to be favorable for attaining maximal CR), there are no clear correlations with the temperature and time of the process. Experiments on isothermal heating of the samples at 200°C in a vacuum for 10 h and at 300°C in SGA for 4 h revealed only the expected dependence of the CR on the ambient gas medium. In thermolysis in a vacuum, i.e., under conditions of continuous removal of degradation products, the CR is approximately 10–15% lower, compared to the heat treatment in SGA. As for the time of heat treatment and temperature, the CR of cellulose ethers and copolymers shows no direct correlation with these parameters. As in experiments on dynamic heating,

the competition of degradation and cross-linking should be taken into account in some cases; the development of these processes is closely associated with the chemical structure of the polymers. For example, the CR of an AOEC sample with $\gamma = 8$ after heating for 10 h in a vacuum at 200°C is 40.7%, whereas the copolymer with PAN under the same conditions gives a CR of 27.6%. Furthermore, there is no direct correlation even with the PAN content: As the PAN content increases, the CR varies from 49 to 38%, passing through a minimum (27%).

One more interesting feature of the carbonization of the examined cellulose ethers and their copolymers with PAN in SGA is the appearance of endothermic peaks at 450–600°C in the DTA curves (Fig. 1b, curves *3* and *4*). It is clearly seen that, when a sample of PAN–AOEC copolymer ($C = 480$) is heated at a constant rate, endothermic peaks appear at 441 and 535°C. Similar, but weaker peaks at 471 and 553°C are seen in the DTA curve of PAN. Related peaks, slightly differing in the position and differing in the area, are also observed in the DTA curves of the other copolymers with different degrees of PAN grafting. These endothermic peaks are apparently associated with the formation of ordered areas in the carbonizate structure. The shapes and intensities of these peaks suggest that the initiator of the formation of the ordered crystallite-like structures is PAN, but carbonizates of cellulose ethers are also involved in the processes, increasing the degree of orientation of the ordered areas. Special spectroscopic studies are required to gain insight into this phenomenon; here we can tentatively suggest formation of primary turbostratic structures with various degrees of ordering in this temperature range of precarbonization. Depending on the concentration and mutual orientation of the cyclic products of the reaction of PAN and AOEC, intermediate polycyclic compounds with a crystalline structure can form, and their melting is detected by DTA. Similar effects have also been observed with PAN–ACMC copolymers, with the only difference that the endothermic effect was the most pronounced in the range 440–460°C [1].

Both the carbonization and degradation are influenced by the ambient atmosphere. For example, when thermolysis is performed in CO_2, changes occur only in the carbonizate structure originating from cellulose ethers, and no ordered structures are formed. No structural rearrangements are observed in the copolymers in the range from 400 to 800°C. As for carbonization in a vacuum, a noticeable weight loss below 500°C and a certain release of hydrogen above 650°C cause loosening and amorphization of the carbonizate.

CONCLUSIONS

(1) Hydroxyethyl, allyloxyethyl, and allylcarboxymethyl cellulose ethers and their graft copolymers with acrylonitrile show promise for preparation of carbon compounds.

(2) The composition of the surrounding atmosphere in carbonization exerts a decisive influence on the carbon residue, which reaches 30–40% for some ethers.

(3) In carbonization of graft copolymers in CO_2, the carbon residue reaches 55–60%.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Controlling the Viscosity of Melts of Partially Crystalline Polyimides Used for Preparing Carbon-Reinforced Plastics

T. A. Kostereva, Yu. N. Panov, A. L. Didenko, I. G. Silinskaya, V. M. Svetlichnyi, V. E. Yudin, and V. V. Kudryavtsev

Abstract—The influence exerted by the molecular weight of partially crystalline polyimide derived from 4,4'-bis(4-aminophenoxy)diphenyl and 1,3-bis(3,4-dicarboxyphenoxy)benzene on the viscosity of its melt was studied.

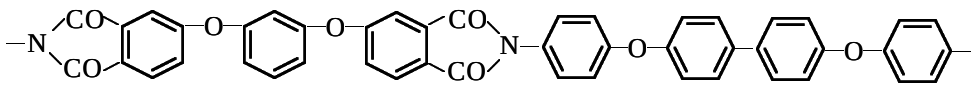
Composites with a partially crystalline polyimide (PI) matrix are promising structural materials. This matrix exhibits high mechanical and adhesion parameters, enhanced resistance to solvents, and high resistance to heat and thermal oxidation. Composite materials based on such a polymer exhibit an increased interlayer failure viscosity in combination with a high softening point, determined not by glass transition but by the melting of the binder [1]. An important property of the PI binder is its capability to crystallize after melting and subsequent cooling. The crystallizability of the polymer increases with a decrease in the molecular weight of PI and on addition of a bisimide structurally related to the macromolecule unit or diamine moiety [2]. The film-forming properties of the binder are preserved when the molecular weight of the polymer compounded with a bisimide is decreased only to a strictly definite level.

Apparently, the melting point and viscosity of PI depend on its molecular weight and on the bisimide added. When preparing a composite from a prepreg, it is necessary to know the behavior of the melt of the polymeric matrix (polymeric compound).

Our goals were to determine how the viscosity of the melt of a PI compound varies with time, depending on the molecular weight of the starting PI and on the bisimide content, and to find a formulation with a stable and relatively low melt viscosity.

EXPERIMENTAL

The polyimide derived from 1,3-bis(3,4-dicarboxyphenoxy)benzene dianhydride (R, mp 163–164°C) and 4,4'-bis(4-aminophenoxy)diphenyl (OP_2O, mp 193–194°C) was prepared in two stages [3]. In the first stage, we prepared a solution of the polyamido acid (PAA), which was applied to a glass support and dried. In the second stage, the resulting film was subjected to thermal imidization with step heating to 280°C. The chemical structure of PI is as follows:



R OP_2O

The molecular weight of PAA was decreased by varying the stoichiometric ratio of the monomers. In the first procedure, the dianhydride was taken for preparing PAA in a 3 or 5 mol % excess relative to the stoichiometry, and in the second procedure, the dianhydride was taken in a 3, 5, or 10 mol % deficiency relative to the diamine, with phthalic anhydride (PA) added in the final stage in the amount equivalent to the content of the remaining amino groups (6, 10, and 20 mol %, respectively).

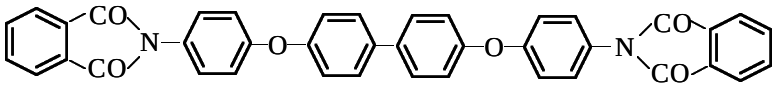
Table 1. Intrinsic viscosities and molecular weights of PAA

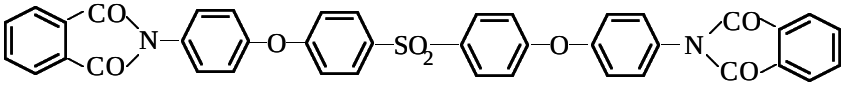
Sample no.	Dianhydride : diamine molar ratio	PA, mole	$[\eta]_{DMF}$, dl g^{-1}	$M_w \times 10^{-4}$	Sample no.	Dianhydride : diamine molar ratio	PA, mole	$[\eta]_{DMF}$, dl g^{-1}	$M_w \times 10^{-4}$
1	1.05 : 1	–	0.61	2.0	4	0.97 : 1	0.06	0.67	2.4
2	1.03 : 1	–	0.74	2.9	5	0.95 : 1	0.1	0.50	1.3
3	1 : 1	–	1.67	15.0	6	0.90 : 1	0.2	0.38	0.8

Bisimides 1 and 2 were prepared by thermal imidization of bisphthalamido acids prepared by the reaction of OP_2O and 4,4'-bis(p-aminophenoxy)diphenyl sulfone, respectively, with PA in 1 : 2 molar ratio in *N*-methylpyrrolidone (MP):

Bisimide 1



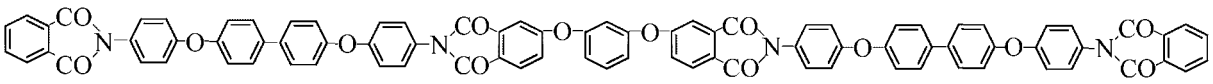
Bisimide 2



Bisimide 1 or 2 was added to a PAA solution in an amount of 1, 3, 5, or 10 wt %.

Oligoimide 3 was prepared by three-step synthesis. Reaction of a twofold excess of OP_2O with 1,3-bis-(3,4-dicarboxyphenoxy)benzene in MP gave the corresponding oligomeric diamino amido acid, to which we subsequently added phthalic anhydride in the amount equivalent to the amount of amino groups. The solution was imidized thermally, with azeotropic distillation of water with toluene, to obtain the oligoimide:

Oligoimide 3



The intrinsic viscosity of PAA [η] was measured with an Ubbelohde viscometer at 25°C in DMF. The molecular weight of the samples was determined by measuring the light scattering. The characteristics of the polymers are listed in Table 1.

The viscosities of PI solutions were measured on a PIRSP cone–plate rheogoniometer [4] (angle at the cone apex 1°, diameter 40 mm, shear rate 0.02 s^{-1}, 350°C).

Among samples prepared by the first procedure, only the polymer with MW 2.0×10^4 (sample no. 1) melts; higher-molecular-weight sample nos. 2 and 3 do not melt at 350°C. The initial viscosity of sample no. 1 was 1.4×10^4 Pa s; the viscosity rapidly grew in time, reaching 10^6 Pa s in 30 min.

To decrease the viscosity of melts, we added to PI 10 wt % bisimide 1, containing the same diamine fragment as the PI and acting as plasticizer [5]. However, sample no. 3 (MW 1.5×10^5) did not melt even at 350°C. For the other two samples, addition of bisimide 1 decreased the initial viscosity of the melt; the effect was more pronounced with PI of lower molecular weight (Fig. 1, curves *4*, *5*). Similarly to the sample without bisimide addition, the melt viscosity grew

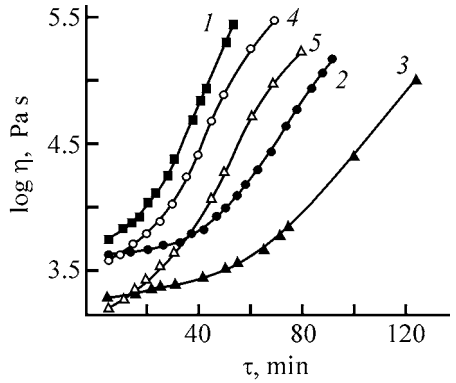


Fig. 1. Viscosity η of melts of sample nos. 1–3 with addition of (*1–3*) 10% bisimide 2 and (*4, 5*) 10% bisimide 1 vs. time τ. 350°C; $\gamma = 0.02\ s^{-1}$; the same for Fig. 2. R : OP_2O molar ratio: (*1*) 1 : 1, (*2, 4*) 1.03 : 1, and (*3, 5*) 1.05 : 1.

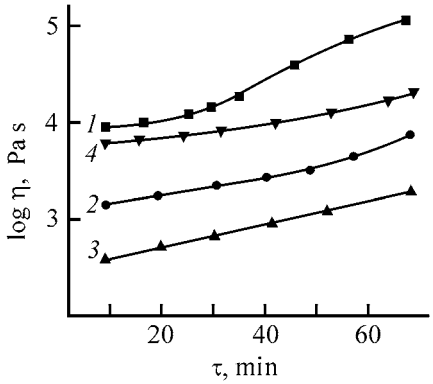

Fig. 2. Viscosity η of sample nos. 4–6 vs. time τ. R : OP_2O PA molar ratio: (*1*) 0.97 : 1 : 0.06, (*2*) 0.95 : 1 : 0.1, (*3*) 0.9 : 1 : 0.2, and (*4*) 0.97 : 1 : 0.06 with addition of 10 wt % bisimide 2.

fairly rapidly. The viscosity grows in two steps. The rates of these steps are equal for both samples (Table 2, sample nos. 4 and 5, b_1 and b_2).

Bisimide i is insoluble in amide solvents. Therefore, the system formed upon its mixing with PAA in MP is heterogeneous, and the performance of bisimide 1 as plasticizer for high-molecular-weight PI is poor. In the subsequent experiments, bisimide 1 was replaced with bisimide 2, which is soluble in MP owing to the introduction of an SO_2 bridge between the phenylene groups in the amine fragment. With this plasticizer, all the mixed systems melted at 350°C. The initial viscosities of melts of sample nos. 1 and 2 were the same as those of the samples with bisimide 1; the viscosity also grew in two steps (Fig. 1, curves *1–3*). However, the rate of viscosity growth in this case depends on the molecular weight of the PI. With lower-molecular-weight PI samples, the second step began later and at lower viscosities, and the viscosity growth was slower.

The viscosity growth with time was described by the relationship $\log \eta = a + bt$. Its parameters were determined from the slopes of the tangents to the experimental curve. The interception point of the tangents is the point of transition from the slow to the fast step (Table 2).

Thus, we found that only a compound of the lowest-molecular-weight PI with 10% bisimide 2 has the low initial viscosity of the melt and the viscosity grows slowly during relatively long time; however, the viscosity grows more steeply in the second step, probably owing to mutual linking of macromolecules through terminal groups at high temperature.

To eliminate this process, we used samples with PI of decreased molecular weight, obtained by the second procedure (endcapping with PA). The effect was demonstrated for the example of a compound modeling the chemical structure of PI (oligoimide 3). This oligoimide is crystalline, but its melting point is lower than that of PI. Therefore, its viscosity was measured at 330°C, and it remained virtually unchanged over a period of 2 h.

Figure 2 (curves *1–3*) shows how the viscosities of melts of sample nos. 4–6 (Table 1) vary with time. A decrease in MW by endcapping with PA resulted in a significant stabilization of the viscosity. However, only sample no. 4 with MW 2.4×10^4 showed satisfactory film-forming properties, necessary for obtaining composite PI materials with the required properties. This sample showed an insignificant growth of the viscosity with time. To further decelerate the viscosity growth, we compounded this polymer with 10% bisimide 2. As a result, we not only ensured the slowest growth of the melt viscosity (Fig. 2, curve *4*), but also decreased the initial viscosity of the melt.

Table 2. Coefficients of the equation $\log \eta = a + bt$ for the slow (1) and fast (2) steps of viscosity growth; time and viscosity corresponding to the transition from the slow to fast step

CONCLUSIONS

(1) The viscosity of melts of partially crystalline polyimide prepared from 1,3-bis(3,4-dicarboxyphenoxy)benzene dianhydride and 4,4'-bis(4-aminophenoxy)diphenyl and of its compounds with bisimides 1 and 2 rapidly grows with time.

(2) The initial viscosity of the melt decreases on compounding of the polyimide with 10 wt % bisimide 1 or 2. The viscosity growth decelerates with bisimide 2, soluble in *N*-methylpyrrolidone; the effect is the more pronounced, the lower the molecular weight of the initial polyimide.

(3) To obtain a polyimide whose melt would exhibit the viscosity most stable in time, the macromolecule ends can be capped with phthalimide groups. The viscosity characteristics of a compound of such polyimide with soluble bisimide 2 is the optimal for preparing composites.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Molecular Weight of Polyacrylic Acid on the Rate of Copper Dissolution

V. N. Kislenko and R. M. Verlinskaya

L'vovskaya Politekhnika National University, Lviv, Ukraine

Received October 16, 2003; in final form, April 2004

Abstract—The weight of polyacrylic acid adsorbed on copper from an aqueous solution and the rate of copper dissolution in the presence of hydrogen peroxide as functions of molecular weight of the polymer were studied.

Dispersions and solutions of acrylic polymers containing carboxy groups find growing use in metal-protection paints and adhesives. In this context, a need arises to study the processes on the metal surface being in contact with solutions of carboxyl-containing polymers. Numerous papers are devoted to the mechanism of adsorption of polymers from solutions [1–5], which is caused by the wide industrial use of this process. In the majority of publications, the conditions of adsorption equilibrium and kinetics of polymer adsorption were studied. A study of competitive adsorption of polymers from dilute and semidilute solutions of polymers [6–8] showed that, in a number of cases, one polymer is substituted for another polymer in the adsorption layer. Desorption of polymers has not been adequately studied. A study of polystyrene desorption under conditions of varied solvent flow upon the adsorbed polymer layer [9, 10] showed that, with increasing velocity gradient, the amount of the adsorbed polymer decreases, reaching a minimum. The thickness of the adsorption layer of polyacrylamide and polystyrene [11, 12] decreases with increasing velocity of the solvent flow over the layer.

A study of the kinetics of dissolution of copper(II) oxide in polyethylenimine [10] and polyacrylic acid (PAA) [11], dissolution of zinc oxide in PAA [12], and also adsorption of polymer at their surfaces showed that the rate at which the metal concentration in the solution grows depends on the amount of adsorbed polymer.

Here we studied the influence of molecular weight of PAA on the adsorption of the polymer at the copper surface and the rate of copper dissolution in aqueous solution of PAA and hydrogen peroxide [13–15].

As seen from Fig. 1 (curve *1*) and data listed in the table, the weight of PAA adsorbed on 1 m^2 of copper surface increases with increasing molecular weight of polymer and is virtually independent of the initial concentration of the polymer in the solution at its concentration above 10 g l^{-1}. The latter suggests that the saturation of the adsorption layer is reached in this range of PAA concentration.

The copper surface area occupied with one macromolecule in the saturated adsorption layer was evaluated by the formula

$$S_b = M/(AN_A), \quad (1)$$

where M is molecular weight of PAA, A is the weight of PAA adsorbed at the unit surface area, and N_A is the Avogadro number.

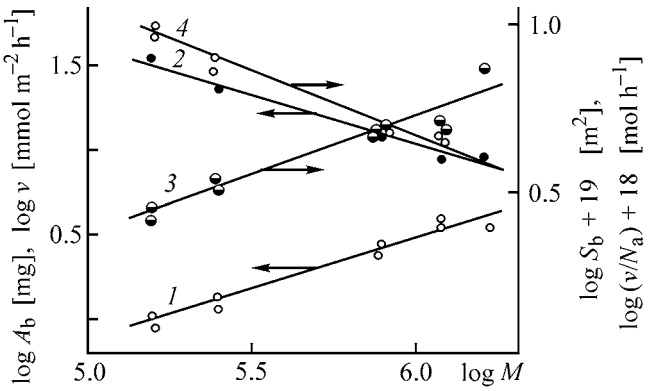

Fig. 1. (*1*) Weight of PAA adsorbed on 1 m^2 of copper surface A, (*2*) dissolution rate v, (*3*) surface area of copper occupied by one macromolecule S_b, and (*4*) ratio of the rate of copper dissolution to the amount of PAA macromolecules adsorbed on 1 m^2 of copper surface, v/N_a, vs. the molecular weight of PAA, M.

* Molecular-weight distribution.

As seen from the table, the surface area occupied by one macromolecule in the adsorption layer of the copper surface increases with increasing molecular weight of PAA.

The dependence of the surface area occupied by a macromolecule in the absorption layer on the molecular weight of the polymer is linear in the logarithmic coordinates. The correlation coefficient of the straight line is 0.949, and the slope, 0.35 ± 0.07. Hence, the dependence of the surface area occupied by a PAA macromolecule on its molecular weight can be written as

$$S_b = 10^{-17.4} M^{0.35}. \quad (2)$$

The H_2O_2 concentration in dissolution of copper in PAA was chosen so that the rate of copper oxidation to copper(II) ions was significantly lower than the rate of formation of polyacrylates and the rate of their desorption. During the experiment, the copper plate was not coated with a copper(II) oxide layer. The PAA concentration in the solution was chosen so that it corresponded to a plateau in the adsorption isotherm, which is suggested by the close weights of PAA adsorbed on the unit copper surface area at various initial PAA concentrations in the solution (see table). This allowed us to determine the influence of the degree of filling of the plate surface with the polymer and to reveal the influence exerted by the molecular weight of the polymer on the rate of copper dissolution.

A study of the rate of copper dissolution in aqueous PAA showed that, in the examined concentration range, it does not noticeably depend on the initial concentration of the polymer in the solution (Fig. 2). The linear dependence of the amount of dissolved copper on time in the initial stage of the process suggests an insignificant influence of the copper ion concentration on the process rate. At the same time, an increase in the molecular weight of PAA results in a noticeable increase in the process rate (Fig. 1, curve *2*). The rate of copper dissolution varies regularly with variation of the weight of PAA adsorbed on the unit copper surface area (see table). This suggests that the rate of accumulation of copper(II) ions in the solution is proportional to the rate of desorption of copper(II) polyacrylates from the adsorption layer:

$$v = d[Cu^{2+}]/dt = \gamma k_d N_a, \quad (3)$$

where γ is the coefficient of proportionality between the rate of copper dissolution and the rate of polymer desorption, k_d is the rate constant of PAA desorption, and N_a is the amount of PAA macromolecules adsorbed on the unit copper surface area,

$$N_a = AN_A/M. \quad (4)$$

To elucidate the influence of PAA molecular weight on the rate constant of its desorption, we rearranged expression (3) to obtain the equation

$$\log (v/N_a) = B + b \log M. \quad (5)$$

As seen from Fig. 1, curve *4*, the dependence of the experimental data in the coordinates of Eq. (5) is linear. The correlation coefficient of the straight line

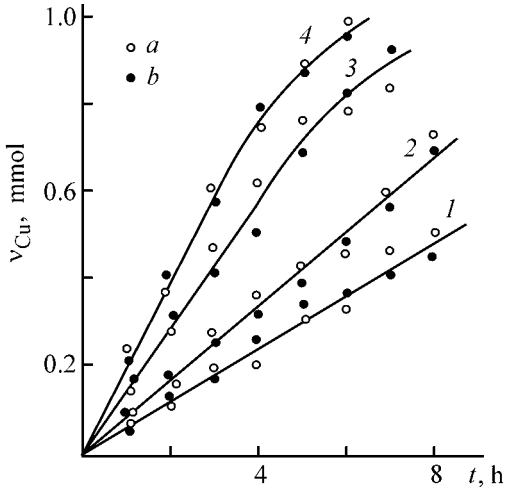

Fig. 2. Variation of the amount of dissolved copper, v_{Cu}, in time t at PAA concentration of (*a*) 10 and (*b*) 20 g l^{-1}. H_2O_2 concentration 12 mmol l^{-1}, 70°C. Molecular weight of PAA, $M \times 10^{-5}$: (*1*) 11.5, (*2*) 7.6, (*3*) 2.43, and (*4*) 1.54.

is 0.944. The parameter b is -0.29 ± 0.8. Thus, expression (3) can be written in the form

$$v = 10^{-15.5} N_a / M^{0.29}. \quad (6)$$

A comparison of the exponents at molecular weights in Eqs. (2) and (6) shows that, to a first approximation, the rate of desorption of macromolecules from the adsorption layer is proportional to the amount of macromolecules adsorbed on the unit copper surface area and is in inverse proportion to the surface area occupied by one macromolecule:

$$v = \gamma k_d N_a / S_b \approx \gamma k_d N_a / M^{0.35}. \quad (7)$$

Our attempt to linearize dependence (7) in the logarithmic coordinates failed. The correlation coefficient was less than 0.4, and the errors in determination of the slope and the intercept on the ordinate axis were significantly greater than the value itself. This can be accounted for by the fact that the rate of polymer desorption is affected by the number of bonds between the macromolecule in the adsorption layer and active centers of the surface. In general case, this effect is not proportional to the surface area occupied by a macromolecule in the adsorption layer.

It is well known that formation of copper salts with PAA results in variation of the hydrodynamic cross section of the macromolecule globule in the solution [16, 17], and reaction of PAA with H_2O_2 results in degradation of macromolecule. Monitoring of the variation of the relative viscosity of PAA solution, which can characterize the variation of the state of the polymer macromolecule, showed that, in dissolution of copper at high H_2O_2 concentration (0.12 M), this value noticeably decreases (Fig. 3, curve *1*). It should be noted that copper(II) oxide is formed in this case at the plate surface even within the first minutes after the beginning of the process. The rate of copper dissolution is an order of magnitude higher than that in the above studies. The insignificant decrease in the solution viscosity in time suggests that the degradation of the polymer in reaction of H_2O_2 with PAA in the absence of copper ions is slow (Fig. 3, curve *2*). An increase in the concentration of copper ions in the solution (Fig. 3, curves *3* and *4*) accelerates the PAA degradation under the experimental conditions.

An increase in the concentration of copper ions in PAA solution results in a decrease in the relative viscosity of the PAA solution (Fig. 4, curve *1*). However, this dependence is less pronounced that the dependence of the relative viscosity of the solution on the molecular weight of PAA (Fig. 4, curve *2*).

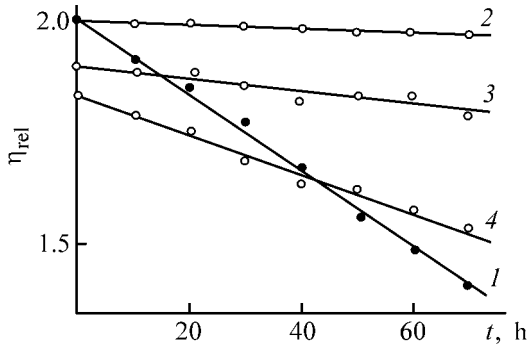

Fig. 3. Variation of the relative viscosity of PAA solution η_{rel} with time t (*1*) in dissolution of copper, and in reaction of PAA with H_2O_2 (*2*) in the absence of copper ions and in the presence of (*3*) 5.7 and (*4*) 21.4 mmol l^{-1} of copper(II) sulfate at 70°C. Molecular weight of PAA 11.5×10^5, PAA concentration 20 g l^{-1}, H_2O_2 concentration 120 mmol l^{-1}.

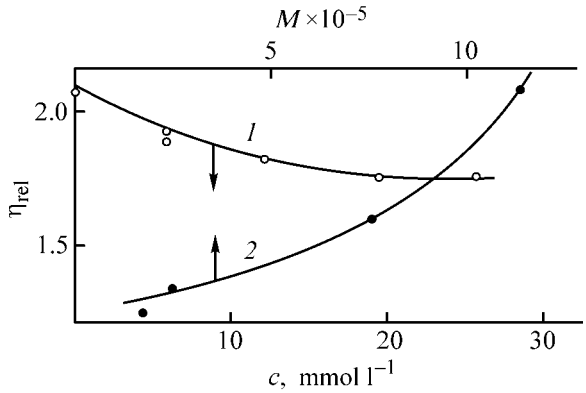

Fig. 4. Relative viscosity η_{rel} of solution with a PAA concentration of 21 g l^{-1} vs. the (*1*) concentration of copper(II) sulfate in solution c and (*2*) molecular weight of PAA M.

Thus, in the initial stage of copper dissolution in PAA solution in the presence of H_2O_2, the polymer degradation and, accordingly, the variation of the hydrodynamic characteristics of the macromolecule due to formation of copper salts with PAA insignificantly affect the rate of the polymer desorption.

EXPERIMENTAL

We used PAA samples with various molecular weights, prepared by radical polymerization in an aqueous solution. We used acrylic acid distilled at 140°C (freezing point 13°C), potassium persulfate recrystallized from aqueous solution, and hydroquinone of chemically pure grade. The purity of acrylic acid, determined from the content of double bonds by the bromide-bromate method [18], was 99.6%, and that determined from the content of carboxy groups (titra-

tion with 0.05 N NaOH) was 99.8%. The polymerization was carried out at 80–90°C; the concentrations of acrylic acid, sodium persulfate, and hydroquinone were 180–230, 5–10, and 0–6 g l^{-1}, respectively. The molecular weight was adjusted by addition of various amounts of hydroquinone to the reaction mixture. The PAA samples were recrystallized with hydrochloric acid and dried at room temperature. The molecular weights evaluated from the intrinsic viscosity of PAA solution in dioxane at 30°C and the molecular-weight distribution of PAA samples, determined by fractional dissolution, are listed in the table. The rate of copper dissolution in PAA was studied using a copper plate (purity 99.9%, total surface area 65×10^{-4} m^2). The adsorption of PAA was studied on a copper powder produced electrochemically with average particle size of 3×10^{-6} m. Before experiments, the copper plate and copper powder were washed with acetone to remove organic impurities and with hydrochloric acid to remove copper oxide from the surface.

Preliminary studies showed that the rate of copper dissolution in PAA at room temperature is very low both in the absence and in the presence of the oxidizing agent, H_2O_2. Therefore, further studies were carried out at 70°C with continuous rotation of the metallic plate in the solution of the polymer and the oxidizing agent. To determine the copper concentration in the solution upon the plate, 10-ml samples of the polymer solution were taken at certain intervals and an excess of concentrated ammonia solution was added to this sample.

The concentration of copper salts in the samples was determined from the spectrum of the ammonia complex of copper at 448 nm (Specord 40 spectrophotometer, cell thickness from 0.2 to 10 mm, depending on the concentration of the copper complex). The amount of copper was evaluated by the formula

$$v(t_n) = c_r(t_n)V_r(t_n)(1000M) + \sum_{j=1}^{n} c_s(t_j)V_s(t_j)/(1000M),$$

where $v(t_n)$ is the amount of copper (mole) released by the instant of time t_n; $c_r(t_n)$, $c_s(t_j)$, $V_r(t_n)$, and $V_s(t_j)$ are the concentrations (g l^{-1}) and volumes (ml) of the solution in the reactor and in the samples at the instants of time t_n and t_j, respectively; M = 63.5 is the atomic weight of copper.

The adsorption of PAA on copper powder was studied in the absence of H_2O_2 at 70°C. A study of the process kinetics showed that the equilibrium concentration of polymer in the adsorption layer is reached within 1–5 min after the beginning of the process. Therefore, to study the adsorption isotherm, a copper suspension in a PAA solution was stirred for 0.5 h and centrifuged for 15 min at a rate of 8000 rpm. The PAA concentrations in the initial solution and in the solution after centrifuging were determined by potentiometric titration with 0.01 N NaOH on a pH-646 pH-meter. The concentration of adsorbed PAA in the mixture was determined from the difference between these concentrations. The PAA adsorption was evaluated by division of the concentration of adsorbed PAA by the concentration of the dispersed phase.

CONCLUSIONS

(1) Adsorption of polyacrylic acid on the copper surface increases with increasing molecular weight of the polymer.

(2) A decrease in the molecular weight of the polymer results in a higher rate of copper dissolution in polyacrylic acid solution in the presence of hydrogen peroxide.

(3) The rate of copper dissolution is governed by the rate of desorption of polyacrylates; it is proportional to the amount of polymer macromolecules adsorbed on the unit surface area and is in inverse proportion to the surface area occupied by the macromolecule in the adsorption layer.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Variation of the Parameters of Inhibited Oxidation of Polyethylene in the Region of Phase Transition

Yu. A. Shlyapnikov and N. N. Kolesnikova

Emanuel' Institute of Biochemical Physics, Russian Academy of Sciences, Moscow, Russia

Received February 10, 2004

Abstract—Parameters of oxidation of polyethylene with molecular oxygen in the presence of a phenolic antioxidant, 2,2'-methylenebis(4-methyl-6-methylcyclohexylphenol), at 80–210°C were studied. The possible mechanism of interaction of the polymer with the antioxidant near the melting point was considered theoretically. The suggested theoretical relationships are consistent with experimental data.

Polymeric materials are usually intended for long-term service. However, tests performed in the course of their development are limited in time, and it is difficult to reliably estimate from their results the service life of the materials under real conditions. Accelerated tests are performed at elevated temperatures at which the polymer exists as a melt, and it is important to know to what extent the results of accelerated tests can be extrapolated to the real service conditions. One of the factors complicating the extrapolation is the phase transition (melting) of the polymer.

A polymeric substance differs from its low-molecular-weight analogues in a number of characteristics, among which the most significant for studies of oxidation processes are the virtually zero vapor pressure in the entire temperature range of existence of the polymer and the extremely low translation mobility of polymer macromolecules in combination with the high the vibration mobility of the segments.

In this study, we examined the inhibited oxidation of the simplest polymer, polyethylene (PE), with molecular oxygen in the temperature range 80–210°C including the range of melting of this "crystalline" polymer (108°C). As inhibitor we used 2,2'-methylenebis(4-methyl-6-methylcyclohexylphenol) (MCHP). The relatively high molecular weight of this antioxidant, M = 400, decreased its volatilization in the course of the reaction, but, at the same time, made us to use an indirect method for monitoring its consumption: a study of the dependence of the induction period on the initial antioxidant concentration.

In going from a low-molecular-weight substance to its high-molecular-weight analogue, the role of the cage effect substantially increases. As a result, the yield of hydroperoxides decreases from approximately 100% in hydrocarbons to 5–20% in hydrocarbon polymers (polyolefins) [1, 2], and stable nonuniformities in the macromolecular packing play the role of a second component dissolved in a polymeric substance [3]. In crystalline polymers, crystalline formations appear below the melting points; their content increases with lowering temperature, and in some cases they behave as radical (or, more precisely, free-valence) scavengers. It was interesting to understand to what extent the properties of the intercrystallite amorphous substance differ from the properties of a melt of the same polymer.

The main steps of oxidation of hydrocarbon polymers are similar to the related steps of oxidation of low-molecular-weight hydrocarbons:

$$R^{\bullet} + O_2 \rightarrow RO_2^{\bullet}, \quad (1)$$

but the differences become significant in the step

$$RO_2^{\bullet} + RH \rightarrow ROOH + R^{\bullet}. \quad (2)$$

In polymers, the primary products are located close to each other, and their reaction, e.g., by the scheme

$$ROOH + R^{\bullet} \rightarrow RO^{\bullet} + ROH. \quad (3a)$$

is highly probable. As a result, the yield of the hydroperoxide per mole of uptaken oxygen (α) is considerably lower than unity (or 100%) and depends on the oxygen concentration [1, 2]. Therefore, the process can be described by the overall reaction

1070-4272/04/7708-1364 © 2004 MAIK "Nauka/Interperiodica"

$$RO_2^{\bullet} + RH \rightarrow \alpha ROOH + R^{\bullet}. \quad (3b)$$

Common antioxidants (IH), phenols and aromatic amines, react with oxygen more readily than do monomeric units of the polymer [1, 4]; therefore, the initiating step of the oxidation is the reaction of the antioxidant with oxygen. Since the majority of the radicals generated in the process decays in the reaction with the same antioxidant, the process can be described by the scheme [5]

$$IH + O_2 \rightarrow I^{\bullet} + HO_2^{\bullet} \quad (4)$$

(rate constant k_0),

$$HO_2^{\bullet} + IH \rightarrow H_2O_2 + I^{\bullet} \quad (5)$$

with the subsequent reaction of hydrogen peroxide with the antioxidant:

$$H_2O_2 + 2IH \rightarrow H_2O + 2I^{\bullet}. \quad (6)$$

Thus, one event of antioxidant oxidation [reaction (4)] leads to consumption of $f = 4$ antioxidant molecules. A minor part of radicals generated in the process reacts with monomeric units of the polymer RH, initiating the oxidation:

$$HO_2^{\bullet} + RH \rightarrow H_2O_2 + R^{\bullet}. \quad (7)$$

However, the chains initiated by these radicals are subsequently terminated by the same antioxidant. Therefore, reaction (7) does not affect f.

The chain termination occurs in reaction of IH with $RO_2^{\bullet}$ radicals involved in the polymer oxidation:

$$RO_2^{\bullet} + IH \xrightarrow{k_t} ROOH + I^{\bullet}. \quad (8)$$

The $I^{\bullet}$ radicals can also recombine with $R^{\bullet}$, i.e., they can inhibit oxidation, but the major fraction of $I^{\bullet}$ radicals finally transforms into a nonvolatile colored product inhibiting the oxidation in the absence of the starting antioxidant species [1, 6].

The reaction of hydroperoxy groups with adjacent monomeric unitgs RH results in chain branching. In all the steps of branching, the cage effect preventing the escape of free radicals plays an important role:

$$ROOH + RH \rightarrow RO^{\bullet} + R^{\bullet} + H_2O$$
$$\rightarrow \ldots \rightarrow \sigma R^{\bullet} + \text{products}. \quad (9)$$

In a developed chain reaction, free radicals mainly arise in chain branching processes (formation and decomposition of hydroperoxy groups). If the chain branching rate is higher than the chain termination rate, the reaction is autoaccelerating; otherwise the reaction occurs in the steady-state mode, i.e., the reaction rate is a single-valued function of the concentrations of the reactants: monomeric units of the polymer [RH], oxygen, and antioxidant. The antioxidant concentration corresponding to the point of transition from the steady-state to autoaccelerating mode is termed the critical concentration. As shown in [1, 7], it is determined as follows:

$$[IH]_{cr} = \frac{\alpha\sigma k_2 [RH]}{(1 - \sigma)k_t}. \quad (10)$$

Thus, the expression for $[IH]_{cr}$ contains the ratio of two rate constants and the product of two coefficients, each of which may be temperature-dependent.

Above the critical concentration, the antioxidant is mainly consumed for oxidation [steps (4)–(6)]; the process is first-order with respect to the antioxidant. Then

$$-\frac{d[RH]}{dt} = k_{app}[IH], \quad (11)$$

where the constant k_{app} is equal to the rate constant of the reaction IH + O_2, k_0, multiplied by f. The first order of consumption of strong antioxidants in oxidation of polyolefins has been observed repeatedly [1, 3].

When the antioxidant concentration decreases to the critical level in the course of its consumption, the reaction rate steeply increases, and the residual amount of the antioxidant is consumed in a short time τ_{cr}. The dependence of the induction period on the initial antioxidant concentration $[IH]_0$, calculated with this assumption, can be described by the formula [1, 7]

$$\tau = \tau_0 + \frac{1}{k_{app}} \ln \frac{[IH]_0}{[IH]_{cr}}. \quad (12)$$

Formula (12) can be used to determine the parameters of inhibited oxidation: critical antioxidant concentration and apparent rate of its consumption. In particular, the rate constant k_{app} (s^{-1}) is

$$k_{app} = \frac{\Delta \ln [IH]_0}{\Delta \tau}, \quad (13)$$

and the well-defined inflection in the curve of induction period τ vs. the initial antioxidant concentration $[IH]_0$ corresponds to the critical antioxidant concentration.

EXPERIMENTAL

We used low-density PE (molecular weight M_w = 55700) and MCHP antioxidant. Polyethylene was reprecipitated from *m*-xylene and washed with alcohol; MCHP (mp 140°C) was recrystallized from alcohol. Samples were prepared by blending the polymer and antioxidant powders with addition of a small amount of alcohol, which subsequently vaporized. Samples of 0.05 g weight were oxidized in a static vacuum unit [1] at an oxygen pressure of 150 mm Hg (which approximately corresponds to the partial pressure of oxygen in the atmosphere).

Figure 1 shows the kinetic curves of the O_2 uptake and accumulation of the –OH and >CO groups in oxidation of a sample containing 1.25×10^{-4} mol kg^{-1} MCHP at 100°C. Oxidation under these conditions occurs with a significant induction period; all the three curves start to ascend at the same temperature. According to the theory [1, 7], the onset of the ascent corresponds to the instant of time at which the antioxidant concentration decreases to the critical value.

In accordance with formula (12), the induction periods of PE oxidation at all the temperatures vary with the initial antioxidant concentration, following the logarithmic law (Fig. 2). This allowed is to obtain the temperature dependences of the rate constants k_{app}. In the portions above and below the melting point, k_{app} varies according to the Arrhenius law with the apparent activation energy of 153 and 126 kJ mol^{-1} below and above the melting point, respectively (Fig. 3). An unexpected result was a strong variation of the preexponential factor; its common logarithm decreased from 15.6 to 10.0 [s^{-1}] on melting of the polymer.

The critical MCHP concentration also varied differently above and below the melting point. It is more convenient to determine this concentration from the nontransformed curves of the induction period vs. the initial antioxidant concentration. In contrast to k_{app}, the apparent activation energy of variation of $[IH]_{cr}$ in the solid polymer was lower than that in the melt: 12.6 and 48.2 kJ mol^{-1}, respectively (Fig. 4). The expression for the critical concentration contains several rate constants, and we cannot assign the observed jump to any of them.

According to Eqs. (4)–(6), the direct reaction of IH with O_2 is followed by a series of secondary reactions, and the constant k_{app} can be expressed as $k_0[O_2]f$. Variation of the local IH concentration in the phase transition should not affect the value of the constant, which is first-order with respect to [IH]. The quantity f, equal to 3 according to (5)–(7), should not significantly change either, even if the actual reaction mechanism is different.

The higher activation energy of the antioxidant oxidation below the melting point can be readily explained as follows. According to the sorption mechanism suggested in [3, 8], molecules dissolved in a polymer are mainly concentrated at the sorption centers Z_a (sites of distorted short-range order) matching most closely the dissolved molecules (MCHP in our case) in size and shape. Below the melting point of a polymer, crystalline formations arise, preventing migration of macromolecules and their segments, and rearrangement of a sorption center required for formation of a reaction complex requires more energy. The increased (by five orders of magnitude) preexponential factor below the melting point is more difficult to explain.

CONCLUSIONS

(1) An experimental study of polyethylene oxidation with molecular oxygen in the presence of a dipolar antioxidant revealed breaks in the temperature dependences of kinetic parameters near the melting point polyethylene (180°C). This fact indicates that the completely molten polymer essentially differs in properties and structure from the amorphous substance remaining below the melting point.

(2) Extrapolation of data on inhibited oxidation of polyethylene beyond the melting point with the simple Arrhenius law is incorrect.

Abstract— The kinetics of viscosity variation and the concentration and kinetic modes of precondensation of a mixture of epoxy-4,4'-isopropylidenediphenyl and phenol-formaldehyde oligomers in Cellosolve solutions in the presence of phosphoric acid at 333 K were studied. The cluster structure parameters of the chemical network of epoxy-phenolic polymeric coating on a tin plate, obtained by thermal curing of precondensates of an oligomer mixture, were determined using the silver chloride sputtering method.

In studying the structure of cross-linked epoxy-phenolic polymers we have demonstrated previously [1, 2] that a uniform chemical network is formed on the surface of polymeric coatings at an epoxydiane (EO) to phenol-formaldehyde (PO) oligomer molecular weight ratio close to 4 : 1, the optimal molecular weight of EO (M_n) being about 3500. To improve the compatibility of EO and PO in solutions and to obtain an epoxy-phenolic polymer by thermal curing of the oligomers, precondensation of EO and PO is carried out in the presence of phosphoric acid [3, 4]. On adding H_3PO_4 to a solution of the oligomers, mono-, di-, and triphosphates of EO are formed [5]. In the course of thermal curing of a mixture of the oligomers, the methylol (butoxy) groups of PO react with the epoxy (hydroxy) groups of EO, and the methylol groups of PO form etheric cross-linking bonds [6, 7].

In [1, 2, 8], we suggested a cluster mechanism of aggregation of oligomeric molecules in solutions in the course of thermal precondensation of EO/PO mixtures. Following the cluster model [9, 10], one can distinguish three major kinetic stages of precondensation of the oligomers, as well as the corresponding topological types of the chemical network structure of cross-linked epoxy-phenolic polymer. The precondensation mechanism in EO–PO mixed solutions, i.e., the structural evolution of aggregates of the oligomers, involves disaggregation of EO and PO aggregates and formation of mixed EO–PO aggregates and then of an infinite cluster of these macromolecules. Such an approach is useful for optimization of the molecular, concentration, and kinetic parameters of precondensation of the oligomers in solutions [2]. Previously we have shown [8] that the oligomer molar ratio $N_1(EO)/N_2(PO)$ and the phosphoric acid concentration N_3 predetermine the shape of the kinetic curves characterizing the viscosity dynamics in EO–PO mixed solutions.

A uniform chemical network of the epoxy-phenolic polymer is formed in curing of the oligomer mixture, provided that the density of EO and PO aggregates approaches that of the infinite cluster in the vicinity of the threshold concentration of the particles in the solution [2]. Such a network is not formed in the initial and intermediate stages of precondensation of the oligomers. In this case, the correlation radius ξ of clusters representing the network junctions initially decreases from ~250 to ~50 nm and then increases to ~500 nm with precondensation time, which is consistent with data on the Rayleigh light scattering in EO and PO solutions [11].

The topology of the points of the chemical network on the surface of the epoxy-phenolic polymer depends on the molecular weight M_n and concentration of EO and PO [1]. At $M_n(EO) = 2100$ and $M_n(PO) = 850$, some extended discrete clusters ("lattice monsters" [1, 9]) are found, which have a low lattice density and constitute an inhomogeneous chemical network of the crosslinked polymer. A uniform and homogeneous network of the epoxy-phenolic polymer is formed at $M_n(EO) = 2800–3500$ [1, 2]. At the same time, it

1070-4272/04/7708-1368 © 2004 MAIK "Nauka/Interperiodica"

should be noted that the structure of the points of the chemical network in the epoxy-phenolic polymer obtained by curing the oligomers in the presence of phosphoric acid remains to be understood [4, 12].

In this study, we examined the kinetics of viscosity variation in mixed solutions of EO and PO oligomers in the course of precondensation in the presence of phosphoric acid. The distribution of the points of the chemical network on the epoxy-phenolic polymeric coatings on a tin plate, prepared by curing of precondensates of oligomer mixtures containing various phosphoric acid concentrations, was also determined.

EXPERIMENTAL

Samples of E-05 epoxy-4,4'-isopropylidenediphenyl resin and DFFr phenol-formaldehyde resin (based on diphenylolpropane and formaldehyde) (Pigment holding company) were characterized by capillary viscometry and gel chromatography [13, 14]. The number-average molecular weight M_n and the M_w/M_n ratio (M_w is the weight-average molecular weight) of the oligomers are listed in Table 1. The intrinsic viscosity [η] of the oligomers was determined in Cellosolve (C).

The dependences of the viscosity η of mixtures of E-05 and DFFr in Cellosolve on the precondensation time t were obtained at c(E-05) = 26.7 g dl^{-1} and c(DFFr) = 9.12 g dl^{-1}, which corresponds to N_1(E-05)/N_2(DFFr) = 1 [2]. Precondensation and viscosity measurements in E-05 and DFFr mixed solutions in C in the presence of H_3PO_4 were carried out directly in a cylinder–cylinder cell of a Rheotest-2 rotary viscometer at 333 K. The results are presented in Fig. 1 and Table 2. The viscosity was measured at a shear rate g = 81 s^{-1} to within 3 mPa s.

omers. The H_3PO_4 concentration in the mixed oligomer solution was varied from 14.3 to 490 rel % (a quantity of 0.25 g of H_3PO_4 per 36 g of the E-05–DFFr mixture was taken as 100% [3]) (Table 2, sample nos. 1–9). Polymeric coatings 4 to 6 μm thick were prepared by casting 20% solution of the precondensate in C onto electrolytic tin plate, followed by air-curing for 15 min at 483 K [15, 16] (Table 3, sample nos. 1–9).

The cluster structure of the epoxy-phenolic polymer was studied by depositing silver chloride by thermal evaporation onto the coating surfaces in a vacuum (1.33×10^{-3} Pa) to an effective thickness of the layer of 0.4 nm. Carbon replicas with decorating AgCl nanoparticles were obtained using the procedure described in [1] and then studied with an EVM 100 L electron microscope. The electron micrographs of the surface of polymer films on food tin were improved by digital image processing [2] (Figs. 2a–2f).

The kinetic curves characterizing the variation of the viscosity in the course of precondensation of an E-05–DFFr mixture in the presence of H_3PO_4 show extrema (Fig. 1). Previously, it has been demonstrated [8] that the position of the extrema in the viscosity curves as well as that of the ascending and descending portions and those of saturation depend on the parameter $N_3/(N_1 + N_2)$. The dip in the curves corresponds to $N_3/(N_1 + N_2) < 0.04$, and the peak was observed at $N_3/(N_1 + N_2) = 0.09 - 0.13$ (Table 2, sample nos. 5, 6). With increasing phosphoric acid concentration at $N_3/(N_1 + N_2) > 0.17$, the viscosity of the mixed oligomer solution does not approach the saturation in a finite time interval (Fig. 1*d*; Table 2, sample nos. 8, 9).

The observed different shapes of the viscosity curves can be interpreted in terms of the cluster mechanism of precondensation of the EO–PO mixture [2]. This mechanism predicts that the density of the aggregates of oligomeric molecules changes in the course of precondensation with the H_3PO_4 concentration [8]. We have demonstrated previously [2] that the dip in the viscosity curves is caused by the formation of mixed elementary aggregates of the oligomers, having high packing density, and the peak in the curves can be attributed to the formation of aggregates with a relatively lower density of molecular packing.

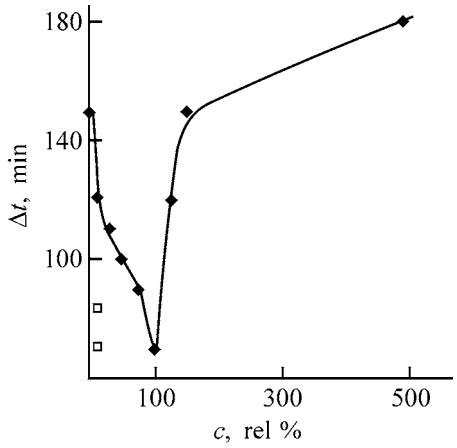

Fig. 3. Relative time Δt of precondensation of the oligomer mixture in C vs. the concentration c of phosphoric acid.

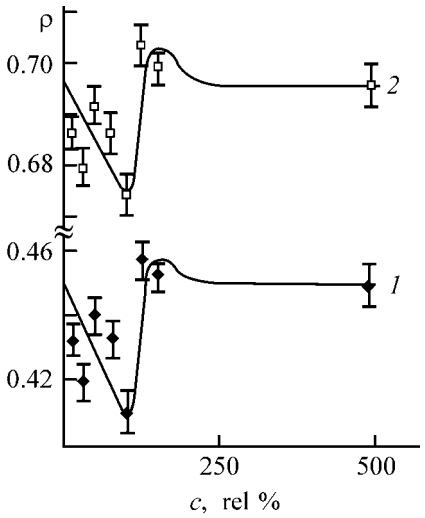

Fig. 4. Density ρ of aggregates of the oligomeric molecules vs. the concentration c of phosphoric acid. Fractal dimension D of aggregates: (*1*) 1.7 and (*2*) 2.

Table 2 allows us to derive a correlation between the limiting viscosity η of the mixture and the time t in which it is attained in the course of precondensation of the oligomers in the solution. From these data one can estimate the optimal H_3PO_4 concentration and the parameter $N_3/(N_1 + N_2)$ corresponding to the minimum viscosity of the oligomeric mixture. The time t in which the limiting viscosity η of the mixed oligomeric solution is attained, estimated relative to the position of the extremum in the η-vs.-t curve, is the shortest at $N_3/(N_1 + N_2) \approx 0.1$, like that for η (Fig. 3). If the parameter $N_3/(N_1 + N_2)$ deviates from this optimal value, the time of precondensation increases (Table 2, sample nos. 1–4, 7–9).

Using the cluster model, the density ρ of the aggregates of E-05 and DFFr molecules can be expressed in terms of the relative viscosity η_{rel} of the oligomer mixture in the solution [8]:

$$\rho \sim w^{(3-D)/D}([\eta]c/\ln \eta_{rel})^{(3-D)/(3-2D)},$$

where $w = 0.637$ is the factor of random packing of hard spheres; D, the fractal dimension of the aggregates in the solution [9]; and $\eta_{rel} = \eta/\eta_0$ (η and η_0 are the viscosities of the solution and the solvent, respectively) [14].

The density of the aggregates of the oligomeric molecules in the solution was estimated for the precondensates of the E-05–DFFr mixture in Cellosolve at $[\eta]c = 5.0$ (dimensionless parameter) and the intrinsic viscosity of the precondensates $[\eta] = 0.15$ dl g^{-1} (Table 2, sample nos. 1–9). The fractal dimension D of the aggregates of the oligomeric molecules was taken to be 1.7 and 2 (Fig. 4).

Figure 4 shows that the density ρ of aggregates of the oligomers changes in parallel with the limiting viscosity of the oligomer mixture in the solution in the course of precondensation. The density is the lowest near $c(H_3PO_4) = 100\%$, which corresponds to $N_3/(N_1 + N_2) \approx 0.1$ and to $N_3/N_1 \sim 0.3$ (Table 2, sample no. 6). In this case, the observed relatively low density of aggregates of the oligomers is caused by the fact that EO monophosphates are preferentially formed in the solution [5]. The increase in the limiting viscosity η of the oligomer mixture and in the density ρ of aggregates of the oligomeric molecules within the range $N_3/(N_1 + N_2) = 0.17–0.66$ is probably due to the formation of di- and triphosphates [7].

The patterns of distribution of decorating particles on the surface of the epoxy-phenolic polymer reveal an inhomogeneous structure of the coatings, which is represented by regions of localization of fine (20–30 nm) and coarse (150–500 nm) AgCl particles (Fig. 2). The inhomogeneous energy microprofile of the polymeric coating, i.e., different strengths of binding of the adsorbed AgCl particles to the support, is caused by the parameters of distribution of the reactive functional groups of E-05 and DFFr on the surface. Clusters of fine AgCl particles firmly bound to the polymer surface primarily reflect the distribution of EO functional groups [1, 2]. Clusters of coarse AgCl particles on the surface of the epoxy-phenolic coatings are formed, as demonstrated previously [1, 2], via coalescence of fine particles and topologically correspond to the distribution of the functional groups of PO.

The mechanism of interaction of silver chloride with the functional groups of PO involves partial

reduction of AgCl to metallic silver by quinonemethide groups of the epoxy-phenolic polymer formed in thermal curing of the oligomer mixture [7]. In the next stage, nucleation of Ag nanoparticles starts, providing growth of coarse decorating particles of AgCl. Reduction of silver chloride by hydroxybenzenes, which, taken as a mixture with hydroquinone, are effective reducing agents for silver halides, are widely used in chemical photographic processing of silver halide materials [17]. This mechanism of interaction of AgCl with the functional groups of PO is additionally supported by the fact that the amount of coarse AgCl particles on the surface of the epoxy-phenolic polymer falls with decreasing PO concentration in the oligomer mixture [1, 2].

Spatially correlated groups of fine and coarse decorating particles can be regarded as lattice clusters [9] differing in the fractal dimension D, coordination number m, density of the quasilattice points, and correlation radius ξ. These parameters control the short-range distribution of particles on the surface of polymeric films on the scale $R < \xi$ [18], and they can be estimated from the radial distribution function [1, 2] (Table 3).

On the surface of the film prepared by thermal curing of the precondensate of the oligomer mixture in the absence of phosphoric acid (Tables 2 and 3, sample no. 1), we found a two-phase macroinhomogeneous structure of the resulting polymer (Figs. 2a, 2b). The fine and coarse AgCl fractions are localized separately. These fractions are represented by extended domains hundreds of micrometers in size. In this case, a uniform chemical network is not formed on the polymer surface on the scale close to the correlation radius ξ of AgCl clusters as a result of the poor compatibility of the oligomers in the solution.

In the presence of phosphoric acid, thermal curing of the precondensates gives a more uniform chemical network of the epoxy-phenolic polymer (Tables 2 and 3, sample nos. 2–9). Generally, two types of fractal clusters of fine and coarse AgCl particles are distinguished on the polymer surface, which form two chemical networks whose points contain either E-05 or DFFr (Figs.2c–2f). The size and lattice density distribution of these clusters on the polymer surface depend on the phosphoric acid concentration in the mixed oligomer solution.

The mean cluster lattice density ρ_l, estimated by the method described in [1], varies as a function of the radius R of the circle with a center at the lattice point occupied by a particle by the law $\rho_l(R) \sim (R)^{D-2}$

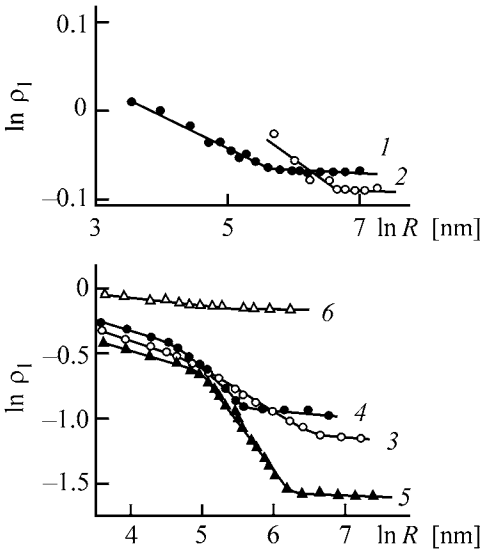

Fig. 5. Lattice density ρ_l of the clusters of decorating AgCl particles vs. the radius R of the circle surrounding a cluster of the particles. Coatings on tin plate. H_3PO_4 concentration (rel %): (*1*, *2*) 0 (curves *1* and *2* correspond to the fragments of the surface of sample no. 1, Table 3), (*3*) 30, (*4*) 100, (*5*) 125, and (*6*) 150.

[9]. Transition to the network is controlled by changing D on the scale $R = \xi$ [18].

Table 3 summarizes parameters of the cluster structure of the polymer prepared by curing the precondensates at various H_3PO_4 concentrations. In the absence and at a large excess of phosphoric acid in the precondensate, the cluster lattice density ρ_l on the polymer surface is higher than that at $c(H_3PO_4)$ = 30–125%.

For coatings prepared by curing the precondensates in the absence of phosphoric acid and also for those obtained at a large excess of the acid in the oligomer mixture, the dependences $\rho_l(R)$ plotted in the logarithmic coordinates are represented by of two linear portions (Fig. 5). For the coating obtained in the absence of the acid, two dependences $\rho_l(R)$ were obtained, corresponding to polymeric phases enriched with either E-05 or DFFr (Fig. 5, curves *1*, *2*). At $c(H_3PO_4)$ = 14–125 rel %, the $\rho_l(R)$ curves consist of three portions (Table 3, sample nos. 2–6). At $c(H_3PO_4) \geq$ 150 rel %, the chemical network of the epoxy-phenolic polymer is characterized by a unique correlation radius ξ, and within the range 14–125 rel %, by two values ξ_1 and ξ_2 corresponding to the short- and long-range order in the AgCl particle density distribution on the surface (Fig. 5, curves *3*–*6*).

The mean radius of the clusters, $\langle R \rangle$, which characterizes the average distance between the chemical network points on the scale $R \leq \xi_1$ [9], reaches the

minimum value at $c(H_3PO_4)$ = 75 rel % (Table 3, sample no. 5). Here the particle size and the distance between coarse AgCl particles on the surface are at a minimum, and their concentration is at a maximum. In this case, the coordination number $m \approx 6$ corresponds to a triangular quasilattice [8], and the lattice density $\rho_l(\xi_1)$ of the clusters reaches a local maximum (correlation radius ξ_2 reaches a local minimum). It is significant that, in this case, a uniform network of the infinite cluster is formed from coarse and fine AgCl particles, and the localization regions can be imagined as two fractal (infinite) clusters nested within each other, the coverages of the surface with these clusters being approximately equal.

According to the percolation theory [9], the threshold of percolation in microinhomogeneous systems for two types of points on a triangular lattice corresponds to the critical percolation probability $p_{cr} = 0.5$. In our case, points of such a lattice are occupied by coarse and fine AgCl particles, and the lattice density ρ_l of fractal clusters of fine and coarse particles is close to the critical value corresponding to an infinite cluster [9, 18]. Therefore, it may be suggested that, at $c(H_3PO_4)$ = 75 rel %, the chemical network of the epoxy-phenolic polymer is the most uniform, which is confirmed by high protective characteristics of the polymeric coatings in simulated media [8].

At small deviations from $c(H_3PO_4)$ = 75 rel %, less uniform networks are formed on the surface, and the coordination number *m* of the quasilattice decreases from 6 to 4–5 (Table 3, sample nos. 4, 6). At $c(H_3PO_4)$ = 50 rel. %, the infinite cluster consists of only coarse AgCl particles with inclusions of discrete domains of localization of fine particles. At $c(H_3PO_4)$ = 100 rel %, the uniform network is formed by only fine AgCl particles (no uniform network of coarse particles).

In the range $c(H_3PO_4)$ = 100–125 rel %, the fractal structure of the chemical network is represented by an infinite cluster of fine AgCl particles and extended discrete domains of localization of coarse particles. The cluster structure of these extended regions of localization of coarse AgCl particles is similar to lattice monsters on a square lattice ($m = 4$) [19], since an extended cluster of coarse particles does not spread throughout the lattice, but only partially covers the surface [1, 9]. Such a cluster has a branched structure. However, its lattice density ρ_l on the scales $R < \xi$ and $R > \xi$ is lower than the critical lattice density ($\rho_{cr} \approx 0.59$) at which an infinite cluster starts to form on a square lattice [19].

At $c(H_3PO_4)$ = 50, 100, and 125 rel % (Table 3, sample nos. 4, 6, and 7), the chemical network of epoxy-phenolic coatings is characterized by noticeable fluctuations of the lattice density ρ_l in the vicinity of ξ_1 and ξ_2 corresponding to the short- and long-range orders of AgCl particle distribution on the surface. Such coatings demonstrate worse protective properties as compared to those obtained at $c(H_3PO_4)$ = 75 rel % [8].

At a considerable excess of phosphoric acid in the precondensate, the coordination number *m* of the lattice on the coating surface grows with increasing acid concentration in parallel with the lattice density ρ_l of clusters, and also in parallel with the limiting viscosity of the oligomer mixture in the solution in the final stage of precondensation (Tables 2 and 3, sample nos. 8, 9). In these cases, a highly cross-linked chemical network of the epoxy-phenolic polymer is formed on the coating surface.

CONCLUSIONS

(1) The minimum values of the limiting viscosity of the oligomer mixture and the density of aggregates of the oligomers in the final stage of precondensation, and also the preferential formation of monophosphates of the epoxy-4,4'-isopropylidenediphenyl oligomer in solution, were observed at the orthophosphoric acid to oligomer molar ratio $N_3/(N_1 + N_2) \approx 0.1$.

(2) The most uniform cluster structure of the chemical network of the epoxy-phenolic polymer is formed on the coating surface at $N_3/(N_1 + N_2) \approx 0.1$. In this case, the lattice density of infinite clusters of AgCl particles, which represent points of the chemical network formed in thermal curing of a mixture of the epoxy-4,4'-isopropylidenediphenyl and phenol-formaldehyde oligomers is close to the threshold of percolation on a triangular lattice, and the coverages of the surface with these clusters are nearly equal.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Radical Polymerization of the Quinone Derived from Monoethanolamine Vinyl Ether and Chloranil

E. E. Ergozhin, B. A. Mukhitdinova, S. A. Shoinbekova, A. I. Nikitina, and G. N. Zhunusova

Bekturov Institute of Chemical Sciences, Ministry of Education and Science of the Republic of Kazakhstan, Almaty, Kazakhstan

Received March 19, 2004

Abstract—Radical polymerization of the quinone derived from monoethanolamine vinyl ether and 2,3,5,6-tetrachloro-1,4-benzoquinone (chloranil) was studied by classical polarography. The conditions of preparation of the redox polymer were optimized. The kinetic characteristics of the process were calculated.

One of the main lines of the Kazakhstan-2030 strategic development program is the use of domestic raw materials and their processing into materials useful for industry and agriculture, with the aim to replace imported materials. The use of redox polymers (or redox ion exchangers) in research and practice is restricted by the lack of starting monomers for their synthesis.

Systematic studies are made to develop procedures for preparing new unsaturated monomers based on monoethanolamine vinyl ether (MEAVE) produced in Kazakhstan. Previous studies have been concerned with the preparation of new redox polymers derived from MEAVE and suitable for production of redox ion exchangers [1], conditions of radical homopolymerization of some compounds derived from MEAVE and quinones, kinetic characteristics of the process [2–4], and copolymerization of these compounds with acrylic acid, styrene, 4-vinylpyridine, and *N*-vinylpyrrolidone. For these reaction systems, the relative activity constants, resonance stabilization factors *Q*, and polarities *e* have been calculated [5, 6].

In this study, we analyzed polarographically the radical polymerization of the disubstituted derivative of chloranil and MEAVE, MEAVE–CA–MEAVE.

EXPERIMENTAL

Azobis(isobutyronitrile) (AIBN) was recrystallized from absolute methanol, mp 102–103°C.

2,5-Bis[*N*-(2-vinyloxy)ethyl]amino-3,6-dichloro-1,4-benzoquinone ($C_{14}H_{16}N_2O_4Cl_2$) (MEAVE–CA–MEAVE) was prepared according to [1].

The radical polymerization was performed as described in [2–4]. The optimal conditions were determined polarographically: 80°C, initiator concentration 6 wt %, monomer concentration in DMF 20 g l^{-1}, polymerization time 5 h. The polymer yield under these conditions is 80.47%. The reaction kinetics was monitored polarographically (by the amount of unchanged monomer) and gravimetrically (by the polymer yield).

The polarograms were recorded in a temperature-controlled cell of a PU-1 polarograph at 25 ± 0.5°C, using a mercury dropping electrode with the open-circuit capillary characteristic $m^{2/3} t^{1/6} = 4.38$ mg$^{2/3}$ s$^{-1/2}$, vs. saturated calomel electrode. The supporting electrolyte was phosphate buffer solution (pH 7.4) in 25% DMF. Prior to polarographic measurements, the solutions were bubbled with argon to remove oxygen.

The IR spectra were measured on a Specord M-80 spectrophotometer using KBr pellets (200 mg KBr + 1 mg sample). In the spectra of the polymers, the vinyl C–H band at 2928 cm^{-1} disappears, but the NH stretching (3248 cm^{-1}) and bending (1592 cm^{-1}) bands are preserved, as well as the bands of the ring C=C bonds at 1504 cm^{-1}, =C–N bond at 1328 cm^{-1}, ether group at 1208 cm^{-1}, and C–Cl bonds at 712 and 752 cm^{-1}. The quinone carbonyl band is broadened

Table 1. Elemental composition and some physicochemical properties of the disubstituted monomer derived from chloranil and MEAVE and of its polymer

Compound	Calculated, % / found, %				Yield, %	mp, °C	[η], dl g^{-1}	ρ, g cm^{-3}	SEC	RC
	C	H	N	Cl					mg-equiv g^{-1}	
Monomer	48.43 / 48.55	4.64 / 4.64	8.06 / 8.18	20.42 / 20.36	86.20	103–105	–	0.2385	–	–
Polymer	48.43 / 48.55	4.64 / 4.64	8.06 / 8.18	20.42 / 20.36	80.47	190	0.16–0.18	1.0424	1.45	2.12

and shifted to higher frequencies (1688 cm^{-1}, against 1660 cm^{-1} for the monomer), which is typical of quinone polymers.

Viscometric studies were performed in Ubbelohde capillary viscometers in a temperature-controlled cell at 25°C in DMF; the density, static exchange capacity (SEC), and redox capacity (RC) were determined as described in [2–4].

The reaction of chloranil with MEAVE yielded an unsaturated redox monomer capable, in contrast to the starting ether, of radical polymerization. The chemical composition and some physicochemical characteristics of the MEAVE-substiututed quinone and its polymer are listed in Table 1.

From the measured content of the unchanged monomer, we determined the degree of its conversion and constructed the kinetic curves of polymerization (FIg. 1).

To calculate the rate constants of the overall polymerization process, we determined the reaction order. From the linear dependence of log c of the monomer on the reaction time (Fig. 2), we found that the process is monomolecular with respect to the monomer (m = 0.74) and is described by first-order reaction relationships.

The rate constants of MEAVE–CA–MEAVE polymerization, calculated from the first-order kinetic equation, and the preexponential factors k_0, calculated from the Arrhenius equation $k = k_0 e^{-E/RT}$, are listed in Table 2.

The plot of ln k vs. 1/T (Fig. 3) is a straight line; from its slope, we determined the activation energy:

$$E = 4.571 \,|\tan\alpha\,|\,\xi,$$

where α is the slope of the straight line relative to the abscissa, and ξ is the ratio of scales along the abscissa and ordinate.

In the chosen scales, $\tan\alpha = \tan 30° = 0.5774$, $\xi = 10^3$, and the activation energy $E = 4.571 \times 0.5774 \times 10^3 = 26.393$ kcal mol^{-1} (110.35 kJ mol^{-1}).

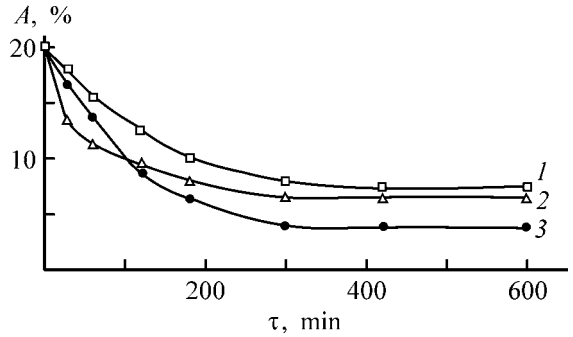

Fig. 1. Kinetic curves of MEAVE–CA–MEAVE polymerization. (*A*) Polymer yield and (τ) time. Temperature, K: (*1*) 346, (*2*) 360, and (*3*) 353.

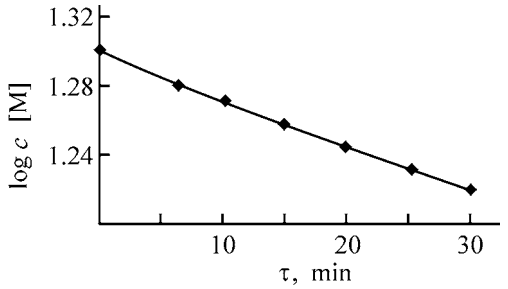

Fig. 2. Concentration c of the monomer vs. the time τ of MEAVE–CA–MEAVE polymerization.

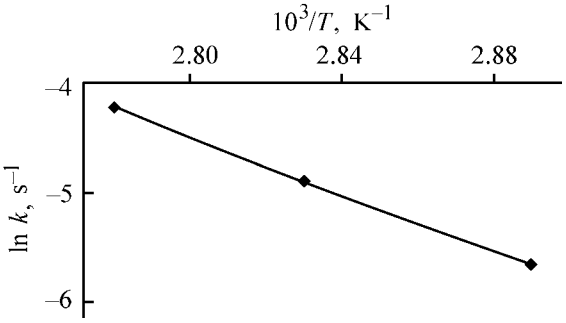

Fig. 3. Rate constant k of MEAVE–CA–MEAVE polymerization vs. temperature T.

The redox monomer prepared from MEAVE and chloranil is capable of polymerization, whereas MEAVE does not form homopolymers in the presence of radical initiators [2–4]. It should be noted, however, that the reactivity of MEAVE–CA–MEAVE in homopolymerization is considerably lower than that of other MEAVE-substituted quinones:

Redox monomer	E, kJ mol^{-1}
MEAVE–1,4-benzoquinone–MEAVE	11.95
MEAVE–2,3-dichloro-5,6-dicyano-1,4-benzoquinone	47.34
MEAVE–1,2-naphthoquinone	62.50
MEAVE–1,4-benzoquinone	76.71
MEAVE–1,4-naphthoquinone	82.84
MEAVE–chloranil–MEAVE	110.35

Comparison of the activation energies of polymerization of structurally related disubstituted 1,4-benzoquinone and chloranil derivatives shows that the monomer based on 1,4-benzoquinone is considerably more reactive than the chloranil derivative. Apparently, the two symmetrically situated chlorine atoms cause redistribution of the electron density, leading to a certain decrease in the polarization of the double bond. As a result, the activity of the radical and hence the homopolymerization rate decrease.

CONCLUSIONS

(1) The conditions of radical polymerization of a new disubstituted quinone derivative obtained from monoethanolamine vinyl ether and 2,3,5,6-tetrachloro-1,4-benzoquinone (chloranil) were optimized.

Table 2. Kinetic characteristics of polymerization of the disubstituted monomer derived from MEAVE and chloranil

T, K	$10^{-3}/T$	$k \times 10^{-4}$, s^{-1}	$\ln k$	$k_0 \times 10^{12}$, s^{-1}
346	2.89	0.58	–5.65	2.71
353	2.83	1.23	–4.90	2.69
360	2.78	2.42	–4.22	2.54

(2) The kinetic of radical homopolymerization was studied, and the rate constants of the process, activation energies, and preexponential factors of the Arrhenius equation were determined. The presence of two chlorine atoms in the monomer affects the activity of the radical and considerably decreases the reactivity of the monomer in radical polymerization.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Sample Pretreatment and Chromatographic Determination of Benz[*a*]pyrene in Wastewater

N. I. Kayutkina, I. A. Platonov, and A. V. Bulanova

Samara State University, Samara, Russia

Received September 16, 2003

Abstract—A procedure was developed for gas-chromatographic determination of benz[*a*]pyrene in wastewater, with similar pretreatment of reference solutions used for plotting the calibration diagrams and of real wastewater.

The environmental monitoring becomes an increasingly topical problem, because the development of industrial production gives rise to a greater number of pollution sources.

Among the known toxic agents, polyaromatic hydrocarbons (PAHs) require the most stringent control in environmental objects due to their carcinogenic activity.

Polycyclic aromatic hydrocarbons are formed in incomplete combustion of organic compounds; they appear in air, soil, and water from various cultural and natural sources, such as combustion of fuels, smoking, oil refining, forest fires, volcanic activity, etc. In the atmosphere, PAHs are transferred with air masses to long distances and their fall-outs contaminate the environment. One of the known PAHs exhibiting high carcinogenic activity is benz[*a*]pyrene (3,4-benzpyrene, BP); its maximum permissible concentration (MPC) in the atmosphere and in air in working areas of industrial plants is 0.1×10^{-5} and 1.5×10^{-4} mg m^{-3}, respectively; MPC for water and soil is 5×10^{-6} mg l^{-1} and 0.02 mg kg^{-1} [1], respectively.

Analysis of PAHs occurring in the environmental objects in so small concentrations requires that rather stringent requirements should be satisfied at any stage of the procedures used and, thus, very selective and sensitive analytical methods should be developed. The procedures devised in [2, 3] for analysis of PAHs in water are based on capillary gas chromatography with mass-spectrometric detection. Due to simplicity of experimental equipment and availability of modern methods for data recording and treatment, these procedures can be used in both routine and proximate analyses. However, these procedures are based on the quantitative treatment of the gas-chromatographic data and do not take into account experimental errors originating from the sample preparation.

Since monitoring of water samples for the content of BP impurities involves its determination at concentrations not higher than MPC, this problem cannot be solved without preconcentration. Small amounts of PAHs (including BP) are recovered using extraction and sorption methods, supercritical fluid extraction, etc. Despite the significant number of studies devoted to optimization and use of various procedures for sample pretreatment, no one can be considered preferable. However, the main stage in almost all the known procedures of sample pretreatment is still liquid-liquid extraction [4], with benzene as extractant providing the best recovery of PAHs from water. It should be noted that only thoroughly purified solvents and freshly prepared references should be used in the analysis.

EXPERIMENTAL

In this study, wastewater samples were treated using liquid–liquid extraction with benzene as extractant.

The chromatographic tests were performed on a GALS-311 gas chromatograph (LYuMEKS company, Russia) equipped with a flame-ionization detector and a capillary quartz column (3000×0.025 cm) with a low-polarity stationary phase; ultrapure nitrogen carrier gas was used.

The following hydrocarbon impurities occurring in water (aliphatic hydrocarbons C_1–C_{10}, benzene, tolu-

* (c_{BP}) concentration of BP and (Δ) relative error.

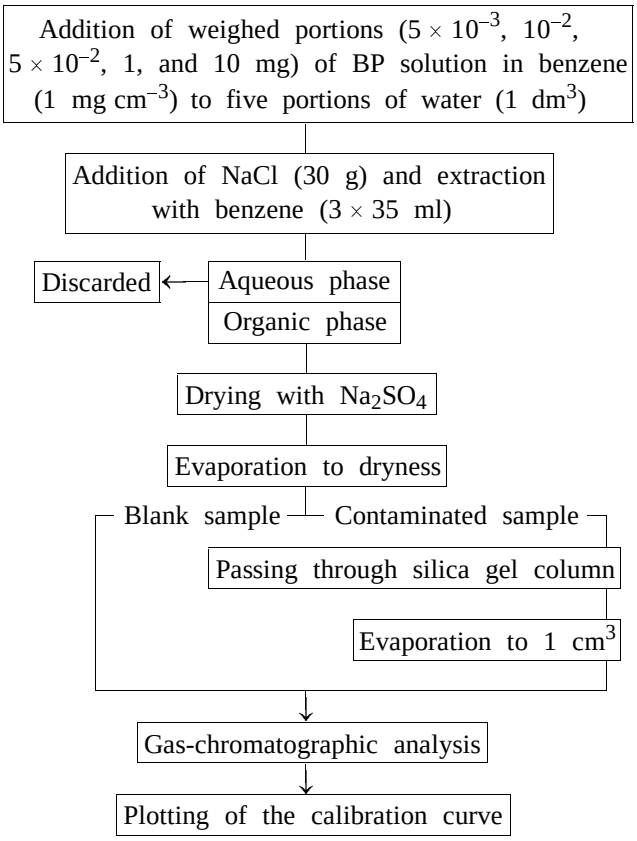
ene, ethylbenzene, xylene isomers, acetone, carbon tetrachloride, chloroform, 1,2-dichloroethane, 1,2-dibromoethane, chloroethane, bromoethane, naphthalene, 2-methylnaphthalene, 1-methylnaphthalene, biphenyl, acenaphthene, etc.) do not interfere with the chromatographic determination of BP, because these compounds are efficiently separated on the column used. Benz[*a*]pyrene was identified by the retention time of the reference (t_{Rsr} = 17.2 min).

In this study, we employed the published procedure [5] in which the reference solutions with known contents of compounds in question is used for constructing calibration diagrams, being subjected to the same pretreatment as the samples to be analyzed. The effect of the sample pretreatment on the results of qualitative gas-chromatographic determination of BP was studied using model systems.

In procedure A, we prepared a series of reference solutions in benzene with known concentrations of BP and then plotted the chromatographic peak areas vs. the BP concentration [6].

In procedure B, the calibration curve was plotted using the data of chromatographic analysis of reference solutions subjected to the same pretreatment as real water. We prepared five model mixtures with known BP concentration; for this purpose, the required weighed portions of the State Reference Sample (benzene solution with BP concentration of 1 mg cm^{-3}) were added to distilled water (1 dm^3). The resulting solution was thoroughly mixed, sodium chloride was added, and the system was extracted with three portions of benzene. The benzene solutions were combined and passed through anhydrous Na_2SO_4, which was then twice washed with benzene. Then, the combined extracts were evaporated to nearly 1 cm^3 volume. The whole procedure B is shown in the scheme.

Preparation of the calibration by procedure B.



As indicated by the experimental results (see table), the relative error in determining BP in water by procedure A at its low content is 86%, and it does not exceed 12% in procedure B.

The results of a quantitative gas chromatographic analysis of real wastewater are also listed in the table.

CONCLUSIONS

(1) Chromatographic analysis of benz[a]pyrene is based on comparison with the calibration curves for reference solutions subjected to the same treatment as real wastewater in question.

(2) In contrast to the procedure involving solutions subjected to the same pretreatment as the samples to be analyzed, the straight use of reference solutions of known concentration can cause underestimation of the benz[*a*]pyrene content in real systems by up to an order of magnitude.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation and Vulcanizing Properties of 1,3,5-Trinitrosobenzene

O. R. Klyuchnikov, F. G. Khairutdinov, and Ya. O. Klyuchnikov

Kazan State Technological University, Kazan, Tatarstan, Russia

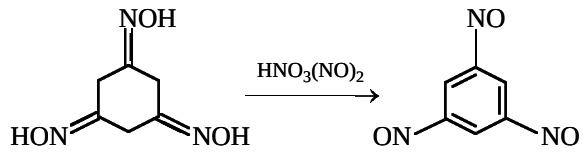
Received May 11, 2004

Abstract—A procedure was developed for preparing a new trifunctional vulcanizing agent for unsaturated rubber composites, 1,3,5-trinitrosobenzene; its suitability as an additive to rubber–substrate adhesive formulations was examined.

Dinitrosoarenes are used as highly active vulcanizing agents for unsaturated rubbers and composites thereof [1]; *p*-dinitrosobenzene (DNB) is widely used in rubber–substrate adhesive formulations [2]. The curing power of dinitrosoarenes is based on their bifunctional structure allowing cross-linking of two unsaturated rubber molecules. Calculations predict [3] that 1,3,5-trinitrosobenzene (TNB) should be more reactive in vulcanization than DNB. Therefore, synthesis of trifunctional TNB is of theoretical and applied interest.

The goal of this study was to develop a facile procedure for preparing TNB and to evaluate its vulcanizing properties and adhesive power in rubber–substrate formulations.

The initial attempts to prepare TNB by reduction of 1,3,5-trinitrobenzene to 1,3,5-tri(hydroxylamino)benzene, followed by oxidation, failed because of side reactions yielding azo and azoxy derivatives. Another route led to success: oxidation of cyclohexane-1,3,5-trione trioxime (CTO) with 30–35% HNO_3 in the presence of minor amounts (~0.1%) of nitrogen oxides. In the course of the reaction, TNB is formed as a hydrophobic foam:



In dilute nitric acid free of nitrogen oxides, CTO readily dissolves to form a brown solution, without oxidation to TNB. Addition of a small amount of sodium nitrite as a source of nitrogen oxides initiates oxidation of CTO to TNB; thus, NO_2 and N_2O_4 are key compounds in the reaction.

EXPERIMENTAL

Cyclohexane-1,3,5-trione trioxime was prepared as described in [4].

1,3,5-Trinitrosobenzene. Dilute nitric acid was prepared by adding 16 ml of 98% HNO_3 containing 0.2–0.4% nitrogen oxides to 50 g of ice. To the resulting 35% HNO_3 solution containing dissolved nitrogen oxides (~0.1%), 1.0 g of CTO was added with vigorous stirring at 12–15°C. Virtually immediately after the dissolution of CTO, TNB was formed as a hydrophobic foam. The product was filtered off, washed with water to neutral reaction and then with acetone, and dried. Yield 0.32 g (34%); light turquoise powder, mp 170°C with decomposition. No tarring was observed. Analytical data:

Found, %: C 43.90, N 25.20, H 1.65.

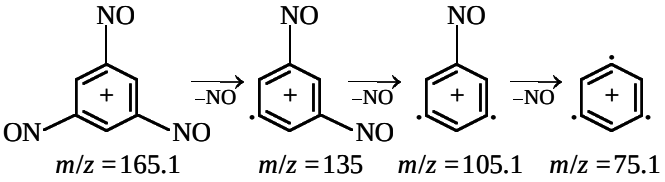
$C_6H_3N_3O_3$.

Calculated, %: C 43.65, N 25.45, H 1.83.

The mass spectrum (EI, 70 eV) recorded on a Finnigan MAT-212 device showed that the sample completely sublimed on being introduced into the ion source. Mass spectrum, m/z (I_{rel}, %): 165.1 $[M]^+$ (59), 135 $[M–NO]^+$ (42), 105.1 $[M–NO–NO]^+$ (8), 75.1 $[M–NO–NO–NO]^+$ (100). The fragmenta-

1070-4272/04/7708-1382 © 2004 MAIK "Nauka/Interperiodica"

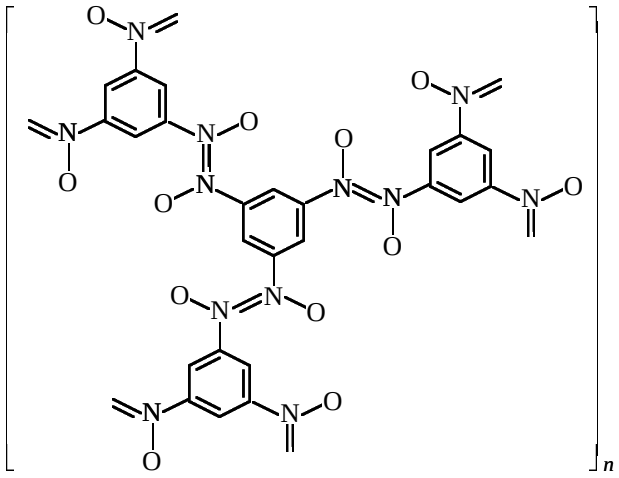
tion pattern involves the loss of NO groups characteristic of nitrosoarenes [5] and can be described by the scheme



At room temperature, TNB is virtually insoluble in organic solvents and sparingly soluble in hot (100°C) toluene or xylene with the formation of an unstable green solution.

Oxidation of TNB yields 1,3,5-trinitrobenzene, similarly to oxidation of nitrosoarenes [2]. In particular, addition of 1 g of TNB to 20 ml of hot (80°C) 98% nitric acid, followed by keeping at this temperature for 2–3 min and dilution with 100 ml of water, yields 0.9 g (70%) of 1,3,5-trinitrobenzene, mp 121–122°C; its spectral (IR, ^{1}H NMR) and TLC (R_f) characteristics coincide with those of an authentic sample.

The IR spectrum of TNB (KBr), recorded on a Bruker Vector-22 spectrometer (Fig. 1), contains a strong band at 1272 cm^{-1}, characteristic of nitroso-arene *trans* dimers [5]; the band at 3119 cm^{-1} is assigned to stretching vibrations of the aromatic C–H bonds. The spectrum suggests that solid TNB has a polymeric structure with *trans*-dimerized nitroso groups, which makes this compound difficultly soluble and relatively stable, comparable in properties with polymeric *p*-dinitrosobenzene having similar *trans*-azo-*N,N*'-dioxide structure [6–8]:



In agreement with the theoretical predictions [3], TNB surpasses DNB in the vulcanizing activity and is of interest as a high-rate curing agent for composite systems based on unsaturated rubbers.

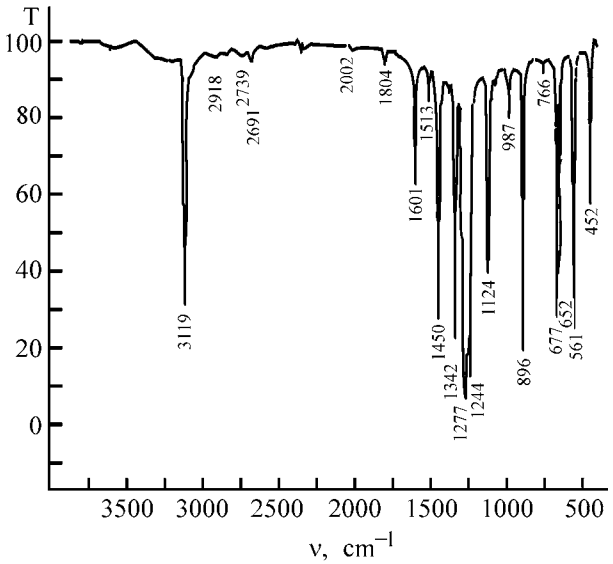


Fig. 1. IR spectrum of TNB in KBr. (T) Transmission and (ν) wave number.

We compared the physicomechanical properties of vulcanized products obtained under "cold" (25°C) vulcanization conditions with TNB and its structural analogue applied in the same field, DNB. The stock compounding was performed on cold rollers; the weight proportions of the components were as follows: butyl rubber 100, DG-100 channel black (filler) 50, stearic acid (plasticizer) 2, and DNB or TNB (vulcanizing agent) 1.

Vulcanization of rubber stocks was performed with 1–1.2-mm-thick plate samples at room temperature for 24 h, after which the physicomechanical characteristics of the vulcanizates were studied with an RMI-250 tensile testing machine (Table 1).

As seen from Table 1, cold vulcanization of a model formulation with TNB ensures better physicomechanical characteristics.

We also examined the possibility of using TNB as a component of a rubber–substrate adhesive formulation. The impregnating compound was prepared by mixing 100 wt parts of *o*-xylene, 10 wt parts of SKN-

Table 1. Physicomechanical characteristics of vulcanizates

Vulcanizing agent	Tensile strength, MPa cm^{-2}	Elongation at break, %
DNB	7.5	320
TNB	9.3	380

Table 2. Results of tests by the H method

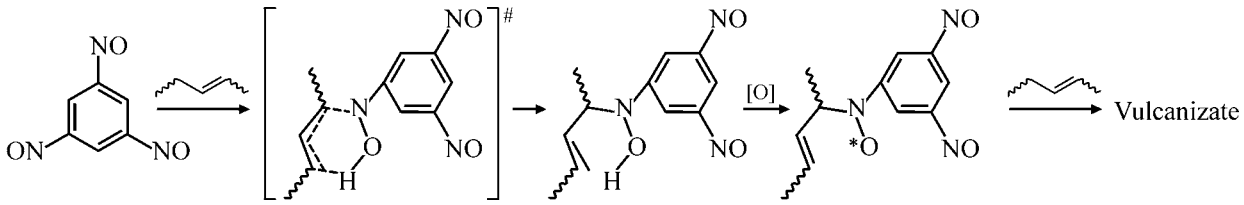
Cord thread	Strength H with indicated agent	
	DNB	TNB
25KNTS	175	195
13ATL-VU	103	128

40 butadiene–acrylonitrile rubber, 5 wt parts of chlorinated Nairit (chloroprene rubber), and 5 wt parts of DNB or TNB. The resulting compound was used to treat 25KNTS polycaprolactam cord threads and 13ATL-VU Anid (nylon) threads by their short dipping into a tank with the impregnating compound. After drying, the impregnated cord threads were placed in a mold for vulcanization with a standard rubber stock based on SKI-3 isoprene rubber, with subsequent determination of the rubber–cord binding strength by the H method [9]. The results are listed in Table 2.

As seen from Table 2, TNB used as component of a rubber–substrate adhesive formulation ensures higher adhesive characteristics, compared to the formulation with DNB.

An ESR study of the vulcanization mechanism with TNB (Radiopan SE/X 2544 spectrometer) revealed, in the initial steps of the reaction of SKDK divinyl rubber (toluene solution) with TNB, the signals of nitroxyl radicals (Fig. 2; a_N = 1.06, a_H = 0.28 mT; g = 2.0057).

The mechanism of unsaturated rubber vulcanization with TNB presumably involves depolymerization of TNB to the monomer and subsequent reactions similar to those of DNB with olefins [10, 11]: pseudo-Diels–Alder addition to the alkene unit, formation and oxidation of the hydroxylamine derivative to nitroxyl, and reactions yielding a three-dimensional network:



Owing to the presence of three reactive nitroso groups, TNB shows advantages over dinitrosoarenes.

CONCLUSIONS

(1) A procedure was developed for preparing 1,3,5-trinitrosobenzene by oxidation of cyclohexane-1,3,5-trione trioxime with dilute nitric acid in the presence of nitrogen oxides.

(2) Solid 1,3,5-trinitrosobenzene is a polymer owing to the intermolecular dimerization of the nitroso groups and formation of *trans*-azo-*N*,*N*'-dioxide fragments.

(3) The trifunctional structure of 1,3,5-trinitrosobenzene ensures higher physicomechanical characteristics of vulcanizates and higher adhesive characteristics of rubber–substrate adhesive formulations prepared with this agent.

BRIEF COMMUNICATIONS

Influence of Fulleroid Nanoparticles (Astralenes) on Absorption of Water by Epoxy Resin

D. V. Kositskii, V. M. Yudovich, M. E. Yudovich, and A. N. Ponomarev

Astrin-Kholding Private Company, St. Petersburg, Russia

Received April 29, 2004

Abstract—Water absorption by ED-20 epoxy resin modified with fullerid nanoparticles, astralenes, was studied as influenced by the modifier content.

Epoxy resins, epoxy-acrylic copolymers, and their composites are used in electrical engineering and radioelectronic industry, aircraft construction, shipbuilding, and mechanical engineering. These materials are also used in building industry as components of potting and impregnation compounds, adhesives, sealants, and binders of reinforced plastics. The adhesion of epoxy resins to most of fillers, supports, and reinforcing fibers is high. Epoxy adhesives are among the best known polymers in the adhesive strength. Cured epoxy resins have good mechanical properties, low shrinkage, and high chemical resistance.

Since polymeric epoxy composites are used in large (usually multilayer) power and insulating structures, water absorption of the epoxy matrix should be estimated. It should be noted that the strength and elastic modulus decrease by 15–20% and the glass transition point substantially decreases at water absorption of 5–8 wt % [1]. The dielectric properties of polymeric composites used for electrical and radio engineering purposes are strongly deteriorated by water absorption.

Epoxy matrices with water absorption of no higher than 1% are the most promising for preparing modern polymeric and composite structures [1].

In this study, we examined the modification of ED-20 epoxy-4,4'-isopropylidenediphenol resin with astralene carbon nanoparticles to decrease its water absorption.

EXPERIMENTAL

We used astalenes, carbon fulleroid nanoparticles, [2] as the modifier.

A typical polyhedral multilayer particle 150 nm long with internal slit capillary is shown in Fig. 1. Similar particles are shown in Fig. 2. Their

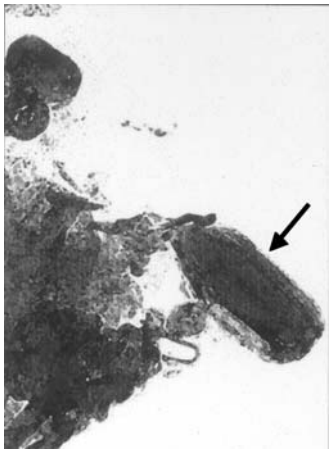

Fig. 1. Typical polyhedral multi-layer particle 150 nm long with internal slit capillary. Scale 1 : 1; the same for Fig. 2.

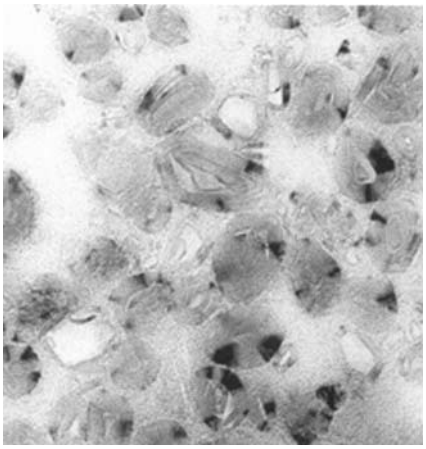

Fig. 2. General view of dispersed astralenes.

shape and the configuration of the slit capillary are clearly seen.

We used ED-20 epoxy resin [GOST (State Standard) 10587–84], PEPA curing agent [TU (Technical Specification) 2413-357-00203447–99], and carbon nanomodifier (TU 2166-001-13800624–2003). The experiments were performed using a VLR-200 analytical balance and an UZV2-1.6/18 ultrasonic bath with an UZG16-1.6/22 ultrasonic generator.

The epoxy resins were modified by two methods. The first method was developed in our laboratory. The nanomodifier was dispersed for 15 min in acetone in an ultrasonic bath, and then the acetone was removed. The epoxy resin was also treated in the ultrasonic bath for 15 min. Then a weighed portion of the modifier was added in small portions to the resin with stirring over a period of 20 min without interrupting the ultrasonic treatment. The curing agent was introduced with continuous vigorous stirring over a period of 5 min. The weight ratio of the curing agent to the resin was 1 : 10. The finished formulation was cast into a mold and cured at room temperature for 24 h. The completely cured sample was weighed and boiled in 0.2 wt % NaCl solution to remove the excess curing agent. Then the sample was weighed again and boiled in NaCl solution for 2 h. After that it was dried between pieces of filter paper and weighed to determine the water absorption.

The second procedure was performed in accordance with GOST 4650–80. Each point of the concentration dependence of water absorption was obtained with 10–15 samples of two different batches of the resin. The experimental dependences of the water absorption by the epoxy matrix on the nanomodifier concentration are shown in Figs. 3a and 3b.

The relative error for each point of the concentration dependences does not exceed 18 rel % at the confidence level of 0.95.

As seen from both figures, the water absorption is low. It is this fact that necessitates the use of the original procedure. The sample obtained by the procedure performed in accordance with GOST 4650–80 should be weighed within 3 min after its removal from the cooled solution. In this case, residual moisture is retained on its surface. The presence of surface water masks the actual water absorption in the bulk of the epoxy matrix. The almost constant (0.7 wt %) water

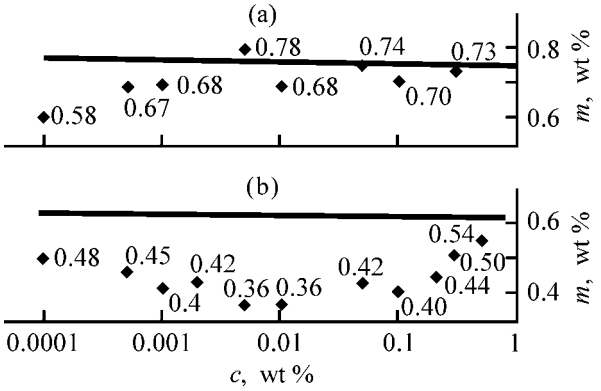

Fig. 3. Water absorption *m* by ED-20 epoxy resin, determined by (a) conventional and (b) original procedure, vs. the content *c* of nanomodifier (astralene) in the polymeric matrix. *Bold line* shows water absorption by the unmodified resin. *Figures at the points* denote water absorption (wt %).

absorption for all the samples prepared by the conventional procedure (Fig. 3a) is due just to this fact. The water absorption by the unmodified resin is shown by the bold line.

The water absorption determined by the original procedure, which involves removal of the surface water, strongly depends on the modifier content (Fig. 3b). It should be noted that the dependence passes through a minimum at the astralene concentration of 5×10^{-2} to 2×10^{-3} wt %. Probably, this concentration of fulleroid particles catalyzes formation of the polymeric matrix.

This is also the case for other astralene-containing composites.

CONCLUSION

The dependence of water absorption by ED-20 epoxy resin on the concentration of a fulleroid modifier was obtained. The water absorption decreases by a factor of 2 at the modifier concentration of 5×10^{-2}–2×10^{-3} wt %.

Jons Jakob Berzelius (To 225th Anniversary of His Birthday)

Professor Jons Jakob Berzelius, a member of the Royal Swedish Academy of Sciences (since 1808), its president (1810–1818) and permanent secretary (since 1818), an honorary foreign member of the Imperial Petersburg Academy of Sciences (since 1820), and a member of academies of sciences and scientific societies of many other countries occupies a rather honorary place in the history of chemistry.

Being one of the best experts on chemistry of his time, he made an outstanding contribution to the creation and development of quite a number of its most important fields.

J.J. Berzelius was born on August 20, 1779, in southern Sweden into a teacher's family. Having received his primary education at home, he entered the gymnasium at a small Swedish town of Linköping in 1793. Already at an early age, Berzelius was interested in natural science and studied the flora and fauna of the neighborhood. Having early lost his parents, he was obliged to earn his living already when studying at the gymnasium and gave lessons. In the end of September 1796, the seventeen-years-old youth entered the old-established university of the town of Uppsala. Founded in 1477, this educational institution was deservedly famed. When being an undergraduate medical student, Berzelius become interested in chemistry and gained an opportunity to use the facilities of the university's chemical laboratory. Berzelius was particularly attracted by the basic research conducted by a prominent French chemist A.L. Lavoisier (1743–1794) and by fundamentals of his oxygen theory explaining the processes of burning and oxidation. The young Swedish scientist took an active interest in the results of investigations carried out by an English physicist and chemist J. Dalton (1766–1844), which were published at the very beginning of the XIX century, and in studies of his Italian colleagues: physiologist L. Galvani (1737–1798) and physicist A. Volta (1745–1827).

In May 1801, the degree of a candidate of medicine was conferred on Berzelius for his studies of medicinal mineral water. Having completed his education, Berzelius obtained the place of supernumerary assistant at the Medical-Surgical Institute in Stockholm. During those same years, Berzelius managed, with assistance of W. Hisinger (1766–1852), a Swedish industrialist and scientist, to equip a laboratory and fabricate instruments necessary for investigations, in-luding a voltaic pile. Already in May 1802, he presented a paper devoted to the effect of electricity on living organisms and became a doctor of medicine and pharmacy. In that same year, at the age of 23, Berzelius was appointed an adjunct of medicine and pharmacy at the Medical-Surgical Institute in Stockholm. In 1807, he was appointed an ordinary professor of chemistry and pharmacy at the same institute. In 1807, Berzelius founded the Swedish Society of Physicians.

In 1808, the young scientist was inducted into the Royal Swedish Academy of Sciences, and was elected its president in 1810. Beginning in 1818, he was the permanent secretary of the Academy for thirty years. In 1818, Berzelius was ennobled; he became

1070-4272/04/7708-1388 © 2004 MAIK "Nauka/Interperiodica"

a baron in 1835. In 1832 he terminated his teaching activities and concentrated all his attention on scientific studies. As mentioned in the monograph [1], already by the end of the 1810s, Berzelius became the leading figure in world's chemical science and attracted the attention of scientists from many countries.

The scientific activities of Berzelius were diverse and successful, their scale is astonishing. Having started with an analysis of the influence exerted by electricity on organic bodies, Berzelius performed, together with Hisinger, a first study in the field of electrochemistry of solid solutions already in 1802. He subjected aqueous solutions of various salts of sulfuric acid to electrolysis. In the same year, he published in Swedish the book *Treatise on Galvanism*. The results of his experiments were described in more detail and more completely in an article published by Berzelius and Hisinger in German in 1803. Already this first publication presented new concepts of the behavior of chemical compounds in electrolysis. In the following years, these concepts were transformed into the electrochemical theory of affinity. Much attention was given to investigations by Berzelius and the closely related studies carried out by G. Davy (1778–1829) in the same years in a book by I.A. Kablukov [2]. According to Berzelius, any complex body can be separated into two parts, one electronegative and the other electropositive. In a comparatively finished form, the main concepts of the electrochemical theory developed by Berzelius were formulated in papers published in 1812 and 1815 [1].

In 1803, Berzelius and Hisinger discovered, virtually simultaneously with M.H. Klaproth (1743–1817), a German chemist analyst, a new element, cerium. In 1817, Berzelius discovered in the waste from sulfuric acid production one more new element, an analogue of tellurium. This element was named selenium. In 1828, Berzelius discovered and, in the next year, isolated in pure form a new element and named it thorium. In 1823, Berzelius obtained silicon in pure form for the first time.

In 1817, a Swedish chemist J.A. Arfwedson (1792–1841) discovered lithium at Berzelius's laboratory and under his supervision and described the properties of this element. In 1830, another pupil of Berzelius, N.G. Sefström (1787–1845), discovered vanadium. Berzelius studied the chemistry of vanadium compounds.

In addition to isolating thorium and silicon, Berzelius was the first to obtain zirconium and tantalum, which had been only known in compounds, in the form of individual metals. The Swedish scientist paid a considerable attention to ores and minerals, in which the nature of Scandinavia is so rich. Having done an enormous amount of work and performed a great number of analyses, Berzelius systematized, in fact, for the first time the available minerals and, based on the results of chemical analyses and on electrochemical concepts developed by the him, combined them in families and groups. Berzelius also improved the existing methods for qualitative analysis of minerals. Before the beginning of the XIX century, mineralogy had been a purely descriptive science. After Berzelius's works, the chemical composition of minerals became their basic classification characteristic. The investigations performed by the Swedish scientist laid the foundation of the chemical area in geology and mineralogy, which was further developed in the second half of the XIX century.

In 1811–1818, Berzelius analyzed and determined the percentage composition of about two thousand compounds, and determined the atomic weights of a great number of elements known by that time. This enormous work served as a confirmation and experimental substantiation of Dalton's atomistic concepts. Dalton introduced the notion of the atomic weight at the very beginning of the XIX century and compiled the first table of relative atomic weights of the most important elements, with the atomic weight of hydrogen taken to be unity, and formulated the law of multiple proportions. The standpoint of Berzelius in the field of atomism and its transformation were analyzed in detail in the monograph by Yu.I. Solov'ev and V.I. Kurinnoi [1]. In 1826, based on newly discovered laws and results of investigations (Dulong–Petit law, investigations of isomorphism), Berzelius composed a new system of atomic weights for 29 chemical elements, with the atomic weights of 23 of these being very close to their modern values.

Berzelius suggested a simple and understandable notation of chemical elements, which is used by chemists until now. This notation was first described by the author in 1813, and in a more complete form, in 1815. So the chemists got a unified chemical language.

In 1811, Berzelius commenced a study of organic compounds, having started with the fabrication of instruments for their elemental analysis. This made it possible to analyze with high precision quite a number of important organic compounds and to conclude that their composition can be described using chemical formulas. This aspect of Berzelius's activities was considered in detail in the monograph [3]. Berzelius him-

self wrote in 1839: "A chemical study of the organic nature have become one of the most interesting subject of natural science" [3]. By the end of Berzelius's life, organic chemistry occupied the leading position in chemistry.

During a number of years, Berzelius worked on a textbook of chemistry and was occupied with its reedition and improvement. The first volume was published in 1808, and the following four volumes, in 1812, 1818, 1827, and 1828. The textbook was translated into other languages. For example, in 1843–1848 a translation of the fifth edition was published in German in five large volumes; in 1845–1850, a French translation was published. The textbook written by Berzelius discussed for the first time such notions as isomerism, allotropy, and catalysis.

Berzelius was the first organizer of scientific information in the history of science. In 1821, *Annual Report of Advances in Physics and Chemistry* was published in Swedish. During the period of time from 1821 till 1847, 27 issues of *Annual Reports* were published, all of which were translated into German. During the first years of publication, the issues covered investigations in physics, chemistry, astronomy, zoology, botany, and technology. The issues published in 1825 to 1839 covered only physics and chemistry. Beginning in 1840, the issues were devoted to chemistry and mineralogy. Berzelius not only reviewed a great number of scientific publications, but also attempted to make an objective critical estimate of most of these works.

Berzelius maintained close scientific relationships with many leading scientists of his time. In the summer of 1812, he visited London and got acquainted with of Davy, whose works in electrochemistry had long been known to Berzelius. In 1818, the Swedish scientist made a long trip abroad, during which he visited England, France, Switzerland, and Germany. He became closely acquainted with C.L. Berthollet (1748–1822), P.L. Dulong (1785–1838), and German and Swiss chemists. Later, Berzelius repeatedly visited Germany and got acquainted with outstanding representatives of this country: poet, philosopher, and natural scientist J.W. Goethe (1749–1832); scientist, traveller, and public figure A. Humboldt (1769–1859); and well-known chemist J. Liebig (1803–1873). Such prominent and, later, well-known German chemists as Ch.G. Gmelin (1792–1860), H. Rose (1795–1864) and his brother G. Rose (1798–1873), F. Wöhler (1800–1882), and H.G. Magnus (1808–1871) were trained in different times at Berzelius's laboratory. Among the Russian chemists who improved their education at this laboratory were G.I. Gess (1802–1850), Yu.V. Fritsshe (1808–1871), G.V. Struve (1822–1908), and K. Shmidt (1822–1894). Later, Gess and Fritsshe were elected members of the St. Petersburg Academy of Sciences (in 1830 and 1852, respectively), and Struve and Shmidt, corresponding members (in 1876 and 1873). The scientific relationships between Berzelius and Russian scientists were analyzed in a monograph [1] and in [4, 5]. As already noted, Berzelius was elected for "outstanding achievements in chemistry" an honorary member of the St. Petersburg Academy of Sciences. A great number of his works were published in Russian translation in periodical [mostly in Gornyi zhurnal (Mining Journal)] and other publications. In turn, Berzelius paid a sufficient attention to works of Russian scientists and noted their high level and practical value [4]. Berzelius corresponded with a number of Russian scientists; the correspondence with Gess was especially intensive [5].

Jons Jakob Berzelius died of a continuous illness on August 7, 1848. His life and activities were described in detail in monographs [1, 6]. A vast literature: articles in journals [7] and reference publications [8–10], is devoted to the outstanding Swedish scientist. The achievements of Berzelius in chemistry of rare-earth metals were considered by D.N. Trifonov [11]. The contribution of the Swedish scientist to the theory of catalysis was discussed by V.I. Kuznetsov [12]. The known historian of chemistry B.N. Menshutkin (1874–1938) named Berzelius "the most outstanding chemist of the first half of the XIX century" [13].

INFORMATION

Third International Scientific-Practical Conference "New Fuels with Additives"

III International Scientific-Practical Conference "New Fuels with Additives" was held in St. Petersburg on June 1–3, 2004. The conference was organized by the St. Petersburg Scientific Center of the Russian Academy of Sciences, Scientific Council for Combustion and Explosion of the Russian Academy of Sciences (Northwestern division), Administration of St. Petersburg (Committees for Transport and for Nature Management, Environment Protection, and Ecological Safety), Prikladnaya Khimiya Russian Scientific Center, a number of other institutes, and St. Petersburg fuel company. Among the participants of the conference were 136 institutions and associations from 9 countries, including 26 research institutions, 18 higher school institutions, 62 plants of oil-refining and fuel industry, and 5 plants for manufacture and repair of engines.

The conference was timed with the 95th birthday of V.S. Shpak, an outstanding scientist in the field of applied chemistry, Honored scientist and technologist of the Russian Federation, Honorary chemist, and academician of the Russian Academy of Sciences. Opening the conference, Shpak mentioned that the requirements to the quality of all kind of fuels have become increasingly stringent, primarily as regards the ecological conditions of their use. Also important is the energy resource saving. To significantly improve the ecological safety of fuels, raise their energy content, increase the reliability and service life of stationary and on-board power installations, it is necessary to use new chemical means of doping of the hydrocarbon raw materials. This leads to creation of a wide variety of chemical products, which are named fuel additives and are new to the chemical industry.

The widening of the variety of products and organization of their manufacture should be consistent with the development of petrochemical industries, because oils and base fuels may differ strongly and this circumstance complicates the doping of fuels and bringing their quality in conformity with the new international standards. Shpak urged the conference participants to actively discuss these problems.

The conference participants were also addressed by the deputy chairman of the St. Petersburg Scientific Center of the Russian Academy of Sciences, Academician G.F. Tereshchenko. He conveyed to them the greeting message of Zh.I. Alferov, Nobel Prize Laureate and academician of the Russian Academy of Sciences, and wished successful work.

More than 80 reports devoted to various aspects of manufacture and use of fuels with additives were delivered at the conference. Review reports were presented by leading specialists of our country: T.N. Mitusova (Volgograd), V.E. Emel'yanov (Moscow), A.M. Danilov (Moscow), F.V. Turovskii (Moscow), V.N. Lozhkin (St. Petersburg), V.V. Sokolov (Moscow), E.M. Mokhnatkin (St. Petersburg), A.L. Dmitriev (St. Petersburg), V.F. Bol'shakov (St. Petersburg), A.V. Nikolaenko (St. Petersburg), S.N. Volgin (Moscow), O.I. Shapovalenko (St. Petersburg), and many others. The reports were mostly devoted to development and manufacture of fuel additives in Russia. Production of cetane-improving additives based on nitrates and peroxides and octane-improving additives containing compounds of iron, nickel, and manganese, as well as amines and oxygenates, were discussed.

Problems associated with the use of oxygenate fuels from renewable sources of raw materials, and also liquefied natural gas, were considered. A lengthy discussion was aroused by reports devoted to methods for obtaining, storing, and using hydrogen in internal combustion engines.

As a result of the discussion of the reports, a conclusion was made that the quality of the most part of fuels manufactured in Russia fail to conform to the modern requirements.

The main achievement of the domestic oil-refining industry was the complete termination of the manufacture and use of leaded gasoline, beginning on July 1, 2003. The speakers noted the insufficiency of the material resources of testing centers and laboratories for carrying out certification, qualification, and validation tests of new and alternative fuels with additives. Until now there is no sufficient coordination of works in the field of manufacture of a variety of additives to motor fuels. At the same time, there exist domestic technologies for manufacture of additives that make

1070-4272/04/7708-1392 © 2004 MAIK "Nauka/Interperiodica"

it possible to obtain fuels on a level with the highest world's standards.

The conference participants noted the benefits of the exchange of views and familiarization with the newest developments in the field of production and use of new fuels and additives. It was found advisable to hold such scientific-practical conferences once in two years and a decision was made to hold the next conference in 2006.

One of the most promising ways to improve the quality of motor fuels and diminish noxious discharges into the atmosphere is to use oxygen-containing additives, combustion catalysts, and alternative fuels, such as liquefied natural gas and hydrogen.

In order to diminish the dependence of Russia on the import of additives, the conference found it appropriate to commission the Scientific council for combustion and explosion of the Russian Academy of Sciences with addressing the Government. A suggestion is to be made to create on the basis of the Council for combustion and explosion, with specialists from other organizations, a Center for coordination of development and manufacture of additives to fuels. The resolution of the conference makes quite a number of recommendations aimed to improve the production and quality evaluation of fuels, additives, and other petroleum products.

BOOK REVIEWS

Sergeev, G.B., *Nanokhimiya* (Nanochemistry), Moscow: Mos. Gos. Univ., 2003, 288 pp.

The book by G.B. Sergeev, a professor of Moscow State University, is the first domestic monograph devoted to the new and rapidly developing scientific area, nanochemistry. Nanosize particles have been actively studied in various fields of science in the recent 15–20 years. These investigations became particularly intensive in the 1990s, and the term nanochemistry appeared in those same years. Presently, such terms as "nanoparticles," "nanoclusters," "nanocomposites," and "nanotechnologies" are already in wide use.

The monograph comprises an introduction, eight chapters, a conclusion, and a bibliographic list. In the brief introduction (pp. 9–11), the author, in particular, notes that studies of nanoparticles composed of various elements of the periodic system open up new areas of chemical research, which cannot be understood in terms of the already developed concepts. The presently available experimental material makes it possible to define nanochemistry as a field of science that is concerned with production, properties, and reactivity of particles and ensembles of particles that have, at least in one direction, a size less than 10 nm. Determining how the particle size or the number of atoms in a particle affect its physicochemical properties and reactivity is one of the most fundamental problems of modern chemistry. The monograph being discussed gives primary attention to the specifics of obtaining and chemical transformations of atoms, clusters, and nanoparticles of metals belonging to various groups of the periodic system. A separate chapter is devoted to nanoparticles based on carbon and silicon.

The small first chapter (pp. 12–20) is devoted to a general characterization of the problem, presents the author's classification of nanoparticles, and formulates some important concepts. It is, in particular, noted that the particle size is an active variable, which determines, together with other variables, the state of the system and its reactivity. Reactions into which solid substances do not enter are possible for their nanoscale particles.

The second chapter (pp. 21–53) considers ways to obtain and stabilize nanoparticles. The high chemical activity characteristic of metal atoms is preserved in dimers, trimers, and in clusters formed from these atoms, as well as in nanoparticles with a great number of atoms. Studies of active particles of this kind are only possible if various stabilizing agents are used. The following methods are discussed: chemical reduction mainly in the liquid phase; reactions in micelles, emulsions, and dendrimers;, photo- and radiation-induced chemical reduction; cryochemical synthesis; and physical techniques. The material presented in the chapter is mainly based on publications of 2000 and 2001.

The third chapter (pp. 54–66) is devoted to methods for determining the size and studying some properties of nanoparticles in the gas phase, on a surface, in the bulk, or in a matrix. To methods of this kind belong transmission or scanning electron microscopy, electron-probe microscopy, diffraction techniques (X-ray and neutron diffraction analysis), and a number of other physical techniques. Despite the wide diversity of the existing methods for studying individual nanoparticles in the gas phase and in the bulk of nanostructures, the author notes the necessity for developing new techniques that should not only measure various parameters of nanoparticles, but also trace in detail how these parameters vary in the course of formation and subsequent self-organization of nanoparticles and upon fabrication of nanotechnological devices on their base.

The fourth chapter (pp. 67–135) presents the main concepts of the intensively developing new scientific area: cryochemistry of nanosize particles or cryonanochemistry.[1] The chapter is mainly constituted by results of experimental studies of processes involving nanoparticles of magnesium, silver, and rare-earth metals at low (77 K) and ultralow (4–7 K) temperatures. The final section of the chapter considers the possibility of modeling of the physicochemical properties and reactivity of metal nanoparticles.

The fifth chapter (pp. 136–191), named "Chemical nanoreactors" by the author, pays considerable attento application of the method of matrix isolation for

[1] G.B. Sergeev is a known specialist in cryochemistry and one of the authors of the monograph *Kriokhimiya* (Cryochemistry) (Moscow: Khimiya, 1978).

1070-4272/04/7708-1394 © 2004 MAIK "Nauka/Interperiodica"

stabilization of active particles. The method consists in that substances are accumulated under the conditions that hinder reactions. For example, the matrix in a solid inert substance at low temperature hinders diffusion, and active particles are virtually immobile (stable), frozen in the medium that cannot react with them. Inert gases can serve as matrices. A great number of examples of reactions involving various metals in inert and active matrices are given.

The rather small sixth chapter (pp. 192–200) contains evidence concerning the nanochemistry of carbon and silicon. The author emphasizes the importance of the discovery of fullerenes and, later, carbon nanotubes for development in the future of nanotechnologies applicable in actual practice.

The seventh chapter (pp. 201–219) is devoted to dimension effects in nanochemistry. By dimension effects in chemistry is understood the fundamental change in the physicochemical properties and reactivity, depending on the number of atoms or molecules in a substance particle, which occurs at particles sizes of less than 100 atomic-molecular diameters. The manifestation of dimension factors is one of the basic distinctions of nanochemistry from the chemistry of reactions that occur under ordinary conditions. It is emphasized at the end of the chapter that it is studying the dimension factors and establishing a relationship between the number of atoms involved in a reaction and the resulting fundamental chemical changes that is the main subject of nanochemistry. The size, shape, and organization of metal particles in the nanometer range directly affect the chemical activity of the resulting systems, stability and properties of the materials obtained and the possibility of their use in nanotechnology.

The eighth chapter (pp. 220–253) contains the most recent evidence (the years of 2000–2002) concerning various fields of application of nanoparticles in science and technology: development of new catalysts, use of highly active nanocrystalline metal oxides in various syntheses, use of semiconductor nanoparticles, and development of nanophotonics, which is a new area of research concerned with optical properties of objects with a size considerably smaller than the wavelength of light. A separate section of the chapter is devoted to application of carbon nanotubes.

In the conclusion (pp. 254–260), the author formulates, on the basis of an analysis of the experimental material described, some general conclusions and points out promising areas of investigations into the chemical properties and reactivity of various elements of the periodic system, depending on the particle size. The origination and development of nanoscience, and nanochemistry as its most important component, is in line with the modern development of natural science.

The bibliographic list (pp. 261–284) contains 606 references to publications by domestic and foreign authors. Noteworthy is the fact that more than 75% of references is to publications of the years of 1990 to 2002. Particularly great is the number of publications in the field of nanochemistry in 2000 and 2001. The monograph by G.B.Sergeev has a subject index (pp. 285–287).

Nanoscience has an interdisciplinary nature; it relies upon the approaches and investigation techniques used in physics, chemistry, biology, and materials science. The importance and role of this science will grow in the XXI century year by year. The very interestingly and rather simply written monograph by G.B.Sergeev may be undoubtedly of interest to a wide audience of specialists. The book will arouse interest in nanochemistry, its possibilities, fundamental aspects, and tasks.

Russian Journal of Applied Chemistry, Vol. 77, No. 9, 2004, pp. 1397–1403. Translated from Zhurnal Prikladnoi Khimii, Vol. 77, No. 9, 2004, pp. 1409–1415.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Features of Oxidation of Titanium Group Metals in Air

V. I. D'yachkov

St. Petersburg State University, St. Petersburg, Russia

Received July, 9, 2004

Abstract—The kinetics and mechanism of oxidation of titanium, zirconium, and hafnium in air at 973–1473 K were studied in relation to the properties of the metals.

The kinetics and mechanism of oxidation of titanium, zirconium, and hafnium were extensively studied, but the behavior of these metals actually was not compared under identical conditions, except for certain data in [1]. At the same time, such data are of both practical and scientific interest, as they give insight into the features of oxidation of these metals.

The purpose of this work was to reveal how the properties of titanium, zirconium, and hafnium affect the kinetic parameters, temperature dependence of rate constants, and activation energy of the oxidation, the diffusion mechanism of scaling, and properties of the scale.

Experiments were carried out in air with controllable humidity at a pressure of 101.3 kPa in the range 973–1473 K. The materials under study were high-purity metals (99.93% Ti, 99.80% Zr, and 99.70% Hf) melted in a fluidized bed in an electromagnetic field in an atmosphere of purified argon [2]. The technique of the preparation of $1.0(1.5) \times 1.0 \times (0.2–0.5)$-cm samples with a grain size of about 50 μm and the experimental procedures in use are described in [3–5].

Comparison shows that the parameters of the oxidation of titanium, zirconium, and hafnium are essentially different. In particular (Table 1), the rate of Ti oxidation at 1073–1473 K is much lower than that of Zr, but much higher (at $T > 1073$ K) than that of Hf.

Processing of the oxidation curves (Fig. 1) shows that Evans equation (1) [6] and laws close to parabolic, cubic, and sometimes linear (2)–(4) are obeyed:

$$K_l q^2 + K_p q = K_l K_p \tau + C, \quad (1)$$

$$q^2 = K_p \tau + C, \quad (2)$$

$$q^3 = K_c \tau + C, \quad (3)$$

$$q = K_l \tau + C, \quad (4)$$

where q is the weight of absorbed gases; τ, time; C, a constant; K_l, K_p, and K_c, rate constants of the oxidation by linear, parabolic, and cubic laws, respectively.

In fact, laws (2)–(4) are not strictly fulfilled in the case of the Zr and Hf oxidation, and the experimental data can be formally described by expression (5) with various n values.

$$q^n = K\tau + C. \quad (5)$$

As follows from Table 2, the kinetics of Ti oxidation (3 h) at 1073–1373 K almost fully follows Evans equation (1) (Fig. 2), which suggests nonstationary character of this process and, hence, comparable control of its rate by diffusion and by interphase reactions [6, 7]. At $T < 1073$ K, the equation is obeyed only at the beginning of the test, being then replaced by another relationship with $2 < n < 3$ in expression (5). Above 1373 (1423) K, the Evans law is not obeyed owing to a considerable influence of a strong overheating of the sample surface on the kinetics of the oxidation in the initial period [8]. With Hf (3 h), the Evans law is obeyed only at 973–1023 K and, as opposed to Ti, above 1423 K, whereas in the range 1073–1423 K it is obeyed only at the beginning of the oxidation (Fig. 2), with the subsequent transition to dependence (2), which is close to parabolic. With

* (i.p.) Initial period; (a.i.p.) after initial period.

Zr, the Evans equation is not obeyed at all, and the oxidation process is usually described by parabolic law (2) and subsequently by cubic law (3), or by laws close to them.

In some cases, the cubic law converts to almost linear law (4) with a noticeable increase in the oxidation rate, suggesting a decrease in the protective properties of the oxide film. It should be noted that almost all papers devoted to the kinetics of oxidation of Ti, Zr, and Hf in air at 973–1473 K [4, 9–11] contain evidences for the validity of laws (2)–(4) or those close to them. The nonstationary character of Ti and Hf oxidation under the same conditions was found for the first time in [3, 5].

Figure 3, in which $K_l^{(1)}$ and $K_p^{(1)}$ characterize the oxidation according to Evans equation (1) and $K_p^{(2)}$, the oxidation according to parabolic law (2), shows that the temperature coefficient $K_l^{(1)}$ for Ti increases on passing to the region $T > 1173$ K, whereas in the case of Hf oxidation, on the contrary, it decreases. The dependences $\log K_p^{(1)} = f(1/T)$ for both metals are similar and consist of three sections; however, the intermediate region in the case of Hf is longer compared to Ti and is shifted toward higher temperatures. The dependences $\log K_p^{(2)} = f(1/T)$ for Zr and Hf are also similar in shape and somewhat differ from each other in the inflection points and lengths of separate regions.

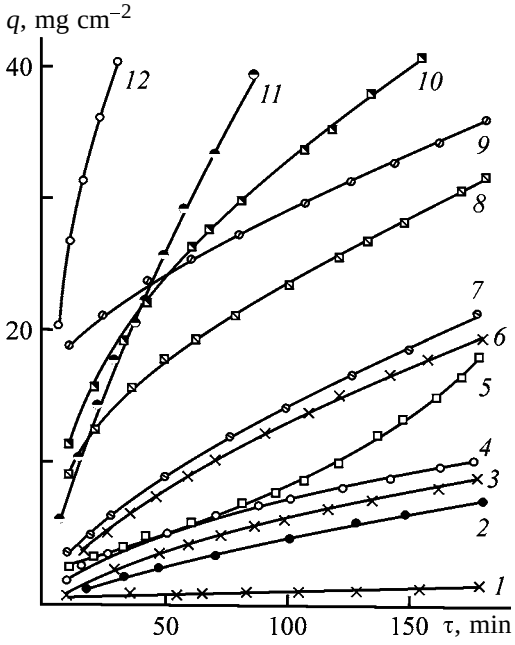

Fig. 1. Curves of the oxidation in air of (*2, 7, 9, 11*) titanium, (*5, 8, 10, 12*) zirconium, and (*1, 3, 4, 6*) hafnium. (q) weight gain and (τ) time; the same for Fig. 2. Temperature (K): (*1, 2, 5*) 1173, (*3, 7, 8*) 1273, (*10, 11*) 1373, and (*6, 9, 12*) 1473.

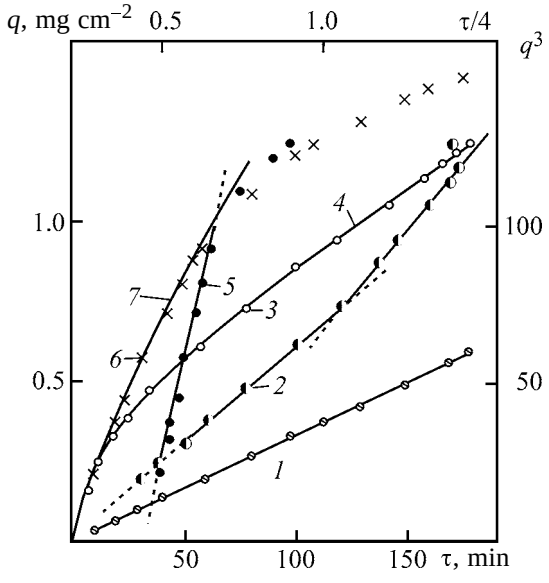

Fig. 2. Data on the of oxidation in air of (*1*) zirconium, (*2–4*) titanium, and (*5–7*) hafnium in the coordinates of (*2, 5*) Evans equation and (*1*) cubic law; position of (*3, 6*) experimental points relative to (*4, 7*) curves of Evans equation constructed with the values of $K_l^{(1)}$ and $K_p^{(1)}$ obtained.

Table 3. Apparent activation energy of oxidation of Ti, Zr, and Hf by linear [$E_l^{(1)}$], parabolic [$E_p^{(1)}$, $E_p^{(2)}$], and cubic (E_c) laws

M	$E_l^{(1)}$	$E_p^{(1)}$	$E_p^{(2)}$	E_c
	kJ mol^{-1}			
Ti	71 (973–1173)*	235 (973–1123)	–	–
	199 (1173–1423)	510 (1123–1223)	–	–
	–	159 (1223–1373)	–	–
Zr	–	–	125 (973–1173)	175 (973–1173)
	–	(1173–1323)	300 (1173–1323)	460 (1173–1273)
	–	–	–	235 (1273–1473)
Hf	150 (973–1173)	90 (973–1173)	95 (1073–1223)	–
	100 (1173–1473)	220 (1173–1373)	250 (1223–1423)	–
	–	98 (1373–1473)	–	–

* Temperature, K, is given in parentheses.

The apparent activation energies of the oxidation by the corresponding laws (Table 3) are determined with an error of ±(3–7)%. As compared to Hf, for Ti the apparent activation energy $E_l^{(1)}$ of interphase processes at T < 1173 K in Table 3 is lower, and at T > 1173 K, much higher. In the case of $E_p^{(1)}$, the relationship is inverse. The activation energy of oxidation of Zr by parabolic law, $E_p^{(2)}$, and by cubic law, E_c, is much greater than $E_p^{(1)}$ and $E_p^{(2)}$ for Hf in all the temperature ranges.

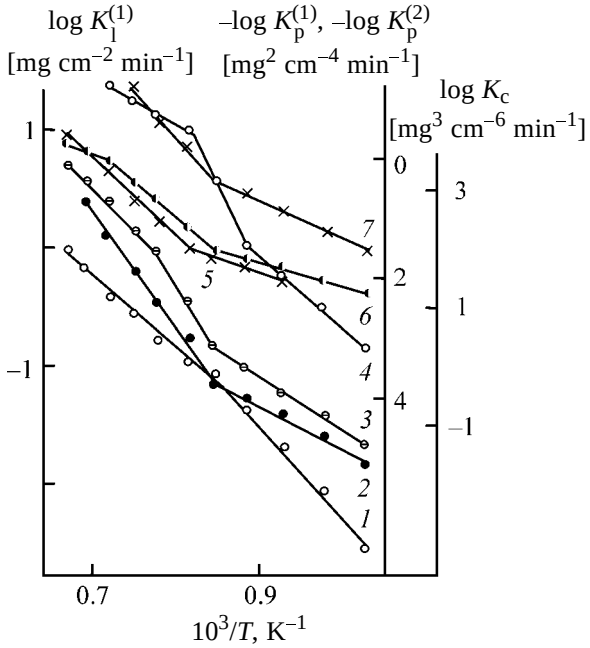

Fig. 3. Temperature dependence of (*1, 2*) $K_l^{(1)}$, (*4, 6*) $K_p^{(1)}$, (*5–7*) $K_p^{(2)}$, and (*3*) K_c for the oxidation in air of (*2, 4*) titanium, (*3, 7*) zirconium, and (*1, 5, 6*) hafnium. K_l, K_p, and K_c are constant of the oxidation by linear, parabolic, and cubic laws, respectively.

According to Table 4, the role of the formation of a diffusion oxygen layer (DOL) in the overall oxidation process sharply increases in going from Ti to Hf, whereas the rate of its growth by parabolic law (2) increases less significantly. This is caused, in particular, by higher protective properties of the scale on Hf. Indeed, on the replacement of titanium by hafnium the total oxidation rate decreases (Table 1) owing to a noticeable decrease in the scaling rate (Table 4).

In both cases, especially in the case of Ti, the oxygen fraction z in DOL decreases as the time of isothermal oxidation (1273 K) increases. This is attributable to the fact that the DOL increases by parabolic law (2), and the oxide layer, by Evans equation (1), i.e., the first process is retarded faster than the second one. As the temperature increases up to approximately 1273 K, the role of the DOL formation in the overall

process of Ti oxidation noticeably decreases, but it sharply increases as the temperature increases to 1473 K. However, in the case of Hf, passing to the region of $T > 1273$ K is accompanied, on the contrary, by an essential decrease in both the DOL growth rate and the oxygen fraction in it.

According to the X-ray diffraction analysis, the scale formed in oxidation of Ti, Zr, and Hf at 973–1473 K consists of their dioxides: tetragonal TiO_2 (rutile), monoclinic (α-phase) and, above 1223 K, also tetragonal (β-phase) ZrO_2, and monoclinic HfO_2. A practically white oxide film is formed on Ti at 973–1473 K, whereas in the case of Zr and Hf the film is formed only at $1273 < T < 1373$ and $1173 < T < 1423$ K, respectively, which is usually accompanied by cracking of the sample along edges. Outside these regions the scale on Zr and Hf has an anthracitic color. Unlike Ti with a regular microlayered structure of the scale on edges ($T \le 1373$ K), a denser oxide layer of pillared crystals with pores arranged mainly perpendicularly to the sample surface is formed in oxidation of Zr and Hf at temperatures of up to 1473 K.

The scale on Ti obtained at $T > 1073$ K has a weak adhesion to the matrix surface after cooling, whereas in the case of Zr and Hf it is very strongly linked to the metal, which makes practically impossible its quantitative mechanical separation.

According to the experiments with "inert" labels, the oxide film on Zr and Hf grows up to 1473 K almost exclusively owing to diffusion of O_2 [4, 5]. In the case of Ti, the role of cationic diffusion in the formation of the oxide film becomes noticeable above 1373 K, and some authors believe [9] that it is dominating even at $T < 1273$ K.

It follows from Table 5 that the ratio $K_l^{(1)}/K_p^{(1)}$ noticeably increases in going from Ti to Hf, suggesting an increasing role of diffusion processes in the control over the rate of the nonstationary oxidation. As the temperature increases, at least within certain limits [up to 1273 (1323) K for Ti and up to 1273 K for Hf], the ratio $K_l^{(1)}/K_p^{(1)}$ decreases, suggesting an increasing role of interphase processes in the resulting oxidation rate according to the theoretical concept [12]. The increase in $K_l^{(1)}/K_p^{(1)}$ at $T > 1273$ (1323) K is associated with specific features of the temperature dependences of $K_l^{(1)}$ and $K_p^{(1)}$ (Fig. 3) and with a change in the mechanism of the nonstationary oxidation.

Thus, the data obtained show that, in going from Ti to its chemical analogs, the overall rate and the type of kinetic relationships of the oxidation considerably change, with Evans equation (1) not obeyed at all for Zr. The position and length of particular regions of the temperature dependence of the rate constants, its character in the case of K_l^1, and the activation energy of oxidation also change essentially.

Simultaneously the role of diffusion in the control over the rate of the nonstationary oxidation and the fraction of oxygen in DOL increase, the adhesion of the oxide film to the matrix surface strengthens, its color and morphology change, and the role of anionic diffusion in scaling grows. The behavior of Zr during the test especially strongly differs from that of Ti. As far as the type of oxidation relationships is concerned, hafnium is more similar to titanium, but with respect to the role of reacting components in the diffusion process of scaling and certain properties of the scale it is similar to zirconium.

The specific features of the oxidation of Ti-group metals in air are apparently associated with differences in their physical and chemical properties (Table 6). In particular, the similarity of a number of important characteristics of Zr and Hf and their dioxides, such as the electronic configuration of the outer shell, atomic and ionic radii, crystal structure, unit cell parameters, ionization potential, molar volume, and Pilling–Bedworth coefficient ($\nu MO_2/\nu M$), and the same type of point defects in the lattices of the dioxides determine similarity of their behavior in oxidation. It appears, for example, in the identity of the diffusion mechanism of scaling, the similarity of its morphology, color, and adhesion properties, in a common parabolic law of the oxidation, and in the same type of temperature dependences of $K_p^{(2)}$. At the same time, certain differ-

ences in the properties of Zr and Hf and their dioxides (Table 6) cause the observed differences in the oxidation rate, type of kinetic relationship (Table 2), and also in apparent activation energy $E_p^{(2)}$, though sometimes this correlation is ill-defined.

However, many important characteristics for Ti and TiO_2 differ from those of Zr, Hf, and their dioxides more essentially, except for types of crystal lattices of the metals, TiO_2, ZrO_2 (T > 1273–1373 K), and HfO_2 (T > 1973 K). This is manifested, e.g., in substantial growth in the energy of interatomic bonds $m\theta^2$ in going from Ti to its analogs and in the strength of the lattices of their dioxides in going from TiO_2 to HfO_2, which favors the observed increase in the Hf resistance to oxidation (T > 1073 K). A decrease in the electronegativity in the same direction is accompanied, in particular, by a decrease in the solubility of oxygen in the α- and β-phases of the metals. This explains the observed decrease in the rate of DOL growth (T > 1273 K) in going from Ti to Hf (Table 4). Taking into account the opposite effect exerted on the DOL growth by oxygen dissolution in a metal proper and by transfer of the interface with scale into the depth of the matrix, we should expect a similar result in the range T < 1273 K. Furthermore, higher energy of interatomic bonds in Zr and Hf lattices, as compared to Ti, increases the relative role of intercrystallite boundaries as the most reactive surface regions in the oxidation process. As a result of the penetration of the oxide in these regions into the depth of the metal, the strength of the adhesion of the oxide film with the matrix sharply increases, which is proved experimentally. In the case of Ti, the role of this factor is much weaker.

Owing to the stronger bonding between scale crystallites on Zr and Hf and to high Pilling–Bedworth coefficients for monoclinic ZrO_2 (1.56) and HfO_2 (1.62), the stress arising in the scale results in its cracking along edges of the sample, and sometimes even in its deformation. When titanium is oxidized in air, owing to the even higher Pilling–Bedworth coefficient for rutile (1.74) and lower strength of adhesion between the scale and the matrix and between scale particles, as compared to Zr and Hf, the scale integrity gets disturbed, which results in increasing chemical potential of oxygen. This promotes formation of rutile with approximately stoichiometric composition. Virtual absence of this phenomenon in the case of Zr and Hf at a higher scale density is proved, in addition to other facts, by a considerable role of the near-parabolic and cubic laws in their oxidation. According to the existing concept [16], cubic law (3) of the growth of thick oxide films is a result of superposition on the diffusion process of secondary

phenomena in the scale such as the aging, retarding the oxidation.

These factors ultimately determine a number of morphological features of the scale and its phase boundary with the metal. However, an important circumstance, usually neglected in such studies, should be noted. Namely, structures of the forming scale and the scale after cooling the sample withdrawn from the hot zone can differ essentially owing to unequal coefficients of thermal expansion, plasticity, and cooling rates of the metal and the oxide film. In fact, the samples of refined and commercial titanium VT1-0 withdrawn from a hot zone (1273 K) had a regular microlayer structure of porous scale and a cavity on its boundary with the matrix, whereas the oxide film obtained by cooling the samples with the furnace to room temperature tightly adhered to the metal surface and showed no microlamination. In this case, pores were mainly arranged as chains parallel to the interface between the metal and oxide phases. These results show that the existing concept of the mechanism of formation of the microlayered scale [1, 9, 12] should be corrected.

The influence of the properties of Ti and Hf on the temperature dependence of $K_l^{(1)}$ is manifested as a decrease in its slope for Hf as compared to Ti in going to the range $T > 1173$ K. In the case of the $\log K_p^{(1)} = f(1/T)$ dependence, the inflection points are somewhat shifted toward higher temperatures, and the length of the middle region increases in going from Ti to Hf.

It is know that inflections in the temperature dependences of the rate constants suggest a change in the oxidation mechanism. The first bend (Fig. 3) is attributable to the fact that the allotropic $\alpha \rightarrow \beta$ transition in the metal phase starts to affect the oxidation process. This transformation, which takes place at 1155 and 1135 K for pure Ti and Zr [14], respectively, is accompanied by loosening of the metal lattice in excited states of the atoms. However, the fact that in the same temperature region there is also a bend for Hf, which is characterized by a change in the temperature coefficient $K_l^{(1)}$ different from that for Ti and by $T_{\alpha\rightarrow\beta} = 1973$ K (Table 6), suggests the action of another mechanism in this case. The effect of the $\alpha \rightarrow \beta$ transition on the oxidation appears not only at the equilibrium temperature, but also within a certain temperature range. It is caused, in particular, by the fact that the equilibrium temperatures of the $\alpha \rightarrow \beta$ transition on the surface and in the bulk of the metal are essentially different (80 K for Ti) [17]. The second bend is attributable to stabilization of the β-phase, and for Zr, also to the transformation of monoclinic ZrO_2 into the tetragonal form at $T \geq 1273$ K [14].

Because of the greater accepting power of Ti compared to Zr (owing to incomplete filling of its 3*d* shell, whereas in the case of Zr the 4*d* shell is filled completely), the metallic bonding predominates in Ti_6O and Ti_3O suboxides and covalent bonding, in Zr_6O and Zr_3O [14, 15]. As a result, the strength of the interatomic bonding in the titanium lattice increases as the concentration of oxygen in it grows, which enhances the scale resistance of Ti–O alloys, whereas the dissolution of oxygen in Zr is accompanied by a decrease in the strength of the interatomic bonding [14, 15]. In particular, this fact seems to be responsible for the observed increase in the oxidation rate in going from Ti to Zr.

The predominance of oxygen vacancies $V_O^{\cdot\cdot}$ in ZrO_2 and HfO_2 lattices [13] causes the observed scale growth up to 1473 K owing to anionic diffusion. At the same time, when Ti is oxidized in air at high temperatures ($T > 1373$ K), owing to the presence of interstitial $Ti_j^{""}$ cations in the rutile lattice along with $V_O^{\cdot\cdot}$ [13], the participation of the titanium cations in scaling becomes apparent.

As found earlier [18], the higher activity of oxygen in scale on its boundary with the metal, compared to the equilibrium activity, is a reason for the nonstationary oxidation of Ti in oxygen and in air. The results obtained in this work do not contradict the assumption that in the case of Hf nonequilibrium conditions of the oxidation in air are mainly localized on the scale–gas boundary. However, precise solution of this problem requires a special study.

CONCLUSIONS

(1) Many basic parameters of the oxidation essentially change in going from Ti to Zr and Hf, which is primarily caused by the fact that the strength of chemical bonds in the crystal lattices of the metals and their dioxides, accepting powers of these elements, types of point defects in the lattices of the dioxides, and Pilling–Bedworth coefficients are different.

(2) The similarity of the physical and chemical properties of Zr and Hf, and of their dioxides causes the similarity of the diffusion mechanism of scaling and of the scale characteristics. The behavior of Zr in the oxidation differs from that of Ti most sharply, whereas Hf is more similar to Ti than to Zr as far as the type of oxidation relationships is concerned.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation of α-Fe_2O_3 by Thermal Hydrolysis of Iron(III) Basic Sulfate

L. S. Eshchenko and V. A. Salonikov

Belarussian State Technological University, Minsk, Belarus

Received June 15, 2004

Abstract—Features of the hydrolytic transformation of iron(III) basic sulfate under hydrothermal conditions at 140–200°C were studied. The influence of the conditions of the hydrothermal treatment of iron(III) basic sulfate on the rate and degree of its hydrolysis was examined. The chemical and phase composition of metastable intermediates was ascertained, and conditions for the formation of the final product of thermal hydrolysis, hematite of high phase purity, were determined.

Hydrothermal technique plays a growing role in production of the α modification of superfine iron(III) oxide. This technique allows fine control of the particle sizes and shapes and preparation of virtually monodisperse products. The monodispersity ensures high physicochemical characteristic of pigments, whereas the variation of particle sizes and shapes makes it possible to vary color tints over a wide range [1].

Procedures for the production of α-Fe_2O_3 at elevated temperatures from aqueous suspensions of iron(III) α-, β-, and γ-oxyhydroxides have been described in the literature, and the influence of various factors on the transformation rate and product characteristics has been elucidated [2–4]. Data on the production of α-Fe_2O_3 by hydrothermal treatment of iron(III) basic salts, particularly of $FeOHSO_4$, are available [5, 6]. However, data on the phase and chemical transformations occurring during the process are limited, which prevents development of a method for the production of α-Fe_2O_3 from $FeOHSO_4$. Therefore, the aim of this work was to study chemical, phase, and disperse composition of the products of $FeOHSO_4$ hydrolysis in relation to the treatment conditions.

EXPERIMENTAL

Iron(III) basic sulfate was prepared by thermal treatment of pure grade iron(II) sulfate heptahydrate first at 105°C for 1.5 h and then at 250°C for 4–6 h [6]. The resulting iron(III) basic sulfate with the composition $Fe_2O_3 \cdot 2.01SO_3 \cdot 0.01FeO \cdot 1.19H_2O$ was suspended in water and then subjected to the hydrothermal treatment at 140–200°C. The treatment was performed in Teflon-lined steel autoclaves. The temperature was maintained with the accuracy of ±1°C. After the treatment, the autoclave was quickly cooled to room temperature, and the precipitate was separated from the liquid phase by filtration and dried at 105°C. The content of iron(III) and sulfate ions in the liquid and solid phases was determined by chemical analyses. The degree of hydrolysis was calculated from the content of Fe^{3+} and SO_4^{2-} ions in the solid phase. Products of the $FeOHSO_4$ hydrolysis were studied by X-ray phase analysis (DRON-2 installation, filtered CoK_α radiation), by a microscopic technique (a Cam Scan scanning electron microscope equipped with an AN-1000 EDS detector), by a stereologic method (a Mini-Magiscan automatic image analyzer, Jojce Loebl), and by thermogravimetry (a Paulik–Paulik–Erdey Q-1500 derivatograph, heating rate 5 deg min^{-1}).

Our study has shown that hematite, α-Fe_2O_3, is the final stable phase of the hydrothermal treatment of the aqueous suspension of iron(III) basic sulfate. Phase and chemical transformations occurring in the system iron(III) basic sulfate–water are manifested as significant changes in sizes and shapes of solid phase crystals, occurring during the hydrothermal treatment. The difference in the crystal habit (morphology) of the starting $FeOHSO_4$ and final hematite phase is clearly seen in the electron micrographs (Fig. 1). Particles of the starting $FeOHSO_4$ have a globular shape with a size of 10–30 μm. Particles of α-Fe_2O_3 have a pillared shape with an average length of 1 μm and average width of 0.5 μm. Such a significant change in

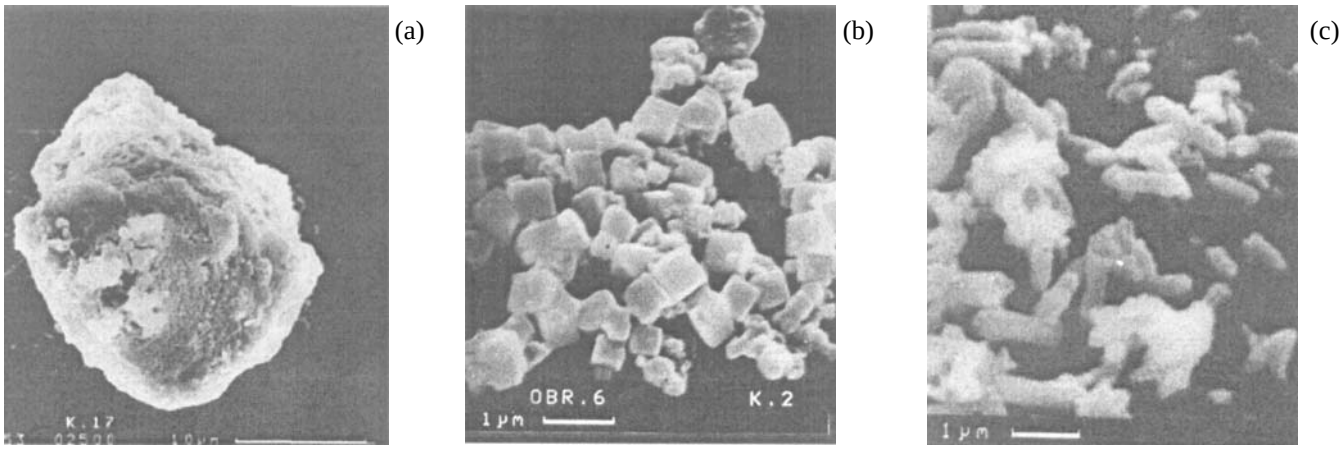

Fig. 1. Electron micrographs. Sample: (a) starting $FeOHSO_4$, (b) intermediate hydrolysis product, and (c) α-Fe_2O_3.

the crystal morphology suggests that the transformation of $FeOHSO_4$ into α-Fe_2O_3 occurs by the dissolution–precipitation mechanism.

It is known that one of the main synthesis parameters determining the habit of α-Fe_2O_3 crystals is pH of the medium. For example, according to [6], needle-shaped hematite crystals are formed in an acid medium and isometric crystals, in neutral and weakly basic media, but the crystals formed in a strongly basic medium have a platelike shape [4]. It is most likely that in our case the formation of pillared hematite crystals is determined by low pH of the medium produced by the hydrolysis of $FeOHSO_4$.

It should be noted that the distribution of hematite particles over both length and width is narrow (Fig. 2). Such a narrow distribution is attained owing to the uniformity of nucleation and crystal growth in the entire reaction volume.

Data on the composition of the forming solid and liquid phases as influenced by the conditions of $FeOHSO_4$ hydrolytic transformations are given in the table. According to these data, the rate of formation the α-Fe_2O_3 phase and the phase purity depend on temperature, duration of hydrothermal treatment, and the $FeOHSO_4 : H_2O$ ratio in the suspension. The rate of iron oxide formation significantly increases as the H_2O weight fraction in the suspension and treatment temperature increase. For example, according to the X-ray phase analysis, hematite is detected after 12-, 8-, 4-, and 2.5-h treatment of the $FeOHSO_4$ suspension at 140, 160, 180, and 200°C, respectively.

Single-phase α-Fe_2O_3 precipitates (according to the X-ray data) are formed at high degrees of hydrolysis when the residual content of sulfate ions is less than 3%.

The dependences of the degree of hydrolysis of the iron(III) salt on the $FeOHSO_4 : H_2O$ ratio, temperature, and hydrothermal treatment duration are shown in Fig. 3, which indicates that the highest degree of

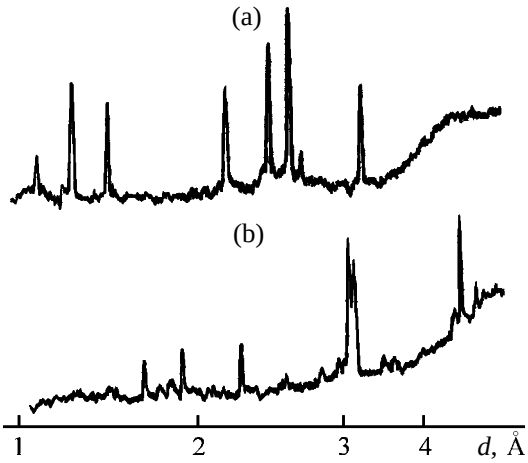

Fig. 4. X-ray diffraction pattern of hydrolysis products obtained at 160°C after a treatment for (a) 40 h and (b) 2 h. (*d*) Interplanar spacing.

$FeOHSO_4$ hydrolysis (98.5%) is attained at 200°C and an $FeOHSO_4 : H_2O$ ratio of 1 : 25. As the synthesis temperature decreases and the $FeOHSO_4 : H_2O$ ratio increases, the degree of hydrolysis decreases, with its value depending on the synthesis conditions. For example, the hydrothermal treatment of an $FeOHSO_4$ suspension at 140°C makes it possible to attain the degree of hydrolysis of 79.2%.

According to X-ray data (Fig. 4), the hydrolytic transformation of $FeOHSO_4$ occurs under the experimental conditions to give an intermediate phase of iron basic sulfates with the gross composition $Fe(OH)_{3-2x}(SO_4)_x \cdot nH_2O$ (x and n are variables depending on the solid : liquid ratio in suspension, temperature, and treatment duration; x = 0.5–0.9 and n = 0.6–1). When the degree of hydrolysis reaches 70%, in addition to the $Fe(OH)_{3-2x}(SO_4)_x \cdot nH_2O$ phase, the α-Fe_2O_3 phase appears, its amount increasing with the progress of the hydrolysis. Consequently, the formation of a series of iron hydroxysulfates of variable composition, which are stable within a wide temperature range, precedes the formation of hematite in the $FeOHSO_4$–H_2O system. The study of these hydrolysis products shows that they have a well-pronounced crystal structure and the crystals are of a regular cubic shape (Fig. 1b). According to the experimental data on this phase, the crystal size monotonically increases as the temperature and duration of the hydrothermal treatment increase. The maximal edge length attains 1.2–1.5 μm.

The derivatogram of the starting $FeOHSO_4$ appreciably differs from that of the intermediate product (Fig. 5). According to the structural data [7], water in the iron(III) basic sulfates $3Fe_2O_3 \cdot 4SO_3 \cdot 9H_2O$,

$Fe_2O_3 \cdot 2SO_3 \cdot H_2O$, and $Fe_2O_3 \cdot 2SO_3 \cdot 5H_2O$ can be in various forms. In particular, in $Fe_2O_3 \cdot 2SO_3 \cdot H_2O$ water is entirely in the form of OH^- groups and hence the endothermic effect in the range 500–550°C is caused by its removal. Apparently, $Fe(OH)_2(SO_4)_{0.5} \cdot 0.7H_2O$ contains water of crystallizatiopn, coordinated water, and bridging hydroxy groups, responsible for three endothermic effects in the sample thermogram (Fig. 5b). The removal of bridging hydroxy groups from iron(III) hydroxysulfate at 500°C is accompanied by the breakdown of the structure and formation of two phases: α-Fe_2O_3 and $Fe_2(SO_4)_3$. The deep endothermic effect in the range 680–750°C corresponds to the decomposition of iron(III) sulfate. Hematite is the final product of the thermal treatment of iron(III) basic sulfates.

In contrast to the thermal transformation, the hydrolytic transformation of the intermediate phase $Fe(OH)_{3-2x}(SO_4)_x \cdot nH_2O$ to hematite under hydrothermal conditions is more complicated. In this case, the formation of hematite follows the dissolution–precipitation mechanism involving formation of nuclei of a new phase and their further growth. The mechanism of the hydrolysis of iron(III) salts and of the formation of insoluble products with a composition strongly depending on the conditions of their formation is considered in [8–10]. It was shown [10] that possible products of the hydrolysis of iron(III) salts are goethite, lepidocrocite, hematite, and amorphous hydrogel. In the course of prolonged aging at a temperature below 90°C, amorphous hydrogel transforms into goethite, and at higher temperatures, into α-Fe_2O_3. Direct precursors of the forming solid phase of iron(III) oxides and hydroxides are polynuclear hydrolysis products containing from 3 to 13, from 13 to 33, and from 33 to 100 iron(III) atoms in a molecule [8–10]. The composition of the polymers affects significantly the structure and physicochemical properties of the precipitates. The oligomers (3–13) under certain conditions can transform both into a solid phase and into oligomers (13–33). In turn, these oligomers can participate in the aggregation of the goethite precipitate (α-FeOOH) or transform into stable hydroxylated polymers. As the polymer lifetime decreases with increasing temperature [8], the rate of the α-Fe_2O_3 phase formation grows. Thus, according to our experimental data, at 200°C this phase is formed within 2–4 h, and at 160°C, within 15–24 h.

It is known [10] that the nature of an anion appreciably affects the whole pattern of the hydrolysis of Fe^{3+} ions. Anions block one or more coordination sites of iron(III) in the stage of the formation of equilibrium hydrolysis products and thus significantly affect the structure and sizes of polymers by incorporation into their molecules, hindering formation of the solid phase. For example, in the presence of sulfate ions, goethite and hematite appear as additions to sulfate-containing solid phases. Therefore, it is quite natural that the intermediate phase of the variable composition $Fe(OH)_{3-2x}(SO_4)_x \cdot nH_2O$, which is stable within a wide temperature range, is formed in the course of the $FeOHSO_4$ hydrolysis.

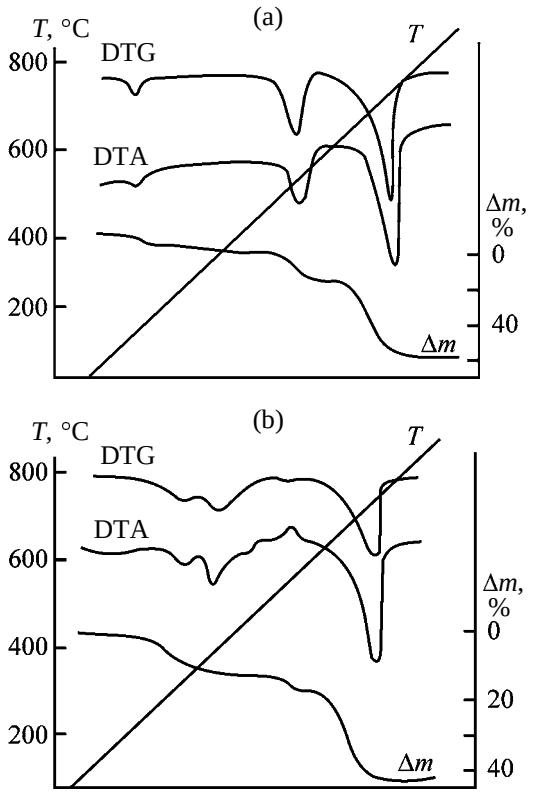

Fig. 5. Derivatograms of (a) initial iron(III) basic sulfate and (b) iron(III) basic sulfates obtained at 160°C and the $FeOHSO_4 : H_2O$ ratio of 1 : 15 after 5-h treatment. (*T*) Temperature and (Δ*m*) weight loss.

The experimental data on the effect of the $FeOHSO_4 : H_2O$ ratio on the degree and rate of the hydrolysis of Fe^{3+} ions can be explained as follows. As the $FeOHSO_4$–H_2O suspension is diluted, i.e., the water content in it increases, the equilibrium is shifted toward formation of hydrolysis products. The accumulation of H^+ ions in the liquid phase in the process leads to a decrease in pH, an increase in the degree of dissolution of hydrolysis intermediates, and the growth of iron(III) concentration in the liquid phase. In this case, the rate of hydrolytic transformations giving rise to stable insoluble hydrolysis products, hematite in particular, increases.

CONCLUSIONS

(1) The influence of the $FeOHSO_4 : H_2O$ ratio, temperature, and time of the hydrothermal treatment on the rate and degree of the hydrolysis of iron(III) basic sulfate was studied. The hydrolysis of $FeOHSO_4$ is accompanied by the formation of a metastable phase of iron(III) basic sulfates of variable composition, $Fe(OH)_{3-2x}(SO_4)_x \cdot nH_2O$.

(2) Hematite is the final hydrolysis product in the system $FeOHSO_4$–H_2O. The hematite crystals have a pillared shape and are characterized by a narrow size distribution.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Hydrated Cobalt(II) and Nickel(II) Ammine Diphosphates Isolated from Aqueous Solutions

National Agricultural University, Kiev, Ukraine

Received May 12, 2004

Abstract—Hydrated amorphous cobalt and nickel(II) ammine diphosphates were prepared.

The chemistry of binary compounds of double-charged metal ions is fairly well studied, and the possibilities for development of new phosphate materials based on them are almost exhausted or require higher-level approaches [1, 2]. Amorphous phosphates having an increased reactivity owing to their thermodynamic instability are of special interest even among known compounds [3]. They are formed as aqua and hydroxo complexes in ammonia solutions [4]. In this context, it was interesting to isolate new phosphate compounds containing coordinated ammonia from ammonia solutions. Such compounds can exhibit a biological or catalytic activity [5–8] and also can be used as luminophores or their components [9].

Published procedures for preparing transition metal ammine complexes [10–14] can be subdivided into homogeneous and heterogeneous procedures. The homogeneous procedures are based on reactions of metal salt solutions with an aqueous ammonia solution, followed by precipitation of ammine complexes with an organic solvent, evaporation, or freezing of the solution. In the heterogeneous procedures, a solution or a solid metal salt is treated with gaseous ammonia.

The main problem of isolating solid diphosphates of double-charged metal ammine complexes from a homogeneous mixture is very high solubility of salts with complex $[M(NH_3)_n]^{2+}$ ions; therefore, it appears difficult to achieve the solubility product (SP) for precipitating complex phosphate salts.

EXPERIMENTAL

We prepared hydrated nickel(II) ammine diphosphate by salting it out from an ammonia solution with an organic solvent [14]. As the starting reagent we used $Ni_2P_2O_7 \cdot 6H_2O$ (37.0% NiO) synthesized according to [15]. We dissolved 1 g of this compound in 10 ml of 23% ammonia. We added 25 ml of acetone to the resulting solution. In so doing, a blue substance precipitated, which was then separated from the mother liquid and kept at 15–25°C in air until it completely solidified (to constant weight). Found, %: NiO 33.41; P_2O_5 32.56; NH_3 10.70; H_2O 23.34. Nickel(II) ammine diphosphate $Ni_2P_2O_7 \cdot 3NH_3 \cdot 6H_2O$. Calculated, %: NiO 32.41; P_2O_5 32.11; NH_3 11.24; H_2O 23.78.

The composition of the anionic component was determined by quantitative paper chromatography [1] (% of P_2O_5): $P_2O_7^{4-}$ 95.50, PO_4^{3-} 4.50. The starting nickel diphosphate contained 3.50% of P_2O_5 as PO_4^{3-}.

We prepared hydrated cobalt(II) ammine diphosphate by the procedure similar to that used for preparing cobalt(II) ammine monophosphate [7]. The starting cobalt diphosphate $Co_2P_2O_7 \cdot 6H_2O$ was prepared according to [16, 17]. The synthesis included saturation of $Co_2P_2O_7 \cdot 6H_2O$ powder with gaseous ammonia under static conditions at 15–25°C for 96 h, followed by keeping in air of the resulting powder at 15–25°C to a constant weight. Found, %: CoO 32.95; P_2O_5 32.01; NH_3 13.26; H_2O 21.69. Cobalt(II) ammine diphosphate $2Co_2P_2O_7 \cdot 7NH_3 \cdot 11H_2O$. Calculated, %: CoO 32.97; P_2O_5 32.11; NH_3 13.12; H_2O 21.80.

Composition of the anionic component (quantitative paper chromatography [1], % of P_2O_5): $P_2O_7^{4-}$ 93.80 and PO_4^{3-} 6.20. The starting cobalt(II) diphosphate contained 5.30% of P_2O_5 as PO_4^{3-}.

The content of Ni^{2+} and Co^{2+} was determined complexometrically, that of P_2O_5, gravimetrically [19], that of ammonia, by distilling it off on a Seren'ev apparatus [20], and that of water and ammonia (in total), by the weight loss on heating for 2 h at 650°C.

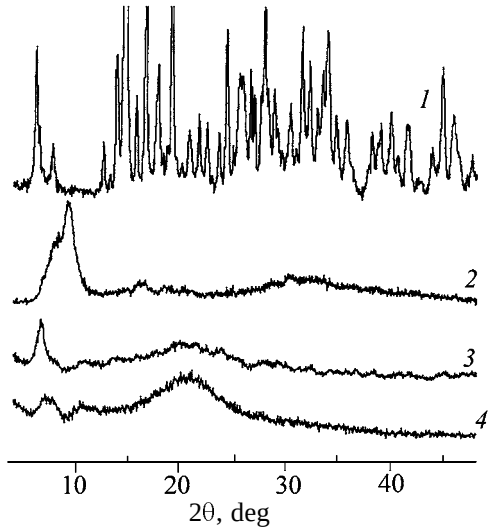

Fig. 1. X-ray patterns of the starting hydrated diphosphates and of nickel and cobalt ammine diphosphates (*1*) $Ni_2P_2O_7 \cdot 6H_2O$, (*2*) $Ni_2P_2O_7 \cdot 3NH_3 \cdot 6H_2O$, (*3*) $Co_2P_2O_7 \cdot 6H_2O$, and (*4*) $2Co_2P_2O_7 \cdot 7NH_3 \cdot 11H_2O$. (2θ) Bragg angle.

The X-ray analysis was carried out on a DRON-UM1 diffractometer (CuK_α radiation), with a graphite single crystal fixed in the diffracted beam as a monochromator. The X-ray patterns were recorded by step-by-step scanning over the angle range 2θ 4°–80°. The scanning step was 0.05°, and the exposure time in a point, 3–9 s. The measured diffraction maxima were approximated by the Voight pseudofunction, separating out the K_{α_1} component. The IR spectra were recorded with a Specord 75-IR spectrophotometer using KBr pellets (sample concentration 0.2–0.3 wt %). The electronic diffuse reflection spectra were taken on a Specord M-40 device in the range 30 000–12 000 cm^{-1}.

The results of the X-ray analysis show that the starting $Ni_2P_2O_7 \cdot 6H_2O$ is crystalline, whereas the starting $Co_2P_2O_7 \cdot 6H_2O$ as a whole is X-ray amorphous with a single distinct reflection maximum at 2θ = 6.5° and a broad band with a maximum at 2θ = 19°–20°. Their X-ray patterns agree with the published data [21, 22]. Ammine diphosphates of Ni(II) and Co(II) synthesized from these compounds were found to be X-ray amorphous. In the case of $Ni_2P_2O_7 \cdot 3NH_3 \cdot 6H_2O$, a reflection maximum is observed at 2θ = 9.5°, and $2Co_2P_2O_7 \cdot 7NH_3 \cdot 11H_2O$ has ill-defined maxima at 2θ = 7.0°, 11.0°, and 19°–21°, which may correspond to a proportional distance in the subsequent formation of the crystal structure in the compounds (Fig. 1).

The IR spectra of the starting nickel and cobalt hydrated diphosphates and of the ammine diphosphates obtained from them are given in the table. In the spectra of all the compounds, there is a strong

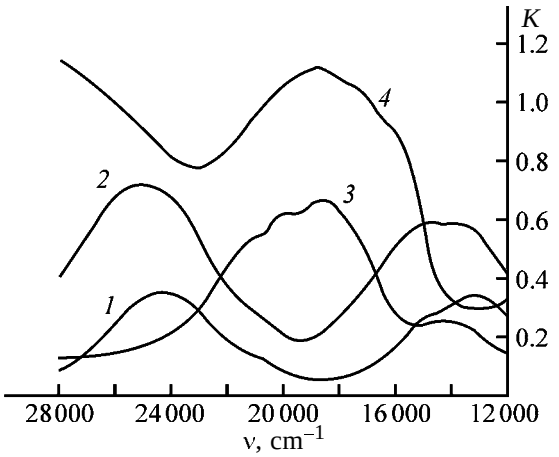

Fig. 2. Electronic diffuse reflection spectra of (*1*) $Ni_2P_2O_7 \cdot 6H_2O$, (*2*) $Ni_2P_2O_7 \cdot 3NH_3 \cdot 6H_2O$, (*3*) $Co_2P_2O_7 \cdot 6H_2O$, and (*4*) $2Co_2P_2O_7 \cdot 7NH_3 \cdot 11H_2O$. (ν) Wave number and (*K*) reflection coefficient.

broad absorption band in the range 3400–3000 cm^{-1}, corresponding to the stretching vibrations of NH and OH groups. In the range 1675–1540 cm^{-1}, there are absorption bands corresponding to the bending vibrations of H_2O and asymmetric bending vibrations of NH_3 in the ammine complexes. The vibrations of coordinated NH_3 and H_2O in these regions could not be distinguished. The range 1465–1410 cm^{-1} of the spectra of the ammine diphosphates suggests the presence of NH_3 involved in a stable hydrogen bond with proton transfer with the $P_2O_7^{4-}$ anion. It is accompanied by averaging of the electron density over the whole chain of atoms forming the hydrogen bond [23, 24]. These compounds have an absorption band in the range of 1325 cm^{-1}, assignable only to the symmetric bending vibrations of coordinated NH_3 molecules [25]. The asymmetric and symmetric stretching vibrations of the $P_2O_7^{4-}$ group are manifested in the range 1125–800 cm^{-1} as strong absorption bands. At 720–540 cm^{-1}, weak absorption bands assignable to the vibrations of P–O–P and O–P–O groups are observed. In the range 510–545 cm^{-1}, the stretching vibrations of M–N and M–O bonds are observed in the spectra of the ammine diphosphates [23, 26].

Thus, examination of the IR spectra suggests that two different types of NH_3 molecules are present in the composition of nickel(II) and cobalt(II) ammine diphosphates: the molecules interacting with metal ions by the donor–acceptor mechanism only and the molecules additionally involved in hydrogen bonding with charge transfer.

The electronic reflection spectra of the starting aqua and ammine diphosphates of nickel(II) and cobalt(II) are shown in Fig. 2. The long-wave reflection (absorption) maximum in the reflection spectra is known to shift to higher frequencies on successive substitution of ammine ligands for aqua ligands [27]. The comparison of the spectra of $Ni_2P_2O_7 \cdot 6H_2O$ (Fig. 2, curve *1*) and nickel(II) ammine diphosphate (Fig. 2, curve *2*) shows that the reflection maxima are shifted from 13200 to 14840 cm^{-1} and from 24360 to 25240 cm^{-1}, i.e., toward higher frequencies. The electronic reflection spectra of $Co_2P_2O_7 \cdot 6H_2O$ (curve *3*) and cobalt(II) ammine diphosphate (curve *4*) are also shown. In these spectra we also observe the shift of the reflection maxima from 18640 to 18880 cm^{-1}.

CONCLUSIONS

(1) Solid X-ray amorphous hydrated ammine diphosphates of nickel(II) and cobalt(II), $Ni_2P_2O_7 \cdot 3NH_3 \cdot 6H_2O$ and $2Co_2P_2O_7 \cdot 7NH_3 \cdot 11H_2O$, were prepared.

(2) The synthesized compounds were studied by IR and electronic spectroscopy, and their coordination structure was confirmed.

Karpov Institute of Physical Chemistry, State Scientific Center of Russian Federation, Moscow, Russia

Received February 20, 2004

Abstract—Impurities accumulated in the extractant in the course of operation of the plant for purification of wet-process phosphoric acid, obtained from apatite concentrate, by extraction with tri-*n*-butyl phosphate are identified by IR and mass spectra.

According to [1], by 2000 the world output of pure phosphoric acid was about 2.3 million tons (recalculated on P_2O_5), including 1.7 million tons of purified phosphoric acid (PPA) from wet-process phosphoric acid (WPPA). At the Voskresensk Institute of Fertilizers and Phosphoric Acid, Joint-Stock Company, an experimental-industrial plant for production of PPA from WPPA by tributyl phosphate (TBP) extraction on pulsating columns operates since 1995. Its annual output capacity is above 15000 t of P_2O_5.

It should be pointed out that purification of WPPA is performed using crude TBP. In the recycling mode, TBP is rapidly contaminated with impurities contained in WPPA. This changes for worse the hydrodynamic parameters of the pulsating columns, resulting in reduction of their output capacity and even in flooding of the apparatuses. It was demonstrated in studying the phase separation rate in the emulsions H_3PO_4–TBP and H_3PO_4–actual extractant at various densities of the aqueous and organic phases that, over the entire density range, the settling rate of the emulsion in the system extractant–H_3PO_4 is considerably lower than that in the system TBP–H_3PO_4. The results are given in Table 1 and Fig. 1. The experiments were performed under practically identical conditions (viscosity, density, stirring rate) (see, for example, experiment nos. 6 and 18, 8 and 20, 11 and 23, etc.). Evidently, in the systems, some surfactants are gradually accumulated, acting as emulsifiers, emulsion stabilizers, and interfacial layer blockers.

The sedimentation rate of an actual emulsion in the gravitational field is described by Eq. (1) [2].

$$v = \frac{2gr^2(\rho_1 - \rho_2)}{3\mu_2}\frac{\mu_1 + \mu_2}{3\mu_1 + 2\mu_2}, \quad (1)$$

where ρ_1 and ρ_2 are the densities of the dispersed and continuous phases, respectively (determined experimentally); μ_1 and μ_2 are the viscosities of the dispersed (from [3]) and continuous (determined experimentally) phases; and r is the radius of dispersed particles.

The mean radii of the dispersed particles r (cm) in the H_3PO_4–TBP and H_3PO_4–extractant emulsions, estimated by Eq. (1), are given in Table 1. At identical densities and viscosities of the phases, the mean size of the dispersed particles in the H_3PO_4–extractant emulsions is lower by a factor of 1.5–3.5 than in the H_3PO_4–TBP emulsions.

To remove organic impurities from the extractant, we used the method described in [4]. The extractant was washed with 15% Na_2CO_3 ($V_o : V_w = 3 : 1$) at 50°C. The resulting aqueous solution containing sodium phosphates and some organic admixtures was treated with 40% phosphoric acid (recalculated on P_2O_5) at a 5 : 1 volume ratio with continuous stirring. At this stage we observed separation of either a powder-like deep brown substance (sample no. 1) or a resin also colored deep brown (sample no. 2). These substances were separated by filtration or decanting, washed with distilled water, and dried at about 60°C

in an oven. The chemical composition of sample no. 2 was as follows (wt %): C 30.6, H 5.6, N 1.05, S 1.4, P 14.31, F 2.17, Cl 0.3, Si 0, Na 0.59, Fe 0.16, and Ca 0.16.

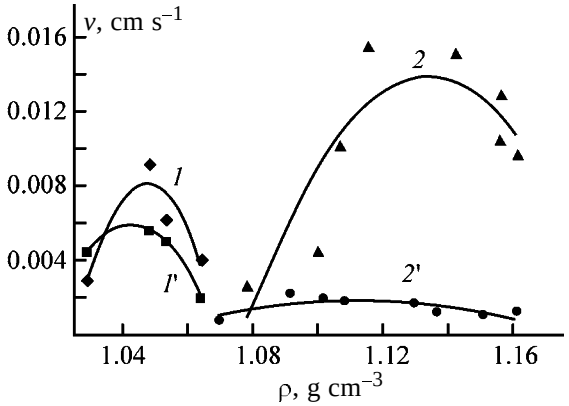

Fig. 1. Settling rate v in emulsions: (*1*, *2*) H_3PO_4–TBP and (*1'*, *2'*) H_3PO_4–extractant as a function of the viscosity of the organic phase ρ.

As seen, the product separated from the extractant has a complex composition. Presumably, in addition to organics it contains some inorganic compounds such as phosphoric acid, phosphogypsum, fluorides, and sodium and iron phosphates.

To identify compounds composing the products separated from the extractant, we measured the IR spectra of sample nos. 1 and 2 with a Perkin–Elmer 983 spectrometer (Fig. 2). The spectra show the bands due to C–H stretching vibrations at 2931 and 2955 cm^{-1}; CH bending vibrations at 1457 cm^{-1}; and C=O vibrations (1709, 1710 cm^{-1}) characteristic of saturated and unsaturated aliphatic acids [5]. Also the spectra show the band at 1606 cm^{-1} typical of C=C in-plane vibrations of aromatic compounds [5]. It should be pointed out that this band becomes more distinctly pronounced after recrystallization of sample no. 2 from acetone. For comparison, in Fig. 2 are presented the spectra of crude TBP [TU (Technical

Specifications) 2435-305-05763458–01], OP-4 emulsifier (TU 6-02-997–90), and crude oleic acid [GOST (State Standard) 7580–55].

We also studied the product separated from the extractant by mass spectrometry in the electron impact mode. The sample was placed into a gold crucible and heated in a vacuum (10^{-5} Pa) until a vapor appeared. The spectra were recorded at 150°C (Fig. 3).

The mass spectra of both samples are identical. Comparison with reference data reveal that the samples contain tri-*n*-butyl phosphates [6, 7]; oleic, abietic, and stearic acids; and, possibly, butanol, poly(acrylamide) [8], and naphthenic acids.

According to the reference data [7], the mass spectrum of TBP shows the following peaks (*m*/*e*) [relative intensity (%) is given in parentheses]: 237 (0.3), 211 (15), 183 (1), 181 (1.5), 167 (2), 156 (1), 155 (22), 154 (1.5), 153 (2), 137 (5), 127 (2), 125 (8), 113 (1), 112 (1), 111 (2), 100 (3), 99 (100), 83 (1), 82 (2), 81 (1), 57 (12), 56 (5), and 55 (4). To these values we can also add the peak *m*/*e* 41 [6]. All these peaks were found in the spectra of sample nos. 1 and 2.

According to [8], the mass spectrum of oleic acid is as follows (*m*/*e*): 41 (100), 55 (94.9), 43 (64.9), 83 (34.4), 67 (33.3), 57 (33.3), 54 (26.7), 56 (24.4), 81 (23.6), and 97 (23.1). All the ten peaks were found in sample no. 2 and nine of them, in sample no. 1.

In the spectrum of sample no. 1 we found the following peaks assigned to stearic acid (*m*/*e*): 43, 57, 41, 55, 71, 73, 60, and 69; and in sample no. 2: 43, 57, 41, 55, 71, 73, and 69. The peaks assigned to abietic acid are as follows (*m*/*e*): 91, 105, 77, 79, 121, 93, 67, and 81 (sample no. 2).

Furthermore, in the spectrum of sample no. 2 we found practically all the peaks reported in [8] for such naphthenic acids and esters as cyclopentyl acetate, cyclohexanecarboxylic acid, cyclohexyl acetate, and cyclohexylpropionic acid.

In addition to electron impact, the samples were also studied by such a mild mass-spectroscopic method as field desorption (Table 2).

In the field-desorption mass spectrum of sample no. 1 (powder), the most intensive peak corresponds to the sodium atom, suppressing all the other peaks. The next in the intensity is the peak corresponding to the potassium atom. The peaks found in the spectrum of sample no. 2 can be assigned to several individual compounds such as TBP (MW 266.3), dibutylphosphoric acid (MW 210), phosphate of oxyethylated alkylphenol $CH_3(CH_2)_8–C_6H_4O(CH_2–CH_2O)_3–CH_2CH_2O–P(OH)_2O$ (MW 476), its fragment $CH_3·(CH_2)_8–C_6H_4$ (MW 203), and also oxyethylated alkylphenol $CH_3(CH_2)_{10}C_6H_4O(CH_2–CH_2O)_4H$ (MW 424).

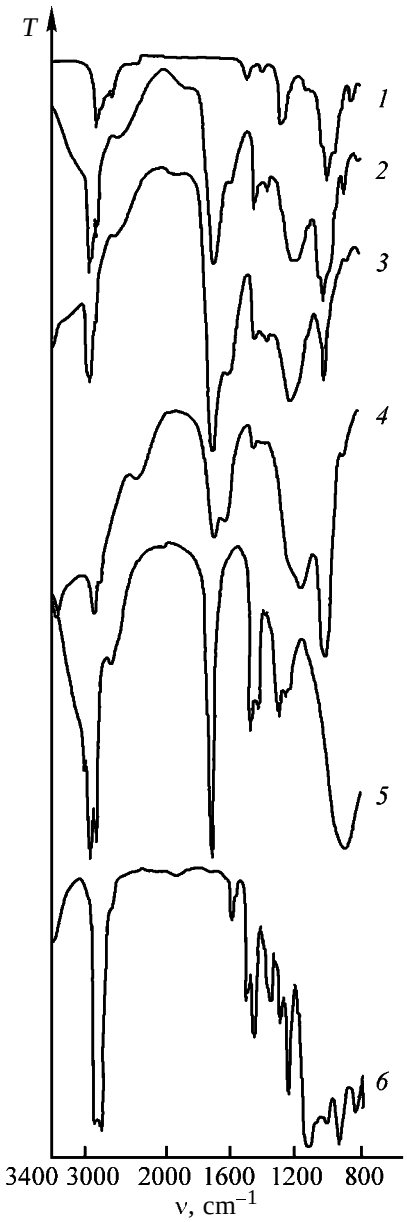

Fig. 2. Infrared spectra of organic compounds: (*1*) TBP, (*2*) sample no. 1, (*3*) sample no. 2, (*4*) sample no. 2 recrystallized from acetone, (*5*) oleic acid, and (*6*) OP-4 emulsifier. (*T*) Transmittance and (ν) wave number.

Thus, our results show that the extractant circulating in the system contains such impurities as dibutylphosphoric acid, oxyethylated alkylphenols and their phosphates, oleic, abietic, and stearic acids, butanol, amines, naphthenic acids, etc.

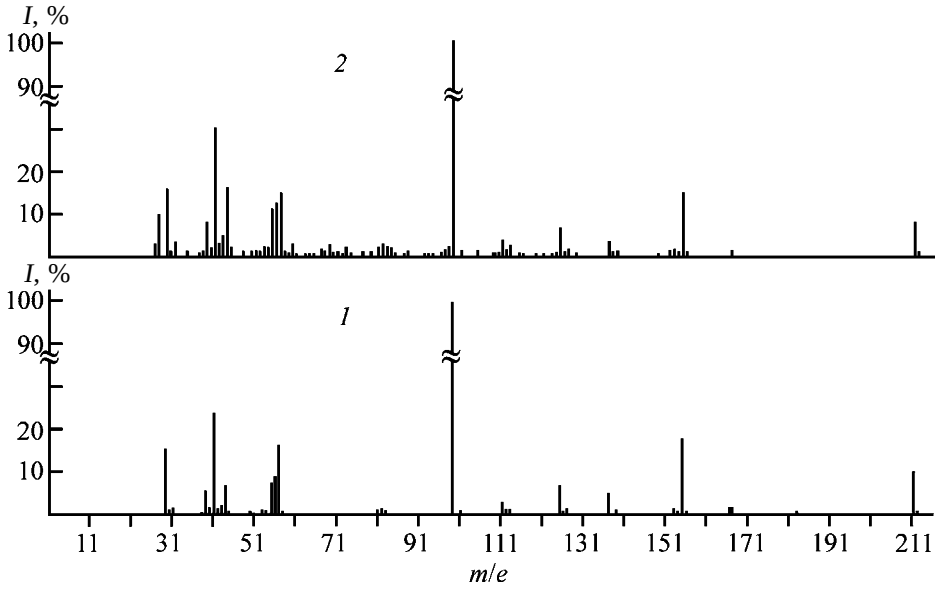

Fig. 3. Mass spectra of substances separated from the extractant: (*1*) sample no. 1 and (*2*) sample no. 2. (*I*) Intensity.

The product separated from the extractant by soda washing, being introduced into the process solutions, demonstrates the surfactant effect. It was found that introduction of 0.1% of this product into TBP decreases the phase separation rate in the system TBP–H_3PO_4 by a factor of 6.5.

The source of the indicated compounds is apatite concentrate containing some flotation agents such as oleic acid, tall oil, OP-4 emulsifier, and also compounds, e.g., poly(acrylamide), formed in the stage of sulfuric acid decomposition of the concentrate and in the course of clarification of H_3PO_4. OP-4 emulsifier is the source of oxyethylated alkylphenols with the general formula $C_nH_{n+1}C_6H_4O(CH_2–CH_2O)_mH$, where m = 3, 4. Tall oil is the source of resin acids (e.g., abietic acid) and unsaturated (oleic) and saturated (stearic) acids. Note also that crude oleic acid contains up to 10% of naphthenic acids. Furthermore, sulfuric acid decomposition of apatite is accompanied by sulfonation and phosphatization. Evidently, oxyethylated alkylphenols are involved in phosphatization with formation of phosphates.

Table 2. Field-desorption mass spectra with acetone as a solvent

Sample no.	I_{rel}, %	Mass
1	2.5	127
	2.8	99
	2.3	89
	9.0	58
	9.1	39
	100.0	23
2	17.6	477
	6.9	422
	27.9	421
	9.5	268
	61.6	267
	10.6	212
	100.0	211
	7.0	203
	9.9	189
	86.2	59
	19.0	57

The product separated has a complex composition, containing the major impurities from the extractant. Therefore, it is advisable to use it as a reference for photocolorimetric determination of the degree of contamination of the extractant. The applicability of this method is limited by the maximal content of organic impurities in the extractant at a level of 2 mg ml^{-1}. At higher contamination level, poorly separable systems are formed.

To conclude, surfactants accumulated in the system deteriorate extraction purification of WPPA with TBP. To keep the operating parameters of the system at a reasonable level (i.e., to avoid accumulation of surfactants), it is necessary to introduce the stage of soda washing of the extractant. Furthermore, it is necessary to avoid introduction of surfactants to the WPPA purification system and, as far as possible, at the stage of manufacture of WPPA.

CONCLUSION

The extractant (tri-*n*-butyl phosphate) circulating in the system of extraction purification of wet-process phosphoric acid, obtained from apatite concentrate, contains impurities of dibutylphosphoric acid, oxyethylated alkylphenols and their phosphates, oleic, abietic, stearic, and naphthenic acids, butanol, amines, etc.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Thermodynamic Study of Extraction of Cerium(III) and Yttrium(III) with Tributyl Phosphate

D. E. Chirkst, T. E. Litvinova, A. A. Chistyakov, and M. Yu. Ionova

St. Petersburg State Mining Institute, St. Petersburg, Russia

Received February 25, 2004

Abstract—To increase the efficiency of hydrometallurgical processing of lean rare-earth raw material, the effect of salt anion and metal cation on the characteristics of Ce(III) and Y(III) recovery from dilute aqueous solutions with tri-*n*-butyl phosphate was studied on the basis of the thermodynamic theory of extraction.

Modern hydrometallurgy of rare-earth metals (REM) is based on the extraction of their nitrates with tri-*n*-butyl phosphate (TBP). However, as lean rare-earth raw materials, for instance, eudialyte ores of the Kola peninsula, are involved in the process the efficiency of extraction recovery and separation of lanthanide salts should be increased. It becomes urgent to search for new, more efficient extractants and study the effect of the salt anion on the extractability. It is advisable to characterize the extraction by Gibbs constants and energies of extraction. Previously, we studied the thermodynamics of extraction of zirconium salts with TBP and solutions of trialkylbenzylammonium salts (TABA, alkyl: C_4H_9–$C_{10}H_{21}$) in *o*-xylene [1, 2] and extraction of cerium and yttrium sulfates with TABA sulfate in *o*-xylene [3, 4]. In this work, we compare the characteristics of extraction of Ce(III) and Y(III) salts with TBP and TABA.

The features of Ce(III) and Y(III) extraction with TBP were studied using model systems REM nitrate–$Mg(NO_3)_2$. The REM content was approximately preset by the weight of the metal nitrate taken and was then refined photometrically. All the reagents were of chemically pure grade. The metal ion concentration was similar to the REM content in solutions from leaching of eudialyte concentrates and was about 0.01 mol kg^{-1}.

The extraction and phase separation were performed in separating funnels. The stirring rate was 2000 rpm and was preset with an automatic stirrer. The duration of phase contact required for equilibration was determined experimentally and amounted to 30 min. The phases fully separated within 15 min.

The content of cerium(III) and yttrium(III) in the aqueous phase (initial and equilibrium) was determined photometrically (λ 670 nm) with Arsenazo III in the acetate buffer solution at pH 3 [5]. The chemicals used in the analysis were of analytically pure grade. The REM content in the organic phase was determined as the difference of the concentrations in the initial and equilibrium aqueous phases with regard to the difference in the phase volumes (weights):

$$c_{org} = (c_0 - c_{aq})\frac{m_{aq}}{m_{org}}, \quad (1)$$

where c_{org} is the equilibrium metal concentration in the organic phase (mol kg^{-1}); c_{aq}, REM concentration in the equilibrium aqueous phase (mol kg^{-1}); c_0, initial content of cerium or yttrium in the aqueous phase (mol kg^{-1}); and m_{aq}/m_{org}, ratio of weights of the aqueous and organic phases, respectively.

The experimental values of the metal distribution coefficients were determined as follows:

$$D = c_{org}/c_{aq}, \quad (2)$$

where D is the metal ion distribution coefficient; c_{aq}, c_{org}, equilibrium concentrations of the metal ion in the aqueous and organic phases, respectively (mol kg^{-1}).

The experimental data were obtained at pH 3. pH was monitored with a pH-150M pH-meter with a combined electrode.

To elucidate the mechanism of REM extraction with tributyl phosphate and calculate the extraction constants, we measured the dependences of the Ce(III) and Y(III) distribution coefficients between the aqueous and organic phases on the TBP concentration in *o*-xylene at a constant ionic strength supported by 2 M

$Mg(NO_3)_2$. The initial concentration of Ce(III) or Y(III) nitrates was 0.01 mol kg^{-1}. Thus, change in the concentration of REM nitrates during extraction should not noticeably affect the solution ionic strength, equal to 6 mol kg^{-1}. The measured ln–ln dependences of the Ce(III) and Y(III) distribution coefficients on the TBP mole fraction are shown in Figs. 1a and 1b. The TBP concentration was expressed in mole fractions, because the standard state of the extractant is the pure liquid with the mole fraction $X = 1$. Logarithmic coordinates were used to obtain linear dependences. The equation of the extraction reaction is

$$M^{3+}(aq) + 3NO_3^-(aq) + n\text{TBP(org)} \rightleftarrows Me(NO_3)_3 \cdot n\text{TBP(org)}, \quad (3)$$

where M is Ce or Y.

The law of mass action (for Ce) appears as

$$K = \frac{[Ce(NO_3)_3 \cdot n\text{TBP}]}{[Ce^{3+}][NO_3^-]^3 \gamma_{Ce^{3+}} \gamma_{NO_3^-}^3 [\text{TBP}]^n}, \quad (4)$$

where γ_i are activity coefficients of ions.

We replace the product of activity coefficients by the mean ionic activity coefficient of cerium(III) nitrate:

$$\gamma_\pm = (\gamma_{Ce^{3+}} \gamma_{NO_3^-})^{1/2}. \quad (5)$$

With regard to (2), Eq. (4) transforms into

$$K = \frac{D}{[NO_3^-]^3 \gamma_\pm^4 [\text{TBP}]^n}. \quad (6)$$

and, after taking the logarithm, into

$$\ln D = \ln K + 3\ln[NO_3^-] + 4\ln\gamma_\pm + n\ln[\text{TBP}]. \quad (7)$$

It follows from (7) that the dependence of $\ln D$ on $\ln[\text{TBP}]$ for Ce(III) or Y(III) should be linear at the constant ionic strength with the slope equal to the solvation number in the extractable complex. The dependences in Fig. 1 are approximated by straight lines with the confidence factors R^2 0.94 and 0.96 for Ce(III) and Y(III), respectively:

$$\ln D = 1.64\ln[\text{TBP}] + 2.25 \text{ for Ce(III)}, \quad (8)$$

$$\ln D = 1.93\ln[\text{TBP}] + 1.55 \text{ for Y(III)}. \quad (9)$$

It follows from Eq. (8) that about 36% of cerium

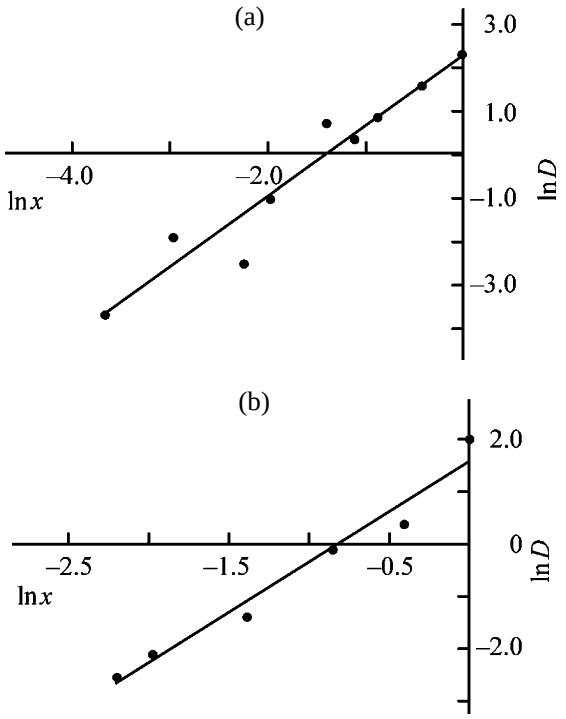

Fig. 1. Logarithm of distribution coefficient D of (a) cerium(III) nitrate and (b) yttrium(III) nitrate as a function of logarithm of TBP mole fraction x in *o*-xylene.

nitrate solvates contain one TBP molecule and 64%, two TBP molecules. According to Eq. (9), the solvation number of yttrium nitrate within the error limits is equal to 2. The extraction constants can be calculated from the absolute terms of the equations

$$\ln K = 2.25 - 3\ln[NO_3^-] - 4\ln\gamma_\pm \text{ for Ce(III)}, \quad (10)$$

$$\ln K = 1.55 - 3\ln[NO_3^-] - 4\ln\gamma_\pm \text{ for Y(III)}. \quad (11)$$

The concentration of nitrate ions in the experiments was 4 mol kg^{-1}. The value of the mean ionic activity coefficient was taken equal to that for $LaCl_3$ at the ionic strength of 6 mol kg^{-1}, $\gamma_\pm = 0.342$ [6]. From these values, we calculated the extraction constants $K_{Ce} = 10.8$ and $K_Y = 5.4$ and the Gibbs free energies $\Delta G^0_{298}(Ce) = -5.90$ and $\Delta G^0_{298}(Y) = -4.18$ kJ mol^{-1}.

We also studied the dependence of $\ln D$ on the concentration of the salting-out agent, $Mg(NO_3)_2$. Experiments were performed at the initial cerium concentration of 0.01 mol kg^{-1} without diluent. The results are shown in Figs. 2a and 2b.

The ln–ln dependences of the distribution coefficients of Ce(III) and Y(III) on the nitrate ion concentration are described by the following linear equations

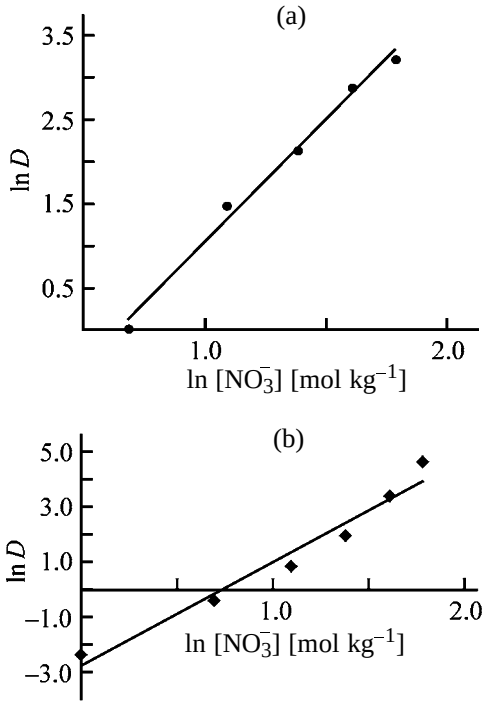

Fig. 2. Logarithm of distribution coefficient D of (a) cerium(III) nitrate and (b) yttrium(III) nitrate as a function of logarithm of nitrate ion concentration $[NO_3^-]$.

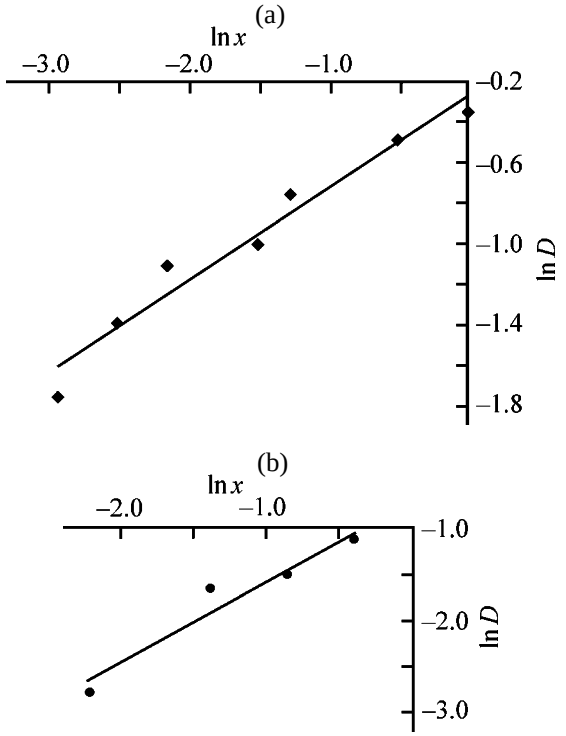

Fig. 3. Logarithm of distribution coefficient D of (a) cerium(III) chloride and (b) yttrium(III) chloride as a function of logarithm of TBP mole fraction x in *o*-xylene.

with the confidence factor R^2 0.92 and 0.99, respectively:

$$\ln D = 2.93\ln[NO_3^-] - 1.89 \quad \text{for Ce(III)}, \tag{12}$$

$$\ln D = 3.29\ln[NO_3^-] - 2.67 \quad \text{for Y(III)}. \tag{13}$$

The slopes of straights lines (12) and (13) within the error limits are close to 3, i.e., to the stoichiometric coefficient at nitrate ion in Eq. (3) (in other words, to the number of anions in the extractable complex). The extraction constants can be calculated from the absolute terms of Eqs. (12) and (13). Since neat TBP was used, its activity in the equation for the law of mass action is equal to 1. Then, Eq. (7) transforms into

$$\ln D = \ln K + 4\ln\gamma_{\pm} + 3\ln[NO_3^-]. \tag{14}$$

As above, the mean ionic activity coefficient is taken equal to 0.342. From (12) and (13) we obtain

$$\ln K = -1.89 - 4\ln\gamma_{\pm} = 2.40 \quad \text{for Ce(III)}, \tag{15}$$

$$\ln K = -2.67 - 4\ln\gamma_{\pm} = 1.62 \quad \text{for Y(III)} \tag{16}$$

and calculate the constants and Gibbs free energies K_{Ce} = 11.0 and K_Y = 5.0; ΔG^0_{298}(Ce) = –5.95 and ΔG^0_{298}(Y) = –4.02 kJ mol^{-1}. Thus, the consistent thermodynamic characteristics of the extraction were obtained by two independent methods. The averaged values are $K_{Ce} = 10.9 \pm 0.1$ and $K_Y = 5.2 \pm 0.2$; $\Delta G^0_{298}(Ce) = -5.92 \pm 0.03$ and $\Delta G^0_{298}(Y) = -4.10 \pm 0.08$ kJ mol^{-1}.

To study the effect of anion on REM extraction, we measured the ln–ln dependences of the distribution coefficients of $CeCl_3$ and YCl_3 on the TBP mole fraction in *o*-xylene at the concentration of the salting-out agent, $MgCl_2$, of 2 mol kg^{-1} (Figs. 3a, 3b). The logarithmic dependences are well described by straight lines with the confidence factor R^2 0.96 and 0.93, respectively:

$$\ln D = 0.5\ln[TBP] - 0.27 \quad \text{for Ce (III)}, \tag{17}$$

$$\ln D = 0.9\ln[TBP] - 0.69 \quad \text{for Y (III)}. \tag{18}$$

Their slopes give solvation numbers of 0.5 for $CeCl_3$ and approximately 1 for YCl_3 in the organic phase, and hence the extraction reactions are described by the following equations:

$$Ce^{3+}(aq) + 3Cl^-(aq) + 0.5TBP(org) \rightleftarrows CeCl_3 \cdot 0.5TBP(org), \tag{19}$$

$$Y^{3+}(aq) + 3Cl^-(aq) + TBP(org) \rightleftarrows YCl_3 \cdot TBP(org). \quad (20)$$

The extraction constants were calculated from the absolute terms of Eqs. (17) and (18). Here, the formula similar to (7) is also valid:

$$\ln D = \ln K + 3\ln[Cl^-] + 4\ln\gamma_\pm + n\ln[TBP]. \quad (21)$$

The mean ionic activity coefficient was taken equal to 0.342, similarly to nitrates. Hence,

$$\ln K_{Ce} = -0.27 - 3\ln[Cl^-] - 4\ln\gamma_\pm = -0.14, \quad (22)$$

$$\ln K_Y = -0.69 - 3\ln[Cl^-] - 4\ln\gamma_\pm = -0.56; \quad (23)$$

$K_{Ce} = 0.87$ and $K_Y = 0.57$; $\Delta G^0_{298}(Ce) = 0.35$ and $\Delta G^0_{298}(Y) = 1.39$ kJ mol^{-1}.

We also studied the dependence of the distribution coefficient of $Ce_2(SO_4)_3$ on the TBP concentration in *o*-xylene at a $MgSO_4$ concentration of 2 mol kg^{-1} (ionic strength 8 mol kg^{-1}) (Fig. 4). It is described by the equation

$$\ln D = 1.5\ln[TBP] - 2.40. \quad (24)$$

In accordance with the condition of electroneutrality, the equation of the extraction equilibrium is

$$2Ce^{3+}(aq) + 3SO_4^{2-}(aq) + n TBP(org) \rightleftarrows Ce_2(SO_4)_3 \cdot n TBP(org). \quad (25)$$

In this case, the law of mass action is

$$K = \frac{[Ce]_{org}}{2[Ce^{3+}]^2[SO_4^{2-}]^3\gamma_\pm^5[TBP]^n} = \frac{D}{[Ce^{3+}][SO_4^{2-}]^3\gamma_\pm^5[TBP]^n}. \quad (26)$$

The Ce concentration in the organic phase should be divided by two to take into account association of $Ce_2(SO_4)_3$ in the solvate [it follows from (24) that the solvation number in cerium sulfate extraction is equal to 1.5]. The extraction constant was calculated by the equation

$$\ln K = -2.40 - \ln[Ce^{3+}] - 3\ln[SO_4^{2-}] - \ln 2 - 5\ln\gamma_\pm = 2.90. \quad (27)$$

The cerium(III) concentration in the organic phase was, on the average, taken equal to 0.01 mol kg^{-1}, the concentration of sulfate ions, 2 mol kg^{-1}, and the mean ionic activity coefficient, 0.5, which is equal to that of lanthanum chloride at an ionic strength of 8 mol kg^{-1} [6]. For reaction (25), we obtain $K = 18.2$ and $\Delta G^0_{298} = -7.19$ kJ mol^{-1}. Per mole of Ce(III), the solvation number is 0.75, $K = 4.3$, and $\Delta G^0_{298} = -3.60$ kJ mol^{-1}.

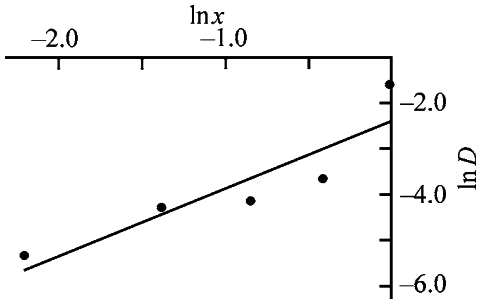

Fig. 4. Logarithm of distribution coefficient *D* of cerium(III) sulfate as a function of logarithm of TBP mole fraction *x* in *o*-xylene.

The characteristics of extraction of Ce(III) and Y(III) salts with TBP at the concentration of the corresponding magnesium salts of 2 mol kg^{-1} are listed in Table 1. All the values are given per mole of REM.

It follows from Table 1 that in the series chloride–sulfate–nitrate the solvation number and extraction constant increase and the Gibbs energy decreases. This is caused by a decrease in the charge on the terminal oxygen atoms in anions, *z*, which was calculated as a quotient of division of the anion charge by the number of terminal atoms. The *z* value characterizes the density of the negative charge on the anion. The lower the charge density, the more strongly the cation polarizes the phosphoryl group of TBP and binds TBP according to the scheme

$$An^{z-} \rightarrow Ce^{3+} \leftarrow O{=}P(OC_4H_9)_3.$$

Table 1. Molar characteristics of extraction of cerium(III) and yttrium(III) salts with TBP

Salt	[*z*]	Solvation number	*K*	ΔG^0_{298}, kJ mol^{-1}

Table 2. Comparison of extraction characteristics of cerium(III) and yttrium(III) salts with TBP and TABA (100% TBP, extraction of nitrates; 0.5 M TABA, extraction of sulfates; pH 3; concentration of magnesium salts 2 mol kg^{-1}; REM concentration about 0.01 mol kg^{-1})

M^{3+}	TBP		TABA	
	D	ΔG^0_{298}, kJ mol^{-1}	D	ΔG^0_{298}, kJ mol^{-1}
Ce(III)	8.6	-5.92 ± 0.03	35 ± 4	-8.9 ± 0.3
Y(III)	7.3	-4.10 ± 0.08	10.2 ± 2.0	-7.5 ± 0.2
Separation coefficient	1.18		3.5	

The solvation numbers of yttrium(III) are higher than those of Ce(III), which can be explained by smaller ionic radius of yttrium. The smaller the cation radius, the higher is its ionic potential and the more strongly the cation polarizes the phosphoryl group. However, the extraction constants for yttrium(III) salts are lower and the Gibbs energies, higher than for the Ce(III) salts. This can be explained as follows. During extraction, TBP molecules substitute water from the first coordination sphere of the cation. In the process, the H-bonds with the second coordination sphere are ruptured. Water molecules, which are more polar than TBP molecules, are bound more strongly with Y(III) than with Ce(III) having lower ionic potential. Therefore, the energy consumption for dehydration of Y(III) cations is not compensated by the energy of solvation, and the thermodynamic characteristics of extraction of Y(III) salts are less favorable as compared to Ce(III).

Virtually no separation of yttrium and cerium in extraction with TBP is observed. The distribution coefficients of Ce(III) and Y(III) nitrates in extraction with neat TBP and those of their sulfates in extraction with 0.5 M TABA sulfate in *o*-xylene [3, 4] at pH 3 and magnesium salt concentration of 2 mol kg^{-1} are listed in Table 2. The initial REM concentrations were 0.01 mol kg^{-1}. As seen, the efficiency and selectivity of REM extraction with TABA is substantially higher than with TBP. This result is especially important in hydrometallurgical processing of lean rare-earth raw materials.

CONCLUSIONS

(1) The constants and Gibbs energies of cerium(III) and yttrium(III) extraction with TBP are determined. The extraction constants and solvation numbers increase and Gibbs energies decrease in the series chloride–sulfate–nitrate, which can be explained by a decrease in the charge density on the anion and the corresponding growth in polarization of the phosphoryl group. In going from cerium(III) to yttrium(III), the solvation number increases, but the extraction constants decrease.

(2) The extraction constants and distribution and separation coefficients of cerium(III) and yttrium(III) are higher in extraction with trialkylammonium salts than with TBP.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Heat Treatment on Thermal Stability of Limestone

A. A. Kabanov

Krasnoyarsk State Pedagogical University, Krasnoyarsk, Russia

Received April 15, 2004

Abstract—The nature of the anomalous effect exerted by the heat treatment of limestone at 500 and 600°C on its thermal stability at 825°C was studied.

The author's method involving preliminary heat treatment of limestone in air at 500 and 600°C to accelerate its thermal decomposition at high temperatures has been patented [1]. After the heat treatment at both temperatures, the positive effect was obtained; after treatment at 500°C, the effect was stronger, which seems to be abnormal. The nature of this effect could be discussed only after the composition and thermal stability of calcium carbonate and natural limestone were studied in detail [2–6]. In this study we supplemented and developed these studies with the aim to elucidate the nature of the effect discovered in [1].

After natural limestone was dispersed [1], its <0.08-mm fraction was sieved and heat-treated in air for 6 h at 200, 500, and 600°C. Then, the preparations were stabilized again by keeping over P_2O_5 for no less than 10 days. The preparation heat-treated at 200°C was considered as the starting sample.

The composition of the starting samples and results of the phase analysis are presented in [5, 6]. The minerals present in the starting samples from the Solomenskoe deposit are as follows (wt %): $CaCO_3$ (calcite) 96.20, α-$Fe_2O_3 \cdot 0.38H_2O$ (hydrohematite) 1.06, $(Fe^{III}, Al_4)[OH]_8(Si_4O_{10}) \cdot 1.74H_2O$ (ferrihalloysite) 1.47, and other impurities 1.17.

The kinetic curves of the limestone decomposition were taken at 825 ± 0.1°C with 0.100-g samples using the volumetric analysis [3]. The X-ray phase analysis (XPA) was done on a DRON-3 diffractometer. The magnetic susceptibility of the powdered samples (0.20 g) was measured on a pendular magnetic balance [6] at a heating rate of 2.0 ± 0.1 deg min^{-1}. The IR spectra were recorded on a UR-20 spectrophotometer using mulls in mineral oil. The Mössbauer spectrum was obtained on an electrodynamic spectrometer based on an AI-5006-3M-V100 analyzer operating in the constant acceleration mode. The spectra were processed on an ES-1022 computer. The ^{57}Co isotope with an activity of 0.5 GBq in a chromium matrix was the γ-radiation source.

The kinetic curves of the thermal decomposition of limestone show that, compared to heat treatment at 600°C, the heat treatment at 500°C produces an abnormal effect on the decomposition rate (Fig. 1). The thermal decomposition was performed till the first, metastable state [6] of the limestone samples was attained. The heatings decrease the time of attaining the final degree of the sample decomposition. The reason why the decomposition after heating to 500°C is accelerated to a greater extent can be suggested on the basis of the XPA data (Figs. 2a, 2b). The impurities formed in the limestone at 500°C are oxides α-Fe_2O_3 and Fe_3O_4, whereas at 600°C only the FeO impurity is formed. As compared to wüstite FeO,

hematite at 825°C is a stronger catalyst of the calcite decomposition. This is due to the fact that the magnetic susceptibility of hematite at a temperature of the limestone decomposition is higher than that of wüstite [4]. Magnetite Fe_3O_4 is a well-known ferromagnetic, and, owing to high magnetic susceptibility, its catalytic activity should be higher than that of hematite and wüstite.

The above hypothesis is confirmed by the results of the magnetic measurements (Fig. 3). Indeed, the magnetic susceptibility of the samples heated at 500°C is higher at all the temperatures, up to the temperature of limestone decomposition (825°C), than that of the samples heated at 600°C. In both cases, the magnetic

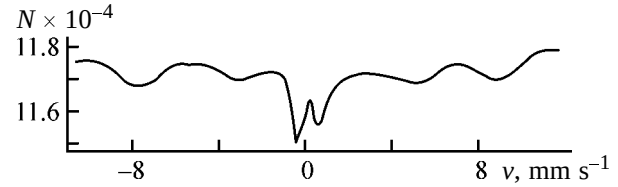

Fig. 5. Mössbauer spectrum of limestone. (*N*) Counts per channel and (*v*) velocity of the γ-ray source.

susceptibility of the samples is higher than that of the starting sample (curve *1*). The magnetic susceptibilities of the samples heat-treated at 825°C (curve *4*) show that both the main substance (calcite) and the impurities of iron compounds present in it undergo profound chemical transformations. The IR spectra of the samples heated at 200 and 500°C are similar (Fig. 4, curve *1*). Their assignment is given in [3]. The IR spectra taken after the heating at 825°C (curve *2*) revealed significant changes in the main substance, with a certain portion of calcite and water retained in the product, as in the case of reagent-grade calcium carbonate [3]. In other words, calcite does not fully decompose in this case either, and structural water stabilizes its lattice. The Mössbauer spectrum (Fig. 5) revealed hematite in the samples heated at 825°C. Comparison of this spectrum with that of the starting limestone [6] shows that, after heating at 825°C, the hematite particles are agglomerated, which accounts for the decrease in their magnetic susceptibility (Fig. 3, curve *4*).

CONCLUSIONS

(1) The limestone from the Solomenskoe deposit, heat-treated at 500°C for 6 h, shows lower thermal stability at 825°C than that heat-treated at 600°C.

(2) The abnormal temperature effect exerted by the limestone heat treatment on its thermal stability during the subsequent heating to 825°C is due to the different catalytic activities of iron oxides, which are formed in the limestone from impurities in the course of the heat treatments.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Activity of Copper in Liquid Nickel–Copper–Iron Alloys

A. G. Morachevskii, L. B. Tsymbulov, and E. Yu. Kolosova

St. Petersburg State Polytechnic Institute, St. Petersburg, Russia
Gipronikel' Institute, Open Joint-Stock Company, St. Petersburg, Russia

Received July 26, 2004

Abstract—The activities of copper in liquid nickel–copper–iron alloys at 1600°C were calculated along sections with constant $x_{Ni} : x_{Fe}$ ratios of 3 : 1, 1 : 1, and 1 : 3 (x_i is the mole fraction of a component in an alloy).

The integral molar excess Gibbs energies ΔG^{ex} and enthalpies ΔH of mixing of liquid Ni–Cu–Fe alloys at 1600°C, calculated from experimental data for binary boundary systems, have been reported previously [1, 2]. A number of geometric models and the polynomial Redlich–Kister method have been used in the calculations. Modern techniques for calculation of integral thermodynamic characteristics of liquid ternary metallic systems on the basis of the corresponding properties of binary systems were considered in detail in [3]. As a kind of a calculation reliability criterion in the absence of experimental data for a ternary system can serve the closeness of the results obtained using different geometric models and the analytical technique. For the Ni–Cu–Fe system, calculations of ΔG^{ex} and ΔH by different methods yield reasonably consistent results [1, 2].

The partial molar thermodynamic characteristics of copper in liquid alloys of the system Ni(1)–Co(2)–Fe(3) can be calculated using the known expressions relating the partial and integral parameters in ternary systems [3]. For example, the partial excess Gibbs energy for copper (component 2) along a path with a constant ratio of the other two components ($x_1 : x_3$) is given by

$$\Delta G_2^{ex} = \Delta G^{ex} + (1 - x_2)(\partial \Delta G^{ex}/\partial x_2)_{x_1/x_2}, \qquad (1)$$

where ΔG_2^{ex} is the partial molar excess Gibbs energy for the composition determined by the mole fractions x_1, x_2, and x_3 (or x_2, $x_1 : x_3$), and ΔG^{ex} is the integral molar excess Gibbs energy of the ternary system for the composition under consideration.

Another possibility of estimating the partial molar parameters of copper or any other component of the ternary system is to calculate them from the related quantities for binary boundary systems. This method is applied to liquid metallic systems rather rarely [4]. At the same time, it follows from the basic equation of the Toop method [3, 4], which is widely used for calculating the thermodynamic characteristics of ternary systems, that

$$\Delta G_2^{ex} = \left[\frac{x_1}{1 - x_2}\Delta G_{2(12)}^{ex} + \frac{x_3}{1 - x_2}\Delta G_{2(23)}^{ex}\right]_{x_2} - (1 - x_2)^2[\Delta G_{13}^{ex}]_{x_1/x_3}, \qquad (2)$$

where $\Delta G_{2(12)}^{ex}$ and $\Delta G_{2(23)}^{ex}$ are the excess partial molar Gibbs energies for component 2 in binary boundary systems 1–2 and 2–3 at a given x_2; and ΔG_{13}^{ex} is the excess integral molar Gibbs energy of the binary boundary system 1–3 at a given ratio $x_1 : x_3$.

The available data on the thermodynamic properties of liquid alloys in the binary boundary systems Ni–Cu, Cu–Fe, and Fe–Ni have been discussed in detail [1, 2]. The input data used in calculations for the system Ni–Cu were based on the results of [5–7], and the ΔG^{ex} and ΔH values recommended by Batalin [8, 9] were adopted for the systems Cu–Fe and Ni–Cu. The dependence of the integral thermodynamic functions on composition was expressed analytically with the use of Redlich–Kister polynomials [1, 2]. The table compares the activities of copper in liquid alloys of the ternary system Ni–Cu–Fe, calculated using Eqs. (1) and (2) for compositions that lie on secants of the concentration triangle with $x_{Ni} : x_{Fe}$ ratios of 3 : 1, 1 : 1, and 1 : 3. The agreement between the results obtained is quite satisfactory. If the only goal of a calculation of the thermodynamic properties of a ternary system from data on binary boundary systems is to obtain the partial molar parameters of a component of

Activity of copper in liquid nickel–copper–iron alloys at 1600°C, calculated using Eqs. (1) and (2)

x_{Cu}	$x_{Ni} : x_{Fe} = 3 : 1$		$x_{Ni} : x_{Fe} = 1 : 1$		$x_{Ni} : x_{Fe} = 1 : 3$	
	(1)	(2)	(1)	(2)	(1)	(2)
0.10	0.35	0.33	0.41	0.41	0.45	0.46
0.20	0.53	0.53	0.61	0.59	0.64	0.62
0.30	0.67	0.64	0.72	0.69	0.74	0.70
0.40	0.74	0.72	0.76	0.75	0.77	0.76
0.50	0.79	0.77	0.80	0.80	0.79	0.80
0.60	0.82	0.81	0.84	0.83	0.83	0.84
0.70	0.85	0.84	0.88	0.86	0.89	0.87
0.80	0.89	0.87	0.91	0.88	0.93	0.89
0.90	0.93	0.92	0.94	0.92	0.94	0.92

the ternary system, then calculation by Eq. (2) seems to be preferable, compared to that by Eq. (1). Figure 1 shows isoactivity lines for copper in Ni–Cu–Fe liquid alloys at 1600°C.

Equation (2) makes it possible to estimate, on the basis of data for binary boundary systems, the limiting activity coefficient for copper in Ni–Fe liquid alloys. At $x_2 = 0$ ($x_{Cu} = 0$), Eq. (2) takes the form

$$(\Delta G_2^{ex})^{\infty} = x_1[\Delta G_{2(12)}^{ex}]^{\infty} + x_3[\Delta G_{2(23)}^{ex}]^{\infty} - [\Delta G_{13}^{ex}]_{x_1/x_3}. \quad (3)$$

In turn, knowledge of the limiting excess Gibbs energy for component 2 enables calculation of the activity coefficient for this component at infinite dilution by considering liquid alloys 1–3 of various compositions as solvents:

$$(\Delta G_2^{ex})^{\infty} = RT\ln\gamma_{2(13)}^{\infty}. \quad (4)$$

The quantities $\Delta G_{2(12)}^{ex}$ and $\Delta G_{2(23)}^{ex}$, related to binary systems 1–2 and 2–3, can be calculated using the Redlich–Kister polynomial, which describes the concentration dependence of the integral excess Gibbs energy in these systems. For example, the following dependences were obtained for the Ni–Cu system (ΔG^{ex} is in kJ mol^{-1}, 1873 K):

$$\Delta G^{ex} = x_{Ni}(1 - x_{Ni})[18.8829 - 3.5732(2x_{Ni} - 1) - 0.3147(2x_{Ni} - 1)^2],$$

and for the Cu–Fe system

$$\Delta G^{ex} = x_{Cu}(1 - x_{Cu})[29.5990 + 0.2475(2x_{Cu} - 1) + 6.8151(2x_{Cu} - 1)^2].$$

As already reported [1], equations of this kind describe experimental data with high precision.

Now, a polynomial relation for the binary system 1–2 is considered in the general form:

$$\Delta G^{ex} = x_1(1 - x_1)[b_1 + c(2x_1 - 1) + d(2x_1 - 1)^2]. \quad (5)$$

For the binary system 1–2, Eq. (1) takes the form

$$\Delta G_1^{ex} = \Delta G^{ex} + (1 - x_1)(\partial\Delta G^{ex}/\partial x_1)_{P,T}, \quad (6)$$

$$\Delta G_2^{ex} = \Delta G^{ex} - x_1(\partial\Delta G^{ex}/\partial x_1)_{P,T}. \quad (7)$$

Differentiation of Eq. (5) and substitution of the appropriate values into Eqs. (6) and (7) yields

$$\Delta G_1^{ex} = (1 - x_1)^2[b + c(4x_1 - 1) + d(12x_1^2 - 8x_1 + 1)], \quad (8)$$

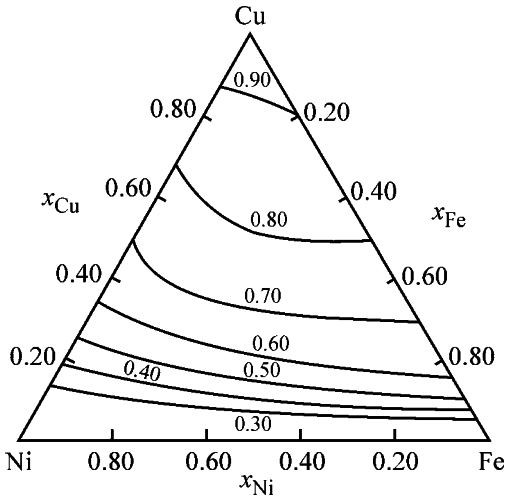

Fig. 1. Isoactivity lines for copper in liquid Ni–Cu–Fe alloys at 1873 K.

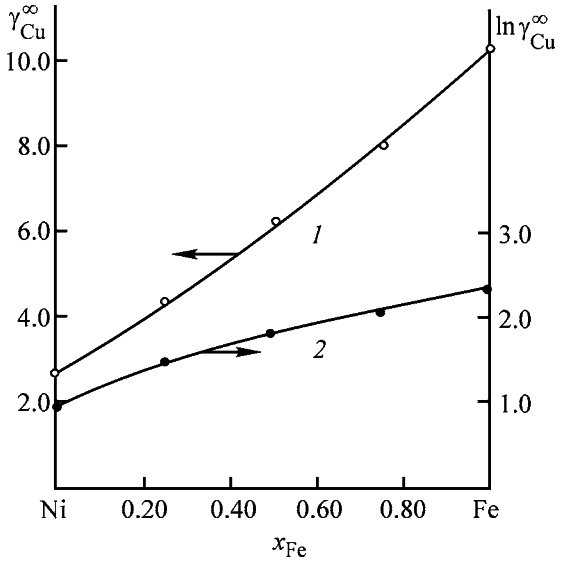

Fig. 2. (*1*) Limiting activity coefficient of copper, γ^{∞}_{Cu}, and (*2*) its logarithm vs. the composition x_{Fe} of the liquid Ni–Fe alloy at 1873 K.

$$\Delta G_2^{ex} = x_1^2[b + c(4x_1 - 3) + d(12x_1^2 - 16x_1 + 5)]. \quad (9)$$

At $x_1 \to 0$ or $x_1 \to 1$ ($x_2 \to 0$), accordingly,

$$(\Delta G_1^{ex})^{\infty} = b - c + d, \quad (10)$$

$$(\Delta G_2^{ex})^{\infty} = b + c + d. \quad (11)$$

In the boundary system Ni–Cu, copper is component 2 and Eqs. (9) and (11) are to be used for calculating ΔG^{ex}_{Cu} and $(\Delta G^{ex}_{Cu})^{\infty}$. At the same time, copper is component 1 in the boundary system Cu–Fe, and similar calculations require that Eqs. (8) and (10) should be used.

Thus,

$$[\Delta G^{ex}_{Cu(Ni)}]^{\infty} = 18.8829 - 3.5732 - 0.3147$$

$$= 14.995 \text{ kJ mol}^{-1},$$

$$\ln\gamma^{\infty}_{Cu(Ni)} = 0.963, \quad \gamma^{\infty}_{Cu(Ni)} = 2.619.$$

$$[\Delta G^{ex}_{Cu(Fe)}]^{\infty} = 29.5990 - 0.2475 + 6.8151$$

$$= 36.167 \text{ kJ mol}^{-1},$$

$$\ln\gamma^{\infty}_{Cu(Fe)} = 2.323, \quad \gamma^{\infty}_{Cu(Fe)} = 10.201.$$

The limiting values of the activity coefficients of copper in liquid alloys with nickel or iron are reasonably consistent with published experimental data [1].

For the iron–nickel system, the dependence of ΔG^{ex} on the alloy composition at 1873 K is described by the equation

$$\Delta G^{ex} = x_{Fe}(1 - x_{Fe})[-11.0909 + 6.1995(2x_{Fe} - 1)$$

$$- 0.9194(2x_{Fe} - 1)^2].$$

Data on ΔG^{ex} for the system Fe–Ni at $x_{Ni} : x_{Fe}$ of 3 : 1, 1 : 1, and 1 : 3 are required for substitution into Eq. (5). In other words, it is necessary to know ΔG^{ex} at $x_{Ni} = 0.75$, 0.50, and 0.25:

x_{Ni}	0.75	0.50	0.25
x_{Fe}	0.25	0.50	0.75
ΔG^{ex}_{Ni-Fe}, kJ mol^{-1}	–2.704	–2.770	–1.541

As a result, the following values of the limiting thermodynamic functions are obtained for copper in liquid Ni–Fe alloys of various compositions at a temperature of 1873 K:

x_{Ni}	0.75	0.50	0.25
$[\Delta G^{ex}_{Cu}]^{\infty}$, kJ mol^{-1}	22.992	28.351	32.414
$\ln\gamma^{\infty}_{Cu}$	1.476	1.821	2.082
γ^{∞}_{Cu}	4.378	6.176	8.016

Figure 2 shows that the dependence of $\ln\gamma^{\infty}_{Cu}$ and γ^{∞}_{Cu} on the composition of the liquid Ni–Fe alloys is very close to a linear dependence.

CONCLUSIONS

(1) Calculation of the activity of copper in liquid nickel–copper–iron alloys at 1600°C by two different methods yields consistent results.

(2) Estimates of the limiting values of the activity coefficients of copper in liquid Cu–Ni, Cu–Fe, and Cu–(Ni–Fe) alloys are presented. The dependence of γ^{∞}_{Cu} on the composition of the Ni–Fe alloy is nearly linear.

Received July 23, 2004

Abstract—The synthesis of magnesium oxide with high adsorptive properties by the sulfate–ammonia and sulfate–carbonate methods and the effect exerted by the conditions of synthesis of magnesium oxide and hydroxide on their adsorptive activity were studied. The thermograms of the synthesized samples are presented. The activity of the samples, evaluated by the iodine number, was determined in relation to the synthesis conditions.

Chemically synthesized magnesium oxide and hydroxide have large specific surface area and high mechanical strength, and therefore they have high catalytic activity and good adsorptive properties [1]. Magnesium hydroxide has high adsorption capacity with respect to the majority of Group III–VIII elements [2]. Also, magnesium compounds form cements of the type of hydroxy salts, crystallizing in mixing of magnesium oxide with various water-soluble magnesium salts [3, 4]. This study was aimed to develop an adsorbent of radioactive iodine for its utilization and disposal.

The sorption capacity of magnesia depends on the specific surface area and is characterized in industry by the iodine number N, i.e., by the amount of absorbed iodine (mg-equiv) per 100 g of MgO. The ability of magnesium compounds to take up iodine and form cements with various anions suggests the possibility of synthesis of magnesium hydroxide and oxide with high adsorptive properties and subsequent preparation of stone-like structures suitable for utilization and disposal of radioactive iodine.

The surface and adsorptive properties of synthetic magnesia strongly depend on both the kind of the starting compounds and the synthesis method [5].

The effect exerted by synthesis conditions on the chemical composition and surface properties of magnesium hydroxide and oxide has been determined previously by the example of the magnesia synthesis from pure solutions of analytically pure grade $MgSO_4$, which involved precipitation of $Mg(OH)_2$ with ammonia [6]. It was shown that the synthesis conditions, including temperature T, concentration of the initial solution c_{init}, amount of alkaline reagent, and process time τ, essentially affect the specific surface area S_{sp} of magnesium hydroxide and oxide.

In this study, we studied the properties and performed the qualitative analysis of magnesia obtained from natural caustic magnesite. The raw material was caustic magnesite from the Sadkinskoe deposit (Chelyabinsk oblast) containing (wt %) MgO 86, CaO 4.06, Fe_2O_3 1.46, CO_2 1.3, Al_2O_3 0.8, and the insoluble residue 0.8. Magnesia was prepared by the sulfate–ammonia and sulfate–carbonate processes. The bound magnesium was transferred into the solution using H_2SO_4 and $(NH_4)_2SO_4$ solutions.

The sulfate–ammonia process for production of magnesia from caustic magnesite involves treatment of the raw material with 10–15 wt % solutions of $(NH_4)_2SO_4$ (amount 100–110% of the stoichiometry), yielding $MgSO_4$ solutions and gaseous ammonia. After the precipitate is separated, the $MgSO_4$ solution is treated with ammonia to precipitate $Mg(OH)_2$, from which magnesium oxide is obtained by calcination. The process involves the reactions

$$MgO\downarrow + (NH_4)_2SO_4 = MgSO_4 + 2NH_3 + H_2O,$$

$$MgSO_4 + 2NH_3 + 2H_2O = Mg(OH)_2\downarrow + (NH_4)_2SO_4,$$

$$Mg(OH)_2 = MgO + H_2O.$$

The process time is 2 h; temperature interval, 80–100°C; and the concentration of the resulting $MgSO_4$ solution, 12–15 wt %. The $MgSO_4$ solutions contain the following impurities (wt %): CaO 0.12, SiO_2

0.01–0.02, and Al_2O_3 0.002. Solutions of such composition do not require additional purification. The solid phase consisting of undecomposed magnesite and impurities was filtered on a vacuum filter.

Magnesium hydroxide $Mg(OH)_2$ was precipitated from the $MgSO_4$ solution at 20–80°C for 2–10 min. The precipitate was filtered off, dried, and calcined at 250–900°C.

The chemical composition of the magnesium hydroxide precipitate prepared at different temperatures is given in the table.

Composition of the magnesium hydroxide precipitate

T, °C	Content in precipitate, wt %	
	$Mg(OH)_2$	$MgSO_4 \cdot 3Mg(OH)_2 \cdot 8H_2O$
20	66.6	33.4
30	70.4	29.6
40	81.4	18.6
60	82.5	17.5
80	92.4	7.6

The table shows that, along with magnesium hydroxide, $MgSO_4 \cdot 3Mg(OH)_2 \cdot 8H_2O$ is present in the precipitates at lower synthesis temperatures; the lower the temperature, the higher its mass fraction. The compound $MgSO_4 \cdot 3Mg(OH)_2 \cdot 8H_2O$ exhibits binding properties, and its presence in the cements will improve the quality of stone-like structures.

The sulfate–carbonate synthesis of magnesia included dissolution of caustic magnesite in sulfuric acid at pH 3–3.5 to prepare a magnesium sulfate solution, into which caustic magnesite was added to remove impurity calcium compounds and sesquioxides. The precipitate was separated on a vacuum filter, the resulting magnesium sulfate solution was neutralized with a solution of potassium carbonate, and magnesium subcarbonate was precipitated. To obtain magnesia, magnesium subcarbonate was calcined at 250–900°C. The process involves the reactions

$$MgO + H_2SO_4 = MgSO_4 + H_2O,$$

$$3MgSO_4 + 3K_2CO_3 + 5H_2O = 2MgCO_3 \cdot Mg(OH)_2 \cdot 4H_2O + 3K_2SO_4 + CO_2\uparrow,$$

$$2MgCO_3 \cdot Mg(OH)_2 \cdot 4H_2O = 3MgO + 2CO_2 + 5H_2O.$$

Magnesium subcarbonate synthesized by the above technology contains (wt %) MgO 40, CO_2 29, H_2O 24, and CaO 0.26.

The chemical analysis of the synthesis products was done by the methods presented in [7]. The surface properties of magnesium hydroxide and oxide were characterized by the iodine number *N*. The iodine number was determined according to [8].

The dependences of the iodine numbers of magnesium hydroxide on the temperature of its synthesis and of magnesium oxide on the calcination temperature are shown in Fig. 1 for the samples synthesized by the sulfate–ammonia method. The magnesium hydroxide samples were obtained by drying in air of wet hydroxide obtained at different temperatures of the synthesis.

The dependence of *N* on the synthesis temperature for the samples dried at 20°C shows that the lower the synthesis temperature, the higher the iodine number *N* of magnesium hydroxide (curve *3*). The sample synthesized at 20°C and dried in air has the highest adsorption activity (*N* = 155). With increasing synthesis temperature, *N* decreases to 124 at 40°C and to 70 at 80°C.

The adsorption activity of magnesium oxide samples depends on the calcination temperature. Among magnesium hydroxide samples calcined in the range 450–700°C, the samples calcined at 450°C have the highest *N* value; for example, the sample synthesized at 20°C (Fig. 1, curve *1*) has *N* = 340. With increasing synthesis temperature, *N* decreases markedly, to 275 at 40 and to 230 at 80°C. Increasing the calcination temperature to 500°C decreases *N* by a factor of 1.3 (curve *2*). Under these conditions, *N* of magnesium oxide is, however, larger than that of hydroxide

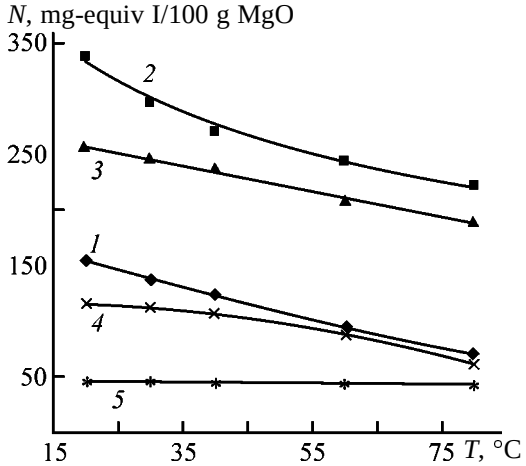

Fig. 1. Iodine number *N* vs. the synthesis temperature *T* of magnesium hydroxide. Temperature of calcination of magnesium oxide (°C): (*1*) 450, (*2*) 500, (*4*) 600, and (*5*) 700. Temperature of drying of magnesium hydroxide (°C): (*3*) 20.

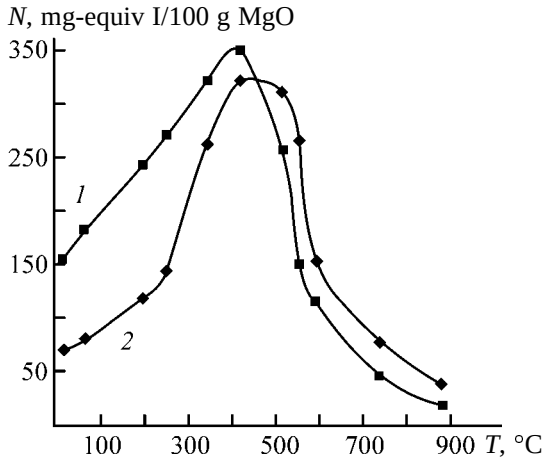

Fig. 2. Iodine number *N* vs. the calcination temperature *T* of magnesium hydroxide and magnesium subcarbonate. Sample: (*1*) no. 1 and (*2*) no. 2.

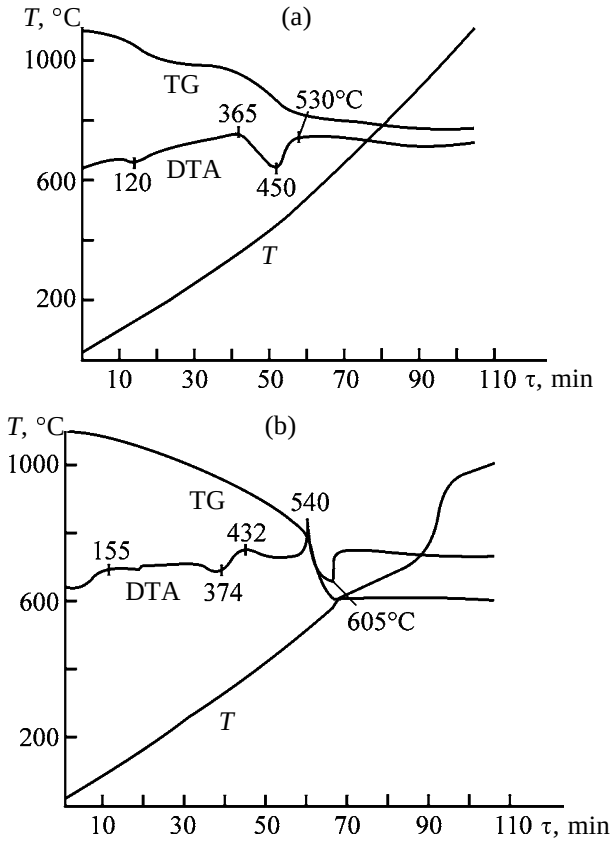

Fig. 3. DTA and TG curves of (a) magnesium hydroxide and (b) magnesium subcarbonate. (*T*) Temperature and (τ) time.

(curve *3*). As the calcination temperature is increased further to 600 and 700°C, *N* decreases drastically, irrespective of the temperature of the magnesium hydroxide synthesis.

Examination of the microstructure of the precipitates obtained under the different conditions shows that small particles with a more developed surface are formed at lower synthesis temperatures and coarser particles with a less developed surface, at higher temperatures. This accounts for the dependences characterizing the effect of temperature on the hydroxide surface properties.

The magnesium oxide samples synthesized by the sulfate–ammonia (sample no. 1) and sulfate–carbonate (sample no. 2) methods have different surface characteristics. The *N* value of the starting samples is 155 for sample no. 1 and 70 for sample no. 2. The dependence of the iodine number on the calcination temperature has a maximum (Fig. 2). At a calcination temperature of 450°C, the *N* value of the samples synthesized by the ammonia and carbonate methods is maximal (340 and 320, respectively). At lower calcination temperatures, the *N* values differ considerably: e.g., at 350°C *N* is 322 (sample no. 1) and 262 (sample no. 2).

As the calcination temperature is increased to 500–530°C, *N* remains fairly high, 250–260, for both the samples. At higher temperatures *N* drastically decreases, and at 700–900°C its value for the sample synthesized from magnesium hydroxide is lower than in that for the sample obtained using potassium carbonate.

Such a trend in variation of the surface properties of the calcined samples with temperature is due to the fact that, in the course of the calcination of sample no. 1 to 450°C, water of hydration is removed with formation of pores, with the magnesium hydroxide skeleton preserved. At higher temperatures, the structural rearrangement, agglomeration, and sintering take place.

For sample no. 2, the removal of water of hydration, which is complete at 450°C, is accompanied by decarbonation, with most of carbon dioxide being also removed in the range 400–500°C. Variation of the carbon content in the calcined magnesium subcarbonate (sample no. 2) confirms this result.

T, °C	CO_2, vol %
20	30.5
300	28.9
350	28.2
400	7.5
450	1.1

Heating to higher temperatures results in the agglomeration and sintering. This is also confirmed by the thermogravimetric analysis of the samples.

The thermogravimetric analysis of sample no. 1 (Fig. 3a) shows that, at 120–130°C, hygroscopic

moisture and a part of water of hydration are removed, which is associated with the presence in magnesium hydroxide of the impurity salt $MgSO_4 \cdot 3Mg(OH)_2 \cdot 8H_2O$. The removal of hygroscopic and hydration water from the above salt is confirmed by a diffuse endothermic effect at 130°C. Water of hydration is removed stepwise through hydrates of magnesium oxosulfate. The weight loss in the process is 12.8%. The dehydration of magnesium hydroxide is complete at 450°C, with the weight loss of 22.2%.

The thermogravimetric analysis of sample no. 2 (Fig. 3b) shows that its water of hydration is removed at 315°C, giving rise to an endothermic effect. The weight loss is 19.3%. The endothermic effect at 432°C corresponds to the magnesium carbonate dissociation. The weight loss is 8.3%. Magnesium hydroxide is dehydrated within 400–420°C. The decarbonation is complete at 580°C, with the weight loss of 31.7%.

The methods proposed make it possible to synthesize magnesium oxide surpassing in the surface properties the samples produced by the leading world companies.[1]

CONCLUSION

Highly active magnesia can be synthesized from natural material using sulfate reagents for the dissolution and ammonia and potassium carbonate for the precipitation of magnesium compounds.

SORPTION AND ION-EXCHANGE PROCESSES

Thermodynamic Parameters Characterizing Adsorption of Organic Compounds from Aqueous Solutions on Iron Oxide α-Fe_2O_3

B. N. Afanas'ev, E. A. Aleksandrova, and Yu. P. Akulova

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received October 22, 2003

Abstract—Adsorption of a series of organic compounds on the surface of α-Fe_2O_3 is studied. The experimental data are analyzed using the Frumkin and Langmuir isotherms. The standard Gibbs energies of adsorption ΔG_A^0 and ΔG_{ads}^0 corresponding to different standard states are estimated.

Adsorption of organic compounds from aqueous solutions on iron and its oxides should be taken into account in studying inhibition of ferrous metal corrosion, flotation of ores, and electroplating [1, 2]. To control these processes, it is necessary to find parameters uniquely characterizing the binding of an organic molecule to the metal or oxide surface. In the works on adsorption of surfactants on metals or oxides, the common method is to obtain an adsorption isotherm describing the dependence of the coverage of the surface with adsorbed molecules (θ) on their molar concentration in the bulk of the solution c_{org} [1–3].

From the experimental adsorption isotherm

$$f(\theta) = Bc_{org}, \quad (1)$$

the constant B is determined, and then the standard Gibbs energy of adsorption ΔG_A^0, corresponding to asymmetric standard state, is calculated by well-known Eq. (2) [2, 3]:

$$\Delta G_A^0 = -RT\ln(55.5B). \quad (2)$$

In this case, the activity coefficient of the organic compound in the bulk of the solution $f_{org} \to 1$ if $c_{org} \to 0$.

In practice, the Langmuir isotherm [$f(\theta) = \theta/(1 - \theta)$] or the Frumkin isotherm is commonly used. In the latter case,

$$f(\theta) = [\theta/(1 - \theta)]\exp(-2a\theta).$$

If the adsorption isotherm is written in the form of Eq. (3),

$$f(\theta) = Ba_{org} = \exp(\Delta G_{ads}^0/RT)x_{org}\gamma_{org}, \quad (3)$$

where x_{org} and γ_{org} are the mole fraction and activity coefficient of the organic compound in the bulk of the surfactant-containing aqueous solution, the standard Gibbs energy of adsorption ΔG_{ads}^0 corresponds to the symmetrical standard state in the bulk of the solution [4]. In this case, the pure substance is taken to be the standard state, for which the condition $a_{org} = x_{org} = 1$ is valid.

From Eqs. (1) and (3), taking into account Eq. (2), we obtain the standard Gibbs energy of adsorption expressed via the activity coefficient of the organic compound at infinite dilution [4]:

$$\Delta G_A^0 = \Delta G_{ads}^0 - RT\ln\gamma_{org}^{\infty}. \quad (4)$$

In this case, the surfactant activity coefficient γ_{org}^{∞} corresponding to the symmetrical standard state at infinite dilution ($x_{org} \to 0$) includes all kinds of interactions occurring in the solution between the surfactant molecule and water. Depending on the nature of the organic molecule, the γ_{org}^{∞} value can range from 1 to 10^3–10^4 [5]. It follows from Eqs. (1), (2), and (4) that ΔG_A^0 depends on both the metal–surfactant binding energy and the properties of the aqueous surfactant solution. Therefore, the ΔG_A^0 value does not provide an unambiguous information on the surfactant–metal or surfactant–oxide binding energy, and this parameter cannot be used for characterization of the interaction between the surfactant molecule and the surface of a solid, as was made in [6, 7].

At the same time, it follows from Eq. (4) that the Gibbs energy ΔG_{ads}^0 characterizes the binding of an organic molecule to the metal or oxide surface, since

the bulk properties of the solution are taken into account through the parameter $RT\ln\gamma_{org}^{\infty}$ [4].

The goal of this work is experimental study of adsorption of a series of surfactants from aqueous solutions on the surface of α-Fe_2O_3 and estimation of ΔG_{ads}^0 using Eq. (4), to characterize the surfactant–oxide surface binding.

EXPERIMENTAL

As a subject matter we selected surfactants strongly different in their chemical and physicochemical properties. The difference between the first ionization energies of the organic molecules I, which, to a first approximation, reflect the energy of the highest occupied molecular orbitals, is about 3 eV (1 eV = 96.485 kJ mol^{-1}) (Table 1).

Organic compounds (analytically or chemically pure grade) were purified as follows. β-Naphthylamine was recrystallized from hot distilled water to obtain pearl white-pink flakes; β-naphthol, from hot distilled 90% ethanol, as white crystals; naphthalene, from hot distilled 90% ethanol, as white flakes; benzoic acid, from hot distilled water, as white crystals. Phthalic anhydride was purified by sublimation, to obtain white needles; and aniline, by distillation, to obtain a transparent liquid. The adsorbent was prepared as follows. Iron(III) oxide (analytically pure grade) was fired at 650°C for 3 h, furnace-cooled to 150–200°C, transferred into an desiccator with dry silica gel, and cooled to room temperature. This procedure provided removal of water and CO_2 molecules from the oxide surface, dehydration of iron(III) hydrous oxide occurring at 300–420°C, and finally, its conversion into reddish-brown α-Fe_2O_3 (hematite). All the aqueous solutions were prepared with double-distilled water. Initially, nearly saturated stock surfactant solutions were prepared (Table 1), which then were diluted to the desired concentrations. The oxide was contacted with a surfactant solution with intermittent stirring for 2 h at 19±1°C and then separated by centrifugation. The surfactant concentration in the solution after centrifugation was determined by the optical density D measured on an SF 2000 spectrophotometer in a 1-cm cell. This instrument provides reliable measurements over the optical density range from 0.3 to 1.0, so that the solutions should be diluted to obtain distinct UV spectra. The amount of the adsorbed surfactant Γ_{org} (mol m^{-2}) was estimated by Eq. (5).

$$\Gamma_{org} = \frac{(c_{org}^0 - c_{org})V}{A}, \qquad (5)$$

where A is the effective surface area (m^2) of the oxide sample (g); V, volume of the solution (l); and c_{org}^0 and c_{org} are the surfactant concentrations (M) in the solution before and after adsorption.

Table 2. Parameters of surfactant adsorption on α-Fe_2O_3

Surfactant	Frumkin isotherm					Langmuir isotherm

* Parameters B and Γ_{max} were estimated by Eq. (8).

The concentrations of the surfactants in solutions were determined using the calibrating curves D–c_{org} at the corresponding wavelengths λ (Table 1). The optical density at these wavelengths was demonstrated to be proportional to the surfactant concentration.

The BET surface area of the α-Fe_2O_3 powder, determined by the low-temperature adsorption of nitrogen, was from 6.1 to 11.7 m^2 g^{-1}, depending on the sample, which is well consistent with the reference data for zirconium [8] and zinc [9] oxides.

For a given surfactant, adsorption was studied with the same oxide sample. The sample weight was 1 or 2 g. The surface area of the oxide powder was greater by a factor of at least 10^3 than the surface area of the cell and that of the air/solution interface. Therefore, the interfacial adsorption could be neglected.

For poorly soluble surfactants, the activity coefficient γ^0_{org} can be estimated by Eq. (6) [5].

$$RT \ln \gamma^{\infty}_{org} \cong -RT \ln x^{sat}_{org}, \quad (6)$$

where x^{sat}_{org} is the surfactant concentration in the saturated aqueous solution (mole fraction).

The solubilities of the organic compounds in water were taken from [10–12]. Since we found no published data for β-naphthylamine, its solubility was determined experimentally. A saturated solution of β-naphthylamine was prepared in distilled water saturated with Ar at 19°C with continuous stirring for 3 days in the dark. The solubility was estimated at 1.45×10^{-3} from the optical density by extrapolation of the calibrating curve.

The $RT \ln \gamma^0_{org}$ values estimated by Eq. (6) are given in Table 2.

The experimental Γ and c_{org} isotherms were analyzed by the Frumkin isotherm equation reduced to the form of Eq. (7), using the Origin program pack.

$$y = \left[\frac{x}{P_3(P_1 - x)}\right] \exp(-P_2 x), \quad (7)$$

where $y \equiv c^0_{org}$, $x \equiv \Gamma$ (mol m^{-2}), $P_1 \equiv \Gamma_{max}$, $P_2 \equiv 2a/\Gamma_{max}$ (a is the attraction constant in the Frumkin isotherm equation), and $P_3 \equiv B$. In so doing, we found the empirical coefficients P_1, P_2, and P_3, the variance Δ of c_{org}, correlation factor r, and standard deviations for P_1, P_2, and P_3.

Note that Eq. (7) includes dimensionless parameters $\Gamma/(\Gamma_{max} - \Gamma)$ and $2a(\Gamma/\Gamma_{max})$. Therefore, the true value of B was determined regardless of how reliable is the parameter A in Eq. (5). At $2a = 0$, the Frumkin isotherm is reduced to the Langmuir isotherm. To obtain reasonably reliable parameters of Eq. (7), the number of experimental Γ values estimated by Eq. (5) should be at least 15–20 (see figure).

Table 2 summarizes data on the parameters Γ_{max}, $2a$, and B, and also on the variance Δ for Eq. (7) and correlation factor r.

The Langmuir isotherm can be written as

$$\frac{1}{c_{org}} = B\frac{\Gamma_{max}}{\Gamma} - B. \quad (8)$$

Representation of the experimental data in the coordinates $1/c_{org}$–$1/\Gamma$ makes it easy to determine the parameters B and Γ_{max}. Table 2 shows these parameters estimated by Eq. (7) at $2a = 0$ using the Origin program pack, and also by Eq. (8). The results obtained by these two methods are well consistent. Changing the Frumkin isotherm for the Langmuir isotherm results in increasing Γ_{max} at $2a > 0.5$ or in decreasing Γ_{max} at considerably negative $2a$ values. It follows from Eq. (4) that ΔG^0_{ads} depends on the Gibbs energy ΔG^0_A, and the latter, in turn, on the equation of the adsorption isotherm. It also follows from Table 2 that, if $0 < 2a < 1.5$, changing one isotherm for another has practically no effect on B. Therefore, in this case, within the errors indicated in Table 1, the Gibbs energy ΔG^0_A estimated by Eq. (2) does not depend on the equation of the adsorption isotherm used for analysis of the experimental c_{org}–Γ curves.

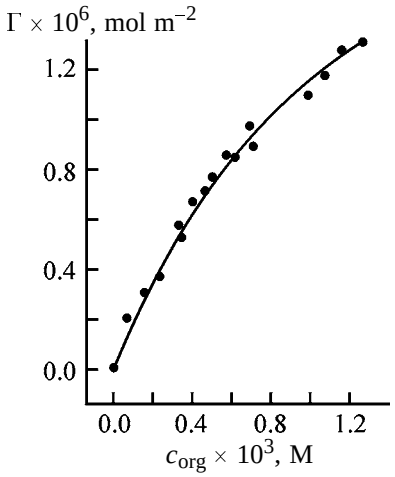
Nikolenko *et al*. [8] studied adsorption of a series of surfactants on the surface of ZrO_2 in 0.1 M KCl. Addition of a strong electrolyte to water results in salting-out of the surfactant from the aqueous solution (Sechenov effect):

$$(\Delta G^0_A)_{sol} = \Delta G^0_A + \Delta G^0_{sol}, \quad (9)$$

where $(\Delta G^0_A)_{sol}$ is the Gibbs energy of adsorption of the surfactant in the aqueous electrolyte solution and ΔG^0_{sol}, difference of the Gibbs energy of adsorption caused by salting-out of the surfactant.

In 0.1 M KCl, $\Delta G^0_{sol} \approx -1$ kJ mol^{-1} [13]. The $(\Delta G^0_A)_{sol}$ values for benzoic acid and aniline are –23.3 and –17.6 kJ mol^{-1}, respectively [8]. Therefore, the ΔG^0_A values characterizing adsorption of these surfactants on ZrO_2 are –22.3 and –16.6 kJ mol^{-1}, respectively, which is consistent with the ΔG^0_A values from Table 1.

Table 1 also includes the standard Gibbs energy of adsorption ΔG^0_{ads} corresponding to the symmetrical standard state, estimated by Eq. (4). The values of this energy are small for all the surfactants studied except aniline. Table 1 shows that aniline is rather readily soluble in water, and, therefore, estimation of γ^∞_{org} by Eq. (6) can provide an error of 2 to 3 kJ mol^{-1} in determination of the parameter $RT\ln\gamma^\infty_{org}$. Since the error of determination of the surfactant solubilities is unknown, one cannot estimate the error of determination of ΔG^0_{ads}.



c_{org} vs. Γ plot for β-naphthylamine adsorbed on α-Fe_2O_3, estimated by Eq. (7) using the Origin program pack with the parameters given in Table 2. (Γ) Amount of adsorbed surfactant and (c_{org}) surfactant concentration in the solution.

Previously we demonstrated [4] that there is a distinct correlation between ΔG^0_{ads} and the first ionization potentials of the surfactant molecules adsorbed on bismuth. Table 1 shows, firstly, that such a correlation is lacking and, secondly, that $|\Delta G^0_{ads}| \ll |\Delta G^0_A|$. Except for aniline, one may accept ΔG^0_{ads} = const. Then, the arithmetic mean $\overline{\Delta G^0_{ads}} \approx 0$.

It follows from Eq. (4) that the observed high negative ΔG^0_A values and, correspondingly, high adsorbability of the surfactants on iron(III) oxide are controlled by the surfactant activity coefficients in the bulk of the solution. In other words, the adsorbability of the surfactants on α-Fe_2O_3 is controlled not by the interaction of the surfactant with the oxide surface, but by the bulk characteristics of the aqueous surfactant solution. Dissolution of the organic surfactant is accompanied by distortion of the structure of water, and the solvent tends to throw out the organic molecules to the interface layer.

In this context, it becomes clear why the adsorbability of carboxylic acids on ZrO_2 decreased with increasing pH [8]. At pH >7.5, readily soluble carboxylates are formed. Decreasing γ^∞_{org} results in increase in ΔG^0_A and, correspondingly, in decrease in the adsorption constants B and θ.

Table 2 shows that, in most cases, the Frumkin isotherm better fits the experimental Γ–c_{org} curves than does the Langmuir isotherm (Δ is lower, and r is

somewhat higher). It is seen also that, for all the surfactants except phthalic anhydride, Γ_{max} corresponds to the vertical orientation of the organic molecules on the surface. This is clear from the physical standpoint, since the solvent tends to push out as many surfactant molecules as possible to the interface layer.

Adsorption of a surfactant from a solution on the surface of a solid is always accompanied by replacement of water molecules from the surface to the bulk of the solution. It was demonstrated in [3, 4] that, in this case, the expression for ΔG^0_{ads} can be written as

$$\Delta G^0_{ads} = \Delta G^0_{org} - \nu \Delta G^0_{H_2O}, \quad (10)$$

where ΔG^0_{org} and $\Delta G^0_{H_2O}$ are the standard Gibbs energies characterizing the work of transfer of a mole of the pure substance (surfactant or water) from the bulk to the surface and ν is the number of moles of water replaced from the surface layer formed at the interface in adsorption of 1 mol of the surfactant.

Parameter ν is estimated by Eq. (11) [14]:

$$\nu = \Gamma_{max, H_2O}/\Gamma_{max}, \quad (11)$$

where Γ_{max, H_2O} is the maximal coverage of the surface with water (mol m^{-2}).

It is commonly accepted that $\Gamma_{max, H_2O} = 12 \times 10^{-6}$ mol m^{-2} [14]. The ν values estimated by Eq. (11) are given in Table 1.

The numerical values of parameters ΔG^0_{org} and $\Delta G^0_{H_2O}$ are resultants of the work that should be done for partial break of the bonds between the molecules and for their transfer to the surface, and the work spontaneously expended for the formation of a new bond between the adsorbed molecules and the oxide surface.

The work associated with the transfer of ν moles of water from the bulk to the surface is written as [4]

$$W = \nu \sigma_{H_2O} A_{H_2O}, \quad (12)$$

where σ_{H_2O} is the surface tension of water ($\sigma_{H_2O} = 71.96 \times 10^{-3}$ J m^{-2} [15]); A_{H_2O}, area occupied by 1 mol of water on the surface ($A_{H_2O} = 8.3 \times 10^4$ m^2 mol^{-1}). At $\nu = 2.5$ (Table 1), $W = 15$ kJ mol^{-1}. This value is well comparable with the dispersion interaction energy [16].

The result that $\Delta G^0_{ads} \approx 0$ is probably due to the fact that the water and surfactant molecules are bound to the oxide surface by the dispersion forces. In this case, ΔG^0_{org} and $\nu \Delta G^0_{H_2O}$ are small as a result of the compensating effects of different factors.

For the case of $\Delta G^0_{ads} \approx 0$, ΔG^0_A, B, and, correspondingly, θ can be estimated theoretically by Eqs. (1), (2), and (4) without performing laborious measurements on the adsorption of the surfactants.

CONCLUSIONS

(1) The adsorbability of organic surfactants from aqueous solutions on the surface of α-Fe_2O_3 is controlled not by the specific interaction of organic molecules with the oxide surface, as commonly believed, but by the surfactant activity coefficients γ^∞_{org} in the bulk of the solution.

(2) The γ^∞_{org} values depend only on the properties of the binary solution, and knowing γ^∞_{org} allows estimation of the adsorbability of surfactant on α-Fe_2O_3.

SORPTION AND ION-EXCHANGE PROCESSES

Development of the Specific Surface Areas of Natural Coal in the Course of Thermolysis in the Presence of Potassium Hydroxide

Yu. V. Tamarkina, V. A. Kucherenko, and T. G. Shendrik

Litvinenko Institute of Physical Organic Chemistry and Coal Chemistry, National Academy of Sciences of Ukraine, Donetsk, Ukraine

Received April 14, 2004

Abstract—The development of the surface of natural coal from Donets field in the course of thermolysis with KOH was studied. The dependences of the specific surface area of coal containing 90% carbon on the activation time, temperature (400–800°C), and KOH/coal ratio (0.75–4.5 g g^{-1}) were determined. The effect exerted on the development of the porous coal structure by low-temperature (20 ± 2°C) oxidative modification causing formation of oxygen functional groups and reorganization of the coal three-dimensional structure was studied.

Thermolysis in the presence of alkali metal hydroxides (chemical activation) is widely used for preparing activated carbons (ACs) with a high specific surface area and a developed system of nanopores (down to 2 nm) [1, 2]. Nanoporous ACs are of particular importance owing to their use in air and water treatment, metal sorption, etc., and also in storage of methane and hydrogen as fuels for internal-combustion engines [3]. As a rule, thermolysis in CO_2 or steam atmosphere (physical activation) does not yield nanoporous ACs, because in this case meso- (2–50 nm) and macropores (more than 50 nm) are mainly developed [1].

Various carbon materials, especially, biomass wastes or coals with low degree of metamorphization (DM) are used for preparing ACs by chemical activation [1]. However, data on conversion of highly metamorphized coals and anthracites into nanoporous ACs by chemical modification are virtually lacking, despite the fact that these carbons are very promising as AC precursors owing to high content of aromatic carbon and high strength, which can be retained in the final activation products. We studied the conversion of highly metamorphized coals from Donets field into materials with a high specific surface area by heat treatment in the presence of alkali metal hydroxides.

EXPERIMENTAL

In this work we used highly metamorphized coals with the carbon content from 90 (OS brand coal) to 95.2 wt % (anthracite) and particle size of 0.16–0.25 mm; the detailed characteristics of these coals are given in [4]. The chemical activation was performed in two stages: (1) mixing of carbon with 50% aqueous KOH solution, storage for 72 h at 20 ± 2°C, drying, and grinding (KOH/dry coal weight ratio was varied within R_{KOH} = 0.75–4.5 g g^{-1}); (2) heating of carbon with alkali in a horizontal quartz tubular reactor in an argon flow (2 dm^3 h^{-1}) at activation temperature T for time τ. The solid product was cooled, washed to remove alkali successively with water, HCl, and again water (to negative reaction for Cl^- ions), and dried at 105 ± 5°C. The yield of AC Y (wt %) was determined, and the specific surface area S_{BET} (m^2 g^{-1}) was measured by low-temperature adsorption of argon [5].

The structure of carbon samples was studied by X-ray diffraction (XRD) analysis on a DRON-3 UM diffractometer (CuK_α radiation) and by diffuse reflection Fourier IR spectroscopy on a Bio-Rad Win-IR spectrometer in the 4000–400 cm^{-1} range (5% carbon samples in KBr, 500 scans, 2 cm^{-1} resolution).

Thermolysis of the initial carbons in the absence of alkali at 800°C for 2 h gives products with a low specific surface area (Fig. 1, curve *1*); the S_{BET} values vary in the 11–16 m^2 g^{-1} range and are independent of the carbon content. In the presence of alkali, the specific surface area of carbons increases, but this increase strongly depends on DM (Fig. 1, curve *2*). This effect, being minimal for anthracite, approximately linearly increases with decreasing carbon content,

1070-4272/04/7709-1440 © 2004 MAIK "Nauka/Interperiodica"

being maximal for OS coal. The development of the specific surface area of this coal as influenced by the main factors of chemical activation (time, temperature, and alkali/coal weight ratio) was studied more comprehensively. As seen from the kinetic data, first S_{BET} sharply increases within 1 h of activation (T = 800°C), then nearly exponentially decreases, and remains constant within the experimental error at $\tau \geq$ 2 h. The AC yield changes in the opposite direction. Since our results are similar to those given previously in [6], the activation time in further experiments was 2 h.

The AC specific surface area remains unchanged in the 400–550°C temperature range and linearly increases with temperature from 550 to 800°C (Fig. 2, curve *1*). The S_{BET} values increase with increasing KOH content up to $R_{KOH} \leq 2$ g g^{-1}, whereas further increase in the alkali content does not affect the specific surface area (Fig. 2, curve *2*). These data show that the maximal specific surface area of AC prepared form OS coal using the activation procedure is $S_{BET} = 500 \pm 50$ m^2 g^{-1}. This value is relatively low for ACs prepared by chemical activation, because their specific surface area is usually higher than 1000 m^2 g^{-1} [1, 2].

In this work we also studied the influence exerted on the development of the specific surface area by low-temperature preactivation. This low-temperature chemical modification of the coal structure with oxidants can precede both chemical and physical activation. Atmospheric oxygen and perchloric and nitric acids are often used as oxidants; HNO_3 can be used as vapor, aqueous solution, and mixtures with $HClO_4$ or Ac_2O [7].

We studied modification of OS coal, whose chemical activation was the most efficient (Fig. 1). The activation was performed using the HNO_3–Ac_2O modifying system, which, according to [8], rapidly reacts with coals of various nature and DM at room temperature, and modification proceeds not only in the surface layer, but also in the coal matrix bulk.

In contact with HNO_3–Ac_2O mixture (50 mol kg^{-1} coal), the structure of the OS coal is completely reorganized within 6 h at 18 ± 2°C; as a result, the coal is converted into structurally modified coal (SMC) [4, 6]. This new material is characterized by higher content of oxygen (by a factor of 3.7) and nitrogen (by a factor of 3.6) and lower content of carbon (see table). In contrast to the initial coal, the main structural elements of SMC are polynuclear nitroarenes. The IR spectra of SMCs show the C=C skeleton vibrations at 1600 cm^{-1} and the stretching (1540 and 1350 cm^{-1}) and bending (750 cm^{-1}) vibrations of the aromatic nitro groups. The side substituents of nitroarenes are methyl (2955 and 2870 cm^{-1}) and methylene (2925, 2865, 1440 cm^{-1}) groups and oxygen-containing functional groups: carboxy (1720 cm^{-1}), phenolic (1280 cm^{-1}), ether (1270, 1230 cm^{-1}), and quinoid (1564 cm^{-1}).

Composition of the initial and modified OS coal

Composition	Content in coal, %	
	initial	SMC
Ash	1.1	0.8
C	90.0	66.4
H	4.4	4.1
S	0.9	0.9
N	1.6	5.8
O	3.1	22.8

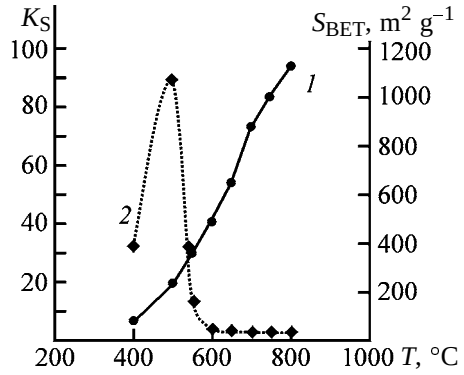

Fig. 3. (*1*) Specific surface area S_{BET} and (*2*) efficiency coefficient K_S as functions of temperature T at activation of SMC (R_{KOH} = 1.5 g g^{-1}, τ = 2 h).

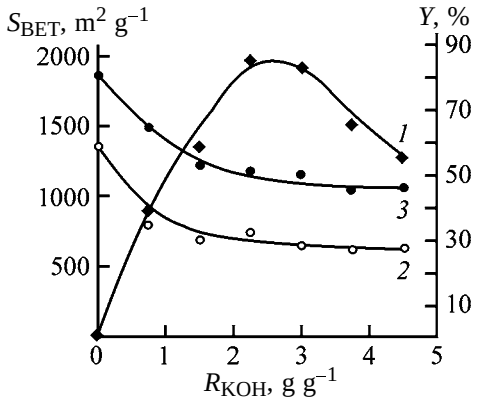

Fig. 4. (*1*) Specific surface area S_{BET} and (*2, 3*) yield Y as functions of the alkali/coal weight ratio R_{KOH} Coal: (*1, 2*) SMC and (*3*) initial OS coal.

Similarly to arenes in the initial coal, nitroarenes in SMCs are aggregated in "crystallites," but the parameters of the supramolecular structure are different. Owing to modification, the interlayer spacing d_{002} increases from 0.378 to 0.381 nm, whereas the height L_c and average diameter L_a of crystallites decrease from 1.05 to 0.9 and from 1.38 to 1.33 nm, respectively. As compared to the initial coal, SMC is more reactive to alkali even at stage of mixing (20 ± 2°C), due to reaction of KOH with OH-acidic functional groups. In the course of thermolysis, SMC is converted into AC with the best characteristics.

The temperature dependence of S_{BET} for SMC is shown in Fig. 3 (curve *1*). In contrast to the initial carbon (Fig. 2, curve *1*), the development of SMC surface begins at 400°C, and the specific surface area almost linearly increases to 1200 m^2 g^{-1} in the temperature range studied (400–800°C). The effect of structural modification can be illustrated by the efficiency coefficient K_S, which is the ratio of the specific surface area of ACs prepared from SMC and from the initial coal at similar T, τ, and R_{KOH}. The highest modification effect is observed at 400–600°C; in the 600–800°C range K_S varies within 2.5–3.8.

With increasing KOH/SMC ratio, the specific surface area passes through a maximum (Fig. 4, curve *1*). The maximal values are obtained at R_{KOH} = 2.5–3.0 g g^{-1} and reach 2000 m^2 g^{-1}. The yields of ACs from SMC and initial carbon decrease with increasing R_{KOH} (Fig. 4, curves *2, 3*). The shapes of the curves are similar, but the yields of ACs from SMCs are lower by a factor of 1.5–2.0. Thus, in the presence of KOH the specific surface area of the modified carbon develops more intensively as compared to the initial carbon. This effect is probably due to the presence of a significant amount of functional groups appearing in the carbon structure in the course of modification. At mixing, functional groups react with KOH with formation of potassium phenolates and carboxylates and cleavage of the ester groups. These reactions promote penetration of K^+ and OH^- ions and KOH molecules and their fixation in the carbon skeleton as separate ions, molecules, and molecular aggregates (clusters).

Occupation of the intermolecular space with ionic and molecular aggregates of alkali sterically hinders formation of the C–C bonds in the AC skeleton, which is formed at 400–800°C under the thermolysis conditions. Probably, the volume of the alkali cluster is the volume of the future pore, whose size and hence the internal surface area are determined by the cluster size.

At low content of functional groups in carbon, the content of incorporated alkali and the number of clusters is small, which causes small pore volume and low specific surface area of SCs. This explains low S_{BET} for the initial OS coal (Fig. 2); the content of oxygen in it is 3.1 wt %, compared to 22.8 wt % in the modified coal (see table). With increasing steric hindrance to penetration of alkali into the carbon matrix on passing from OS coal to anthracites, the efficiency of chemical modification decreases (Fig. 1, curve *2*) and treatment with KOH does not noticeably affect the development of the specific surface area of anthracites. However, the efficiency of chemical modification for anthracites is rather high and allows preparation of ACs with a specific surface area of up to 450 m^2 g^{-1} [9].

CONCLUSIONS

(1) Thermolysis of natural coals in the presence of KOH increases the specific surface area of activated

carbons. The effect decreases with increasing degree of metamorphization of the coal and increases with temperature in the 400–800°C range; it is determined by the alkali/coal weight ratio.

(2) Low-temperature oxidative modification significantly (by a factor of 2.5–3.8) promotes the development of the specific surface area at activation in the presence of KOH. Heating of modified carbon in the presence of KOH (2–3 g of KOH per gram of coal) at 700–800°C yields a carbon material with a highly developed surface area (1800–2000 $m^2 g^{-1}$) in a yield of 28–30%.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Zinc Complex Ions from Chloride Solutions with Ion Exchangers

V. I. Skorokhodov, B. K. Radionov, and O. Yu. Goryaeva

Ural State Technical University, Yekaterinburg, Russia

Received March 17, 2004

Abstract—To characterize the reaction of zinc ions with anion exchangers of various types, the equilibrium compositions of all the components of the sorption system (zinc salt, hydrochloric acid, and water) and distribution of associated molecules in the resin phase were considered.

Anion exchangers are widely used in chemical analysis and in hydrometallurgy for concentration of zinc ions and their separation from concomitant elements in chloride solutions [1–3]. In analytical chemistry, a series of ion-exchange resins are recommended for separation of non-ferrous metals in the hydrochloric acid media [1, 2, 4, 5]. In hydrometallurgy, anion exchangers of various basicities (VP-1aP, AMP, VP-1P, AP, EDE-10P) and ampholytes Dowex-1, ANKB-35, etc. [1, 6, 7] are used for purification of nickel and cobalt-containing solutions. In spite of extensive data on sorbents for zinc(II) recovery, there is no common opinion on interaction between zinc chloride complexes and resin functional groups. The prevailing opinion is that zinc(II) exists in the solution and is sorbed by anion exchangers mainly in the form of negatively charged complexes $[ZnCl_3]^-$ and $[ZnCl_4]^{2-}$ [1–7]. Theoretically, sorption of neutral species $[ZnCl_2]^0$ by the nonexchange mechanism is not ruled out also [8]. The preferred adsorption of Zn(II) neutral complexes with anion exchangers because of weak hydration is suggested in [9]. Tremillon [10] explains sorption of Zn(II) from chloride solutions by participation of counterions of the fixed anion-exchange groups (in this case, chloride ions) in completion of the coordination sphere of the unsaturated zinc(II) acido complexes. Balakin *et al*. [11] studied the effect of the basicity and degree of hydration of amino groups on the zinc ion sorption and concluded that the selectivity with respect to zinc chloride complexes is caused by the "electroselectivity" phenomenon. All the above shows that, by now, the sorbed zinc species have not been identified reliably, and no criteria allowing selection of the most efficient sorbent for zinc(II) recovery from various process solutions have been formulated. In this work, the equilibria in the ion exchanger–HCl–KCl–$ZnCl_2$–H_2O system were studied to characterize the interaction of Zn(II) acido complexes with the ion exchanger ionogenic groups and the influence of amino group structure and other factors on this interaction, with the aim of predicting sorption properties of ion exchangers.

EXPERIMENTAL

The following ion exchangers of various types were used in the study: AV-17, VP-1P, VP-1aP, SN-3, SB-1, AN-18, AN-31, and ANKB-35.

ANKB-35,

where Res_1 is copolymer of vinylpyridine and divinylbenzene (DVB); Res_2, copolymer of styrene and DVB.

Pretreatment of ion exchangers and determination of their anion-exchange capacity were performed as in [12, 13]. All the ion exchangers were transferred into the Cl^- form. The main properties of the ion exchangers used are listed in Table 1.

The acid–base properties of ion exchangers were determined potentiometrically [12] in 0.5 M KCl as supporting electrolyte. The pK was calculated by the Henderson–Hasselbach equation as pH of 50% neutralization (protonation) of amino groups. The ion-exchange equilibrium in the anion exchanger–electrolyte system was studied at the liquid-to-solid ratio of 50 : 1. The solutions were prepared using ultrapure grade HCl and analytically pure grade zinc chloride and KCl. The duration of ion exchanger contact with solution was 7 days, which is sufficient to attain the ion-exchange equilibrium. The capacity of ion exchangers for zinc was determined from the difference between the metal concentrations in the solution before and after sorption and from the results of regeneration of the anion exchanger with distilled water (l : s = 200 : 1). The amount of hydrochloric acid sorbed was monitored from its content in the eluate. The concentrations of the components were determined: HCl potentiometrically, Zn^{2+} complexometrically, and Cl^- conductometrically. The moisture content in ion exchangers was determined from thermograms [12] measured on a Q-1500 D derivatograph.

Ion exchangers differing in the acid–base properties of amino groups, matrix structure, functional composition, and synthesis method were taken (Table 1).

Ion exchangers SB-1 and AN-31 are epoxy–amine resins of polycondensation type; the other resins are of polymerization type and are based on copolymer of styrene with DVB (AV-17, AN-18, ANKB-35) or of vinylpyridine with DVB (VP-1aP, AN-31, SN-3).

Ion exchangers SB-1, AN-31, and AV-17 have the gel structure of the matrix, all the others have the porous structure.

Ion exchangers AV-17, AN-18, AN-31, SB-1, and ANKB-35 contain aliphatic amino groups of various compositions; anion exchangers VP-1aP, VP-1P, and SN-3 contain pyridine fragments.

Ion exchangers AV-17, AN-18, and VP-1P are virtually monofunctional, while all the other resins contain combinations of amino groups of various types (SN-3). Furthermore, anion exchangers SN-3, SB-1, and AN-31 additionally contain hydroxy groups and ampholyte ANKB-35, carboxy groups.

It is known [1, 8, 10] that the maximal capacity of highly basic anion exchangers with respect to zinc is attained at 2–3 M Cl^- in the solution. This is also true for sorbents considered in our study (Fig. 1). In spite

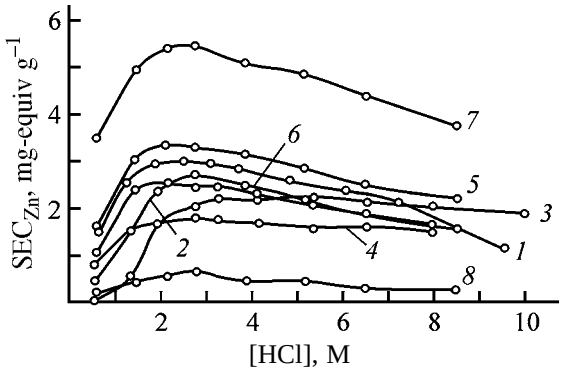

Fig. 1. Static exchange capacity of ion exchangers SEC_{Zn} as a function of hydrochloric acid concentration [HCl] in the equilibrium solution. (*1*) AV-17, (*2*) SN-3, (*3*) AN-31, (*4*) SB-3, (*5*) VP-1P, (*6*) AN-18, (*7*) VP-1aP, and (*8*) ANKB-35.

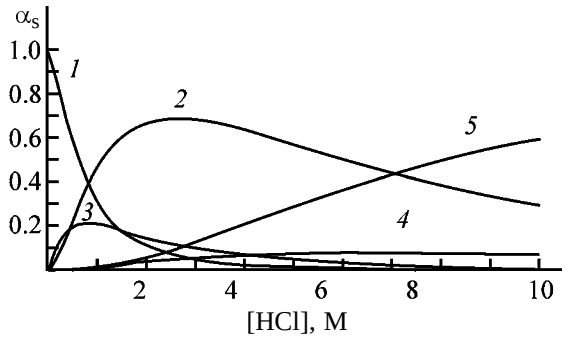

Fig. 2. Influence of the chloride ion concentration on zinc(II) speciation. (α_s) Fraction of the given zinc(II) species in the solution and ([HCl]) concentration of hydrochloric acid. (*1*) Zn^{2+}, (*2*) $[ZnCl_2]^0$, (*3*) $[ZnCl]^+$, (*4*) $[ZnCl_3]^-$, and (*5*) $[ZnCl_4]^{2-}$.

of the difference in the absolute values of the static exchange capacity for Zn(II) (SEC_{Zn}) apparently connected with physicochemical properties of the polymers, similar shape of the dependences for so different resins (Fig. 1) suggests similar mechanism of adsorption of zinc acido complexes.

The reaction of functional groups with zinc ions can be analyzed in detail from data on zinc(II) speciation in chloride solutions. Figure 2 shows that, at $[Cl^-]$ = 2–3 M, only 20% of zinc(II) exists as cationic species (Zn^{2+}, $ZnCl^+$) unsorbable by anion exchangers; 70% as the neutral complex $[ZnCl_2]^0$; and only 10%, as negatively charged ions $ZnCl_3^-$ and $ZnCl_4^{2-}$. Such a distribution and the above-indicated similar trends in the Zn(II) sorption (Fig. 1) suggest that the sorption equilibrium is determined by the concentration of the prevailing neutral complex $[ZnCl_2]^0$. The statistical treatment of zinc sorption with AV-17 anion exchanger (Table 2) confirms this suggestion, since SEC_{Zn} maximally correlates with the $ZnCl_2$ content in the solution (R^2 = 0.99), and the $ZnCl_2$ distribution coefficient between the solution and ion exchanger is virtually independent of the Cl^- concentration.

Similar pattern is shown by the other ion exchangers studied, except polyfunctional ion exchangers for which $K_d(ZnCl_2)^0$ tends to increase with the HCl concentration (Table 3). More pronounced influence of the acidity on the sorption of Zn(II) ions is demonstrated by Fig. 3, which shows the results obtained at different concentrations of HCl but constant concentration of Cl^- supported by KCl ([HCl] + [KCl] = const).

With increasing HCl concentration, the sorption capacity for Zn(II) is practically constant for AV-17 monofunctional anion exchanger and increases by 15–25% for SN-3 and SB-1, by 40% for AN-31, and by 60% for ANKB-35 within the 0–2.5 M HCl concentration range.

The increase in the sorption capacity, characteristic for anion exchangers with additional donor centers, is caused by the induction effect discussed in [14–16]. It was shown in these works that, in aminocarboxylic ampholytes, the basicity of amino groups substantially depends on the solution acidity due to positive charge on carboxy groups, which is transferred along the conjugated polymer chain to amino groups. Thus, when the concentration of the chloride ions is sufficient to form the neutral complex $[ZnCl_2]^0$ (total concentration of HCl + KCl 2.5 M) and this species predominates, the exchange capacity is maximal and constant for AV-17 monofunctional ion exchanger and somewhat increases with increasing HCl content for polyfunctional ion exchangers with additional active centers affecting the basicity of the sorbent amino groups.

It is interesting that the exchange capacity for Zn(II) of AV-17 and VP-1aP ion exchangers is by a factor of 1.5–3 higher than the exchange capacity of the functional groups themselves {similar effect was observed previously with highly basic anion exchanger Dowex 2×10 in sorption of mercury(II) chloride complexes [10]}. This excess is observed within virtually the whole interval of HCl concentrations studied (0.7–9 M). This phenomenon is in conflict with the exchange equivalence if we assume that zinc ions are sorbed as negatively charged ions, especially as $[ZnCl_4]^{2-}$, taking into account their small fraction among the other Zn(II) species in the chloride solution. This "anomaly" in the Zn(II) behavior can be explained assuming that the neutral zinc complexes

are sorbed. It is believed in [9] that one of the causes of the sorption selectivity is solvation of both ionogenic group and sorbable species in the solution and in the ion exchanger phase, i.e., the selectivity is considered as competition between solvation of fixed active groups of the ion exchanger and solvation of the sorbable species in the solution and in the ion exchanger phase. If zinc(II) is sorbed from chloride solutions with anion exchangers in the form of neutral complexes, we can suggest that this process should be accompanied by the loss of neutral molecules forming the solvation shell around the ionogenic groups. The experimental data on distribution of the components of the system between the electrolyte and resin phase, listed in Table 4, confirm the above mechanism of the sorption.

In particular, in accordance with run nos. 2–7 (Table 4), increase in HCl (or KCl) concentration in the electrolyte naturally increases the degree of their penetration into the ion exchanger due to Donnan effect [8, 9]. At the same time, this phenomenon is accompanied by substantial loss of hydration water from the sorbent. Even small amounts of Zn ions in the system (run nos. 10, 14) promote not only sorbent dehydration but also displacement of HCl and (or) KCl molecules. The higher the sorption of zinc complexes, the smaller amount of the competing molecules of the electrolyte components remains in the ion exchanger phase (run nos. 8, 10).

Table 1 reveals a correlation between the degree of sorption of zinc acido complexes and basicity of amino groups. This correlation becomes more obvious when the experimental data are graphically presented in the pK_d–$\log K_d^n$ coordinates, where K_d^n is the average distribution coefficient related to the concentration of ion exchanger amino groups.

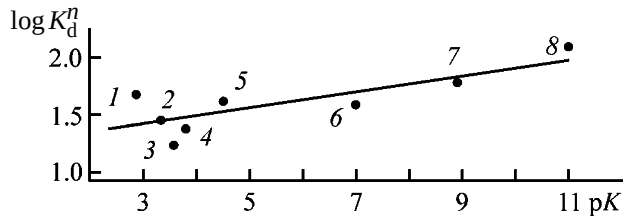

Fig. 4. $[ZnCl_2]^0$ distribution coefficient as a function of the basicity of amino groups: (*1*) ANKB-35, (*2*) SN-3, (*3*) SB-1, (*4*) AN-31, (*5*) VP-1P, (*6*) AN-18 × 10P, (*7*) VP-1aP, and (*8*) AV-17.

The linearity of this dependence (Fig. 4) shows that the basicity of amino groups, along with their content, is the governing factor in sorption of zinc acido complexes, except $K_d(ZnCl_2)^0$ for amino carboxylic ampholyte ANKB-35, which, as mentioned above, substantially depends on HCl concentration in the equilibrium solution. The results obtained suggest the following interpretation of the sorption process. Amino groups in the chloride solutions are surrounded by the solvation shell consisting of water and HCl molecules. Interaction of the neutral complexes $[ZnCl_2]^0$ with the resin functional groups results in substitution of HCl and H_2O molecules from the solvation shells of these groups. Thus, sorption of Zn(II) with anion exchangers from chloride solutions is due to competition of neutral molecules (HCl, H_2O, $ZnCl_2$) for solvation of the resin functional groups, rather than to ion exchange proper.

CONCLUSIONS

(1) The study of the equilibrium in the Zn^{2+}–HCl–KCl–H_2O system showed that sorption of zinc acido complexes with an ion exchanger proceeds not by the anion-exchange mechanism but by the solvation

mechanism, i.e., $[ZnCl_2]^0$ molecules exchange with neutral molecules forming the solvation shell of the resin amino groups.

(2) The main factors affecting Zn(II) sorption from solutions are the amount and basicity of anion exchanger amino groups; these factors should govern the choice of ion exchangers for practical tasks.

(3) The procedure of the synthesis, type of the matrix, porosity, and degree of monofunctionality (structure of ionogenic groups) of ion exchangers, the mutual position of nitrogen atoms in the chain of ionogenic groups, and other factors affect the zinc(II) sorption equilibrium insignificantly.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Capture of Chlorine with Carbon Adsorbents from Waste Gases Yielded by Electrolysis of Chloride Solutions

Abstract—The performance of various carbon materials in sorption capture of chlorine from waste gases yielded by electrolysis of nickel–manganese solutions was studied. A simple method was proposed for regeneration of carbons after sorption of chlorine, which makes them suitable for repeated use in sorption installations for chlorine capture.

Sorption methods are widely used for capture of toxic impurities such as ammonia, CO_2, SO_2, NO_x, H_2S, CS_2, methanol, chlorobenzene, ethyl acetate, *o*-xylene, diethylamine, acetic acid, and methane from waste gases yielded by various production processes. We found [1–7] that the capacity and selectivity of carbon sorbents can be significantly improved by modification with metal ions, their salts, and nitrogen, sulfur, and phosphorus heteroatoms; also, we elucidated the role played by surface complexing and by other factors affecting sorption of the above-mentioned substances.

In this work we tested the suitability of sorption for removal of one of the most toxic gases, chlorine, yielded by electrolysis of nickel–manganese solutions.

Activated carbons are known as fairly efficient sorbents of gaseous Cl_2; they were used in development of war gas masks since World War I [8–11]. More recent works [12–14] concerned interaction of carbon materials (CMs) with Cl_2 under various conditions. For example, activated carbons were suggested as sorbents for removal of dissolved molecular chlorine and its oxygen-containing compounds (so-called "active chlorine") from water after its disinfection, as well as from process solutions such as, e.g., anolyte after electrolysis of sodium chloride [15–17].

All these facts suggested that Cl_2 would be efficiently sorbed by CMs from waste gases yielded by electrolysis of nickel–manganese solutions. To quantitatively estimate the sorption efficiency, we studied here the sorption power of a number of CMs with respect to gaseous and dissolved chlorine generated on a laboratory electrolysis installation[1] and formulated recommendations on chlorine capture from waste gases.

To estimate the efficiency of binding Cl_2 by various CMs, we carried out experiments on a model sorption installation. The carbon under study was charged either into a vessel (column) with the desired volume (for room-temperature experiments) or into a quartz tube (for experiments at 200–650°C). In the latter case, the tube was placed into an oven with controlled temperature. The amount of carbon varied with the specific CM, depending on the volume of the column used (typically 30×3 cm) and the bulk weight of the carbon. The weighed portion was 40–60 g on the average. Gaseous Cl_2 was produced by reacting concentrated HCl with crystalline $KMnO_4$. In all the experiments, 100 ml of HCl was gradually added to 100 g of $KMnO_4$. The rate of supply of the Cl_2 being released (initial concentration 22 mg l^{-1}) was governed by the rate of its formation in the above-mentioned reaction. The chlorine that broke through was absorbed by an alkali solution.

We tested as sorbents commercial carbons BAU, AR-B, SKT, activated anthracite (AA), and carbon fabric (AUT). Selected structural characteristics of these carbons are listed in Table 1.

The amount of bound chlorine was estimated both from the sorbent mass increment and by chemical analysis (iodometric titration) of the solutions absorbing the chlorine that broke through or was desorbed [18].

The sorbed Cl_2 was washed out from the carbons with water both under static (by shaking a known amount of the sorbent with the required amount of water) and dynamic conditions. The amount of the desorbed chlorine and its concentration in other solu-

[1] This work was carried out jointly with the Institute of Superhard Materials, National Academy of Sciences of Ukraine.

1070-4272/04/7709-1450 © 2004 MAIK "Nauka/Interperiodica"

tions were determined similarly [18]. It should be noted that iodometric determination of active chlorine in the electrolyte is hindered by high concentrations of nickel and manganese salts.

We found that various CM samples take up significant amounts of Cl_2, namely, 300–600 mg g^{-1} and over (Table 2). The highest capacities for chlorine were exhibited by activated anthracite and SKT commercial carbon. These materials are also characterized by acceptable mechanical strength and are relatively inexpensive and readily available. AR-B carbon and carbon fabric (AUT) have considerably lower capacities; the BAU granules markedly break down after several runs. The capacity of the carbons for chlorine was increased by moistening, as well as by preheating at 200°C.

Table 2 shows that the amount of the Cl_2 sorbed tends to increase with temperature. This suggests a complex chemical interaction between this gas and carbon [19], which can involve adsorption and a substitution, addition, or another reaction. The nature of interaction can vary depending on the composition of the carbon material, the presence of reactive impurities promoting such interaction, chemical nature of the surface, pore structure characteristics (the presence of pores with a definite size), and other factors.

Probably, in the case of anthracite and SKT carbon these factors were favorably combined, making these materials the most efficient agents for capture of Cl_2 from waste gases yielded by electrolysis. For example, Table 1 shows that carbons with high capacities for chlorine contain significant amounts of micropores V_{micro} (cf. BAU, AR-B, and SKT).

To prevent release of toxic Cl_2 into the environment, it is essential to estimate not only the total capacity for chlorine but also the capacity of sorbents until breakthrough (or the related parameter, protective action time [5, 6, 9]). These parameters are typically different: The breakthrough occurs before the sorption power of an adsorbent is exhausted. Our experiments showed that this is the case for sorption of Cl_2 by the carbons. However, with activated anthracite and SKT the protective action time remains fairly long. Also, we observed the so-called "rest" of sorbent, i.e., resumption of sorption, evidently, after diffusion of the sorbed Cl_2 inside the sorbent grains. When the process is terminated, Cl_2 fills the internal space of the pores, the surface gets free, and the process continues. Similar effect was observed by Zelinskii and Sadikov [8].

Based on the sorption capacities and specific features of sorption of Cl_2 on CMs, revealed in model laboratory experiments, we calculated the characteristics of a sorption installation for sorption of Cl_2 from waste gases yielded by electrolysis of Ni–Mn solutions. This installation incorporates two vertical fixed-bed carbon adsorbers. One adsorber is placed directly at the bath outlet and operates until saturation with chlorine, and another adsorber serves for exhaustive capture of Cl_2 in cases of a possible breakthrough in the first adsorber and of possible fluctuations of the amount of chlorine released.

To estimate the amount of the sorbent required for Cl_2 capture, we determined the content of Cl_2 in waste gases from electrolysis on a laboratory electrochemical installation with the electrolyte volume of 500 l. We found that electrolysis of Ni–Mn-containing solutions in this installation at room temperature yields 35.5 mg l^{-1} of active chlorine, or 213 mg l^{-1} at elevated temperatures (60–70°C).

Table 1. Selected structural characteristics of carbon sorbents*

Carbon	W_s for C_6H_6, cm^3 g^{-1}	Pore volume, m^3 g^{-1}		S_{sp}, m^2 g^{-1}
		V_{meso}	V_{micro}	
BAU	0.35	0.25	0.10	750
AR-B	0.45	0.30	0.15	418
SKT	0.40	0.36	0.28	650
AUT	0.63	0.53	0.10	1200
AA	0.28	0.05	0.23	742

* W^s is the total volume of sorption pores for benzene [9], V_{meso}, volume of mesopores; V_{micro}, volume of micropores; and S_{sp}, specific surface area of the sorbent.

Table 2. Chlorine sorption by various carbon materials

Sample no.	Sorbent	Moisture content	T, °C	Capacity for chlorine, mg g^{-1}
1	AA	Air-dry	25	305
2	″	Dried at 200°C	25	358
3	″	Moistened	25	452
4	″	Air-dry	200	521
5	″	″	450	525
6	″	″	650	540
7	BAU	″	25	270
8	″	Dried at 200°C	>25	370
9	AUT	Air-dry	25	102
10	AR-B	″	25	260
11	SKT	″	25	610

Based on the capacity for chlorine, capacity until breakthrough, the amount of the Cl_2 released from the anode space of the electrolysis installation, and bulk density of the carbon, the amount of SKT or activated anthracite required for exhaustive capture of the Cl_2 released from a 500-l electrolysis bath within a month was estimated at 15–20 kg (50–60 l).

The sorption filter should be shaped as a cylindrical column manufactured from a chlorine-resistant material (polyvinyl chloride, fluoroplastic) with recommended diameter of 25 cm and height of 130–150 cm.

The nature and strength of chlorine binding under various sorption conditions differ substantially (Table 2). This is of deciding importance for the fate of the waste sorbent which can be suitable either for repeated use without discharging in the same process of Cl_2 sorption after regeneration or for use in other processes (after discharging) as a sorbent with different properties. The properties of the spent sorbent can actually be different, since the contact of Cl_2 with carbon under certain conditions can involve chemical interaction modifying the chemical nature of the carbon surface. We showed [19] that chlorinated carbons acquire new, e.g., bactericidal, properties. For example, we prepared a number of samples containing strongly bound chlorine, exerting a persistent disinfecting effect, which do not release chlorine into the environment or release it into water in amounts close to those specified by GOST (State Standard) 2874–82 "Potable Water" (0.3–0.5 mg l^{-1}).

In this work we focused on regeneration of carbon to make it suitable for repeated runs in adsorbers. Carbons are typically regenerated by thermal, eluent (desorption), and destructive methods [20, 21].

Clearly, the deciding factor in choosing the method is the nature and strength of Cl_2 binding. Therefore, we determined the sorption capacity of the carbons with respect to Cl_2 at different temperatures and also tested the possibility of washing out chlorine sorbed under different conditions. Table 2 shows that the carbons exhibit high sorption capacities for Cl_2 both at room temperature and upon heating to 200–650°C.

Below we characterize desorption of chlorine, sorbed under various conditions, with water.

It is seen that Cl_2 sorbed by the carbons at room temperature is easily and rapidly, virtually exhaustively, washed out with water in a single washing run (sample nos. 2–5, 10), and there is almost no desorption of Cl_2 sorbed at high temperatures (sample no. 6). This is, most probably, due to different characters of Cl_2 sorption. For example, despite fairly low capacity for chlorine at room temperature, AUT carbon exhibits no desorption of chlorine, probably because of its too strong binding by the fibrous sorbent. Desorption is enhanced by repeated water treatment of the carbon being regenerated.

Desorption of active chlorine from various carbons by single washing with distilled water. Weighed portion of carbon 1 g; water volume 100 ml; contact time 1.5 h; initial concentration c_0 of active chlorine (per gram of sorbent) ca. 6.0 mg l^{-1}

Table 2

Sample no.	2	3	4	5	6	9	10
c_d,* mg l^{-1}	5.39	5.04	5.39	3.69	0.14	0.00	4.54

* Active chlorine concentration in the desorbate.

Triple washing out of active chlorine from anthracite with distilled water. Weighed portion of carbon 15 g; water volume 200 ml; contact time 15 min; initial concentration c_0 of active chlorine (per gram of sorbent) ca. 5.4 mg l^{-1}

Washing	First	Second	Third
c_d, mg l^{-1}	4.20	0.40	0.05

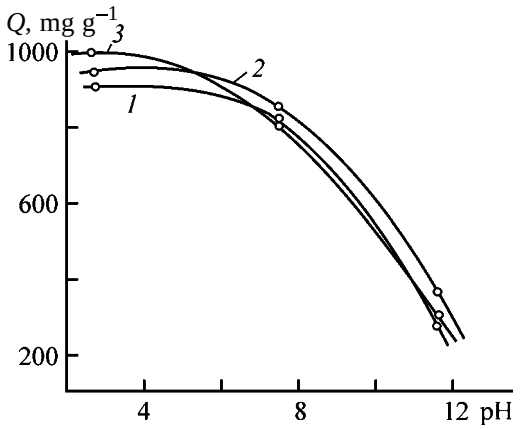
After the first washing of activated anthracite, the chlorine concentration decreases from 5.4 to 4.2 mg l^{-1} (by 22%); after the second, by 92%; and the third washing affords 99% regeneration of AA.

Our data suggest that conventional thermal methods of carbon regeneration are unsuitable in our case. Evidently, regeneration is favored by weak binding of chlorine with carbon or reduction of chlorine into chloride ions directly in carbon pores [15–17].

We showed that, although the capacity for chlorine increases at high temperatures, regeneration of such spent sorbents is hindered. Therefore, it is reasonable to capture chlorine from waste gases without specially rising the temperature and to regenerate carbons by water treatment.

Our previous studies [17] on removal of active chlorine with activated carbons from spent anolyte (saturated NaCl solution) yielded by chlorine production revealed conditions suitable for regeneration of carbon sorbents saturated with chlorine. Indeed, we found (see figure) that chlorine is most efficiently removed by washing spent carbons with acidic solutions (pH 2–4).

We found that, upon contact with carbons, chlorine is removed from anolyte mostly via reduction of



Amount Q of active chlorine removed from the anolyte with (*1*) AR-B, (*2*) AA, and (*3*) SKT carbons as influenced by pH of the medium.

HClO and molecular chlorine to chloride ions; carbon is oxidized to oxide compounds both on the surface and in the bulk.

The procedure for dechlorination in acidic medium, developed by us, was tested under process conditions at active chlorine concentrations of 100–300 ml l^{-1}. The experiments were run under dynamic conditions on two columns containing 20 kg of SKT each, at 80°C and the anolyte flow velocity of ca. 22 m h^{-1}. Both columns operated for over 75 days in total, and throughout this period there was no breakthrough of active chlorine.

Our results show that washing out of the sorbed chlorine from spent carbons with acidified water will involve not only desorption but also reduction of chlorine to chloride ions. Conversion of the sorbed chlorine into chloride ions, followed by washing of carbon, can be used for utilization of chlorine and regeneration of the sorbent.

The content of chlorine in wash waters can be reduced to MPC either by dilution or by dechlorination with carbon materials, involving reduction of active chlorine to chloride ions. The latter process can occur under certain conditions in carbon pores as well.

CONCLUSIONS

(1) Sorption capture of Cl_2 with various carbon sorbents was studied, and the capacities of the sorbents for chlorine were estimated at different temperatures and other experimental conditions; the best sorbents were selected.

(2) Specific features of Cl_2 sorption on carbon materials were revealed, namely, the sorbent "rest" phenomenon, i.e., resumption of sorption after diffusion of the sorbed Cl_2 inside the sorbent grains, and the required predominance of micropores.

(3) The amount of the sorbent required for exhaustive capture of chlorine within 1 month for a 500-l electrolysis bath was tentatively estimated from the capacity of the sorbent for chlorine, the capacity until breakthrough, the amount of the chlorine released in electrolysis of Cl_2, and the bulk density of the carbon. The dimensions of the sorption filter proposed were estimated.

(4) Spent sorbents can be regenerated by desorption of active chlorine by a single or repeated treatment with water, as well as under conditions favoring dechlorination via reduction of active chlorine to chloride ions at pH of wash waters of 2–4.

Abstract—The influence exerted by a number of benzaldehyde derivatives on the rate of hydrogen evolution from a lead–acid battery was studied.

The market of sealed lead–acid batteries shows a steady rising tendency [1]. Use of batteries of this kind makes it possible to virtually rule out any gas evolution and to dramatically diminish the amount of maintenance work. The last factor is of primary importance, because, for some batteries, the maintenance cost during the service life is comparable with the initial price of the battery itself [2]. The possibility of sealing the lead–acid battery is based on the fact that virtually the whole amount of O_2 evolved at the positive electrode in charging is reduced at the negative electrode (closed oxygen cycle). Performing a similar hydrogen cycle is impossible without using additional catalytic systems because of the extremely low rate of H_2 oxidation at the positive electrode. According to [3], the rate of H_2 oxidation at the PbO_2 electrode is lower than that of O_2 reduction on Pb by a factor of 10^3. Thus, sealing the lead–acid battery requires that the rate of H_2 evolution should be minimized.

The scheme shows the sequence of operations carried out to diminish the rate of H_2 evolution in the sealed battery. It can be seen that the task of inhibiting H_2 formation in the battery is integrated and involves solutions related to the design and the composition of the components of the electrode block (1.1, 1.3, 2.1), to use of external, with respect to the block, devices (2.2, 2.3, 2.4), and to optimization of the charging mode (1.3).

Apparently, the most efficient are the operations intended to diminish the H_2 evolution rate, rather than those aimed to oxidize the gas that has already evolved within the battery, because the former operations control the causes, and the latter, the consequences of the negative phenomenon.

The rate of H_2 evolution can be markedly diminished by (i) excluding elements with low hydrogen overvoltage (Sb, Cu, Ag, As, Fe, Mn, Ni, Co) from the composition of the active paste and structural materials [4], (ii) using additives that make higher the overvoltage of H_2 evolution at the negative electrode, (iii) optimizing the relative amounts of the active pastes [5, 6], and (iv) optimizing the charging mode [7].

At present, neither catalytic electrodes made of platinum or carbon materials nor H_2 absorbents find use in the world practice. Their use, on the one hand, is inefficient and unreliable (catalyst poisoning, low absorption of H_2 because of its low partial pressure within the battery), and on the other, makes higher the cost of batteries.

Additives are widely used in lead batteries to improve their energy-storage and resource parameters. An important role of additives as expanders of negative active pastes, which slow down the rate of recrystallization of spongy lead and preserve its large specific surface area, is well known [8]. Additives are also used as inhibitors of self-discharge [9]. The mechanism of their action commonly consists in that the overvoltage of H_2 evolution on lead and phase impurities increases, which makes slower the rate of the conjugated reaction of Pb oxidation. Additives are also introduced into positive active pastes to improve their mechanical strength and preclude their sagging [10]. Additives of this kind can be introduced in the form of fibers, powders, or suspensions. A considerable progress has been made in all of these areas. However, the specific features of operation of a sealed battery, on the one hand, impose restrictions on additives used in ordinary batteries, and on the other, require that new types of additives should be developed.

The aim of this study was to examine additives that inhibit H_2 evolution in a lead–acid battery.

General scheme of operations aimed to diminish the rate of H_2 evolution in a sealed battery.

It is known that Pb belongs to metals with a high overvoltage of H_2 evolution. The constant *a* in the Tafel equation for lead is 1.52–1.56 V. However, phase impurities composed of metals with a low H_2 overvoltage can be formed in a working battery on the surface of the negative current lead. To elements of this kind primarily belong Sb and Cu, for which *a* is 0.9 and 0.8 V, respectively. Antimony finds its way to the negative electrode through corrosion of the current lead (made of lead–antimony alloys) of the positive electrode, and lead-plated copper current leads of the negative electrode serve as a source of Cu. During the service life of a battery, the protective properties of the lead coating are impaired and Cu appears on the surface of the negative active paste. Thus, an additive that would make higher the overvoltage of H_2 evolution on Sb and Cu but would not affect the course of the main current-producing processes at the negative and positive electrodes is necessary. With account of the fact that the mechanism by which the gas evolution is hindered is associated with adsorption of additives (surfactants) onto the metal surface, an efficient additive that would inhibit gas evolution must exhibit a high adsorption selectivity with respect to Cu and Sb, on the one hand, and Pb, on the other. As possible additives were studied benzaldehyde derivatives. In [11, 12], it was shown that aromatic aldehydes, which are characterized by clearly pronounced polarity with high dipole moment and, therefore, exhibit an increased adsorption capacity, exert an inhibiting influence on H_2 evolution. However, their adsorption capacity largely depends on a substituting group, which determines the electron distribution between the benzene ring and this group. The choice of an inhibitor is determined by the following: it should exhibit a selective adsorption on Sb and Cu impurities, without decelerating the current-producing reaction or O_2 reduction. The following benzaldehyde derivatives were examined in this study: 2-hydroxybenzaldehyde $C_7H_6O_2$ (2-HB) and 2-methoxybenzaldehyde $C_8H_8O_2$ (2-MB).

The study was carried out with Sb of SU1 brand, copper foil, and Pb of S1 brand in specially purified

5 M H_2SO_4. The performance of the additives was estimated by analyzing the polarization curves measured at current in the range 0.5–50 mA cm^{-2} at 25 ± 0.1°C.

Figure 1 shows the polarization curves obtained on Sb and Cu in an H_2SO_4 solution with addition of 0–1.30 g l^{-1} of 2-MB and 0–1.17 g l^{-1} of 2-HB. The table lists the efficiency factors K_{eff}, defined as the ratio of H_2 evolution rates at a potential of 0.6 V in solutions with and without an additive, for the additives studied.

Figure 1 shows that 2-MB and 2-HB are exceedingly efficient in hindering the H_2 evolution on both Sb and Cu. At their concentration in the electrolyte equal to 9.6×10^{-3} M, K_{eff} is 11.6–22.9 on Sb and 48–50 on Cu. It also follows from Fig. 1 that the inhibiting effect of 2-MB and 2-HB grows as their concentration in solution increases, to become the most pronounced at a concentration of 9.6×10^{-3} M. However, the results obtained give no reason, as yet, to recommend 2-MB and 2-HB as inhibitors of H_2 evolution for lead batteries. For this purpose, it is necessary to make sure that these additives do not affect simultaneously the current-producing reactions and the reactions of the closed oxygen cycle.

Figure 2 shows the polarization curves obtained on a porous lead cathode in a 5 M H_2SO_4 solution with addition of 0–0.9 g l^{-1} of 2-MB and 0–0.8 g l^{-1} of 2-HB. It can be seen that addition of 2-MB leads, in the entire range of concentrations, to an increase in the overvoltage of H_2 evolution. This indicates that the additive can be adsorbed on the Pb surface and can thereby affect the main current-producing processes. At the same time, addition of 2-HB affects the rate of H_2 evolution on Pb only slightly, suggesting its low adsorption capacity with respect to the Pb surface.

It is known that the zero-charge potentials for Pb, Cu, and Sb are –0.69, –0.04, and 0.0 V, respectively (relative to a standard hydrogen electrode). Thus, the surface of Pb is charged positively, and that of Cu and Sb, negatively, at potentials of the negative electrode. Therefore, the surface of Pb is covered in H_2SO_4 with an adsorption layer of HSO_4^- ions, and that of Sb and Cu, with H^+ ions [13]. It is also known that introduction of various substituent groups into the structure of benzaldehyde changes its electronic configuration and the dipole moment of the molecule [14].

The concept of moderate and strong inhibitors of H_2 evolution, which are derivatives of aromatic hydrocarbons [13], can be used to account for the experimental data obtained. It should be assumed that strong inhibitors hinder not only the H_2 evolution on Sb and Cu through their adsorption on the surface of these metals, but also the processes on the surface of Pb because of the ability of such inhibitors to displace HSO_4^- ions and be adsorbed on the surface. As a result, the current-producing reaction is hindered.

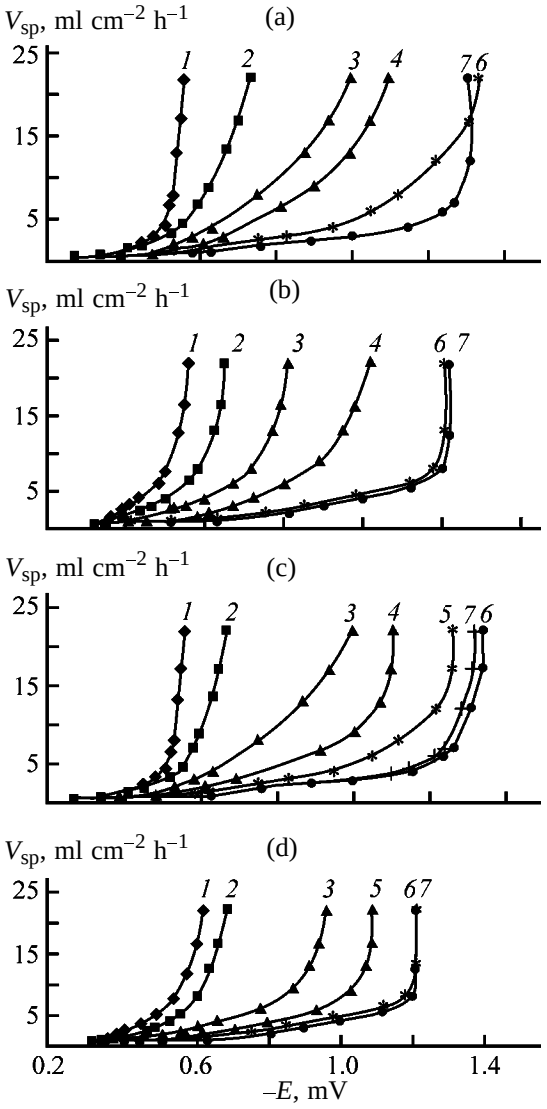

Fig. 1. Specific rate of hydrogen evolution, V_{sp}, on (a, b) antimony and (c, d) copper in a 5 M H_2SO_4 solution with addition of (a, c) 2-MB and (b, d) 2-HB vs. the polarization potential E. Concentration (g l^{-1}): 2-MB: (*1*) 0, (*2*) 0.05, (*3*) 0.17, (*4*) 0.34, (*5*) 0.65, (*6*) 0.83, and (*7*) 1.30; 2-HB: (*1*) 0, (*2*) 0.23, (*3*) 0.47, (*4*) 0.58, (*5*) 0.70, (*6*) 0.88, and (*7*) 1.17.

It was shown that the 2-MB additive has a high adsorbability not only on Sb and Cu, but also on Pb. The latter is strongly undesirable because of the de-

Efficiency factors of 2-MB and 2-HB additives

0.17 (1.2×10^{-3})	12.5	0.47 (3.8×10^{-3})	10.5
0.34 (2.5×10^{-3})	16.7	0.70 (4.7×10^{-3})	24.0
0.65 (4.8×10^{-3})	45.0	0.88 (7.2×10^{-3})	42.0
0.83 (6.1×10^{-3})	50.0	1.17 (9.6×10^{-3})	48.0
1.30 (9.6×10^{-3})	50.0	–	–

creasing rate of the main current-producing process at the negative electrode. Thus, the 2-MB inhibitor cannot be recommended for use in lead batteries despite its high performance. In the opinion of Böhnstedt and Radel [13], moderate inhibitors cannot displace HSO_4^- and be adsorbed on Pb, which predetermines the high degree of their selective adsorption. Inhibitors of this kind are mainly adsorbed on detrimental impurities (Sb, Cu) and suppress H_2 evolution on these elements. At the same time, they are not adsorbed on Pb and do not exert any negative influence on the processes that occur on this element. Consequently, the 2-HB inhibitor can be classed with moderate inhibitors and recommended for use in lead batteries.

However, prior to recommending 2-HB for use in lead batteries, it is necessary to find out whether or not it has an effect on the operation of the positive electrode and, primarily, on the rate of O_2 evolution, which characterizes the efficiency of utilization of the charging current, as well as on the kinetics of the current-producing reaction. An influence of this kind is, in principle, possible because of the contact between the inhibitor introduced into a solution with the positive active paste. For this purpose, polarization curves were measured on a PbO_2 electrode in the anodic potential range in a solution containing the 2-HB inhibitor (Fig. 3a). Figures 3a and 3b show that 2-HB has no effect on the rate of O_2 evolution at the PbO_2 electrode and on its discharge characteristics.

The performance of the 2-HB inhibitor was tested in stationary batteries with a rated capacity of 12000 A h. At the end of the service life of these batteries, the rate of H_2 evolution was 600 (battery no. 1) and 700 $cm^3\ min^{-1}$ (battery no. 2). A 2-HB

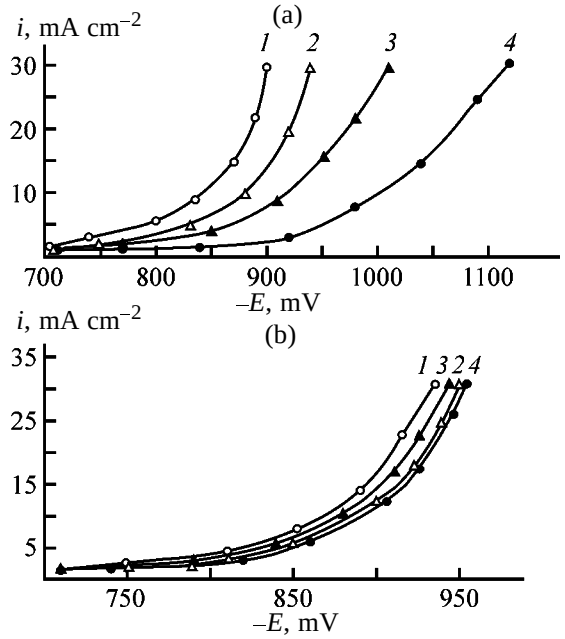

Fig. 2. Polarization curves obtained on a porous lead cathode in a 5 M H_2SO_4 solution with addition of (a) 2-MB and (b) 2-HB. (*i*) Current density and (*E*) potential. Concentration (g l^{-1}): 2-MB: (*1*) 0, (*2*) 0.01, (*3*) 0.09, and (*4*) 0.9; 2-HB: (*1*) 0, (*2*) 0.01, (*3*) 0.1, and (*4*) 0.8.

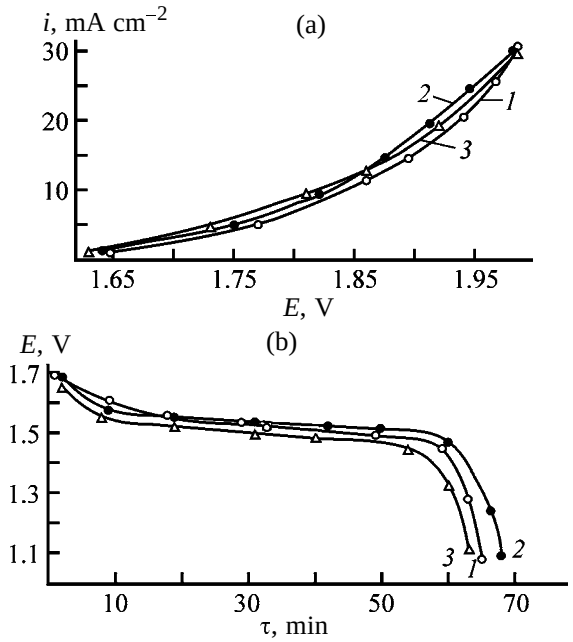

Fig. 3. (a) Polarization and (b) discharge curves obtained on a PbO_2 electrode in a 5 M H_2SO_4 solution (*1*) without additives and with addition of (*2*) 2-MB and (*3*) 2-HB. Concentration (g l^{-1}): 2-MB, 0.9; 2-HB, 0.8. (*i*) Current density, (*E*) potential, and (τ) time.

additive was introduced into battery no. 2, with the result that the rate of gas evolution decreased to 200 $cm^3 min^{-1}$ in the subsequent cycle. In battery no. 1, into which no additive was introduced, the gas evolution rate increased to 670 $cm^3 min^{-1}$.

CONCLUSIONS

(1) According to our results, 2-hydroxybenzaldehyde can be recommended as an additive effectively inhibiting the evolution of H_2 in sealed lead–acid batteries.

(2) This inhibitor can diminish the rate of H_2 evolution on Sb and Cu by factors of 10–12 and 15–29, respectively, with the discharge characteristics of the electrodes and the efficiency of the closed oxygen cycle remaining virtually unaffected.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic-Spark Layers on Aluminum and Titanium Alloys in Electrolytes with Sodium Phosphotungstate

I. V. Lukiyanchuk, V. S. Rudnev, V. G. Kuryavyi, and P. S. Gordienko

Institute of Chemistry, Far Eastern Division, Russian Academy of Sciences, Vladivostok, Russia

Received June 16, 2003; in final form, January 2004

Abstract—The influence exerted by the pH of an aqueous 0.0083 M solution of $Na_2H[PW_{12}O_{40}]$ on the composition and morphology of anodic coatings galvanostatically formed on aluminum and titanium alloys at sparking and breakdown voltages was studied.

Anodic treatment of rectifying metals in aqueous electrolytes in the sparking and microarc mode (henceforth, anodic-spark deposition) can give coatings that contain, in addition to oxides of a metal or alloy being treated, oxygen compounds of elements contained in the electrolyte. As a result, coatings that exhibit functions typical of anodic films and are promising for use in catalysis [1], as active elements of gas analyzers [2, 3], and bioinert compounds [4] can be obtained. As an example can serve the formation on titanium of layers that contain barium, strontium, or lead titanates and exhibit ferroelectric properties [5, 6].

One of the main processes that determine the composition of the forming anodic-spark layers is thermolysis of the electrolytic deposit around electric-breakdown channels. Use of electrolytes containing anionic complexes opens up additional opportunities for directed formation of oxide structures. Coatings of various compositions and purposes can be obtained in electrolytes of this kind. For example, wear-resistant coatings containing α-Al_2O_3 are obtained in solutions with hexafluoroaluminate complexes [7]; corrosion-resistant coatings with vanadium oxides, in electrolytes with phosphovanadate heteropolyanions [8, 9]; biocidal coatings with zinc phosphates, in solutions with zinc polyphosphate complexes [10]; bioinert coatings with hydrooxyapatite for implants, in electrolytes with calcium glycerophosphate complexes [4]; and light-reflecting coatings that contain ZrO_2 and are resistant to the action of hard ultraviolet, in solutions with alkali metal hexafluorozirconate complexes [11].

At the same time, the processes of coating formation in electrolytes with anionic complexes are now in the stage of research and accumulation of experimental data. Among such electrolytes, those containing iso- and heteropolyanions (IPA and HPA) are the least studied. The interest in these electrolytes is due to the following.

(a) The variety of IPA and HPA is rather wide. Only the position of the central atom in an HPA can be occupied by more than 60 elements [12]. Formation of coatings with diverse chemical compositions would be expected in electrolytes with HPA. These compositions must, apparently, reflect the scheme of thermal transformations of HPA or of products formed in their interaction with a metal being anodized.

(b) Conditions for formation of IPA and HPA are satisfied in many aqueous solutions that are used in anodic-spark oxidation and contain compounds of vanadium, molybdenum, and tungsten in higher oxidation states. Consequently, revealing the relationship between the presence or absence of HPA in electrolytes and the composition of the anodic-spark layers being formed is both practically and theoretically important.

(c) Thermal decomposition of heteropoly compounds is used to produce oxide catalysts [13]. It is quite possible that thermolysis of HPA or products of their interaction with a metal being anodized, which occurs near electric-breakdown channels, will make it possible to form on metals oxide structures promising as regards their possible catalytic activity.

(d) It has been shown previously that films formed in electrolytes with HPA show satisfactory protective properties [8, 14, 15].

Until now, fundamental aspects of how the elements contained in HPA are incorporated into coatings on rectifying metals have been studied in multicomponent electrolytes containing simultaneously

phosphate or borate anions and anions of transition metals [9, 16–18]. Publications that report use of commercial heteropoly compounds to form anodic-spark coatings are scarce [14, 15]. The functional properties and surface morphology of coatings formed in electrolytes of this kind remain virtually unstudied. Data on how coatings are formed in electrolytes with phosphate and tungstate ions and various concentrations of salts and pH values are contradictory [17].

It is known that the forms in which IPA and HPA are present in the electrolyte depend on its pH [12]. The aim of this study was to determine how the composition and morphology of anodic-spark layers on aluminum and titanium alloys depend on transformations of tungsten–phosphorus (phosphotungstate) HPA that occur when the pH value of the electrolyte is varied.

EXPERIMENTAL

The electrolytes were prepared from distilled water and commercial $Na_2H[PW_{12}O_{40}]\cdot 9H_2O$ and NaOH of chemically pure grade. All the electrolytes were produced by mixing the solutions at room temperature. The concentration of sodium hydrotungstophosphate in all the electrolytes was 0.0083 M, which corresponds to a total tungsten(VI) concentration in solution equal to 0.1 M. The electrochemical cell employed and the procedure for pretreatment of aluminum (AMtsM) and titanium (VT1-0) samples (40 × 10 × 1 mm) have been described previously [19, 20]. In each of the electrolytes, oxide layers were successively formed on the samples in the galvanostatic mode in the course of 10 min at current densities of 1 to 10 A dm^{-2} for the aluminum alloy and 10 A dm^{-2} for the titanium alloy (because it was impossible to reach the sparking mode for titanium in 10 min at lower i). The electrolyte temperature did not exceed 20°C in anodic-spark oxidation of aluminum and became as high as 30°C in anodic-spark treatment of titanium. After the treatment, samples with coatings were thoroughly washed first with tap water and then with distilled water and dried in air at room temperature.

The sparking voltage was estimated from the appearance of first visually observed sparks on the anode surface or by analyzing $U = f(t)$ curves (from the beginning of deviation of the dependence of the voltage U across the electrodes on time t from linear behavior). The phase composition of the coatings was studied by X-ray phase analysis (XPA) on a DRON-2.0 diffractometer (CuK_α radiation). The elemental composition of the coatings was determined with a JEDE JXA-5A X-ray fluorescence analyzer. ^{31}P NMR spectra of aqueous solutions were recorded on a Bruker WP-80SY high-resolution spectrometer at a frequency of 32.442 MHz. The chemical shifts are given in the δ scale (ppm) relative to 85% H_3PO_4. The surface morphology was studied with an LEO 430 scanning electron microscope (SEM).

The pH values and the electrical conductivities of tungstophosphate electrolytes before and after anodic-spark treatment, and also the phase compositions of the coatings formed, are listed in Table 1. It should be noted here that the pH strongly increases in the course of anodic-spark deposition from the initial values of 4.1 and 7.8 at an only slight change in the electrical conductivity of the solutions, and the electrical con-

Fig. 1. (a) pH: (*1*) 2.0, (*2*) 4.1, (*3*) 6.5, (*4*) 7.8, and (*5*) 12.6. (b) i (A dm^{-2}): (*1*) 2, (*2*) 3, (*3*) 8, and (*4*) 10.

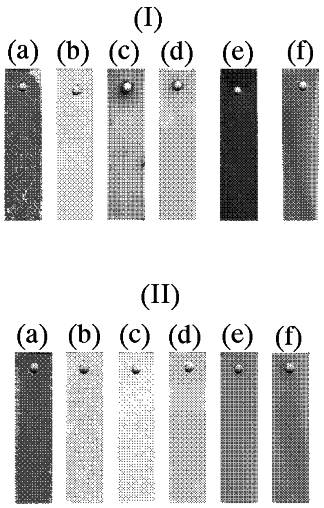

Fig. 2. Effect of pH of an electrolyte with 0.0083 M of $Na_2H[PW_{12}O_{40}]$ on the outward appearance of coatings on the aluminum and titanium alloys. Coating: (*I*) on the AMtsM alloy, i = 2 A dm^{-2}; (*II*) on the VT1-0 alloy, i = 10 A dm^{-2}. pH before/after coating formation: (a) 2.0/1.8, (b) 4.1/6.8, (c) 6.5/7.0. (d) 7.1/7.3, (e) 7.8/10.9, and (f) 12.6/13.0.

ductivity decreases on passing from an electrolyte with pH 2.0 to that with pH 4.1. The coatings formed on both aluminum and titanium alloys contain $WO_{2.9}$ or $Na_{0.1}WO_3$. The coatings formed on the aluminum alloy at low current densities at pH 7.8–13.0 are X-ray amorphous. The position of the curves describing the $U = f(t)$ dependences changes with the pH value and the electrical conductivity (Fig. 1a). All the pH dependences of the sparking voltage U_i show a maximum at pH 4.1 and a minimum at pH 7.1.

The outward appearance of the coatings formed on aluminum and titanium samples at various pH values of the electrolyte is shown in Fig. 2. The coatings formed on aluminum and titanium alloys in weakly acidic and neutral electrolytes are green (white in black-and-white photographs). In other cases, the coatings on titanium are gray-green, and those on aluminum are constituted by gray and green layers. The outer green layer of the coatings formed in an electrolyte with pH 6.5 show blue point-like inclusions (darker in the photograph). Despite the differences in the outward appearance, most of the coatings contain phases of nonstoichiometric tungsten oxide and sodium–tungsten bronze (Table 1). As green regions nucleate and grow on the surface of the aluminum samples, peaks of these phases appear in X-ray diffraction patterns and their intensity increases; in the absence of green regions, XPA shows that the coatings are amorphous. Thus, gray layers formed on the aluminum alloy in electrolytes with pH 2.0, 7.8, and 12.6 are amorphous, and green layers contain crystalline compounds of tungsten. The green regions may appear as separate points and grow in the radial direction, which is observed in electrolytes with pH 2.0 and 7.8–10.6. Crystalline tungsten-containing layers are formed in an electrolyte with pH 12.6. They appear at sample edges and expand as a whole front over the surface, with the surface coverage depending on the quantity Q of electricity passed. At Q = 6 C cm^{-2}, there are no green regions as yet; at Q = 12 C cm^{-2}, the area of the anode surface covered with green regions is small; and, beginning with Q = 60 C cm^{-2}, the layer of a new phase of green color occupies more than half of the anode surface, with the arrangement of green regions symmetrical for both sides of a sample.

The dependence of the content of the main elements in the coatings on pH is shown in Figs. 3a–3c. The content of tungsten in the surface layers of the coatings is maximal, and the content of aluminum or titanium, minimal at pH 4.1–7.3, i.e., in the range of formation of crystalline tungsten-containing oxide layers. The amorphous layers formed on the aluminum alloy at pH 2.0 and 7.8–10.9 have approximately the same elemental composition (Table 2), with the W/P atomic ratio for these layers close to 12.

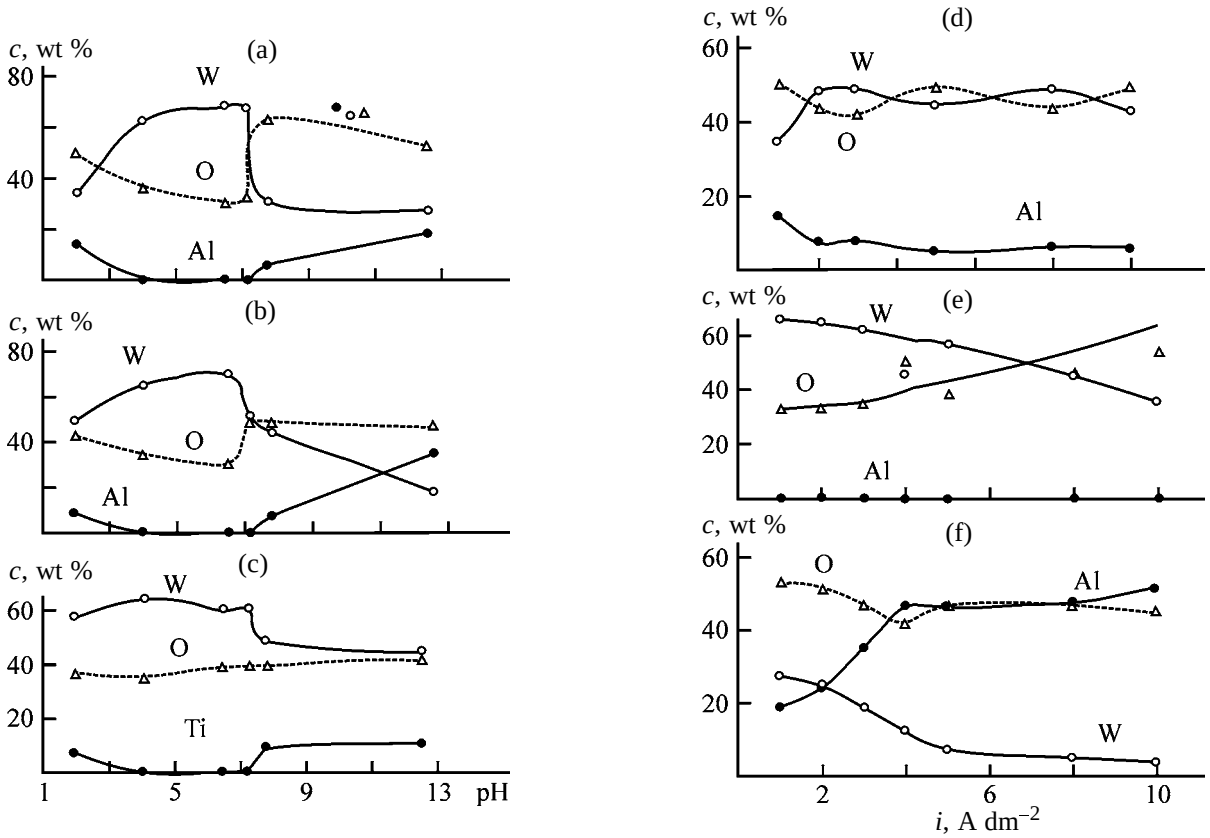

Fig. 3. Effect of pH of an electrolyte and of the current density i on the content c of the main elements in the coatings formed on (a, b, d–f) aluminum and (c) titanium alloys. Current density i (A dm^{-2}): (a) 1, (b) 3, and (c) 10. pH: (d) 2.0, (e) 4.1, and (f) 12.6.

SEM images of the surface of the coatings formed on the aluminum alloy in electrolytes with pH 2.0, 7.8–10.9, and 12.6–13.0 are shown in Fig. 4(I). Noteworthy is the similarity of the surface morphologies of amorphous layers [Figs. 4(I)b, 4(I)d] obtained in acid (pH 2.0) and alkaline (pH 12.6–13.0) electrolytes. The only difference consists in the size of depressions and partly fused raised formations, which are larger in the latter case [Fig. 4(I)d]. Amorphous layers deposited from an electrolyte with pH 7.8–10.9 [Fig. 4(I)c] are formed of threads or fibers 3–10 μm in diameter on a cellular partly melted surface. Cracks are present on the surface of the fibers. Spherical embedded particles (lighter in black-and-white photographs), which are crystalline inclusions of nonstoichiometric compounds of tungsten, are observed on the surface of the amorphous layer formed in an acid electrolyte [Fig. 4(I)b)] and mostly on the surface of fibers in the coatings formed in an electrolyte with pH 7.8–10.9. Of the same crystalline formations are composed more extended green regions, as shown in Fig. 4(I)a (projecting fragment in the photograph).

The influence exerted by the current density on the composition of coatings formed on the aluminum alloy is illustrated by Figs. 3d–3f. The content of the main elements (Al, W) in the amorphous layers of the coatings formed in an acid electrolyte (pH 2) is independent of current density in the range i = 2–10 A dm^{-2} (Fig. 3d). When anodic-spark coatings are formed in an alkaline electrolyte (pH 12.6), the concentration of aluminum grows and that of tungsten falls as the current density increases (Fig. 3f); the composition of the coatings is constant in the range i = 5–10 A dm^{-2}. The crystalline tungsten-containing green layers show a general tendency toward a decrease in the concentration of tungsten with increasing current density (Fig. 3e), despite that the phase composition is constant and aluminum is virtually absent. As can be seen in SEM images of the crystalline layers ([Fig. 4(II)], the fragments of the surface profile become coarser, and the distances between them, longer, as the current density increases.

The sparking voltage U_i is related to the electrical conductivity of the anodizing solution by the following expression [21]:

$$U_i = a - b\ln æ. \quad (1)$$

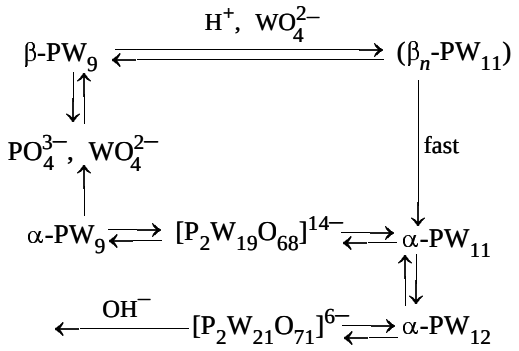
* The content of the element is determined as difference.
** The contents of elements obtained in experiments at different current densities were averaged.

In the given case, æ depends on the amount of the alkali added (Fig. 5a). The curve describing the dependence of pH of a 0.0083 M solution of $Na_2H[PW_{12}O_{40}]$ on the volume of a 1 M NaOH solution (titration curve) shows two steps at pH 3–7 and 8–12 (Fig. 5b). The first step corresponds to neutralization of the acid salt (2), which leads to a smaller number of charge carriers and, consequently, to a decrease in æ (Fig. 5b):

$$Na_2H[PW_{12}O_{40}] + NaOH \rightarrow Na_3[PW_{12}O_{40}] + H_2O. \quad (2)$$

In accordance with Eq. (1), a decrease in the electrical conductivity leads to an increase in the sparking voltage [to the minimum value of æ in the æ = $f(V_{NaOH})$ plot corresponds the maximum value of U_i in the $U_i = f(\text{pH})$ plot, Fig. 1b]. At the same time, the minimum in the dependence $U_i = f(\text{pH})$ is not accompanied by changes in the type of the electrical conductivity of the solutions or steplike changes in pH. By contrast, it lies in the range of stable pH values (Fig. 5b).

The following scheme of mutual transformations at different pH values of an aqueous solution is known for tungsten–phosphorus HPA [12]:



Already at pH 1–2, an equilibrium is established between PW_{12} and PW_{11}:

$$[PW_{12}O_{40}]^{3-} + (5 - x)OH^- \rightleftarrows [H_xPW_{11}O_{39}]^{(x-7)} + HWO_4^- + (2 - x)H_2O. \quad (3)$$

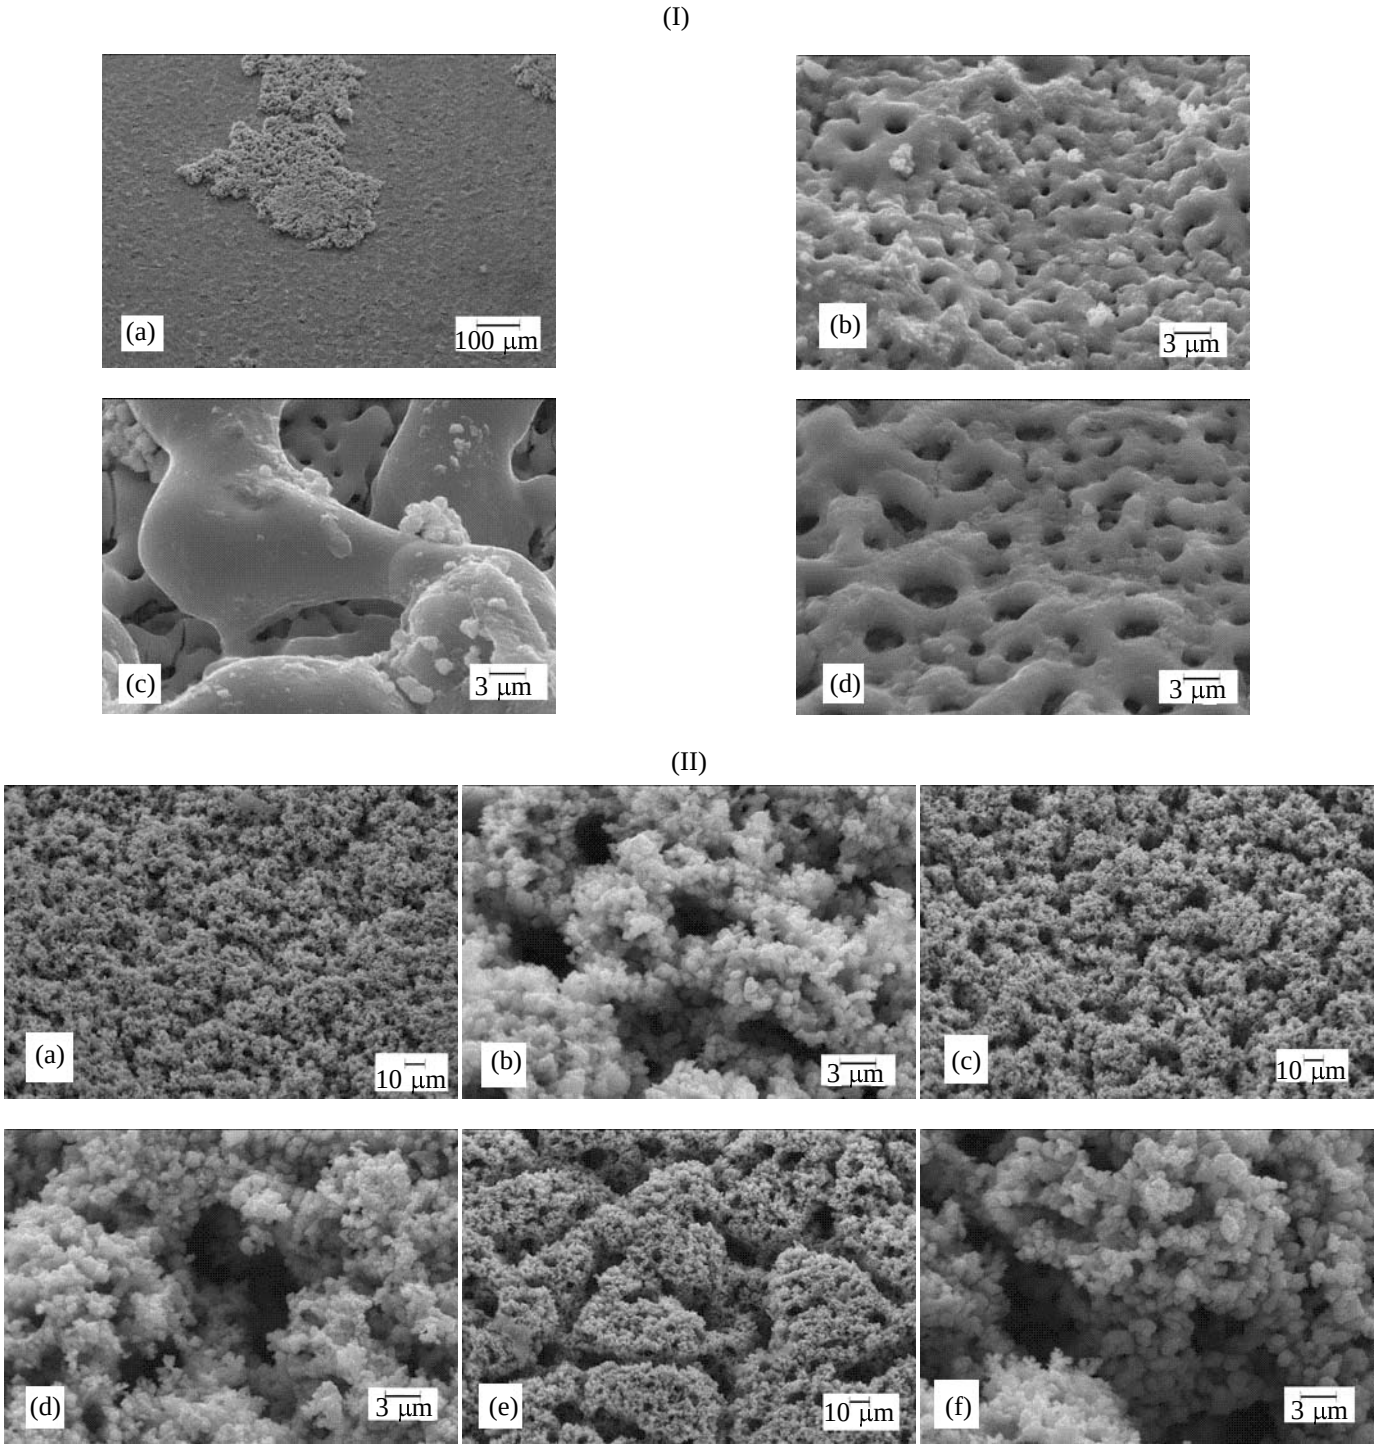


Fig. 4. SEM images (45° view) of the surface of coatings formed on aluminum (I) at i = 2 A dm^{-2} in electrolytes with pH (a, b) 2.0, (c) 7.8, and (d) 12.6 and (II) in electrolytes with pH 4.1 at i (A dm^{-2}): (a, b) 1, (c, d) 3, and (e, f) 8.

$[PW_{11}O_{39}]^{7-}$ solutions are stable in the range pH 2–6; however, PW_{11} anions are in equilibrium with PW_9 and PO_4^{3-} + WO_4^{2-} at pH > 5. Simultaneously with the appearance of lacunar HPA in solution, mono- or polytungstate will be present, depending on pH. At pH > 9, tungsten–phosphorus HPAs decompose. In the ^{31}P NMR spectra of a 0.0083 M $Na_2H[PW_{12}O_{40}]$ solution, this is accompanied by appearance of a peak at δ = +2.9 ppm. This peak corresponds to the phosphate anion [22] and is absent

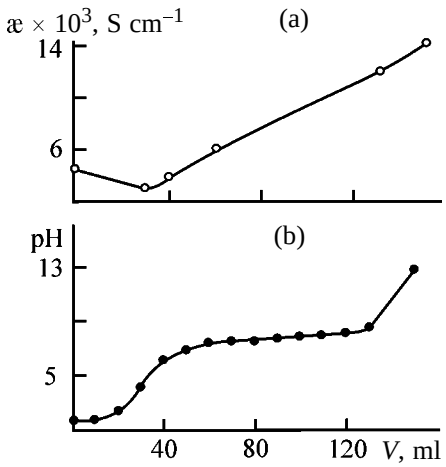

Fig. 5. Effect of the volume V of 1 M of NaOH in a 0.0083 M $Na_2H[PW_{12}O_{40}]$ solution on (a) electrical conductivity æ and (b) pH.

at lower pH. The complex transformations in the electrolyte correlate with the run of the curves describing the dependences $U = f(t)$ (higher or lower position in the plot depending on pH, Fig. 1a) and $U_i = f(\text{pH})$ (occurrence of maxima and minima, Fig. 1b) and with the outward appearance (Fig. 2) and composition of the coatings obtained (Fig. 3; Tables 1, 2). Analysis of the titration curve (Fig. 5b) and the data in Table 1 (comparison of the initial and final pH values) shows the following. In cases when the initial electrolyte has the pH corresponding to that portion of the curve for which the pH is nearly independent of the amount of the alkali added (range of buffer solution), the final pH value varies only slightly in the course of anodic-spark deposition. If, however, the initial pH value corresponds to the onset or middle of the titration step, the variation of pH in the course of the anodic-spark treatment will be pronounced. This is also observed in electrolytes with initial pH 4.1 and 7.8, i.e., the narrowest variation of the pH value in the course of anodic-spark deposition corresponds to the minimum U_i.

As also in the case of tungstate electrolytes [23], the electrical conductivity of solutions varies in the course of anodic-spark deposition only slightly even when pH changes considerably (Table 1). At high mobility of hydroxide ions, this fact can be attributed to a decrease in the number of charge carriers, e.g., as a result of discharge of tungstate ions to give WO_3.

The green layers must seemingly contain WO_3 (yellow) with a minor admixture of W(V) compounds (blue). According to [16], one of processes that lead to incorporation of the electrolyte components into the coatings obtained is thermolysis of compounds that are present on the anode near the electric-breakdown channels. It was established experimentally that crystalline WO_3 is a product formed upon annealing of $Na_2H[PW_{12}O_{40}]\cdot 9H_2O$ in a muffle furnace in air at 600°C for 2 h. In addition to thermal decomposition of the heteropoly compound in anodic-spark deposition, there occurs thermolysis of water [24]. In the breakdown channel and in regions adjacent to this channel, tungsten(VI) oxide is reduced in the presence of hydrogen formed in thermolysis of water, which is accompanied by the appearance of blue point regions in the green layer (Fig. 2, pH 6.5/7.0). The fact that XPA does not reveal WO_3 is presumably due to lower crystallinity of this phase. In all probability, the green layers of the coatings contain both WO_3 and phases of nonstoichiometric composition, which include W(V) (Table 1).

The dependence of the elemental composition of the coatings (Figs. 3a–3c) and of the atomic ratio W/P (Table 2) on pH is, apparently, associated with changes in the electrolyte composition. At pH 2.0, the same W/P ratios in the coatings formed on aluminum and in the electrolyte can be accounted for by involvement of PW_{12} HPA in the coating formation. Being adsorbed on the surface of aluminum oxide, HPA can favor transfer of Al^{3+} ions from the crystal lattice into solution in the form of soluble salts of aluminum [25] or as aluminum-substituted heteropolytungstates [26, 27]. The anionic complexes formed can be involved in coating formation. Presumably, these processes affect the content of aluminum in an anodic-spark layer.

The change in the ionic composition of the electrolyte at pH 4.1–7.3, which is associated with the formation of lacunar species of HPA and isopolytungstates, may favor growth of WO_3-containing oxide layers [23]. In this range of pH, aluminum and titanium oxides are virtually insoluble [28], so that the deposition of tungsten-containing oxide layers may occur at the minimum involvement of the substrate components.

At high pH values, hydrolysis of tungsten–phosphorus HPAs to monomeric anions leads to a decrease in the concentration of tungsten in amorphous layers and in the number of regions that contain crystalline compounds of tungsten. At the same time, raising the concentration of hydroxide ions in the electrolyte promotes chemical dissolution of aluminum and leads to a rise in the concentration of hydroxoaluminate or hydroxotitanate complexes in the electro-

lyte and to their involvement in coating formation. As a result, the content of aluminum or titanium in the coatings grows (Table 2). Despite the disintegration of HPA in alkaline electrolytes (according to the above scheme [12]), the atomic ratio W/P in coatings formed on aluminum in electrolytes with pH 7.8–13.0 is 11.3–15.7, i.e., is the same as that for coatings formed in acid electrolytes. The value of the W/P ratio can be understood in this case as follows. Amorphous insoluble aluminum phosphates and tungstates or compounds of composition $Al_2O_3 \cdot mP_2O_5 \cdot nWO_3$ are formed in the coatings, and phosphorus and tungsten atoms are incorporated into the anodic-spark layers in proportion to the concentrations of these atoms in the electrolyte. The formation of aluminum tungstates in electrolytes with pH 7.8–10.6, presumably in the amorphous form, is indicated by the closeness of the elemental composition and the morphology of the coatings to those formed in a 0.1 M solution of Na_2WO_4 [23, 29].

The fact that the dependences of the elemental composition of the anodic-spark layers on aluminum and titanium on the pH value of the electrolyte are the same confirms that HPAs are involved in their formation. However, it remains unclear why the W/P and W/Ti atomic ratios for coatings formed by anodic-spark deposition on aluminum in an acid electrolyte are nearly twice the W/P and W/Al ratios for coatings on aluminum (Table 2). It should be noted that not only the composition of HPAs, but also the solubility of aluminum and titanium compounds in aqueous electrolytes is a function of the solution pH. In acid and alkaline media, the processes of chemical dissolution of amphoteric oxides are enhanced, and those in neutral media are insignificant. These processes can affect formation, composition, and morphology of coatings.

Despite certain differences between the elemental compositions of amorphous layers formed on aluminum in acid and alkaline electrolytes (pH 2.0 and 12.6), their SEM images [Figs. 4(I)b, 4(I)d] are similar and the coatings resemble in the surface structure those obtained in an electrolyte with H_3PO_4 and Na_2WO_4 [30]. The coatings formed in electrolytes with pH 2.0 and 7.8 have close elemental compositions, but differ in surface morphology. The morphology of crystalline tungsten-containing layers depends on the current density or amount Q of electricity expended for their formation [Fig. 4(II)], rather than on pH of the electrolyte. As Q increases, both the projecting fragments or surface profile motives and depressions become larger, which is accompanied by an increase in the volume of voids. In the case of a microprobe analysis, the presence of voids leads to a decrease in the surface-averaged concentration of tungsten in the coatings, furnished by this method (Fig. 3e).

CONCLUSIONS

(1) The composition of coatings formed on aluminum and titanium alloys in electrolytes with sodium tungstophosphate reflects the pH dependence of the composition of heteropolyanions in an electrolyte solution.

(2) Multilayer coatings that contain in their outer layer oxides of elements constituting the ligand sphere of heteropolyanions are formed in weakly acidic, neutral, and weakly alkaline electrolytes. In acid and alkaline solutions, the components of heteropolyanions are incorporated into coatings formed on aluminum and titanium to a lesser extent.

(3) The surface layers formed in electrolytes with sodium phosphotungstate contain $WO_{2.9}$ or $Na_{0.1}WO_3$, products of thermolysis of tungsten-phosphorus heteropolyanions.

(4) The surface of coatings formed in a neutral medium is constituted by loose layers of crystalline tungsten oxide compounds. The size of fragments of these layers depends on the current density. The surface of coatings formed in an alkaline medium has a cellular structure.

(5) The data obtained confirm the direct relationship between the forms in which iso- and heteropolyanions are present in electrolytes and the composition of the layers being formed.

ACKNOWLEDGMENTS

The authors thank T.A. Kaidalova for performing the X-ray phase analysis, E.S. Pankina for performing microprobe X-ray fluorescence analysis of the coatings, L.M. Tyrina for carrying out experiments on thermal decomposition of sodium tungstophosphate, and V.V. Kon'shin for measuring the NMR spectra of solutions.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Optimization of Electroplating Processes in Drum Baths To Obtain a More Uniform Coating

V. I. Karavaev and Yu. V. Litovka

Tambov State Technical University, Tambov, Russia

Received April 6, 2004

Abstract—The optimization of the electroplating process in drum electrolyzers to minimize the standard deviation of the coating thickness is considered.

The uniformity of a deposited metal layer is one of the main quality parameters of electroplated coatings obtained in baths with drums. The problems of achieving a prescribed or the minimum possible variance of the coating thickness arise both in design of electrochemical systems and in control of the processes. Solution of these problems is complicated by the lack of a well-developed theory of the process and by inconsistency of experimental data on how parameters of an electrochemical system affect the uniformity of a coating.

Technical specifications for fabrication of articles with electroplated coatings commonly give the minimum acceptable thickness of deposits, which predetermines the electrolysis duration. If the coatings deposited are nonuniform, then, on obtaining the minimum possible deposit thickness in some parts of an article, the thickness of deposits in other regions may exceed the minimum value severalfold. This leads to an unproductive increase in the expenditure of a metal deposited, electrolyte, and electric power, lowers the output capacity of the electroplating apparatus, and makes higher the production cost of the articles manufactured.

The choice of the electrolyte composition and electrolysis parameters, as well as of the design of the electroplating equipment and feeding units is governed by the necessity for obtaining articles with the highest possible thickness uniformity in their different parts.

As an optimization criterion is commonly used the root-mean-square deviation (also termed standard deviation) σ of the thickness of a coating on articles from its average value.

The main factors that affect the chosen criterion are the current I, drum filling C_t, drum rotation frequency ω, and drum parameters: diameter D and degree of wall perforation f_0. Let I, C_t, and D be variables. Then, to optimize the drum electrolyzer, it is necessary to find the current I, drum filling C_t, and drum diameter D at which the standard deviation of the coating thickness, $\sigma(I, C_t, D)$ is the smallest:

$$\sigma(I, C_t, D) \rightarrow \min,$$

at constraints determined by the equations of a mathematical model and by process limitations.

A particular case of the optimization problem to be solved is a search for process variables: current I and filling C_t for an available drum. In this case, it is necessary to find the current I and drum filling C_t at which the standard deviation of the coating thickness, $\sigma(I, C_t)$, is the smallest:

$$\sigma(I, C_t) \rightarrow \min.$$

To relate the chosen criterion to the variables, we construct a system of equations of the mathematical model. Theoretical concepts of the process and generalized experimental data formed a basis for the constraint equation suggested in [1], which relates the standard deviation of the thickness of a coating deposited onto articles in a rotating drum to the parameters of the system:

$$\sigma = K\bar{h}\Delta\tau^{-0.5}, \quad (1)$$

where K is the scatter factor; h, average coating thickness; and $\Delta\tau$, electrolysis duration.

The average coating thickness is found from the equation

$$\bar{h} = \frac{\sum_{i=1}^{n} h_i}{n},$$

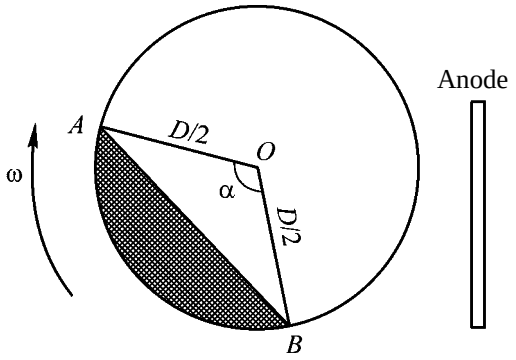

Fig. 1. Cross section of a drum electrolyzer.

where h_i is the deposit thickness on the surface of ith article, and n is the number of articles in the drum.

The scatter factor K is found using the formula

$$K = \left[(\gamma D f_e - 1)\frac{\alpha}{390\omega E_m}\left(1 + \frac{\omega D \sin(\alpha/2)}{V_t \alpha/360}\right)\right]^{0.5}, \quad (2)$$

where γ is the current distribution parameter; D, drum diameter; f_e, filling factor; α, central angle opposite to the charge surface; ω, drum rotation frequency; E_m, efficiency of stirring of the articles; and V_t, article falling velocity (V_t = 525 cm min^{-1} was recommended in [1]).

The parameter ψ is determined by the geometry of the articles being processed and by the electrolyte properties in accordance with the equation

$$\gamma = [(S/V_z)ZFi_0/(\chi RT)]^{0.5}, \quad (3)$$

where S/V_z is the ratio of the total area of the charge to its volume; i_0, exchange current density (the physical meaning of this quantity is the rate of the ion exchange between the metal and solution in equilibrium; it has a tabulated value determined by the type of the electrode and the composition of the electrolyte); χ, electrical conductivity of the solution; Z, number of electrons involved in the electrochemical reaction; F, Faraday number F = 96 484.56 C mol^{-1}; R, universal gas constant, R = 8.31433 J mol^{-1} K^{-1}; and T, absolute temperature of the solution.

Taking into account that $V_z = V_{ar}$ and $S = nS_{ar}$, where V_{ar} and S_{ar} are the volume and surface area of an article, respectively, we have

$$S/V_z = S_{ar}/V_{ar}.$$

Then formula (3) takes the form

$$\gamma = [(S_{ar}/V_{ar})ZFi_0/(\chi RT)]^{0.5}.$$

The feed factor f_e is calculated using the equation [2]

$$f_e = \frac{\alpha/360 - 1/(2\pi)\sin\alpha - V_d/V_b}{8[f_0\alpha/360 - 1/\pi \sin(\alpha/2)]}, \quad (4)$$

where V_d is the volume of the cathode contacts; V_b, drum volume; and f_0, degree of perforation of drum walls.

The drum filling C_t is the quantity found from the formula

$$C_t = V_z/V_b. \quad (5)$$

Let us consider a cross section of a round drum that is perpendicular to its axis (Fig. 1).

The hatched region is that part of the drum in which the articles are contained. Let L be the drum length. Then $V_b = S_bL$ and $V_z = S_zL$, where S_b is the cross-sectional area of the drum, and S_z is the area of the feeding cross section. Hence,

$$C_t = S_z/S_b. \quad (6)$$

The cross-sectional area of the drum is found as

$$S_b = \pi D^2/4,$$

and the area of the feeding cross section is defined as the difference of areas of sector AOB and triangle AOB:

$$S_z = \frac{\alpha}{2\pi}(\pi D^2/4) - 0.5(D^2/4)\sin\alpha.$$

Then Eq. (6) is brought to the form

$$C_tS_b = S_z,$$

$$C_t(\pi D^2/4) = \frac{\alpha}{2\pi}(\pi D^2/4) - 0.5(D^2/4)\sin\alpha,$$

$$C_t\pi = \alpha/2 - \sin(\alpha/2),$$

$$\alpha = \sin\alpha + 2C_t\pi. \quad (7)$$

If the drum filling is known, we can find from Eq. (7) the central angle α (rad) opposite to the charge surface.

In [1], the stirring efficiency E_m is defined as the number of random agitations of the charge, divided by the number of drum revolutions or, in other words,

the number of random agitations of the charge per revolution of the drum.

Let us assume that the drum electrolyzer has the form of a rotating smooth drum, within which a granular substance, loaded articles, moves. The substance in the drum moves in the rolling mode and circulates around point *C*, the circulation center (Fig. 2).

It has been shown that the average time τ_{av} of a cycle of circulation of the material around point *C* can be found as

$$\tau_{av} = \frac{2Q}{4\rho_{bl}\omega(R^2 - R_c^2)},$$

where $Q = 1/2L\rho R^2(2\delta_0 - \sin 2\delta_0)$ is the total amount of the material in the drum; *R*, drum radius; ρ_{bl}, bulk density of the material; δ_0, angles *AOC* and *COB* (Fig. 2); and R_c, distance from the drum axis to the circulation center *C*.

Then

$$\tau_{av} = \frac{LR^2(2\delta_0 - \sin 2\delta_0)}{4\omega(R^2 - R_c^2)}. \quad (8)$$

As $\tau_{av} \geq 0$ and $Q \geq 0$, it follows from (8) that $R^2 - R_c^2 > 0$, $R > R_c$ or $R_c < R$. This condition is satisfied when the drum is less than half-filled. Consequently, $C_t < 0.5$. The average number *N* of circulation cycles during the time $\Delta\tau$ spent by the material in the drum is given by

$$N = \Delta\tau/\tau_c. \quad (9)$$

Then, at $\Delta\tau$ equal to the time of a revolution, $N = E_m$. The time of a revolution

$$\tau_1 = 1/\omega. \quad (10)$$

Combining formulas (8)–(10) and taking into account that $2\delta_0 = \alpha$, we have

$$E_m = \frac{4}{L(\alpha - \sin\alpha)}[1 - (R_c/R)^2].$$

In [4], a procedure for calculating R_c was reported, whence follows that, as a rule, the circulation center *C* is situated at a distance equal to one third of the charge depth from the charge surface. Then

$$R_c = a + 1/3(R - a) = (2a + R)/3 = (2R\cos\delta_0 + R)/3$$

$$= R/3[2\cos(\alpha/2) + 1].$$

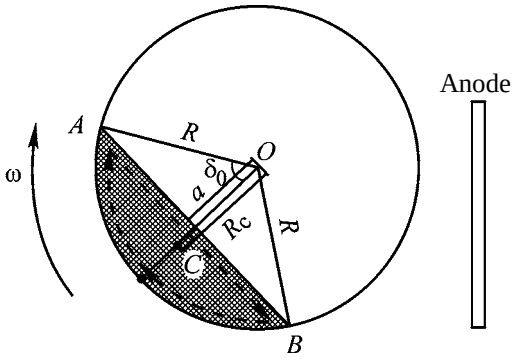

Fig. 2. Circulation of articles in the drum.

Hence,

$$E_m = \frac{4}{L(\alpha - \sin\alpha)}\left[1 - \left(\frac{2\cos(\alpha/2) + 1}{3}\right)^2\right]. \quad (11)$$

The average coating thickness $\bar{h}$ on articles from the same charge is determined from the Faraday law [5]:

$$\bar{h} = (E\eta/\rho_m)i\Delta\tau, \quad (12)$$

where η is the current efficiency; *E*, electrochemical equivalent of a metal being deposited (g A^{-1} h^{-1}); ρ_m, density of the metal being deposited (g cm^{-3}); and *i*, average current density (A cm^{-2}).

When the articles move within the drum, the charge is strongly agitated. As a result of the mechanical impact, the coatings being deposited are partly rubbed away, which is particularly pronounced in electrodeposition of soft metals (zinc, tin, etc.). In [6], the wear loss factor ξ was introduced, which has the following values: 20–40 and 40–60% for hard and soft metals, respectively. With account of the coefficient ξ, Eq. (12) takes the form

$$\bar{h} = [E\eta/\rho_m(1 + 0.01\xi)]i\Delta\tau. \quad (13)$$

The current density is the ratio of the current *I* to the area of that surface of the layer of articles, which faces the anode:

$$i = I/S_a. \quad (14)$$

Let us assume that the surface facing the anode is a rectangle with sides *AB* and *L* (Fig. 1). The side *AB* = $D\sin(\alpha/2)$. Then the area S_a is given by

$$S_a = LD\sin(\alpha/2). \quad (15)$$

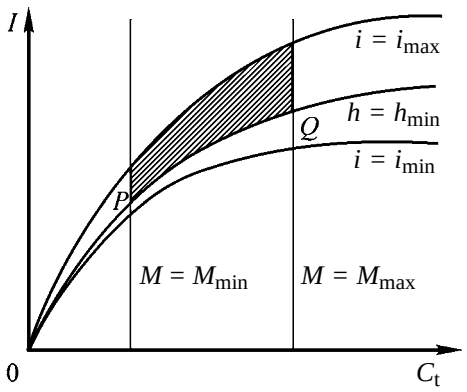

Fig. 3. Constrains and feasibility region for the optimization problem. (I) Current and (C_t) drum filling; the same for Figs. 4–6. $I = i_{min}$ and $i = i_{max}$ are the curves of constraints on the average current density i; $M = M_{min}$ and $M = M_{max}$, straight lines of constraints on the charge mass M; and $h = h_{min}$, curve of constraint on the thickness h of a coating being deposited.

With account of (14) and (15), Eq. (13) takes the form

$$\bar{h} = [E\eta/\rho_m(1 + 0.01\xi)][I/LD\sin(\alpha/2)]\Delta\tau. \quad (16)$$

Let us determine how the charge area S_z depends on the drum filling C_t.

Provided that identical articles are coated in the drum, we have for the charge area

$$S_z = nS_{ar}.$$

It follows from Eq. (5) that the charge volume $V_z = C_t V_b$. The bulk density can be defined as

$$\rho_{bl} = M/V_z,$$

where M is the mass of the charge.

Hence follows that $M = \rho_{bl} V_z = \rho_{bl} C_t V_b$. Then the number of articles in the drum

$$n = M/M_{ar} = \rho_{bl} C_t V_b/(\rho_{ar} V_{ar}),$$

where M_{ar} is the mass of an article, and ρ_{ar} is the density of its material.

The charge area

$$S_z = nS_{ar} = C_t V_b S_{ar}/V_{ar}\rho_{bl}/\rho_{ar}.$$

With account of the mathematical model we constructed, the mathematical formulation of the optimization problem is as follows: it is necessary to find the current I, drum filling C_t, and drum diameter D at which the standard deviation of the coating thickness, $\sigma(I, C_t, D)$, is at a minimum:

$$\sigma(I, C_t, D) \rightarrow \min.$$

The constraint equations are the following:

$$\sigma = K\bar{h}\Delta\tau^{-0.5},$$

$$\bar{h} = [E\eta/\rho_m(1 + 0.01\xi)][I/LD\sin(\alpha/2)]\Delta\tau,$$

$$K = \left[(\gamma D f_e - 1)\frac{\alpha}{390\omega E_m}\left(1 + \frac{\omega D\sin(\alpha/2)}{V_t\alpha/360}\right)\right]^{0.5},$$

$$E_m = \frac{4}{L(\alpha - \sin\alpha)}\left[1 - \left(\frac{2\cos(\alpha/2) + 1}{3}\right)^2\right],$$

$$f_e = \frac{\alpha/360 - 1/(2\pi)\sin\alpha - V_d/V_b}{8[f_0\alpha/360 - 1/\pi\sin(\alpha/2)]},$$

$$\gamma = [(S_{ar}/V_{ar})ZFi_0/(\chi RT)]^{0.5}, \quad (17)$$

$$\alpha = \sin\alpha + 2C_t\pi,$$

$$i = I/S_a,$$

$$M = C_t V_b \rho_{bl},$$

$$V_b = L\pi D^2/4.$$

Constraints:

$$\bar{h} \geq h_{min}, \quad (18)$$

$$\Delta\tau \leq \Delta\tau_{max}, \quad (19)$$

$$M_{min} \leq M \leq M_{max}, \quad (20)$$

$$i_{min} \leq i \leq i_{max}, \quad (21)$$

where h_{min} is the prescribed minimum coating thickness; $\Delta\tau_{max}$, maximum acceptable time of coating deposition; M_{min}, minimum mass of charge (determined by the prescribed output capacity): M_{max}, maximum acceptable mass of charge (determined by the drum design); i, average current density; i_{max}, maximum acceptable current density (exceeding this value leads to appearance of rejects); and i_{min}, minimum acceptable current density.

With i_{min} and i_{max} known, we can determine the constraints on the current: $I_{min} = S_a i_{min}$, $I_{max} = S_a i_{max}$ at a fixed surface area S_a of the layer of articles that faces the anode. We start solving the optimization problem from a particular, the simplest, case.

First, it is necessary to make analysis for existence of a solution to the optimization problem. The problem can be solved if there exists a feasibility region specified by constraints (18) and (20)–(21) (Fig. 3).

The plots of the functions $i = i_{min}$, $i = i_{max}$, and $h = h_{min}$ are curves emerging from the origin of coordinates. The slope of these curves is directly proportional to the current density i. For the first function, $i = i_{min}$; for the second, $i = i_{max}$; and for the third, $i = i_{hmin}$, where i_{hmin} is the current density at which the coating thickness is h_{min}. The value of i_{hmin} can be found from Eq. (13):

$$i_{hmin} = \frac{h_{min}(1 + 0.01\xi)\rho_m}{E\eta\Delta\tau}.$$

The condition for existence of a feasibility region and, consequently, of the solution itself is as follows: the plot of the function $h = h_{min}$ must run above the plot of the function $i = i_{min}$, but below that of the function $i = i_{max}$, which is possible if the following condition is satisfied:

$$i_{min} \le i_{hmin} \le i_{max}. \quad (22)$$

The optimization problem is two-dimensional (2D), because it has two sought-for variables. Let us consider Eq. (1). Let us assume that the scatter factor K is constant. Then, with account of $\Delta\tau$ = const, the standard deviation of the coating thickness, σ, will be at a minimum at the smallest average coating thickness h, i.e., the sought-for solution (C_t^*, I^*) will lie on the curve $h = h_{min}$ in the feasibility region (PQ portion).

The minimum standard deviation of the coating thickness $\sigma = Kh_{min}\Delta\tau^{-0.5}$. The scatter factor K is independent of $\Delta\tau$. Then $\sigma = \text{const}\,\Delta\tau^{-0.5}$. Consequently, the standard deviation of the coating thickness, σ, decreases as the time of coating deposition, $\Delta\tau$, becomes longer, and the minimum value of σ is observed at $\Delta\tau = \Delta\tau_{max}$. Therefore, inequality (19) is transformed into the equality $\Delta\tau$ = const = $\Delta\tau_{max}$.

The scatter factor function K is independent of the current I, being determined only by the drum filling C_t. Then, having found the value of C_t^* at which the scatter factor function $K(C_t)$ takes the minimum value, we can determine the precise position of the sought-for solution to the optimization problem on the $h = h_{min}$ curve in the feasibility region:

$$I^* = \text{Si}_{hmin} = LD\sin(\alpha/2)\,i_{hmin}. \quad (23)$$

Thus, the 2D optimization problem is reduced to a 1D problem that consists in a search for a minimum of the function $K(C_t)$ on the interval $[C_{t_P}, C_{t_Q}]$, where

$$C_{t_P} = M_{min}/(\rho_{bl}V_b),$$

$$C_{t_Q} = M_{max}/(\rho_{bl}V_b).$$

To solve the general optimization problem, which is of the 3D type, we considered particular cases at different diameters D of the drum electrolyzer.

The minimum standard deviation of the coating thickness $\sigma = Kh_{min}\Delta\tau^{-0.5} = K(D)$const. In formula (2) for the scatter factor K, the diameter D is in the numerator with a positive sign, and, therefore, the standard deviation of the coating thickness, σ, increases as D becomes larger. Thus, the minimum value of σ is achieved at the minimum possible values of the diameter D.

Then, the general optimization problem is solved as follows: D is raised, beginning with D_{min}, with a step ΔD until there exists the feasibility region [condition (22) is satisfied]. This diameter is taken to be the optimal diameter D^*. Further, the minimum of the function $K(C_t)$ is found on the interval $[C_{t_P}, C_{t_Q}]$ using a method for 1D optimization (e.g., the bisection method). The resulting optimal value of C_t^* is used to calculate by formula (23) the optimal current I^*.

Thus, a 1D algorithm is used in the final stage when solving the 3D optimization problem.

If constraint (18) is used, negative deviations of the coating thickness from the average value are possible for a large number of articles. It is more correct to use constraints of the following type:

$$\bar{h} - \sigma \ge h_{min},$$

$$\bar{h} \ge h_{min} + \sigma. \quad (24)$$

The standard deviation of the coating thickness, σ, will be at a minimum at the smallest h, i.e., at

$$\bar{h} = h_{min} + \sigma,$$

The coordinate C_t^* corresponds to the minimum of the function $K(C_t)$. I^* can be calculated from h and C_t^* by formulas (7) and (16).

It is necessary to satisfy condition (24). This is achieved as follows.

(1) The starting value $\sigma^{(0)} = 0$ is set. It is taken that $h_{min} = h_{min} + \sigma^{(0)}$. The optimization problem is solved with constraint (18). As a result, the optimal value $\sigma^{(1)}$ is obtained.

(2) It is taken that $h_{min} = h_{min} + \sigma^{(1)}$. The optimization problem is solved with constraint (18). As a result, the optimal value $\sigma^{(2)}$ is obtained, etc.

This procedure is continued until the condition

$$|\sigma^{(i+1)} - \sigma^{(i)}| \le \varepsilon,$$

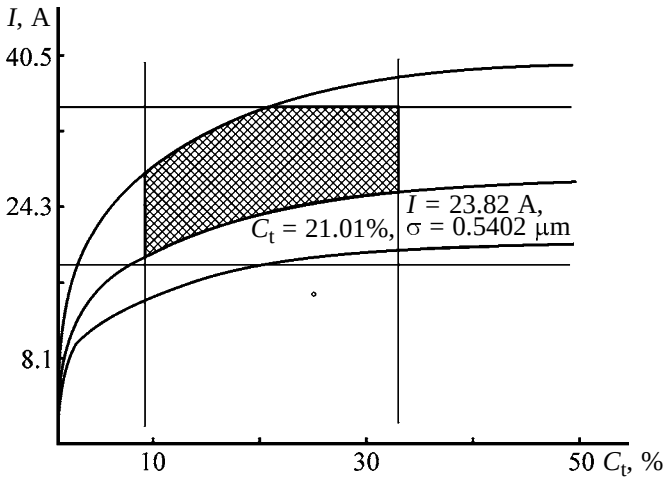

Fig. 4. Solution of the optimization problem for the operation mode of a drum electrolyzer for $10 \le M \le 40$ kg.

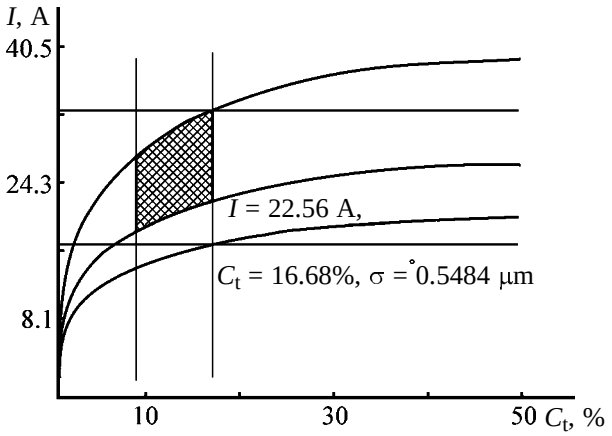

Fig. 5. Solution of the optimization problem for the operation mode of a drum electrolyzer for $10 \le M \le 20$ kg.

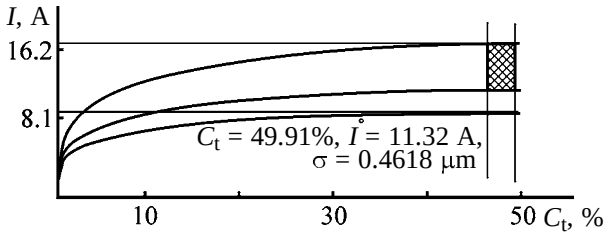

Fig. 6. Solution of the optimization problem in designing a drum electrolyzer.

where i is the number of iteration and ε is prescribed accuracy, is satisfied.

In the study, the problem of optimization of the operation mode of a drum-type nickel-plating bath is solved. As an example is taken a drum electrolyzer with the following parameters: diameter D = 22.5 cm, length L = 60 cm, rotation frequency ω = 8 rpm, and degree of wall perforation f_0 = 22%.

The parameters of the metal being deposited (nickel) and the electrolyte are as follows: electrochemical equivalent E = 1.095 g A^{-1} h^{-1}; current efficiency η = 0.97; wear coefficient ξ = 40%; number of electrons involved in electrolysis z = 2; exchange current density i_0 = 0.001 A cm^{-2}; electrical conductivity χ = 0.5 Ω^{-1} cm^{-1}; electrolyte temperature T = 313 K; and metal density ρ_m = 8.9 g cm^{-3}.

Articles with a total surface area S_{ar} = 6 cm^2 and volume V_{ar} = 1 cm^3 are to be nickel-plated. The density of the material of the articles ρ_{ar} = 7.8 g cm^{-3}, bulk density ρ_{bl} = 5 g cm^{-3}, time of coating deposition $\Delta\tau$ = 30 min. The minimum acceptable coating thickness h_{min} = 8 μm. The constraint on the charge mass M: $10 \le M \le 40$ kg; and the current density $1.5 < i < 3$ A dm^{-2}.

The solution of the problem produced the following result (Fig. 4): drum filling C_t = 21.01%, current I = 23.82 A, standard deviation σ = 0.5402 μm, average coating thickness $\bar{h}$ = 8.5402 μm, charge surface area S = 1.927 m^2, charge mass M = 25.06 kg, current density i = 2.004 A dm^{-2}, and constraint on the current I: $17.84 < I < 35.67$ A.

At another constraint on the charge mass ($10 \le M \le 20$ kg), the following result was obtained (Fig. 5): drum filling C_t = 16.68%, current I = 22.56 A, standard deviation σ = 0.5484 μm, average coating thickness $\bar{h}$ = 8.5484 μm, charge surface area S = 1.531 m^2, charge mass M = 19.91 kg, current density i = 2.006 A dm^{-2}, and constraint on the current I: $16.87 < I < 33.75$ A.

Solving the problem in designing a drum electrolyzer, when not only process, but also design parameters are sought for, yielded the following result (Fig. 6): drum diameter D = 9.5 cm, drum filling C_t = 49.91%, current I = 11.32 A, standard deviation σ = 0.4618 μm, average coating thickness $\bar{h}$ = 8.4618 μm, charge surface area S = 0.8163 m^2, charge mass M = 10.61 kg, current density i = 1.985 A dm^{-2}, and constraint on the current I: $8.55 < I < 17.1$ A.

CONCLUSION

The problem of optimization of a drum electrolyzer in order to minimize the standard deviation of the article coating thickness from the average value was formulated and solved. The definition domain of the optimization problem was analyzed. An algorithm for a search for the optimal parameters of a drum electrolyzer was developed.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Intensification of Impregnation of Metal–Ceramic Supports in Fabrication of Nickel Oxide Electrodes by the Nitrate Technique

T. E. Kuzina and A. A. Bachaev

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received December 2, 2003; in final form, May 2004

Abstract—The possibility of making shorter the time of fabrication of a nickel oxide electrode by impregnation of a metal–ceramic support in a nickel nitrate solution with addition of sodium nitrite was studied.

The duration of multicycle procedures in fabrication of nickel oxide electrodes (NOE) on metal–ceramic (MC) supports is mainly determined by the time of impregnation of MC supports in a solution that contains nickel salts, most frequently $Ni(NO_3)_2$ (pH < 7) [1]. Up to 97–98% of the total impregnation time (up to 15 h) is necessary for obtaining the active substance via oxidation of nickel from the support, which occurs by the electrochemical mechanism [1, 2]. The fraction of the active substance obtained via oxidation of nickel from an MC support in a $Ni(NO_3)_2$ solution is about 30% [3]. To make shorter the time in which MC NOEs are fabricated and to diminish the power consumption and labor intensity of the process, it is necessary to accelerate the oxidation of nickel in the course of impregnation.

The influence exerted by $NaNO_2$ on impregnation of MC supports was studied by Zhdanov *et al.* [4]. However, in contrast to our study, Zhdanov *et al.* [4] used a chloride solution, which has a lower oxidation capacity and does not undergo disproportional self-regeneration.

The aim of this study was to examine the influence exerted by addition of $NaNO_2$ to $Ni(NO_3)_2$ solution on the rate of etching of nickel contained in MC supports and on the electrical characteristics of MC NOEs obtained.

EXPERIMENTAL

The electrodes studied were fabricated on $30 \times 10 \times 1.6$-mm MC nickel supports with a bulk porosity of 70–75%. The MC supports were filled with nickel(II) hydroxide by the following scheme: impregnation with an $Ni(NO_3)_2$ solution ($c_{Ni(II)}$ = 300–330 g l^{-1}) containing $NaNO_2$ (5–10 g l^{-1}), pH 1–5, temperature 60–80°C, τ = 1 h; crystallization in air (30 min); treatment in an alkali solution (c_{KOH} = 300–330 g l^{-1}, T = 60–80°C, τ = 1 h); washing to remove the alkali; and drying (T = 110°C). Changes in the mass of the MC supports were determined as the difference of masses before impregnation and after a full cycle of the procedures performed. The mass of nickel dissolved from the MC support was determined by complexometric titration [5]. The characteristics of the nickel etching process were found using the model described in [5]. The chemical composition of the active substance in NOE was determined by the procedure described in [6].

The composition of the corrosion products formed was identified by X-ray diffraction analysis on a DRON-2 diffractometer at an acceleration voltage of 32 kV, current of 0.8 mA, slit dimensions of $1 \times 8 \times 1$ mm, and filter wavelength of 0.58 Å. Qualitative analysis of the X-ray diffraction patterns was made using the procedure described in [7].

The rate-determining stage of reduction of NO_3^- and NO_2^- was identified using a potentiodynamic method in which polarization curves were measured with a linear potential sweep at a rate of 2–20 mV s^{-1}.

The capacity characteristics of the electrodes fabricated were determined by discharge in cells with auxiliary electrodes made of cut-through nickel foil with separators fabricated from perforated rigid PVC. As an electrolyte served a KOH solution (1.19–1.20 g cm^{-3}). In the course of charging, 150% of the theoretical capacity of the electrodes was imparted to them at a current density of 4.4 mA cm^{-2} [8]. The

1070-4272/04/7709-1476 © 2004 MAIK "Nauka/Interperiodica"

discharge was performed at the same current density until the working potential changed abruptly.

Analysis of the corrosion diagram obtained for the system under study (Fig. 1) shows that nickel is etched in a $Ni(NO_3)$ solution with a $NaNO_2$ additive by the electrochemical mechanism with a cathodic control. The rate of nickel dissolution in solutions with addition of sodium nitrite increases by a factor of approximately 5 as compared to that of nickel etching in a $Ni(NO_3)_2$ solution (Fig. 1).

The introduction of a $NaNO_2$ additive into a $Ni(NO_3)_2$ solution changed its oxidation power: the equilibrium potential of the redox system in solution was 1.1 V, and the shift of the potential, 0.13 V (Fig. 2). At first sight, this dependence seems to be anomalous: the product formed in cathodic reduction of nitrates, NO_2^- ions, has a higher oxidation power than the starting reagent, NO_3^-. Such an anomaly can be accounted for only by formation of an electrochemically active substance with a higher oxidation power.

According to [9], the following slow reaction of autocatalysis, which precedes the discharge, occurs in concentrated nitrate solutions:

$$HNO_3 + HNO_2 \rightleftarrows N_2O_4 + H_2O. \quad (1)$$

Nitrites are always present in nitrate solutions because of the partial decomposition of the $Ni(NO_3)_2$ solution at elevated temperatures (100–300°C) [6]:

$$2Ni(NO_3)_2 \rightarrow 2NiO + 4NO_2 + O_2. \quad (2)$$

Nitrogen oxide NO_2 reacts with water [10]:

$$2NO_2 + H_2O \rightarrow HNO_3 + HNO_2. \quad (3)$$

The presence of NO_2^- ions in a $Ni(NO_3)_2$ solution must facilitate formation of the active component N_2O_4 by shifting the equilibrium of reaction (1) to the right. The content of nitrite in the $Ni(NO_3)_2$ solution will be maintained constant, in the case of its low values, by disproportionation of HNO_2 in hot acid solutions [10]:

$$3HNO_2 \rightleftarrows HNO_3 + 2NO + H_2O. \quad (4)$$

Nitrogen(II) oxide being formed by reaction (4) can be oxidized in the presence of oxygen to NO_2 [10], which dimerizes to N_2O_4 [9, 11]. This dimer is a strong oxidizing agent (E^0 = 1.2 V [12]), which can convert basic salts of nickel(II), contained within

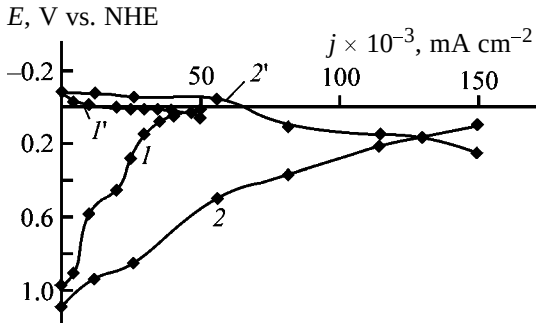

Fig. 1. Corrosion diagram obtained on nickel in a $Ni(NO_3)_2$ solution without an additive and with a $NaNO_2$ additive. T = 80°C, $c_{Ni(II)}$ = 320 g l^{-1}, pH 3; the same for Fig. 2. pores of the MC supports, into NiOOH (E^0 = 0.6–1 V [8]).

The voltammetric curve obtained on Pt in a $Ni(NO_3)_2$ solution at a potential sweep rate of 2 mV s^{-1} shows at potentials of 0.35–0.1 V a region of the limiting current density, which is associated with reduction of NO_3^- ions to NO_2^- (Fig. 2). Upon addition of $NaNO_2$ to a $Ni(NO_3)_2$ solution, the limiting current density increases by a factor of approximately 5 (Fig. 2). This suggests the occurrence of joint reduction of NO_3^- and NO_2^- ions ($E^0_{NO_3^-/NO_2^-}$ = 0.83 V, $E^0_{NO_2^-/NH_4^+}$ = 0.86 V [12]) and increase in the total concentration of the depolarizing agent in solution.

At potential sweep rates of 5–10 mV s^{-1}, the voltammograms show a peak of the cathodic current. A $Ni(NO_3)_2$ solution without additives and with a $NaNO_2$ additive is characterized by a linear dependence of the current density on the square root of the

Table 1. Effect of the solution composition on the intensity of lines in the X-ray diffraction pattern

Solution	Film composition	*I*
$Ni(NO_3)_2$	$Ni(NO_3)_2 \cdot Ni(OH)_2$	100, 58, 50
$Ni(NO_3)_2$ + $NaNO_2$	$Ni(NO_3)_2 \cdot Ni(OH)_2 \cdot \beta$-NiOOH	84, 32

potential sweep rate, $j_p = f(V^{1/2})$. This dependence is extrapolated into the origin of coordinates, which is due to a slowed-down diffusion of the depolarizing agent to the electrode surface [13]. As the potential sweep rate is made faster, films of basic compounds of nickel, which appear when the pH of the near-electrode zone increases, have not enough time to be formed. The process passes into the quasi-reversible region: the dependence $j_p = f(V^{1/2})$ deviates from a linear behavior, which suggests occurrence of a slowed-down chemical reaction preceding the discharge.

The diffusion coefficient was calculated by the Randles–Shevchik equation [13]

$$j_p = 0.446 \frac{n^{3/2} F^{3/2}}{R^{1/2} T^{1/2}} D^{1/2} V^{1/2} c_{ox}^0, \quad (5)$$

where j_p is the peak current density (A cm^{-2}); c_{ox}, oxidant concentration (M); D, diffusion coefficient (cm^2 s^{-1}); V, potential sweep rate (V s^{-1}); n, number of electrons exchanged in an elementary event; T, process temperature (K); F, Faraday number (C mol^{-1}); and R, universal gas constant (J K^{-1} mol^{-1}).

For a $Ni(NO_3)_2$ solution with addition of $NaNO_2$, the diffusion coefficient of the oxidizing agent was 9.4×10^{-5} cm^2 s^{-1}, which exceeds by a factor of 6 its value in the $Ni(NO_3)_2$ solution (1.5×10^{-5} cm^2 s^{-1}). This indicates that the diffusion hindrance to the process is partly lifted in the case of joint reduction of NO_3^- and NO_2^- ions. The rate of the cathodic process in a $Ni(NO_3)_2$ solution with addition of $NaNO_2$ starts to be determined, to a greater extent than that in the $Ni(NO_3)_2$ solution, by the rate of the chemical reaction (1), in which nitrate ions react with nitrite ions.

The presence of a $NaNO_2$ additive in the $Ni(NO_3)_2$ solution makes higher the rate of the cathodic stage and the overall intensity of the process. In addition, impregnation of MC supports in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive leads to formation of higher nickel oxides of general formula $NiO_{1.5–1.6}$ within the pores of the electrode. The high electrochemical activity of the resulting compound is confirmed by the fact that electrodes subjected to a single act of impregnation in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive have a specific discharge capacity of 2.25 mA h cm^{-3} without any preliminary charging. The deep oxidation of nickel in the impregnation of MC supports was favored by the presence in solution of a strong oxidizing agent, formed in disproportionation of NO_2^- ions.

An X-ray diffraction analysis demonstrated (Table 1) that a smaller amount of the solid phase is formed in the presence of NO_2^- ions, compared to a $Ni(NO_3)_2$ solution without additives, as indicated by the lower intensity I of diffraction lines. In this case, higher nickel oxides with a structure of β-NiOOH are contained in the film formed on cathodic areas of nickel in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive.

The optimal conditions of impregnation of MC support in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive were determined taking into account that the equilibrium of reaction (4) must shift to the right as temperature is elevated and pH of the solution decreases [10]. It is inadvisable to raise the impregnation temperature to above 80°C for process reasons. The rate of nickel etching in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive does increase as the acidity of the solution is made higher. In this case, the oxidation state of nickel increases to $NiO_{1.8}$ at pH 1. This can be attributed to a shift of the equilibrium of reaction (4) to the right, which leads to an increase in the content of the oxidizing component N_2O_4 in solution.

The rate of nickel etching in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive grows during the first hour of the process and then decreases somewhat, which is due to the formation of difficultly soluble films of basic nickel compounds on the surface.

The greatest weight gain of the MC support and a fairly high nickel etching rate (0.1 g g^{-1} h^{-1}) were obtained at the following impregnation conditions: $c_{Ni(II)}$ = 300–330 g l^{-1}, c_{NaNO_2} = 5–10 g l^{-1}, pH 3, T = 60–80°C, τ = 1 h.

The results obtained in impregnation of MC supports and the electrical characteristics of the MC NOEs fabricated under the optimal impregnation conditions are listed in Table 2.

The rate of Ni dissolution in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive is by a factor of approximately 4 higher than that in the $Ni(NO_3)_2$ solution (Table 2). In the second cycle of impregnation, when higher nickel oxides are present in pores of the MC supports, the maximum rate of nickel oxidation is observed

Table 2. Parameters of the process and MC NOE after impregnation in a $Ni(NO_3)_2$ solution*

because of the operation of a Ni–NiO_x cell. The subsequent decrease in the oxidation rate in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive is due to partial exhaustion of the oxidizing agent, N_2O_4. The mass of the active substance, necessary for obtaining a specific discharge capacity of 0.3 A h cm^{-3} [2] of MC supports impregnated by the technique developed, is accumulated in 5 cycles of impregnation for 1 h (Table 2). At the same time, only 76% of the required mass is obtained in metal–ceramic supports impregnated under the same conditions in a $Ni(NO_3)_2$ solution without an additive. Up to 61% of the active substance is formed through etching of nickel contained in an MC support in the case of impregnation in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive, and only 35%, in impregnation of MC supports in a $Ni(NO_3)_2$ solution (Table 2). The stronger oxidation of the nickel support in nitrate–nitrite solutions does not impair the mechanical strength of the electrodes obtained, because only 15% of the total amount of nickel is oxidized (up to 20% is acceptable [8]).

The electrochemical activity of $Ni(OH)_2$ obtained from a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive was tested in forming of MC NOE. The utilization coefficient of the active substance in electrodes of this kind is the same as that for electrodes impregnated in a $Ni(NO_3)_2$ solution (Table 2).

When a $NaNO_2$ additive was introduced into a $Ni(NO_3)_2$ solution, the total time of impregnation of MC supports decreased to 5 h, whereas in the case of the "nitrate" technique, the necessary amount of the active substance in an MC support is only accumulated after 18 h of impregnation in a $Ni(NO_3)_2$ solution [3]. As demonstrated by experiments on dissolution of nickel from an MC support, the influence exerted by the $NaNO_2$ additive is preserved during 5 to 6 cycles. Further, the rate of Ni oxidation in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive becomes the same as that in the $Ni(NO_3)_2$ solution.

CONCLUSIONS

(1) The time of impregnation of metal–ceramic supports of nickel oxide electrodes becomes 30–38% shorter, compared to an ordinary nitrate impregnation, upon introduction of 5–10 g l^{-1} $NaNO_2$ into a $Ni(NO_3)_2$ solution. A process for nitrate–nitrite impregnation is suggested.

(2) The effect of the nitrite additive is attributed to disproportionation of nitrites to give an electrochemically active dimer of nitrogen(IV) oxide.

Vyatka State University, Kirov, Russia

Received March 22, 2004

Abstract—Recovery of zinc from solid wastes from production of fluoropolymers is studied. The processes of zinc utilization for preparation of zinc–graphite and zinc–phosphate–poly(tetrafluoroethylene) anticorrosion coatings are developed, including those using mother liquors from production of fluoropolymers.

Composite electrochemical coatings (CECs) are widely used today thanks to valuable properties of their metallic matrix and nonmetallic inclusions. In this work we developed processes for preparation of zinc–graphite and zinc–phosphate–poly(tetrafluoroethylene) (PTFE) coatings, including those using by-products from production of fluoropolymers.

EXPERIMENTAL

In zinc electroplating, large amounts of zinc salts and zinc anodes are expended. In this connection, a process has been developed for utilization of zinc catalyst waste from production of trifluorochloroethylene, which is used in manufacture of fluorocopolymers. Significant contents of zinc and its compounds in the sludge (12 wt % Zn, 10 $ZnCO_3$, 64 ZnO, and 8–14 $ZnCl_2$) allows electrochemical recovery of zinc on a cathode. To prepare the electrolyte (230–300 g l^{-1} $ZnSO_4$), zinc was leached with an estimated amount of sulfuric acid with heating and stirring. After filtration, pH was adjusted to 3–4, and the precipitated iron(III) hydroxide was filtered off.

Zinc was deposited onto aluminum cathodes (S = 0.36–0.45 dm^2) using lead anodes at various current densities and an electrolysis time of 1.5 h. The dependence of the current efficiency (CE) on the current density is parabolic (Fig. 1) with a maximum at I_c = 400–600 A m^{-2}. Visual observations showed that the grey grainy zinc deposit is formed with small dendrites at the edges of the cathode.

In full utilization of by-products from production of fluoropolymers (see scheme), the zinc-containing sludge goes from the storage tank to washing with deionized water and dissolution of salts. After settling, the solution is separated by decantation. The precipitate of Zn, ZnO, and $ZnCO_3$ goes to sulfuric acid dissolution to convert it into $ZnSO_4$. Simultaneously Zn^{2+} is recovered from the decanted $ZnCl_2$ solution by adding NaOH to pH 8–9 at which $Zn(OH)_2$ is formed [1] (pH 10.5 corresponding to dissolution of the precipitate [1] must not be reached). The resulting precipitate of $Zn(OH)_2$ is settled, separated from the solution, washed, and directed to sulfuric acid leaching. The solutions are mixed in a reactor. The resulting electrolyte goes to filtration, analysis, and conditioning. A conditioned solution should contain 70–120 g l^{-1} Zn(II) and 50–100 g l^{-1} sulfuric acid [2]. The electrolyte prepared for use is fed to a galvanic tank, representing a flow-through electrolyzer, where zinc is deposited onto aluminum cathodes using lead anodes. Spent electrolyte is depleted of zinc(II) and enriched with sulfuric acid according to the reaction

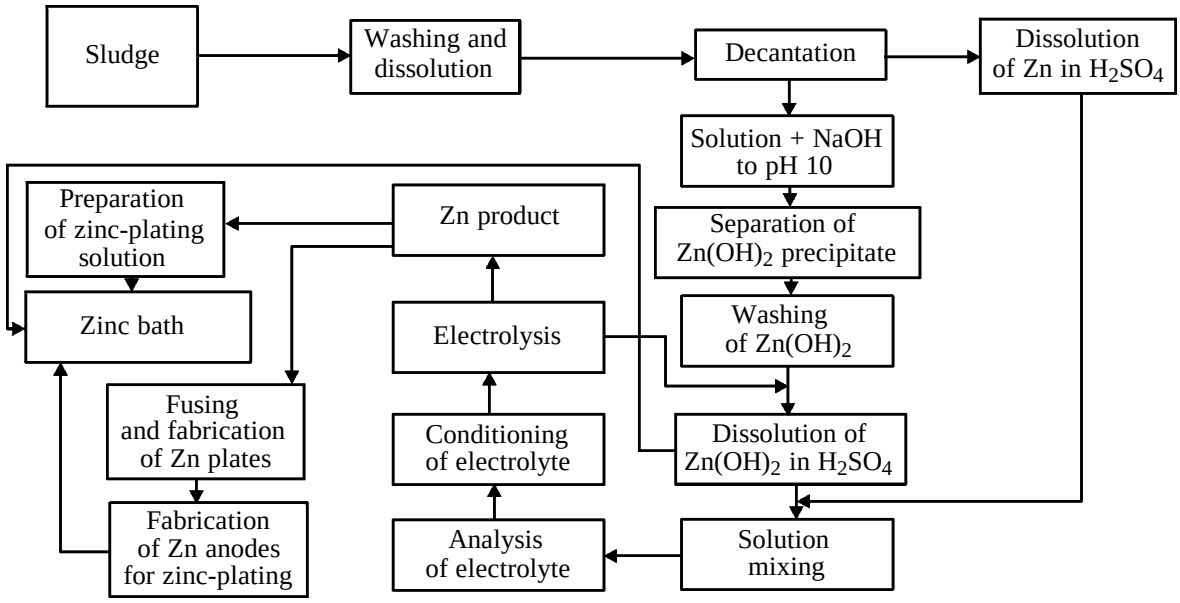
$$ZnSO_4 + H_2O \rightleftarrows Zn + H_2SO_4 + 0.5O_2.$$

The spent electrolyte is conditioned by adding zinc hydroxide.

In the next stage, zinc is mechanically removed from the cathodes and directed to fusing and manufacture of plates, and then, to fabrication of anodes and preparation of the electrolyte fed to a zinc-plating bath. Zinc anodes are also arranged in an electrolytic tank. Also electrochemically reduced zinc can be returned to the trifluorochloroethylene production cycle. Composite electrochemical coatings can be prepared by adding a disperse phase to the zinc electrolyte.

We studied the possibility of preparing Zn–graphite CEC. To prepare a suspension electrolyte we used ammonium chloride zinc solution with a composition

1070-4272/04/7709-1481 © 2004 MAIK "Nauka/Interperiodica"



Flowsheet of utilization of zinc-containing wastes from production of monomer-3.

($g\ l^{-1}$): $ZnCl_2$ 40–120, NH_4Cl 180–220, Likonda A 30–70, Likonda B 3–5; pH 5.4–6.5; T = 15–30°C; i_c = 0.5–3.0 A dm^{-1}. The particle size in colloidal graphite was 0.5–1.0 μm. Coatings were applied onto heat-treated 08 kp steel.

The corrosion resistance of the coatings was studied using the procedure described in [3]. The free corrosion potentials were determined for 08 kp steel and the same steel but zinc-plated or coated with a CEC layer (graphite concentration 5–15 $g\ l^{-1}$). The contacting time of the samples with a drop of an electrolyte (1% NaCl) was 15 min at 20°C. The results are given in Table 1.

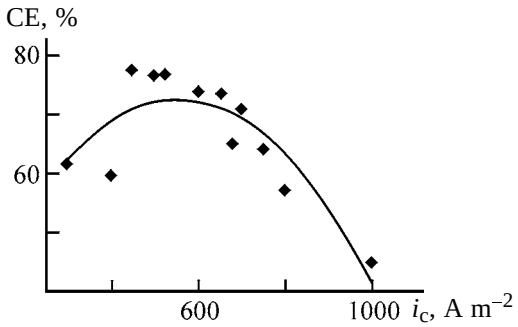


Fig. 1. Current efficiency CE as a function of the current density i_c in the electrolyte prepared from the zinc sludge.

Table 1. Free corrosion potential ε_{cor}

Graphite concentration, $g\ l^{-1}$	08 kp steel	$-\varepsilon_{cor}$, V
0	No coating	0.175
0	Zinc coating 10 μm thick	0.695
5	CEC coating 10 μm thick	0.680
10		0.680
15		0.690

As seen, the corrosion potential of Zn is more negative than that of steel, being close to the standard potential of the zinc electrode (–0.76 V [3]). As expected, inclusions of positively charged graphite particles only slightly shift the potential to the positive direction. Therefore, CEC, like the zinc coating, will be a protector for steel.

The observed insignificant positive shift of the potential is a result of the self-lubricating effect in the coating. Comparison of the emf values of the contacting pairs Zn–Fe, CEC–Fe, and CEC–Zn obtained under similar conditions at τ = 5 min showed the increase in the protective effect:

$$\Delta E = \mathrm{emf}^{CEC} - \mathrm{emf}^{0},$$

where emf^{CEC} is the contact potential in the pairs Fe–CEC or Zn–CEC; and emf^{0}, the contact potential in the pairs Fe–Zn or Zn–Zn.

The measured data are given in Table 2. Increasing graphite concentration in CEC provides a proportional increase in ΔE of the pair CEC (Zn–graphite)–iron. This is also the case for the pair CEC (Zn–graphite)–zinc.

The potential of the CEC–iron couple increases more significantly as compared to CEC–zinc. There-

Table 2. Contact potential of voltaic couples

Graphite concentration, g l^{-1}	Graphite content in CEC, vol %	Voltaic couple	emf $\times 10^3$	$\Delta E \times 10^3$
			V	
0	0	Zn–Fe	609 ± 13	–
0	0	Zn–Zn	0	–
5	21.7	CEC–Fe	626 ± 17	17
		CEC–Zn	15 ± 2	15
10	26.8	CEC–Fe	642 ± 21	33
		CEC–Zn	25 ± 4	25
15	35.6	CEC–Fe	660 ± 12	51
		CEC–Zn	35 ± 0	35

fore, CEC is more efficient protector for steel than zinc. If there is a need in more effective protection, it is recommended to apply a two-layer coating Zn/Zn–graphite.

The corrosion resistance of steel coated with zinc or CEC was studied in a corrosion cell under water vapor at 40°C for 900 h. The area of the samples was 15.2 cm^2; the coating thickness, 5, 8, and 10 μm. We determined the gravimetric corrosion index $K = \Delta m/(\tau S)$ (g h^{-1} cm^{-2}) and counted up the number of corrosion spots per 1 cm^2 of the coating.

Visual examination revealed that the marks of corrosion occur on all the samples studied (as a white thin film and multiple dark areas). However, the number of corrosion spots was smaller in the CEC-coated samples.

Data on the gravimetric corrosion index are presented in Table 3.

The gravimetric corrosion index of zinc-plated steel decreases by half with increasing coating thickness from 5 to 10 μm, but the corrosion rate is independent of the CEC thickness.

Thus, zinc–graphite coating effectively protects steel from corrosion in chloride solutions.

It appeared interesting to change the graphite disperse phase for a more inert, polymeric phase. For this purpose we used a PTFE suspension. It was found that the deposits formed in ammonium chloride zinc-plating solution with PTFE are inhomogeneous and show no corrosion resistance. Therefore, we modified the composition of the polymer-containing zinc coating.

Zinc coatings were obtained on flat and screw samples of 30KhGSA steel. To improve the adhesion, the zinc-plated surface was subjected to additional processing (phosphatization) in the solutions whose compositions are given in Table 4.

The selection criterion of a solution was the specific weight of the phosphate coating. To attain the optimal characteristics, it should be 2–10 g m^{-2}.

Visual examination revealed that the phosphate coatings formed on steel and zinc are quite homogeneous. Light-grey or dark-grey deposits consisting of fine or medium-sized crystals are formed. For differently shaped samples, at the same process time, the specific weight of the phosphate coatings was approximately the same, regardless of the solution composition.

Modification of the phosphate coating with PTFE particles was performed by dipping in a stabilized suspension. The film was held in it for 1 min, after which the samples were air-dried. A phosphate layer with PTFE particles in the pores [phosphate–PTFE composite chemical coating (CCC)] was formed on the surface. With 25% PTFE suspension, we obtained a smooth, transparent CCC, but having insufficient adhesion to the surface. The formation of a metal–CCC friction couple resulted in exfoliation of the coating under a stress below 2 kg cm^{-2}. Presumably, this is due to insufficient penetration of the hydrophobic PTFE particles to the phosphate coating, which is caused by water occurring in the pores. In the subsequent experiments we used 50% aqueous PTFE suspension stabilized with OP-10 stabilizer. In this case, we attained reasonable adhesion, but the coating was inhomogeneous in the composition and thickness. To remove the excess of PTFE, the freshly coated samples were centrifuged for 1 min at 1000 rpm.

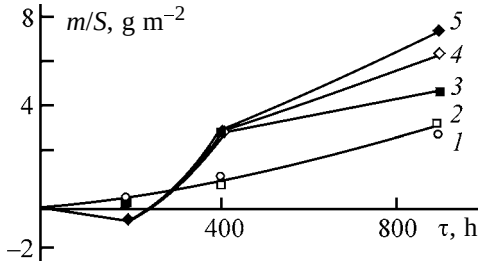

Fig. 2. Specific weight of the samples m/S as a function of the time τ of the corrosion tests in the salt spray cell with natural spraying. Sample shape: (*1, 2*) flat and (*3–5*) screw. Phosphatizing solution no.: (*1, 3, 4*) 1 and (*2, 5*) 2. Phosphatization time (min): (*1–3, 5*) 5 and (*4*) 10.

This operation provided dehydration of the coating, which became more uniform. The specific weight of CCC before centrifugation was 21 g m^{-2}. After centrifugation it became 2–3 times lower. To attain a desired weight, it was sufficient to centrifuge differently shaped samples for no more than 5 min.

Corrosion tests of the three-layered coating were carried out gravimetrically in a salt spray cell with artificial spraying for 200 h and also electrochemically in the galvanostatic mode.

After completion of gravimetric corrosion tests, the samples were analyzed for corrosion products. The results are summarized in Table 5.

Flat sample nos. 1 and 4 and screw sample no. 7 did not pass the corrosion tests after centrifugation for 1 min. Therefore, phosphatization of flat samples and screw joints can be performed with any of the solutions tested at a centrifugation time of no less than 5 min.

The samples were also tested in a cell with natural spraying for 900 h. The weighing results obtained after 200, 400, and 900 h are presented in Fig. 2. It is seen that, after 200 h, the specific weight is slightly decreased in the screw samples phosphatized in solution nos. 1 and 2 for 10 and 5 min, respectively. With increasing testing time to 400 h, the weight of all the samples studied increased, the effect being more pronounced in the screw samples. We observed no corrosion of the support throughout the 900-h test, i.e., the coatings and deposition modes could be recommended for practical use.

Electrochemical corrosion tests were carried our by measuring the free corrosion potential on the surface of 08 kp steel (30 × 50 mm) and also on the coated surfaces (Fig. 3). The corrosion potential of steel in 3% NaCl was found to be –0.3 V. Application of a Zn coating shifts the potential by 0.56 V to the negative region. Phosphatization of the surface shifts the free corrosion potential of the coating by 0.07 V to the positive direction. The subsequent modification of the coating by impregnation with PTFE shifts the potential to 0.62 V.

The results show that the multilayered metal–phosphate–polymer coating effectively protects steel against corrosion.

Finally, we recommend the process for preparation of multilayered coatings involving chemical degreasing, acid activation, zinc-plating, phosphatization, impregnation with PTFE, centrifugation, and drying.

In the dispersion method of PTFE production, large amounts of wastes, including liquid wastes, are

formed. Therefore, we made efforts to utilize them as solvents and surface-active additives in preparation of zinc solutions.

The mother liquor contains F 4D fluoroplastic (>0.1%) or SKF rubber (3.5–5%). The examination by gas–liquid chromatography–mass spectrometry (GC–MS) revealed the presence of oligomers, molecular weight stabilizers, polymerization initiators, and ammonium carboxylates used in the process as emulsifiers.

We performed a series of experiments with the aim to utilize the mother liquors for preparing composite electrochemical coatings containing zinc, fluoroplastic and fluoroelastomer particles, and oligomers. Previously [4, 5] we demonstrated that the stabilizers and initiators of polymerization are nonionic species, which are nonspecifically adsorbed in the cathode and anode spaces and can be used as surfactants increasing the overvoltage of the cathodic process.

To elucidate the contribution of the surfactants to the properties of the zinc–polymer coating, we examined perfluorinated quaternary ammonium salts of amido amines of hexafluoropropylene oxide oligomers (ChAS-T). Data on the electrophoretic mobility of polymeric species are presented in Fig. 4 with an example of PTFE.

Figure 4 shows that, at a PTFE concentration in the electrolyte suspension of 10 g l^{-1}, the electrophoretic potential passes through a maximum at a ChAS-T concentration of 2 g l^{-1}. In the absence of ChAS-T, the ζ potential is lower than the maximal value by a factor of 3.5. As the electrophoretic mobility of the PTFE particles increases in the presence of ChAS-T, their concentration in the coating should increase. It should be expected also that the current efficiency of zinc increases in the presence of PTFE in the cathode space, since PTFE serves as an additional carrier for the $[Zn(NH_3)_2]^{2+}$ ions. Data on the current efficiency of zinc are given in Table 6.

Introduction of PTFE into the solution, indeed, slightly increases the current efficiency of the coating, regardless of the current density used. With increasing PTFE concentration, the current efficiency decreases, i.e., the dependence of the current efficiency on the PTFE concentration is parabolic with a maximum at 5 g l^{-1} PTFE and 1 g l^{-1} ChAS-T.

To conclude, our results show that wastes from production of fluoropolymers can be utilized for preparing corrosion-resistant coatings.

CONCLUSIONS

(1) A process is developed for preparing zinc coatings from zinc-containing sludge from production of trifluorochloroethylene.

(2) A zinc–graphite composite electrochemical coating is prepared from ammonium chloride zinc-plating solution.

(3) A zinc–phosphate–poly(tetrafluoroethylene) three-layered composite coating is prepared, which demonstrated anticorrosion properties.

(4) The mother liquors from production of fluoropolymers were suggested as a disperse phase in preparation of the coatings.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

A Study of Adsorption of Lead, Cadmium, and Zinc Ions on the Glass Surface by Stripping Voltammetry

I. E. Stas', B. P. Shipunov, I. N. Pautova, and Yu. V. Sankina

Altai State University, Barnaul, Russia

Received February 20, 2004

Abstract—Stripping voltammetry was applied to study the influence exerted by the brand of glass on the amount of adsorption of heavy metal ions from solution. The dependence of the amount of the adsorbed ions on their concentration in solution and on the concentration of the supporting electrolyte was analyzed.

The material from which laboratory glassware and vessels for storage of solutions are fabricated may be a source of contamination and a reason for a change in the concentration of solutions they contain [1]. The laboratory glassware is most frequently made of glass. Various brands of glass differ in the composition, chemical resistance, and sorption power [2]. It is known that the glass surface is charged negatively in aqueous solutions because of the surface dissociation of silanol groups [3]. Therefore, glass can adsorb cations.

To determine microscopic amounts of a substance, on the order of 10^{-7} M and less, stripping voltammetry (SVA) is widely used [4–6]. For this technique, changes in the concentration of elements to be determined, which occur as a result of adsorption–desorption processes, are important. This is so because, when working with concentrations of about $n \times 10^{-7}$ M, $n \times 10^{-9}$ mol of a substance is contained in a solution being analyzed (at a sample volume of 10–20 ml), whereas the adsorption of ions may be as high as $n \times 10^{-10}$ mol cm^{-2} [7]. However, no systematic studies of the adsorption of heavy metal ions, conventionally determined by SVA, on the glass surface and no comparative estimates of the adsorption capacity of various brands of glass have been performed.

The aim of this study was to examine the adsorption of lead, cadmium, and zinc ions on the glass surface by SVA at ion concentrations in solution of $n \times 10^{-7}$ M.

EXPERIMENTAL

The study was carried out using a PU-1 polarograph with two-electrode cells fabricated from various brands of glass. A needle-like mercury-film electrode on a silver substrate (S = 0.35 cm^2) served as indicator electrode, and a silver chloride electrode, as reference. Reference and supporting-electrolyte solutions were prepared using demineralized water and chemically pure reagents. As supporting electrolyte served 0.01 M KCl (pH 5.95). Reference solutions of the elements being studied were prepared by the known method [8]. The concentration of the elements to be determined in the solutions under study was $c_{Pb^{2+}} = c_{Cd^{2+}} = 4 \times 10^{-7}$, $c_{Zn^{2+}} = 9 \times 10^{-7}$ M. Dissolved oxygen was removed by bubbling preliminarily purified gaseous nitrogen through a solution. The same flow of nitrogen served to agitate ground glass (adsorbent).

Zinc, lead, and cadmium were accumulated on the electrode at a potential E_e = –1.3 V in the course of 60 s, after which the dissolution current of the resulting amalgam was recorded at a linear potential sweep at a rate of 60 mV s^{-1}. The interval of potential scanning was from –1.3 to 0.1 V. In the course of the experiment, reproducible analytical signals of the elements were recorded, and then a certain amount of ground glass was added and the solution was agitated for 5 min without recording any voltammograms. Then the agitation was terminated and the substances under study was again accumulated on the electrode. After reproducible voltammograms were recorded, a new portion of the adsorbent was introduced and the solution was again agitated for 5 min. The elements to be determined were accumulated and voltammograms were recorded from an unagitated solution, because recording with an agitated solution with an adsorbent yielded unsatisfactory results as a consequence of the irreproducibility of hydrodynamic conditions and adhesion of adsorbent particles to the electrode sur-

face. The extent to which the signal of the element being determined decreased was calculated by the formula

$$I_{rel} = \frac{\Delta I}{I} = \frac{I_0 - I_m}{I_0}, \quad (1)$$

where I_0 is the peak current measured without adsorbent addition, and I_m is the peak current in the presence of an adsorbent in an amount m (g).

The adsorption of ions was calculated by the equation

$$\Gamma = \frac{(c_{in} - c_f)}{1000m}, \quad (2)$$

where Γ is the adsorption (mol g^{-1}); c_{in}, initial concentration of metal ions in the starting solution (M): c_f, concentration of metal ions in solution in the presence of an adsorbent (M); V, solution volume (ml); and m, mass of the adsorbent (g).

The pretreatment of the glass included several stages: (1) glass grinding in an agate mortar and sieving with a mesh of 1.5 mm; (2) boiling of the resulting powders in triple-distilled water, with water replaced several times to remove adsorbed contaminants; and (3) drying of filtered-off glass powder in an oven at 150°C.

Table 2. Current I of anodic peaks of heavy metal ions for various brands of glass. Supporting electrolyte 0.01 M KCl; $c_{Cd^{2+}} = c_{Pb^{2+}} = 4 \times 10^{-7}$, $c_{Zn^{2+}} = 9 \times 10^{-7}$ M; $E_e = -1.3$ V; $t_e = 60$ s; $V_s = 60$ mV s^{-1}

Glass	I, μA		
	Zn^{2+}	Cd^{2+}	Pb^{2+}
Pyrex	14.0 ± 1.0	13.0 ± 1.1	17.0 ± 1.5
MG	14.6 ± 1.2	19.8 ± 2.3	19.0 ± 2.0
ChG no. 23	9.2 ± 0.5	9.6 ± 0.6	10.6 ± 1.0

Molybdenum glass (MG), chemical glass no. 23 (ChG), and Pyrex were used in the study. Table 1 lists the chemical compositions of the glasses. Their chemical resistance decreases in the order Pyrex > MG > ChG. In the same order vary the heat resistance, brittleness, and hardness.

It should be noted that the magnitudes of the analytical signals of the elements to be determined and their relative values depended on the brand of a glass used to fabricate electrochemical cells (Table 2). The weakest signals were recorded in a cell made of ChG, and the strongest signals, in an MG cell. The greatest difference was observed for the signal of cadmium: The peak current decreased twice in going from MG to ChG. The results obtained indicate that the adsorption of heavy metal ions on the glass surface is strong and selective.

To determine the optimal time of agitation of a solution with the adsorbent, we measured the kinetic curves. These curves demonstrate that the analytical signal decreases as a result of adsorption of an element to be determined during the first 5 min. Upon further agitation, the signals of lead and cadmium remained virtually unchanged, and that of zinc changed only slightly. The efficiency of suppression of the analytical signal (anodic current peak) of the metal ions under study was analyzed as a function of the mass of the glass added. The scatter of experimental data in parallel measurements did not exceed 10%.

Figure 1 shows the dependences of the extent to which the peak currents I_{rel} of heavy metal ions simultaneously present in solution decrease on the mass of Pyrex glass added. The analytical signals of the elements under study were suppressed on introducing this brand of glass into solution when its mass increased to 0.20 g. The extent of depression of the signal was the greatest for Pb^{2+} ions and decreased in order $Pb^{2+} > Zn^{2+} > Cd^{2+}$ (Fig. 1). A similar dependence was obtained with ChG. With MG used as adsorbent, the maximum depression of signals was observed even on introducing it into solution in an amount of 0.15 g. The extent to which the signal was

suppressed decreased in the order Zn^{2+} > Pb^{2+} > Cd^{2+}. It was established that the adsorption of the ions under study is the strongest on molybdenum glass and the weakest on Pyrex. The strongest difference was observed in the case of adsorption of Cd^{2+} ions. For example, the signal of cadmium decreased by 23% on introducing 0.24 g of powdered Pyrex and by 63% on introducing an MG powder of the same mass. The difference in the adsorbability of zinc and lead ions is considerably less pronounced. The peak current decreased, depending on the brand of glass, by 70–90% for Zn^{2+} and by 74–85% for Pb^{2+}. Thus, it was established that cadmium ions are adsorbed on the glass surface to the smallest extent, but the selectivity of their adsorption is the highest. Data on how the analytical signals of the elements under study decrease in the presence of powdered glass of various brands are presented in Fig. 2.

It should be noted that the adsorbability of the ions under study on glass powder differs from that on a flat surface. Table 2 shows that the adsorption of the ions is the weakest on the MG surface (peak currents are the highest), whereas the analytical signals of the ions are the lowest in the presence of a powdered glass of this brand, which indicates that their adsorption is the strongest. Possibly, grinding of MG gives rise to a greater number of active centers per unit surface, compared with other brands of glass. At the same time, grinding of different brands of glass may yield particles of unequal sizes because of the difference in hardness between these glasses, which affects the surface area of the adsorbent. This circumstance invites further analysis.

It is known that heavy metal ions are specifically adsorbed on solid surfaces [7]. However, competitive adsorption of Zn^{2+}, Pb^{2+}, and Cd^{2+} ions and indifferent cations of the supporting electrolyte, whose concentration is several orders of magnitude higher than that of heavy metal ions, must be observed in the presence of a large excess of a supporting electrolyte. Our experiments show that raising the concentration of the supporting electrolyte leads to a significant decrease in the adsorption of Zn^{2+}, Pb^{2+}, and Cd^{2+} ions. This is manifested in a decreased depression of the analytical signal. Table 3 illustrates the influence exerted by the concentration of the supporting electrolyte (KCl) on the degree of suppression of the peak current of heavy metal ions in the presence of powdered glass of various brands (m_g = 0.1 g). Table 3 shows that raising the concentration of the supporting electrolyte to 1 M minimizes the adsorption of the ions being determined. In this case, cadmium ions are virtually not adsorbed at all, and the

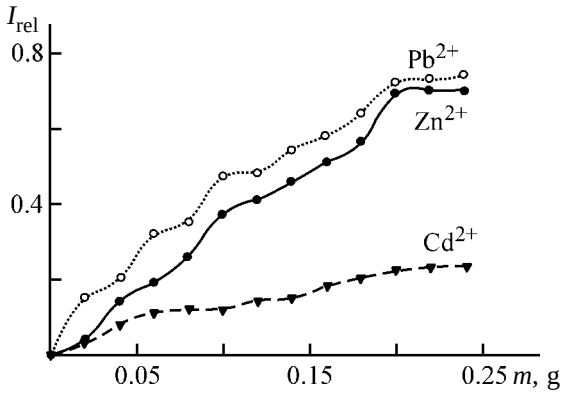

Fig. 1. Extent to which the currents of the anodic peaks of heavy metal ions are suppressred, I_{rel}, vs. the mass m of powdered Pyrex glass. Supporting electrolyte 0.01 M KCl; $c_{Cd^{2+}} = c_{Pb^{2+}} = 4 \times 10^{-7}$, $c_{Zn^{2+}} = 9 \times 10^{-7}$ M; E_e = –1.3 V; t_e = 60 s; V_s = 60 mV s^{-1}; the same for Fig. 2.

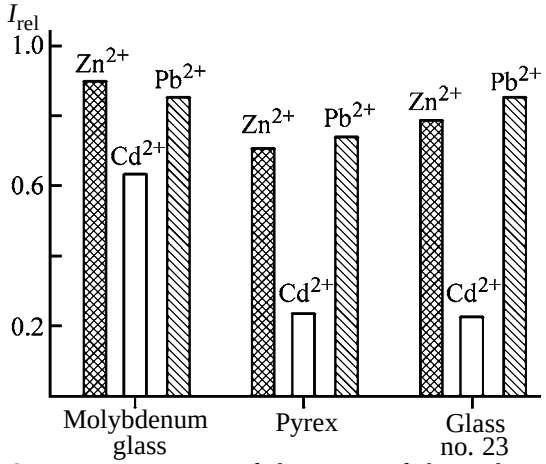

Fig. 2. Maximum extents of depression of the analytical signals I_{rel} of heavy metal ions in the presence of powdered glass of various brands (m_g = 0.24 g).

signals of zinc and lead are suppressed by less than 30%. Irrespective of the glass brand and concentration of the supporting electrolyte, the adsorbability of heavy metal ions decreases in order Pb^{2+} > Zn^{2+} > Cd^{2+}. Zn^{2+} ions are best adsorbed on the ChG surface, and Cd^{2+} ions, on the MG surface. The brand of a glass on whose surface Pb^{2+} ions are adsorbed to the greatest extent changes as the concentration of the supporting electrolyte increases.

The adsorption of ions also depends on the concentration of ions being adsorbed. On determining the concentrations of heavy metal ions before and after adsorption by the SVA method, their adsorption Γ on the surface of various brands of glass was calculated using Eq. (2). The results obtained with Zn^{2+}, Pb^{2+}, and Cd^{2+} at their concentrations in the range 10^{-7}–10^{-5} M are given in Table 4. An increase in the concentration of the ions in solution shifts the adsorption–

desorption equilibrium toward the adsorption process. If the concentration of the ions being adsorbed increases by an order of magnitude, their adsorption becomes 1.5–2 times stronger. At a concentration of the ions in solution on the order of 10^{-5} M, the analytical signals of lead and cadmium are overlapped, which hinders their identification. Therefore, the adsorption of zinc and cadmium ions at their content in solution of 1×10^{-5} M was determined in the absence of lead ions. In this case, the amounts of adsorbed Zn^{2+} and Cd^{2+} ions became closer to each other. The data obtained suggest that the adsorption of heavy metal ions is competitive: adsorption of Pb^{2+} ions hinders adsorption of Cd^{2+} ions. In the absence of lead ions, the adsorption of cadmium ions is considerably stronger.

The study performed demonstrated the importance of adsorption processes at the glass–solution interface in determining low concentrations of ions, which may make incorrect the analytical results. The adsorption of heavy metal ions can be markedly diminished by an appropriate choice of the material of a storage vessel and electrochemical cell and also by use of sufficiently concentrated supporting-electrolyte solutions. To make smaller the determination error, it is recommended to prepare reference solutions in a supporting electrolyte rather than in pure water.

CATALYSIS

Ni–Cu Catalysts on Ceramic Supports

Abstract—The physicochemical and catalytic characteristics of catalysts fabricated on ceramic supports of various types was studied. The influence exerted by addition of cobalt and manganese on the catalytic activity of supported nickel–copper catalysts in high-temperature treatment of off-gases to remove nitrogen oxides was studied.

It is known that catalysts based on noble metals, such as platinum, palladium, ruthenium, rhodium, and iridium, exhibit unique catalytic properties, and primarily polyfunctionality, which is responsible for their wide use in various catalytic processes, especially those intended for treatment of off-gases to remove noxious impurities [1, 2]. However, despite all their advantages, these catalysts are exceedingly expensive and their operation leads to irrecoverable loss of noble metals. In this context, a ceaseless search for catalytic formulations that contain no noble metals is being conducted. One of formulations of this kind is the nickel–copper catalytic system, which is employed in quite a number of catalytic processes, because it also exhibits polyfunctionality [3–7]. There is evidence that nickel–copper systems are close in their catalytic properties to platinum [8].

Among the most widely used methods for fabrication of nickel–copper catalysts are fusion with subsequent leaching, mixing, coprecipitation of components, and deposition of the active component onto a support by impregnation. Since the requirements to a catalyst for treatment of off-gases demand that it should have a high activity, mechanical strength, and stability in operation at high temperatures and space velocities, as well as an invariably low hydraulic resistance, the last of the above-mentioned techniques seems to be the most promising, because the support can satisfy most of these requirements [9].

The aim of this study was to examine supported nickel–copper catalysts with addition of cobalt and manganese, which are fabricated using various supports and are intended for use in detoxication of off-gases and, in particular, for treating these gases to remove nitrogen oxides.

EXPERIMENTAL

Samples were prepared on ceramic supports used in fabrication of catalysts of NIAP-18[1] [10] and NIAP-03-01[2] [11] brands for conversion of natural gas with steam, which show good working characteristics, as well as on a cellular block support. An annular pelletized ceramic support of the NIAP-18 catalysts is fabricated by high-temperature calcination. The support of the NIAP-03-01 catalyst, which is produced by slip casting followed by high-temperature calcination, has an intricate geometric shape with seven apertures [13]. The cellular support is composed of a highly porous cellular material (HPCM) obtained by replication of cellular polymeric matrices (foamed polymers) by deposition of inorganic coatings on these matrices and their subsequent thermal treatment, during which the organic component burns out and the cellular structure of the block support is formed [14]. A structure of this kind has a developed geometric surface and low hydraulic resistance and provides an increased mass-exchange coefficient and the most efficient utilization of the deposited active component [15]. The basic characteristics of the supports used are listed in Table 1.

The catalysts were prepared by impregnation of supports with aqueous solutions of Ni(II), Cu(II), Co(II), and Mn(II) nitrates. As starting substances served $Ni(NO_3)_2 \cdot 6H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, $Co(NO_3)_2 \cdot 6H_2O$, and $Mn(NO_3)_2 \cdot 6H_2O$. The supports were submerged in an impregnating solution and kept there at 6°C for 1.5 h.

The impregnated samples were dried and then calcined at 400°C for 4 h. Depending on the goal of an

experiment, one to four impregnations with intermediate calcination of the samples were carried out. Integrated thermal analysis was made in air on an OD-102 derivatograph with linear heating at a rate of 5 deg min^{-1}. X-ray phase analysis was made on a DRON-2 diffractometer with copper-filtered monochromated radiation. Temperature-programmed reduction (TPR) was done on a thermochromatographic installation with linear heating at a rate of 5 deg min^{-1}. The catalytic activity of the samples was studied in high-temperature reduction of nitrogen oxides contained in off-gases on a flow-through laboratory installation in the temperature range 500–800°C at a space velocity of 15000 h^{-1}. Composition of the working gas (vol %): O_2 3, NO_x 0.10–0.15, CH_4/O_2 = 0.6, N_2 the rest.

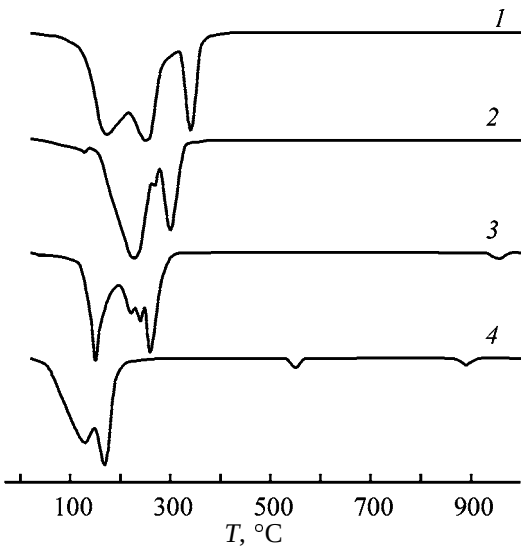

Fig. 1. DTG curves for decomposition of metal nitrates. (*T*) Temperature; the same for Figs. 2 and 4–6. (*1*) $Ni(NO_3)_2 \cdot 6H_2O$, (*2*) $Cu(NO_3)_2 \cdot 3H_2O$, (*3*) $Co(NO_3)_2 \cdot 6H_2O$, and (*4*) $Mn(NO_3)_2 \cdot 6H_2O$.

The temperature at which the impregnated samples were calcined (400°C) was chosen on the basis of data obtained by thermal analysis of the corresponding metals (Fig. 1). Thermolysis of these salts is accompanied by a number of endothermic effects of varied intensity, which correspond to removal of hydration water and stepwise decomposition of a salt. The lowest decomposition temperature is observed for $Mn(NO_3)_2$ (140–170°C). Water is removed in the first stage, which is accompanied by partial decomposition of the salt, and the remaining anhydrous $Mn(NO_3)_2$ decomposes in the second stage [16]. $Cu(NO_3)_2$ decomposes via formation of basic copper nitrate, which then decomposes to the oxide at 300°C [17–19]. The endothermic effect corresponding to $Co(NO_3)_2$ decomposition has a maximum at 260°C. It follows from [17, 18, 20] that thermolysis of $Co(NO_3)_2$ occurs via formation of basic salts. However, Kalinichenko *et al*. [19] did not record any intermediate formation of basic salts and suggested that $Co(NO_3)_2 \cdot 6H_2O$ dehydrates stepwise and then decomposes to the oxide. The highest decomposition temperature is characteristic of $Ni(NO_3)_2$ (340°C). The endothermic effects peaked at 550 and 890°C in the derivatogram of $Mn(NO_3)_2$ and at 960°C in the derivatogram of $Co(NO_3)_2$ can be assigned to conversion of manganese and copper oxides to less oxidized species.

To reveal the essence of the processes that occur when supported catalysts are formed, one-, two, and three-component systems were considered. In order to obtain catalysts with exactly the prescribed content of active components, it was of interest to study the competing capacity of metal nitrates in support impregnation. For this purpose, impregnating solutions of $Ni(NO_3)_2$, $Cu(NO_3)_2$, $Co(NO_3)_2$, and $Mn(NO_3)_2$ with a concentration of 75 g l^{-1} in terms of the metal were prepared. Four impregnations of supports were performed, with intermediate calcinations. The deriva-

tograms of the impregnated supports are shown in Fig. 2. The differential thermogravimetric (DTG) curves of the samples are similar to the DTG curves of the pure salts. It should be noted that the effects corresponding to decomposition of the deposited salts are somewhat broadened and their peaks are shifted to lower temperatures, compared to the pure salts. The presence of effects with characteristic temperatures of 310 and 450°C in the derivatograms of all the salts deposited on the support of the NIAP-18 catalyst can be attributed to stepwise dehydration of $3CaO \cdot Al_2O_3$ $6H_2O$, which is formed via hydration of $CaO \cdot 2Al_2O_3$ in support impregnation.

According to the results of X-ray phase analysis (Table 2), NiO and CuO are products of $Ni(NO_3)_2$ and $Cu(NO_3)_2$ decomposition at 400°C. Cobalt nitrate decomposes to Co_3O_4. The X-ray diffraction patterns of manganese-containing systems show the β-MnO_2 phase and a minor amount Mn_2O_3. The crystallite size L (Å) of the active components present in the oxide form is within 260–310 Å for all the systems studied. In manganese-containing systems, the size of MnO_2 crystallites could not be determined because of the low intensity of the diffraction lines of β-MnO_2 and the superposition of α-Al_2O_3 and β-MnO_2 lines.

The results of chemical analysis of the samples after each impregnation are presented in Fig. 3. It can be seen that the largest amount is contained in the support of NIAP-18, which can be attributed to its higher water absorption (Table 1). The difference in the concentrations of nickel, copper, cobalt, and manganese in this support at equal number of impregnations is slight. However, a similar trend is observed with all the supports tested: The content of cobalt is the greatest, and that of copper, the smallest, at equal number of impregnations. Under identical conditions, the impregnating capacity of nitrates decreases in the order $Co(NO_3)_2$ > $Mn(NO_3)_2$ > $Ni(NO_3)_2$ > $Cu(NO_3)_2$.

The reduction of nickel systems (Fig. 4a) begins at 280–300°C and reaches its maximum rate at 280–320°C. A slight effect in the TPR curves at 450–470°C is presumably due to reduction of nickel oxide more strongly bound to the support. This conclusion is confirmed by the results of [21], where the interaction of such an inert support as α-Al_2O_3 with the nickel component of the catalyst is substantiated. The deposited copper oxide is reduced (Fig. 4b) at lower temperatures (230–270°C), whereas CuO that is more strongly bound to the support is reduced at 330–360°C. The TPR curves of cobalt systems (Fig. 4c) also show two peaks at 360–380 and 480–490°C.

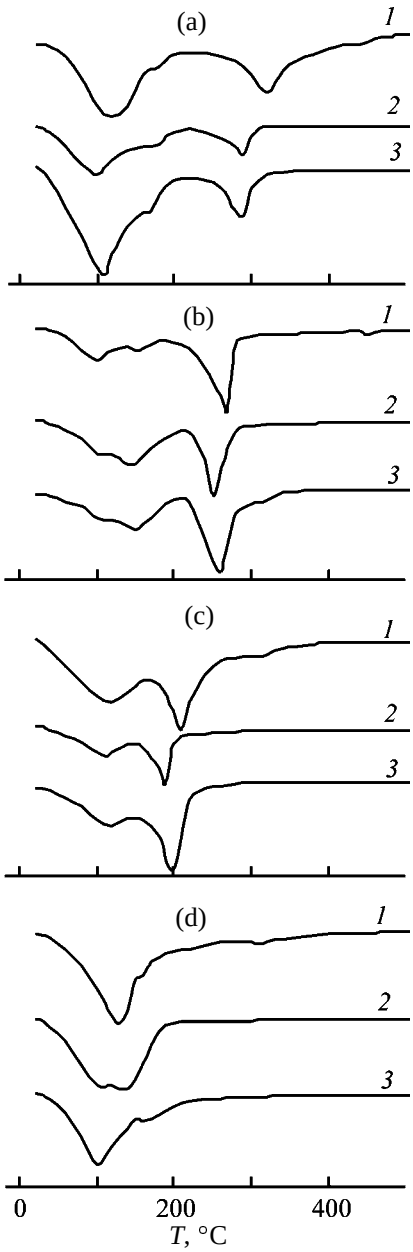

Fig. 2. DTG curves for decomposition of (a) nickel, (b) copper, (c) cobalt, and (d) manganese nitrates deposited on (*1*) NIAP-18, (*2*) NIAP-03-01, and (*3*) HPCM supports.

The activation in manganese systems (Fig. 4d) occurs in several stages, which is due to stepwise reduction of manganese oxides. The activation process can be represented [22] by the reactions

$$2MnO_2 + H_2 = Mn_2O_3 + H_2O, \quad (1)$$

$$3Mn_2O_3 + H_2 = 2Mn_3O_4 + H_2O, \quad (2)$$

$$Mn_3O_4 + H_2 = 3MnO + H_2O. \quad (3)$$

It should be noted that the temperatures of the reduction peaks in the TPR curves for all the active components increase in order HPCM < NIAP-03-01 < NIAP-18. This is presumably due to different strengths of binding of the active components to the supports. For example, the presence of calcium aluminates in the support of NIAP-18 favors stronger binding of the active component. In the support based on HPCM, the reduction temperature is strongly affected by the developed geometric surface of this support, which facilitates supply of reagents and removal of reduction products.

According to the results of X-ray phase analysis, all the oxides deposited on supports are reduced to metals upon heating in a flow of H_2 at 600°C (Table 3). The only exception are manganese-containing systems whose reduction under the given condi-

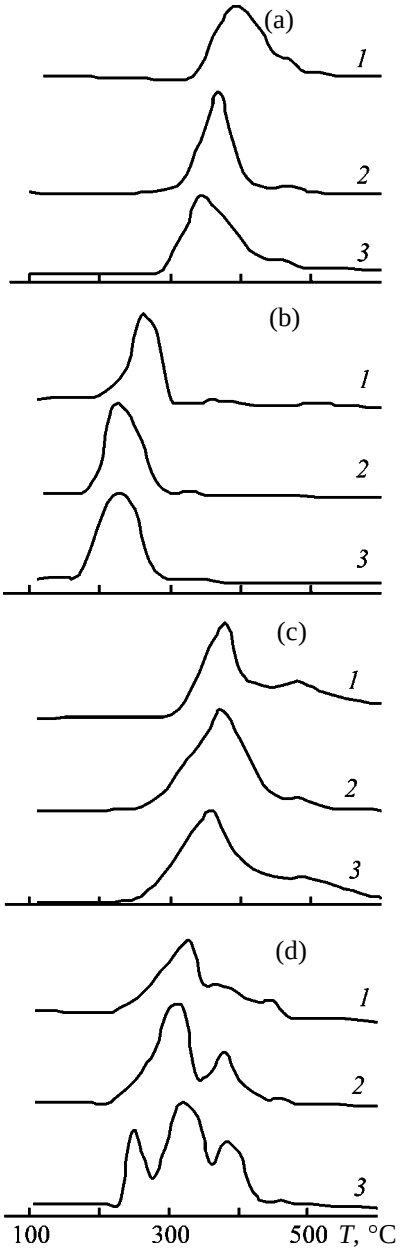

Fig. 4. TPR curves for (a) nickel, (b) copper, (c) cobalt, and (d) manganese systems on the supports studied. Support: (*1*) NIAP-18, (*2*) NIAP-03-01, and (*3*) HPCM; the same for Figs. 5 and 6.

tions ends in the formation of MnO. The calculated unit cell parameters a_0 of the active components are in good agreement with their tabulated values. In contrast to the oxide phases, the sizes of Cu and Ni crystallites formed upon reduction differ by a factor of 2: L = 550–600 Å for copper systems and 220–310 Å for those with nickel. The cobalt systems occupy an intermediate position. The dispersity of Co formed under the given conditions is within 350–390 Å.

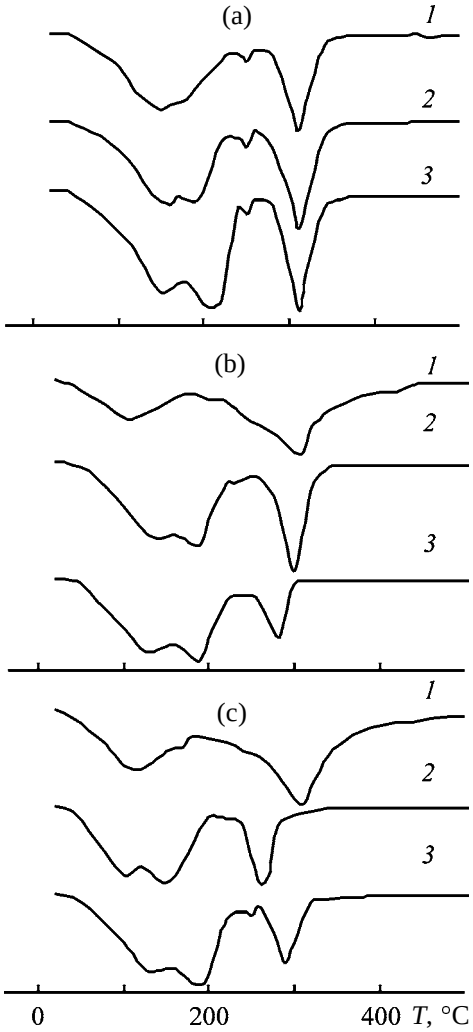

Fig. 5. DTG curves for decomposition of (a) Ni–Cu, (b) Ni–Cu–Co, and (c) Ni–Cu–Mn systems on the supports studied.

Thus, it may be concluded that Cu crystallites show an enhanced tendency toward sintering at high temperatures.

In preparing two-component nickel–copper and three-component nickel–copper–manganese systems, a NiO : CuO ratio of (2.3–3) : 1 was chosen. This ratio ensures the highest activity of the catalyst in high-temperature reduction of nitrogen oxides [23]. The content of cobalt and manganese oxides in samples of three-component catalysts was maintained within the range 1.0–1.5%.

The pattern of decomposition of nickel, copper, cobalt, and manganese nitrates in binary and ternary systems (Fig. 5) is virtually the same as that of decomposition of these nitrates in the single-component systems. The characteristic endothermic peaks are

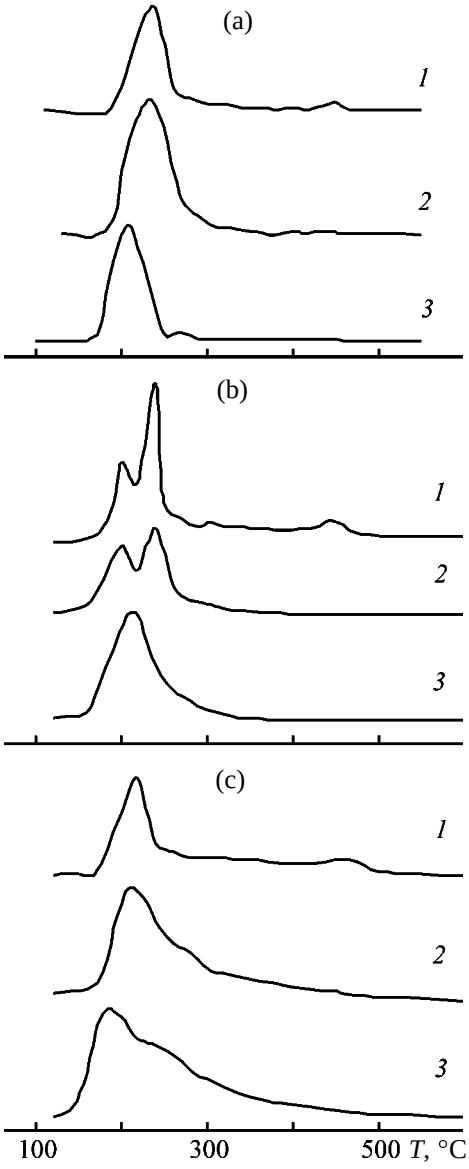

Fig. 6. TPR curves for (a) Ni–Cu, (b) Ni–Cu–Co, and (c) Ni–Cu–Mn systems on the supports studied.

observed at 130–140, 180–190, 250–260, and 280–310°C.

Figure 6 shows the results of TPR of two- and three-component systems in H_2. The difference between the characteristic reduction temperatures of samples prepared on different supports is to be noted. For example, a peak in the TPR curve is observed at 210°C for a nickel–copper sample on HPCM, at 230°C on NIAP-03-01, and at 240°C on NIAP-18 (Fig. 6a). The reduction curves of one-component nickel systems on the same supports show peaks in the range 340–390°C (Fig. 4a), and the reduction of one-component copper systems occurs at 230–260°C (Fig. 4b). Such a difference in the type of reduction of two- and one-component systems is due to the promoting effect of Cu on activation of Ni [24]. The final product of this process in two-component systems is a Ni–Cu solid solution. This conclusion is confirmed by the results of X-ray diffraction studies of reduced two- and three-component systems (Table 4). Ni and Cu phases were recorded in one-component nickel and copper samples. The diffraction lines of Cu are absent in the X-ray diffraction patterns of two- (Ni–Cu) and three-component (Ni–Cu–Mn) systems. For one-component samples, the unit cell parameters a_0 of Ni and Cu are close to the tabulated values. For two- and three-component samples, a_0 differs rather strongly from the tabulated crystal lattice parameters for Ni and Cu. The distortion of a_0 is due to incorporation of Cu atoms into the crystal lattice of Ni, resulting in the formation of a nickel–copper solid solution with $a_{0(Ni–Cu)}$ = 3.541–3.560 Å, which occupies an intermediate position between $a_{0(Ni)}$ = 3.524 and $a_{0(Cu)}$ = 3.615 Å [4]. A similar dependence is observed for unreduced calcined samples. The forming nickel–copper oxide solution has the unit cell parameter $a_{0(NiO–CuO)}$ = 4.186–4.194 Å (Table 4), which also occupies an intermediate position between $a_{0(NiO)}$ = 4.177 and $a_{0(CuO)}$ = 4.684 Å. The presence of a weak effect peaked at 440–450°C in the TPR curve of samples fabricated by impregnation of the NIAP-18 support can be accounted for by decomposition of products of hydration of $CaO \cdot 2Al_2O_3$, formed in the course of impregnation of the support.

A similar run of the TPR curves is observed for nickel–copper–manganese systems (Fig. 6c), but with peaks shifted to lower temperatures. The more complex nature of reduction of nickel–copper–cobalt systems (Fig. 6b) is presumably determined by partial displacement of copper by cobalt from the Ni–Cu solid solution and by separate reduction of free copper oxide to Cu and of the Ni–Cu–Co oxide solid solution. This assumption is confirmed by the results of X-ray diffraction analysis of these systems (Table 4).

The catalytic activity of the samples under study was evaluated by the conversion α of nitrogen oxides. Our studies show that one-component nickel, cobalt, and manganese systems exhibit no noticeable activity up to 800°C, with the conversion not exceeding 20–30%. The temperature at which a 50% conversion of nitrogen oxides on copper samples is reached is very high (730–750°C). This gives no way of recommending these catalysts for use in treatment of off-gases to remove nitrogen oxides. The results obtained in a study of the catalytic activity of nickel–copper,

nickel–copper–cobalt, and nickel–copper–manganese systems are presented in Fig. 7. The catalytic activity tends to grow with increasing process temperature. The introduction of copper into the nickel system results in that the temperature at which 50% conversion is reached decreases to 620–630°C. The size of crystallites of the Ni–Cu solid solution in these samples is 230–330 Å (Table 4). At 680–750°C, the activity of all the samples is virtually the same. The residual content of nitrogen oxides in the purified gas is 0.004–0.005 vol %. These parameters are level with those obtained with an APK-2 palladium catalyst [25, 26], which is widely used in the industry. The strongest difference in the catalytic activity is observed at 550–650°C. The maximum activity is exhibited by nickel–copper–cobalt samples. It is noteworthy that the crystallite size in these samples is 40–150 Å smaller than that in nickel–copper samples. The activities of the nickel–copper and nickel–copper–cobalt systems are virtually the same. Thus, addition of Co makes it possible to enhance somewhat the activity of the nickel–copper catalysts under study, whereas Mn is not an effective promoting additive under the given conditions. The temperature at which 50% conversion is reached with all the samples under study is within the range 570–640°C, which somewhat exceeds the same parameter for the APK-2 catalyst. It was found that the most effective are catalysts on NIAP-18 support, which is due to the greater amount of active components because of its higher water-absorption capacity (Table 1), and on HPCM because of the network-cellular structure of this

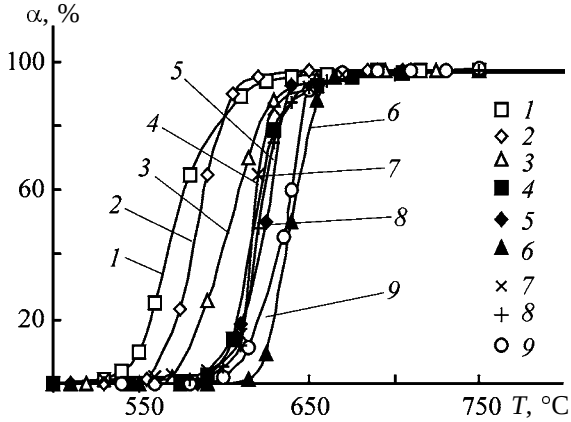

Fig. 7. Conversion α of nitrogen oxides vs. temperature T for various catalyst samples. Catalyst: (*1*) HPCM/NiCuCo, (*2*) NIAP-18/NiCuCo, (*3*) NIAP-03-01/NiCuCo, (*4*) HPCM/NiCuMn, (*5*) NIAP-18/NiCuMn, (6) NIAP-03-01/NiCuMn, (*7*) HPCM/NiCu, (*8*) NIAP-18/NiCu, and (*9*) NIAP-03-01/NiCu.

support, which ensures an increased mass-exchange coefficient and a developed geometric surface making it possible to utilize more efficiently the deposited active component.

Our experimental data were used to develop specifications for NIAP-15-12 and NIAP-15-13 catalysts [27] intended for performing the catalytic high-temperature treatment of off-gases to remove nitrogen oxides, deep oxidation of methane, and catalytic treatment of process gases to remove oxygen. The NIAP-15-12 catalyst is manufactured with NIAP-03-01 support, and NIAP-15-13, with NIAP-18 support.

To charge two reactors for catalytic treatment of gases to remove nitrogen oxides in UKL-7-76 installations at a shop for manufacture of aqueous nitric acid, 2 t of the NIAP-15-13 catalyst and 4 t of the NIAP-15-12 catalyst were fabricated.[3] The NIAP-15-12 catalyst was charged in an amount of 2 t on the grate of the first shelf of the reactor for catalytic treatment.[4] The bed of this catalyst was covered, through a separating Nichrome grid, with a mixture of the NIAP-15-13 and fresh APK-2 catalysts in amounts of 1 and 0.65 t, respectively. The addition of the APK-2 catalyst to the main catalytic mass made it possible to lower the "ignition" temperature of the process.

The tests were carried out at loads on the oxidation reactor of 4900 to 6000 $m^3 h^{-1}$ by ammonia and 45000 to 57000 $m^3 h^{-1}$ by air (recalculated to normal conditions). The CH_4/O_2 ratio was maintained in the range 0.4–0.6 in the course of the catalytic treatment. The content of nitrogen oxides at the inlet of the reactor for catalytic treatment was in the range 0.09–0.11 vol %. The gas temperature at the reactor inlet was 460–480°C. In the course of purification, the temperature increased to become 460–480°C at the outlet. The residual content of nitrogen oxides in gases leaving the reactor was 0.002–0.003 vol % (required ≤0.005 vol %), and that of CO, 0.01–0.04 vol % (required ≤0.10 vol %).

CONCLUSIONS

(1) Distinctive features of catalysts on various supports in the stages of impregnation, calcination, and reduction were revealed.

(2) The impregnating capacity of nitrates in impregnation of ceramic supports decreases in the order $Co(NO_3)_2 > Mn(NO_3)_2 > Ni(NO_3)_2 > Cu(NO_3)_2$.

(3) Cobalt is a promoting additive enhancing the activity of nickel–copper catalysts in treatment of off-gases to remove nitrogen oxides. Addition of manganese has virtually no effect on the catalytic activity.

(4) The industrial tests performed demonstrated high performance of the catalysts in high-temperature treatment of off-gases to remove nitrogen oxides in manufacture of aqueous nitric acid.

Received August 6, 2003; in final form, May 2004

Abstract—The effect of reduced palladium on the thermal stability of the hydrogen and magnesium forms of FIBAN K-1 fibrous sulfonic cation exchanger was studied. The activity of palladium catalyst supported by the H and Mg forms of the cation exchanger in hydrogen oxidation was determined, as influenced by the temperature of treatment of the catalyst with the reaction mixture.

As shown previously [1–5], the thermal stability of sulfonic cation exchangers in the metal forms is higher than that of the H forms. In particular, a mass-spectrometric study (10^{-7} torr) of the physicochemical properties of FIBAN K-1 sulfonic cation exchanger in the alkali metal and alkaline-earth metal forms showed that the Mg form had the highest thermal stability [4, 5]. Hence, the Mg form can be used as a support for metal catalysts of redox reactions.

However, the effects exerted by the metal phase on the thermal stability of sulfonic cation exchanger and by the metal cation on the catalytic activity of the supported metal were not understood. In this work we studied the thermal stability of the H and Mg forms of FIBAN K-1 sulfonic cation exchanger containing reduced palladium, the palladium dispersity in these matrices as influenced by the exchangable cation, and the palladium activity in hydrogen reduction as influenced by the temperature of the treatment of the catalysts with the reaction mixture.

EXPERIMENTAL

The H form of FIBAN K-1 fibrous sulfonic cation exchanger was prepared by bulk radiation grafting of styrene (98%)–divinylbenzene (2%) copolymer to polypropylene staple fiber, followed by sulfonation of the poly(styrene–divinylbenzene) matrix with concentrated H_2SO_4 [6].

Pure Mg form was prepared by washing of a column packed with the H form (exchange capacity 3 mg-equiv g^{-1}) with excess 0.5 M $MgCl_2$ solution until pH of the solution at the outlet became neutral. Then the column was washed with distilled water until the absence of chloride ions in the wash waters and then was dried in air.

To prepare catalysts with 2.5 wt % Pd content, the H or Mg form of the cation exchanger was treated under static conditions with a solution of tetrammine-palladium(II) chloride $[Pd(NH_3)_4]Cl_2$ of a definite concentration at room temperature and pH 8–8.5. The Pd(II) concentration in the solutions before and after ion exchange was measured spectrophotometrically [7]. Then the samples were washed with distilled water until the absence of chloride anions in the wash waters, and the $[Pd(NH_3)_4]^{2+}$ cations were reduced with an aqueous solution of $N_2H_4 \cdot H_2O$ at 40°C for 30 min. After that, the samples were washed again with distilled water to neutral reaction and were dried at room temperature.

To determine the degree of Pd(II) reduction, the ion-exchangeable Pd(II) species were completely washed out from the samples with excess 1 M NaCl and then the palladium concentration in the solution was measured. In the course of reduction, the ion-exchange sites of the catalyst are converted to the H form after removal of $[Pd(NH_3)_4]^{2+}$ cations. To convert these sites into the Mg^{2+} form, the reduced samples were repeatedly treated with a $MgCl_2$ solution, washed, and dried.

X-ray phase analysis of the palladium catalysts was performed on a DRON-1 diffractometer using CuK_α radiation. Thermal gravimetric analysis of the supports and catalysts was performed on an MOM derivatograph (Hungary) in the temperature range 20–450°C.

The mass spectra of the gaseous thermolysis products of the samples were recorded on an MKh 1320

mass spectrometer interfaced with a computer. A ampule with a sample was placed in the inlet system of the mass-spectrometer. The sample was heated with a platinum wire used also as a temperature gage. The mass spectra of thermolysis products were recorded at an ionizing voltage of 50 V and an accelerating voltage of 2.5 kV.

The thermal stability of the initial sulfonic cation exchangers and the palladium catalysts was studied as follows. A weighed portion of a sample was placed in the reactor and heated in an inert gas flow. The temperature at which a $KMnO_4$ solution in a Drechsel vessel arranged at the outlet of the reactor was decolorized with thermolysis products of the sulfonic cation exchanger was recorded.

The dependence of the catalytic activity on the temperature of pretreatment of the catalysts with the reaction mixture was studied in a glass flow reactor with automatic electric heating. A weighed portion of the catalyst (1 g) was placed in the reactor. The height of the catalyst bed was about 40 mm. The sample was heated at 130°C in a helium flow for 1 h. Then the catalyst was treated with a reaction mixture (3 vol % H_2 in air) at a definite temperature from 100 to 250°C for 1 h. The flow rate of the reaction mixture was 250 $cm^3\ min^{-1}$. After that, the reactor was cooled to 100°C. Samples of the gas phase were taken at the reactor outlet in 15–20 min and were analyzed on a Gazokhrom 31 chromatograph. The hydrogen conversion was calculated as the difference between the hydrogen content at the inlet and outlet of the reactor.

The specific activity of Pd A ($cm^3\ g_{Pd}^{-1}\ s^{-1}$) at 100°C was calculated by the equation

$$A = V_{H_2}\,\alpha\, m_{Pd}^{-1} \times 100,$$

where V_{H_2} is the hydrogen feed rate ($cm^3\ g_{cat}^{-1}\ s^{-1}$), α is the hydrogen conversion (vol %), and m_{Pd} is the palladium content in the catalyst ($g_{Pd}\ g_{cat}^{-1}$).

The initial catalytic activity was determined by the above procedure without treatment of the samples with the reaction mixture. The composition of the reaction mixture in all the experiments was the same.

The weight loss Δm on heating of FIBAN K-1 in the H form and 2.Pd/H-K1 catalyst and FIBAN K-1 in the Mg form and 2.5Pd/Mg-K-1 catalyst is plotted in Figs. 1a and 1b, respectively. It should be noted that it is difficult to determine the onset temperature of thermolysis of the sulfonic cation exchanger by TG. Since the thermolysis starts before the H_2O molecules strongly bound by hydrogen bonds with the sulfo

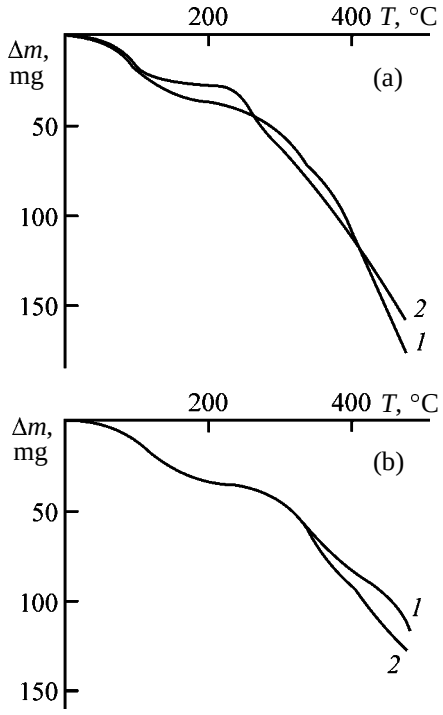

Fig. 1. Weight loss of FIBAN K-1 fibrous sulfonic cation exchangers not containing and containing palladium as a function of temperature. Sample weight 200 mg. Sample: (a) (*1*) H-K-1 and (*2*) 2.5Pd/H-K-1; (b) (*1*) Mg-K-1 and (*2*) 2.5Pd/Mg-K-1; the same for Fig. 2.

groups are completely desorbed from the sample, it is possible to determine only the temperature range of thermolysis of the ion exchanger. Nevertheless, as seen from Fig. 1a, the weight loss of 2.5Pd/H-K-1 in the range 110–215°C is substantially decelerated as compared to the initial H-K-1 resin.

Previous results of TG and chemical analysis show [8–11] that the H form of the sulfonic cation exchanger is desulfonated in air at 150–220°C. Thus, we suggest that the thermal stability of the sulfo groups of the sulfonic cation exchanger in the H form increases after introduction of Pd particles into the sample.

It should be noted that reduced Pd has virtually no effect on the thermal stability of the functional groups of the Mg form of the ion exchanger: the Δm vs. T dependences for Mg-K-1 and 2.5Pd/Mg-K-1 are similar up to 330°C. The differences in the thermal stability are observed only at higher temperatures (Fig. 1b).

It is known that palladium catalyzes a number of redox reactions including thermal oxidative degradation of organic compounds [12]. The fact that the thermal stability of 2.5Pd/Mg-K-1 at temperatures

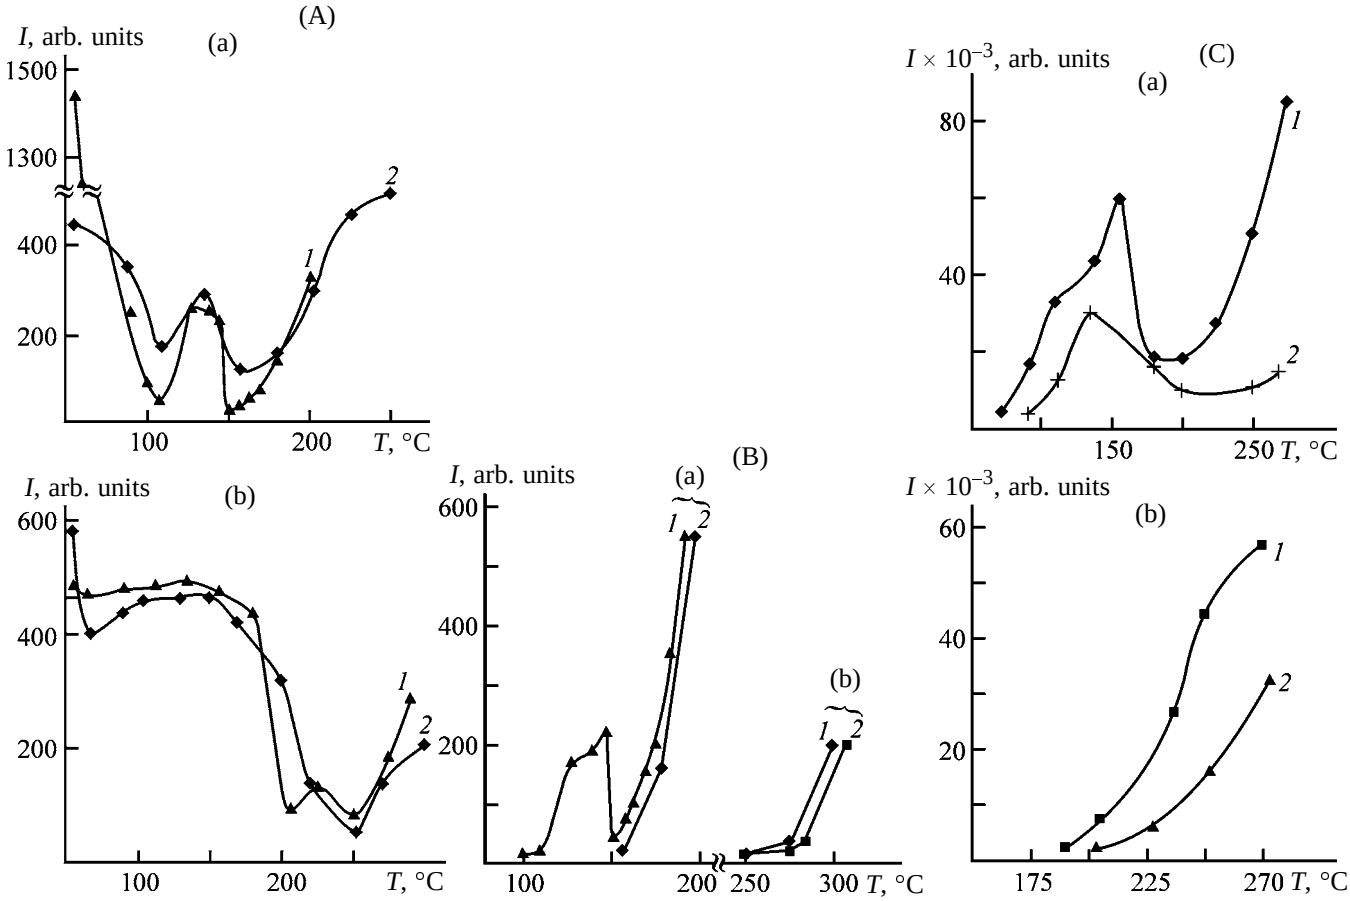

Fig. 2. Relative intensity of ion currents I of (A) H_2O^+, (B) SO_2^+, and (C) hydrocarbon fragments with m/e = 70–150 in the gas phase as a function of temperature T. For explanations, see text.

higher than 330°C is lower than that of Mg-K-1 can be due to the catalytic effect of palladium.

The volatile thermolysis products of H-K-1 and Mg-K-1 and palladium catalysts on their base were studied by mass spectrometry. The results are shown in Figs. 2A–2C. The temperature dependence of the relative content of H_2O^+ ions (m/z = 18) in the gas phase in thermolysis of H-K-1 (Fig. 2Aa, curve *1*) has three distinct sections: up to 110 (desorption of free and weakly bonded water), 110–150 (dehydration and decomposition of dissociated sulfo groups to form water), and above 150°C (thermolysis of nondissociated and associated sulfo groups to form water). The similar dependence was observed for 2.5Pd/H-K-1 (Fig. 2Aa, curve *2*). However, in this case water is liberated in greater amount and the onset temperature of decomposition of nondissociated and associated sulfo groups is higher by approximately 10°C. The onset temperature of thermolysis of dissociated and nondissociated sulfo groups of Mg-K-1 is 200 and 250°C, respectively (Fig. 2Ab, curve *1*). At the same time, the functional groups of 2.5Pd/H-K-1 start to decompose above 250°C (Fig. 2Ab, curve *2*).

The dependences of the intensity of SO_2^+ ion currents (m/z = 64) on the sample temperature (Fig. 2B) show that introduction of reduced Pd into H-K-1 increase the onset temperature of thermolysis of the sulfo groups from 100 to 155°C, whereas desulfonation of Mg-K-1 and 2.5Pd/Mg-K-1 starts at the same temperature (250°C).

Hydrocarbon fragments with m/z = 70–150 (cleavage of the C–C bond) are detected in the gas phase over the H form of the cation exchanger (Fig. 2Ca, curve *1*) at temperatures substantially lower than those in the case of the Mg form (Fig. 2Cb, curve *1*). Introduction of Pd particles enhances the thermal stability of the FIBAN K-1 matrix. The temperature at which hydrocarbon fragments are detected in the gas phase increases by 20–25°C for both 2.5Pd/H-K-1 (Fig. 2Ca, curve *2*) and 2.5Pd/Mg-K-1 (Fig. 2Cb, curve *2*). In addition, the amount of hydrocarbons liberated into

the gas phase on heating of the samples up to 275°C is substantially lower than that on heating of the initial H-K-1 and Mg-K-1 cation exchangers.

Thus, Pd particles enhance the thermal stability of FIBAN K-1 sulfonic cation exchanger in the H and Mg forms at moderate temperatures (up to 200–275°C).

Evaluation of the thermal stability of the ion exchangers by the temperature of decolorization of a $KMnO_4$ solution gave the similar results (see table). Introduction of reduced palladium enhances to a greater extent the thermal stability of the H form of the ion exchanger (growth form 130 to 180°C).

The degree of palladium reduction in 2.5Pd/H-K-1 and 2.5Pd/Mg-K-1 is 98 and 93%, respectively. The initial specific activity of Pd in the Mg form (8.7 $cm^3\ g_{Pd}^{-1}\ s^{-1}$) is substantially higher that in the H form (3.4 $cm^3\ g_{Pd}^{-1}\ s^{-1}$) (see table).

The X-ray pattern of 2.5Pd/H-K-1 contains sharp reflections with *d* 2.234, 1.958, and 1.166 Å assigned to crystals of metallic Pd. In the pattern of 2.5Pd/MgK-1, these reflections are broadened, suggesting lower crystallinity of Pd. Hence, the fact that the catalytic activity of 2.5Pd/Mg-K-1 in oxidation of H_2 is higher than that of 2.5Pd/H-K-1 is probably due to finer dispersity of Pd in 2.5Pd/Mg-K-1.

However, not only the dispersity of Pd but also its electronic state governed by strong metal–support interaction (SMSI) can affect the catalytic activity. As shown previously [13–18], the electronic state of metals supported by inorganic ion exchangers, zeolites, depends on the acid–base properties of the support. Metals on strongly acidic zeolites have low electron density, and metals supported by basic zeolites have excess electronic density. In this work we also studied the influence of the acid–base properties of the sulfonic ion exchangers on the activity of supported palladium catalysts.

These experiments were performed as follows. A sample of reduced catalyst 2.5Pd/H-K-1 was treated with 0.5 M $MgCl_2$ solution until H^+ ions were completely exchanged for Mg^{2+}. Then the sample was thoroughly washed with distilled water to the absence of chloride ions in the wash waters, dried, and heated in a helium flow as described above.

The palladium dispersity in this sample (2.5Pd/Mg-K-1) and in the initial catalyst (2.5Pd/H-K-1) is the same. The specific activity *A* of these catalysts is 5.7 and 3.4 $cm^3\ g_{Pd}^{-1}\ s^{-1}$, respectively (see table). This difference in the catalytic activity can only be due to the different cationic form of the support affecting the electronic state of Pd. Thus, the increased catalytic activity of 2.5Pd/MgK-1 compared to 2.5Pd/H-K-1 is caused not only by finer dispersity of metallic palladium but also by different effective charge of palladium particles (the absence of deficiency of the electron density).

Thermal stability and specific activity *A* in H_2 oxidation of palladium catalysts supported by the H and Mg forms of FIBAN K-1 sulfonic cation exchanger

Sample	Onset temperature of thermolysis, °C	*A*, $cm^3\ g_{Pd}^{-1}\ s^{-1}$
H-K-1	130	–
Mg-K-1	225	–
2.5Pd/H-K-1	180	3.4
2.5Pd/Mg-K-1	250	8.7
2.5Pd/Mg-K-1'	250	5.7

Thus, the effective charge of metal particles supported by both organic and inorganic ion exchangers depends on the acid–base properties (cationic form) of the support. In the case of an organic ion exchanger, the electron density is transferred along the polymeric chain over relatively long distances. This phenomenon, caused by the presence in the polymeric chain of atoms with different electronegativity, was discussed in our previous work [19] when we found that the degree of reduction of $[Pd(NH_3)_4]^{2+}$ cations introduced into sulfonic cation exchanger by the ion-exchange procedure depended on the salt form of the resin.

As seen from Fig. 3, the catalytic activity increases after treatment of the palladium catalysts with the reaction mixture at 100–180°C. Previous EXAFS spectroscopic studies showed that the active metal

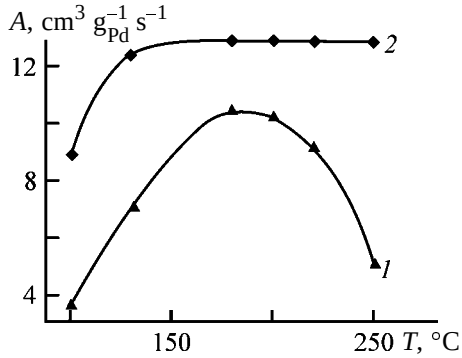

Fig. 3. Activity *A* of (*1*) 2.5Pd/H-K-1 and (*2*) 2.5Pd/Mg-K-1 as a function of temperature *T* of treatment of the catalysts with the reaction mixture.

oxide phase containing Pd–Pd and Pd–O bonds was formed after treatment of a palladium-containing zeolite with a mixture of 1% CO and air at 100–200°C. The activity of the palladium-containing zeolite was found to linearly increase with the ratio of O_2 and CO chemisorbed on the metal surface [21]. The fact that the catalytic activity of 2.5Pd/H-K-1 and 2.5Pd/Mg-K-1 in H_2 oxidation increases after high-temperature treatment of these catalysts with the reaction mixture is probably due to formation on Pd particles of a thin oxide layer which readily chemisorbs oxygen.

The activity of 2.5Pd/Mg-K-1 remains the same and the activity of 2.5Pd/H-K-1 sharply decreases after treatment at higher temperature (from 180 to 250°C). This decrease in the catalytic activity (see table) is clearly due to thermal degradation of the H form, which starts, as shown above, at temperatures higher than 180°C.

CONCLUSIONS

(1) The presence of reduced palladium in the H and Mg forms of FIBAN K-1 fibrous sulfonic cation exchanger enhances their thermal stability. The onset temperature of thermolysis of both the sulfo groups and the hydrocarbon matrix of the H form increases as well as the onset temperature of thermolysis of the hydrocarbon matrix of the Mg form.

(2) The activity of 2.5Pd/Mg-K-1 in H_2 oxidation is higher than that of 2.5Pd/H-K-1. This is due to different dispersities and electronic states of reduced palladium in these matrices.

(3) The catalytic activity in H_2 oxidation increases after treatment of the samples with the reaction mixture at temperatures from 100 to 180°C. After treatment at higher temperature (180–250°C), the activity of the catalyst based on the Mg form remains the same and the activity of the catalysts based on the H form of the ion exchanger sharply decreases owing to thermolysis of the support.

PRODUCTION AND USE OF NEW MATERIALS

New Materials for Sorption of Hydrogen

A. A. Ol'shanskaya, N. A. Sobgaida, and S. S. Popova

Engels Technological Institute, Saratov State Technical University, Engels, Saratov oblast, Russia

Received January 28, 2004

Abstract—The influence of temperature, duration of thermal treatment, and oxidation modes of the aluminum base on processes in which intermetallic compounds LiLaAl are formed by the method of electrochemical cathodic intercalation was studied. The optimal modes of formation of $LiLaAl_{ox}$ compounds exhibiting high sorption capacity for hydrogen were determined.

Hydrogen is a versatile and environmentally clean kind of fuel. One of the most important tasks of hydrogen power engineering is the development of efficient systems for hydrogen storage, because none of the existing systems for hydrogen storage under high pressure, in absorbed state at low temperature, in liquid state, and in the form of metal hydrides and intermetallic compounds satisfies the requirements to H_2 accumulators. In the case of mobile storage systems, the mass content of H_2 should be no less than 6.5 wt %, and the volume content, no less than 63 kg m^{-3} [1, 2]. According to the regulations by the International Energy Agency, an H_2 accumulator should contain no less than 5 wt % H_2 and release it at a temperature not higher than 373 K [1–3].

One of the most promising and presently widely studied ways to solve the above-mentioned problem is accumulation of H_2 by metals and alloys, based on reversible sorption of hydrogen.

The interaction of H_2 with metals or alloys commonly involves the following processes: physical adsorption on the surface, activated absorption in the bulk, diffusion, migration, and molecular absorption (occlusion), to form hydrides [2–10]. The nature of a metal or an alloy and presence of defects in their structure strongly affect the mechanism by which H_2 interacts with the base. Diffusion, or mass transfer, commonly leads to formation of interstitial or substitution solid solutions. The key factor in the sorption process is the defectiveness of the crystal lattice and existence of hydrogen dissolved in it in the form of protons [5–8]. The solubility of H_2 and its sorption by various matrices are affected by such factors as pressure, mechanical treatment of the surface, grain size of the metal, presence of impurity compounds on the metal surface, pH value of the solution, and electrolyte composition [1, 4–13]. Thus, the surface and volume properties of a material that sorbs H_2 and the number of defects (vacant places for hydrogen atoms) can be changed by means of various physicochemical or electrochemical methods.

The aim of this study was to examine the possibility of using the method of cathodic intercalation to obtain reversible H_2 sorbents based on lithium–aluminum–lanthanum (LiAlLa) alloys.

EXPERIMENTAL

Aluminum foil (A 99.95) was conditioned with synthetic corundum of M-28 brand, twice washed with double-distilled water, and dried. Then, electrodes with a geometric working surface area of 1 cm^2 were subjected to a 30-min preliminary thermal treatment (Al_{th}; T_{tr} = 200–500°C, step 50°C). After that, lanthanum was introduced into the Al_{th} matrix by cathodic intercalation from a 0.03 M solution of lanthanum sulfanilate in dimethylformamide (DMF) at the cathodic polarization potential E_{cp} = –2.7 V for 1 h. Then, lithium was introduced into the resulting $LaAl_{th}$ alloy from a 1 M solution of $LiClO_4$ in a mixture of propylene carbonate (PC) and dimethoxyethane (DME) taken in a 1 : 1 volume ratio at E_{cp} = –2.9 V for 1 h. $LiLaAl_{th}$ phases with the highest energy storage capacity are obtained after thermal treatment of the Al base at 400°C. In the next stage, the duration of the thermal treatment was varied: the starting Al samples were treated at 400°C for 15–120 min (step 15 min), and then Al_{th} samples were treated in nonaqueous solutions of La and Li salts as described above. In another set of experiments, the starting Al or Al_{th} was preliminarily oxidized, in order to "develop" the electrode surface, in a

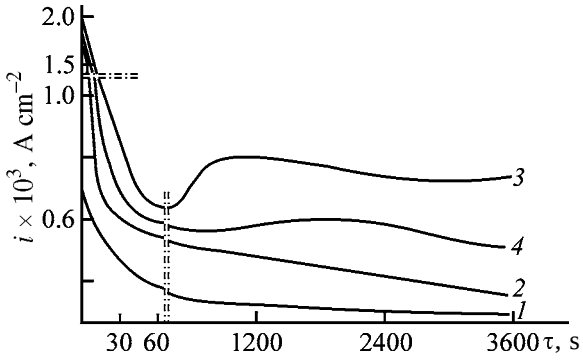

Fig. 1. Potentiostatic curves of cathodic intercalation of La into aluminum matrices from a 0.03 M solution of lanthanum sulfanilate in DMF. E_{cp} = –2.7 V (relative to a nonaqueous silver chloride electrode), 20°C. (*i*) Current density and (τ) time; the same for Figs. 2–5. Matrix: (*1*) Al, (*2*) Al_{th}, (*3*) Al_{ox}, and (*4*) $(Al_{th})_{ox}$.

mixture of acids (g l^{-1}): sulfuric 150, oxalic 30, citric 30, and nicotinic 10, at anode current densities i_a = 10–50 mA cm^{-2} (step 10 mA cm^{-2}) and oxidation time t_{ox} = 10–60 min (step 10 min). As counter electrodes in oxidation served lead plates (S = 10 cm^2). Al plates (S = 10 cm^2) were used in cathodic intercalation of La and Li. As reference electrode was used nonaqueous silver chloride electrode fabricated from an EVL-1 standard silver chloride electrode, placed in a working electrolyte solution, 1 M $LiClO_4$ in PC + DME (1 : 1). LiCl crystals were introduced into the electrolyte in order to eliminate the diffusion potential. The potential of the nonaqueous silver chloride electrode at 20°C is –0.06 V vs. standard silver chloride electrode, 0.163 V vs. hydrogen electrode, and 3.05 V vs. lithium electrode in the working electrolyte solution. In measurements in DMF-based solutions, an intermediate vessel with the working solution was used. The silver chloride electrode Ag^+/Ag is reversible and stable in the aprotic solvents used in the study [14]. In studying the sorption of H_2 by the formed LiLaAl, $LiLaAl_{ox}$, and $LiLa(Al_{th})_{ox}$, HCl and $HClO_4$ solutions with concentrations of 0.375, 0.750, 1.500, and 2.000 wt % were used. The sorption was performed at potentials E_{cp} from –1.0 to –2.2 V (step 0.1 V) in the course of 1 h. All the measurements in this study were carried out at 20°C on a P-5848 potentiostat with a KSP-4 recorder. The diffusion-kinetic parameters of the process were determined using the potentiostatic method. The initial portions of current decay in curves plotted in the coordinates i–$1/\tau^{1/2}$ were analyzed in terms of the Cottrell equation [15] for solid-state diffusion in thin films

$$K_i = \Delta i/\Delta(1/t^{1/2}) = zFc^*D^{1/2}/\pi^{1/2},$$

where K_i is the diffusion-kinetic parameter of intercalation (A s$^{1/2}$ cm^{-2}); i, current density (A cm^{-2}), F = 96 485 C mol^{-1}, Faraday number; and D, diffusion coefficient (cm^2 s$^{1/2}$).

Table 1. Diffusion-kinetic characteristics of intercalation of La into Al matrices and Li into Al–La matrices

Electrode	$K_i \times 10^4$, A s$^{1/2}$ cm^{-2}	$c^0D^{1/2} \times 10^{-9}$, mol cm^{-2} s$^{-1/2}$
LaAl	1.3	2.4
$LaAl_{th}$	2.7	4.9
$LaAl_{ox}$	3.4	6.2
$La(Al_{th})_{ox}$	5.2	9.5
LiLaAl	4.3	7.9
$LiLaAl_{th}$	7.6	13.9
$LiLaAl_{ox}$	9.7	17.8
$LiLa(Al_{th})_{ox}$	1.1	2.0

An oxide film with a structure that is looser than the natural structure can be formed on the surface of Al (A 99.95) by selecting the temperature (200–500°C) and time (15–120 min) of thermal treatment. It was found that the optimal mode is mode I: T_{tr} = 400°C and τ_{tr} = 60 min. Similarly, the optimal mode in the case of anodic oxidation in a mixture of acids (g l^{-1}): sulfuric 150, oxalic 30, citric 30, and nicotinic 10 is mode II: anode current density i_a = 20 mA cm^{-2}, τ_{ox} = 20 min (Fig. 1). Under the chosen conditions of thermal treatment and oxidation, the oxide film on the surface of Al has such properties and structure which, as shown previously [16, 17], favor introduction of La into the Al electrode from a lanthanum sulfanilate solution. Upon the introduction of lanthanum at E_{cp} = –2.7 V and τ_{cp} = 60 min, the negative potential of the formed electrode $(Al_{th})_{ox}La$ was about –2.0 V. The calculated diffusion-kinetic parameters of the processes of successive introduction of La and Li into the starting Al and aluminum and lanthanum–aluminum bases preliminarily formed in modes I and II are listed in Table 1.

Upon introduction of lithium into $La(Al_{th})_{ox}$ electrodes from a 1 M solution of LiCl in PC + DME (1 : 1) in the potentiostatic mode (Fig. 2), a classical curve of cathodic intercalation was obtained [18–20]. Incorporation of La and Li atoms into the structure of thermally treated and oxidized Al (Figs. 1, 2) leads to successive distortion of the initial crystal lattice of Al and to formation of additional vacancies and structural defects and zones with increased diffusion rate.

This must facilitate sorption of H_2 and its accommodation at the forming vacant sites. The study demonstrated that the best parameters of the processes are achieved for the $LiLaAl_{ox}$ electrode (Figs. 1, 2; Table 1).

The quantitative and qualitative pattern of the process of H_2 sorption by preliminarily formed $LiLaAl_{ox}$ electrodes depends on the nature of a hydrogen-containing agent (HCl and $HClO_4$), its concentration, and cathodic polarization potential E_{cp} (Figs. 3, 4).

According to Smith's classification [1, 3], all metals can be divided into three groups by their relation to hydrogen: the first comprises metals, including Li, that form with H_2 saltlike hydrides; the second, metals that form with H_2 chemical compounds with covalent bonding, covalent hydrides (Al); and the third, endo- and exothermic absorbers of hydrogen and, in particular, La [3]. Thus, the metal components of the $LiLaAl_{ox}$ alloy under study belong to different groups and, therefore, the variety of alloys formed with H_2 may be exceedingly wide. In cathodic polarization of the $LiLaAl_{ox}$ electrode in HCl solutions of various concentrations at a potential E_{cp} = –1.1 V, the rate of discharge of H^+ ions grows 3–4-fold when the HCl concentration increases from 0.375 to 1.5 wt % (Fig. 3). Analysis of the influence exerted by the cathode potential on the sorption of H_2 by the $LiLaAl_{ox}$ alloy shows (Fig. 4) that a shift of the potential in the negative direction accelerates saturation of the electrode surface with discharged hydrogen atoms and makes shorter the critical time in which the first nuclei of a new phase are formed, when prerequisites for their growth and formation of a layer of this phase are created. At E_{cp} = –1.1 V, this critical time is not reached under the given experimental conditions; at E_{cp} = –1.5 V, it is as long as 300 s, and at E_{cp} = –2.0 V, as short as 10 s.

In the initial stage of the current decay, the dependence i–$1/\tau^{1/2}$ is represented by straight lines with a sharp bend, which make intercepts i_∞ on the ordinate axis (Fig. 5). This may be due to parallel occurrence of two processes: introduction of H^+ ions into the oxide layer (i_{ox}) and intercalation of discharged hydrogen ions into the metal at the inner M | oxide interface (i_M). The resistance of the protonated oxide layer is so high that, at E_{cp} = –1.1 V, the electrode current remains constant during approximately 18 s. And only after that there appears a concentration gradient of hydrogen ions, dc_{H^+}/dx, that is sufficient for ensuring the diffusion of H^+ ions to the inner interface with the metal of the electrode, where the fol-

Table 2. Constants of hydrogen sorption by $LiLaAl_{ox}$ electrode from a 1.5% HCl solution and $c^0D^{1/2}$ product at different cathodic polarization potentials

$-E_{cp}$, V	$K_i \times 10^3$ (ox), A $s^{1/2}$ cm^{-2}	$c^0D^{1/2} \times 10^8$ (ox), mol cm^{-2} $s^{-1/2}$	$K_i \times 10^3$ (M), A $s^{1/2}$ cm^{-2}	$c^0D^{1/2} \times 10^8$ (M), mol cm^{-2} $s^{-1/2}$
2.2	1.2	2.2	0.25	0.5
2.0	1.4	2.6	0.44	0.8
1.5	1.3	2.4	0.38	0.7
1.1	1.0	1.8	0.42	0.8

lowing exchange reactions are possible:

$$LiAl + xH^+ + xe = AlH_xLi_{1-x} + xLi$$

or

$$La + xH^+ + xe = LaH_x,$$

$$Li + xH^+ + xe = LiH_x.$$

It was established experimentally that hydrogen is sorbed from HCl solutions at a higher rate. In the case of $HClO_4$, adsorption of ClO_4^- anions on the alloy surface hinders introduction of H^+ ions into the structure of the electrode, and an additional energy is required for this process to begin. This is achieved, for example, at a significant shift of the cathodic polarization potential in the negative direction (to + 0.05 V relative to Li^+/Li and –3.0 V relative to the nonaqueous silver chloride electrode).

Raising the concentration of HCl from 0.375 to 1.5 wt % makes the rate of hydrogen intercalation 3–4 times faster. In this case, the electrochemical parameters of the process depend on E_{cp} (Table 2).

CONCLUSIONS

(1) In the chosen modes of preliminary thermal treatment and oxidation, an oxide film whose properties and structure favor cathodic intercalation of La and Li into an aluminum electrode is formed on the Al surface.

(2) Introduction of lithium and lanthanum is accompanied by successive distortion of the crystal lattice by La and Li and formation of additional vacancies and structural defects and of zones with an increased diffusion rate. This facilitates the subsequent sorption of hydrogen and its accommodation in the structure of the LiLaAl alloys formed.

(3) Hydrogen sorption is affected by the solution concentration and nature (anionic composition) of a hydrogen-containing agent.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Mechanism and Products of Thermal Treatment of Slimes Obtained at Treatment of Wastewaters Using Ferroferrihydrosol

D. Budilovskis and L. S. Eshchenko

Gediminis Vilnius Technical University, Vilnius, Lithuania

Received June 15, 2004

Abstract—Phase, dispersion, and chemical compositions of the products of thermal treatment of slimes obtained by treatment of model solutions and industrial wastewaters from electrochemical production using ferroferrihydrosol were studied. The dependence of the phase composition of the slime treatment products as influenced by the content and ratio of heavy metals in wastewaters was evaluated.

One of procedures for reagent treatment of electrochemical production wastewaters is based on the use of ferroferrihydrosol (FFH) [colloidal suspension of iron(II) and iron(III) oxyhydrates] exhibiting high sorption, coagulation, and reduction powers [1]; this agent is prepared by electrochemical treatment of steel cuttings. This treatment procedure provides simultaneous removal of a wide spectrum of heavy metals without separation into certain (e.g., zinc-containing, copper-containing) fractions. The resulting slime, being low-toxic, stable to aggressive media, and enriched with iron, can be a valuable secondary raw material.

Utilization of slimes from electrochemical production is of particular social and economical importance, because solution of this problem can decrease expenses for building of environmentally hazardous treatment fields and save natural resources owing to use of secondary raw materials. The procedures for treatment and utilization of electrochemical production slimes are analyzed in [2–7]. These data show that the slimes can be used as additives in bulk coloring of ceramics and in brick production to improve its strengths and frost resistance, as claydite-like light porous filters, pigments, and pigment-fillers. Published data suggest that the most advisable solution is preparation of inorganic pigments whose properties are not inferior to those of standard commercial samples. This is especially the case for pigments based on the slimes from treatment of the wastewaters with FFH, because the content of iron in them exceeds 50%.

The main stage of the slime treatment to prepare pigments and pigment-fillers is their thermal treatment, which allows formation of hexagonal or cubic structure of iron oxide (α-Fe_2O_3, γ-Fe_2O_3) providing color properties of the products. It should be noted that compounds of chromium, nickel, copper, zinc, and some other metals can strongly affect the chemical and phase transformations proceeding in the course of slime heating and thus the composition and color properties of the resulting products. The data on thermal transformations of iron, chromium, nickel, zinc, and copper compounds in precipitates, e.g., in the slimes from treatment of the electrochemical production wastewaters with FFH, are lacking, which hinders determination of the optimal conditions of their treatment to prepare pigments and pigment-fillers. Hence, in this work we studied the mechanism and products of thermal treatment of precipitates (slimes) obtained by treatment of model solutions and industrial wastewaters using an electrochemically prepared reagent, FFH.

EXPERIMENTAL

In our work we used the precipitates (slimes) from treatment of model solutions and industrial wastewaters from the following plants: Chermet (Grodno, Belarus) and Vilma and Vingis (Vilnius, Lithuania). The thermal transformations in the course of slime heating were studied by differential thermal analysis (DTA) using an OD-102 derivatograph (MOM, Hungary) at a heating rate of 10 deg min^{-1} (0.5–1.0 g

8	600	10	10	10	600	Zn : Cr : Ni : Cu : Fe = 60 : 1 : 1 : 1 : 60	NaOH
9	10	10	600	10	600	Zn : Cr : Ni : Cu : Fe = 1 : 1 : 60 : 1 : 60	NaOH
10	10	10	10	600	600	Zn : Cr : Ni : Cu : Fe = 1 : 1 : 1 : 60 : 60	NaOH
11	10	600	10	10	900	Zn : Cr : Ni : Cu : Fe = 1 : 60 : 1 : 1 : 90	NaOH

sample weight). The phase compositions of the treatment products were determined on a DRON-2 diffractometer with an iron anode. The chemical compositions of the slimes and final products were determined by chemical analysis and X-ray spectral microanalysis. The dispersion composition was studied by transmission and scanning microscopy on a Mini-Magiscan certified automatic pattern analyzer using a Genias 26 program. For scanning microscopy, a layer of gold was preliminarily sputtered over the sample surface.

The compositions of the model solutions prepared from $ZnSO_4$, $NiSO_4$, $CuCl_2$, CrO_3, and tap water containing calcium and magnesium ions (5–7 mg-equiv l^{-1}) are listed in Table 1. Then, an aqueous suspension of FFH and alkaline reagents [NaOH, $Ca(OH)_2$, or degreasing solution] were added to pH 8.1–8.5. In FFH, the crystalline phase is Fe_3O_4, and the Fe(II) : Fe(III) ratio is (1–2) : 10.

The mechanism of FFH treatment of wastewaters containing simultaneously double- and triple-charged cations involves complex physicochemical transformations in the solid phase. The Cu(II), Zn(II), Cr(III), and Ni(II) ions occurring in the wastewaters can be sorbed with FFH and react with iron compounds. As a result, complex spinel-like crystalline structures can appear, as in the case of electrochemical wastewater treatment [8]:

$$n\mathrm{M}^{2+} + (3 - n)\mathrm{Fe}^{2+} + 6\mathrm{OH}^- \rightarrow \mathrm{M}_n\mathrm{Fe}_{3-n}(\mathrm{OH})_6,$$

$$\mathrm{M}_n\mathrm{Fe}_{3-n}(\mathrm{OH})_6 \xrightarrow{+0.5\mathrm{O}_2} \mathrm{M}_n\mathrm{Fe}_{3-n}\mathrm{O}_4 + 3\mathrm{H}_2\mathrm{O}.$$

Thus, the precipitates obtained by wastewater treatment with FFH are mixtures of iron oxyhydrates with sorbed compounds of heavy metals, magnetite Fe_3O_4 and ferrites $M_nFe_{3-n}O_4$. Moreover, formation of amorphous heteropoly compounds with molecular units containing Fe(M)(OH)–O– groups and of hydroxides of metals present in the purified water cannot be ruled out [9]. The chemical compositions of the dried precipitates obtained from the model solutions and industrial wastewaters are listed in Table 2. As seen, the content of metal and water in the precipitates depends on the composition of the initial wastewater.

The XRD analysis of the precipitate samples also showed certain differences in their phase composition. For example, there are no well-crystallized phases in the precipitates obtained by treatment of industrial wastewaters with FFH, whereas the XRD patterns of the samples precipitated from the model solutions exhibit the reflections typical for magnetite at predominant content of chromium or nickel ions in solution or belonging to an unidentified phase at predominant content of copper ions in solutions. It should be noted that the lattice parameters of the magnetite phase are slightly distorted, probably due to the formation of intercalation or substitution solid solutions.

As seen from the data of the transmission and scanning microscopy, the average particle size is 0.36–0.41 μm. As for industrial samples, the average size of the particles prepared at the Chermet and Vilma plants is slightly greater than those formed upon precipitation from the model solutions and wastewaters from the Vingis plant.

Table 2. Composition of precipitates obtained from model solutions and industrial wastewaters

Sample no.	Content of the main components recalculated on metal oxides						
	Fe_2O_3	FeO	Cr_2O_3	ZnO	NiO	CuO	H_2O

10	44.6	0.1	0.6	0.7	0.7	36.2	16.8
11	66.7	4.0	12.1	0.3	0.3	0.3	18.7
Chermet	52.9	–	6.1	3.7	1.9	4.3	19.3
Vilma	39.2	–	4.4	1.9	13.6	5.0	25.8
Vingis	48.5	–	3.3	14.3	0.9	0.8	22.1

* Sample no. corresponds to the number of the model solution treated with FFH.

The DTA curves of the slimes in question are shown in Fig. 1. The endothermic effects in the 100–400°C range are due to the slime dehydration. As seen, the water molecules are liberated stepwise on heating. This process is characterized by two and more endothermic peaks in the DTA curves; the first of them in the 100-210°C range is due to the loss of hydration water, whereas the second peak is due to liberation of crystallization water and probably cleavage of the bridging OH groups. The heating curves of sample nos. 2 and 3 obtained from the model solutions exhibit only two endothermic effects: the first peak with a minimum at 125°C and the second broad peak in the 200–400°C range. These curves correspond to the heating curves of iron(III) oxide hydrates

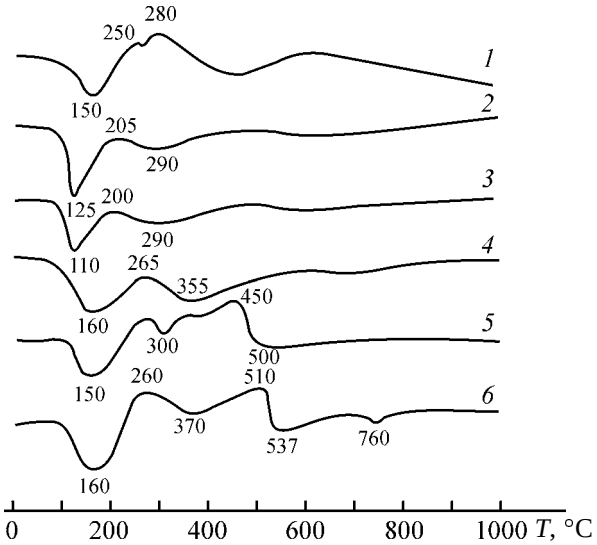

Fig. 1. DTA curves of (*1*) FFH and precipitates obtained from model solution (*2*) no. 4 and (*3*) no. 5 and from industrial wastewaters of the (*4*) Vilma, (*5*) Vingis, and (*6*) Chermet plants. (*T*) Temperature.

[10], in particular, of goethite FeOOH, but differ from the DTA curve of FFH (Fig. 1), which suggests chemical and phase transformations of FFH in the wastewaters. The heating curve of the slime prepared under the operation conditions at the Vilma plant is similar to curves *2* and *3*, but it is characterized by a more diffuse broad endothermic effect, probably due to the differences in the chemical composition, particle size, specific surface area, and thus the amounts of adsorbed and hydration water. The DTA curves of sample nos. 5 and 6 are characterized by ascending baseline in the 320–510°C range, which corresponds to the γ-$Fe_2O_3 \rightarrow \alpha$-$Fe_2O_3$ phase transition. The height and position of the endothermic peak at 510°C are determined by the degree of crystallinity of Fe_2O_3, amount of this phase, and its particle size [5]. It is known that the DTA peaks can shift toward lower temperatures with decreasing particle size.

The phase compositions of the products obtained by the slime thermal treatment at 800°C for 0.5 h was studied by XRD analysis. The XRD data (Figs. 2a, 2b) show that the products of the slime thermal treatment contain at least two crystalline phases, and one of them is hematite Fe_2O_3.

In accordance with the sets of the interplanar spacings, the XRD patterns can be divided in several groups. The first group includes the diffraction patterns with interplanar spacings corresponding to hematite. These patterns are typical for the products of thermal treatment of the samples prepared from model solutions with the concentrations of zinc, chromium, nickel, and copper of 10 mg l^{-1}, and with the concentrations of copper and zinc of 200 mg l^{-1}. The second group includes the patterns typical for Fe_2O_3 and Fe_3O_4 phases. These two crystalline phases are

formed at treatment of both model solutions containing chromium (200 and 600 mg l^{-1}) and copper (600 mg l^{-1}) ions and industrial wastewaters from the Vilma and Chermet plants. With increasing chromium concentration in the wastewater, the content of crystalline phase with the magnetite structure decreases (Fig. 2).

As the zinc concentration in wastewaters from the Vingis plant is high (Table 1), the precipitates heated at 800°C yield a mixture of α-Fe_2O_3 and ZnO, which is confirmed by interplanar spacings *d* 2.476, 2.816, and 2.602 Å in the XRD patterns. Similar phases are obtained from zinc-rich model solutions.

The products of annealing of the precipitates obtained from the model solutions containing 200 mg l^{-1} nickel give the XRD patterns exhibiting the reflections typical for α-Fe_2O_3 and γ-Fe_2O_3. With increasing nickel content to 600 mg l^{-1}, we obtained the precipitates whose thermal treatment yields a phase with a magnetite-type structure. Thus, our experimental data show certain dependence between the content of copper, zinc, and nickel ions in the wastewaters and phase composition of the products of the slime thermal treatment.

The phase transformations proceeding at thermal treatment of the slimes can be described as follows. The α-Fe_2O_3 phase is formed by dehydration of iron(III) oxide hydrates present in the precipitates and subsequent transformations of magnetite according to the following reaction:

$$2FeO \cdot Fe_2O_3 + 0.5O_2 \rightarrow 3\gamma\text{-}Fe_2O_3 \rightarrow 2\alpha\text{-}Fe_2O_3.$$

The other crystalline phases and, in particular, magnetite in the products of thermal treatment probably result from formation of intercalation and substitution solid solutions with participation of metal ions present in the wastewaters. For example, magnetite, as ferrite, has the structure of inverse spinel $Fe^{3+}[Fe^{2+}Fe^{3+}]O_4^{2-}$ with the random distribution of double- and triple-charged cations in the octahedral sites of the lattice containing both cationic and anionic vacancies. It is known that ferrites of several metals also have the inverse spinel structure. These structures can be formed both in treatment of the wastewaters and in annealing of the precipitates. Similarly, ferrite-type spinel can appear at filling of the vacancies in the structure of γ-Fe_2O_3 with crystallographic formula $Fe^{3+}[\square_{1/3}Fe^{3+}_{5/3}]O_4^{2-}$, where $\square$ is the cationic vacancy. In accordance with XRD data, the phases with the γ-Fe_2O_3 structure are formed by thermal treatment of precipitates obtained from the model solutions with

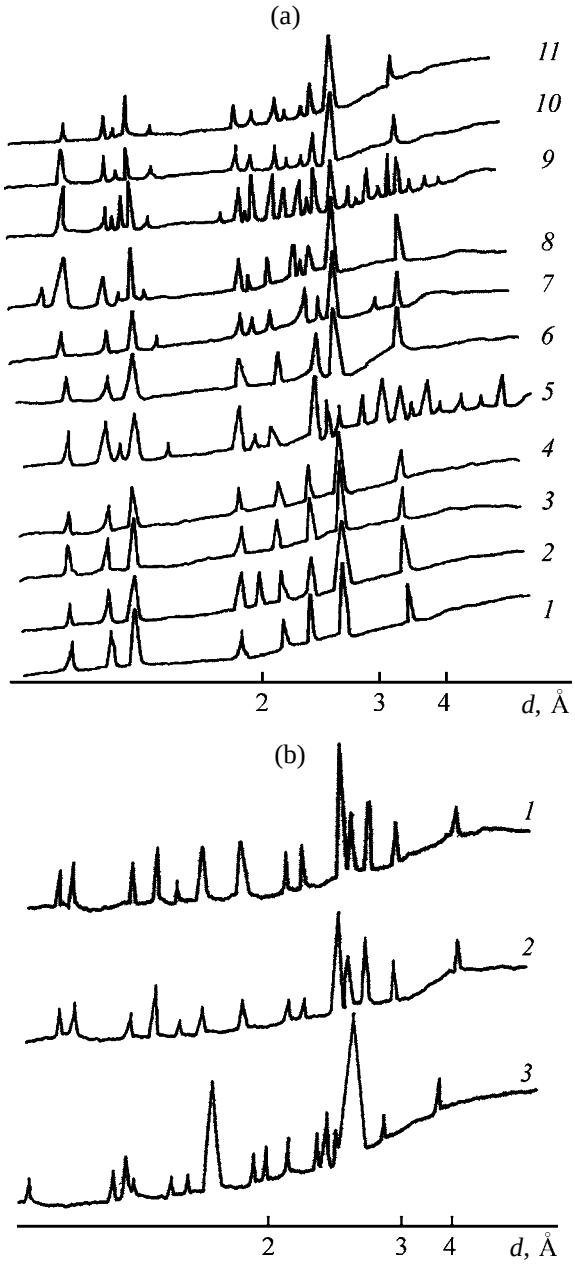

Fig. 2. XRD patterns of the products obtained by thermal treatment of precipitates (a) formed in model solution nos. 1–11 (respective curve numbers) and (b) formed by treatment of wastewaters from the (*1*) Vingis, (*2*) Vilma, and (*3*) Chermet plants. (*d*) Interplanar spacing.

the prevalence of nickel ions. At the same time, chromium ions promote formation of spinel with the magnetite structure. The effect of zinc and copper ions on the composition of the resulting crystalline phases is quite different from that of nickel and chromium. At a content of these metal in model solutions of 200 mg l^{-1}, after annealing we obtained only crystalline α-Fe_2O_3, and no spinels of magnetite of γ-Fe_2O_3

types were found. With increasing content of zinc in the model wastewater, zinc oxide appeared in the annealing products, whereas in the case of copper, the spinel-type crystalline phase was formed.

Similar phase transformations as influenced by the content of heavy metals in the wastewaters were detected in slimes obtained by FFH treatment at the Chermet, Vilma, and Vingis plants. The effect of chromium and nickel on the phase transformations in the course of thermal treatment becomes pronounced only at their high content in the wastewaters. For example, at 14.3% zinc content in the slime from the Vingis plant, the annealing product contains hematite and zinc oxide, whereas heating of the slimes obtained from the Chermet and Vilma plants at 800°C yields α-ferrite and ferrite with magnetite structure, due to high concentrations of nickel and chromium in the wastewaters.

The scanning microscopy data showed that the average particle size in the samples after heating at 800°C is similar to the average particle size of the samples dried at 105°C. For example, the average particle sizes of the precipitate obtained from model solution no. 11 (Table 1) and of the product of its thermal treatment is 0.36–0.37 μm. At the same time, the granulometric composition of the product changes as compared to the initial material at the expense of the finest fraction at thermal treatment.

CONCLUSION

The phase, dispersion, and chemical compositions of slimes obtained by treatment of model solutions and industrial wastewaters using FFH and of their annealing products were studied. Based on these dada, the dependence of the phase composition of the slime treatment products as influenced by the content of chromium, nickel, zinc, and copper was evaluated.

Abstract—Adsorption of butanol under static conditions on two types of activated charcoals, prepared from birch and a blend of oak and beech, was studied. The adsorption on birch charcoal was carried out under dynamic conditions. The limiting stage of the process was determined. The dependence of the purification efficiency on the fractional composition of activated charcoal and the feed rate of the contaminated solution was studied. The regeneration of birch charcoal with steam and by calcination was performed.

The efficient nature management is largely associated with recovery of individual components from wastes formed in reprocessing of the initial raw materials, in particular, from wastewater. This allows a decrease in consumption of natural resources and in detrimental impact on water objects.

Lower alcohols are widely used in industry and get into wastewater. Butanol, isobutanol, and *tert*-butanol contaminate paint-and-varnish industrial wastewater; ethanol and butanol, wastewater from production of photographic films and ascorbic acid, and also from other branches of organic synthesis and food industry [1].

During the main processes, alcohols form mixtures with water and should be separated before water recycling or discharge. In traditional processes, such as extraction or special distillation procedures (azeotropic, extractive, etc.), as a rule, alcohols are recovered from aqueous solutions at their high content and water purification is incomplete. Therefore, it is necessary to use additional purification procedures, one of which is adsorption [2, 3].

High cost of sorbents often hampers wide industrial use of adsorption. Therefore, it would be appropriate to use adsorbents produced from industrial wastes, such as activated charcoals prepared from a blend of oak and beech or from birch, produced by the ANITIM Joint-Stock Company.[1]

Previous studies [4] showed the advantages of birch activated charcoal. It has lower moisture content, greater pore volume, and high sorption capacity with respect to iodine. However, further experiments showed that birch charcoal has lower mechanical strength than charcoal produced from a blend of oak and beech. First we studied recovery of butanol from water on the above nonfractionated activated charcoals.

As a result of studying adsorption under static conditions, we obtained isotherms of adsorption of butanol on activated charcoals (Fig. 1). As seen from Fig. 1, the sorption curves in the range of low concentrations of butanol (less than 0.5 wt %) coincide, but with increasing concentration of butanol in water the sorption capacity of birch charcoal becomes significantly greater than that of mixed charcoal. Thus, at the equilibrium concentration of alcohol of 7.5 wt %, the sorption capacity of birch charcoal is 0.84 g g^{-1}, which is greater than that of mixed charcoal by a factor of 2 (0.42 g g^{-1}).

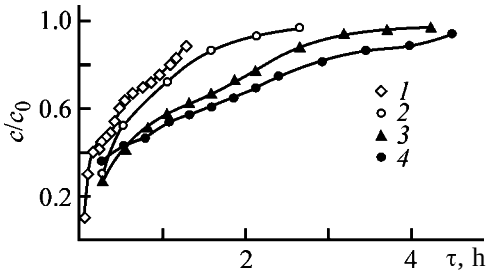

Fig. 2. Kinetics of adsorption under dynamic conditions. (c, c_0) Current and initial concentrations, respectively; (τ) time. Concentration of butanol in the initial solution (mg l^{-1}): (*1*) 4000, (*2*) 1500, (*3*) 800, and (*4*) 600.

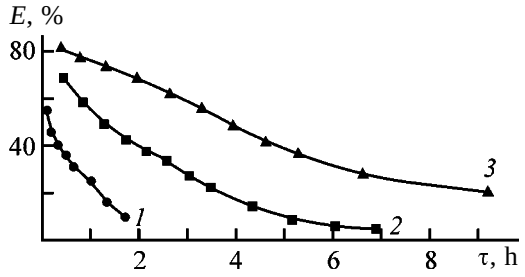

Fig. 3. Purification efficiency E as a function of time τ at various feed velocities of contaminated solution at c_0 = 800 mg l^{-1}. Feed velocity, m h^{-1}: (*1*) 4, (*2*) 2, and (*3*) 1.

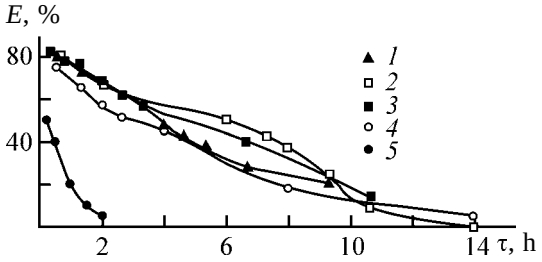

Fig. 4. Purification efficiency E as a function of time τ with charcoal of various fractional composition at c_0 = 800 mg l^{-1}. (*1*) Nonfractionated charcoal; fractional composition, d_{eff} (mm): (*2*) <1.5, (*3*) 1.5–3, (*4*) 3–6, and (*5*) >6.

We studied the dynamics and kinetics of adsorption for only birch charcoal, since studying the main characteristics of charcoals and sorption isotherms revealed apparent advantages of birch charcoal. The kinetic data (Fig. 2) show that the highest purification efficiency, i.e., the lowest ratio of the butanol concentration at the outlet from the adsorber c to its initial concentration c_0 is reached at low initial concentrations of butanol. With increasing concentration of butanol, the c/c_0 ratio increases and the purification efficiency decreases.

We studied the influence of the solution feed velocity on adsorption. We found that the purification efficiency noticeably increases with decreasing feed velocity of the contaminated solution, irrespective of the initial concentration of alcohol. The dependence of the purification efficiency on the feed velocity of the contaminated solution (Fig. 3) shows that, after 2 h of operation of activated charcoal at a feed velocity of the contaminated solution of 1 m h^{-1}, the purification efficiency is approximately 70%; at a feed velocity of 2 m h^{-1}, approximately 40%; and at a feed velocity of 4 m h^{-1}, 4–5%.

As a rule, in adsorption purification the charcoal with a definite fractional composition is used [5]; therefore, birch charcoal was subjected to sizing. The study of the dependences of the purification efficiency on time and fractional composition showed that the highest purification efficiency is reached with the fraction with d_{eff} < 1.5 mm (Fig. 4). However, this fraction has very high hydrodynamic resistance, which makes it unsuitable for adsorption purification. As for the other fractions, the purification efficiency decreases in the order: d_{eff} = 1.5–3 mm, nonfractionated charcoal, d_{eff} = 3–6 mm, and d_{eff} > 6 mm. The increase in the purification efficiency with decreasing grain size of adsorbent can be explained by the limiting role of the inner diffusion [6].

The dependence of the hydraulic resistance of the adsorption bed (lost head expressed in kPa) on the fractional composition is shown in Fig. 5. It is seen that the fraction with d_{eff} = 3–6 mm has the lowest hydraulic resistance, and the fraction with d_{eff} < 1.5 mm, the highest hydraulic resistance. In this case, with increasing velocity of solution filtration through the sorbent bed variation of resistance is insignificant for the coarsest fraction and is maximal for the finest fraction.

Purification on activated charcoals necessarily involves regeneration of the adsorbent with the aim to recover the adsorbed component (in regenerative purification) and reuse the sorbent [6]. Initially the regeneration was carried out by steam. The influence of regenerate volume on the alcohol concentration in the regenerate at various alcohol concentrations in the solution to be purified was established. The content of alcohol in the regenerate increases by a factor of no more than 3 in comparison with the initial solution, and the alcohol concentration in the regenerate decreases with increasing volume of steam condensate.

Regeneration with steam requires high power consumption for production of steam, and the alcohol concentration in the regenerate does not exceed 2 g l^{-1}, which makes it unsuitable for further use. We also attempted to regenerate activated charcoal by calcina-

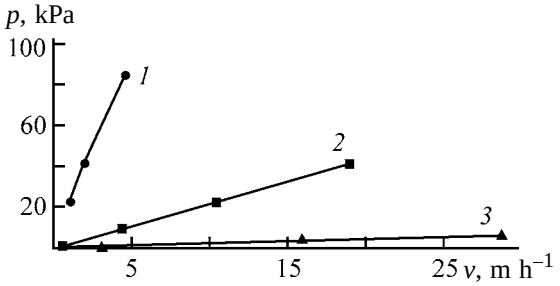

Fig. 5. Hydraulic resistance of charcoal bed p (H = 35 cm) as a function of solution velocity v for various fractional compositions. Fractional composition d_{eff} (mm): (*1*) <1.5, (*2*) 1.5–3, and (*3*) 3–6.

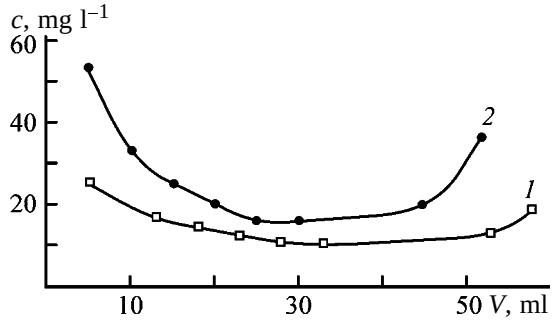

Fig. 6. Alcohol concentration c in the regenerate as a function of regenerate volume V in thermal regeneration of charcoal. c_0 (mg l^{-1}): (*1*) 800 and (*2*) 1500.

tion. The results of thermal regeneration of activated charcoal at 100–300°C at various initial concentrations of alcohol are presented in Fig. 6. For c_0 = 1500 mg l^{-1}, the alcohol concentration in the regenerate reached 53 g l^{-1}, and for c_0 = 800 mg l^{-1}, 25 g l^{-1}. The highest content of alcohol in the regenerate is reached at the beginning of charcoal calcination and at the process completion. This can be explained by the fact that, at the beginning of regeneration, water and alcohol molecules weakly bonded by sorption forces vaporize at approximately 100°C. By process completion at 300°C, molecules tightly bonded by adsorption interactions are released.

To compare the adsorption capacities of freshly prepared and regenerated charcoals, we studied adsorption of butanol on regenerated birch charcoal. The adsorption powers of freshly prepared and regenerated birch charcoals are shown in Fig. 6. As seen, the adsorption power of charcoal does not noticeably decrease upon regeneration.

CONCLUSIONS

(1) At equilibrium concentration of alcohol of 7.5 wt % the sorption capacity of birch charcoal is 0.84 g g^{-1}, which is greater by a factor of 2 than that of the charcoal prepared from a blend of oak and beech (0.42 g g^{-1}).

(2) The dependence of the purification efficiency on the solution feed velocity was elucidated: with increasing solution feed velocity from 1 to 4 m h^{-1}, the purification efficiency decreases from 70 to 4–5%.

(3) The purification efficiency decreases with increasing equivalent diameter of activated charcoal grains from d_{eff} < 1.5 to d_{eff} > 6 mm. The limiting stage of adsorption is inner diffusion.

(4) At 100–300°C, the alcohol concentration in the regenerate reaches 53 g l^{-1} at c_0 = 1500 mg l^{-1} and 25 g l^{-1} at c_0 = 800 mg l^{-1}. In this case, the adsorption characteristics of charcoal in its subsequent use do not appreciably vary.

Abstract—Thermolysis of hexachlorocyclohexane in a flow-through packed system in an inert gas atmosphere was studied.

The aim of the study is to analyze experimentally the thermolysis of hexachlorocyclohexane in a laboratory flow-through packed reactor, elucidate the mechanism of the process, and determine its kinetic parameters using a macrokinetic model that allows modification of the process from a laboratory reactor to an industrial installation.

EXPERIMENTAL

The thermal decomposition was studied under dynamic conditions by passing hexachlorocyclohexane through a heated U-shaped reactor made of Pyrex glass. A glass packing with a grain size of 0.4–0.63 mm served to increase the reaction surface area. The study was performed on a Tsvet-530 chromatograph. A heated reactor in a thermally insulated jacket was placed in the thermostat of the chromatograph, with the reactor inlet connected directly to the evaporator. Four packed reactors with lengths of 0.107, 0.215, 0.322, and 0.427 m were used.

The temperature mode of the reactor was controlled with a quartz furnace. The temperature was set and maintained in the range from 250 to 500°C, with a step of 50°C, using a Proterm-100 microprocessor temperature controller. The temperature fluctuated around the preset value in the course of thermostating within ±1°C.

A sample introduced was mixed and diluted with an inert gas (N_2) in the evaporator of the chromatograph. The carrier gas ensured that the reaction mixture flowed within the heated zone of the reactor in the plug mode. In the experimental regard, the study performed is similar to a pulsed version of the chromatographic method.

The results of a chromatographic–mass-spectrometric analysis (MD800/GC8060 instrument, HP 5MS column 60 m long and 0.32 mm in diameter) were used to identify the composition of products formed in thermolysis of hexachlorocyclohexane that was performed preliminarily under static conditions. Five components were recorded under the chosen chromatographic conditions: 1,2,4-trichlorobenzene, 1,2,4,5-tetrachlorobenzene, 1,2,3,4,5-pentachlorocyclohexene, and two of the possible eight stereoisomers of hexachlorocyclohexane, α-hexachlorocyclohexane and γ-hexachlorocyclohexane.

The starting substances and the thermolysis products were analyzed under the following chromatographic conditions: 100 × 0.4-cm glass column packed with Inerton AW-DMCS with grain size of 0.25–0.315 mm (impregnated with 5% SE-30); column temperature in the temperature-programmed mode varied from 100 (2 min) to 210°C (5 min) at a rate of 10 deg min^{-1}; temperature of the evaporator and detector (FID) 200°C; flow rate of the carrier gas (nitrogen) in the reactor and in the column 20 ml min^{-1}; flow rates of hydrogen and air equal to 26 and 300 ml min^{-1}, respectively; motion velocity of the chart paper 600 mm h^{-1}. The substance was introduced in the form of a melt on the needle of a microsyringe directly into the evaporator.

To construct a calibration dependence for the substrate, hexachlorocyclohexane solutions in acetone were prepared. The calibration was made under conditions similar to those in which products formed in thermal decomposition of hexachlorocyclohexane were analyzed, with the volume of a sample introduced equal to 1 μl.

The experimental dependences of the composition (mole fraction) of hexachlorocyclohexane and conver-

sion products on the reactor length are shown in Fig. 1.

For a steady-state mode of operation of a plug reactor, the material balance for ith component along a reactor length element dz can be represented as [1, 2]

$$d\dot{n}_i/dz = S_a\tilde{r}_i, \qquad (1)$$

where S_a is the surface area of the packing and reactor walls per unit reactor length; $\dot{n}_i$, component flow rate; and $\tilde{r}_i$, component velocities for the overall reaction.

The kinetic scheme of the process is constituted by J concurrent reactions:

$$0 = \sum_{i=1}^{I} \nu_{ji} A_i, \qquad 1 \le j \le J, \qquad (2)$$

where the stoichiometric coefficients of ith component in jth reaction $\nu_{ji} < 0$ for reactants and $\nu_{ji} > 0$ for reaction product, and I is number of components (substances) appearing in the equations of the chemical reactions [Eqs. (2)].

Instead of the component flow rates $\dot{n}_i$ (mol s^{-1}), reaction flow variables $\dot{\xi}_j$ (mol s^{-1}), reaction flow rates, can be used. In this case, the component flow rates $\dot{n}_i$ are expressed in terms of the reaction flow rates as

$$\dot{n}_i = \dot{n}_{0i} + \sum_{j=1}^{J} \nu_{ji}\dot{\xi}_j, \qquad 1 \le i \le I, \qquad (3)$$

where $\dot{n}_{0i}$ are the component flow rates at the reactor inlet ($z = 0$).

The component rates $\tilde{r}_i$ can be expressed in term of the reaction rates $\tilde{R}_j$ as

$$\tilde{r}_i = \sum_{j=1}^{J} \nu_{ji}\tilde{R}_j, \qquad 1 \le i \le I. \tag{4}$$

Substitution of (3), (4) into Eq. (1) gives another, equivalent to (1), form of material balance equations for J independent reactions:

$$d\dot{\xi}_j/dz = S_a\tilde{R}_j, \quad 1 \le j \le J, \tag{5}$$

The change in enthalpy of the components in the reactions, which is due to the flux of heat across the reactor walls along its length element dz [expression (6)] gives an additional, with respect to relation (5), differential equation (7) for the temperature of the reaction mixture:

$$\sum_{i=1}^{I} d(\dot{n}_i\bar{H}_i) = \alpha S_S(T_S - T)dz, \tag{6}$$

$$\frac{dT}{dz} = \frac{\alpha S_S(T_S - T) - S_a\sum_i \tilde{r}_i\bar{H}_i}{\sum_i \dot{n}_i C_{pi}}, \tag{7}$$

where $\bar{H}_i$ is the molar enthalpy of ith component; α, heat-transfer coefficient; S_S, lateral heat-exchange surface area per unit reactor length; T_S, temperature of the heat-carrying agent in the jacket; and C_{pi}, molar specific heats of the components.

In this case, the sum over the components in the numerator of (7) can be expressed in terms of the rates $\bar{R}_j$ and enthalpies $\Delta H_j = \sum_{i=1}^{I} \nu_{ji}\bar{H}_i$ of the reactions:

$$\sum_i \tilde{r}_i\bar{H}_i = \sum_j \tilde{R}_j\Delta H_j. \tag{8}$$

An equation similar to (7) describes the variation of the temperature of the heat-carrying agent in the temperature-control jacket:

$$\frac{dT}{dz} = \frac{\alpha S_S(T_S - T)}{\dot{n}_S C_{pS}}, \tag{9}$$

where the flow rate of the heat-carrying agent $\dot{n}_S > 0$ if its flow direction coincides with that of the flow in the reactor (forward flow) and $\dot{n}_S < 0$ otherwise (counterflow).

Additional expressions that relate and define the quantities used have, as functions of z, the form

$$y_i = \dot{n}_i/\dot{n}, \qquad \dot{n} = \Sigma\dot{n}_i, \tag{10}$$

$$\dot{V} = \dot{n}_i RT/\tilde{P}P^0, \qquad v = \dot{V}/S, \tag{11}$$

$$c_i = \dot{n}_i\dot{V}, \tag{12}$$

$$\tilde{P}_i = c_i RT/P^0, \qquad \tilde{P} = \sum_i \tilde{P}_i, \tag{13}$$

where y_i is the mole fraction; $\dot{n}_i$, total gas flow rate in the second of formulas (1); $\dot{V}$ and v, space velocity and linear flow velocity [formulas (11)]; S, cross-sectional area of the reactor; c_i, component concentrations in the flow; $\tilde{P}_i$ and $\tilde{P}$, partial and total pressures (atm) (P^0 = 101 325 Pa).

Pressure can also be a sought-for function of the coordinate, if the hydrodynamic resistance is taken into account. However, the pressure is considered in this study to be constant along the reactor.

The system of differential equations is supplemented with boundary conditions at the reactor inlet (z = 0)

$$T(0) = T_0, \quad T_S(0) = T_{S0} \quad \text{(for the forward flow)}, \qquad \dot{\xi}(0) = 0 \ (1 \le j \le J). \tag{14}$$

The coordinate at the outlet is equal to the reactor length ($z = L$).

It is noteworthy that, when solving the system numerically, its composition can be determined both from Eqs. (1) and from Eqs. (5). The software implementation of the method is preceded by a procedure in which a change to dimensionless variables is performed. The system of ordinary nonlinear differential equations was solved using the fourth-order Runge–Kutta method with automatic choice of the step interval.

In terms of the given model, a heterogeneous chemical process is considered to be defined if its following characteristics are defined and prescribed: kinetic scheme (2) of chemical reactions at the surface; block of thermodynamic data represented by quantities X_j, which determine the direction and extent of jth reaction:

$$\ln X_j = \Delta_r G/RT = \Delta_r g = \sum_i \nu_{ji}[g_i^0(T,P) + \ln x_i]$$

$$= -\ln K_j^{(x)} + \sum_i \nu_{ji}\ln x_i, \tag{15}$$

$$g_i^0(T,P) = g_i^0(T) + \delta_i \ln \tilde{P}, \quad (16)$$

where x_i is the mole fraction of ith component, and g_i^0 are the standard reduced chemical potentials of the components.

The chain of equalities (17), derived from (15) with account of expressions that relate the equilibrium constants, demonstrates the invariance of the quantities X_j expressed on different concentration scales:

$$X_j = \exp \Delta_r g_j = \prod_i x_i^{\nu_{ij}} / K_j^{(x)} = \prod_i \tilde{P}_i^{\nu_{ij}} / K_j^0 = \prod_i c_i^{\nu_{ij}} / K_j^{(c)}, \quad (17)$$

$$K_j^{(x)} = K_j^0 (\tilde{P})^{-\Delta\nu_j}, \qquad K_j^{(c)} = K_j^0 (RT/P^0)^{-\Delta\nu_j}, \quad (18)$$

where $\Delta\nu_j = \sum_i \nu_{ij}$ is the change in the number of moles in jth reaction, and $K_j^0 = \exp[-\sum g_i^0(T)]$ is the standard equilibrium constant.

The validity of Eqs. (17) and (18) is confirmed using the relations between the partial pressures $\tilde{P}_i$ (atm) of the components, mole fractions x_i, and volume concentrations c_i (mol m^{-3}) of ith components: $\tilde{P}_i = x_i \tilde{P} = c_i RT/P_0$.

The diffusion-kinetic model used in the study is based on the known law of summation of the diffusion and kinetic resistances [1]:

$$\frac{1}{\beta_{ij}^*} = \frac{1}{\beta_{ij}} + \frac{1}{k_j}, \qquad k_j = A_j \exp(-E_j/RT). \quad (19)$$

The effective coefficient β_{ij}^* of mass transfer of ith component to the reaction surface is determined by the smallest of the following two quantities: β_{ij}, the initial diffusion mass-transfer (mass-supply) coefficient for ith component, and k_j, the coefficient describing the "efficiency of a chemical event of transfer" of a component from the category of reactants to that of products of jth reaction. In the latter case, the actual rate constant k_j of the heterogeneous reaction is represented in expression (19) by an Arrhenius term with an activation energy E_j and a pre-exponential factor A_j, which also determines the dimension of the rate constant of the heterogeneous reaction (m s^{-1}).

The constant A_j can be conveniently redefined and expressed in terms of the known, and more illustrative parameter T_j^*, the temperature at which the reaction passes from the kinetic to the diffusion control. In doing so, a natural condition of its definition is the equality $k_j = \beta_{ij}$ of the diffusion and kinetic components in expression (19). Substitution of the formula $k_j = \beta_{ij}(T_j^*) \exp[(E_j/R)(1/T_j^* - 1/T)]$, which follows from this equality, into the first of expressions (19) yields, after obvious rearrangements, the relation

$$\frac{1}{\beta_{ij}^*} = \frac{1}{\beta_{ij}} \left\{ 1 + \frac{\beta_{ij}(T)}{\beta_{ij}(T_j^*)} \exp[-E_j R^{-1}(1/T - 1/T_j^*)] \right\}. \quad (20)$$

Neglecting the considerably weaker temperature dependence of the diffusion mass-transfer coefficient (which is commonly proportional to $T^{1/2}$), compared to the exponential dependence of the co-factor containing E_j, gives the following relations for the effective mass-transfer coefficient:

$$\beta_{ij}^* = \beta_{ij} w_j, \quad w_j = \frac{1}{1 + \exp[-E_j R^{-1}(1/T - 1/T_j^*)]}. \quad (21)$$

The resulting expression for the rate of jth heterogeneous reaction [2]

$$\tilde{R}_j = [(1 - X_j) w_j][\sum_i \nu_{ij} (\beta_{ij} c_i)^{-1} \sum_i \nu_{ij} + X_j \sum_i{}' \nu_{ij} (\beta_{ij} c_i)^{-1} \sum_i{}' \nu_{ij}]^{-1} \quad (22)$$

contains a factor $0 < w_j < 1$, which has the form of a switch that "turns on" the diffusion-controlled mode of the reaction at temperatures $T > T_j^*$ and "switches" it into the kinetically controlled mode at $T < T_j^*$. The range of temperatures close to the transition temperature T_j^* corresponds to a mixed diffusion-kinetic control, and at $T = T_j^*$ the shares of each of the limiting modes are equal ($w_j = 0.5$). The simultaneously high activation energy E_j (which exceeds its estimate based on bond dissociation energies) and T_j^* (above the temperature range under study) give $w_j \to 0$, which indicates that this equation is to be excluded from the kinetic scheme. Thus, the trial, but insignificant within the experimental error, equations were rejected in the stage of experimental data processing.

The information data block for solving the macrokinetic problem included the following factors: standard thermodynamic functions [3], which were evaluated for unstudied substances by the group contribution method [4]; transfer coefficients (viscosity, heat conductivity) calculated using the procedures described in [4]; and heat- and mass-transfer coefficients in the form of criterial relations for a grainy bed from [5–7].

Raw experimental data (areas of chromatographic peaks), converted to mole fractions, were subjected to a smoothing approximation processing. The kinetic

4	$C_6H_6Cl_7 \rightleftarrows C_6H_2Cl_4 + 3HCl$	2136.06	34 282.2
5	$C_6H_7Cl_5 \rightleftarrows C_6H_4Cl_2 + 3HCl$	–	–

parameters of the reactions were found by solving the inverse problem (see table). The average relative deviation of the calculated curves from the experimental values was 5.7%.

In the mathematical processing, the concentrations of by-product components: 1,2,4,5-tetrachlorobenzene, 1,2-dichlorobenzene, and 1,4-dichlorobenzene, were taken into account in addition to the data for the main substances (loss of hexachlorocyclohexane and increase in the concentration of 1,2,4-trichlorobenzene). However, the available data gave no way of understanding in detail the mechanism of their formation. A numerical solution made it possible to specify the parameters of the corresponding overall reaction nos. 3–5, with the last of these occurring under purely diffusion control.

The kinetic scheme of thermal decomposition of hexachlorocyclohexane is oriented toward the observable products and comprises a set of overall reactions that only indirectly take into account a number of possible intermediate species, including radicals. For example, reaction no. 2, in which 1,2,4-trichlorobenzene is formed, actually includes two successive stages. As already mentioned, this refers to an even greater extent to the compound reaction nos. 4 and 5.

In the temperature range studied, products of deeper stages of thermolysis of hexachlorocyclohexane, which include breakdown of the benzene ring, were not observed, and, therefore, they are not reflected in the kinetic scheme.

CONCLUSIONS

(1) Thermolysis of hexachlorocyclohexane in its conversion into trichlorobenzene occurs by the commonly accepted mechanism of successive elimination of HCl in two stages, with an intermediate, pentachlorocyclohexene, formed in the first of these (which is rate-limiting).

(2) The formation of by-products, 1,2,4,5-tetrachlorobenzene, 1,2-dichlorobenzene, and 1,4-dichlorobenzene, is due to the concurrent bimolecular reaction of exchange of hydrogen and chlorine atoms in the substrate; dilution of the system with an inert component must make higher the yield of 1,2,4-trichlorobenzene.

(3) The mechanism of the process, established in the study, and the obtained kinetic parameters of the occurring reactions, which account for the properties of the packing and the heat-and-mass-exchange characteristics of the process, enable a scaling transition from a laboratory reactor to an industrial installation for processing of outdated and prohibited pesticides based on hexachlorocyclohexane.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Reactivity of Congeners of Sovol Technical Mixture of Polychlorinated Biphenyls toward Sodium Methoxide

Received April 29, 2004

Abstract—The reaction of Sovol technical mixture of polychlorobiphenyls with sodium methoxide in bipolar aprotic solvents was studied. The reactivity of polychlorobiphenyls was evaluated using gas chromatography and gas chromatography–mass spectrometry.

With adoption in 2001 of the Stockholm Convention on Persistent Organic Pollutants, which prohibited the use of technical polychlorobiphenyls (PCBs), the number of papers concerning these pollutants increased. Primary attention is given to detection of PCBs in various natural objects and biological media, determination of pollution levels, and elucidation of pathways of PCB transformations and metabolism in living bodies. Considerably less attention was given to development of new procedures for rendering PCBs harmless, which is largely due to wide use of efficient methods involving complete breakdown of PCBs (e.g., thermolysis). Other possible procedures for PCB treatment are often considered to be of low promise, either because of incomplete conversion or because of possible formation of more toxic polychlorodibenzofurans and polychlorodibenzodioxins in side reactions.

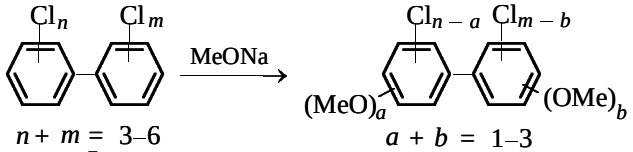
The major drawback of alternative pathways of rendering PCBs harmless is that it is impossible to predict reliably the behavior of particular PCB congeners in the processes, since technical PCBs contain up to 50–70 congeners differing in the number of chlorine atoms and their mutual positions in aromatic structures [1, 2].

Previous studies of reagent (chemical) processing of PCBs showed that reactions of PCBs with various sodium or potassium alcoholates formally result in substitution of two aryl-bonded chlorine atoms by alkoxy groups [3]. These conclusions were confirmed by elemental analysis, IR spectroscopy, and some data on the solubility of the resulting derivatives. The reactivity of PCB congeners present in the mixture was not discussed.

In this context, our goal was to determine the chemical composition of mixtures obtained by reaction of Sovol PCB mixture with sodium methoxide, to evaluate the reactivity of PCB congeners in this mixture, and to find conditions ensuring the most complete conversion of the starting compounds.

Previously we determined the composition and content of PCB congeners in Sovol and identified more than 30 components; the total contents of tetra-, penta-, and hexachlorobiphenyls were found to be about 20, more than 50, and about 20%, respectively; minor amounts of trichloro- and heptachlorobiphenyls were also detected [2]. A typical chromatogram of Sovol is shown in Fig. 1. The IUPAC designations of all the possible PCB congeners are given in [1]; the components of Sovol are listed in Table 1.

Published data on nucleophilic substitutions in PCB aromatic systems **I** are virtually lacking. The reaction of technical PCB mixture **I** with sodium methoxide can formally be described by the scheme



$n + m = 3–6$ (**I**) $\quad a + b = 1–3$ (**II**)

Our first goal was to find the optimal conditions for nucleophilic substitution of aryl-bonded chlorine atoms by methoxy group: solvent, reactant ratio, temperature, and time.

Mixtures **II** obtained from the reactions were analyzed by capillary gas–liquid chromatography with flame-ionization (GLC–FID) and mass-spectrometric (GLC–MSD) detectors. The trends in variation of the

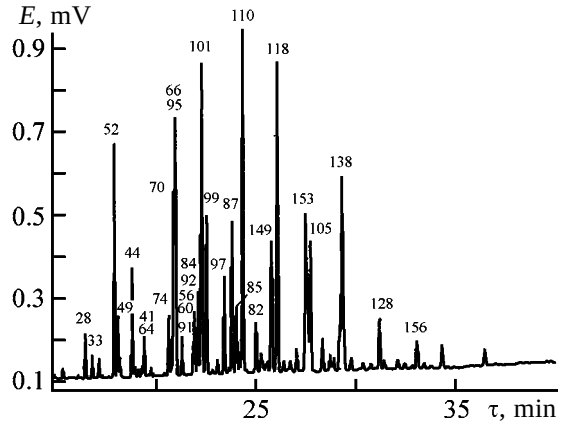


Fig. 1. Chromatogram of Sovol technical mixture of polychlorinated biphenyls: (*E*) potential and (τ) time; the same for Figs. 2.

retention times and the relative intensities of peaks were evaluated under optimal conditions of GLC–FID analysis.

EXPERIMENTAL

The reaction progress was monitored with a Shimadzu GC-17A gas chromatograph [flame-ionization detector; MDN 5S (30 000 × 0.25 mm) quartz capillary column coated with 0.25 μm of methylphenylsilicone stationary phase containing 5% grafted phenyl groups; carrier gas nitrogen; flow division ratio 1 : 30; column temperature: 100°C, 1 min; heating to 200°C, 10 deg min^{-1}; heating to 300°C, 2 deg min^{-1}; vaporizer temperature 250°C; detector temperature 280°C; solvent toluene; sample volume 0.2 μl].

Table 1. Major congeners of Sovol technical mixture of polychlorinated biphenyls

56	2, 3, 3', 4'	128	2, 2', 3, 3', 4, 4'
60	2, 3, 4, 4'	156	2, 3, 3', 4, 4', 5

The compounds were identified with a Fisons gas chromatograph–mass spectrometer [MD 800 detector; HP-5 (25 000 × 0.25 mm) quartz capillary column coated with 0.25 μm of stationary phase; carrier gas helium; flow division ratio 1 : 20; column temperature: 100°C, 1 min; heating to 200°C, 10 deg min^{-1}; heating to 300°C, 2 deg min^{-1}; vaporizer temperature 250°C; ionization by electron impact, 70 eV; scanning rate 1 mass spectrum per second; scanning of total ion current in the range 20–700 amu.

Quantitative calculations were performed by the internal normalization method.

Reaction of PCB I with sodium methoxide. A round-bottomed flask equipped with an air condenser and a $CaCl_2$ tube was charged with 5.4 g (0.1 mol) of freshly dried MeONa and 25 ml of dimethyl sulfoxide (DMSO) dried over molecular sieves. The flask was heated on a Wood's alloy bath for 5–10 min at 165–170°C with shaking. Then 8.2 g (0.025 mol) of PCB **I** was added, and the mixture was heated on a Wood's alloy bath at 170°C for 25 min with shaking. After cooling, the mixture was diluted with 100 ml of water and transferred into a separating funnel. The homogeneous mixture was extracted with toluene (2 × 20 ml); the toluene extracts were combined, washed with water (5 × 100 ml), filtered, and dried over $CaCl_2$; the solvent was evaporated, and the residue was kept in a vacuum. The resulting yellow oily mass was analyzed.

The reaction of PCB **I** with sodium methoxide was performed in bipolar aprotic solvents: DMSO, dimethylformamide (DMF), sulfolane, *N*-methyl-2-pyrrolidone, diglyme, and 1,4-dioxane. Under similar conditions [the same PCB concentration, PCB : MeONa ratio 1 : 4, 25 min, boiling point of the solvent], the best results were obtained in DMSO, DMF, sulfolane, and *N*-methyl-2-pyrrolidone.[1] In diglyme and 1,4-dioxane, no reaction of PCB **I** with MeONa was observed. Thus, the requirements to solvents for this process are high polarity and high electron density on the oxygen atom (ε > 15) [4]. Such properties ensure strong interaction of Na^+ ions with the solvent, enhancing the reactivity of MeO^-.

The degree of conversion was evaluated from a decrease in the areas of the peaks of the starting PCBs **I** and increase in the areas of the peaks of methoxy derivatives **II**. Figures 2a and 2b show chromatograms of mixtures obtained from the reactions.

[1] The reactions of PCB **I** with sodium methoxide in sulfolane and *N*-methyl-2-pyrrolidone were performed at 175–180°C.

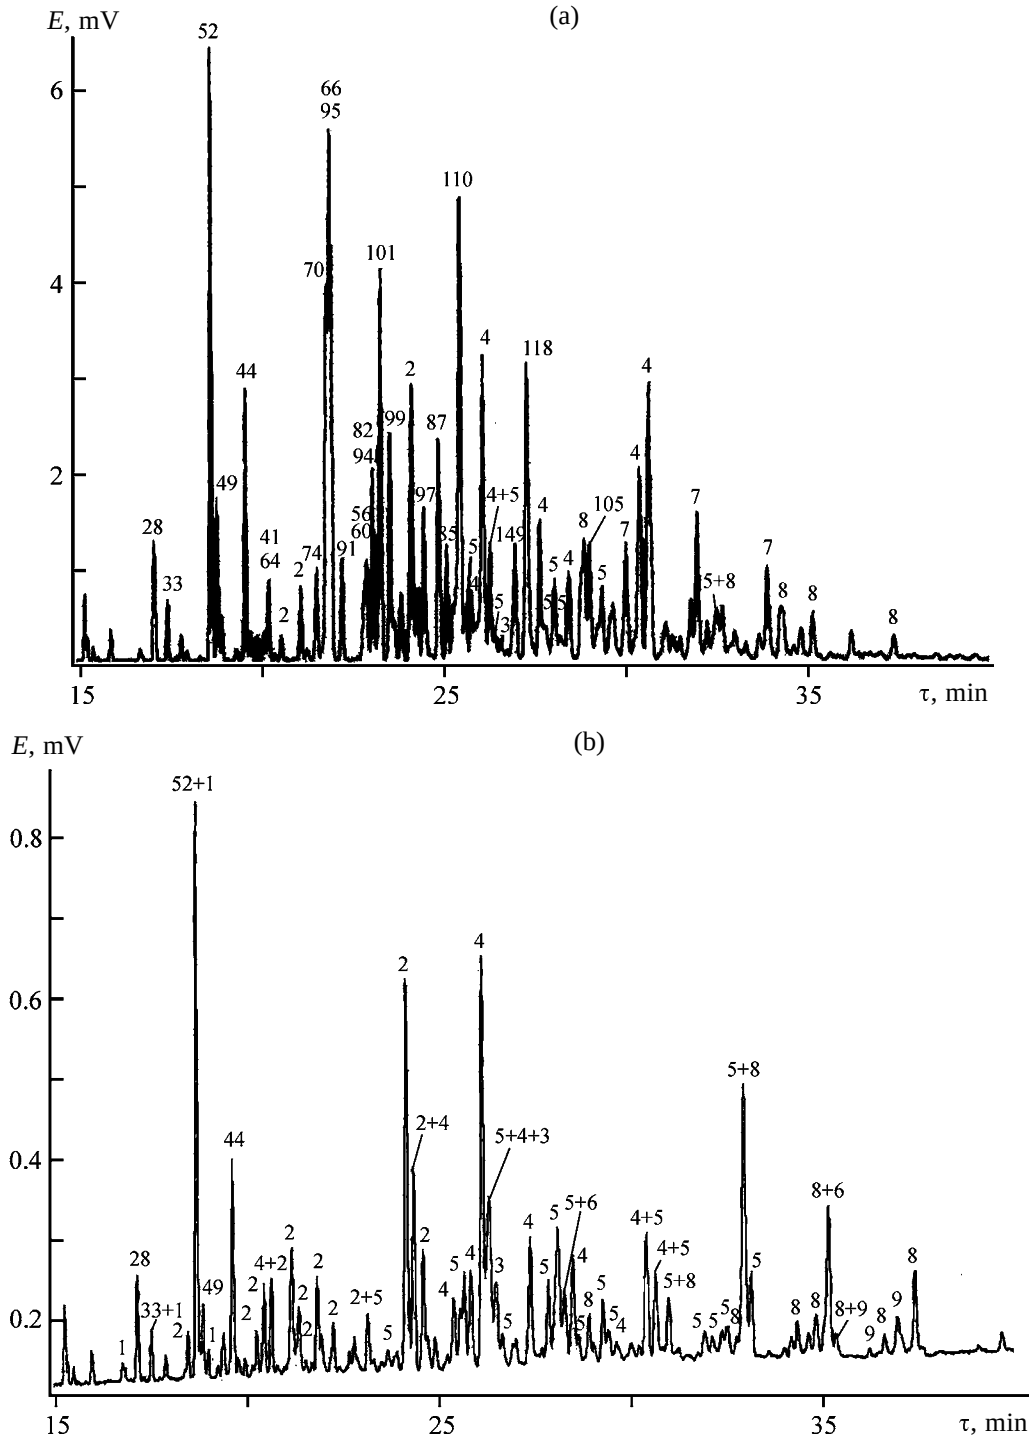

Fig. 2. Chromatogram of reaction products **II**. 170°C, DMSO, 25 min. **I** : MeONa: (a) 1 : 1 and (b) 1 : 4. Peak assignment: (1) $C_{12}H_7Cl_2OCH_3$, (2) $C_{12}H_6Cl_3OCH_3$, (3) $C_{12}H_6Cl_2(OCH_3)_2$, (4) $C_{12}H_5Cl_4OCH_3$, (5) $C_{12}H_5Cl_3(OCH_3)_2$, (6) $C_{12}H_5Cl_2 \cdot (OCH_3)_3$, (7) $C_{12}H_4Cl_5OCH_3$, (8) $C_{12}H_4Cl_4(OCH_3)_2$, and (9) $C_{12}H_4Cl_3(OCH_3)_3$; for other designations, see Table 1.

The reactions in DMSO, DMF, sulfolane, and *N*-methyl-2-pyrrolidone gave qualitatively and quantitatively similar results. The composition of mixtures **II** was complex, with increased number of chromatographic peaks. Under the optimal conditions, 8–15% of the starting PCBs **I** (mainly tri- and tetrachlorobiphenyls) remained unchanged.

The chemical composition of mixtures **II** and de-

gree of conversion of PCBs **I** were determined by GLC–MSD. To do this, we reconstructed the mass chromatograms for particular ions characteristic of the starting tri-, tetra-, penta-, and hexachlorobiphenyls and thus estimated the relative content of unchanged PCBs **I**. Then, as far as possible, we studied the mass spectra of all the detected products.

Synthesis of individual monomethoxypolychlorobiphenyls by cross coupling of the corresponding monoaromatic systems and the fragmentation patterns of these compounds under electron impact were reported in [5, 6]. A specific feature of the mass spectra of pure monomethoxypolychlorobiphenyls is the presence of strong molecular peaks. No such data are available in mass-spectrometric databases on di- and trimethoxypolychlorobiphenyls. We have revealed in the mass spectra of **II** strong molecular peaks belonging to monomethoxydi(tri-, tetra-)chlorobiphenyls, dimethoxydi(tri-, tetra-)chlorobiphenyls, and trimethoxydi(tri-)chlorobiphenyls.

Reconstruction of the mass chromatograms for the molecular peaks of PCB methoxy derivatives **II** allowed us to assign the peaks and reveal the cases of joint elution of the derivatives. Since the columns used in GLC–FID and GLC–MSD experiments were similar, we obtained similar chromatograms, which allowed peak assignment in the chromatograms obtained by GLC–FID (Fig. 2).

As described previously for monomethoxypolychlorobiphenyls [5, 6], the fragmentation pattern of such compounds under electron impact depends on the position of the methoxy groups. However, their position in components of **II** cannot be determined from the available data.

For example, *p*-monomethoxy derivatives of PCBs show the peaks $[M - 15]^+$ ($M - CH_3$) and $[M - 43]^+$ ($M - CH_3 - CO$); *o*-isomers, the peaks $[M - 35]^+$ ($M - Cl$) and strong peaks $[M - 50]^+$ ($M - CH_3Cl$); and *m*-isomers, medium-intensity peaks $[M - 43]^+$ and $[M - 50]^+$. All the three types of fragmentation were detected in our study.

The characteristic peaks of dimethoxy derivatives of PCBs were $[M - 65]^+$ ($M - CH_3 - CH_3Cl$), $[M - 93]^+$ ($M - CH_3Cl - CH_3 - CO$), and $[M - 156]^+$ ($M - CH_3Cl - CH_3 - CO - COCl$). In some cases, we also detected the peaks $[M - 15]^+$ and $[M - 43]^+$, and in other cases, the peaks $[M - 50]^+$ and $[M - 65]^+$, which may be associated with the location of the two methoxy groups.

The mass spectra of PCB trimethoxy derivatives contain peaks characteristic of monomethoxy ($[M - 15]^+$, $[M - 43]^+$, $[M - 50]^+$) and dimethoxy ($[M - 65]^+$, $[M - 93]^+$) derivatives.

To evaluate the reactivities of PCB congeners, we studied in more detail the reaction of **I** with sodium methoxide in DMSO; we varied the reaction temperature and time and the molar ratio of the reactants. The results are listed in Table 2.

Quantitative treatment of the chromatographic data for mixtures **II** shows that the reactivity of PCB congeners grows with increasing number of chlorine atoms.

Hexachlorobiphenyls (PCB 149, PCB 153, PCB 138, PCB 128) started to transform at a relatively low temperature (60°C), mainly into monomethoxy derivatives $C_{12}H_4Cl_5OCH_3$ (Figs. 2a, 2b, peak 7). Their reactivity increased with temperature, methoxylation proceeded further, and, starting from 150°C, monomethoxypentachlorobiphenyls were no longer detected; the reaction yielded dimethoxy [$C_{12}H_4Cl_4 \cdot (OCH_3)_2$, 8] and trimethoxy [$C_{12}H_4Cl_3(OCH_3)_3$, 9] derivatives, with dimethoxytetrachlorobiphenyls prevailing. The starting hexachlorobiphenyls were not detected in the reaction products. These results were obtained in all the four solvents: DMSO, DMF, sulfolane, and *N*-methyl-2-pyrrolidone.

Pentachlorobiphenyls started to react with sodium methoxide at 60°C, and their reactivity also increased with temperature. The major products were monomethoxy ($C_{12}H_5Cl_4OCH_3$, 4) and dimethoxy [$C_{12}H_5 \cdot Cl_3(OCH_3)_2$, 5] derivatives. Minor amounts of trimethoxy derivatives [$C_{12}H_5Cl_2(OCH_3)_3$, 6] were also detected by GLC–MSD. PCB 85, PCB 99, PCB 105, and PCB 118 containing chlorine atoms in both *p*-positions appeared to be more reactive. These congeners entered into the reaction earlier than the other pentachlorobiphenyls.

Tetrachlorobiphenyls were characterized by relatively low degree of reaction with sodium methoxide, with predominant formation of monomethoxytrichlorobiphenyls ($C_{12}H_6Cl_3OCH_3$, 2); minor amounts of dimethoxydichlorobiphenyls 3 also formed. PCB 47, PCB 60, PCB 66, and PCB 74 containing two chlorine atoms in the *p*-positions showed high reactivity; PCB 41, PCB 49, PCB 64, and PCB 70 containing one chlorine atom in the *p*-position appeared to be less reactive.

Tetrachlorobiphenyls PCB 52 and PCB 44 containing no chlorine in *p*-positions did not noticeably react under the experimental conditions. Trichlorobiphenyls PCB 28 and PCB 33 containing one chlorine in *p*-position under the optimal conditions partially trans-

170	25	1 : 6	11	$C_{12}H_7Cl_2OCH_3$	$C_{12}H_6Cl_3OCH_3$ $C_{12}H_6Cl_2(OCH_3)_2$	$C_{12}H_5Cl_4OCH_3$ $C_{12}H_5Cl_3(OCH_3)_2$ $C_{12}H_5Cl_2(OCH_3)_3$	$C_{12}H_4Cl_4(OCH_3)_2$ $C_{12}H_4Cl_3(OCH_3)_3$
170	25	1 : 1	59	Unchanged	$C_{12}H_6Cl_3OCH_3$ $C_{12}H_6Cl_2(OCH_3)_2$	$C_{12}H_5Cl_4OCH_3$ $C_{12}H_5Cl_3(OCH_3)_2$	$C_{12}H_4Cl_5OCH_3$ $C_{12}H_4Cl_4(OCH_3)_2$
170	120	1 : 4	10	$C_{12}H_7Cl_2OCH_3$	$C_{12}H_6Cl_3OCH_3$ $C_{12}H_6Cl_2(OCH_3)_2$	$C_{12}H_5Cl_4OCH_3$ $C_{12}H_5Cl_3(OCH_3)_2$ $C_{12}H_5Cl_2(OCH_3)_3$	$C_{12}H_4Cl_4(OCH_3)_2$ $C_{12}H_4Cl_3(OCH_3)_3$

formed into monomethoxydichlorobiphenyls $C_{12}H_7 \cdot Cl_2OCH_3$ (1).

Thus, we have revealed the features of chemical transformations of PCB (Sovol) congeners under the action of sodium methoxide, as influenced by the number of chlorine atoms in the molecule, their relative location, and reaction conditions.

CONCLUSIONS

(1) Reaction of Sovol mixture of polychlorobiphenyls with sodium methoxide is the most efficient in bipolar aprotic solvents (dimethyl sulfoxide, dimethylformamide, sulfolane, *N*-methyl-2-pyrrolidone).

(2) Among Sovol congeners, the most reactive toward sodium methoxide are hexa- and pentachlorobiphenyls; tetra- and trichlorobiphenyls are less reactive.

(3) Reaction of polychlorobiphenyls with sodium methoxide (170°C, 25–120 min, PCB : MeONa 1 : 4) in various solvents does not ensure complete conversion of the main pollutants.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Copper Stearate on Oxidation of Polyethylene Stabilized with Neozon D

D. G. Lin, E. V. Vorob'eva, and N. V. Marchenko

Skorina State University, Gomel, Belarus

Received March 19, 2004

Abstract—Catalytic reaction of copper(II) stearate with Neozon D in a polyethylene melt was studied.

Maizus *et al*. [1] showed that decomposition of decyl hydroperoxide is catalyzed by a mixture of an aromatic amine (*N*-phenyl-2-naphthylamine) and copper(II) stearate. Based on this result, Maizus *et al*. suggested [1] that mixtures of variable-valence metal salts with inhibitors of free-radical reactions can be used to develop new antioxidants (AO). This possibility was extensively studied, in particular, in [2, 3]. It was found that a Neozon D–copper(II) stearate mixture is rapidly consumed in decane oxidation. Based on the fact that the induction period of hydrocarbon oxidation (IPO) lasted for a long time after complete consumption of the AO, Vetchinkina *et al*. suggested [2] formation of a new compound inhibiting the oxidation. Two pathways giving rise to a new, more effective AO were proposed [2]. The first is reaction of *N*-phenyl-2-naphthylamine with copper(II) stearate to form a copper(I) complex with $C_{10}H_7NC_6H_5$ radical and stearic acid. The second pathway involves reaction of the liberated stearic acid with the free AO to form a salt that cannot react with copper(II) stearate. Vetchinkina *et al*. [2, 3] believe that specifically copper(I) complexes effectively inhibit oxidation after consumption of amine-containing AO. Clearly, the antioxidative effect of the copper(I) complex will be maximal if free oxidation catalysts {copper(II) stearate [4, 5] and stearic acid [5]} will be absent in the system after the complex formation. If AO reacts only with copper(II) stearate and with liberated stearic acid, the molar ratio of Neozon D and copper(II) stearate should be 2 : 1. At other molar ratios of these components, some amount of either AO or copper(II) stearate and stearic acid will remain unchanged in the system.

To improve the antioxidative properties of Neozon D, we studied in this work the influence of copper(II) stearate on oxidation of a polyethylene (PE) melt stabilized with Neozon D.

EXPERIMENTAL

We used nonstabilized high-density PE [GOST (State Standard) 16338–85, base trademark 20308-005). Films to be studied were prepared from PE powder or form a composite of PE with a modifier. Copper(II) stearate [TU (Technical Specifications) 6-09-12-152–75] and Neozon D (*N*-phenyl-2-naphthylamine, GOST 39–79) were used as the modifiers. The composite was prepared as follows. Powders of copper stearate and Neozon D were dissolved in acetone (GOST 2603–79) and the resulting solution was stirred with a magnetic stirrer for 3 min. Polyethylene powder was impregnated with these solutions (or their mixture) and dried at room temperature. The PE films were oxidized by heating in an oven in air at 150°C. This temperature is higher than the melting point of the polymer.

The degree of PE oxidation was estimated form the optical density of the carbonyl band at 1720 cm^{-1}. The optical density was determined by the baseline method using the absorption band at 1460 cm^{-1} as an internal reference. The IR spectra were recorded on a Specord-75 IR spectrophotometer.

Neozon D-copper(II) stearate mixtures with molar ratios of 0.5 : 1, 1 : 1, 2 : 1, 4 : 1, 6 : 1, 8 : 1, and 10 : 1 (hereinafter, these mixtures will be referred to I–VII, respectively) were prepared. These mixtures were introduced in PE in the amount providing 0.1 wt % concentration of Neozon D in the resulting composite. The copper(II) concentration in samples I–VII decreased in the following order (wt %, $\times 10^3$): 147, 29, 14, 7, 5, 4, and 3, respectively.

The kinetic curves of accumulation of carbonyl groups in samples I, III, IV, and VII are shown in Fig. 1a. We expected that introduction of a Neozon D–copper(II) stearate mixture into the polymer would

1070-4272/04/7709-1528 © 2004 MAIK "Nauka/Interperiodica"

increase its IPO. However, we obtained the opposite result (accumulation of carbonyl groups in the reference film containing only 0.1 wt % Neozon D is described by curve *1*). The induction period of hydrocarbon oxidation is shortened when the copper(II) concentration increases from 3×10^{-3} (sample VII) to 7×10^{-3} wt % (sample IV) and slowly increases with increasing copper(II) concentration to 0.147 wt % (sample I), i.e., the dependence of IPO on the copper(II) stearate concentration passes through a minimum (Fig. 1b, curve *7*).

The abnormal behavior of PE containing Neozon D and copper(II) stearate is due to the fact that no copper(I) complexes exhibiting strong antioxidative power are formed in the molten polymer. In this case, the probability of formation of copper complexes is low owing to slow diffusion of the modifiers. Under these conditions, AO inhibits oxidation of the polymer and copper(II) stearate catalyzes this reaction. As a result, small additions of copper(II) stearate make the IPO shorter. We suggest that the experimental dependence of IPO on the copper concentration (Fig. 1b, curve *7*) is caused by specific features of the effect of copper(II) stearate on PE oxidation [5, 6].

We also studied oxidation of nonstabilized PE containing copper(II) stearate with concentrations from 0 to 0.020 wt % (this concentration range corresponds to that in samples I–VII). In this case, the dependence of IPO on the copper(II) concentration also passes through a minimum (Fig. 1b, curve *6*). This result confirms the known fact that small amounts of copper(II) stearate catalyze PE oxidation [5, 6]. When the modifier concentration increases, the oxidation is inhibited and the induction period increases (Fig. 1b, curve *6*).

Copper(II) stearate taken in an amount of approximately 7×10^{-3} wt % [in terms of copper(II)] has the strongest catalytic effect on oxidation of both nonstabilized PE and PE stabilized with Neozon D (Fig. 1b, curves *6* and *7*). Thus, introduction of copper(II) stearate in a PE melt stabilized with Neozon D does not significantly enhance the antioxidative power of the AO. Probably these modifiers do not react with each other and work independently.

At the same time, introduction of copper(II) compounds can enhance the inhibiting properties of the amine AO. Accumulation of carbonyl groups in PE films oxidized on reactive (copper) and inert (KBr) supports is shown in Fig. 2. Oxidation of nonstabilized PE on the copper support is faster and is characterized by shorter induction period than that on KBr supports (Fig. 2, curves *1*, *2*). Introduction of

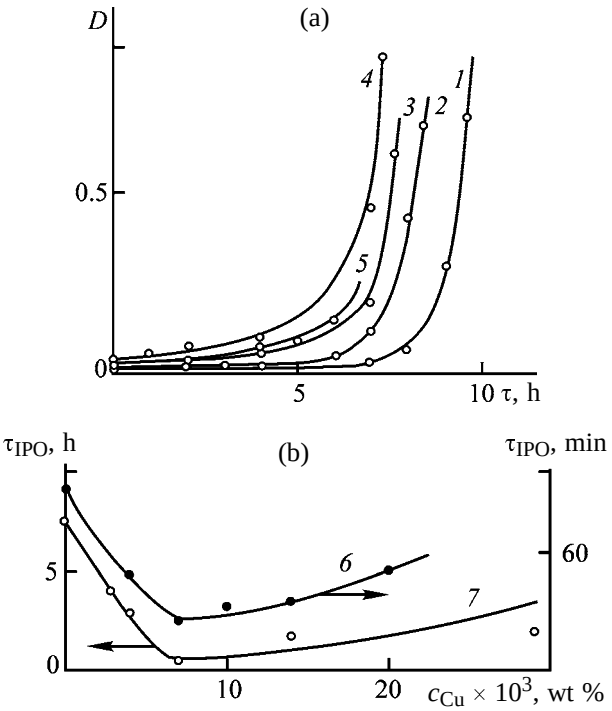

Fig. 1. (a) Accumulation of carbonyl groups in PE samples containing (*1*) 0.1 wt % Neozon D and mixtures (*2*) I, (*3*) III, (*4*) IV, and (*5*) VII; (b) IPO of PE (*6*) nonstabilized and (*7*) stabilized with 0.1 wt % Neozon D as a function of copper(II) stearate content in the samples. (a) (*D*) optical density and (τ) oxidation time; the same for Figs. 2 and 3. (b) (c_{Cu}) Copper(II) concentration and (τ_{IPO}) IPO duration.

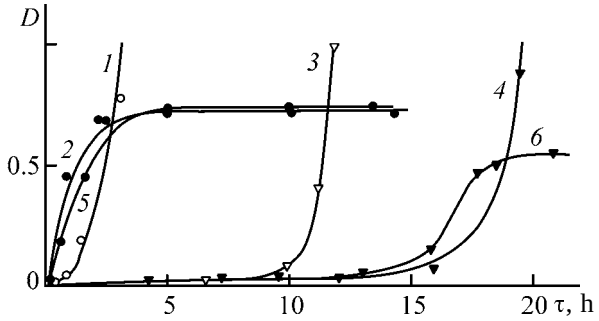

Fig. 2. Accumulation of carbonyl groups in PE films with a Cu powder content of (*1–4*) and (*5*, *6*) 10 wt % and Neozon D content of (*1*, *2*, *5*) and (*3*, *4*, *6*) 0.3 wt %, as a function of time of their oxidation τ (h) on (*2*, *4*) copper and (*1*, *3*, *5*, *6*) KBr supports.

Neozon D increases the IPO. Curiously, the IPO of PE on a copper support increases to a greater extent that that on KBr plates (Fig. 2, curves *3*, *4*). Apparently, Neozon D in PE films on copper supports is converted into a more effective AO.

To confirm these results, we studied oxidation of PE filled with copper powder. The oxidation was per-

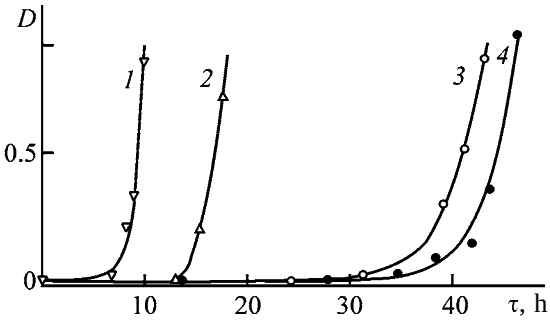

Fig. 3. Accumulation of carbonyl groups in the course of oxidation of PE films stabilized with 0.1 wt % of (*1*) initial AO, (*2*) AO thermally modified at 150°C for 10 h, and a mixture of copper(II) stearate and Neozon D taken in a ratio of (*3*) 1 : 24 and (*4*) 1 : 246, as a function of oxidation time τ.

formed on KBr plates. As in the case of oxidation on a copper support, IPO of the polymer stabilized with Neozon D increases, which indicates the enhanced performance of the amine AO.

We can give two possible explanations of modification of the AO after contact with a copper support. The first is penetration of the AO to the polymer–support interface and direct reaction with copper to form a more effective compound. The second mechanism is more complex. It is known [4, 6, 7] that copper carboxylates are formed in oxidation of PE on copper. These compounds can diffuse into the polymer matrix and react there with AO to form copper complexes with strong antioxidative power. The second mechanism, however, is improbable. First, no copper(I) complexes with Neozon D were found in a PE melt containing copper(II) stearate (analog of copper compound formed in PE oxidation). Second, the concentration of copper compounds that diffused in the polymer matrix by the end of IPO is negligible. Hence, the amount of copper(I, II) complexes with Neozon D, formed in the polymeric matrix, should be insufficient. We believe that the direct reaction of AO with the copper support is the most probable explanation.

To study direct reaction of AO with copper, we performed the following experiment. A thin (~1 mm) layer of Neozon D was applied to a copper support and was heated at 150°C in air for 10 h. Then 0.1 wt % of thermally modified AO was introduced into PE, and the IPO of the composite was measured. This treatment of AO substantially enhances its performance. The induction period of hydrocarbon oxidation of PE stabilized with thermally modified AO increases by a factor of more than 2 (Fig. 3, curves *1, 2*).

Similar experiments were performed with mixtures of the AO with copper(II) stearate. We studied two mixtures with Neozon D : copper(II) stearate molar ratios of 24 : 1 (mixture A) and 242 : 1 (mixture B). These ratios are substantially higher than the ratio optimal for complex formation (2 : 1). After the heat treatment, the mixtures were introduced into PE in the amount required to obtain 0.1 wt % AO in the polymer. The inhibiting power of AO substantially increased after the heat treatment. The IPO of samples containing mixtures A and B increased by factors of 5 and 6, respectively. The inhibiting power of the AO increased with decreasing the copper(II) amount in the mixture. If the properties of the initial AO changed due to the complexation, the pattern would be inverse. Since this is not the case, we believe that the inhibiting properties of the amine AO are enhanced in the course of its contact with copper and its compounds.

Probably, strong antioxidation stabilization of PE with Neozon D in the presence of copper (Fig. 2, curves *4, 6*) or its salts (Fig. 3, curves *3, 4*) is caused by copper-catalyzed oxidation of Neozon D to form stable nitroxyl radicals:

$$C_{10}H_7\text{–}NH\text{–}C_6H_5 \xrightarrow{Cu} C_{10}H_7\text{–}N^{\bullet}\text{–}C_6H_5$$

$$\xrightarrow{[O]} C_{10}H_7\text{–}NO^{\bullet}\text{–}C_6H_5.$$

Nitroxyl radicals (>NO$^{\bullet}$) terminate chain oxidation reactions of polymers, thus enhancing the performance of AO [9].

Since copper(II) stearate and Neozon D are separated by low-mobile PE macromolecules (Fig. 1), the modifiers work independently: copper stearate catalyzes polymer oxidation and Neozon D inhibits this reaction.

CONCLUSIONS

Inhibiting power of the amine AO can be enhanced by its catalytic reaction with copper or copper(II) stearate in the course of oxidation of a PE melt.

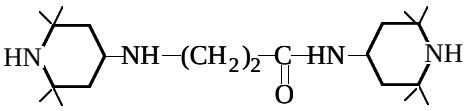
Abstract—The mechanism by which selected photostabilizing sterically hindered amines (Tinuvin-622, Diacetam-5, Polyacetam-81) affect the photostability of the complex $Eu(Phen)_2(NO_3)_3$ in low-density polyethylene was studied by the luminescence, ESR, and ^1H NMR spectroscopy.

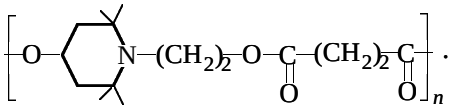
Light-transforming polymeric materials find wide application in agriculture (as plant growth stimulants), medicine, and electronics [1, 2]. As polymer base for such materials serve commercial polymers widely used in agriculture, in particular, low-density polyethylene (LDPE), and as luminescent additives efficiently stimulating plant growth, Eu(III) complexes [1, 2]. In processing, exploitation, and storage, polymers are exposed to numerous factors (heat, light, penetrating radiation, oxygen), which is responsible for their accelerated aging. Combined introduction into polymers of photostabilizers and agents inhibiting thermal oxidative degradation significantly improves such performance characteristics of films as weather and light stability. This makes it urgent to elucidate the mechanism by which the photostability of luminescent complexes is affected by sterically hindered amines (SHAs) and other types of photostabilizers (antioxidants, UV absorbers, etc. [3]).

Data on interaction of luminescent Eu(III) complexes and photostabilizers in LDPE are scarce. We [4, 5] and Raida *et al*. [6] found that, when introduced into luminescent compositions, Diacetam-5 and Polyacetam-81 photostabilizers decrease the photoluminescence intensity and accelerate photodegradation of the europium complex. At the same time, photostabilizer Tinuvin-622 enhances luminescence of the europium complex and inhibits its UV-induced photodegradation [5, 6].

This work, continuing our previous studies [4, 5], is aimed at elucidating the mechanism by which selected photostabilizing SHAs affect the luminescence intensity of the europium(III) complex and its photostability in photolysis. As luminophore to be introduced into LDPE we chose $Eu(Phen)_2(NO_3)_3$, where Phen is 1,10-phenanthroline. As SHA photostabilizers we used those commercially used for producing photoresistant LDPE articles: Diacetam-5 [3-(2,2,6,6-tetramethylpiperidin-4-yl)aminopropionic acid 2,2,6,6-tetramethylpiperidin-4-ylamide], Polyacetam-81, Tinuvin-622 [oligomeric photostabilizer derived from 1-(2-hydroxyethyl)-2,2,6,6-tetramethyl-4-hydroxypiperidine and dimethyl succinate; Ciba Geigy AG] [7]. Notably, Tinuvin-622 is the only SHA used in food industry as stabilizer for polymeric packaging materials. Unlike oligomeric Tinuvin-622, low-molecular-weight Diacetam-5 contains NH groups capable of complexing with metal atoms. The structural formulas of Diacetam-5 and Tinuvin-622 are presented below.



Diacetam-5



Tinuvin-622

EXPERIMENTAL

Film samples were prepared by introducing $Eu(Phen)_2(NO_3)_3$ (0.3 wt %) and a stabilizer (0.1–0.9 wt %) into LDPE. The components were thoroughly mixed, pressed on a hydraulic press at T = 150°C and p = 110 atm, and cooled to obtain films. Accelerated aging of the films was achieved by irradiating the samples with unfiltered light of a DRT-250 mercury lamp. The lamp–sample distance was 20 cm. The luminescence spectra were recorded on an SDL-1

1070-4272/04/7709-1532 © 2004 MAIK "Nauka/Interperiodica"

spectrometer (excitation by a DRSh-250 lamp; UFS-6 filter; λ_{exc} = 365 nm). The luminescence excitation spectra were recorded on a Shimadzu RF-5000 instrument (λ_{lum} = 612 nm, $^5D_0$–$^7F_2$ transition of Eu^{3+}). The ESR spectra were recorded in the *X* frequency range on an ESR-231 spectrometer (Germany). The sample was UV-irradiated in the spectrometer resonator with a DRSh-100 lamp. The ^1H NMR spectra were measured on a Bruker NMR AS-250 spectrometer (Germany) in $CDCl_3$ at 300 K with tetramethylsilane as internal reference.

Studies of the photodegradation rate of the Eu(III) complex in a polymer composition as influenced by the photostabilizers should take into account the fact that the complex can degrade both during irradiation and during preparation of the polymer luminescent composition (as a result of a chemical reaction between the complex and the stabilizer).

Indeed, our experiments showed that a combination of the europium complex and a photostabilizer in the composition affords even during primary processing a fourfold decrease in the fluorescence intensity of the composition relative to the composition without stabilizer in the case of Diacetam-5 and a 20% decrease in the case of Polyacetam-81. At the same time, during primary processing of the polymer composition containing Tinuvin-622 the luminescence intensity of the complex increases by a factor of 1.7.

Additional information about the processes of interest comes from analysis of the luminescence excitation spectra of the polymer compositions (Fig. 1). The spectrum of the initial composition (without photostabilizers) contains a broad intense band corresponding to the π–π* electronic transitions in the absorption spectrum of the phenanthroline molecule.

A fine-structured part of the spectrum (330–350 nm) corresponds to intraconfiguration *f*–*f* transitions of Eu(III). Introduction of Diacetam-5 into the composition substantially modifies the luminescence excitation spectrum: A new band appears in the shortwave region of the spectrum (210–250 nm), and the luminescence intensity of the composition decreases fourfold. The excitation spectrum of the luminescent composition with Tinuvin-622 is almost identical to that of the initial composition; however, the relative intensity of the band at 230–280 nm increases (with the luminescence intensity increasing by a factor of 1.7). This suggests a sensitizing effect of Tinuvin-622 on the excitation energy transfer to the energy levels of Eu(III).

Fig. 1. Luminescence excitation spectra of (*2*) $Eu(Phen)_2(NO_3)_3$ in LDPE and (*1*, *3*) $Eu(Phen)_2(NO_3)_3$ + photostabilizer composition in LDPE. (*I*) Intensity and (λ) wavelength. Stabilizer: (*1*) Tinuvin-622 and (*3*) Diacetam-5.

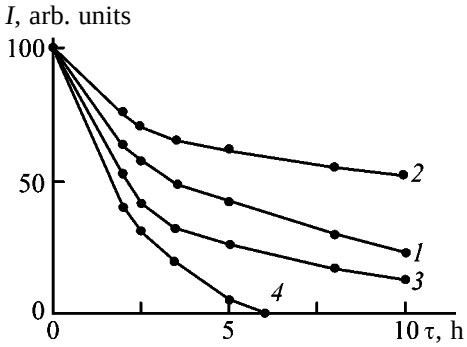


Fig. 2. Luminescence intensity *I* (λ_{lum} = 615 nm) of (*1*) $Eu(Phen)_2(NO_3)_3$ in LDPE and (*2*–*4*) $Eu(Phen)_2(NO_3)_3$ + photostabilizer composition in LDPE as a function of the UV irradiation time τ. Stabilizer: (*2*) Tinuvin-622, (*3*) Polyacetam-81, and (*4*) Diacetam-5.

We followed the photoinduced degradation of the fluorescent characteristics of the $Eu(Phen)_2(NO_3)_3$ + LDPE composition from the fluorescence spectra. UV irradiation weakens the luminescence in the band of Eu(III) with λ = 615 nm and enhances luminescence in the blue-green region (400–500 nm), due to luminescence of the photodegradation products of the compositions [8]. Figure 2 characterizes accelerated photoinduced aging of the compositions in LDPE under the laboratory conditions. It is seen that Diacetam-5 and Polyacetam-81 accelerate photodegradation of the Eu(III) complex: With Diacetam-5 as stabilizer the luminescence of the sample completely disappears already within 6 h of irradiation; at the same time, Tinuvin-622 markedly inhibits photodegradation.

As known, SHAs, whose photolysis yields nitroxyl radicals, act mostly as acceptors of peroxy radicals in

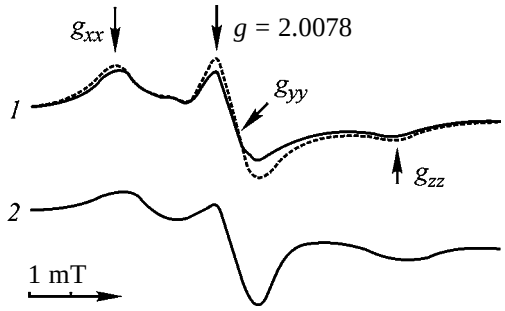

Fig. 3. ESR spectra of (*1*) Diacetam-5 before (solid line) and after (dashed line) UV irradiation for 10 min and (*2*) Tinuvin-622 before UV irradiation. *X*-frequency range, T = 300 K.

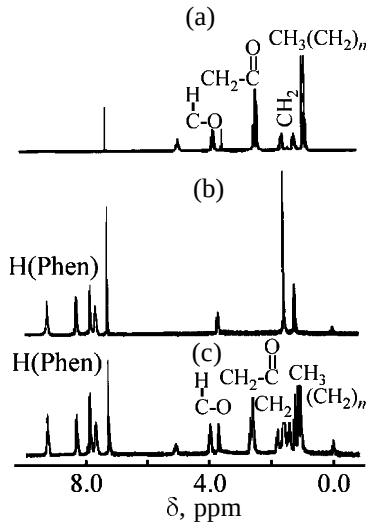

Fig. 4. ^{1}H NMR spectra of (a) Tinuvin-622, (b) $Eu(Phen)_2(NO_3)_3$, and (c) $Eu(Phen)_2(NO_3)_3$ + Tinuvin-622 composition in deuterochloroform (300 K). (δ) Chemical shift; the same for Fig. 5.

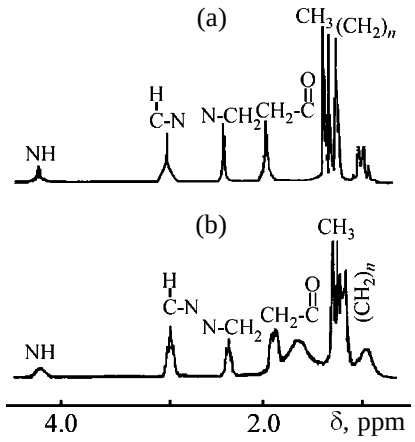

Fig. 5. ^{1}H NMR spectra of (a) Diacetam-5 and (b) $Eu(Phen)_2(NO_3)_3$ + Diacetam-5 composition in deuterochloroform (300 K).

photooxidation of polymers [3]. Additional information about the action mechanism of Diacetam-5 and Tinuvin-622 is furnished by their ESR spectra. They have a triplet structure identical to that of nitroxyl radical (Fig. 3) [9]. Figure 3 shows that irradiation of Diacetam-5 modifies the shape of the ESR spectrum, specifically, the spectral component ratio. We found that UV irradiation of the stabilizers enhances the intensity of all the spectral components, most profoundly in the case of the peak corresponding to the g-tensor component g_{yy}. The ESR data suggest efficient generation of nitroxyl radicals in photolysis of the photostabilizers, with low-molecular-weight Diacetam-5 accumulating the radicals more rapidly than oligomeric Tinuvin-622.

Thus, the NH groups in low-molecular-weight SHAs (Diacetam-5, Polyacetam-81), capable of complexing with metal atoms and exhibiting a greater, compared to oligomeric Tinuvin-622, power for generating nitroxyl radicals, seem to be responsible for the accelerating effect on the photodegradation of the europium complex in a polymeric composition.

We confirmed interaction between Diacetam-5 and the complex and the lack of such interaction in the case of the complex + Tinuvin-622 composition by ^{1}H NMR spectroscopy (Figs. 4, 5). We studied model systems [photostabilizer, Eu(III) complex, Eu(III) complex + photostabilizer] in deuterochloroform at 300 K.

Comparative analysis of the ^{1}H NMR spectra (Fig. 4) shows that the spectrum of the composition is a superposition of the spectra of the complex and the photostabilizer, which unambiguously suggests the lack of interaction in the system. At the same time, comparison of the ^{1}H NMR spectra of solutions of Diacetam-5, Eu(III) complex, and the complex + Diacetam-5 composition reveals broadening of the signals assigned to the protons from the Diacetam-5 molecule in the spectrum of the composition (Fig. 5). This suggests interaction between the photostabilizer and the complex.

CONCLUSIONS

(1) The mechanism by which sterically hindered amines (Tinuvin-622, Diacetam-5, Polyacetam-81) affect the photostability of the $Eu(Phen)_2(NO_3)_3$ complex in low-density polyethylene was studied by luminescence, ESR, and ^{1}H NMR spectroscopy. Tinuvin-622 enhances the luminescence intensity and photoresistance of the europium complex.

(2) A greater, compared to oligomeric Tinuvin-

622, rate of generation of nitroxyl radicals by low-molecular-weight sterically hindered amines under UV irradiation and the presence of NH groups able of complexing with metal ions are responsible for accelerated photodegradation of the europium complex in the polymer matrix.

ACKNOWLEDGMENTS

The authors are grateful to V.V. Isakov for measurement of the NMR spectra and assistance in interpretation of the experimental results.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

An IR Study of Organosolvent Lignin

T. E. Skrebets, K. G. Bogolitsyn, D. S. Kosyakov, and S. A. Verbitskaya

Arkhangelsk State Technical University, Arkhangelsk, Russia

Received November 11, 2003; in final form, April 2004

Abstract—The functional composition of lignin recovered from spruce wood and treated with alkali in aqueous and aqueous-ethanol medium and that of lignins recovered from alkaline cooking solutions in the presence of ethanol were studied by IR spectroscopy. The influence of ethanol on the content of the main functional groups in lignin was examinated.

IR spectroscopy is widely used for studying wood lignin for a long time. Numerous studies are devoted to identification of recovered lignin-containing samples, comparison of lignins recovered from wood by various procedures, establishment of differences between lignins recovered from various types of wood by the same procedure, quantitative determination of lignin in wood and cellulose, and structural studies of lignins produced in various procedures of cellulose cooking [1].

The IR spectra of industrial (soda and kraft) lignins and lignosulfonates are adequately studied, contrary to so-called organosolvent lignins. This is caused by the following factors. First, cooking with organic solvents was developed only recently in comparison with traditional delignification procedures, and practically none of these cooking procedures were brought to industrial use. Second, numerous organic solvents belonging to various types of organic compounds (alcohols, acids, aldehydes, and phenols) are used as agents of organosolvent cooking [2].

In this work we made an IR study of organosolvent lignins recovered from spent solution of aqueous-ethanol cooking of cellulose.

EXPERIMENTAL

For recording the IR spectra, lignin samples were prepared as mulls in Vaseline oil [3]. The spectra were recorded in potassium bromide and cesium iodide pellets on a Specord M80 spectrophotometer (Carl Zeiss, Jena) in the range 4000–400 cm^{-1} with the spectral resolution of 2 cm^{-1}; the monochromator was purged with dry air.

The data obtained were processed using the Softspectra 5.0 software (Etalon Joint-Stock Company, Moscow). The baseline was corrected using transmission maxima at ν 3700, 1800, 700, and 500 cm^{-1}. After that, the optical densities D in the main absorption maxima (except the range of vibrations of aliphatic C–H bonds obscured by absorption of Vaseline oil at 3000–2800, 1460, 1370, and 722 cm^{-1}) were determined. Assuming that the aromatic structures do not degrade under treatment, we selected the absorption band at 1512 cm^{-1} corresponding to the skeleton modes in the aromatic ring as an internal reference and evaluated the relative optical densities (ROD, %) of the other bands with respect to this band [4]:

$$\mathrm{ROD} = \frac{D_\nu}{D_{1512}} \times 100,$$

where D_{1512} is the optical density at 1512 cm^{-1} and D_ν is the optical density at wave number ν.

Since delignification of wood is a complicated process, first we recorded the IR spectra of the samples of spruce dioxane lignin recovered by the Pepper procedure [2] and subjected to treatment in alkaline (8 g l^{-1} NaOH), aqueous, and aqueous-ethanol media at 55, 70, 80, and 90°C. After treatment, the lignin was recovered by acidification of the solution with hydrochloric acid to pH 3.

Both the absorption spectrum of the initial lignin sample and the spectra of the samples subjected to treatment contain a set of absorption bands characteristic of dioxane lignins of coniferous wood. The results of assignment of the bands, based on published data [1, 5], are listed in Table 1.

The similarity of the spectra suggests principal preservation of the chemical structure of dioxane lignin and degree of its polydipersity, affecting spectrum

Table 1. Absorption bands of dioxane lignin samples

ν, cm^{-1}	Assignment

diffuseness in the range 1600–800 cm^{-1}. Noticeable differences in the spectra of the samples studied are observed only in the range of stretching modes of carbonyl groups between 1750 and 1650 cm^{-1}. Treatment at a temperature above 55°C in aqueous medium results in disappearance of the absorption maximum at 1672 cm^{-1}, i.e., the ratio of the amounts of α-carbonyl groups conjugated with an aromatic ring and nonconjugated C=O bonds somewhat decreases.

A comparison of the relative intensities of the main absorption bands of the samples studied (Table 2) shows that, in all of the samples subjected to treatment, especially at low temperatures, the content of carbonyl groups somewhat decreases compared to the initial lignin. Some increase in the content of carbonyl structures at high treatment temperature is apparently caused by development of oxidation processes under the action of dissolved oxygen. Hydroxy groups in lignin remain essentially unchanged at a temperature below 80°C. At 90°C, the content of hydroxy groups increases by approximately 7–8% owing to developing degradation of aryl alkyl ether structures accompanied by release of phenolic and alcoholic groups. This conclusion is confirmed by variation of the optical density at 1080 cm^{-1} corresponding to the stretching modes of the C–O bonds, mainly of those in the C–O–C ether structures.

The similar results were obtained in chemical analysis of functional composition of the samples by the standard procedures [6] (Table 3). These results suggest that conversion of lignin in alkaline aqueous and aqueous-ethanol medium proceeds by the mechanism of oxidative degradation. Then, we studied lignins recovered from the solutions of alkaline (NaOH concentration 60 $g\,l^{-1}$) cooking of spruce wood in aqueous (soda cooking) and 25% aqueous-ethanol (organosolvent cooking) media at 170°C and 160°C, respectively (Table 4). Samples of the cooking solution were withdrawn in 5, 6, and 7 h in soda cooking (samples N/1–N/3, respectively) and every hour in organosolvent cooking (E/1–E/6, respectively). We analyzed the precipitates formed in the liquor

after its keeping for 1 day after cooking completion and the samples recovered immediately after cooking by acidification of the liquor with hydrochloric acid to pH 3. The latter procedure allows recovery of lignin from the cooking liquor practically quantitatively, whereas only high-molecular-weight fraction of lignin precipitates spontaneously. The absorption spectra of these precipitates (Figs. 1a, 1b) contain a strong broad band at approximately 1600 cm^{-1}, which can be assigned to asymmetric stretching vibrations of the carbon–oxygen bond in carboxylate anion. This is confirmed by significant absorption at 1400 cm^{-1}, partially overlapping with absorption bands of Vaseline oil and corresponding to $\nu_s(-COO^-)$. The absorption bands corresponding to the skeleton vibrations of the aromatic ring, bending vibrations of aromatic CH bonds, and vibrations of the ether bonds, characteristic of lignin samples, allow us to assign these samples to coniferous lignin samples in the salt form due to recovery from alkaline solution.

Normalization of the resulting spectra by referencing the optical densities to absorption of aromatic ring, which is a common procedure in IR spectroscopy of lignin, appeared to be impossible because of overlapping of absorption bands corresponding to the skeleton vibrations and those of carboxylate anion. In addition, the lignins recovered by this procedure are not representative samples. Therefore, we further analyzed the samples recovered from liquors by acidification with hydrochloric acid. The spectra of these samples are typical for coniferous lignins and have a set of absorption bands consistent with published data (Table 1).

Comparison of the series of samples N/1–N/3 with E/1–E/6 (Table 4) reveals the influence of alcohol on the functional composition of the resulting lignin. Samples N/1–N/3 prepared by soda delignification are characterized by increased content of hydroxy groups, decreasing in the course of cooking. This is apparently

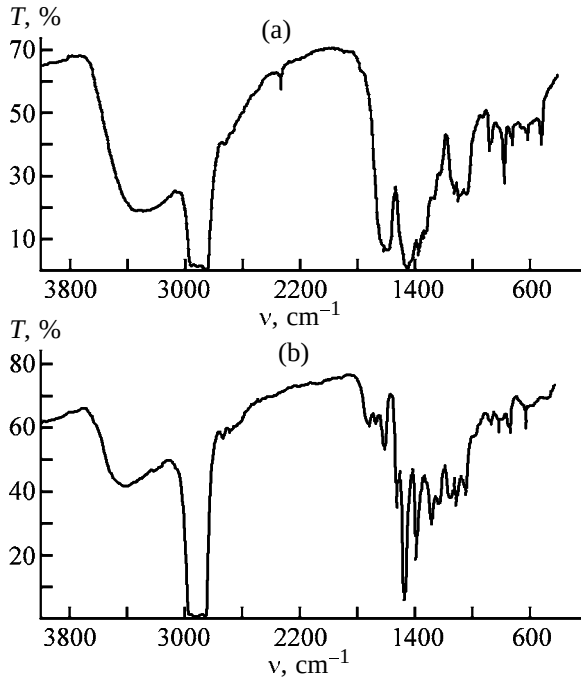

Fig. 1. IR spectra of (a) lignin obtained in keeping of solution of alkaline aqueous-ethanol cooking for 1 day and (b) lignin recovered from the solution of alkaline aqueous-ethanol cooking by acidification. (*T*) Transmission and (ν) wave number.

caused by ethoxylation of phenolic hydroxyls under conditions of alcoholic cookings. In the range of absorption of carbonyl structures, the most pronounced difference between the two series appears for the band at 1700 cm^{-1}: the content of C=O bonds nonconjugated with the aromatic ring in lignin produced by soda cooking is less by 20–50%, i.e., this lignin is significantly more oxidized in comparison with the samples obtained in the presence of ethanol. In the range of absorption of C–O single bonds, no significant differences between these series of samples were observed.

Comparison of the absorption intensity of the samples withdrawn at various instants of time shows some decrease in the relative content of the main functional groups of lignin. This is apparently caused by both elimination of various groups from aromatic ring and development of radical condensation of lignin. This effect is the most typical for soda cooking (N/1–N/3). In the case of alcohol cooking, lignin obtained at various instants of time in the last stage of the process has the smallest differences in the functional structure.

CONCLUSIONS

(1) The IR spectra of organosolvent lignins recovered by alkaline delignification in the presence of ethanol have the set of absorption bands typical for lignin of spruce wood.

(2) Comparison of the IR spectra of organosolvent and alkaline (soda) lignins shows that, in delignification in aqueous-ethanol medium, lignin passes into solution in less oxidized state than in cooking of wood in aqueous alkaline medium.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Nonadditive Effect of Components of a Binary Plasticizer on the Properties of Polyether–Urethane–Ureas

V. V. Tereshatov, V. V. Fedchenko, E. N. Tereshatova, and M. A. Makarova

Institute of Technical Chemistry, Ural Division, Russian Academy of Sciences, Perm, Russia

Received April 28, 2004

Abstract—The effect of a mixture of di(2-ethylhexyl) phthalate and tributyl phosphate on the properties of segmented polyether–urethane–ureas was examined. The data obtained for the elastomers with individual and mixed plasticizers were compared. The efficiency of using the binary plasticizer for controlling the properties of polyether–urethane–ureas was assessed.

One of the ways to control the rheological, thermal, and mechanical properties of polyurethane compounds is their plasticization with liquids of various chemical structures: ethers, esters, chloroparaffins, and other compounds [1–5]. The performance of certain liquids as plasticizers was demonstrated for many block (so-called segmented, SPU) polyurethanes [2–5].

The properties of microheterogeneous plasticized polyurethanes depend on the effect of the plasticizer on the miscibility of liquid and solid polymer blocks. As the solubility of rigid blocks in the flexible phase of the polymer changes, the amount of the rigid component in this phase and the content of the microdispersed filler (domains of rigid blocks) in the material increase or decrease; the SPU properties change correspondingly.

In plasticization of the same polyurethane with different liquids, samples of the material with a lower glass transition point of the flexible phase T_g^s may have higher elastic modulus and higher strength. On the contrary, less strong and softer SPU samples may have higher glass transition point of the flexible polymeric matrix [2]. All these data were obtained with microheterogeneous polyurethane compounds plasticized with individual liquids.

The possibility of controlling the SPU properties by plasticization with mixtures of low-molecular-weight liquids has not been examined. The use of mixed plasticizers instead of individual liquids may offer new opportunities. Of practical interest are mixtures of commercially available plasticizers.

Our goal was to assess the possibility of controlling the properties of segmented polyether–urethane–ureas (SPUUs) by using binary plasticizers consisting of tributyl phosphate (TBP) and di(2-ethylhexyl) phthalate (DEHP). These compounds affect the structure and properties of SPUUs differently. Depending on the structure of flexible polyether blocks, DEHP either does not noticeably affect the microphase segregation in the material or acts as a "precipitant" of rigid blocks, whereas TBP improves the miscibility of flexible polyether and rigid urethane–urea blocks [2].

EXPERIMENTAL

We used plasticized polyether–urethane–ureas based on oligoethers: SPUU-1 with polypropylene oxide flexible segments and SPUU-2 with polytetramethylene oxide flexible blocks. The SPUUs were prepared from oligo(propylene oxide)diol and oligo(tetramethylene oxide)diol prepolymers (Laprol-1052 and SKU-PFL-100, respectively) prepared by reactions of the corresponding oligomeric diols with toluene-2,4-diisocyanate (diisocyanate : diol molar ratio 2 : 1). The molecular weight of the oligomeric diols and prepolymers was ~1000 and ~1400, respectively (estimated from the content of functional groups).

The prepolymers were cured with methylenebis(*o*-chloroaniline) (Diamet Kh) preliminarily dissolved in DEHP, TBP, or their mixtures. The molar ratio of the prepolymers to Diamet Kh was 1.03. Samples were prepared as described in [5].

The plasticizer content in all the samples was 14 wt %. Such amount of the plasticizers ensures high relative strain (>600%) and high strength of the material (tensile strength of SPUU-1 and SPUU-2 no less than 25 and 30 MPa, respectively). The physicome-

chanical characteristics of SPUUs {nominal tensile strength σ_n (maximal stress calculated per initial cross section of the sample), relative elongation at break ε_n (at σ_n), elastic modulus E_{100} (at ε_n = 100%), and breaking stress per actual sample cross section, $f_b = \sigma_n[(\varepsilon_n + 100)/100]$} were determined at an extension rate of 0.28 s^{-1} at 23°C.

The glass transition point of the flexible phase of SPUUs was determined with a DSM-2 differential scanning calorimeter at slow (~0.02 deg s^{-1}) heating.

The rheological properties of the reaction mixture were studied at the compounding and casting temperature of 55 ± 1°C on a Rheotest-2 cone–plate viscometer at a shear rate of 180 s^{-1}.

The IR spectra were recorded on a Bruker IFS 66/S Fourier spectrometer. Elastomer films were prepared without using volatile solvents [5].

The mechanical characteristics, glass transition points T_g^s of SPUUs, and shear viscosities η of the reaction mixtures 30 min after compounding at various contents x_2 of DEHP in the binary plasticizer are listed in the table.

Figure 1 shows the dependence of the breaking tensile stress of SPUU-1 and SPUU-2 on x_2. These data show that components of the mixed plasticizer affect the mechanical properties of the materials and the glass transition point of the flexible phase nonadditively. The effect of DEHP and TBP on the viscosity η of the reaction mixtures after compounding is also nonadditive.

In plasticization solely with TBP, the strength characteristics and elastic modulus of SPUUs are the lowest, and T_g^s, the highest, which is due to the negative effect of TBP on the microphase segregation of flexible polyether and rigid urethane–urea blocks. This is clearly seen, e.g., from the IR spectra of SPUU samples in the range of stretching vibrations of carbonyl groups in urethane and urea fragments (ν = 1620–1750 cm^{-1}) (Figs. 2a, 2b). According to [5–7], the microphase segregation of flexible and rigid blocks in the material can be judged from the intensity of the band at ν = 1640 cm^{-1} (carbonyl vibrations in self-associates of urea groups localized in domains of urethane–urea blocks).

An appreciable decrease in the intensity of this band in the IR spectra of SPUU-1 and SPUU-2 plasticized with TBP (Fig. 2a, curve *5*; Fig. 2b, curve *4*) suggests transition of a part of rigid blocks from the rigid to flexible phase of the elastomer; as a result, the amount of the microdispersed rigid phase acting as reinforcing filler decreases. Increased content of the rigid component in the flexible phase of the polymer in the presence of TBP results in a weaker effect of this plasticizer on the glass transition point T_g^s of SPUU, compared to plasticization with DEHP, despite the fact that the glass transition point T_g of TBP (–131°C) is lower than that of DEHP (–90°C). The T_g^s of nonplasticized SPUU-1 is –16°C. Similar pattern is observed with SPUU-2 (see table).

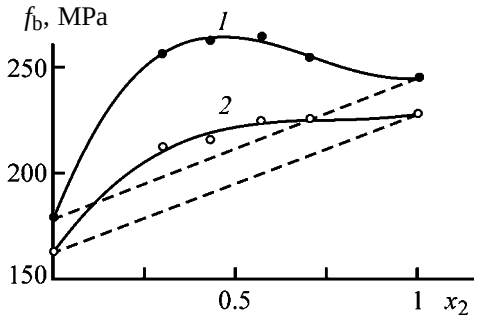

Fig. 1. Breaking tensile stress f_b of (*1*) SPUU-1 and (*2*) SPUU-2 as a function of DEHP content x_2 in the mixed plasticizer. Dashed lines correspond to the additive effect of the plasticizer components.

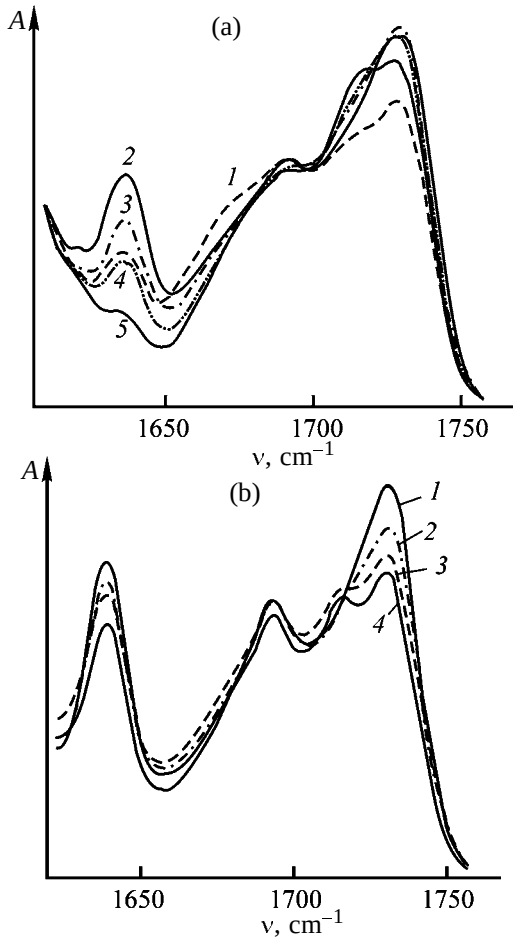

Fig. 2. IR spectra of (a) SPUU-1 and (b) SPUU-2 as influenced by the binary plasticizer composition. (*A*) Absorption and (ν) wave number. (a) (*1*) no plasticizer; DEHP content (wt %) in the binary plasticizer: (*2*) 100, (*3*) 70, (*4*) 30, and (*5*) 0. (b) DEHP content (wt %) in the binary plasticizer: (*1*) 100, (*2*) 70, (*3*) 30, and (*4*) 0.

The influence of individual plasticizers (including DEHP and TBP) on the structure and properties of SPUUs was described in detail in [2].

On replacement of 30 wt % of TBP (x_2 = 0.3) by DEHP, the amount of self-associates of urea groups in SPUU-1 becomes close to the content of these stable species in the nonplasticized material, which can be readily seen from changes in the intensity of the carbonyl absorption band at ν = 1640 cm^{-1} (Fig. 2a, curve *3*). The strength characteristics of the material, σ_n and f_b, sharply increase in going from the individual to mixed plasticizer, and the glass transition point T_g^s decreases because of a decrease in the amount of rigid blocks dissolved in the flexible phase of the polymer.

As the DEHP content in the mixture with TBP is increased further, the glass transition point of the flexible phase of SPUU decreases to a lesser extent. This is especially true for SPUU-2 containing poly(tetramethylene oxide) flexible segments. As already noted, di(2-ethylhexyl) phthalate has virtually no effect on the microphase segregation in the material. Increased DEHP content in the binary plasticizer has a weaker effect on T_g^s of SPUU-2, compared to T_g^s of SPUU-1, which could be expected from the IR data (band at ν = 1640 cm^{-1}, Figs. 2a, 2b).

It is known that the strength of segmented polyurethanes depends not only on the amount of the reinforcing filler but also on other factors, including intermolecular interaction in the flexible phase and orientation of polymeric chains in extension of the material [8]. An increase in the degree of microphase segregation with increasing DEHP content in the plasticizer is accompanied by a decrease in the content of urethane and urea groups capable of hydrogen bonding in the SPUU elastic matrix; this factor negatively affects the strength of the material. Apparently, the superposition of factors oppositely acting on the mechanical properties of SPUUs is responsible for the essentially nonlinear dependence of the material strength on the DEHP content in the binary plasticizer. Even at x_2 = 0.6, the tensile strength and breaking stress of SPUU-1 plasticized with the mixed plasticizer only slightly differ from ε_n and f_b of the elastomer plasticized with individual DEHP (see table, Fig. 1). The dependence of the SPUU-2 strength on the DEHP content in its mixture with TBP passes through a maximum at x_2 = 0.6. The elastic modulus E_{100} of this material is appreciably lower than that of the SPUU plasticized with individual DEHP. For example, at x_2 = 0.57, E_{100} of SPUU-2 decreases from 10.6 to 8.3 MPa. For SPUU-1, the decrease in E_{100} is still more pronounced: from 7.0 to 3.6 MPa.

Thus, the mechanical properties of SPUUs plasticized with the mixed plasticizer and one of its components differ essentially.

Another positive effect achieved on partial replacement of DEHP by TBP in SPUU is a sharp decrease in the viscosity of the reaction mixture, with the high strength of the cured material being preserved. For example, at the TBP weight fraction in the mixture of 0.43 (x_2 = 0.57), the viscosity of the SPUU-1 reaction mixture decreases from 21 to 12 Pa s. The viscosity of the uncured SPUU-2 reaction mixture 30 min after compounding at 50°C is 22 Pa s, whereas with a single plasticizer, DEHP, the viscosity under the same conditions is as high as 43 Pa s.

Preservation for a long time of the low viscosity of polyurethane compounds is necessary for obtaining

reinforced and unreinforced polyurethane items of complex shape without blisters.

For polyurethane items subjected to strong strains in service, it is important to ensure high strength with considerably decreased tension modulus E_{100}. At the same strain, the material with lower E_{100} will experience weaker mechanical load, which will enhance its performance.

It should be noted that, according to our experiments, a similar decrease in E_{100} of SPUU-1 can be attained by introducing 20 wt % DEHP instead of 14 wt % mixed plasticizer. In so doing, however, the material strength decreases from 25 to 17 MPa.

CONCLUSIONS

(1) In plasticization of segmented polyether–urethane–ureas with a mixture of tributyl phosphate with di(2-ethylhexyl) phthalate of various compositions, we revealed a pronounced nonadditive influence of the plasticizer components on the strength and elasticity of these materials, on the glass transition point of the flexible phase, and on the rheological properties of the reaction mixtures.

(2) According to IR data, the plasticizer composition significantly affects the microphase segregation in polyether–urethane–ureas. This is manifested particularly strongly in the material with poly(propylene oxide) flexible blocks.

(3) The strength and strain characteristics of segmented polyurethane–ureas plasticized with a 60 : 40 mixture of di(2-ethylhexyl) phthalate and tributyl phosphate are not inferior to those of the material plasticized solely with di(2-ethylhexyl) phthalate. At the same time, the compositions with the binary plasticizer have two times lower viscosity, with considerably smaller tension modulus E_{100} of the cured material. This is important for preparing high-quality items and ensuring their efficiency at significant strains.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Urea–Formaldehyde Oligomers without a Solvent

T. V. Bezbozhnaya, V. V. Zamashchikov, and A. I. Lutsyk

Litvinenko Institute of Physical Organic and Coal Chemistry, National Academy of Sciences of Ukraine, Donetsk, Ukraine

Received February 5, 2004

Abstract—A urea–formaldehyde oligomer comparing well with commercially avaliable KF-MT and KF-M resins in the adhesive power was prepared from solid paraform and urea without a solvent.

Synthetic urea–formaldehyde oligomers (UFOs) are widely used in wood-working industry as binders and as a base for adhesives. However, UFOs tend to self-cure during prolonged storage and transportation. Furthermore, the modern industrial synthesis of UFOs in multistep [1–4] and involves water as a solvent, with its subsequent distillation.

In this study we examined the possibility of preparing highly stable UFO without a solvent. The starting compounds were paraform (F) and urea (U). The products were tested as binders in production of chip boards.

EXPERIMENTAL

A flask equipped with a power-driven stirrer and a thermometer was charged with urea [pure grade, GOST (State Standard) 6691–77] and paraform [TU (Technical Specifications) 6-09-3208–78] in a definite molar ratio (the U : F ratio was varied from 1 : 1 to 1 : 6), after which solid sodium hydroxide (up to 2% relative to the total weight of U and F) preliminarily ground with a small amount of urea was added. The mixture was heated with stirring at 333 K for 2.5–3 h.

Within 5–10 min after switching on the stirrer, the mixture started to liquefy, and within 15–20 min it fully transformed into a viscous sticky liquid. Upon further heating for 2.5 h, the products with U : F > 1 : 3 hardened, and those with U : F 1 : 3.25, 1 : 3.5, 1 : 4, and 1 : 6 remained liquid. At room temperature, the oligomers with U : F 1 : 3.25 and 1 : 3.5 hardened in several days, and that with U : F 1 : 4 remained a stable viscous sticky liquid for at least 12 months.

The mixture starts to liquefy earlier with increasing temperature, stirring intensity, degree of initial grinding of urea grains, and amount of sodium hydroxide added. In the absence of NaOH, the mixture does not become liquid at 333 K over a period of 2.5 h. The individual components (urea, paraform) separately mixed with NaOH do not form liquid systems under similar conditions.

The liquefaction is not associated with accumulation of water during the reaction. According to GLC data (LKhM-8MD chromatograph, catharometer, stationary phase 5% TSEP on Polysorb, internal reference *n*-PrOH), the water content in the resin (initial ratio U : F = 1 : 4) 3 h after the start of the reaction did not exceed 4%. The change in the aggregation state of the system is undoubtedly caused by the base-catalyzed reaction of urea with paraform: during the first 20 min, the formaldehyde concentration sharply decreases (see figure) with accumulation of methylol groups, and subsequent changes occur more smoothly (the concentration of free formaldehyde in the resin was determined according to GOST 14231–88, and the concentration of methylol groups, by iodometric titration [5]). The main reaction of formation of methylol groups from formaldehyde is accompanied by side Cannizzaro reaction. According to GLC data, the methanol content in the oligomer sample with the initial ratio U : F = 1 : 4 did not exceed 3%.

The solid products obtained at the initial molar ratio U : F > 1 : 3 are virtually insoluble in water. The oligomers obtained at a high initial content of formaldehyde are readily soluble in water, but at U : F = 1 : 6 dissolution in water is accompanied by the release of unchanged paraform.

As the oligomer with U : F = 1 : 4 showed high stability, high solubility in water, and apparent adhesive power, we chose this product for subsequent tests as binder in chip board production.

This product has a high content of methylol groups (up to 30%). The high degree of nitrogen functionali-

1070-4272/04/7709-1544 © 2004 MAIK "Nauka/Interperiodica"

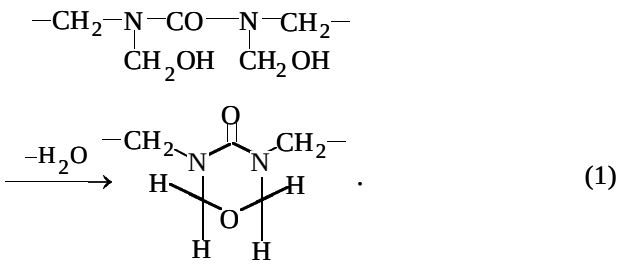
zation is confirmed by IR spectroscopy (Specord 75-IR, film on KBr, ν, cm^{-1}; the bands were assigned according to data of [6]): 3350 vs, br [ν(NH)]; 1000 vs, br [δ(OH) in $–CH_2OH$]; 1655 vs (amide I); 1538 vs (amide II); 1260 s (amide III); 1455 w, 1380 s [ν(CH) in $–CH_2OH$]; 2910 m [ν_{as}(CH) in $–CH_2OH$]; 2960 m [ν_{sym}(CH) in CH_2 of ethers, $–CH_2OH$]; 1170 w, 1060 [ν(C–O) in –C–O–C–]; 970, 935, 845 m, 805 w, 775 m [ν(C–O) in –C–O–C–, symmetric ring].

In the range 3500–3100 cm^{-1}, there is only one very strong band at 3350 cm^{-1}. This means that the amount of NH groups in the resin considerably exceeds the amount of NH_2 groups. The resins with a lower initial formaldehyde content exhibit two bands in this range, 3430 and 3330 cm^{-1}, characterizing the presence of $–NH_2$ and NH groups, respectively. A strong band at 1000 cm^{-1} is consistent with the high content of methylol groups.

There as an apparent unbalance between the initial amount of formaldehyde and total amount of formaldehyde and methylol groups determined in the resin 3 h after the start of the reaction; the unbalance grows with decreasing U : F ratio:

U : F	F_{in}, wt %	F + $–CH_2OH$, wt % (3 h)
1 : 1	33.0	30.1
1 : 1.23	38.0	34.5
1 : 2	50.0	46.5
1 : 3	60.0	52.7
1:3.5	63.6	40.9
1 : 4	66.7	40.4

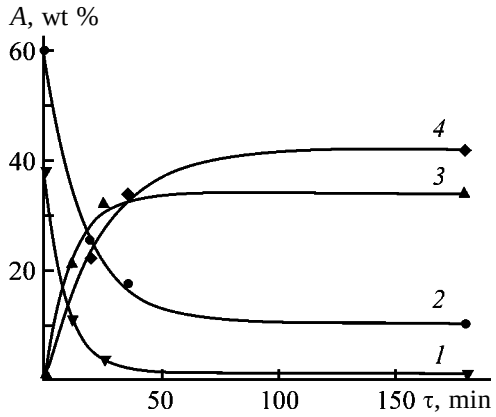
Comparison of these results with the IR data shows that the unbalance is caused by formation of ether fragments in the resin (condensation of methylol groups) or of cyclic fragments like uronic rings [intramolecular reaction of methylol groups, reaction (1)]:



(1)

The bands at 845, 805, and 775 cm^{-1} can be apparently assigned to cyclic structures [6, 7], and the band at 1060 cm^{-1}, to linear ethers.

To check the binding power of the oligomer with U : F = 1 : 4, we prepared by standard procedures experimental chip board specimens. These specimens



Kinetic curves of (*1*, *2*) consumption of free formaldehyde and (*3*, *4*) accumulation of methylol groups in condensation of urea with paraform. U : F (*1*, *3*) 1 : 1.23 and (*2*, *4*) 1 : 3; 333 K. (*A*) Content and (τ) time.

were prepared for tests according to GOST 10632–89 (COMECON Standard 5879–87). Pressing was performed at 433 K. The oligomer was added in an amount of 10 wt % relative to dry wood chips. The curing agent was NH_4Cl (1 wt % relative to the oligomer). As the oligomer with U : F = 1 : 4 is very viscous, it was taken as 40% aqueous solution.

To bring the U : F ratio to the level commonly used in commercial resins and to bind free formaldehyde whose content in the oligomer is 9–10%, we added urea to the oligomer just before use, so that the U : F ratio became 1 : 1.23.

For comparison, we also prepared chip board specimens with commercial resins KF-MT and KF-M, taken in the same amounts as the oligomer (as calculated for the dry matter). As seen from the table, the experimental chip board specimens prepared with our oligomer are not inferior in the bending strength to the specimens prepared with commercial resins KF-MT and KF-M and show lower water absorption and swelling in thickness.

Results of tests of experimental chip board specimens

Parameter	Oligomer*	KF-MT	KF-M
Density ρ, kg m^{-3}	704 ± 9	–	820
Ultimate bending strength σ_b, MPa	19.9 ± 0.4	22.0	21.0
Swelling in thickness in 2 h *h*, %	4.2 ± 0.6	10.0	10.0
Water absorption in 2 h *m*, %	32 ± 3	36.0	36.0

* Mean value for four chip board specimens.

The public-health tests of the experimental chip board specimens performed by the Sanitary-Epidemiological Station of Donetsk oblast showed the absence of formaldehyde emission.

CONCLUSIONS

(1) Urea–formaldehyde oligomers can be prepared without a solvent at the initial urea : formaldehyde ratio varied from 1 : 1 to 1 : 6.

(2) The oligomer with the initial molar ratio U : F = 1 : 4 can be used as a binder in production of chip boards.

CHEMISTRY OF FOSSIL FUEL

A Kinetic Model of Thermochemical Transformation of Solid Organic Fuels

E. A. Boiko and S. V. Pachkovskii

Krasnoyarsk State Technical University, Krasnoyarsk, Russia

Received February 17, 2004

Abstract—A kinetic model of thermochemical transformation of solid organic fuels was constructed. The mathematical model describes the kinetics of drying, release and combustion of volatiles, and combustion and gasification of the nonvolatile (coke) residue at linear heating. The kinetic curves of burn-out of Irsha–Borodino brown coal at various heating rates and model parameters were calculated.

The experience of using solid organic fuels at thermal power plants shows that there are still no pretreatment and combustion procedures ensuring high efficiency, reliability, and environmental safety of boiler operation [1].

To formulate recommendations concerning conditions and modes of combustion of solid organic fuels, it is necessary to elucidate an interrelation, based on kinetic parameters, between various steps and processes of thermochemical transformation of coals [2].

Description of heat and mass exchange and of aerodynamics in combustion chambers of boilers involves elucidation of the mechanism and construction of an adequate kinetic model of burn-out of a solid organic fuel [3–7]. The following questions should be answered [8]: What steps control the overall process kinetics? What steps are excessive in the kinetic scheme under consideration, and can this scheme be simplified? What kinetic mechanism (among several alternatives) is the most probable?

When a solid fuel is burnt as a dust, the degree of its thermochemical conversion is determined by a set of parameters of consecutive-parallel processes, in particular [9–13], by the rate of moisture evaporation, rate of release and combustion of volatiles, and rate of combustion of the nonvolatile residue. The scheme of burn-out of a coal substance is complicated in certain steps by such processes as low-temperature chemisorption of oxygen, gasification of the nonvolatile residue with carbon dioxide, steam, and hydrogen, transformations of chemical components of the mineral matter of the fuel, etc. [14].

As these processes strongly influence each other and their endo- and exothermic effects are significant, they should be taken into account in constructing the pattern of thermochemical transformation. The rates and parameters of the above processes are largely determined by the quality of the initial fuel. In this connection, to correctly describe and calculate the coal burn-out, it is necessary to elucidate the mechanism and construct a kinetic model of themochemical transformation of a solid organic fuel under conditions of a combustion chamber. This would allow proper choice of the process modes and conditions for pretreatment and combustion of solid organic fuels.

Analysis of the mechanism of complex physicochemical processes that occur in combustion of coals involves evaluation of the significance of particular process steps [15] and construction of a hierarchy of this steps following preset criteria [16]. To construct a mathematical model of thermochemical transformation of a solid organic fuel, we used the following process scheme. The process is subdivided into several relatively independent parallel-consecutive multistep stages (Fig. 1): drying and heating of a particle until release or ignition of volatiles; release of volatiles and their combustion near the particle; combustion of the nonvolatile (coke) residue consisting of organic and mineral matter [10].

The physicochemical model of thermal transformation of a solid organic fuel in a wide temperature range suggests that drying of a moist material is characterized by moisture evaporation from the bulk of a coal particle, with the evaporation front moving inside the particle as a phase transition front, under the influence of an increase in the temperature of the dry surface. Since the moisture present in fuel forms bonds

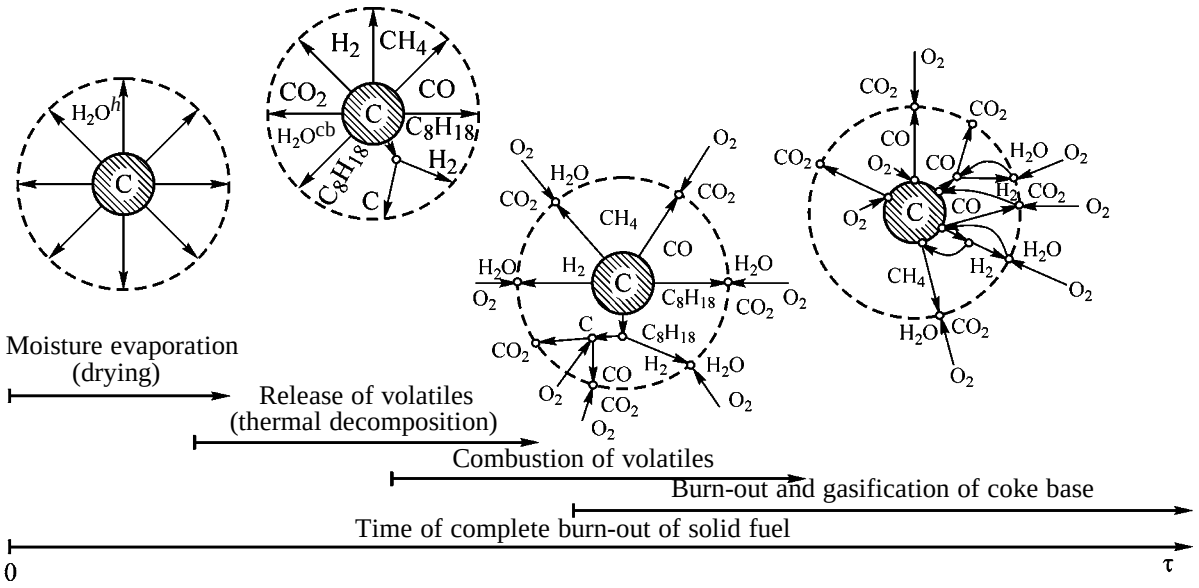

Fig. 1. Physicochemical model of thermochemical transformation of a solid fuel.

of different strength with the coal matter, it is appropriate to consider two independent fronts of evaporation of hygroscopic and chemically bound moisture [17], with the latter lagging behind the former.

As the temperature of the surface layer increases, the organic matter starts to thermally degrade, with the release of volatiles. The modern pyrolysis models consider the organic matter of coal as an ensemble of condensed aromatic, hydroaromatic, and heterocyclic structures (clusters) containing various functional groups as substituents [18]. As a fuel is heated, the bonds linking functional groups to ring clusters are cleaved, with the release of gaseous components (mainly CO_2, H_2, H_2O, CO, CH_4, HCN, aliphatic hydrocarbons). Simultaneously with the release of low-boiling gaseous components, the bridged structure of coal is cleaved, with the release of coarse molecular fragments (resins $C_8H_{18} \cdot 2H_2O$).

The released combustible gaseous compounds, on reaching certain concentration, start to react in the gas phase with atmospheric oxygen to give the final products: CO_2 and H_2O [19]. At deficiency of oxygen, the resins can degrade further to form secondary products, in particular, acetylene, benzene, hydrogen, and carbon black, which, in turn, can also react with oxygen to give products of complete (CO_2, H_2O) and incomplete (e.g., CO) combustion, with their subsequent afterburning [20].

The release of volatiles and their subsequent combustion are accompanied by heating of the coal particle, initiating combustion of its nonvolatile (coke) base. This reaction occurs on the surface of the coal particle and involves adsorption of oxygen from the gas phase on the carbon surface. Oxygen atoms react with the carbon surface to give complex carbon–oxygen species C_xO_y [11]. These species subsequently decay to give products of complete (CO_2) and incomplete (CO) combustion.

Water vapor and carbon dioxide formed by drying, evaporation of ballast volatiles, burning of combustible volatiles and of the coke base, and afterburning of incomplete combustion products can react with the solid phase to form CO and H_2. These reactions occur by the radical-chain mechanism and directly involve hydroxy groups as intermediates, with formation of HCOH molecules and then of donor–acceptor bonds with atomic carbon [21]. Collisions of atoms and molecules with vacant sites results in formation of intermediate complexes. These complexes stimulate electron transfer, providing chemisorption of gaseous components on the surface of the coke base.

The hydrogen formed by secondary reactions can react with carbon to form CH_4 and with oxygen to form H_2O [22]. Methane is oxidized in the gas phase to CO_2 and H_2O. The products of complete (H_2O) and incomplete (CO) combustion can react with each other to form CO_2 and H_2 [10].

The reactions that occur in the gas volume surrounding a particle and the heterogeneous reactions can be described by the following stoichiometric equations [7, 15, 17, 21, 23].

(1) Moisture evaporation: $W_0^h \rightarrow W^h$, where W_0^h is the initial moisture content of a fuel, and W^h is the amount of evaporated moisture in the gas volume.

(2) Release of volatiles: $V_{0i} \rightarrow V_{i,j}$, where V_{0i} is the initial concentration of volatiles in the solid phase of *i*th component, and $V_{i,j}$ is the concentration of volatiles in the gas phase of *i*th component in *j*th step.

(3) Secondary degradation of resins: $a_i V_{i,j,n} \rightarrow g_i V_{i,j,n+1}$, where $V_{i,j,n}$ are *i*th components of *j*th step of *n*th reaction of secondary degradation; $V_{i,j,n+1}$, *i*th components formed by $(n + 1)$st reaction of secondary degradation in *j*th step; and a_i and g_i, stoichiometric coefficients of degradation of *i*th component.

(4) Combustion of volatiles: $a_i V_i + b_i O_2 \rightarrow g_i P$, where $V_y i$ is the concentration of volatiles in the gas phase of *i*th component; O_2, oxygen concentration; *P*, concentration of combustion products of volatiles; and a_i, b_i, and g_i, stoichiometric coefficients in oxidation of *i*th component.

(5) Heterogeneous combustion of coke residue: $a_r c + b_r O_2 \rightarrow g_r P$, where *c* is the carbon concentration in the fuel (solid phase); *P*, concentration of products of complete and incomplete combustion of carbon; and a_r, b_r, and g_r, stoichiometric coefficients of combustion of the coke base.

(6) Homogeneous afterburning of incomplete combustion products: $a_m P_m + b_m O_2 \rightarrow g_m P$, where P_m is the concentration of incomplete combustion products; a_m, b_m, and g_m, stoichiometric coefficients for *m*th component of incomplete combustion products.

(7) Gasification of the coke residue: $a_s c + b_s P \rightarrow g_s P$, where a_s, b_s, and g_s are the stoichiometric coefficients of reactions involved in gasification of the coke base.

(8) Gasification of the products: $a_y P_m + b_y P_u = g_y P$, where P_u is the concentration of complete combustion products; a_y, b_y, and g_y, stoichiometric coefficients of reactions involving products of complete and incomplete combustion.

The suggested physicochemical formulation of the problem can be described by the following calculation scheme which allows construction of a mathematical model allowing control of material balances both for separate steps of coal combustion and for the overall process. In construction of a mathematical model, we assumed that multistep processes of thermochemical transformation of a solid fuel are additive, the functional groups in thermolysis of the fuel transform independently, the ratio of functional groups in the resin is the same as in the initial coal, and the volatiles released in pyrolysis of coal dust and the nonvolatile coke residue are ideally mixed with the oxidant (air) prior to the chemical reaction.

The mathematical model of kinetic processes of thermochemical transformation of a solid organic fuel, taking into account the above assumptions, is given in the differential form below (see scheme).

The kinetic equation of drying describes the kinetics of evaporation of hygroscopic moisture from the coal surface:

$$dH_2O_0^h/d\tau = -k_{0_{H_2O_0^h}} \exp[-E_{H_2O_0^h}/RT(\tau)]H_2O_0^h,$$

where $H_2O_0^h$ is the initial concentration of hygroscopic moisture in the fuel, kg kg^{-1}; k_0, preexponential factor, s^{-1}; *E*, activation energy, J mol^{-1}; *R*, universal gas constant, J mol^{-1} K^{-1}; *T*, process temperature, K; and τ, time, s.

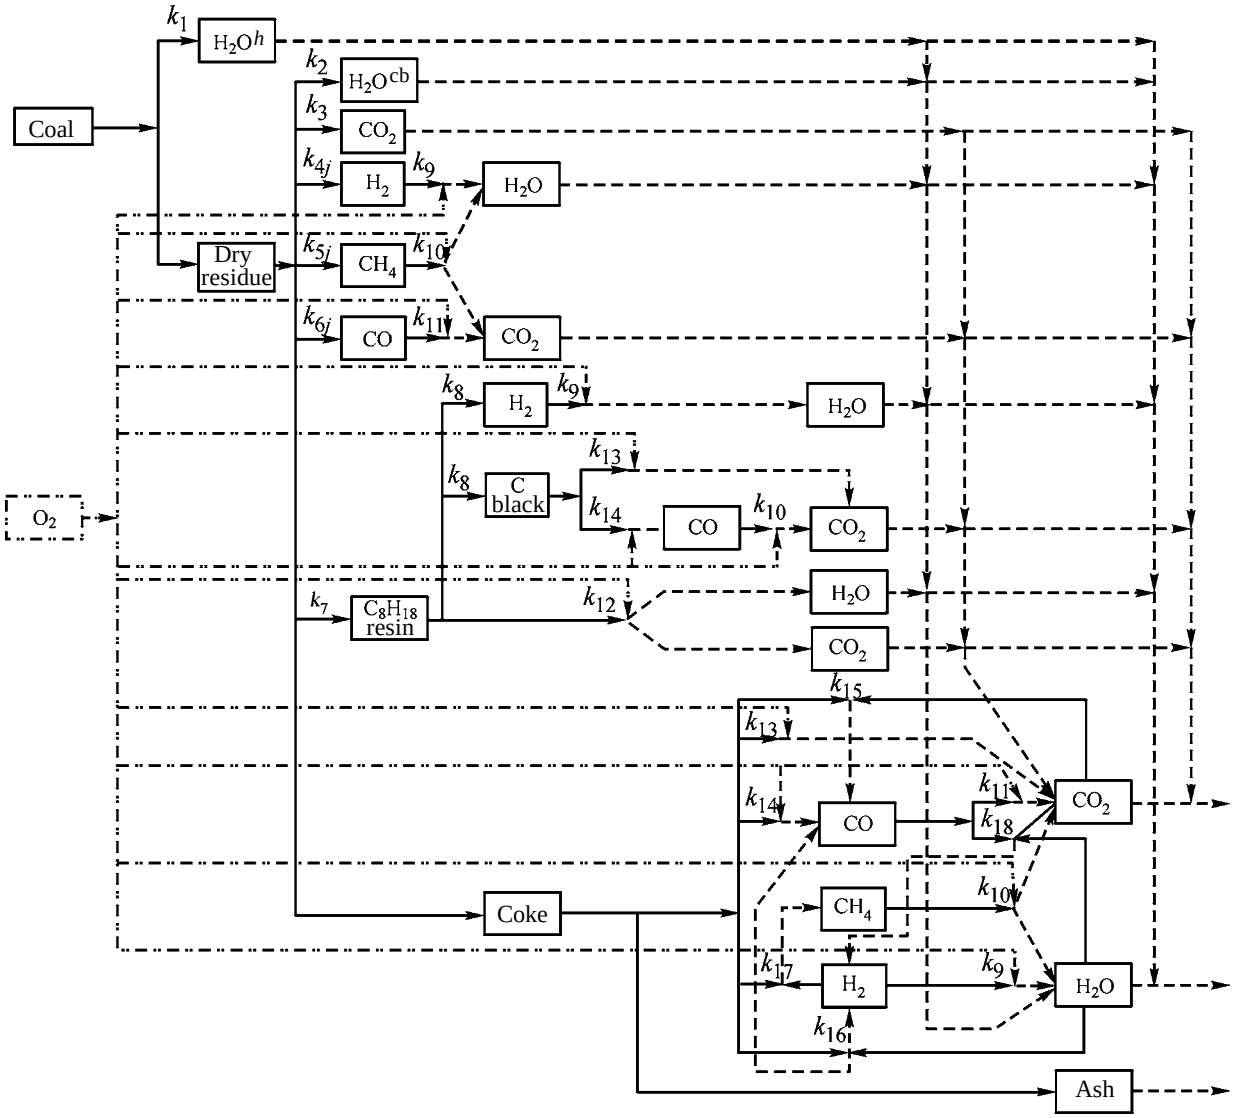
The kinetic equation for the release of volatiles describes the content of residual volatiles in the fuel as a result of a multistep process of bond cleavage with the release of ballast (H_2O, CO_2) and combustible (H_2, CH_4, CO, resins $C_8H_{18} \cdot 2H_2O$) volatile vaporous and gaseous components during thermal decomposition of the coal organic matter [9]:

$$dV_0/d\tau = -\sum_{i=1}^{I}\sum_{j=1}^{J} k_{0_{V_{0i,j}}} \exp[-E_{V_{0i,j}}/RT(\tau)]V_{0i,j},$$

where V_0 is the initial concentration of volatiles in the fuel (solid phase), kg kg^{-1}; $i = 1, ..., I$, numbers of vaporous and gaseous components taken into account; and $j = 1, ..., J$, numbers of separate steps responsible for the release of *i*th component.

The kinetic equation of combustion of volatiles in the gas phase characterizes homogeneous combustion of the released volatiles and products of their secondary degradation in the absence of oxidant (O_2). The first and third terms in this equation describe the dynamics of accumulation of the released volatiles and their subsequent degradation. The second term describes formation of secondary volatile gaseous components by degradation of resins. The fourth term described homogeneous combustion of volatiles formed both by fuel degradation and by secondary degradation of particular vaporous and gaseous components (resins) [20]:

$$dV_0/d\tau = -\sum_{i=1}^{I}\left\{\left[\sum_{j_0=1}^{J_0} k_{0_{V_{0i,j_0}}} \exp[-E_{V_{0i,j_0}}/RT(\tau)]V_{0i,j_0}\phi_{V_{0i,j_0}}\right.\right.$$



Scheme of calculating the kinetic parameters of thermochemical transformation of a solid fuel.

$$+ \sum_{i_d=1}^{I_d} \sum_{j_d=1}^{J_d} k_{0V_{i_d,j_d}} \exp[-E_{V_{i_d,j_d}}/RT(\tau)] V_{i_d,j_d} \phi_{i_d,j_d}$$

$$- \sum_{j=1}^{J} k_{0V_{i,j}} \exp[-E_{V_{i,j}}/RT(\tau)] V_{i,j} \phi_{i,j} \Big]$$

$$- k_{0V_i} \exp[-E_{V_i}/RT(\tau)] a_i V_i^{q_i} O_2^{b_i} \Big\},$$

where V is the concentration of volatiles in the gas phase, kg kg^{-1}; $j_0 = 1, ..., J_0$, numbers of separate steps responsible for the release of ith component from the fuel; $i_d = 1, ..., I_d$, numbers of volatile components whose degradation yielded ith substance; $j_d = 1, ..., J_d$, numbers of separate steps responsible for the release of ith component from an intermediate substance in the course of its degradation; a and b, stoichiometric coefficients; and ϕ_x, coefficient taking into account the mole fraction of component x in the gas phase.

The equation for the kinetics of burn-out and gasification of the coke base describes the consumption of carbon in oxidation of a fuel to CO and CO_2 and in reduction of products of compete and incomplete combustion (CO_2, H_2O, H_2, etc.). The first term describes the dynamics of burn-out of the coke base, and the second term, gasification of the combustion products [21]:

$$dc/d\tau = -\Big\{ \sum_{r=1}^{R} k_{0c,r} \exp[-E_{c,r}/RT(\tau)] a_r c^{a_r} O_2^{b_r}$$

$$+\sum_{s=1}^{S} k_{0_{c,s}} \exp[-E_{c,s}/RT(\tau)] a_s c^{a_s} P^{b_s}\Bigg\},$$

where c is the carbon concentration in the fuel (solid phase), kg kg^{-1}; O_2, oxygen concentration, kg kg^{-1}; P, concentration of fuel thermolysis products: evaporated moisture, released unburned volatiles, and products of complete and incomplete combustion of the nonvolatile residue (coke), kg kg^{-1}; r = 1, ..., R, numbers of groups of reactions taken into account when describing the burn-out of the coke base; and s = 1, ..., S, numbers of groups of reactions taken into account when describing the gasification.

In the equation describing the dynamics of variation of the oxygen concentration in homogeneous and heterogeneous combustion of volatiles and the coke base, the first, second, and third terms reflect consumption of O_2 in combustion of volatiles and the coke base and in homogeneous oxidation of incomplete combustion products, respectively:

$$dO_2/d\tau = -\Bigg\{\sum_{i=1}^{I} k_{0_{V_i}} \exp[-E_{V_i}/RT(\tau)] b_i V_i^{a_i} O_2^{b_i} + \sum_{r=1}^{R} k_{0_{c,r}} \exp[-E_{c,r}/RT(\tau)] b_r c^{a_r} O_2^{b_r} + \sum_{m=1}^{M} k_{0_{P_m}} \exp[-E_{P_m}/RT(\tau)] b_m P_m^{b_m} O_2^{b_m}\Bigg\},$$

where m = 1, ..., M are the numbers of incomplete combustion products of the coke base P_m.

The concentration of products of thermochemical transformation of a coal dust particle is taken into account by the equation describing the dynamics of moisture evaporation, release of ballast volatiles and of volatiles that remained unchanged in oxidation, complete and incomplete combustion of volatiles and the coke base, and gasification of the nonvolatile products [15]. The first term is related to moisture evaporation; the second term, to release or secondary degradation of ballast and unburned volatiles; the third term, to homogeneous combustion of volatiles; the fourth term, to heterogeneous burn-out of the coke base; the fifth and seventh terms, to gasification; the sixth term, to combustion of incomplete combustion products; and the eighth, ninth, and tenth terms, to consumption of components as a result of combustion and gasification of incomplete combustion products:

$$dP/d\tau = -k_{0_{H_2O_0^h}} \exp[-E_{H_2O_0^h}/RT(\tau)] H_2O_0^h + \sum_{i=1}^{I}\Bigg\{k_{0_{V_{0i,j_0}}} \exp[-E_{V_{0i,j_0}}/RT(\tau)] V_{0i,j_0} \phi_{V_{0i,j_0}} + \sum_{i_d=1}^{I_d}\sum_{j_d=1}^{J_d} k_{0_{V_{i_d,j_d}}} \exp[-E_{V_{i_d,j_d}}/RT(\tau)] V_{i_d,j_d} \phi_{V_{i_d,j_d}} - \sum_{j=1}^{J} k_{0_{V_{i,j}}} \exp[-E_{V_{i,j}}/RT(\tau)] V_{i,j} \phi_{V_{i,j}}\Bigg\} + \sum_{i=1}^{I} k_{0_{V_i}} \exp[-E_{V_i}/RT(\tau)] g_i V_i^{a_i} O_2^{b_i} \phi_{V_i} + \sum_{r=1}^{R} k_{0_{c,r}} \exp[-E_{c,r}/RT(\tau)] g_r c^{a_r} O_2^{b_r} \phi_{c,r} + \sum_{s=1}^{S} k_{0_{c,s}} \exp[-E_{c,s}/RT(\tau)] g_s c^{a_s} P^{b_s} \phi_{c,s} + \sum_{m=1}^{M} k_{0_{P_m}} \exp[-E_{P_m}/RT(\tau)] g_m P_m^{b_m} O_2^{b_m} \phi_{P_m} + \sum_{y=1}^{Y} k_{0_{P,y}} \exp[-E_{P,y}/RT(\tau)] g_y P_m^{a_y} P_u^{b_y} \phi_{P,y} + \sum_{s=1}^{S} k_{0_{c,s}} \exp[-E_{c,s}/RT(\tau)] b_s c^{a_s} P^{b_s} - \sum_{m=1}^{M} k_{0_{P_m}} \exp[-E_{P_m}/RT(\tau)] a_m P_m^{b_m} O_2^{b_m} - \sum_{y=1}^{Y} k_{0_{P,y}} \exp[-E_{P,y}/RT(\tau)] a_y P_m^{a_y} P_u^{b_y} - \sum_{y=1}^{Y} k_{0_{P,y}} \exp[-E_{P,y}/RT(\tau)] b_y P_m^{a_y} P_u^{b_y},$$

where y = 1, ..., Y are the number of groups of reactions involving products of complete P_u and incomplete P_m combustion of fuels; a, b, and g are stoichiometric coefficients.

The above system of differential kinetic equations was calculated with the following initial conditions: $H_2O_0^h = H_2O_{0in}^h$, $V_0 = V_{0in}$, $c = c_{in}$, $O_2 = O_{2in}$, $H_2O = 0$, $V = 0$, $P = 0$.

Along with the kinetic equations, this system ensures the law of mass preservation: $H_2O_0 + V_0 + c + O_2 + P = H_2O_{0in} + V_{0in} + c_{in} + O_{2in}$, because the following relationship is valid: $dH_2O_0^h/d\tau + dV_0/d\tau + dc/d\tau + dO_2/d\tau - dP/d\tau = 0$, where $P = P_u + P_m$.

This mathematical model describing the kinetics

of thermochemical transformation of a solid fuel was used as the basis for an analytical experiment related to the burn-out of Irsha–Borodino brown coal (Kansk–Achinsk deposit) at various heating rates. The coal composition (per working mass) is as follows, %: moisture W^r 33, ash A^r 9.98, sulfur S^r 0.29, carbon C^r 41.2, hydrogen H^r 2.89, nitrogen N^r 0.57, and oxygen O^r 12.1, at Q_i^r = 15318 kJ kg^{-1}, V^{daf} = 48.2%. The mathematical model was based on the results of complex thermal analysis of the coal reactivity in various steps and on the evaluated kinetic parameters: numbers of separate steps i and j, activation energies E, probability factors k_0, fraction of the reacted substance, temperature ranges of reactions, etc. [24].

The types of the considered chemical reactions included in the calculation scheme and the kinetic parameters of various processes and steps of thermal transformation of Irsha–Borodino coal are given in Table 1.

To describe the nonisothermicity of themochemical transformation of coal, we supplemented the mathematical model with the linear heating law: $T = T_0 + b\tau$. It should be noted that, because of the large size

and pronounced rigidity of the system of differential equations, the kinetic mechanism can be realized, as a rule, only within the framework of a unidimensional scheme [17]. The calculations were performed with a Pentium 4 computer in the Builder C++ 5.0 environment. The system of kinetic equations was solved numerically by the Runge–Kutta–Fehlberg method with automatic choice of the step and accuracy of 10^{-4}.

The results of calculating the dynamics of processes involved in combustion of Irsha–Borodino coal particles (both in separate steps and in total) are shown in Fig. 2 as degrees of thermochemical transformation ($\omega_i = m_i/m_0$, where m_i is the current weight of ith reacting component and m_0 is the initial weight of the fuel–air mixture) vs. time at various heating rates.

The computational experiment was performed at varied rates of linear heating of a coal particle, $b = dT/d\tau = 0.167$, 10^2, and 10^4 deg s^{-1}.

The results confirm the strong influence of the heating rate on the processes [23, 26]. Figure 2 shows that, as the vapor–gas medium is heated faster, the times characteristic of separate processes become shorter and are shifted relative to each other.

For example, the relative times in which the drying overlaps with the release of volatiles and the combustion overlaps with the gasification of the coke base are, respectively, 6 and 27% at $b = 0.167$ deg s^{-1}, 17 and 38% at $b = 10^2$ deg s^{-1}, and 31 and 42% at $b = 10^4$ deg s^{-1} (Table 2). As the heating rate is increased, the time of the onset of all types of reactions becomes shorter, and the relative times of the processes somewhat change. In particular, the time of moisture evaporation relative to the total burn-out time was 32% at $b = 0.167$ deg s^{-1}, 42% at $b = 10^2$ deg s^{-1}, and 55% at $b = 10^4$ deg s^{-1}; the relative time of the release of volatiles was 55, 55, and 54%; that of the combustion of volatiles, 62, 61, and 61%; and that of combustion and gasification of the nonvolatile (coke) residue, 32, 48, and 54%, respectively. Whereas at a heating rate of 0.167 deg min^{-1} superposition of the processes is insignificant, at 10^4 deg s^{-1} virtually all the processes occur in parallel, and the relative time of their superposition reaches 61%.

The heating rate affects the duration of separate steps of thermochemical transformation of the solid fuel and the rates and temperatures corresponding to the maxima of process steps. In particular, the total release of volatiles from Irsha–Borodino coal at a heating rate $b = 0.167$ deg s^{-1} is $W_{rv}^{max} = 5.66$ mg (g combustible matter)$^{-1}$ deg^{-1} and $T_{rv}^{max} = 340$°C, at

$b = 10^2$ deg s^{-1} $W_{rv}^{max} = 4.82$ mg (g combustible matter)$^{-1}$ deg^{-1} and $T_{rv}^{max} = 720$°C, and at $b = 10^4$ deg s^{-1} $W_{rv}^{max} = 3.56$ mg (g combustible matter)$^{-1}$ deg^{-1} and $T_{rv}^{max} = 830$°C. The burn-up of the coke base of Irsha–Borodino coal at a heating rate $b = 0.167$ deg s^{-1} is $W_{bc}^{max} = 2.95$ mg (g combustible matter)$^{-1}$ deg^{-1} and $T_{bc}^{max} = 460$°C, at $b = 10^2$ deg s^{-1} $W_{bc}^{max} = 2.1$ mg (g combustible matter)$^{-1}$ deg^{-1} and $T_{bc}^{max} = 950$°C, and at $b = 10^4$ deg s^{-1} $W_{bc}^{max} = 0.96$ mg (g combustible matter)$^{-1}$ deg^{-1} and $T_{bc}^{max} = 1750$°C. These data show that, at the coal heating rate increased to 10^2 deg s^{-1}, the burn-up of the nonvolatile residue (up to 50%) can be completed during the fuel heating, and the time of complete thermochemical transformation includes the nonisothermal and isothermal constituents.

CONCLUSION

The results of numerical experiments show that the suggested kinetic scheme and the corresponding mathematical model, on the one hand, allow analysis of the influence exerted by separate steps on the dynamics of the overall process and, on the other hand, are useful for calculating the degree of thermochemical transformation of solid organic fuels under actual industrial conditions.

Abstract—The subsolidus phase diagrams of the systems Ln–Mn–O (Ln = Y, Tm) in air in the range 850–1400°C were constructed, based on the X-ray phase analysis of the homogeneous phases and heterogeneous mixtures of compositions $R = N_{Mn}/(N_{Mn} + N_{Ln})$ 1/5, 1/2 ($LnMnO_3$), 3/5, 2/3 ($LnMn_2O_5$), and 4/5. The boundaries of the phase areas were outlined.

The fact that oxides of systems Mn–M–O (M = Sc, Y, Ho, ..., Lu) exhibit ferromagnetic properties [1] makes it urgent to study the phase diagrams of these systems, as these data are necessary for directional synthesis of the compounds. In this study, the data of the X-ray phase analysis of the homogeneous phases and heterogeneous mixtures of compositions $R = N_{Mn}/(N_{Mn} + N_{Ln})$ 1/5, 1/2 ($LnMnO_3$), 3/5, 2/3 ($LnMn_2O_5$), and 4/5, obtained by the ceramic synthesis from the oxides in air at 850–1400°C, were used to construct the subsolidus phase diagrams of the systems Ln–Mn–O (Ln = Y, Tm) in air.

EXPERIMENTAL

The samples were synthesized by the ceramic technology, which was used in [2] for the Yb–Mn–O and Lu–Mn–O systems to construct the analogous phase diagrams, from the oxides Y_2O_3 (99.99% pure), TuO-2 grade Tm_2O_3 [TU (Technical Specification) 48-4-182–72], and ultrapure grade Mn_2O_3. It should be noted that, as in [2], two methods were used for cooling of the annealed samples to room temperature: quenching in air in a ceramic crucible and cooling with a furnace for 4 h. The X-ray phase analysis (DRON-2.0 diffractometer, CuK_α radiation) of the substances synthesized showed that the cooling procedure does not affect the phase composition of the system and only weakly affects the unit cell parameters of the solid phases.

The results of the performed analysis in the form of the phase diagrams of the systems Ln–Mn–O (Ln = Y, Tm) are presented in Fig. 1. To construct them, we used data on equilibria in the binary systems Ln–O [3] and Mn–O. For example, the temperatures of the α-Mn_2O_3–β-Mn_3O_4 (883.6°C) and β-Mn_3O_4–γ-Mn_3O_4 (1172°C) phase equilibria in air were taken from [4] and [5], respectively.

Area *1* in the diagrams shown in Fig. 1 describes coexistence in air of two phases, Ln_2O_3 (space group *Ia*3) and $LnMnO_3$ (hexagonal crystal structure, space group $P6_3cm$ [4]). $LnMnO_3$ and γ-Mn_3O_4 (spinel structure, space group Fd_3m) are in equilibrium in air in area *2*, and $LnMnO_3$ and β-Mn_3O_4 (hausmannite, space group *I*4/*amd*), in area *3*. Area *4* is the region of coexistence of $LnMn_2O_5$ ($DyMn_2O_5$-like

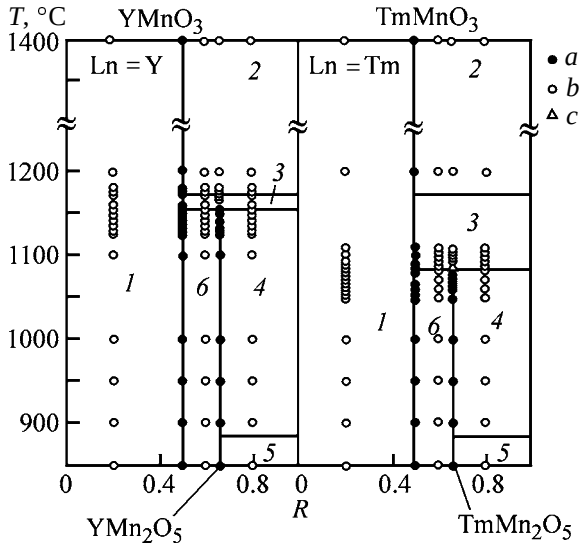

Fig. 1. Phase diagrams of the systems Mn–Ln–O (Ln = Y, Tm) in air. (*T*) Temperature; $R = N_{Mn}/(N_{Mn} + N_{Ln})$; (*N*) mole fraction of the element. Number of phases detected by X-ray analysis: (*a*) 1, (*b*) 2, and (*c*) 3; for the remaining explanations, see text.

orthorhombic crystal structure, space group *Pbam* [4]) and β-Mn_3O_4, and area *5*, the region of coexistence of $LnMn_2O_5$ and α-Mn_2O_3. In area *6*, oxides $LnMnO_3$ and $LnMn_2O_5$ are in equilibrium.

The monovariant equilibria

$$LnMn_2O_5 = LnMnO_3 + 1/3Mn_3O_4 + 1/3O_2 \ (Ln = Y, Tm) \quad (1)$$

were revealed by X-ray phase analysis at 1155±5 (Ln = Y) and 1085±5°C (Ln = Tm). At temperatures higher and lower by 20°C than the equilibrium temperature, the samples for X-ray phase analysis were prepared at 5°C intervals to approach the equilibrium from the different sides [6]. The temperature at which all the three solid phases, $LnMnO_3$, $LnMn_2O_5$, and Mn_3O_4, were detected by X-ray phase analysis was accepted as the equilibrium temperature.

It should be noted that the unit cell parameters of manganese oxides in areas *2–5* are equal within the experimental error to those of the individual oxides annealed at the same temperatures. This is also true for yttrium and thulium oxides in area *1*. This result suggests no mutual solubility of yttrium and manganese oxides and of thulium and manganese oxides. On the contrary, the parameters and volumes of the unit cells of the chemical compounds $YMnO_3$ and YMn_2O_5 differ from the corresponding values of these compounds in the adjacent regions of the bivariant equilibria. This is illustrated by Fig. 2, where the volumes of the unit cells of the individual $YMnO_3$ and YMn_2O_5 are given along with the volumes of these substances in areas *1*, *4*, and *6* of the phase diagram (Fig. 1). The above difference is observed for all the parameters in all the areas of the phase diagrams of the Y–Mn–O system (Fig. 1). The $YMnO_3$ and YMn_2O_5 unit cell parameters as functions of the chemical composition of the systems *R* show that the regions of homogeneity of these systems with respect to metallic components are significant. Therefore, special studies of these regions including, e.g., positions of their boundaries as functions of chemical composition of the system and synthesis temperature should be performed. The dependence of the volume of the $TmMnO_3$ unit cell on the synthesis temperature is shown in Fig. 3. This dependence suggests with high probability the oxygen nonstoichiometry in this substance and its relation to the temperature, in agreement with the data of numerous studies [3, 7] devoted to the oxygen nonstoichiometry of rare-earth element manganites and to the effect exerted on it by the temperature and oxygen pressure.

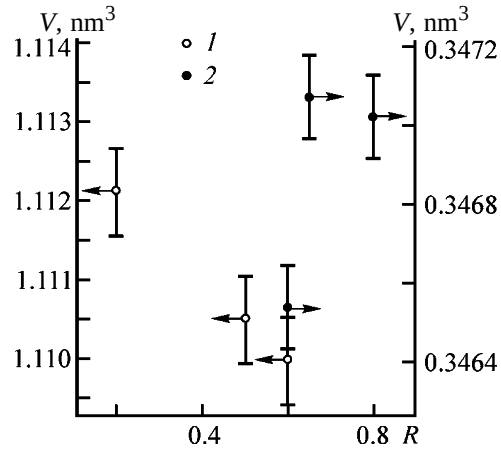

Fig. 2. Volumes *V* of the unit cells of (*1*) $YMnO_3$ and (*2*) YMn_2O_5 quenched from 1140°C vs. the chemical composition of the Y–Mn–O system. $R = N_{Mn}/(N_{Mn} + N_Y)$; (*N*) mole fraction of the element.

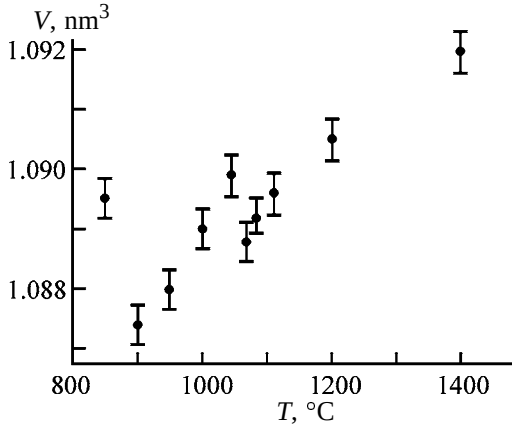

Fig. 3. Volume *V* of the $TmMnO_3$ unit cell vs. the quenching (annealing) temperature *T*.

The fact that the parameters and volumes of the unit cells of $YMnO_3$, YMn_2O_5, and $TmMn_2O_5$ are independent of the synthesis temperature does not rule out the oxygen nonstoichiometry of these compounds.

In the Tm–Mn–O system, the dependences of the $TmMnO_3$ and $TmMn_2O_5$ unit cell parameters on the chemical composition of the system (*R* parameter), similar to those presented in Fig. 2, were not observed. This shows that the regions of homogeneity of the above substances with respect to the metallic components are narrow.

CONCLUSIONS

(1) The thermodynamically stable chemical compounds in the systems Y–Mn–O and Tm–Mn–O at

subsolidus temperatures in air are $LnMnO_3$ and $LnMn_2O_5$ (Ln = Y, Tm).

(2) The double oxides $LnMn_2O_5$ dissociate in air at 1155 ± 5 (Ln = Y) and 1085 ± 5°C (Ln = Tm).

(3) In the system Y–Mn–O, the parameters and volumes of the unit cells of $YMnO_3$ and YMn_2O_5 depend on the chemical composition of the system, suggesting the nonstoiciometry of these substances with respect to metallic components.

(4) The parameters and volumes of the $TmMnO_3$ unit cells depend on synthesis temperature, suggesting the oxygen nonstoichiometry of this compound.

BRIEF COMMUNICATIONS

Extaction of Lanthanide (III) Nitrates from Aqueous Solutions with *n*-Octanol

V. A. Keskinov, A. V. Kudrova, O. V. Valueva, and A. K. Pyartman

St. Petrsburg State Technological Institute, St. Petersburg, Russia

Received October 22, 2003; in final form, April 2004

Abstract—Extraction of lanthanide(III) nitrates (Ln–Gd) with *n*-octanol was studied at 298.15 K. The extraction isotherms were obtained and mathematically treated.

n-Octanol is widely used as an additive in industrial extraction of rare-earth metals to improve phase separation and increase the solubility of extractable complexes in the organic phase [1]. Published data on extraction of cerium-group lanthanide(III) nitrates with alcohols are virtually lacking. Extraction of lanthanum(III), praseodymium(III), and neodymium(III) from aqueous nitric acid solutions and those containing alkali and 3*d*-metal nitrates with butyl, amyl, and isoamyl alcohols was studied in a limited Ln(III) concentration range. For all the systems studied, the lanthanide(III) distribution coefficient was found to increase in going from lanthanum(III) to neodymium(III).

In this work we studied extraction of cerium-group lanthanide(III) (La–Nd, Sm–Gd) nitrates from aqueous solutions with *n*-octanol at 298.15 K.

The initial aqueous solutions of Ln(III) nitrates were prepared by dissolution of the corresponding Ln(III) oxide (ultrapure grade) in nitric acid (ultrapure grade). The Ln(III) concentration in the initial aqueous solution of Ln(III) nitrates and equilibrium aqueous and organic phases was determined complexometrically [3]. *n*-Octanol was of chemically pure grade (ρ = 0.8220 g dm^{-3} at 298.15 K).

We studied the extraction of lanthanide(III) nitrates (La–Gd) from their aqueous solutions with neat *n*-octanol (6.31 mol dm^{-3}). We found (see table) that Ln(III) were not extracted at their initial concentration in the aqueous phase below 0.6 mol dm^{-3}. Comparison of the extraction isotherms of Ln(III) of different types (see figure) shows that, at equal Ln(III) concentration in the aqueous phase, their content in the equilibrium organic phase increases in going from La(III) to Gd(III).

The extraction of Ln(III) from aqueous solution with *n*-octanol can be described by the reaction equation

$$Ln^{3+}(aq) + 3NO_3^-(aq) + i\text{ROH(o)} \rightleftarrows [Ln(NO_3)_3(ROH)_i](o). \quad (1)$$

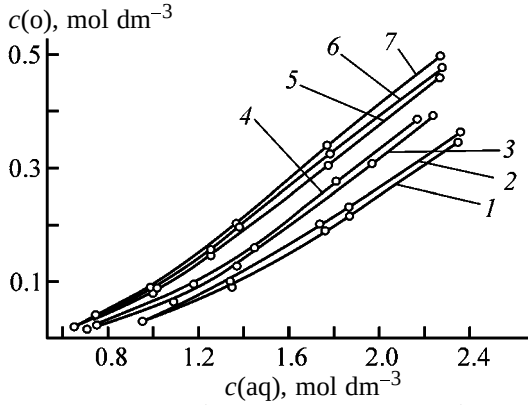
The concentration extraction constant is expressed by the equation

$$K_{ex}^{i} = \frac{\{[Ln(NO_3)_3(ROH)_i](o)\}}{\{Ln^{3+}(aq)\}\{NO_3^-(aq)\}^3\{ROH(o)\}^i}, \quad (2)$$

where braces denote the equilibrium concentrations of species.

The correlation between the thermodynamic and concentration extraction constants is described by the equation

$$K_{ex}^{0,i} = K_{ex}^{i}\frac{Y_{[Ln(NO_3)_3(ROH)_i](o)}}{Y_{\pm}^{4}Y_{[ROH(o)]}^{i}}, \quad (3)$$



Extraction isotherms of lanthanide(III) nitrates from aqueous solutions with neat (6.31 mol dm^{-3}) *n*-octanol at 298.15 K. where Y(o) are the molar activity coefficients of extractable complexes in the organic phase and $Y_{\pm}$ is the mean ionic activity coefficient of Ln(III) nitrate in the aqueous phase.

Taking into account that $Y_{[Ln(NO_3)_3(ROH)_i](o)} \times \{Y^i_{[ROH(o)]}\}^{-1} = \text{const} = 1$, Eq. (3) can be transformed into the form

$$K_{ex}^{0,i} = K_{ex}^{i}/Y_{\pm}^{4}. \quad (4)$$

The mean ionic activity coefficients of lanthanide(III) nitrates were calculated from the data reported in [4].

In calculation of the thermodynamic extraction constants of lanthanide(III) nitrates with neat octanol, the stoichiometric term i was varied from 0 to 6. The results of these calculations for $i = 6$ [formation of $Ln(NO_3)_3(ROH)_6$ extractable complex only] are listed in the table. It seen that $\log K_{ex}^{0,6}$ is virtually independent of lanthanide(III) concentration in the organic phase, which shows that our physicochemical model is suitable for description of extraction of Ln(III) nitrates with *n*-octanol. As seen from the table, the mean extraction constant is close for La(III), Ce(III), and Pr(III) and slightly increases in going from Pr(III) to Gd(III) within the examined lanthanide(III) concentration range.

Thus, the difference between the extraction isotherms of individual Ln(III) nitrates is mainly caused by variation in their activity coefficients in the aqueous phase (see table). To increase the selectivity of extraction of Ln(III) nitrates with *n*-octanol, their extraction should be performed from concentrated aqueous solution.

CONCLUSIONS

(1) The Ln(III) nitrates are not noticeably extracted with *n*-octanol at lanthanide(III) concentration in the aqueous phase below 0.6 mol dm^{-3}. At Ln(III) concentration in the aqueous phase above 0.6 mol dm^{-3}, the extraction increases in going from La(III) to Gd(III).

(2) The thermodynamic extraction constants calculated assuming the formation of the extractable complex $Ln(III)(NO_3)_3(ROH)_6$ as the only species are close for Ln(III), Ce(III), and Pr(III) and slightly increase in going to Gd(III). The difference in the extraction isotherms of Ln(III) nitrates with *n*-octanol is mainly caused by variations of Ln(III) nitrate activity coefficients in the aqueous phase. The selectivity of extraction of Ln(III) nitrates with *n*-octanol increases with increasing their concentration in the aqueous phase.

Synthesis of Di(polyfluoroalkyl) Ethers

A. I. Rakhimov, A. V. Nalesnaya, and O. V. Vostrikova

Institute of Chemical Problems of Ecology, Volgograd State Technical University, Volgograd, Russia

Received July 6, 2004

Abstract—New procedures for preparing di(polyfluoroalkyl) ethers by reactions of polyfluoropropyl chlorosulfonites with polyfluorinated alcohols were tested.

Polyfluorinated dialkyl ethers are promising ozone-friendly and moderately toxic solvents [1]. In particular, tetrafluoroethyl difluoromethyl ether and its closest homolog, di(tetrafluoropropyl) ether can be used instead of perfluorohydrocarbons for dry etching in microelectronics [2], and, with subsequent electrochemical afterfluorination in anhydrous HF, these compounds can be recommended for cleaning of electronic circuits and as polymerization media [3–5]. Polyfluorinated ethers of higher molecular weight are used as compression, motor, and vacuum oils [6].

Alkyl polyfluoroalkyl ethers are prepared by addition of polyfluorinated alcohols to alkenes and fluoroalkenes [1, 7] and by alkylation of alcoholates derived from polyfluorinated alcohols with alkyl halides [8, 9].

We suggest a procedure for preparing polyfluorinated ethers from available raw materials, polyfluorinated alcohols and thionyl chloride, via intermediate polyfluoroalkyl chlorosulfonites [10]. This procedure is environmentally safe and economically attractive, as its cost is determined by the cost of polyfluorinated alcohols (some of them are production wastes) and thionyl choride and by small production expenditures.

With the aim to extend the homologous series of symmetrical and unsymmetrical di(polyfluoroalkyl) ethers, we suggested catalytic and noncatalytic procedures based on reactions of polyfluoroalkyl chlorosulfonites with polyfluorinated alcohols. The catalytic reaction (1) is performed in the presence of dimethylformamide (DMF) as catalyst, and the noncatalytic reaction (2), in the presence of triethylamine:

$$R_FCH_2OS(O)Cl + R'_FCH_2OH \xrightarrow{DMF} R_FCH_2OCH_2R'_F + SO_2 + HCl, \quad (1)$$

$$R_FCH_2OS(O)Cl + R'_FCH_2OH \xrightarrow{NEt_3} R_FCH_2OCH_2R'_F + SO_2 + NEt_3 \cdot HCl, \quad (2)$$

where $R_F = R'_F = H(CF_2CF_2)_2$ (**I**), HCF_2CF_2 (**II**), $H(CF_2CF_2)_3$ (**III**), $R_F = HCF_2CF_2$, $R'_F = H(CF_2CF_2)_2$ (**IV**), $R_F = HCF_2CF_2$, $R'_F = H(CF_2CF_2)_3$ (**V**), $R_F = HCF_2CF_2$, $R'_F = H(CF_2CF_2)_4$ (**VI**), $R_F = H(CF_2CF_2)_2$, $R'_F = H(CF_2CF_2)_3$ (**VII**).

In procedure (1), a solution of polyfluoroalkyl chlorosulfonite was added to appropriate alcohol containing DMF (molar ratio from 1 : 0.005 to 1 : 0.01) at –10°C; the mixture was allowed to stand for 24 h at room temperature. After distilling off the solvent (chloroform, diethyl ether), the product was distilled; yield 59–98%.

In procedure (2), a solution of polyfluoroalkyl chlorosulfonite was added at –10°C to a complex of alcohol with triethylamine, prepared in advance; the resulting mixture (solvent pentane or hexane) was allowed to stand for 24 h at room temperature. The triethylammonium chloride precipitate was filtered off, and the fluorinated ether was distilled; yield 52–85%.

Symmetrical ethers **I**–**III** were prepared by reactions of polyfluoroalkyl chlorosulfonites with the related alcohols. The highest yield (98%) was attained with the most reactive tetrafluoropropyl chlorosulfonite in the presence of DMF. With increasing length of the fluorocarbon chain, the yield of di(polyfluoroalkyl) ethers decreases. Tetrafluoropropyl octafluoropentyl ether was obtained in 85% yield, and the yields of the ethers with longer fluorocarbon chains were still lower.

Although both procedures allow preparation of the ethers in similar yields, the catalytic process is preferable because of lower production cost and higher purity of the target product; the triethylammonium salt formed in reaction (2) appreciably contaminates the resulting ether.

EXPERIMENTAL

The structures of ethers **I**–**VII** were proved by IR and ^{1}H NMR spectroscopy. The IR spectra were recorded on a Specord-M82 spectrometer (thin films). The ^{1}H NMR spectra were taken on a Varian Mercury-300 spectrometer (working frequency 300 MHz, internal reference tetramethylsilane, solvent CCl_4).

Di(1,1,5-trihydroperfluoropentyl) ether I. (a) A 4.4-g portion of 1,1,5-trihydroperfluoro-1-pentanol was mixed with 0.015 ml of DMF in 15 ml of chloroform and cooled to –10°C; a solution of 5.9 g of 1,1,5-trihydroperfluoropentyl chlorosulfonite in 10 ml of chloroform was added with stirring, with the temperature maintained at –10°C. Then the mixture was allowed to warm up to 20°C and was kept at this temperature for 2 h, with bubbling of dry air to remove the released hydrogen chloride. After that, the mixture was allowed to stand for 24 h at room temperature. The solvent was distilled off, and the product was distilled in a vacuum. Yield of **I** 4.5 g (59%), bp 103°C (2 mm Hg), n_D^{20} 1.3385, d_4^{20} 1.7344. IR spectrum, ν, cm^{-1}: 1137 s (νC–O–C), 1176 s (νCF_2), 2860 w, 2946 m (νCH_2), 3016 w (νCHF_2).

(b) A 5.0-g portion of 1,1,5-trihydroperfluoro-1-pentanol was mixed with 2.1 of triethylamine in 15 ml of hexane and cooled to –10°C; a solution of 6.7 g of 1,1,5-trihydroperfluoropentyl chlorosulfonite in 10 ml of hexane was gradually added with stirring, with the temperature maintained at –10°C. Then the mixture was allowed to warm up to 20°C and to stand at this temperature for 24 h. The precipitated salt was filtered off, the solvent was distilled off, and the product was vacuum-distilled. Yield of **I** 5.2 g (52%).

Compounds **II**–**VII** were prepared similarly to **I** by procedure (a) or (b).

Di(1,1,3-trihydroperfluoropropyl) ether II. Procedure (a). Yield 98%, bp 65°C (1 mm Hg), n_D^{20} 1.3575, d_4^{20} 1.6251. IR spectrum, ν, cm^{-1}: 1111 s.br (νC–O–C), 1223 s (νCF_2), 2850 m, 2920 m, 2960 m (νCH_2), 3008 w (νCHF_2). ^{1}H NMR spectrum, δ, ppm (*J*, Hz): 5.803 t.d (H^1, H^6; *J* 52.8, 3.3), 4.274 q (H^3, H^4, *J* 13.2).

Di(1,1,7-trihydroperfluoroheptyl) ether III. Procedure (a). Yield 57%, bp 130°C (1 mm Hg), n_D^{20} 1.3370, d_4^{20} 1.8014. IR spectrum, ν, cm^{-1}: 1124 s (νC–O–C), 1249 s (νCF_2), 2860 w, 2980 m (νCH_2), 3024 w (νCHF_2).

1,1,5-Trihydroperfluoro-1-(1,1,3-trihydroperfluoropropyloxy)pentane IV. Procedure (b). Yield 85%, bp 83°C (2 mm Hg), n_D^{20} 1.3500, d_4^{20} 1.6790. IR spectrum, ν, cm^{-1}: 1116 s (νC–O–C), 1242 s (νCF_2), 2860 w, 2934 w, 2980 m (νCH_2), 3017 w (νCHF_2). ^{1}H NMR spectrum, δ, ppm (*J*, Hz): 5.966 t.t (H^8, *J* 51.6, 5.4), 5.810 t.t (H^1, *J* 52.1, 3.8), 4.432 t (H^3, *J* 13.2), 4.255 t (H^4, *J* 12.6).

1,1,7-Trihydroperfluoro-1-(1,1,3-trihydroperfluoropropyloxy)heptane V. Procedure (b). Yield 51%, bp 95°C (1 mm Hg), n_D^{20} 1.3450, d_4^{20} 1.7310. IR spectrum, ν, cm^{-1}: 1116 s (νC–O–C), 1223 s (νCF_2), 2868 w, 2937 w, 2968 m (νCH_2), 3014 w (νCHF_2).

1,1,9-Trihydroperfluoro-1-(1,1,3-trihydroperfluoropropyloxy)nonane VI. Procedure (a). Yield 34%, mp 49°C, bp 130°C (1 mm Hg). IR spectrum, ν, cm^{-1}: 1120 s (νC–O–C), 1216 s (νCF_2), 2856 m, 2894 w, 2932 m (νCH_2), 2954 w (νCHF_2). ^{1}H NMR spectrum, δ, ppm (*J*, Hz): 5.975 t.t (H^1, H^{12}, *J* 52, 5.1), 4.359 t (*J* 16.6) and 4.331 t (*J* 12.3) (H^3, H^4).

1,1,7-Trihydroperfluoro-1-(1,1,5-trihydroperfluoropentyloxy)heptane VII. Procedure (a). Yield 62%, bp 110°C (1 mm Hg), n_D^{20} 1.3380, d_4^{20} 1.7647. IR spectrum, ν, cm^{-1}: 1120 s (νC–O–C), 1220 s (νCF_2), 2864 w, 2932 m, 2961 m (νCH_2), 3009 w (νCHF_2).

CONCLUSION

A catalytic reaction of polyfluorinated alcohols with polyfluoroalkyl chlorosulfonites in the presence of DMF allows preparation of the corresponding di(polyfluoroalkyl) ethers in 59–98% yield.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Professor Oleg Alekseevich Esin (to Centennial Anniversary of His Birthday)

O.A. Esin, an honored scientist and technologist of the Russian Soviet Federative Socialist Republic and a professor of the Ural Polytechnic Institute, made a major contribution to studies of the physicochemical foundations of metallurgical processes, development of applied electrochemistry, and organization of the higher metallurgical education in the Urals and created a prominent scientific school.

Oleg Alekseevich Esin was born on September 7, 1904, in Yekaterinburg. In 1913, he entered a non-classical secondary school, but was forced to quit when studying in the sixth form by financial difficulties.

The youth of the scientist-to-be coincided with the early time of development of the higher education in the Middle Urals. The Mining Institute was opened in Yekaterinburg in October 1917, and a decision was taken in three years, in October 1920, to organize the Ural State University. It was intended that University is to include mining, polytechnic, and some other institutes, and also a worker's faculty. Esin was sent to this faculty to complete his secondary education and then became a student of the chemical-metallurgical department of the Polytechnic Institute at the Ural University. Among Esin's teachers were such prominent metallurgists of that time as V.E. Grum-Grzhimailo (1864–1928) and I.A. Sokolov (1867–1947), both of whom were well experienced in working at Ural's plants; A.E. Makovetskii, a many-sided chemist-technologist; and S.G. Mokrushin (1896–1986), who became a known specialist in physical chemistry of surface phenomena in the future. Esin recollected Grum-Grzhimailo's and Makovetskii's lectures in the warmest words [1, 2]. Esin performed his first scientific investigations together with Mokrushin. When still being a student, Esin worked as laboratory assistant at the electrochemical laboratory and also found time for scientific research.

In 1925, the Polytechnic Institute, as well as the other institutes that comprised the University, became an independent educational institution. In May 1925, Esin defended his graduation thesis devoted to electrochemistry of aqueous solutions and, as one of the most talented students, was left at the Polytechnic Institute for post-graduate education "to be prepared for professorship." The first Esin's investigations (carried out together with Mokrushin and I.G. Shcherbakov and published in 1926–1928) were concerned with processes for electrolytic production of ammonium persulfate, electrolysis of chromate solutions, and precipitation of metallic chromium from aqueous solutions. At the end of 1928, Esin successfully finished his post-graduate education and was sent to a one-year business trip to Germany to make acquaintance with higher-school institutions and industrial plants of this country. In particular, Esin minutely familiarized himself with the Higher Technical College in Dresden.

All Esin's further scientific and pedagogical activities were associated with the Ural Polytechnic Institute and research institutions of Yekaterinburg. Esin became a professor of the Ural Polytechnic Institute in 1934 and headed the Chair of the Theory of Metallurgical Processes at the same institute from 1943 till 1969. In 1971, he became a scientific consultant of the Institute of Metallurgy, Ural Scientific Center, Academy of Sciences of the USSR.

The first period of Esin's scientific investigations, which continued for 18 years, from 1926 till 1944, was devoted to electrochemistry of aqueous solutions, with both generally theoretical and practical problems tackled. Already in 1932–1933, Esin developed on the basis of a great number of experimental studies a quantitative theory of joint discharge of ions, including hydrogen ions, from solutions of simple and complex salts. Later, a spacious summary paper devoted to joint discharge of hydrogen ions and metal ions was published [3].

Of particular interest is Esin's study, together with B.F. Markov, of electrocapillary curves of a mercury electrode in various aqueous solutions (1939). The authors were first to discover the anomalously strong shift of the zero-charge potential, depending on the activity of an electrolyte. By suggestion of a known American electrochemist D. Grahame (1955) this phenomenon was named the "Esin–Markov effect." This Esin and Markov's study stimulated further

1070-4272/04/7709-1564 © 2004 MAIK "Nauka/Interperiodica"

investigations into the structure of the discrete double layer both by representatives of the school of Academician A.N. Frumkin in the Soviet Union [4] and by a number of foreign scientists.

In 1934, two Esin's monographs were published: *Electroliticheskoe rafinirovanie medi* (Electrolytic Refining of Copper) (written together with A.I. Gaev) and *Affinazh blagorodnykh metallov* (Refining of Noble Metals) (together with O.E. Zvyagintsev). Both these books were intended for a widest audience of engineers and technical workers. In 1937, Esin published already his third monograph *Elektroliz tsinka* (Electrolysis of Zinc) (together with Gaev).

In the severe war years. Esin was among those who initiated organization of assistance of scientists to industrial plants of the Ural region. In the context of the needs of Pyshma copper-electrolyte plant, the possibility of intensification of copper electrolysis was examined, the behavior of arsenic, antimony, and noble metals under these conditions was studied, and a method for manufacture of a copper powder was developed. In 1945–1947, the results of these investigations were published.

The second period of scientific investigations by Esin and the scientific school created by him, from 1945 till 1979, was mainly devoted to studies of the physicochemical foundations of the interaction of metals with slags in the molten state and to development of new processes involving metal–slag systems. Particularly important for the development of wide-scale investigations in this area was Esin's relatively brief, but very informative brochure *Elektroliticheskaya priroda zhidkikh shlakov* (Electrolytic Nature of Liquid Slags) (1946). This brochure formulated a fundamentally new approach to the nature of liquid slags. The author, in particular, noted: "The electrochemical theory of the equilibrium between a metal and a slag, outlined by Tammann, deserves a close attention and requires further development." The above-mentioned study by the outstanding physical chemist and metallographer G. Tammann (1861–1938, moved from Russia to Germany in 1903, an honorary member of the Academy of Sciences of the USSR since 1927) was published in 1931. Wide-scale studies of metals, slags, and metal–slag equilibria in the molten state by Esin and his numerous disciples (P.V. Gel'd, S.I. Popel', I.T. Sryvalin, B.M. Lepinskikh, S.K. Chukmarev, N.A. Vatolin, Yu.P. Nikitin, L.N. Barmin, V.N. Voronenkov, A.I. Sotnikov, *et al.*) developed in various areas. Together with silicate melts, oxide and sulfide systems were the object of considerable interest.

Metal and slag phases and their equilibria were examined using a wide variety of electrochemical techniques: measurement of the electromotive forces in various circuits with solid and molten electrolytes under equilibrium conditions; electrolysis of melts; polarization measurements; analysis of the kinetics of electrode processes; determination of the transport numbers of ions in melts; measurement of the electrocapillary curves and estimation of the capacitance of the double layer in metal–slag systems; determination of the exchange current in these systems; and study of the electrical conductivity of slags, electrotransport of impurities in liquid metals, and diffusion in molten metals and slags.

There is no escape from mentioning the high methodological level of experimental studies of compound high-temperature systems, carried out by Esin and co-workers. They were the first to use the chronopotentiometric method in studying cathodic and anodic processes at the metal–slag interface (1959–1962). This made it possible to estimate the diffusion coefficients of ions in the slag phase and of components of the metallic phase. Important conclusions concerning the oxidation state of ions involved in electrode reactions were made. A rotating disc electrode was used for the first time to study cathodic and anodic processes in molten slags at 1300–1500°C (1963–1965). Beginning in 1967, electrochemical relaxation methods (impedance measurements, coulostatic and potentiostatic studies) came into wide use. Esin and coworkers were the first to demonstrate experimentally the electrochemical nature of the interaction between liquid cast iron, steel, ferroalloys, and mattes with molten slags. The occurrence of all these most important phenomena at the interface between these phases was revealed.

Simultaneously, physicochemical studies were performed: the thermodynamic properties of metallic and slag melts were studied; their volume and surface properties and wetting phenomena were analyzed; the viscosity of slags of varied nature, their structure and conduction type were determined; and magnetic properties of metallic phases were examined. Considerable attention was given to studying the mechanism and kinetics of reduction and oxidation proceses in high-temperature systems, determining the solubility of gases and oxides of some metals in molten slags.

Esin and co-workers carried out quite a number of investigations devoted to solution of applied problems. To these belong development of methods for removing phosphorus and sulfur from liquid steels, electrochemical refining and alloying of ferrous metals, and recovery of valuable nonferrous methods from waste slags.

Based on a vast experimental material, Esing made quite a number of fundamental theoretical generalizations concerning the nature of metallic and slag melts and the interaction between these. For example, he put forward, experimentally substantiated, and confirmed by calculations the concept of microheterogeneity of molten slags, which results from the energetic nonequivalence of different ions. Esin more than once modified the polymeric model suggested by him for silicate solutions, improved the model of regular solutions as applied to description of the concentration dependence of thermodynamic functions in metallurgical melts with varied nature of interaction between components. Esin and Sotnikov substantiated the alternating-sign structure of the liquid plate of the double layer in molten electrolytes.

The development of research in the field of high-temperature physical chemistry in our country was strongly affected by the fundamental monograph by Esin and Gel'd. Its second edition [5, 6] was published, similarly to the first edition, in two parts, which cover a wide variety of problems related to pyrometallurgy. Of particular interest are Esin's large summarizing papers: Ionic Nature of Liquid Slags [7], On the Structure of Molten Silicates [8], Molten Slags and Their Interaction with Metals [9], Electrode Processes in Molten Slags [10], and Application of the Theory of Polymers to Molten Slags [11].

Esin's scientific legacy is vast. In 1974, a special collection of works *Elektrokhimiya i rasplavy* (Electrochemistry and Melts) was published in connection with Esin's 70th birthday. This collection contained papers by prominent domestic scientists, which described recent achievements in the field of electrochemistry of aqueous solutions and high-temperature systems and investigations of the physicochemical properties and structure of liquid metallic and slag systems. In addition to the introductory article by Academician N.V. Ageev, devoted to Esin's scientific activities, a list of Esin's works, which was limited to before the middle of 1973, but still contained 491 items, was presented [12]. Despite that Esin's scientific school was started to be created only during the postwar years, it has no rivals in the field of high-temperature physical chemistry. Esin's closest associates and disciples included such known scientists as Gel'd (1911–1993), corresponding member of the Russian Academy of Sciences; Vatolin, an academician of the Russian Academy of Sciences; E.A. Pastu-

khov, corresponding member of the Russian Academy of Sciences; G.P. Vyatkin, corresponding member of the Russian Academy of Sciences; professor Popel', and many others.

Esin's many-years' pedagogical and scientific activities were honored by high Governmental awards.

Oleg Alekseevich Esin died on February 13, 1979, at the age of 74.

In 1982, Esing and a group of his associates were awarded a State Prize of the USSR in science and technology for a series of investigations Studies of the Structure, Properties, and Interaction of Metallurgical Alloys, published in 1957–1980.

BOOK REVIEWS

Karyakin, N.V., *Osnovy khimicheskoi termodinamiki: Uchebnoe posobie dlya vuzov* (Fundamentals of Chemical Thermodynamics: Textbook for Higher Institutions)

Nizhni Novgorod: Nizhegorodsk. Gos. Univ.; Moscow: Akademiya, 2003, 464 pp.

The book to which readers' attention is called is a somewhat extended presentation of various sections of chemical thermodynamics and theory of phase equilibria and solutions, which are conventionally included in courses of physical chemistry for chemical-technological and metallurgical specialties at higher school institutions.

The book comprises a foreword, introduction, ten chapters combined into three sections, conclusion, and appendix. The brief foreword (pp. 12–15) gives a general notion of the content of sections and chapters of the book. The introduction (pp. 16–19) formulates the object of study and goals of the thermodynamics as a whole and chemical thermodynamics, in particular. Chapters 1–4 are combined into the section named Thermodynamics, Basic Concepts, Phase Equilibria. Chapter 1 (pp. 20–41) discusses the basic concepts of chemical thermodynamics. Chapter 2 (pp. 42–115) presents the first law of thermodynamics and the related issues: application of the first law of thermodynamics to ideal gases, to chemical reactions, to methods for calculation of the enthalpies of chemical reactions, to the effect of pressure and temperature on the enthalpy, and to the specific heat and methods for its calculation.

Chapter 3 (pp. 116–184) contains evidence concerning the second law of thermodynamics. The author discusses in ample detail various formulations of the second law and pays considerable attention to the statistical interpretation of entropy and to calculation of changes in entropy in various processes. Chapter 4 (pp. 185–235) considers phase equilibria, the Gibbs phase rule, polymorphism, and second-order phase transitions.

The second section of the book, Thermodynamics of Solutions, Chemical Equilibrium, comprises five chapters, from 5 to 9. The whole Chapter 5 (pp. 236–296) is devoted to thermodynamic properties of solutions. The author introduces the notion of partial molar quantities, discusses the thermodynamic characteristics of ideal and infinitely dilute solutions, considers the properties of solutions and liquid–vapor equilibria for binary systems, and pays considerable attention to the notion of component activity in solution and to methods for determining the activity. Chapter 6 (pp. 297–321) includes evidence concerning the thermodynamic analysis of chemical reactions and the chemical equilibrium. The chapter considers homogeneous equilibria that involve only gaseous substances and heterogeneous equilibria that include a condensed phase containing a single component. The mass action law and various forms of expression of the equilibrium constant are discussed.

Chapter 7 (pp. 322–353) presents the third law of thermodynamics and considers methods for calculation of equilibria. Also devoted to various kinds of calculations of equilibria are Chapters 8 (pp. 354–365) and 9 (pp. 366–396).

The third section of the book, Foundations of Statistical Thermodynamics, comprises only single, comparatively short Chapter 10 (pp. 397–426), in which the basic terms associated with quantum-statistical calculations of chemical equilibria are explained. The book ends in a brief conclusion (pp. 427–432) and an appendix (pp. 433–455). The appendix presents thermodynamic data for elements and simple inorganic compounds (308 substances), as well as for organic compounds of various classes (114 substances). The appendix also gives solutions of the equation for the mass action law for various types of reactions.

The author included in the textbook 97 examples, frequently very simple, with detailed solutions. It seems not quite justified that the book combines a theoretical material and a collection of examples and problems. At the worst, the examples and problems could be placed in the appendix, without disturbing the compactness and wholeness of the main material. The number of digressions with various comments and explanations is too great (more than 50). The author covers a wide variety of issues, but, unfortunately, there are separate annoying inaccuracies. Here, only several examples will be given. The

1070-4272/04/7709-1568 © 2004 MAIK "Nauka/Interperiodica"

derivation of the phase rule (p. 187) should have been preceded by a proof of the equality of chemical potentials in coexisting equilibrium phases. However, no material of this kind is presented in Chapter 3. The chemical potential always refers to some component of a system, and such expressions as "chemical potential of a solution" and "chemical potential of a mechanical mixture" (pp. 226, 227) are incorrect. The thermodynamic interpretation of the Nernst distribution law (p. 254) seems to be unsatisfactory because it does not cover the choice of the standard state for a component distributed among the phases. It is hardly appropriate to divide components into a "solvent" and a "solute" in discussing the thermodynamic description of phases with a variable composition (p. 275). The expressions for the chemical potential of a component in ideal and real solutions, presented on the same page, need additional explanations. The term "Gibbs energy" is commonly accepted in the world literature, and, in the reviewer's opinion, there is no need to replace it with the term "Gibbs function."

Despite the existence of a sufficient number of textbooks on chemical thermodynamics, written on varied level by both domestic and foreign authors, the appearance of a new one is, undoubtedly, of interest. In the level and type of presentation, the material in Karyakin's book is close, except in some places, to that devoted to chemical thermodynamics and related issues in rather high-level textbooks on physical chemistry, e.g., in that for chemical specialties of chemical higher-school institutions, written by A.G. Stromberg and D.P. Semchenko [*Fizicheskaya khimiya* (Physical Chemistry), Moscow: Vysshaya Shkola, 1999]. Naturally, this fact does not minimize the merits of the book discussed here and its value.

Karyakin paid considerable attention in his textbook to scientific-biographic evidence concerning the scientists who made a major contribution to the development of thermodynamics. Unfortunately, they do not include van't Hoff (1852–1911), who received the first Nobel Prize in chemistry "in recognition of the extraordinary services he has rendered by the discovery of the laws of chemical dynamics and osmotic pressure in solutions." As far as the reviewer knows, biographic evidence has not been included in chemical textbooks since the time of the classical textbook on general chemistry, written by the know historian of chemistry, B.N. Menshutkin [*Kurs obshchei khimii* (A Course of General Chemistry), Leningrad: Goskhimizdat, 1933].

The reference material, presented by Karyakin in the appendix, would be of better use if the corresponding temperature intervals were specified for the temperature dependences of the specific heat and references to sources of these data were given.

INFORMATION

The 2nd International Conference on Times of Polymers

The 2nd International Conference on Times of Polymers (TOP) was held in Italy from June 20 to 23, 2004. The conference was organized by Italian groups on polymer science and sponsored by leading Italian and trans-European companies manufacturing and employing polymeric materials. The Conference Co-chairmen were Alberto D'Amore [Engineering Schools of II University of Naples (SUN), Department of Aerospace and Mechanical Engineering] and Domenico Acierno (Department of Materials and Production Engineering, University of Naples Federico II).

The International Scientific Committee included also Francesco Paolo La Mantia (Italy), Giuseppe Marrucci (Italy), Baltasar Mena (Mexico), Jovan Mijovic (the United States), Luidgi Nicolais (Italy), George Papanicolaou (Greece), and Guennadi E. Zaikov (Russia).

The conference program focused on the recent advances in the following topics: Viscoelasticity, Industrial Rheology, Durability of Polymers and Composites, Processing, Blends, Biomaterials, Nanocomposites, Cultural Heritage, and Fracture and Yielding. All the thirteen plenary lectures were made by invited lecturers. Additionally, there were 35 oral and 27 poster contributions.

About 150 scientists from 16 countries (Bulgaria, Canada, France, Germany, Greece, Israel, Italy, Japan, Mexico, Russia, Slovenia, South Korea, Sweden, Turkey, the United Kingdom, and the United States) participated in the Conference. They represented about 50 leading research centers in the field of chemistry and physics of polymers and polymer production and application.

D'Amore and Acierno in their opening remarks outlined topicality of the Conference for fundamental and applied polymer research.

The first plenary lecture [G.B. McKenna (the United States)] was dedicated to the effects of the molecular architecture on the rheology of polymer melts. In the lecture, a comparison was made of linear, long-chain branched, and ring molecules. The results were recommended for use in industrial rheology.

In the next lecture, G. Marrucci (Italy) also analyzed the rheological problems and proposed solutions for a series of tasks of the industrial rheology.

B. Mena (Mexico) in his lecture reported on the flow of non-Newtonian fluids around bubbles.

A lecture prepared by a group of scientists [J.M. Kenny, A. Terenzi, and S.E. Barbosa (Italy)] was devoted to rheology of polymers, polymer blends, and polymeric nanocomposites.

Considerable interest was aroused in the audience by the lecture prepared by G.C. Papanicolaou, Th.V. Kosmidou, N.K. Anifantis, and D.E. Mouzakis (Greece) in which they considered the effect of damage in macromolecules on the mechanical behavior of polymers.

M. Narkis (Israel) in his lecture reported on polymeric sensors for chemicals based on electrically conductive polymers and their applications in various branches of industry and in private life.

The next plenary lecture [D.E. Kranbuehl (the United States)] concerned the problems of preparation and characterization of hybrid nanoparticle metal polyimide films.

The lecture given by J. Mijovic was devoted to the study of the adhesion properties of a number of polymers, including network polymers. Particularly, the lecturer reported on water–network dynamics in adhesive joints, studied by experimental and computational methods.

Considerable interest has been expressed by the participants in the results reported by S. Simon in her lecture entitled Volume Recovery and the Tau-Effective Paradox: New Measurements on Polymeric Glass-Formers.

The lecture given by F.P. La Mantia (Italy) was devoted to degradation and stabilization of polymer blends and composite materials.

The durability of polymeric materials (fundamental and practical aspects) was the subject of the lecture given by J.L. Gardette (France).

H. Watanabe (Japan) in his lecture analyzed the dielectric and viscoelastic data of thermoelastoplastics in dynamic conditions.

The last plenary lecture was given by G.E. Zaikov (Russia) who reviewed the works concerning degradation of PVC and searching for the ways to its stabilization.

1070-4272/04/7709-1570 © 2004 MAIK "Nauka/Interperiodica"

Oral and poster presentations covered the problems of synthesis, characterization, and applications of a wide variety of polymers, polymer blends, and composites with a special emphasis made on nanocomposites. Several presentations included data on the processes for preparation of polymeric and composite materials.

The Conference revealed that the times of polymers have come long ago, and there are no grounds to expect that these times are soon over.

The next Conference "Times of Polymers"-III is planned to be held in 2006 at the same place.

Proceedings of the Conference will be published in 2005 as a special issue of the journals dedicated to the conference. The Program of the Conference and Abstracts of all the contributions are available from the library of the Institute of Chemical Physics, Russian Academy of Sciences (Moscow, Russia).

REVIEW

Extraction of Gold From Ores and Concentrates by Leaching with the Use of Cyanides and Alternative Reagents

L. F. Kozin and V. T. Melekhin

Vernadskii Institute of General and Inorganic Chemistry, National Academy of Sciences of the Ukraine, Kiev, Ukraine

Ukrpolimetall State Corporation, Kiev, Ukraine

Received January 9, 2003; in final form, June 2004

Abstract—The problems associated with gold mining are considered from the standpoint of application of heap leaching, a method for gold recovery. Data on the kinetics and mechanism of gold dissolution in cyanide and alternative solvents [thiocarbamide solutions containing Fe(III) ions and hypochlorite-chloride bromine-bromide, iodine-iodide, and copper-thiosulfate solutions], which make it possible not only to improve the working efficiency in gold mining, but also to lessen the contamination of the environment with highly toxic compounds.

The method of heap leaching (HL) is a geotechnological method for processing of low-grade gold-containing ores and rejects of concentration plants. Alkaline solutions of cyanides are used in enormous amounts as solvents for gold [1, 2], which gives rise to quite a number of ecological problems. From the standpoint of environment protection [3], it is unsafe to use the HL technique in countries with fertile soils and high population density. Therefore, an exceedingly important problem of the HL technique is that alternative solvents for gold are to be developed [3].

In the HL of gold, special attention is given to taking into account the natural factors, absence of rifts, density of the surface layer of soil, presence of clay strata, and absence of compounds of such elements as arsenic, selenium, cadmium, thallium, lead, etc. in the ores. An exceedingly important specific feature of the HL technique is the possibility of processing of both moderate amounts of gold-containing ores and concentrates (tens and hundreds of thousands of tons) and enormous quantities of gold-containing raw materials of technological origin (tens and hundreds of millions of tons) [1, 2]. At present, the HL of gold is the most cost-effective method for leaching of low-grade gold-containing ores. However, despite the high economical efficiency of the HL of gold, proper attention is not, paradoxically, paid to the environment protection in gold-mining regions [3].

The rise in gold output in many countries all over the world is clearly seen from the data in Fig. 1. A steep rise in the output of gold has been noted in

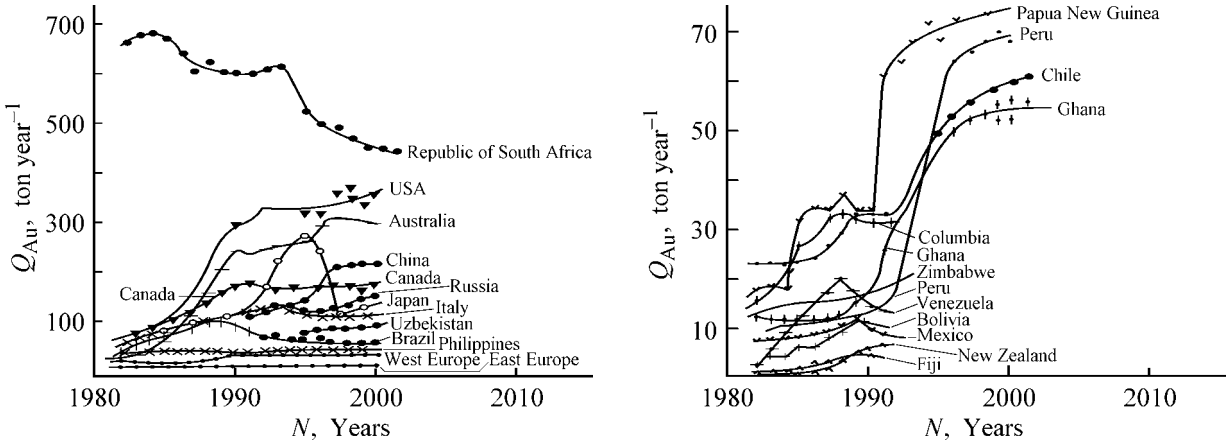

Fig. 1. Output of gold, Q_{Au} in some countries. (N) Years; the same for Fig. 2.

the United States, Australia, Canada, China, Russia, Japan, Italy (Fig. 1a), and also in the Philippines, Brazil, Papua New Guinea, Peru, Chile, Ghana, Venezuela and others (Fig. 1b) [4]. As can be seen, the 1980s, the years in which the HL of gold was mastered, are characterized by an explosive increase in the output of gold all over the world. The only exception is the South African Republic, which, although using the HL method for recovery of gold from gold-fields and raw materials of technological origin, obtains most part of its gold from ledge ores at large depths (1–3 km).

In the world as a whole, the output of gold has been growing linearly beginning in 1980 (Fig. 2).

Calculation shows that the 2010 world's output of gold will be 3320 ± 20 tons per year. The increase in the output of gold leads to higher demand for, and consumption of, gold [5]. However, as can be seen in Fig. 2, the supply of gold fails to satisfy the demand, which is quite understandable because mining of gold is very capital-intensive.

Analysis of the technologies for gold mining shows that the main contribution to the increase in the gold output is made by the heap leaching. The technological process of the HL of gold from gold-containing ores started to be developed in the second half of the 1960s by the US Mining Bureau. The development and fast implementation of the new technology for HL of gold from low-grade ores in the US industry were promoted by the special program devised by the US Mining Bureau and the preferential terms provided by the government, including reasonable taxation.

Already in the early 1980s, there were 110 HL installations with annual throughput of 100 thousand to 3.5 million tons of rock for recovery of gold and silver [1, 2, 6–9]. The steady increase in the annual output of gold in the US and many other countries (Fig. 1) is due to the involvement of low-grade ores in the production process and to recovery of gold and silver from these ores by heap cyanide leaching. The mastering of the method of heap leaching enabled some countries to raise the output of gold dramatically. As can be seen in Fig. 1a, the output of gold increased during the period of time from 1975 till 1992 by factors of 3, 10, and 15 in Canada, United States, and Australia, respectively [9]. Presently, the technology of heap leaching of gold and other noble metals is used at more than 150 plants, with some of these having an annual throughput capacity of 20–30 million tons of rock. Depending on the mineral composition of gold-containing ores and concentrates, the HL process makes it possible to recover 42 to 90% of gold and rapidly process hundreds of thousands and even millions of tons of raw materials, and, therefore, is being intensively developed [1, 2].

The method of heap leaching consists in the following. A certain amount (hundreds of thousands of tons and more) of an ore permeable to a reagent/solvent (commonly alkaline solutions of cyanides) and crushed to a size less than 20 mm is placed on a leaching pad with a concrete (or made of clay, clay with waste rock, etc.) base of a thickness of 0.5–1.0 m with a prescribed slope (frequently double-side). The device for heap leaching is shown schematically in Fig. 3. Such a device can be constructed on a hor-

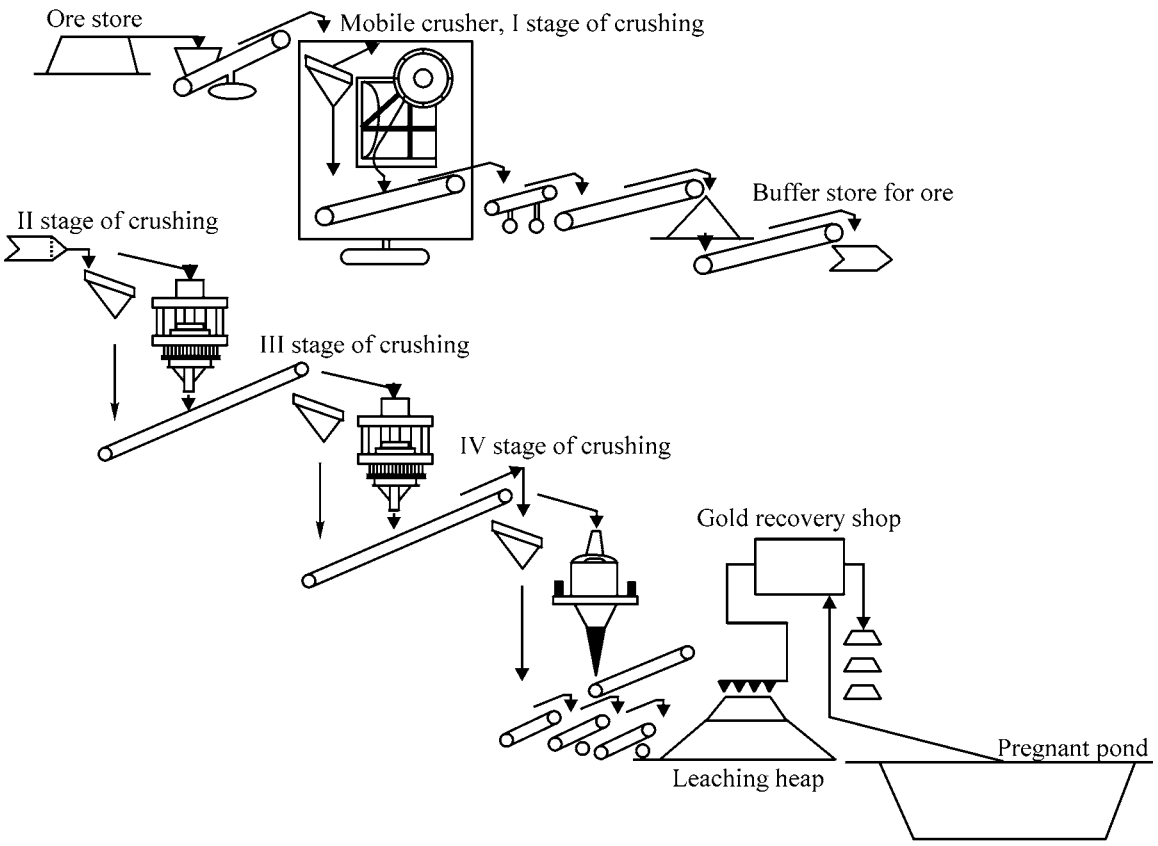

Fig. 4. Schematic of the production process at a plant of the Zarafshan-Newmont joint venture, supplemented with a "pregnant pond" [11].

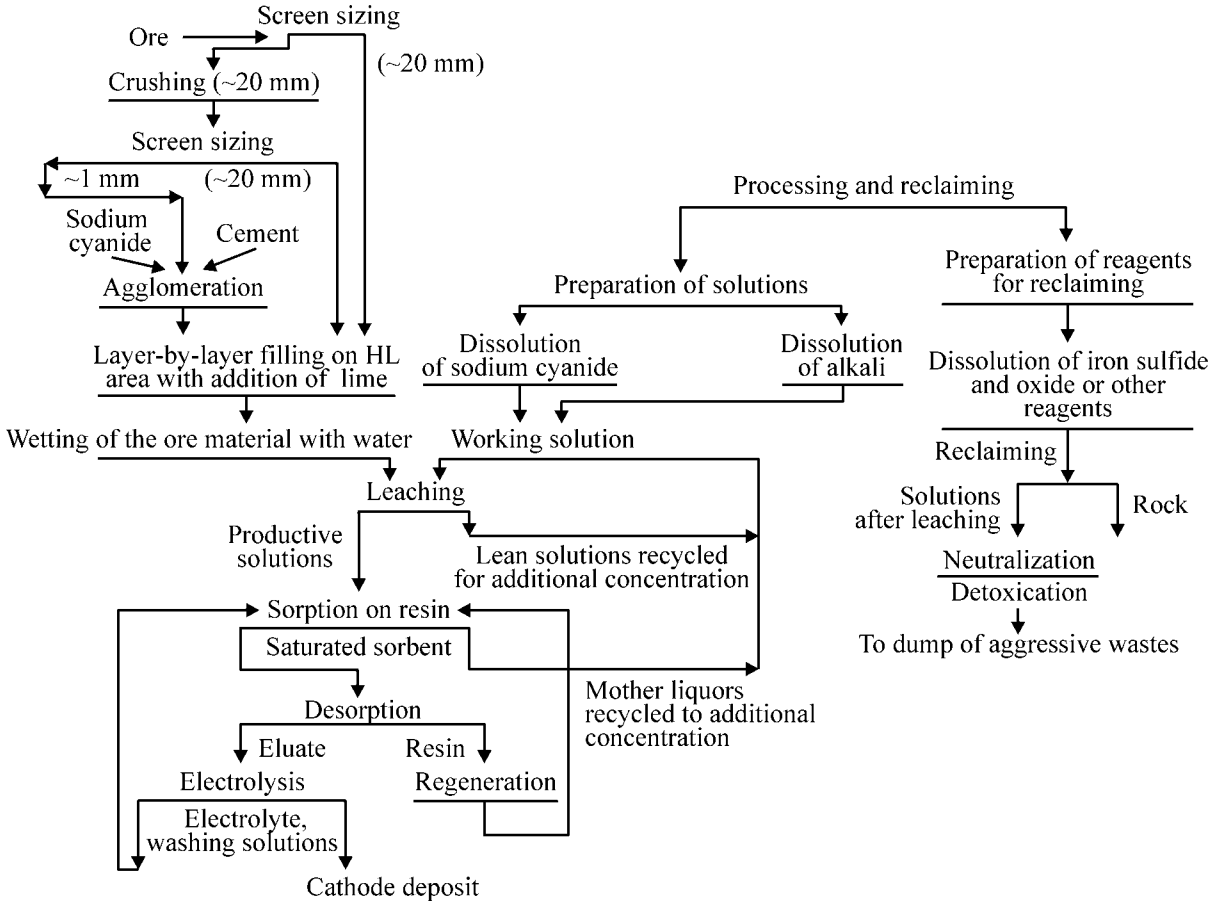
izontal area (Fig. 3a) or on a landscape with a complex profile, with clay or rock walls and a liner impermeable to aqueous solutions (Fig. 3b). To provide a drain for the cyanide solutions, the leaching pad has a slope of 2°–7° toward the collectors of product-containing solutions. The pad of the HL installation may lie on a concrete or rammed-clay bed, on which a water-proofing layer is placed for protection from underground water. This layer has the form of two or three layers of all-welded polyethylene films with raised edges and a buffer sand-gravel layer of thickness 0.25–0.30 m. The total thickness of the base layer depends on its constituent components. In the case of a water-impermeable "pillow" of clay and screens made of concrete and one or two layers of asphalt, the total thickness of the base may exceed 1.2–1.5 m. Schematics of the pads for construction of heaps (or piles) with account of the landscape profile for bulk leaching of gold- and silver-containing materials were presented in [1]. The watertight base is the most important component of the installation for heap leaching, because it is intended to preclude loss of leaching and product-containing solutions. An important part of the leaching pad is the system for collection and removal of product-containing solutions. The ore is laid in bulk as a heap or pile 5–12 m (occasionally 30 m) high and 100–1500 m long. In gold leaching by the HL method, the surface of heaps (piles) is irrigated with cyanide solutions by means of perforated pipes, sprinkling nozzles, perforated outlet pipes in the bulk of the heaps, etc.

The general tendency in the development of the gold-mining industry in the world is the desire to involve in the industrial production in increasing amounts the low-grade and difficultly processable, the so-called stubborn and difficultly concentrated ores. Gold-containing ores, which include silicified and lime sedimentary rocks, hydrothermal rocks, quartzites, quartz-pyrites, sand dolomites, and shales of quartz and eruptive rocks (3–15 g of Au per ton of ore) can be readily dressed and are processed by gravitation or flotation methods [4, 10]. Ores of the same type, but with a low content of gold (0.2–1.8 g/ton), as well as rejects from concentration mills (including those stored in dumps), are a promising raw material for the HL technique. Figure 4 shows schematically how gold is recovered by the HL meth-



Technological scheme for ore processing by the HL with alkaline cyanide solutions [1].

od at a plant of the Zarafshan-Newmont joint venture [11]. The main expenditure in recovery of gold by leaching from resource ores (1.4 g of Au per ton) of the Muruntau deposit (Uzbekistan) is associated with ore pretreatment. The ore is subjected to four-stage crushing to obtain 94% of ore particles 3.25 mm in size. Further, the crushed ore is granulated by addition of cement, lime, and water. In the course of granulation, coarser and dust-like particles are bound into grains, which improves the permeability of the ore bed to the leaching solution. Lime is consumed in the course of granulation for raising the pH value of the cyanide leaching solution. The planned processing capacity of a heap for HL is 80 m (eight layers 10 m in height each). It can be seen from Fig. 4 that the HL process itself involves only a small number of technological procedures.

The simplicity of implementation of the HL process and low capital outlay and operation expenditure, which constitute, respectively, 25 and 35–40% of the expenditure for processing of gold-containing ore by the conventional techniques, make it possible to recover Au, Ag, and nonferrous and less-common metals from low-grade ores that are not economically viable for other technologies (0.2–0.6 g of Au per ton). The HL method is commonly used to process ores with 0.5–3.0 g/ton of gold and rejects from concentration mills (≥0.35 g/ton).

The amount of gold recovered in HL depends on the amount of the gold-containing material being processed. The concentration of Au(I) recovered from product-containing solutions depends on a number of factors: permeability of a material being leached to the solvent, porosity of the material, composition of the solvent, structure of ore materials being leached (gold-containing minerals and porous ore bodies scarred by crevasses, etc.), form in which gold is contained in the material (free, bound, dispersed, etc.), and length of the filtration path. Commonly, the permeability of the ore material and rejects is 0.5–10 cm h^{-1}. The admissible minimum permeability is 0.5–1.5 cm h^{-1}. To improve the permeability of heaps and to raise the rate of leaching and the recovery of gold, the ore is pelletized by treating the crushed ore material (or rejects)

* TC, thiocarbamide $[(NH_2)_2C=S]$.

with a binder, portland cement (2.5–3.0 kg/ton), set with an alkaline cyanide solution [1, 7–9]. The pelletization is carried out in special granulators or on a transporter delivering the mixture to the vertex of a cone. The granulation occurs when the ore material with a binder moves down the sloping wall of the cone. The porosity of the thus obtained grains may be as high as 15–30%.

Alkaline solutions of NaCN commonly serve as solutions for extraction of gold from ores by leaching. However, an intensive search is underway for alternative solutions that can be used for this purpose. These solutions must satisfy the requirements of "green" chemistry and allow creation of gold-recovering shops that would not affect adversely the environment.

Cyanides. The technological scheme for heap leaching of gold with the use of cyanides [1] comprises the whole cycle of the HL process: pretreatment of ore, including crushing, introduction of a granulating additive (mainly portland cement), and agglomeration; leaching with alkaline cyanide solutions of NaCN (1.2–1.5 g l^{-1} at pH 10–11.5; NaOH expenditure 2.2–2.5 kg per ton of ore); and subsequent processing of the solutions obtained [12]. The optimal pH of the solution, equal to 11–11.5, is controlled by introduction of CaO, NaOH, {or $Ca(OH)_2$ [1]}. The expenditure of reagents is as follows (kg/ton): NaCN 0.3–1.5, NaOH 0.15–3.0, CaO 2 [1, 2, 4–8, 12, 13]. The expenditure of reagents and materials for agglomeration is as follows (kg/ton): cement 10–15, NaCN 0.5–3.0, CaO 1–3; H_2O 12–14% [1]. The resulting pellets 15–30 mm in size are directed to HL. The total area of heaps in HL is as large as 200 thousand square meters. The extraction of gold and silver is performed using the standard scheme on a HL pad with the use of solvents in the system for sprinkling, collection, and removal of the solution obtained. Further follow the recovery of the metals from the solutions by sorption on ion-exchange resins or activated carbons, desorption of the metals (accompanied by regeneration of adsorbents) to give an eluate, and electrolysis of the eluate to give a cathode deposit containing gold and silver. Gold can also be recovered from the eluates by cementation on electronegative metals. The technological process of gold leaching includes the following stages: preparation of leaching solutions, construction of dumps for processed rock, and its delivery to utilization.

The dissolution rate of gold and time of its extraction from an ore depend on the structure of the ore, which determines its permeability and porosity, and on the composition of the leaching solvent.

The time of leaching also depends on the mass of the ore and the form in which gold is present in it (bound or free gold, coarsely crystalline or dispersed) and may be in the range from several weeks to a year. In the case of a preliminary pelletization of the ore, the rate of heap leaching commonly increases [1, 2]. The sprinkling density is maintained at the level of 10–15 l m^{-2} h^{-1} in the case of a uniform sprinkling of the heap with the leaching solvent, and at 6–8 l m^{-2} h^{-1} in the case of a low permeability.

The standard potential of the half-reaction in the system constituted by gold and dicyanoaurate(I) anion:

$$Au(CN)_2^- + e \rightarrow Au + 2CN^- \quad (1)$$

is, as can be seen from Table 1, the most electronegative, compared with other media, and equal to

* FAD, formamidine disulfide $(NH_2)_2(NH)_2C_2S_2$.

$E^0_{Au} = -0.611$ V [14, 15]. Therefore, the dissolution of gold can proceed, in the case of heap leaching with cyanide solutions, in the presence of a wide variety of oxidizing agents (electron acceptors): oxygen, hydrogen peroxide, or potassium peroxydisulfate, in accordance with the following equations [16]:

$$2Au + 4NaCN + O_2 + 2H_2O \rightarrow 2Na[Au(CN)_2] + 2NaOH + H_2O_2, \quad (2)$$

$$2Au + 4NaCN + H_2O_2 \rightarrow 2Na[Au(CN)_2] + 2NaOH, \quad (3)$$

$$2Au + 4NaCN + K_2S_2O_8 \rightarrow Na[Au(CN)_2] + 2Na_2SO_4. \quad (4)$$

Table 2 lists the standard potentials [14, 15] of a number of redox systems promising for dissolution (recovery) of gold, silver, and platinum metals from ores, concentrates, and other materials in which they are contained, with the requirements of "green" chemistry satisfied [3]. The same table presents the standard potentials (V, relative to standard hydrogen electrode) of half-reactions with oxygen-based oxidizing agents. However, despite the high potentials of the oxidizing agents and large difference between the potentials of gold, E^0_{Au}, and oxidizing agents, $E^0_{Ox/Red}$, in cyanide solutions, the dissolution rate of gold in cyanide solutions is low. For example, the rate constant of gold dissolution is $k_{Au} = 27$ μmol m^{-2} s^{-1} [17] or $k_{Au} = 2.7 \times 10^{-9}$ mol cm^{-2} s^{-1} even in the presence of hydrogen peroxide. The rate constant of gold dissolution by a first-order reaction to give $[Au(CN)_2]^-$ is $k_{[Au(CN)_2]^-} = 2.33 \times 10^{-7}$ s^{-1} at 298 K. At temperatures of 323, 333, and 353 K, the values of $k_{[Au(CN)_2]^-}$ are, respectively, 1.10×10^{-6}, 1.51×10^{-6}, and 4.7×10^{-6} s^{-1} [18]. Therefore, as can be seen from Fig. 5b, curve *1*, the concentration of gold(I) in the solution reaches, in leaching with cyanides, only 0.8–1.5 mg l^{-1} even after a long time.

To raise the rate of gold dissolution, it has been suggested [17] to introduce Tl(I) ions into the cyanide solutions. However, this leads to a higher load on the environment (MPC 0.1 μg l^{-1} [19, 20]). At a concentration of Tl(I) ions equal to 0.5 mmol, the rate of dissolution of a rotating disc electrode made of gold (ω = 400 rpm) in a solution containing (M): NaCN 0.01, H_2O_2 0.01 at pH 10, $P_{O_2} = 0.21$ atm, and 25°C, increases from 275 to 785 μmol m^{-2} s^{-1}. In the case of Au dissolution in the presence of H_2O_2, the optimal rate is observed at pH 10.5–12.0 and H_2O_2 concentration of 0.005–0.03 M. In the temperature range 20–35°C, the rate of gold dissolution is limited by kinetic factors (activation energy $E_A = 140.8$ kJ mol^{-1}), and

at temperatures higher than 40°C, it is controlled by diffusion (E_A = 4.8 kJ mol^{-1}).

Let us now consider the reasons for the low rate of gold dissolution and the mechanism of gold dissolution in cyanide solutions. In anodic dissolution of gold in a cyanide solution containing 0.1 M of KCN and 0.1 M of KOH, three clearly pronounced peaks are observed in the i_a–E_a curve at potentials of –0.4, 0.3, and 0.6 V (relative to a standard hydrogen electrode), with broad passivation regions resulting from the passivating influence of hydroxide ions being adsorbed [21, 22]. The limiting stage of the anodic process is the stage of detachment of the first electron

$$AuCN^-_{ads} \rightarrow AuCN_{ads} + e \qquad (5)$$

from an $AuCN^-_{ads}$ species formed in adsorption of a cyanide ion on gold. The activation energy of the rate-determining stage is 93 ± 8 kJ mol^{-1}. In view of the fact that the point of zero charge (PZC) of gold is positive: $E^{Au}_{PZC} = 0.19 \pm 0.01$ V (relative to a standard hydrogen electrode) [23], its surface is negatively charged in a cyanide electrolyte at potentials more negative than the PZC ($E^0_{Au(CN)_2^-/Au^0} = -0.61$ V). The adsorption of cyanide ions on the surface of gold is hindered by the electrostatic repulsion of negative charges. Mainly positively charged potassium ions K^+ are adsorbed on the negatively charged surface of gold, and adsorption of CN^- occurs in the form of a secondary layer by the scheme

$$Au^{\delta-} \,|\, {}^{\delta+}K^{(1-\delta+)\delta-}CN^{\delta-}$$

to give a multilayer adsorption system. The adsorbed species $AuCN^-_{ads}$ is formed in this system by the exchange reaction, and then gold is ionized by the redox reaction Au → Au(I) + e with the subsequent binding of gold into a poorly soluble compound AuCN (SP 6.3×10^{-32} [24]). The formation of a neutral poorly soluble compound AuCN is the reason why the surface of gold is passivated. As a result, the ohmic resistance at the interface Au | AuCN–electrolyte increases. The neutral species AuCN blocks active centers on the surface of gold. As a consequence, the second cyanide ion adds to the AuCN species by the donor–acceptor mechanism at a very slow rate to give a soluble anion, dicyanoaurate(I) $[Au(CN)_2]^-$, which, having a negative charge, is repelled from the negatively charged surface of gold. Therefore, the rate of gold dissolution in cyanide solutions is very low.

As an example of low rates in cyanide extraction of gold by the HL method can serve processing of a low-grade ore at the Muruntau deposit of the Zarafshan-

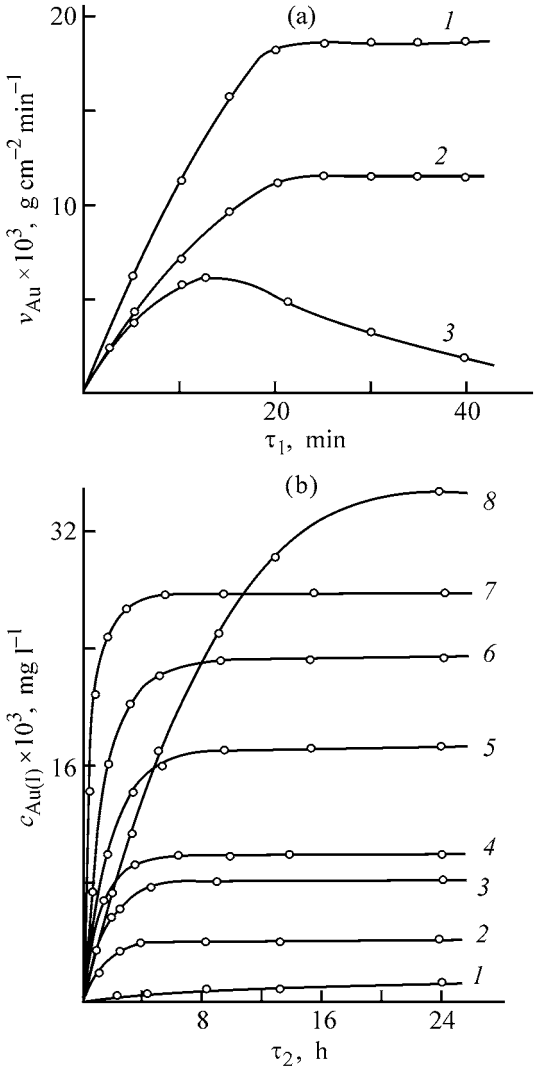

Fig. 5. (a) Rate of gold dissolution, v_{Au}, in a TC solution containing (*1*, *2*) iron(II) sulfate and (*3*) hypochlorite and (b) concentrations of gold ions, $c_{Au(I)}$, in various solutions vs. the time of contact τ_1, τ_2. For solution compositions, see text. (a) Temperature (K): (*1*, *2*) 298 and (*3*) 333. (b) Solution: (*1*) alkaline cyanide; (*2*, *3*) iodine-iodide at pH (*2*) 11.7 and (*3*) 10; (*4*) copper-thiosulfate, (*5*–*7*) thiocarbamide with (*5*) 0.01, (*6*) 0.1, and (*7*) 0.2 M of TC; and (*8*) hypochlorite.

Newmont joint venture [11, 19]. Multilayer piles of height 85 m are constructed for gold leaching [11, 19]. The leaching is carried out during a long period of time (up to 226 days). In this case, the variation of the concentration of gold(I) in the solution depends on the density of sprinkling with a leaching solvent and on the time of ore leaching. For example, in leaching of ore for 0–20 days (density of sprinkling with a leaching cyanide solution χ = 15 l h^{-1} m^{-2}), the concentration of gold slowly increases to 1.3–1.4 mg l^{-1} to reach the maximum of 6–6.3 mg of Au

per liter after τ = 24–50 days (χ = 12 l h^{-1} m^{-2}). Then, after τ = 51–70 days at χ = 10 l h^{-1} m^{-2}, the concentration of gold in solution decreases to 1.9 mg l^{-1}, and further, after τ = 71–100 days at χ = 8 l h^{-1} m^{-2}, falls to 1.2 mg l^{-1}. If the density of sprinkling with the leaching solution is not lowered, then, at τ = 240 days, the concentration of gold in the solution decreases to a level at which the processing of solutions becomes economically inexpedient. Therefore, the spraying density is chosen to be 8 l h^{-1} m^{-2} or less, so that the concentration of gold in the solution should be "maintained at a level of no less than 1.2 mg l^{-1}," [19]. This ensures effective recovery of gold from the solution obtained on a Merrill Crow installation [19]. To catch suspensions, the solution is passed through filtering units. The dissolved oxygen is removed by vacuum deaeration in two towers [11]. Then, zinc dust and lead nitrate are introduced into the solution to diminish the share of the parasitic reaction by raising the overvoltage of hydrogen evolution on lead. The cementate formed is separated on five pressure filters, and the spent solution is recycled into the HL process. The resulting precipitate is calcined in two furnaces at 650°C to oxidize zinc and metals coprecipitated in cementation of gold. The calcined precipitate is mixed with a flux based on borax, saltpeter, and silica and fused in an arc smelting furnace. The gold alloy produced by the smelting contains three main impurities (%): Ag 10, Cu 5, and Pb 2–3, and the total content of other impurities is 2%. The content of gold in the crude metal is 80–81%. After purification by refining, the content of gold in the commercial product is 99.99%. The manufacture of gold by the Zarafshan-Newmont joint venture was 13.683 and 11.724 ton $year^{-1}$ in, respectively, 1997 and 1998 [11], and 13.483–16.886 ton $year^{-1}$ in 1999–2001 [19].

Interesting results were obtained by the authors of [25] in HL of gold-rich grainy long-stored products formed in finishing treatment at a plant for processing of heavy concentrates, which contained mainly quartz and fragments of bearing strata: pyrite, arsenopyrite, and chalcopyrite. Gold was mainly present in the free form (grain size 2 mm) and was associated with quartz and sulfides. According to the results of assaying, the content of gold was 60–80 g of Au per ton. The gold-containing material was crushed (95% to grain size –4 mm and 5% to –0.074 mm). The prepared gold-containing materials were cyanated at a phase ratio l : s = 1 : 2, leaching duration of 72 h, and spraying density of 70–80 l h^{-1} m^{-2}. The recovery of gold into product-containing solutions somewhat exceeded 80%. After the recovery of gold and separation of the liquid phase, 8–16 g of Au per ton remained in the cakes. Only under the above conditions of cyanidation, the content of gold in the cyanide leaching solutions was as high as 10–100 mg l^{-1} [25]. It has been established that cementation on zinc shavings is efficient for recovery of gold from such rich productive solutions. The cemented precipitate of gold is extracted and fused into an alloy ingot of gold after acid treatment to remove zinc and some impurities. The solutions from which gold was extracted and washed cyanidation cakes were detoxicated with a solution of calcium hypochlorite prior to being delivered to special storage facilities [25].

It can be seen from the data presented that the rates of the cyanidation reaction are low both in [11, 19] and in [25].

However, the rate of the cyanidation reaction can be, in our opinion, raised manyfold if the charge of the gold surface is changed. It is known that positively charged ions: Pb^{2+}, Zn^{2+}, Cd^{2+}, Cu^{2+}, Cu^{+}, Ag^{+}, Tl^{+}, can be adsorbed on a negatively charged gold surface. For these ions, the point of zero potentials E_{PZC} of the metallic phase are considerably more negative then the PZC of gold (V): $E_{PZC}^{Pb} = -0.60$, $E_{PZC}^{Zn} = -0.60$, $E_{PZC}^{Cd} = -0.75$ [20], $E_{PZC}^{Cu} = -0.43$ [26], $E_{PZC}^{Ag} = -0.70$, $E_{PZC}^{Tl} = -0.71$. In dissolution of gold in the presence of redox components in solution, the adsorbed ions Pb^{2+}, Zn^{2+}, Cd^{2+}, Cu^{+}, Ag^{+}, Tl^{+} are reduced at more positive potentials (undervoltage effect) [27] to a metal, to form positively charged nanosize islands on the surface of gold. These islands may give rise to a positive, the so-called compromise potential of the gold surface. As a result, the reaction surface of gold acquires a more positive potential, which stimulates the adsorption of cyanide ions [18]. As a consequence, the rate of gold dissolution may increase by several orders of magnitude, by analogy with the anodic dissolution of gold in electrolytes with addition of Tl(I), Pb(II), and other ions [21].

The solutions formed in extraction of gold by leaching are directed into the so-called "pregnant pond" (see scheme). From this pond, solutions containing Au(I) in the form of the anion $[Au(CN)_2]^-$ with the accompanying silver(I) anion $[Ag(CN)_2]^-$ are commonly fed into columns packed with an ion-exchange resin (anionite) or activated carbon. Elution of gold from the anionite or activated carbon by various methods gives concentrated eluates, wherefrom gold is extracted by treatment with powdered zinc [11, 19] or zinc shavings [25], or by electrolysis. The authors of [28] believe that aluminum is to be preferred for recovery of gold from cyanide solutions by cementation. In contrast to zinc, aluminum forms no complex com-

pounds with cyanide ions. Therefore, regeneration of cyanide is observed in cementation of gold from eluates. Aluminum ions can be removed from solutions by simple liming. Aluminum can be used in the form of a dust, shavings, sheets, or alloys with silicon, grains of silumin Al–Si [28]. Gold and silver can also be recovered from solutions by electrolysis with graphitized fiber cathodes, with current efficiencies of 80–90 and 50–60%, respectively [29]. The payback period in industrial implementation of the HL processes described is in the range from several months to a year [30].

The technology of heap leaching of gold has been tested and mastered in Russia, Kazakhstan, and Uzbekistan on the industrial scale since the early 1990s [10, 13, 34].

As examples of use of cyanide solutions in gold mining in CIS countries can serve the following deposits: Muruntau [11] and Besapantau [31] (Uzbekistan); Vasil'kovskoe [32], Pustynnoe, Enbekshi, Ortasoi, Kar'ernoe, Zhanan [33] (Kazakhstan); Maiskoe, Kuznetskoe, Lopukhovskoe, Murtykty, Vorontsovskoe [34] (Russia). The factor that hinders use of the HL of gold for processing of gold-containing ores from the Muruntau and Besapantau deposits is the high sorption capacity (up to 91%) of carbonaceous shales contained in these ores [31].

Particular difficulties are encountered in recovery of gold by the HL and gravitational methods in the case of clayey gold-containing materials [35–37]. Clays form, in the course of gravitational concentration in wet media, colloid solutions and sludges whose particles sorb finely dispersed gold and carry it away to rejects, which results in its low recovery. At the same time, granulation of clayey gold-containing ores markedly raises their permeability to the leaching solutions and improves recovery of gold into leaching solutions.

Thiocarbamides. Rather promising, from the standpoint of "green" chemistry, reagents for gold leaching are thiocarbamides, thiosemicarbamides, thiocyanates, and derivatives of chlorine, bromine, iodine, etc., in which the rates of gold dissolution are higher than those in cyanide solutions [18, 38, 39]. One of properties of these reagents used for extraction of gold and silver by leaching is their capacity for spontaneous redox reactions involving atmospheric oxygen, water (hydrolysis), biota (plants and products of their decomposition, microorganisms), which convert spent (or spilled) solvents into acids (H_2SO_4 reacting with silicates, alumina, etc.) to give neutral salts, microfertilizers, or even food products for microorganisms.

The standard potential of the half-reaction of gold in a solution containing thiocarbamide [$SC(NH_2)_2$, TC] is $E^0_{Au\,TC_2^+}$ = 0.380–0.420 V (Table 1) [14]. Figure 5a shows kinetic curves of gold dissolution in a thiocarbamide solution containing iron sulfate of the following composition (M): $SC(NH_2)_2$ 0.4, $Fe_2(SO_4)_3$ 0.36; H_2SO_4 0.1 (to pH 1.0) at 298 and 333 K. The procedure for measuring kinetic curves was described in [18, 38, 39]. It can be seen that the rate of dissolution of metallic gold depends on the time of its contact with a thiocarbamide solution and on temperature. Gold dissolves in thiocarbamide solutions by the following first-order reaction

$$c = c_{max}(1 - e^{k}3\tau), \quad (6)$$

where c_{max} is the limiting concentration of gold in solution, equal to 1.47×10^{-4} M (28.96 mg l^{-1}); and k is the rate constant (s^{-1}) of gold dissolution, equal to 6.18×10^{-4} s^{-1} at 298 K [18].

The quantity $k_{Au\,TC_2^+}$ exceeds by a factor of 2500 $k_{[AuCN]_2^-} = 2.33 \times 10^{-7}$ s^{-1} at a given temperature. Reactions of the following set occur in solution in the course of gold dissolution:

$$SC(NH_2)_2 + FeSO_4 \rightleftarrows FeSO_4 \cdot SC(NH_2)_2^+, \quad (7)$$

$$2SC(NH_2)_2 + 2FeSO_4 \cdot SC(NH_2)_2^+ \rightleftarrows S_2C_2(NH)_2(NH_2)_2 + 2FeSC(NH_2)_2^{2+} + 2HSO_4^-, \quad (8)$$

$$2Au + S_2C_2(NH)_2(NH_2)_2 + 2SC(NH_2)_2 + 2H^+ \rightarrow 2Au[SC(NH_2)_2]_2^+, \quad (9)$$

$$Au + 2SC(NH_2)_2 + FeSO_4 \cdot SC(NH_2)_2^+ \rightarrow Au[SC(NH_2)_2]_2^+ + FeSO_4 \cdot SC(NH_2)_2. \quad (10)$$

The potential of the reaction

$$2SC(NH_2)_2 \rightleftarrows S_2C_2(NH)_2(NH_2)_2 + 2H^+ + 2e \quad (11)$$

of formation of formamidine disulfide (FAD) is E^0_{FAD} = 0.420 V (Table 2) and depends on the solution pH and concentration of thiocarbamide in accordance with the reaction

$$E_{eq} = 0.420 - 0.059\,pH + 0.0295 \log\{[S_2C_2(NH)_2(NH_2)_2]/[SC(NH_2)_2]^2\}. \quad (12)$$

The rate of gold dissolution in thiocarbamide solutions depends on many factors: rate of FAD formation by reaction (8), whose equilibrium constant is K^0_{eq} =

6.7×10^{10}; optimal Fe(III) : TC ratio, 1 : 2; pH 0.8–1.2; and temperature, 5–25°C [18]. The activation energy of the reaction of gold dissolution in TC solutions in the presence of complex ions formed by iron and thiocarbamide, $FeSO_4 \cdot SC(NH_2)_2^+$, in the temperature range 5–25°C is E_A 13.4 kJ mol^{-1}, i.e., the rate of gold dissolution in TC solutions is controlled by diffusion, and in the temperature range 25–60°C, E_A = 42.8 kJ mol^{-1}, i.e., the rate of dissolution is controlled kinetically. The equilibrium constant of reaction (9) is $K_{eq}^0 = 3.4 \times 10^{13}$. Reactions (7) and (8) are reversible, and reactions (9) and (10) of gold dissolution are irreversible. Interestingly, the standard potential of gold in a carbamide solution is 0.380 V (Table 1). The standard redox potential of formamidine disulfide $[(NH_2)_2(NH)_2C_2S_2]$ is only 0.420 V (Table 2). The difference of the standard potentials, equal to 0.040 V, is sufficient for the reaction of gold dissolution to occur.

It was found in leaching of ores from the Muzhievskoe deposit in laboratory conditions with TC solutions that the concentration of gold(I) in the product-containing solution depends on the TC concentration in solution, being equal to 17, 22.8, and 27.5 mg l^{-1} at [TC] = 0.05, 0.1, and 0.2 M, respectively (Fig. 5b, curves *5–7*). For ores that are richer in gold, the concentration of gold(I) in the leaching solution may be considerably higher. The equilibrium concentration of gold(I) in thiocarbamide solutions may be as high as several tens of grams per liter of solution. As can be seen in Fig. 5a, the kinetic curves of gold dissolution (curves *1, 2*) become parallel to the abscissa axis after the maximum dissolution rate is reached. This may be due to inhibition of the gold surface both by products formed in decomposition of TC (HS^-, S^0) via reactions of hydrolysis and oxidation

$$S{=}C(NH_2)_2 + 2H_2O \rightarrow O{=}C(NH_2)_2 + HS^- + H_3O^+, \quad (13)$$

$$S{=}C(NH_2)_2 + \frac{1}{2}O_2 \rightarrow O{=}C(NH_2)_2 + S^0, \quad (14)$$

$$HS^- + \frac{1}{2}O_2 \rightarrow S^0 + OH^-, \quad (15)$$

and by poorly soluble products {AuHS, AuS^-, $[Au(HS)_2]^-$, $[Au(H_2S)_2]^+$, $[Au_2(HS)_2S]^{2-}$, $[Au(H_2S)_2]^+$, $[Au(H_2S)_3]^+$}. The composition of the hydrosulfide complexes of gold and their solubility in aqueous solutions depend on the solution pH and temperature. It was established that the following complex species are formed in hydrosulfide solutions: $[Au(HS)_2]^-$, $[Au_2(HS)_2S]^{2-}$, $AuHS_2^{3-}$, AuHS, and AuS^-. Processing of experimental data demonstrated that the instability constants K_{ins} of the complex ions $[Au(HS)_2]^-$ and $[Au_2(HS)_2S]^{2-}$ at different temperatures are as follows: 1.0×10^{-36} and 4.0×10^{-70} at 298 K, 1.2×10^{-33} and 2.0×10^{-66} at 323 K, 7.9×10^{-24} and 1×10^{-53} at 448 K, and 3.2×10^{-20} and 1.2×10^{-48} at 523 K.

In the course of dissolution, positively charged species $FeSO_4 \cdot SC(NH_2)_2^+$, TC molecules, and positively charged hydrosulfide complexes $[Au(H_2S)_2]^+$, $[Au(H_2S)_3]^+$ and, as a result of multilayer adsorption, also negatively charged complexes $[Au(HS)_2]^-$, $[Au_2(HS)_2S]^{2-}$, and $AuHS_2^{3-}$ are adsorbed on the surface of gold. The source of sulfide ions in the thiocarbamide solution is its hydrolysis by reaction (13).

As a result of exchange reactions, poorly soluble sulfides (Au_2S) and hydrosulfides (AuHS) of gold are formed in the surface reaction layer of gold. The formation of poorly soluble sulfides in extraction of gold with thiocarbamide solutions is a major disadvantage of this reagent. A study of the surface films on gold by Auger spectroscopy confirmed these conclusions [38].

Figures 6a and 6b show micrographs of the adsorption film on the surface of gold, and Figs. 6c and 6d, electronic Auger spectra of these films. The surface adsorption films were obtained by dissolving a gold disc in a thiocarbamide solution of a composition (M) $SC(NH_2)_2$ 0.138 and Fe(III) 0.046 at pH 2.0 and disc rotation rate ω = 180 rpm in the course of 200 min. It can be seen that the surface film is constituted by dark particles ($\delta \leq 0.1$ μm), coarse conglomerates of particles ($\delta \leq 50 \pm 10$ μm) and light areas. The Auger spectra of the dark particles are shown in Figs. 6c and 6d. The composition of the particles was determined layer-by-layer by Auger spectroscopy, by etching the film with argon ions for τ = 10 (Fig. 6c) and 60 s (Fig. 6d). A layer of thickness 7.0 ± 0.2 Å was removed from the sample surface in 10 s, and 40.0 ± 0.5 Å, in 60 s. The total thickness of the adsorption film was $\delta = 260 \pm 10$ Å. An analysis of the adsorption film by means of Auger spectroscopy demonstrated that it contains gold, sulfur, carbon, and oxygen. The Au : S ratio in the film, equal to 54.5 : 44.7 = 1.21 (10 s) and 65.0 : 35.3 = 1.84 (60 s), indicates that hydrosulfides AuHS and sulfides Au_2S are formed in the adsorption film. The concentration of gold(I) in the thiocarbamide solutions reached a value of 6.156 g l^{-1} in 170 min at a TC : Fe(III) ratio of 0.337 : 0.305 = 1.04.

Hypochlorites. As oxidizing agent for gold can be used sodium [1, 40] or calcium hypochlorites [41]. When brought in contact with water or alkali solu-

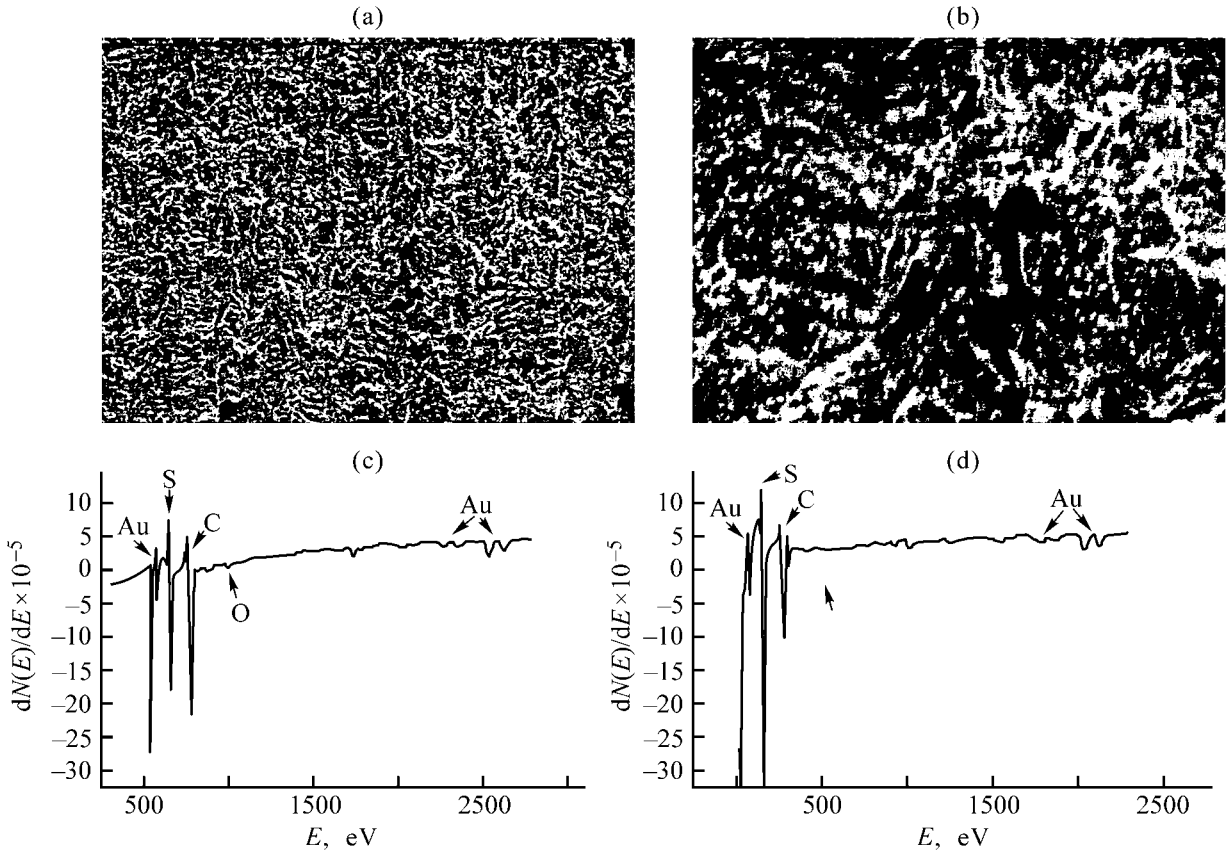

Fig. 6. (a, b) Micrographs of the adsorption film on the surface of gold and (c, d) electronic Auger spectra of (c) dark and (d) light parts of the film. Magnification: (a) 200 and (b) 3000.

tion, chlorine disporoportionates in accordance with the equations

$$Cl_2 + H_2O = HClO + HCl, \quad (16)$$

$$Cl_2 + NaOH = HClO + NaCl, \quad (17)$$

$$Cl_2 + 2NaOH = NaClO + NaCl + H_2O. \quad (18)$$

The equilibrium constant of reaction (16) is $K_{eq} = 4.2 \times 10^{-4}$, and the equilibrium concentration of HClO in water at 298 K is 0.030 M (1.06 g l^{-1}). The solubility of chlorine $Cl_{2\,(aq)}$ at 298 K is 0.0921 M (3.26 g l^{-1}). The equilibrium constant of the reaction of chlorine dissolution in aqueous solutions, $Cl_{2\,(g)}/Cl_{2\,(aq)} = 0.062$. The solubility of Cl_2 in solutions of hydrochloric acid and of the salts NaCl and NaClO markedly increases because of the formation of the anion Cl_3^-.

The equilibrium potential (V) of the redox reaction involving the hypochlorite ion in an alkaline medium:

$$ClO^- + H_2O + 2e \rightleftarrows Cl^- + 2OH^- \quad (19)$$

conforms to the equation [42]:

$$E_{19} = 0.890 + (2.303RT/2F)\log [ClO^-] - (2.303RT/2F)\log [Cl^-] - (2.303RT/2F)\text{pH}. \quad (20)$$

In an acid solution, the redox potential of the reaction

$$HClO + H_2O + 2e \rightleftarrows Cl^- + H^+ + 2OH^- \quad (21)$$

is more positive and conforms to the equation

$$E_{21} = 1.494 + (2.303RT/2F)\log [HClO] - (2.303RT/2F)\log [Cl^-] - (2.303RT/2F)\text{pH}. \quad (22)$$

The value of the potential of reaction (21) points to a high oxidizing capacity of hypochlorites.

The potential of the half-reaction of metallic gold in chloride solutions [43]

$$AuCl_2^- + e = Au + 2Cl^-, \quad (23)$$

$$E_{23} = 1.130 + (2.303RT/F)\log [AuCl_2^-] - 2(2.303RT/F)\log [Cl^-] \quad (24)$$

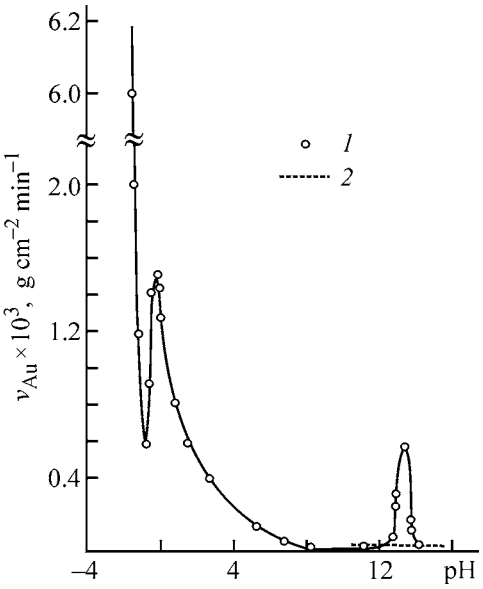

Fig. 7. Rate of gold dissolution, v_{Au}, vs. pH at 298 K in various solutions. Solution (*1*) hypochlorite, with 5.0% NaClO and 4.7% NaCl, pH 1.06; (*2*) alkaline cyanide, 10 g l^{-1} of NaCN and NaOH added to pH 12.2–14.8.

is more negative than the potential of hypochlorite in acid media. The difference of the equilibrium potentials of the redox reaction of gold dissolution

$$2Au + HClO + 3H^+ + 3Cl^- = 2AuCl_2^- + H_2O + 2H^+ \quad (25)$$

conforms to the equation

$$\Delta E_{25} = 0.364 + (2.303RT/2F)\log [HClO] - (2.303RT/F)\log [AuCl_2^-] + 3(2.303RT/F)\log [Cl^-] + 1.5(2.303RT/F)pH. \quad (26)$$

Equation (26) was used to calculate the equilibrium constant of reaction (25) at concentrations (M): [HClO] = 0.1, [HCl] = 0.3, $[AuCl_2^-]$ = 0.1. In this case, ΔE_{25} = 0.346 V and $K_{eq} = 7.15 \times 10^5$. The resulting value of K_{eq} indicates that a sufficiently complete dissolution of gold in acid hypochlorite solutions is thermodynamically possible.

In [40], a method for extraction of noble metals by leaching with in hypochlorite-chloride solutions was suggested. A solution containing >3% NaCl and <0.3% NaClO at pH 5–8 was recommended. However, hypochlorites exhibit in this pH range the minimum redox potential. Therefore, the influence exerted by the pH value (*x* moles of HCl) on the rate of gold dissolution in a wide range of acidities was studied. Figure 7 (curve *1*) shows the rate of gold dissolution in a hypochlorite-chloride (6% NaClO + 4.7% NaCl) solution in the course of 5 min. It can be seen that the rate of gold dissolution at low pH is as high as 6.0×10^{-3} g cm^{-2} min^{-1}. At higher pH, the rate of gold dissolution decreases and passes through a minimum at pH –1. Then, as the pH increases, the dissolution rate gradually becomes higher and passes through a maximum (1.54×10^{-3} g cm^{-2} min^{-1}) at pH –0.2. As the pH value increases further, the rate of gold dissolution gradually decreases to the minimum value of $(1.1–1.2) \times 10^{-4}$ g cm^{-2} min^{-1} at pH 9–12. At pH 12.5–14.5, the rate of gold dissolution again increases at reaches a maximum of 5.6×10^{-4} g cm^{-2} min^{-1} at pH 13.5.

The rate of gold dissolution in hypochlorite solutions substantially exceeds that in alkaline cyanide solutions (Fig. 7, curve *2*) [41]. The latter depends on the concentration of oxygen in the system under study. It has been established that the dissolution rate of gold, v_{Au}, at an oxygen concentration of 11.0, 21.0, and 99.0% in the oxygen–nitrogen mixture and a solution pH > 10.5 is 1.67×10^{-5}, 3.2×10^{-5}, and 1.3×10^{-4} g cm^{-2} min^{-1}, respectively.

The dissolution rate of gold linearly depends on the concentration of NaClO. The curves describing the dependence in the v_{Au}–[NaClO] coordinates at different pH values intersect at a single point on the ordinate axis, forming a fan. They are described by a linear equation that gives, depending on the solution pH, certain values of the slope ratio:

$$v_{Au} = –0.12 + \Psi[NaClO], \quad (27)$$

where Ψ are the slope ratios for hypochlorite solutions with pH 1.06, 4.15, and 6.65, equal to 0.267, 0.1067, and 0.025 g cm^{-2} min^{-1} mol^{-1}, respectively.

These data indicate that, as the solution pH increases from 1.06 to 6.65, the slope ratio decreases by more than an order of magnitude. At NaClO and NaCl content in solution equal to 6.0 and 4.7%, respectively, and the solution pH decreasing from 6.65 to 1.06, the dissolution rate of gold increases by a factor of 26.7. The dissolution rates of gold, v_{Au}, in solutions of TC and hypochlorite are compared in Fig. 5a. It can be seen that, in a hypochlorite solution containing 5.0% NaClO, 3.8% NaCl, and 0.1 M of HCl (at pH 1.08–1.12 and temperature of 298 K) (Fig. 5a, curve *3*) at τ = 20 and 40 min, v_{Au} is 2.2 and 6.3 times, respectively, lower than that in a thiocarbamide solution (Fig. 5a, curve *2*, solution composition is given above). The decrease in the dissolution rate of gold in hypochlorite solutions is due, as demonstrated below, to inhibition of the reaction surface of gold by reaction products.

In hypochlorite solutions, the surface has a positive potential at E_{PZC}. Therefore, hypochlorite ions are adsorbed on the surface of gold (hypochlorite ion adsorbed on an active center captures no less than two atoms of gold) and enter into a redox interaction with surface atoms of gold in accordance with the equations

$$Au^0 + HClO = AuClO^-_{ads} + H^+, \quad (28)$$

$$AuClO^-_{ads} \rightarrow AuCl^*O^-_{ads}, \quad (29)$$

$$AuCl^*O^-_{ads} + Au^0 + H_2O \rightarrow AuCl(OH)^- + AuOH \quad (30)$$

to give an intermediate, $AuCl^*O^-_{ads}$, with a zero charge of the chlorine atom ($Cl^* = Cl^0$) as a result of successive transfers of an electron in ionization of the first atom of gold to the positively charged atom of chlorine [by Eq. (29)], and then in ionization of the second atom of gold and addition of the electron to a neutral atom of chlorine (Cl^*) by Eq. (30). At high concentrations of ligands (e.g., chloride ions from NaCl, HCl) in solutions, negatively charged complex ions $AuCl^-_2$, $Au(OH)^-_2$, $AuCl(OH)^-$ are formed in accordance with the equations

$$AuCl^*O^-_{ads} + Au^0 + HCl \rightarrow AuCl + AuCl(OH)^-, \quad (31)$$

$$AuCl^*O^-_{ads} + Au^0 + 2HCl \rightarrow AuCl^-_2 + AuCl + H_2O, \quad (32)$$

$$AuCl^*O^-_{ads} + Au^0 + NaCl + H_2O \rightarrow AuCl^-_2 + AuOH + NaOH, \quad (33)$$

$$AuCl^*O^-_{ads} + Au^0 + Cl^- + H_2O \rightarrow AuCl^-_2 + Au(OH)^-_2. \quad (34)$$

These ions are adsorbed on the positively charged surface of gold and form adsorption layers. This makes lower the dissolution rate because of the inhibition of the surface. Gold monochloride AuCl is poorly soluble in aqueous solutions. Its solubility product SP_{AuCl} for water is 1.8×10^{-12} [44, 45]. Hence, the calculated concentration of gold(I) in a saturated aqueous solution is 1.34×10^{-6} m. [0.26 mg of Au(I) per liter]. In an excess amount of chlorides, AuCl forms a complex $AuCl^-_2$, which has a higher solubility than gold monochloride. In the hypochlorite-chloride solutions we studied, the concentration of NaCl was close to 1 M. Apparently, complexation of gold monochloride with the chloride ions of the hypochlorite-chloride solution resulted in that the concentration of gold(I) in the leaching solution was, as can be seen in Fig. 5b (curve *8*), 35.3 mg Au per liter.

The rate constants $k_{AuCl^-_2}$ of gold dissolution in a hypochlorite-chloride solution (5.3% NaClO + 0.1 M HCl + 4.06% NaCl) at 277, 289, and 304 K, calculated from the experimental data obtained, are 0.0790, 0.2695, and 0.4030 s^{-1}, respectively. The rate constant of gold dissolution in alkaline cyanide solutions to give complex ions $[Au(CN)_2]^-$, is lower than k_{Au} $AuCl^-_2$ at 304 K by a factor of 1.73×10^6 (k_{Au} $[AuCN]^-_2 = 2.33 \times 10^{-7}$ s^{-1} at 298 K). The activation energy E_A, calculated from the temperature dependence (277–304 K) of the rate constants obtained, $\log k_{Au}$–$1/T$, is 53.43 kJ mol^{-1}. This value of E_A indicates that the rate of gold dissolution in a hypochlorite-chloride solution is kinetically controlled. It is possible to overcome the kinetic limitations by raising the temperature and the concentration of chlorides in the hypochlorite solution and by eliminating the diffusion hindrance to delivery of the reagents to gold. In addition, the deceleration of gold dissolution by the hypochlorite solution because of the formation of adsorption layers composed of reaction products can be prevented if the process is carried out at low pH of the chloride-containing solutions.

Bromine-bromides. Gold(I, III) forms with bromide ions binary (AuBr, $AuBr_3$) and complex compounds ($M[AuBr_2]$, $M[AuBr_4]$). In aqueous solutions, gold(I) bromide disproportionates by the reaction

$$3AuBr^-_2 = 2Au + AuBr^-_4 + 2Br^-. \quad (35)$$

The equilibrium constant of the disproportionation (DPP) reaction is given by

$$K_{DPP} = [AuBr^-_4] \cdot [Br^-]^2/[AuBr^-_2]^3 \quad (36)$$

at an ionic strength $\mu = 1.0$ is $(6.5–8.1) \times 10^4$ (298 K) [45, 46] and 1.4×10^4 (323 K) [46]. The equilibrium constant of the reverse reaction, reaction of coproportionation, $K_{CPP} = 1/K_{DPP} = 1.54 \times 10^{-3}$ (298 K) [47].

The disproportionation of $AuBr^-_2$ is accompanied by changes in the Gibbs free energy, $\Delta G^0 = -28.87$ kJ mol^{-1}, enthalpy, $\Delta H = -61.1$ kJ mol^{-1} [46], and entropy, $\Delta S^0 = -90.79$ J mol^{-1} K^{-1}. The solubility products for AuBr and $AuBr_3$ for water are 5.0×10^{-17} and 4.0×10^{-36}, respectively. According to [48], the solubility product of gold(I) monobromide, $SP_{AuBr} = 7.9 \times 10^{-16}$, and the stability constant of $AuBr^-_2$, $\beta_2 = 1.3 \times 10^{15}$. In bromide solutions, gold ions form planar-square complexes $[AuBr_4]^-$ with a stability constant $K_{1-4} = 3.16 \times 10^{31}$. The standard potentials of half-reactions

$$AuBr^-_4 + 2e = AuBr^-_2 + 2Br^-, \quad E^0 = 0.820 \text{ V}, \quad (37)$$

$$AuBr^-_4 + 3e = Au + 4Br^-, \quad E^0 = 0.854 \text{ V} \quad (38)$$

are more negative than those for the chloride systems. This set of properties indicates that the process of gold extraction with bromine is more favorable than that with chlorine. The solubility of bromine in water is 35 g l^{-1} ($\log[Br_{2(hydr)}] = -0.643$). In solutions with a low concentration of bromides, bromine is present in the form of hydrated particles. In solutions of bromides, iodides, and chlorides, the solubility of bromine increases because of the formation of tribromide ions Br_3^- [49]

$$Br_2 + Br^- = Br_3^- \quad (39)$$

and interhalide compounds BrCl, $BrCl_2$, IBr_2^- [50, 51]. The Br_3^- ions predominate only in solutions with a concentration of bromide ions exceeding 0.89 M. The equilibrium constant of reaction (39) is K_{eq} = 16.3. At higher concentrations of bromides, pentabromide ions Br_5^- are formed

$$2Br_2 + Br^- = Br_5^- \quad (40)$$

with an equilibrium constant K_{eq} = 27.5 [42, 49].

The potential of the half-reaction

$$Br_2 + 2e = 2Br^- \quad (41)$$

is described by the equation

$$E_{41} = 1.0066 + (2.303RT/2F)\log[Br_2] - (2.303RT/F)\log[Br^-]. \quad (42)$$

It should be noted that the Br_3^- and Br_5^- ions can be formed in electrolysis in bromide electrochemical systems

$$3Br^- = Br_3^- + 2e, \quad (43)$$

$$5Br^- = Br_5^- + 4e. \quad (44)$$

The potential of reaction (43) under equilibrium conditions can be represented as

$$E_{43} = 1.0162 + (2.303RT/2F)\log[Br_3^-] - 3(2.303RT/2F)\log[Br^-], \quad (45)$$

and the standard potential of reaction (44) is 1.068 V (relative to a standard hydrogen electrode) [15]. The potential of the half-reaction involving the interhalide compound BrCl (Table 2) is 1.20 V. In water, molecules of bromine undergo a disproportionation reaction

$$Br_2 + H_2O = HBrO + Br^- + H^+ \quad (46)$$

with an equilibrium constant described by the equation

$$\log\{[HBrO][Br^-]/[Br_2]\} = pH - 8.17, \quad (47)$$

and the potential of the redox reaction

$$HBrO + H^+ + 2e = Br^- + H_2O \quad (48)$$

conforms to the equation

$$E_{48} = 1.331 + (2.303RT/2F)\log\{[HBrO^-]/[Br^-]\} - (2.303RT/F)[pH]. \quad (49)$$

Bromides and tribromides are readily oxidized in electrolysis to bromate ions [42, 43]

$$Br^- + 3H_2O = BrO_3^- + 6H^+ + 6e, \quad (50)$$

$$E_{50} = 1.4116 + (2.303RT/6F)\log\{[BrO_3^-]/[Br^-]\} - 6(2.303RT/6F)[pH], \quad (51)$$

$$Br_3^- + 9H_2O = 3BrO_3^- + 18H^+ + 16e, \quad (52)$$

$$E_{52} = 1.4523 + 3(2.303RT/16F)\log[BrO_3^-] - (2.303RT/16F)\log[Br_3^-] - 18(2.303RT/16F)[pH]. \quad (53)$$

Comparison of the standard potentials of the electrode half-reactions of gold in bromide solutions

$$AuBr_2^- + e \rightleftarrows Au + 2Br^-, \quad E^0 = 0.959\ V, \quad (54)$$

$$E_{54} = 0.959 + (2.303RT/F)\log[AuBr_2^-] - 2(2.303RT/F)\log[Br^-], \quad (55)$$

$$AuBr_4^- + 3e \rightleftarrows Au + 4Br^-, \quad (56)$$

$$E_{56} = 0.854 + (2.303RT/3F)\log[AuBr_2^-] - 4(2.303RT/3F)\log[Br^-] \quad (57)$$

with the standard potentials of redox reactions of bromine and its derivatives, (43), 50, and (52), shows that the difference of the standard potential (V) at n = 1 is $\Delta E_{(43)-(54)}$ = 0.0572, $\Delta E_{(50)-(54)}$ = 0.4526, $\Delta E_{(52)-(54)}$ = 0.4933. The difference of the potentials of half-reactions of the interhalide compound BrCl ($E^0_{BrCl/Br^-,\,Cl^-}$ = 1.20 V, Table 2) and of half-reaction (54) is ΔE = 0.241 V. The difference of the standard potentials of the half-reactions at n = 3 is $\Delta E_{(43)-(56)}$ = 0.1622, $\Delta E_{(50)-(56)}$ = 0.5576, $\Delta E_{(52)-(56)}$ = 0.5983. The equilibrium constants of the reactions considered are as follows: at n = 1: $K_{p(43)-(54)}$ = 9.28, $K_{p(50)-(54)}$ =

4.55×10^7, $K_{p(52)–(54)} = 2.22 \times 10^8$, $K_{p(BrCl)–(54)} = 1.22 \times 10^4$, and at $n = 3$: $K_{p(43)–(56)} = 1.7 \times 10^8$, $K_{p(50)–(56)} = 2.02 \times 10^{28}$, $K_{p(52)–(56)} = 2.35 \times 10^{30}$. Consequently, the pathways of the reactions of bromate ions with elementary gold are preferable in bromide solutions. The data obtained suggest that the HL of gold with bromide solutions that are continuously renewed by means of cyclic electrochemical oxidation of bromide ions in the circulating leaching solutions (in flow-through electrolyzers of special design) to molecular bromine Br_2, with the accompanying reactions of formation of tribromide (Br_3^-) and hypobromite ions (BrO^-), can ensure a complete recovery of gold even from a sulfide-containing ore. Commonly, the ore sulfur is removed in processing of sulfide-containing ores prior to recovery of gold by leaching by means of calcination [52, 53], oxidation under elevated pressure of oxygen [54, 55], or by bio-oxidation [56, 57]. The author of [58] suggested a two-stage technology for extraction of gold by bromine leaching. In the first stage, molecular bromine is synthesized in an acid medium with the use of pyrolusite by the reaction

$$2MBr + MnO_2 + 2H_2SO_4 = Br_2 + MnSO_4 + M_2SO_4 + 2H_2O, \quad (58)$$

where M = Na, K.

The standard potential of the redox system MnO_2 : $MnSO_4$ is 1.23 V, and that of the system Br_2/Br^-, 1.0066 V. The potentials of sulfides are, as a rule, negative, e.g. (V, relative to a standard hydrogen electrode): $E_{PtS_2/S^{2-}} = –0.64$, $E_{Ag_2S/S^{2-}} = –0.66$, $E_{HgS/S^{2-}} = –0.70$, $E_{CuS/S^{2-}} = –0.76$, $E_{PbS/S^{2-}} = –0.93$, $E_{FeS_2/S^{2-}} = –0.95$, $E_{CoS/S^{2-}} = –1.07$, etc. Therefore, sulfides are readily oxidized by molecular bromine, e.g., by the reactions

$$3Br_2 + 2FeS_2 = 2FeBr_3 + 4S^0, \quad (59)$$

$$Br_2 + MS = MBr_2 + 2S^0, \quad (60)$$

where M = Hg, Cu, Cd, Pb, Sn, Co, Ni, etc.

The bromide ions formed by reactions (59) and (60) are again oxidized by pyrolusite by reaction (58) to free bromine. The oxidation of the sulfides frees gold and makes the ore porous and permeable to reagents. Therefore, molecular bromine oxidizes gold to gold bromides by Eqs. (37), (38), (54), and (61):

$$2Au + 3Br_2 + 2Br^- \rightarrow 2AuBr_4^-. \quad (61)$$

Experiments have shown that the recovery of gold by the standard cyanide procedure is 56.8%, whereas that in the presence of potassium bromide and pyrolusite is 83.4% at a lower expenditure of reagents [58–61]. A higher efficiency of extraction of gold by leaching from ores has been achieved in a two-stage process that includes calcination of sulfide- and carbon-containing gold-rich ores and leaching of the resulting cake with bromine-containing (Br_3^-, Br_2, HBrO, NaBr) solutions [59]. In this case, the tribromide ion was synthesized by the following reactions:

$$NaBr + Br_2 = NaBr_3, \quad (62)$$

$$CaBr_2 + 2Br_2 = Ca(Br_3)_2. \quad (63)$$

Reactions (62) and (63) are reversible. For fast bromine-bromide leaching, it is suggested to prepare two types of concentrates. The first type, concentrate of tribromide ions is prepared from NaBr (or $CaBr_2$) and Br_2, Commonly, concentrate I contains (wt %): $NaBr_3$ 63–64, Br_2 20.5, and free NaBr 3.0–10.5. In concentrate I, molecular bromine partly undergoes disproportionation (46) to give hypobromous acid HBrO.

The content of hypobromite ions BrO^- in the concentrate was approximately 2–6%. A higher oxidizing capacity with respect to gold is exhibited by the bromate ion, which is formed in alkaline solutions in accordance with the equation

$$3Br_2 + 6OH^- = BrO_3^- + 5Br^- + 3H_2O \quad (64)$$

[compare with Eq. (53) in acid solutions]. Therefore, concentrate of type II, a hypobromite solution based on NaBr, Br_2, and NaOH (10–20%), is specially prepared. The concentrate contains 5–8% sodium hypobromite. Table 3 lists the contents of $NaBr_3$, Br_2, NaBrO,and NaBr in the tribromide (type I) and hypobromite (type II) concentrates.

In preparing a leaching solution, one part of a hypobromite solution was taken per four parts of a tribromide solution, and vice versa. Irrespective of the relative amounts in which type-I and -II concentrates are taken, the pH value of the "resulting" solution should be in the range 6.5–7.5. Table 3 also lists the equivalent concentrations of molecular bromine (ECMB), determined in molar units as a sum of the actual molar concentrations of bromine and tribromide ions, tripled molar concentration of the bromate ions, and concentrations of hypobromite ions and hypobromous acid (HBrO).

Table 3. Composition and properties of leaching solutions obtained at different relative amounts of the tribromide and hypobromite concentrates

Relative amounts of the concentrates, wt fraction		Content, wt %				Density, g cm^{-3}	pH	Content, wt %
I	II	$NaBr_3$	Br_2	$NaBrO_3$	NaBr			
1.0	0	63.64	4.28	–	2.76	2.029	1.0	Not determined
0.8	0.2	50.91	3.42	1.58	7.55	1.826	5.6	39.4
0.5	0.5	31.82	2.14	3.94	14.80	1.612	6.7	34.0
0.2	0.8	12.73	0.86	6.01	22.02	1.444	7.2	28.6
0	1.0	–	–	7.87	26.83	1.345	8.0	Not determined

In [59], a set of experiments on leaching of ores that are rich in gold (265–212 g ton^{-1}) and silver (190–205 g ton^{-1}) or poor in the same elements (5.5 and 61.9 g of Au and Ag, respectively, per ton) was described. Prior to leaching, the ores were calcined in a rotating (5 rpm) tubular furnace at a temperature of 650°C for 120 min in order to remove the sulfide sulfur (15.5 wt %) and carbon (12.5 wt %). The content of the sulfide sulfur in the calcined concentrate was 0.7%. The concentrates were used to prepare a leaching solution that contained type-I and -II concentrates in various relative amounts listed in Table 3. The concentrates taken in any relative amounts were diluted to a concentrate concentration of 2.0 to 6.0 g l^{-1} at pH 5–6. The time of leaching was 6 h. The recovery of gold was in the range from 94 to 96.3%, and that of silver exceeded 50%.

It should be noted that a specific feature of tribromide and bromate concentrates is that they have a lower pressure of bromine vapor, compared with molecular bromine. The concentrate containing about 34% ECMB has a total vapor pressure of only 23 mm Hg at 0°C and 112.5 mm Hg at 35°C. The vapor pressure of liquid bromine is 75 and 214 mm Hg at 0 and 35°C, respectively. Therefore, the concentrates can be used to prepare leaching solutions. The authors of [60] suggested, in order to lower the vapor pressure of bromine in extraction of gold from ores, a leaching solution that contains oxidizing agents: $FeCl_3$, H_2O_2, and NaClO. Investigations demonstrated that the dissolution rate of gold in a solutions containing bromides, $FeCl_3$, H_2O_2, and NaClO exceeds severalfold that in cyanide solutions.

Iodine-iodides. Gold(I, III) also forms with iodide ions binary (AuI, AuI_3) and complex compounds ($M[AuI_2]$, $M[AuI_4]$). The solubility product of gold(I) iodide AuI and gold(III) triiodide AuI_3 in water is 1.6×10^{-23} and 1×10^{-46}, respectively.

According to [48], the solubility product of gold(I) iodide, $SP_{AuI} = 4.0 \times 10^{-23}$, and the stability constant of AuI_2^-, $\beta_2 = 3.2 \times 10^{21}$. Gold(I) iodide is virtually insoluble in aqueous solutions (1.23×10^{-14} g of AuI per liter), and, therefore, it does not disproportionate when in solid state [15]. Upon introduction of potassium iodide (iodide ion) into a solution, the solubility of AuI increases because of the formation of a complex ion, AuI_2^-:

$$AuI + I^- = AuI_2^-. \quad (65)$$

The solubility of molecular iodine (I_2) in water is 0.3 g l^{-1}. The equilibrium constant of the reaction of disproportionation of molecular iodine in water

$$I_2 + H_2O = I^- + H^+ + HIO \quad (66)$$

has a small value $K_{DPP} = 5.32 \times 10^{-13}$ [60]. The solubility of iodine in aqueous solutions of KI and NaI increases manyfold because of the formation of the triiodide ion (I_3^-) or higher-molecular-weight polyiodides. The equilibrium constant of the reaction of formation of the triiodide ion

$$I_2 + I^- \rightleftarrows I_3^-, \quad (67)$$

equal to $K_{eq} = 697.9$, indicates that the equilibrium of the reaction is strongly shifted to the right. Iodide ions are more readily oxidized, compared with bromide ions:

$$3I^- = I_3^- + 2e, \quad (68)$$

$$E_{69} = 0.5364 + (2.303RT/2F)\log[I_3^-] - 3(2.303RT/2F)\log[I^-], \quad (69)$$

and the triiodide ion, to molecular iodine and iodate ions:

$$2I_3^- = 3I_2 + 2e, \quad (70)$$

$$E_{71} = 0.7892 + 3(2.303RT/2F)\log[I_2] - (2.303RT/F)\log[I_3^-], \quad (71)$$

$$I_3^- + 9H_2O \rightleftarrows IO_3^- + 18H^+ + 16e, \quad (72)$$

$$E_{73} = 1.1539 + 3(2.303RT/16F)\log[IO_3^-] - (2.303RT/16F)\log[I_3^-] - 18(2.303RT/16F)\text{pH}. \quad (73)$$

No oxidation of molecular iodine to iodic acid HIO_3 and iodate ion IO_3^- occurs in electrolysis in aqueous solutions, because the standard potentials of these reactions (E^0 = 2.9226 and 2.9454 V) are considerably more positive than that of the oxygen electrode (E^0 = 1.229 V). Therefore, evolution of oxygen from water at the anode is the preferable reaction.

As can be seen in Table 1, the standard potentials of the half-reactions of gold in iodide solutions are as follows (V): $E^0_{AuI/Au}$ = 0.530, $E^0_{AuI_2^-/Au}$ = 0.578, $E^0_{AuI_4^-/Au}$ = 0.550, $E^0_{AuI_4^-/Au}$ = 0.560 [14, 15]. The standard potentials of the oxidizing agents based on iodine are listed in Table 2 (V): $E^0_{I_2/I^-}$ = 0.535, $E^0_{I_3^-/I^-}$ = 0.536, $E^0_{I_2(aq)/I^-}$ = 0.621, $E^0_{I_2/I_3^-}$ = 0.789 [14, 15]. It can be seen that the most positive potential is observed for the system I_2/I_3^-. In this case, the difference of the standard potentials of the half-reactions of gold(I)

$$AuI_2^- + e = Au + 2I^-, \quad E^0 = 0.578 \text{ V}, \quad (74)$$

$$E_{75} = 0.578 + (2.303RT/F)\log[AuI_2^-] - 2(2.303RT/F)\log[I^-] \quad (75)$$

and that of formation of triiodide ions by reaction (68), $E^0_{I_2/I_3^-}$ = 0.789 V, is ΔE^0 = 0.211 V. Therefore, the following reaction is the best acceptable for dissolution of gold with triiodide ions as an oxidizing agent:

$$2Au + I_3^- + I^- = 2AuI_2^-. \quad (76)$$

The equilibrium constant of reaction (78) is $K_{eq} = 3.7 \times 10^3$. This indicates that gold can be extracted from ores with iodine-iodide solutions.

The standard potentials of the electrode reactions of gold in iodide electrolytes [14, 15]

$$AuI_4^- + 2e = AuI_2^- + 2I^-, \quad (77)$$

$$AuI_4^- + 3e = Au + 4I^- \quad (78)$$

are more negative than the potentials of gold in chloride and bromide solutions (Table 1). The dependence of the potentials on the concentrations of iodide and gold(III) ions in solution are described by the following equations [42, 43]:

$$E_{80} = 0.560 + (2.303RT/3F)\log[AuI_4^-] - 4(2.303RT/3F)\log[I^-]. \quad (79)$$

Analysis and comparison of the standard redox potentials of iodide systems and the potentials of gold show that the difference of the standard potentials in the case when triiodide ions are in equilibrium with iodide ions is close to zero. In the case when iodate ions are in equilibrium with triiodide ions in the system, the difference of the standard potentials of the reactions will be 0.5759 and 0.5939 V, respectively. The equilibrium constants of the overall reactions

$$5Au + 2IO_3^- + 12H^+ + 11I^- = 5AuI_2^- + I_3^- + 6H_2O, \quad (80)$$

$$10Au + 6IO_3^- + 36H^+ + 37I^- = 10AuI_4^- + I_3^- + 18H_2O \quad (81)$$

of dissolution of gold to give gold ions AuI_2^- and AuI_4^- in oxidation by iodate ions will be 5.4×10^9 and 1.3×10^{30}, respectively. Consequently, reactions of interaction of iodate ions with elementary gold are also preferable in iodide solutions. In this case, the electrochemical oxidation of triiodide ions to iodate ions in solutions will also favor a more complete recovery of gold from ores and gold-containing raw materials [61–63]. Thermodynamic analysis shows that a necessary condition in dissolution of gold with the use of elementary iodine is the presence of iodide ions, and especially iodide and chloride ions together, in solutions. Systems based on iodine and chlorine, which form interhalide compounds, have more positive potentials than the systems Au/Br_n and Au/I_n. Iodine-chlorine interhalide compounds are particularly promising for development of reagent solutions with a high reactivity toward gold and platinum metals.

The authors of this review used for extraction of gold from ores of the Muzhikhoevskoe deposit an iodine-iodide solution containing ($g\,l^{-1}$) 200 KI, 14 I_2, 5 KOH, and also some other depressants of dissolution of heavy metals and metals of the iron group. The results obtained are shown in Fig. 5b (curves *2*, *3*). It can be seen that the concentration of gold(I) increases as the solution pH decreases.

Copper-thiosulfate solutions. The standard potential of the half-reaction of gold in a thiosulfate solution:

$$Au(S_2O_3)_2^{3-} + e = Au + 2S_2O_3^{2-} \quad (82)$$

is 0.153 V [14]. In Eq. (82), the thiosulfate ion acts as a ligand. The standard potentials of the half-reactions of thiosulfate depend on the final product, which may be HS^-, H_2S, S^0, or S_5^{2-} [14, 15]:

$$S_2O_3^{2-} + 6H^+ + 8e = 2S^{2-} + 3H_2O, \quad E^0 = -0.006 \text{ V}; \quad (83)$$

$$S_2O_3^{2-} + 8H^+ + 8e = 2HS^- + 3H_2O, \quad E^0 = 0.200 \text{ V}; \quad (84)$$

$$5S_2O_3^{2-} + 30H^+ + 24e = 2S_5^{2-} + 15H_2O, \; E^0 = 0.331 \text{ V}; \quad (85)$$

$$S_2O_3^{2-} + 6H^+ + 4e = 2S + 3H_2O, \quad E^0 = 0.465 \text{ V}; \quad (86)$$

$$K_2S_2O_3 + 6H^+ + 4e = 2K^+ + 2S + 3H_2O, \quad E^0 = 0.452 \text{ V}; \quad (87)$$

$$Na_2S_2O_3 + 6H^+ + 4e = 2Na^+ + 2S + 3H_2O, \quad E^0 = 0.455 \text{ V}. \quad (88)$$

It can be seen from the data presented that certain thiosulfate-containing solutions behave as oxidizing agents with respect to gold. The most positive potential is observed for the redox system represented by Eq. (86). As oxidizing agent can be used copper(II) sulfate ($CuSO_4 \cdot 5H_2O$) and rhodanide. The potential of the half-reaction of copper

$$Cu^{2+} + SCN^- + e = CuSCN \quad (89)$$

is 0.96 V [14]. A study of the kinetics of leaching of gold and silver at pH 10 with ammonium-thiosulfate solutions containing $CuSO_4$ as an oxidizing agent demonstrated that the rate of silver dissolution is controlled by diffusion, and that of gold, kinetically [64].

As already noted, the efficiency of the HL of gold from stubborn sulfide-carbon and carbon gold-containing ores by cyanide leaching is, as a rule, very low. Commonly, the sulfide sulfur and carbon are removed in processing of these ores, prior to recovery of gold by leaching, by calcination [52, 53], treatment with nitric acid, or bio-oxidation [56, 57, 65]. Use of ammonium-thiosulfate solutions as leaching solvents markedly facilitates the HL processing of stubborn sulfide-carbon and carbon gold-containing ores [65, 66].

As a thiosulfate leaching solution is commonly used a mixture containing preferably 15 to 30 g l^{-1} of $(NH_4)_2S_2O_3$ and 8–16 g l^{-1} $CuSO_4$ or $Na_2S_2O_3$ + $CuSO_4$ (pH 9.2–10.0). It is believed that ammonium ions and ammonium thiosulfate stabilize copper(II), which acts as an oxidizing agent in accordance with the equation

$$2Au + (NH_4)_2S_2O_3 + 2CuSO_4 = Au_2SO_4 + Cu_2S_2O_3 + (NH_4)_2SO_4, \quad (90)$$

and also catalyze the reaction of dissolution of gold in the presence of oxygen

$$2Au + (NH_4)_2S_2O_3 + H_2O + 1/2\,O_2 = Au_2S_2O_3 + 2NH_4OH. \quad (91)$$

In the HL method, the thiosulfate leaching solution is used in a closed cycle [65–67]. A side reaction in extraction of gold is oxidation of thiosulfate by Cu(II) or dissolved oxygen to give ammonium tetrathionate $(NH_4)_2S_4O_6$ and trithionate $(NH_4)_2S_3O_6$. To improve the cost efficiency of the process of gold leaching, the reactions in which tetra- and trithionate are formed are commonly suppressed to the maximum possible extent [68]. After the thiosulfate leaching solution is saturated with gold, the solution, or its part, is continuously reduced, preferably by cementation, in a special device. Spent leaching solutions are regenerated by addition of sulfur or soluble sulfides [65, 67].

The authors of this review used for extraction of gold from ores of the Muzhikhoevskoe deposit a copper-containing solution of the following composition (g l^{-1}): $Na_2S_3O_3 \cdot 5H_2O$ 74, $CuSO_4 \cdot 5H_2O$ 12, $(NH_4)_2SO_4$ 100, NH_4OH 100 or 50 ml of a 25% ammonia solution per liter of the resulting solution. The results obtained are shown in Fig. 6b (curve *4*). It can be seen that copper-thiosulfate solutions are effective oxidizing agents for gold. In [69], to make lower the expenditure for extraction of gold by thiosulfate leaching, sodium thiosulfate was synthesized from the gold-containing sulfide ore itself by adding elementary sulfur to the raw material, sulfide ore. Such a method lowers the cost of leaching with thiosulfate solutions and makes this process competitive with that based on cyanides, which are, undoubtedly, more toxic by themselves [61–64, 67, 70, 71]. In [61–64, 67–69, 72–75], it was suggested to use bromine-bromide, iodine-iodide, and copper thiosulfate solutions for extraction of gold and silver directly from gold- and silver-containing sulfide ores.

On the whole, thiocarbamide, hypochlorite, and bromine-bromide solutions, as well as iodine-iodide solutions, are rather promising for extraction of gold from ores by leaching. Under natural conditions, these solvents spontaneously undergo conversion into harmless compounds: urea, ammonium sulfate, and halide salts.

Use of thiocarbamide, hypochlorite and halogen-halide solutions, which, in our opinion fully comply with the main requirement to the industry of the XXI century, "make no harm to the ecology," can not only raise the labor productivity in gold mining, but also eliminate the problem of environment contamination.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Willemite by Modified Sol–Gel Technique

A. G. Golovkin, F. F.Grekov, and B. V. Chernovets

State Polytechnic University, St. Petersburg, Russia

Received July 9, 2004

Abstract—Silicate luminophor Zn_2SiO_4 : Mn was synthesized using silica gel as an active form of silicon dioxide. Factors affecting the degree of crystallinity of the silicate obtained were studied. Willemite was doped with manganese(II) in the course of synthesis. The luminescence parameters of the resulting samples were estimated.

The synthesis of luminophors for various applications and the improvement of their working parameters constitute one of the most topical problems of the technology of functional materials.

Doped willemite Zn_2SiO_4 : Mn is one of the first photo-, cathodo-, and X-ray-luminophors. It has been extensively studied with the aim to elucidate the fundamental physical aspects of luminescence and to study the effect of conditions of luminophor formation on the intensity and spectral parameters of luminescence.

Although Zn_2SiO_4 exists in three modifications, α-Zn_2SiO_4 (rhombohedral structure of *R*3 space group) is usually formed under ordinary conditions. Luminophors based on zinc silicate are described in [1–5]. Willemite doped with manganese(II), which replaces Zn(II) in amounts of 0.5–5 wt %, emits light in the green spectral range. Industrial photoluminophors FL-530, FGI-520-1, FGI-528-1, and cathodoluminophors K-35, K-36, K-60, and KV-520-2 have been developed on its basis. To obtain a luminophor with orange-red luminescence, zinc silicate doped with Mn(II) should be formed in the presence of small amounts of beryllium and cadmium silicates, which are isomorphous to willemite [4]. Recently, willemite doped with rare-earth elements has been under investigation [6, 7].

Usually, doped willemite is synthesized by the solid-phase technique, by sintering a mixture of the appropriate oxides with silica at a temperature of about 1350°C for tens of hours [8]. It has been shown [4] that the degree of dispersion of the starting mixture strongly affects the reaction kinetics. This technique produces high-quality luminophors, being, however, rather power-consuming and sensitive to the difficultly controllable stock preparation process.

The crystal perfection of a luminophor governs its luminescence characteristics [1]. In a nonequilibrium (deformed) matrix, many of luminescence centers are involved in nonradiative transitions, which diminishes the quantum efficiency and, accordingly, the intensity of luminescence. The concentration of an activator affects the efficiency both directly (via the number of centers) and indirectly (via the number of structural defects) [4, 5].

Apparently, it is necessary to develop such synthesis methods that would ensure a complete and controlled mixing of components (including dopants) in the preliminary stage and, consequently, an ordering of the forming structure under relatively mild conditions.

The sol–gel technology finds increasing use for synthesis of luminophors. To synthesize doped willemite, oxides are transformed into nitrates. SiO_2 is obtained using a solution of tetraethoxysilane (TES) $(C_2H_5O)_4Si$, which hydrolyzes under heating to give SiO_2. Nitric acid and colloid solutions are mixed in certain proportions, and the mixture is subsequently dehydrated until a jelly-like mass is formed. This mass is dried in a thermostat at 120–140°C and then calcined at 1300°C for 10 h. In the finishing thermal treatment, the formation of the silicate is complete [9, 10].

The coprecipitation method, a modification of the sol–gel technique, is the most advanced. However, as shown by practical experience, this method is extremely sensitive to minute details of the TES hydro-

1070-4272/04/7710-1593 © 2004 MAIK "Nauka/Interperiodica"

lysis (order of component introduction, concentration, temperature, and mixing mode) and, thus, requires further improvement.

In this context, the already obtained active form of silicic acid, specifically, silica-gel, seems to be unappreciated. The chemistry of silica gel was described in detail in the monographs [11–14]. Silica gel in aqueous solutions shows all properties of monosilicic acid, and, consequently, can be regarded as polysilicic acid. At pH > 8, SiO_2 particles pass into solution to form silicate ions.

As is known, different types of silica gel have a wide variety of pore sizes (10–500 Å) and a developed internal surface area. Cations of appropriate sizes readily penetrate into silica gel particles. Heavy-metal ions react with active silica in ammonia solutions to form high-molecular-weight compounds of the type of basic salts. In acid solutions at pH < 6, reactions of metal ions with silica gel yield new functional groups capable of cationic exchange. Adsorption of cations may also occur on dehydrated parts of the silica surface.

The aim of this study was to develop a new method for synthesis of a silicate luminophor and to optimize it with respect to the degree of crystallinity, and also to assess the possibility of doping of the luminophor in the course of synthesis.

The central idea of the approach suggested is to modify the precipitation method (its sol–gel variant) so as to exclude the most difficultly controllable stage of formation of a homogeneous gel of silicic acid.

Partially dehydrated xerogel of silicic acid, with high specific surface area and sorption capacity, was used as an active reagent. Despite that silica gel has a great number of modifications and is widely used as a sorbent, we failed to find any information on its application as a starting reagent for synthesis of silicates in the available literature. This may be due to the fact that silica gel is traditionally regarded as a phase of uncertain composition in the SiO_2–H_2O system. However the amount of SiO_2 in the silica gel composition can be easily determined by gravimetry, and blending with SiO_2 is not difficult. It is convenient to introduce a cation (e.g., zinc or manganese) by saturating silica gel with an appropriate salt, preferably of an organic acid, because the salt should be water-soluble and thermally unstable. The saturation of the xerogel provides a thorough and uniform mixing of the components on the molecular level.

To raise the pH of the solution and to dissolve (partially) the gel, it is expedient to use ammonium hydroxide. At pH > 8, the gel passes into the solution as low-molecular-weight polysilicic acid, $kH_2O \cdot mSiO_2$ (where k and $m < 100$), and the cation precipitated as a hydroxide. This makes it possible to perform the "reverse" process, i.e., to saturate the freshly formed metal hydroxide with micellar particles $mSiO_2 \cdot kH_2O$ from the solution. The possibility of a simultaneous introduction of an activator within such a scheme is apparent.

EXPERIMENTAL

We used silica gel of three brands [GOST (State Standard) 3956–54]: ASK, KSK, and ShSM, differing in porosity and sorption capacity. The reagents were stored for a long time under laboratory conditions at narrowly varying temperature and humidity.

The content of the main substance SiO_2 (wt %) was determined by calcination at 1200°C in a muffle furnace to constant weight: ASK 94.25, KSK 93.2, ShSM 71.8.

It was found in control experiments that the humidity of these sorbents varies within ±0.03 wt % under usual storage conditions, which is comparable with the characteristics of other powders (zinc and manganese oxides) used in the experiments. Silica gel granules were reduced to a powder with particle size of less than 10 μm, using an LDI-65 grinder.

Other reagents (oxides; salts;, acetic, citric, and tartaric acids) were no less than analytically pure.

Weighed samples were prepared on a ZMP analytical balance. The pH values were measured using a standard indicator paper set. Pellets of semi-products were produced in a steel press mold under a pressure of about 21 000 atm. The calcination was carried out in air in an SUOL-0,25.2,5/14K-42 tube furnace at a temperature not exceeding 1250°C. An X-ray phase analysis (XPA) was performed on a TuR M-62 diffractometer with an HZG-4 goniometer with Cr_{K_α} radiation. A qualitative luminescent analysis was carried out on an LYuMAM R1 luminescent microscope (365 nm) and with the use of an LGI-21 (337 nm) nitrogen laser.

Cation-containing solutions were prepared by dissolving weighed samples of ZnO or other metal compounds in an excess amount of acetic, nitric, tartaric, or citric acid. In some experiments, appropriate nitrates were directly used. A weighed sample of silica gel was introduced into a solution, and silica gel was saturated (impregnated) with a cation-containing solution at room or elevated temperature for a specified

time (in some experiments up to several days). Solutions with impregnated gel were dehydrated by evaporation of the suspension in a wide quartz crucible until an air-dry amorphous powder was formed. The powder was calcined with stirring for additional 0.5 h until partial decomposition of thermally unstable salt, which was judged from gas evolution.

Pellets with a mass of about 2 g were produced by compaction without a binder. The pellets were calcined in air in a sinter-corundum container at a specified temperature for 3.5–28 h.

A phase analysis was carried out on the basis of X-ray diffraction patterns of the samples obtained, using the PDF-2 database [15] and the PowderCell for Windows software [16].

To assess the crystal perfection of the samples, we used such a parameter as the "degree of crystallinity." This parameter is not a physical quantity, but shows the extent to which the ideal crystal structure of a substance is attained (or the fraction of the crystalline component in a substance), estimated on the basis of a diffraction pattern. The degree of crystallinity may be approximately determined as [17]:

$$A = \sum_{i=1}^{n} \frac{I_{\text{ref},\,i}}{I_i}.$$

Here A is the degree of crystallinity; $I_{\text{ref},\,i}$, intensity (angular flux density) of a useful reflected signal at ith point; and I_i, intensity (angular flux density) of the total reflected signal at ith point.

All the reflections (X-ray peaks) corresponding to the phase under study were used.

Luminescent properties were examined by the conventional technique [18]. A luminescence spectrum was recorded, and the quantum efficiency was calculated. The quantum efficiency of a sample was determined by comparison with the quantum efficiency of a reference luminophor under the same excitation conditions.

To evaluate the effect of the solution pH on the phase composition and degree of crystallinity of a product synthesized, a series of experiments were carried out. Zinc(II) was added in the form of a freshly prepared acetate solution. Silica gel of ASK brand, taken in an amount necessary for the stoichiometric orthosilicate to be formed, was impregnated for 92 h at room temperature without stirring. A dried compacted mixture was calcined at 1240°C for 24 h. Only one crystalline phase of willemite was found by means of XPA in all the samples. Its lattice parameters somewhat varied between different experiments within the limits slightly exceeding the error of the experiment.

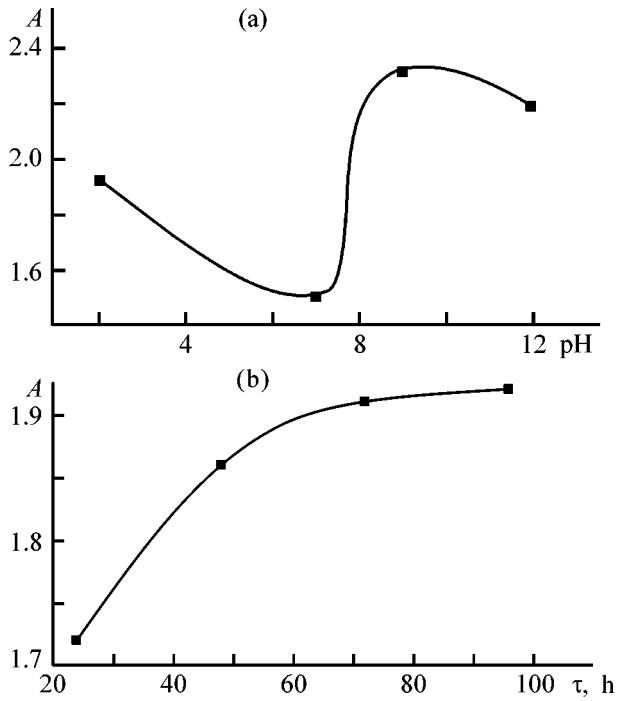

Fig. 1. Degree of crystallinity of willemite, A, vs. (a) pH of $(CH_3COO)_2Zn$ solution and (b) saturation time τ.

The dependence of the degree of crystallinity of willemite on the solution pH is shown in Fig. 1a.

The degree of crystallinity of the product depends on the pH of the impregnating solution of zinc salt nonmonotonically. If the solution is nearly neutral, the resulting product has the minimum degree of crystallinity. This fact is attributable to the saturation (blocking) of the silica gel surface mostly with water molecules. In acid solutions, the results are better because the silica gel surface is saturated with cations to form chemical bonds even at room temperature [13]. The impregnation in alkaline solutions also results in an appreciable tendency toward an increase in the degree of crystallinity of the resulting silicate. In alkaline solutions, the process can yield high-molecular-weight compounds [11] $(Si_2O_5H_2)_{n-p}[Si_2O_5(MOH)_2]_p$ which are close to basic salts, and this also leads to the desired result.

Further, it was of interest to estimate the influence exerted by the duration of saturation on the degree of crystallinity of the resulting Zn_2SiO_4. To avoid the hydrolysis of zinc acetate, the saturation was carried out in an acid medium at pH 2. Other experimental conditions were the same as in the preceding series.

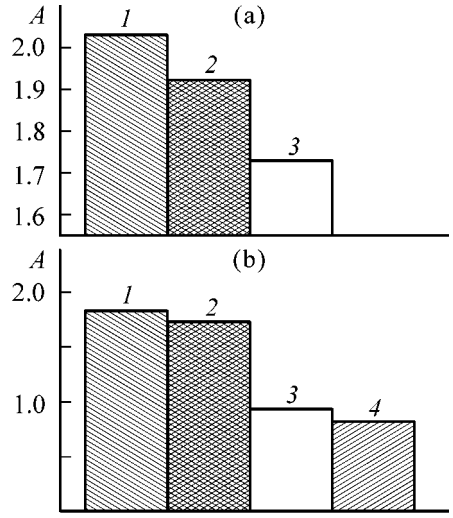

Fig. 2. Effect of (a) type of silica gel and (b) nature of the acid residue on the degree of crystallinity, *A*. Silica gel: (*1*) KSK, (*2*) ASK, (*3*) ShSM. Zinc salt: (*1*) nitrate, (*2*) acetate, (*3*) tartrate, (*4*) citrate.

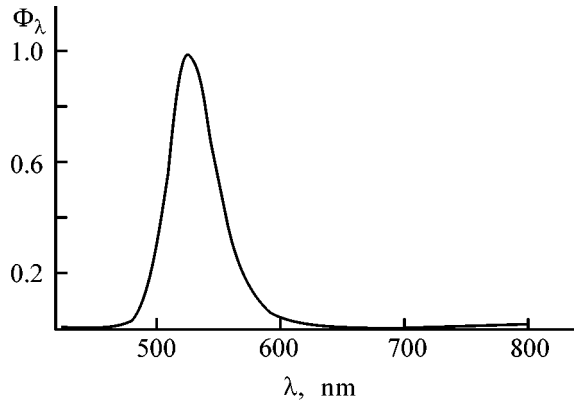

Fig. 3. Luminescence spectrum of Zn_2SiO_4 : Mn (see text). (Φ_λ) Relative intensity of luminescence and (λ) wavelength.

Regardless of the calcination time, only willemite with unchanged lattice parameters (a = 13.74 and c = 9.43 Å) corresponding to the data of [15] was found in the annealed product.

The dependence of the degree of crystallinity of willemite on the duration of saturation of dispersed silica gel is shown in Fig. 1b.

It is apparent that after about 3 days at room temperature the system comes to a steady state, and further increase in the time of treatment hardly affects the result. Similar results were obtained in impregnation with a hot (60–70°C) solution.

The effect of the type of silica gel on the degree of crystallinity of the resulting Zn_2SiO_4 was also studied. The saturation was carried out in an acid solution in the course of 96 h, compacted samples were calcined at 1200°C for 24 h. In all the samples, only a single crystalline phase of willemite was found by XPA. Its lattice parameters varied between the experiments within the limits slightly exceeding the error of the experiment. The results obtained are shown in Fig. 2a in the form of a histogram.

Comparison of the values of A shows that the best results are obtained with KSK and ASK silica gels. Probably, this is associated with the diffusion mechanism of impregnation, which is mainly affected by the sizes and relative volumes of pores. The pore sizes of the KSK and ASK silica gels are comparable (about 300–500 Å), whereas those of the ShSM slica gel are 100–350 Å [14]. Apparently, for a complete and uniform diffusion saturation to be obtained, the size of a solvated cation should be significantly less than that of pores in the silica gel.

The influence exerted by the acid residues of zinc salts on the phase composition of products and the crystallinity of the resulting Zn_2SiO_4 were studied. The impregnation was carried out in acid medium for 48 h, the pellets were calcined at 1200°C for 27 h. When $Zn(NO_3)_2$ and $(CH_3COO)_2Zn$ were used, a single-phase willemite was obtained, whereas the use of zinc tartrate and citrate led to incomplete reactions. In addition to the poorly crystallized willemite, a second phase of ZnO was detected in such samples by XPA.

The effect of the nature of acid residues is shown in Fig. 2b. It follows from the comparison of the values of A that the best results are obtained with $Zn(NO_3)_2$ and $(CH_3COO)_2Zn$. The extent of the reaction and the product quality are strongly impaired if larger anions of tartaric or citric acids are used. This is probably due to the above-mentioned steric hindrances arising upon the impregnation. Despite that the best results are obtained with $Zn(NO_3)_2$, zinc acetate should be preferably used because no toxic oxides are released in its pyrolysis.

Ground ASK silica gel was used to synthesize willemite doped with manganese. Acetate solutions were obtained by separate dissolution of weighed samples of ZnO and Mn_2O_3 in an excess amount of acetic acid. A Mn : Zn atomic ratio of 1 : 99 was obtained in the combined solution (pH ≈ 2). The impregnation and calcination conditions were selected with account of the data presented above. The lattice parameters of the willemite synthesized are as follows: a = 13.94, c = 9.36 Å.

A bright green luminescence which is typical of willemite doped with manganese(II) was observed upon excitation of the crushed product by the 365-nm line (Fig. 3). The relative intensity of luminescence

reaches a maximum at 525 nm. Obviously, manganese(III) is partially reduced in the course of synthesis to be incorporated in the solid solution, statistically occupying lattice sites of zinc(II).

The luminophor synthesized is, as yet, considerably exceeded by industrial specimens in quantum efficiency. The method of synthesis can be additionally optimized, in particular, as regards the purity of the silica gel and also the concentration and initial form of the activator.

CONCLUSIONS

(1) Willemite can be synthesized by a modified sol–gel method with the use of a xerogel of silicic acid as an active form of silica gel and an aqueous solution of a zinc salt (acetate or nitrate).

(2) The solution pH in the initial stage of the synthesis strongly affects the crystallinity of the resulting samples. A primary reaction of amorphous SiO_2 with the salt added seems to occur in acid and alkaline solutions, which leads to a more perfect (equilibrium) structure of the silicate produced by a subsequent calcination.

(3) The degree of crystallinity of the willemite synthesized depends on the size of pores in the starting silica gel and on the nature of acid residues. The primary reaction is facilitated in a macroporous gel and with salts forming compact solvates (nitrate and acetate).

(4) Introduction of manganese(II) in small amounts into the starting solution provides a green luminescence which is typical of a willemite luminophor.

Received April 1, 2004

Abstract—Processes occurring in mechanical activation of pure and mixed La(III), Nd(III), Er(III), Yb(III), and Y(III) oxides in air were studied. The influence exerted by the mechanical activation and by the accompanying absorption of atmospheric carbon dioxide on the selectivity of dissolution of components of mixed oxides in acid treatment were studied.

It has been found previously [1–3] that such stable compounds as silicate minerals of calcium and magnesium undergo deep structural and chemical transformations under a prolonged mechanical treatment. The ability of silicates to absorb significant amounts of CO_2 from the ambient atmosphere in mechanical activation (MA) appeared to be one of the factors responsible for these transformations. Fine grinding in air or in atmosphere of CO_2 leads to a strong saturation of a silicate mineral with carbon dioxide, which "dissolves" in the amorphized mineral, being incorporated into a disordered silicate matrix in the form of carbonate ions. The content of CO_2 in the amorphized samples may be as high as 20–22 wt %. Such considerable changes in the chemical composition and structure of a substance must affect its physicochemical properties. The influence exerted by MA and the accompanying CO_2 absorption on the increase in the reactivity of some minerals toward acids have been studied earlier.

This study is a part of the investigation of the mechanical activation of silicates and composite oxides of varied composition and structure. The aim of the study was to examine processes that occur in mechanical activation of individual and mixed oxides of rare earth elements in air and to analyze the effect of MA on their reactivity.

It is known that, when stored in air, REE oxides absorb in noticeable amounts carbon dioxide and water from the atmosphere to form basic carbonates [4–6]. It is natural to assume that MA of REE oxides would accelerate their reactions with atmospheric moisture and carbon dioxide. As the atomic weight increases in the series of REE, their ionic radii and basic properties decrease owing to lanthanide contraction, and, therefore, we can expect that oxides of light REEs, e.g., lanthanum, will react in the course of MA in air with H_2O and CO_2 to a greater extent than oxides of heavy REEs, e.g., erbium. Therefore, when activated mixed oxides are treated with an acid, the newly formed basic carbonates of REEs must pass into solution before the starting oxides, owing to the removal of CO_2 from the reaction sphere.

In this study, we examined the influence exerted by preliminary MA of mixed REE oxides in air on the selectivity of their separation in dissolution in an acid and also on the crystallization of binary perovskite-like oxides $Ln^{(1)}Ln^{(2)}O_3$ in thermal treatment of the mixed oxides.

EXPERIMENTAL

Mixed oxides of REEs and yttrium were obtained by coprecipitation of hydroxides from solutions of chemically pure nitrates with ammonia and subsequent washing of the precipitates with water and their calcination at 1000°C for 2 h. According to the data furnished by chemical and thermal analyses and also by IR spectroscopy, a complete removal of residual nitrate ions, water, and CO_2 from the samples is achieved in this case [4, 5]. Individual oxides of La, Nd, Y, Er and Yb were obtained similarly from solutions of corresponding nitrates. The content of the main substance in the oxides was no less than 99.9%.

1070-4272/04/7710-1598 © 2004 MAIK "Nauka/Interperiodica"

According to the results of an X-ray phase analysis (XPA), the starting Ln_2O_3 and Nd_2O_3 were of the hexagonal A-form, and Y_2O_3, Er_2O_3, and Yb_2O_3, of the cubic C-form.

Freshly calcined oxides were mechanically activated in a Fritsch mechanical agate mortar (model 5) in air at 293 ± 2 K. The natural content of carbon dioxide in air [$P(CO_2)$ = 30 Pa] was virtually constant, which is confirmed by the reproducibility of the degrees of carbonization of samples in parallel experiments. The relative humidity of air during the experiments was 60–70%. The weight of a sample charged into the mortar was 5 g. After the MA, the samples were kept in a vacuum desiccator over silica gel. The content of CO_2 in the activated samples was determined by a gas-volumetric technique on an AN-7529 express analyzer. IR spectra were measured in pellets with KBr on a modified UR-20 spectrometer supplied with a device for obtaining spectra in the digital form. X-ray diffraction patterns were measured with a DRON-2.0 diffractometer with unfiltered Cu_{K_α} radiation. A differential thermal analysis was carried out on NTR-70 and PRT-1000 instruments with a Pt–Pt/Rh thermocouple in air. The rate of sample heating was 20 deg min^{-1}, calcined Al_2O_3 served as a reference. Thermogravimetric (TG) curves were obtained on a VT-1000 torsion balance. The specific surface areas of the samples were measured by the method of nitrogen thermal desorption (single-point method), using a Micromeritics FlowSorb II 2300 analyzer. Solutions obtained upon acid leaching of the activated samples were analyzed for the content of REE oxides by the atomic-emission method on a Perkin–Elmer Plasma 400 spectrometer. The content of REEs in the mixed oxides and precipitates was determined by the X-ray fluorescent method on a VRA-2 instrument with an external reference after calcination of the samples at 1000°C for 2 h.

The IR spectra of La, Nd, Y, Er, and Yb oxides after 12-h MA are shown in Fig. 1. They indicate that a noticeable hydration and carbonization of the samples occurs because of the absorption of atmospheric H_2O and CO_2. In the case of the oxide of lanthanum, which has the largest ionic radius, a narrow band at 3600 cm^{-1}, associated with stretching vibrations of an isolated hydroxy group, and a band at 643 cm^{-1}, corresponding to pendular bending vibrations of OH groups, indicate that lanthanum hydroxide is formed [7]. This is confirmed by XPA data (not shown), according to which La_2O_3 is completely converted into $La(OH)_3$ already after 3 h of abrasion. Further increase in the time of activation results only in a broadening of $La(OH)_3$ lines in the X-ray diffraction patterns and

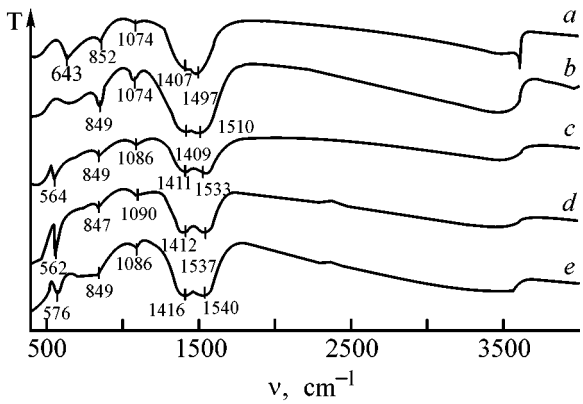

Fig. 1. IR spectra of samples of REEs and yttrium oxides after MA for 12 h. (T) Transmission and (ν) wave number. (*a*) La_2O_3, (*b*) Nd_2O_3, (*c*) Y_2O_3, (*d*) Er_2O_3, (*e*) Yb_2O_3.

in a decrease in their intensity, which indicates that the sample is amorphized and(or) the particles decrease in size. Reflections of $Nd(OH)_3$ also appear in the X-ray diffraction patterns of mechanically activated Nd_2O_3 (not shown) on the background of an appreciable decrease in the intensities of the lines associated with the oxide; however, their intensity is relatively low. After a 12-h abrasion treatment of oxides of yttrium-group elements (Y_2O_3, Er_2O_3, and Yb_2O_3), a diffuse halo appeared in their X-ray diffraction patterns, which points to the presence of a certain amount of an amorphous phase, and the intensities of reflections of the corresponding oxide somewhat decreased.

Broad bands associated with stretching vibrations of OH groups in the range 3300–3600 cm^{-1} are present in the IR spectra of all mechanically activated oxides (Fig. 1). The absence of bands of bending H–O–H vibrations at 1630–1670 cm^{-1} indicates that water is present in samples only in the form of OH groups. The broadening of the band of stretching OH vibrations is presumably due to a noticeable contribution of hydrogen bonds formed by protons of the hydroxy groups [8, 9]. Formation of bridging OH groups between two metal atoms is also not improbable [10]. The absorption bands at 564, 562, and 576 cm^{-1} in the IR spectra of Y_2O_3, Er_2O_3, and Yb_2O_3 (Fig. 1, curves *c*, *d*, and *e*, respectively) correspond to Ln–O stretching vibrations in the crystal lattices of the oxides [11, 12], in agreement with the XPA data.

The high-intensity double band at 1380–1550 cm^{-1}, which appears in the IR spectra of all the oxides under study as a result of their mechanical activation, corresponds to the ν_3 stretching vibrations of CO_3 groups. The splitting of this band, typical of basic carbonates of REEs, is due to lifting of the degeneration by the lowering symmetry of the carbonate group [13–21].

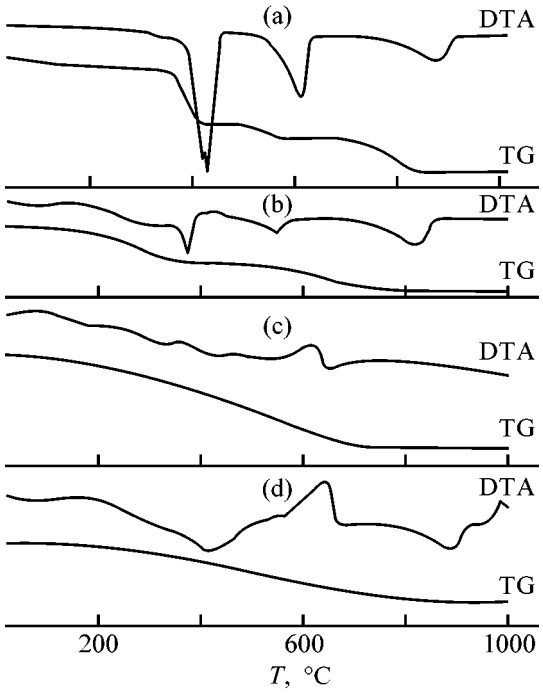

Fig. 2. DTA and TG curves of samples after MA. (*T*) Temperature. (*a*) La_2O_3, (*b*) Nd_2O_3, (*c*) Er_2O_3, (*d*) mixed oxide La_2O_3 and Er_2O_3. MA duration (h): (*a*) and (*b*) 3, (*c*) and (*d*) 12. For the TG curve of Er_2O_3 sample the scale of the ordinate axis is multiplied by a factor of 3.

The splitting $\Delta\nu_3(CO_3)$ equal to 90–125 cm^{-1} points to the monodentate coordination of carbonate groups, which is characterized by the appearance of absorption bands at 1380–1550, 1075, and 850 cm^{-1} [9, 13, 14, 22].

The processes that occur in La_2O_3, CeO_2, Sm_2O_3, Dy_2O_3, and Yb_2O_3 during their storage in air for 2–3 years have been studied by X-ray photoelectron spectroscopy (XPS) [5]. It was found that X-ray-amorphous basic carbonates are formed not only on the surface, but also in the bulk of all the samples under study. The peaks of the corresponding hydroxides appeared in the X-ray diffraction patterns of La and Sm oxides upon their exposure to air. For Dy_2O_3 and Yb_2O_3, only broadening of the reflections of the starting oxides was observed. As would be expected, the MA in our experiments considerably accelerates the reactions of oxides with atmospheric H_2O and CO_2, with the nature of the occurring processes being similar to that described in [5]. The oxide La_2O_3, and to a lesser extent Nd_2O_3, probably first react with moisture to form hydroxides, which are then converted into X-ray-amorphous basic hydroxides in reactions with CO_2. The exposure of $Ln(OH)_3$ to air is known to yield basic carbonates $Ln_2(CO_3)_x(OH)_{2(3-x)} \cdot nH_2O$ [6]. As already mentioned, the IR spectra of the samples subjected to MA contain no bands associated with bending vibrations of H–O–H. This suggests that basic carbonates formed in abrasion in air have the formula $Ln_2(CO_3)_x(OH)_{2(3-x)}$.

It is probable that X-ray-amorphous basic carbonates are also present in mechanically activated oxides of Y, Er, and Yb, which have smaller ionic radii, although the process of their formation is somewhat different. It should be noted that the peaks of the double band associated with stretching vibrations ν_3 of the CO_3 group (Fig. 1) are shifted to shorter wavelengths as the ionic radius of Ln^{3+} decreases:

Ionic radii of REEs by Goldschmidt [4]

Ion	La^{3+}	Nd^{3+}	Y^{3+}	Er^{3+}	Yb^{3+}
r, Å	1.22	1.15	1.06	1.04	1.00

In this case, the splitting $\Delta\nu_3(CO_3)$ for mechanically activated Y_2O_3, Er_2O_3, and Yb_2O_3 exceeds by 20–30 cm^{-1} that for samples of La and Nd oxides obtained under the same conditions. In view of the decrease in the basic properties in the order La > Nd > Y > Er > Yb, this result is somewhat unexpected because the shift of the ν_3 band and the increase in its splitting indicate a stronger binding of the CO_3 group [13, 22]. As formation of hydroxides was observed in MA of La_2O_3 and Nd_2O_3, we may assume that the OH group is a primary ligand in the resulting basic lanthanum and neodymium carbonates, and the CO_3 group is bound to it by hydrogen bonds [15, 18]. In the basic carbonates of Y, Er, and Yb, both the carbonate and hydroxyl groups are probably bound to the metal.

The DTA and TG curves of a lanthanum oxide sample subjected to a 3-h MA are shown in Fig. 2a. The shape of the DTA curve and the position of the peaks of effects are close to those in a similar curve for amorphous basic lanthanum carbonate obtained by precipitation of a hydroxide from a nitrate solution brought in contact with atmospheric CO_2 [5]. The endothermic effects at 400°C are probably associated with removal of water. Further increase in temperature results in the appearance of an endothermic peak at 584°C, which corresponds to the simultaneous removal of H_2O and CO_2 [5]. Carbon dioxide is completely removed at temperatures above 850°C. Three steps in the TG curve of the lanthanum oxide sample after 3 h of MA correspond to three main endothermic effects in the DTA curve (Fig. 2a). The loss of weight by this sample after calcination at 1000°C was

16.6 ± 0.4 wt %. The TG curve in Fig. 2a is similar to the curve of the same kind, obtained for lanthanum oxide after its exposure to air for 2 years, with the weight loss in calcination at 800°C equal to 13.4–14.0 wt % [5].

The DTA curve of neodymium oxide after MA for 3 h (Fig. 2b) is similar to the DTA curve for activated lanthanum oxide (Fig. 2a). The positions of the peaks of the effects for the neodymium oxide sample are shifted to lower temperatures, in agreement with published data [15, 16], which indicate that the decomposition temperatures of basic REE carbonates become lower as the ionic radius decreases. The results of a thermal analysis for an Er_2O_3 sample subjected to 12 h of MA, presented in Fig. 2c (for the TG curve the scale of ordinate axis for this sample is multiplied by a factor of 3), point to a noticeably smaller degree of H_2O and CO_2 absorption and to another nature of thermal decomposition, compared with activated lanthanum and neodymium oxides. As the atomic weight of a metal increases, the shape of the TG curves changes from a steplike for mechanically activated samples of lanthanum and neodymium oxides to almost monotonic for samples of erbium oxide (Fig. 2c). The same tendency was observed for REE oxides exposed to air [5] and for basic REE carbonates precipitated from solutions [21]. It is necessary to note that the thermolysis of basic REE carbonates is of a multistage complex nature. A number of intermediate phases are formed in the process, with the technique used to obtain the starting samples being of importance [5, 15, 16, 21].

The extents of carbonization, P (wt % CO_2), of individual oxides of REEs and yttrium subjected to MA are listed in Table 1. The data obtained indicate that, on the whole, the extent of carbon dioxide absorption in MA is in agreement with the basicity of the metals, which is determined by radii of their ions. Oxides of elements with larger ionic radii (lanthanum and neodymium) are carbonized to the greatest extent, whereas erbium and ytterbium oxides are carbonized to a lesser degree. Yttrium is an exception. Its ionic radius is intermediate between those of light and heavy REEs. At the same time, the CO_2 content in the sample of yttrium oxide after MA is comparable with that for lanthanum oxide (Table 1). It is necessary to note that specific surfaces areas of the starting La, Nd, Y, Er, and Yb oxides are 1.6, 1.7, 7.8, 2.3, and 1.0 $m^2 g^{-1}$, respectively. The relatively large initial specific surface area of yttrium oxide can be one of reasons for the increased content of the carbonate after MA. Another possible reason is the noticeably smaller molecular weight of yttrium oxide, compared with REE oxides. As the weight of the oxide charge in all the activation experiments was the same (5 g), the numbers of moles of the substances absorbing CO_2 were inversely proportional to their molecular weights. It is likely that, in the case of equal inputs of the mechanical energy per unit mass of a sample, a greater number of oxide moles will react with a greater amount of carbon dioxide, all other factors being the same. The extents of carbonization of REE oxides, which are normalized to their molecular weights (Table 1), show a clearly pronounced, although not absolutely strict, tendency toward a decrease in the absorption of CO_2 with decreasing ionic radius of a metal.

Table 1. Extent of carbonization of individual REE oxides after MA*

Oxide	P_3, wt % CO_2	$P_3 M$	P_{12}, wt % CO_2	$P_{12} M$
La_2O_3	3.3 ± 0.1	1075 ± 33	9.1 ± 0.3	2965 ± 98

Yb_2O_3	1.8 ± 0.1	709 ± 39	4.7 ± 0.2	1852 ± 79

* P_3 and P_{12}, the extents of carbonization after MA for 3 and 12 h, respectively; M, the molecular weight of the corresponding REE oxide.

The aim of further experiments was to determine whether or not the REE oxides included in a mixed compound obtained by coprecipitation from a solution of their salts with ammonia, with the subsequent calcination, differ in their tendency to react with atmospheric CO_2 in a mechanical activation similarly to activated individual oxides, and whether or not it is possible to make one of the components (oxide) of such a mixed compound to be converted into a basic carbonate first. Then it would be possible to expect a selective dissolution of this same component when a mixed oxide reacts with an acid. To verify this assumption, we synthesized mixed oxides of the following metals: (1) lanthanum, neodymium, and yttrium; (2) lanthanum and erbium; and (3) neodymium and ytterbium. The first mixed oxide included elements rather close to each other in the susceptibility to carbonization. By contrast, the lanthanum–erbium and neodymium–ytterbium compositions involved the elements as distant as possible from each other in the series of REEs. The choice of elements for the compositions was determined, among other things, by the availability of compounds. The mixed oxides

we synthesized contained approximately equimolar amounts of oxides of each metal, their compositions are listed in Tables 2–4.

To study the effect of MA on the selectivity of leaching of separate components, we dissolved the starting unactivated mixed oxides under identical conditions in dilute nitric acid with continuous stirring for 2 h, until complete neutralization of the acid. The dissolution of the mixed oxides subjected to preliminary mechanical activation and, therefore, carbonized to a considerable extent (Table 5) was carried out similarly. We used for dissolution 0.1 and 0.5 M nitric acid. After that, the solid phase remaining upon partial dissolution of the mixed oxides was separated from the solution by filtering, washed, dried at 100°C, and calcined to oxides at 1000°C for 2 h. To obtain data on the distribution of REEs and yttrium among the liquid and solid phases as a result of reactions of

the starting and activated samples of the mixed oxides with dilute solutions of nitric acid, we analyzed the solid phase and the filtrates for the content of REEs. The total content of REE oxides in the solid phase and in the filtrate always differed from their content in the starting mixed oxide by no more than 1–2%, i.e., the loss was at a minimum. The data on the distribution of REEs and yttrium among the liquid and solid phases after dissolution of mixed oxides in the acid are listed in Tables 2–4. The degree of dissolution of the mixed oxides is represented as the ratio of the amount of oxides that passed into solution and the amount of oxides in a sample before dissolution. For the ternary mixed oxide La–Nd–Y (Table 2), not subjected to preliminary MA, rather selective leaching-out of lanthanum is observed when 5.2% of the sample passes into solution. Its concentration in solution exceeds that of neodymium by more than a factor of 10 and that of yttrium by almost a factor of 200, whereas in the starting sample the oxides were present in approximately equimolar amounts. At higher expenditure of the acid, the selectivity of leaching-out of lanthanum upon dissolution of 17.1% of a sample of the ternary oxide essentially decreases: the concentration of lanthanum in solution exceeds that of neodymium by only a factor of 3, and that of yttrium by a factor of 19. It also follows from Table 2 that the MA leads to a dramatic decrease in the selectivity of leaching. Comparison of samples of the ternary oxide, activated for 3 and 6 h in the mechanical mortar, shows that, at the same extent of sample dissolution (about 13%), the relative concentrations in solution, $La_2O_3 : Nd_2O_3 : Y_2O_3$ are equalized to 1.16 : 0.88 : 1 and 1.06 : 1.00 : 1, respectively. A similar behavior in passing of REEs into solution is observed in dissolution of La–Er and Nd–Yb binary mixed oxides (Tables 3 and 4).

Thus, the experimental data show that the dissolution in an acid of starting mixed oxides not subjected to MA occurs in accordance with the basicity of elements, which is determined by their ionic radii. In the case of a mixed oxide of lanthanum, neodymium, and yttrium (Table 2), the extent to which a metal passes into a solution increases in the order Y < Nd < La, and hence the enrichment of the solid phase occurs in the reverse sequence. When the fraction of the dissolved sum of oxides increases, which occurs at a higher expenditure of the acid, the selectivity of separation falls. A similar trend is observed in reactions involving unactivated binary oxides of lanthanum and erbium, and also of neodymium and ytterbium: lanthanum and neodymium preferentially pass into solution, and heavy REEs are concentrated in the solid phase (Tables 3 and 4).

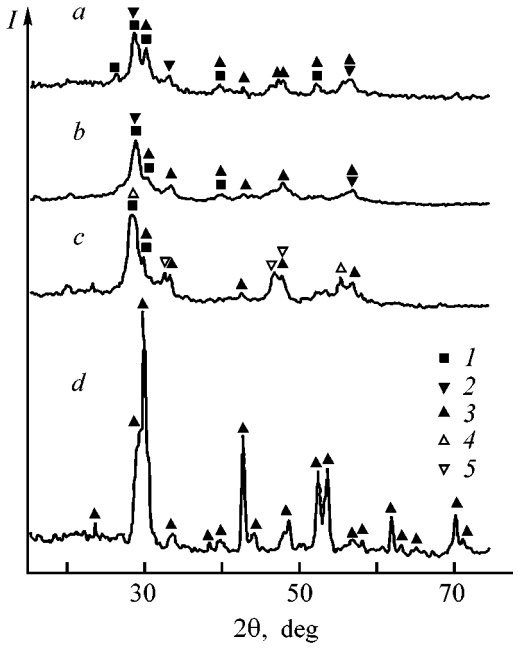

Fig. 3. X-ray diffraction patterns of the mixed oxide La_2O_3 + Er_2O_3. (*I*) intensity and (2θ) Bragg angle. (*a*) Starting oxide calcined at 1000°C; (*b*) sample *a* after MA for 12 h; (*c*) sample *b* after heating at 700°C; (*d*) sample *b* after heating at 1000°C. (*1*) La_2O_3, (*2*) Er_2O_3, (*3*) $LaErO_3$, (*4*) $La_2O_2CO_3$, (*5*) $Er_2O_2CO_3$.

Preliminary MA of the mixed oxides noticeably changes the distribution of elements among the liquid and solid phases in reaction with an acid, because REEs and yttrium pass into solution to approximately the same extent, i.e., virtually no selectivity is observed in dissolution. Thus, the experiments show that the MA of the mixed oxides adversely affects the selectivity of their separation.

The data obtained can be explained as follows. Presumably, several processes occur in MA of the mixed oxides. It is possible that, alongside with carbonization and hydration, a solid-phase reaction occurs to give precursors of binary perovskite-like oxides of REEs $Ln^{(1)}Ln^{(2)}O_3$, which dissolve in the acid congruently. To verify this assumption, we synthesized a mixed oxide of lanthanum and erbium and activated it in a mechanical mortar for 12 h, and then subjected it to a heat treatment. The results of XPA and thermal analysis show that the thermal relaxation of mechanically activated mixed oxide of La and Er results in the synthesis of the perovskite-like oxide $LaErO_3$. The X-ray diffraction patterns of the starting mixed oxide of La and Er and of the same sample after MA for 12 h with the subsequent heating at 700 and 1000°C are shown in Fig. 3. The degree of crystallinity of the starting mixed oxide sample is low

(Fig. 3, curve *a*), and the MA results in a certain broadening of the reflections and in a decrease in their intensity (Fig. 3, curve *b*). The fact that there are no reflections of $La(OH)_3$, which is formed in abrasion of pure La_2O_3, in the X-ray diffraction patterns of a mechanically activated sample (Fig. 3, curve *b*) indirectly shows that a reaction between La and Er oxides occurs in MA. This conclusion is also confirmed by the strong difference between the thermograms of mechanically activated mixed (Figs. 2a and 2d) and individual (Figs. 2a and 2c) oxides of La and Er. The endothermic peaks at 300–640°C in the DTA curve of the mixed oxide of lanthanum and erbium after 12-h MA probably correspond to removal of water and, in part, of CO_2 (Fig. 2d). The exothermic effect at 642°C apparently corresponds to formation of dioxomonocarbonate $Ln_2O_2CO_3$. According to published data [20], the appearance of such an exothermic peak precedes the formation of $La_2O_2CO_3$ in thermal decomposition of the mono-oxocarbonate $La_2O(CO_3)_2 \cdot 1.4H_2O$. This assumption is supported by the fact that reflections that can be assigned to $La_2O_2CO_3$ and $Er_2O_2CO_3$ [23, 24] appear in the X-ray diffraction pattern of the mechanically activated mixed oxide of La and Er heated to 700°C (Fig. 3, curve *c*). At the same time, no changes are observed in the X-ray diffraction pattern of the same sample heated to 500°C (not shown). The endothermic effect at 880°C in Fig. 2d probably corresponds to removal of carbon dioxide. The exothermic peak at 983°C corresponds to crystallization of the binary oxide $LaErO_3$ [25], which is confirmed by the XPA (Fig. 3, curve *d*). The TG curve of the mixed oxide after MA (Fig. 2d) is monotonic, as in the case of mechanically activated erbium oxide (Fig. 2c).

Table 3 lists the data on dissolution in dilute nitric acid of the binary mixed oxide of lanthanum and erbium and of $LaErO_3$ synthesized as described above. The congruence of the $LaErO_3$ dissolution in dilute HNO_3 confirms the assumption concerning the possible reason for the negative effect of the MA of the mixed oxides on the selectivity of REE separation.

It should be noted that a method for synthesis of $Ln^{(1)}Ln^{(2)}O_3$ compounds has been described in the literature [26]. This method consists in a prolonged (10–40 h) heating of coprecipitated hydroxides at 1400–1800°C [26]. The $Ln^{(1)}Ln^{(2)}O_3$ compounds activated with metal ions hold much promise as scintillators and materials for laser technology [27]. The mechanical activation of mixtures of solids finds increasing use in synthesis of complex oxides [28, 29]. The above-mentioned decrease in the temperature of $LaErO_3$ synthesis as a result of a preliminary MA of the stock may be of interest for improving the existing methods for preparation of perovskite-like binary REE oxides.

CONCLUSIONS

(1) The mechanical activation of individual oxides of lanthanum, neodymium, erbium, ytterbium, and yttrium strongly accelerates the absorption of CO_2 and moisture from air by these compounds. As the atomic weights of REEs increase, their ionic radii and also basic properties of the metals decrease owing to the lanthanide contraction. In the same direction decreases the extent of carbonization of the oxides in mechanical activation.

(2) The mechanical activation of individual lanthanum and neodymium oxides results in that they are converted into hydroxides via reaction with moisture contained in air, yielding hydroxides, which form amorphous basic carbonates, presumably of the composition $Ln_2(CO_3)_x(OH)_{2(3-x)}$, by reacting with atmospheric carbon dioxide. Individual oxides of the yttrium-group elements (Y_2O_3, Er_2O_3, and Yb_2O_3) are more stable against mechanical actions.

(3) The effect of the mechanical activation and of the accompanying absorption of atmospheric carbon dioxide on the selectivity of dissolution of components of mixed oxides was studied. The mechanical activation results in a decrease in the selectivity of separation of elements in treatment of the mixed oxides with nitric acid solutions. Presumably, this is due to formation of precursors of binary perovskite-like oxides in mechanical activation. It was established for the example of lanthanum and erbium oxides that a preliminary mechanical activation of a mixture of starting oxides noticeably lowers the temperature of $LaErO_3$ formation in heat treatment.

Received April 22, 2004; in final form, August 4, 2004

Abstract—The material balance of water, phosphoric acid, and tri-*n*-butyl phosphate in the real process of purification of wet-process phosphoric acid by TBP extraction was studied. A process mechanism was suggested.

One of the methods for purification of wet-process phosphoric acid (WPPA) is extraction with tri-*n*-butyl phosphate (TBP). At the Voskresensk Institute of Fertilizers and Phosphoric Acid, Joint-Stock Company, a pilot plant for production of purified phosphoric acid PPA from WPPA by tributyl phosphate (TBP) extraction in pulse columns have been operating for more than eight years. Its daily output capacity was brought to 50–55 tons of P_2O_5 [2]. In this study, we examined the mechanism of water transfer with the extractant from the back-extraction column to the extraction stage. To our knowledge, there is no information on this mechanism in the literature. The process flowsheet is presented below. The material balance was determined from the process parameters measured during seven workdays. This balance appeared to be typical of extraction systems.

Comparison of the sums of the input (G_{WPPA} + G_{H_2O}) and output (G_{raf} + $G_{pur.\,acid}$) aqueous flow rates in the system reveals that the difference between them is 173.9 kg h^{-1}, the major part of the debalance (163 kg h^{-1}) being accounted for by water. It follows from an analysis of the operation of the unit that this amount of water is evaporated from the column in the course of back extraction, since this stage is performed at 52–55°C, which causes high water vapor pressure in the top part of the column.

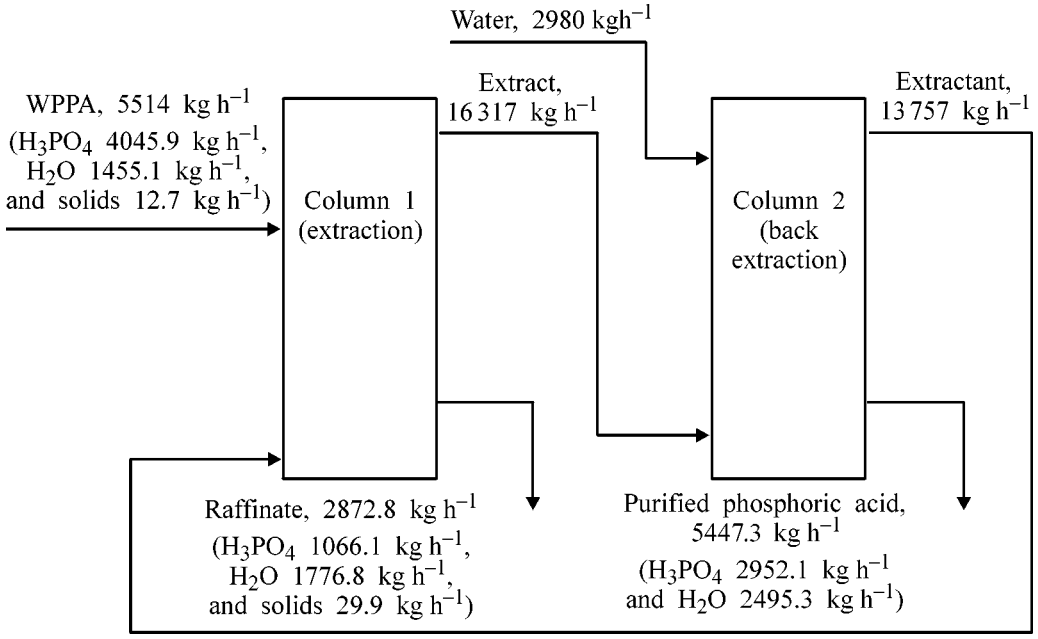
Furthermore, measurements of the WPPA input flow and raffinate flow output from the bottom of the extraction column show that the amount of water input to the column with WPPA (1455.1 kg h^{-1}) is considerably smaller (by 321.7 kg h^{-1}) than that removed from the column with the raffinate. As a result, a more dilute raffinate (26.89% recalculated for P_2O_5) is formed instead of the estimated 30.3%.

At the same time, in determining the rate of the water flow fed into to the column for back extraction, it was found that the amount of water entering the top part of the column (G_{H_2O} = 2980 kg h^{-1}) exceeds by 484.7 kg h^{-1} that necessary for formation of 5447.3 kg h^{-1} of purified phosphoric acid. It was demonstrated that 163 kg h^{-1} is evaporated from the column. It is evident then that the remaining 321.7 kg h^{-1} should enter the first extraction column.

Therefore, it follows from the analysis of the material balance that about 5% of water entering the column is evaporated from it, and the rest (about 11%) passes to the extraction stage and then is removed from the system with the raffinate flow.

To verify this assumption, we analyzed the extract passing to back extraction, and also the extractant passing to the extraction column, for the content of water, using the Fischer titration method [GOST (State Standard) 14 870–77]. Additionally, we analyzed the extract and extractant for H_3PO_4 by potentiometric titration [3]. The results are listed in the table.

The results obtained allowed estimation of the amount of water circulating in the system with the extract and extractant flows: 968 kg h^{-1} passes to the column with the extractant and 739 kg h^{-1}, i.e., an amount smaller by 229 kg h^{-1}, is removed with the extract. According to our estimates (see table), the composition of the extract can be represented as $(C_4H_9O)_3PO \cdot 0.89H_2O \cdot$



Flowsheet of the pilot plant for production of purified phosphoric acid from WPPA by TBP extraction.

$0.73H_3PO_4$, and that of the extractant, as $(C_4H_9O)_3PO \cdot 1.15H_2O \cdot 0.08H_3PO_4$. Therefore, the extraction/back extraction cycle can be described by Eq. (1).

$$100TBP \cdot 115H_2O \cdot 8H_3PO_4 + 65H_3PO_4 \rightleftarrows 100TBP \cdot 89H_2O \cdot 73H_3PO_4 + 26H_2O. \quad (1)$$

It is of interest to compare the results of our measurements with published data on interactions between TBP, H_3PO_4, and H_2O. According to Higgins and Baldwin [4], the water concentration in these phases is 5 and 9%, respectively, at an H_3PO_4 concentration in the extract and extractant of 20.22 and 2.75%.

1.094	20.22	4.53	75.26	0.994	2.75	7.04	90.21	1	0.89	0.73	1	1.15	0.08

Therefore, in the system TBP–H_2O–H_3PO_4 with the content of H_3PO_4 and water equal to 20.22 and 5% and 2.75 and 9%, the hydrosolvates $(C_4H_9O)_3PO \cdot 0.99H_2O \cdot 0.72H_3PO_4$ and $(C_4H_9O)_3PO \cdot 1.51H_2O \cdot 0.08H_3PO_4$ are, respectively, formed. Therefore, the interaction in the TBP–H_2O–H_3PO_4 system can be described by Eq. (2).

$$100\text{TBP} \cdot 151H_2O \cdot 8H_3PO_4 + 64H_3PO_4 \rightleftarrows 100\text{TBP} \cdot 99H_2O \cdot 72H_3PO_4 + 52H_2O. \quad (2)$$

According to [4], 440 kg h^{-1} of water should be transferred with the organic phase from the back-extraction column to the extraction column, which slightly exceeds the amount determined in our study. The cited data were obtained at 25°C, while our results correspond to the actual process temperature (40–50°C), which, most likely, causes the observed discrepancy.

In conclusion, our determinations of the water content in the organic phases by means of Fischer titration allowed a more precise estimation of the water balance in the system. The transfer of water from one column to another, i.e., from the organic phase to the raffinate, was interpreted in terms of the hydration-solvation mechanism.

Abstract—The influence exerted by the composition of film-forming solutions based on acetylacetone on the electrical and optical properties of indium-tin oxide films obtained from these solutions by the dip-coating process was revealed.

Films composed of indium oxide with addition of tin(IV) have a high electrical conductivity and, at the same time, remain transparent in the visible spectral range [1]. Thanks to these properties, these films find wide use in optoelectronics and solar power engineering. One of promising methods for obtaining In_2O_3–Sn coatings, especially on large-area articles, is the dip-coating process (drawing from solution). However, the wide variety of film-forming solutions (FFS) and the scarcity of data on the influence of the FFS composition on the physicochemical characteristics of In_2O_3–Sn films make necessary research in this area.

EXPERIMENTAL

The aim of this study was to reveal the influence of the FFS composition on the electrical and optical properties of indium-tin oxide films.

The FFS were prepared by dissolving acetylacetone (Hacac) and a salt, $InCl_3$, $SnCl_2 \cdot 2H_2O$, or $SnCl_4$, in 96% ethanol. The solutions were kept in a thermostat at 333 K for 1 h. In order to analyze the effect of Hacac concentration and FFS acidity on the properties of the films obtained, a set of alcoholic solutions with c_{Hacac} in the range from 0 to 0.72 M and c_{HCl} of 0 to 0.2 M were prepared. The starting components of all the FFS are listed in Table 1.

The composition of all the FFS was studied by IR and UV spectroscopies. The IR spectra were measured on an IKS-29 spectrophotometer in the frequency range 400–4200 cm^{-1}, and the UV spectra, on an SF-20 instrument at 220–340 nm. The film-forming capacity of all the solutions was evaluated by their viscosity. The viscosity was measured at a temperature of 298 K on a VPZh-2 viscometer with a capillary diameter of 0.73 and 0.99 mm. The measurement error was 0.07 $mm^2\ s^{-1}$.

In_2O_3–Sn(II, IV) films were obtained on glass substrates by drawing from FFS at a rate of 2 $mm\ s^{-1}$. The thermal treatment of the samples was carried out in a muffle furnace at 873 K. The resistance and transparency of the films was determined with a VK7-9 voltmeter in a two-probe circuit and with an IKS-3 spectrophotometer, respectively.

The absorption bands in the IR spectra of FFS nos. 3 and 5 and of the initial Hacac are listed in Table 2. The IR spectrum of Hacac contains a set of

absorption bands that is characteristic of β-diketones [2, 3]. The absorption band at 1735 cm^{-1} points to the presence of a ketone form of Hacac, and the absorption bands at 1514, 1399, and 812 cm^{-1} indicate the existence of a enolic form of Hacac. The IR spectra of FFS nos. 3 and 5 also contain a set of absorption bands that characterizes the keto–enol equilibrium of Hacac. However, these bands are shifted to lower frequencies, compared with the absorption bands of Hacac and Hacac in a 96% ethanol solution. This can be attributed to the influence of the solvent C_2H_5OH and formation of complex species by In(III) and Hacac. In contrast to the IR spectrum of Hacac, the IR spectra of FFS nos. 3 and 5 show absorption at around 510 cm^{-1}, which is associated with vibrations of the In–O bond [4]. It can be seen from Table 2 that an increase in acidity affects vibrations of the ketone and enol groups of Hacac. The absorption bands ν(C=O) and ν[(C–O) + (C–C)] are shifted to higher frequencies. In addition, the intensity of the ν(C=O) band increases. This fact indicates that the equilibrium is shifted toward ketolization of Hacac when the concentration of HCl in FFS becomes higher.

The UV transmission spectrum of FFS no. 5 contains one broad absorption band at λ = 270–275 nm, associated with π–π^* transitions in Hacac. According to published data [5], this region characterizes the keto–enol equilibrium in Hacac, with the enol form of Hacac being undissociated. To the dissociated enol form of Hacac corresponds the absorption band at 290 nm in the UV spectral range [6].

According to the whole set of experimental data, complex ions constituted by In(III) and of the ketone and undissociated enol forms Hacac exist in alcoholic FFS in $[In(Hacac)_3]^{3+}$. The existence of $[SnHacac]^{3+}$ in acidified solutions of ethanol has been established previously [7].

The values of the kinematic viscosity of all the FFS $(1.10–2.35) \pm 0.04$ $mm^2\ s^{-1}$ confirm their film-forming capacity [8]. During the first 15 days, the viscosity of FFS does not reach a constant value. The run of the viscosity-vs.-time curves is about the same for all the FFS, which indicates that similar processes (hydrolysis, polycondensation, changes in the orientation of solvent molecules) occur in alcoholic solutions of complex compounds of Sn(II, IV) and In(III). An increase in the acidity of FFS from pH 2 to pH 0.7 results in that the viscosity grows from 1.83 to 2.00 $mm^2\ s^{-1}$. This is, possibly, due to a rise in the rate of polycondensation of hydrolyzed complex ions of Sn(II, IV) and In(III). A more structured FFS is formed. An increase in the content of Hacac in FFS to 0.72 M results in that the viscosity of the solutions decreases from 2.35 to 1.83 $mm^2\ s^{-1}$. This fact can be accounted for by a decrease in the degree of hydrolysis of complex species of Sn(II, IV) and In(III), which occurs because the content of ethanol falls as the concentration of Hacac increases. As FFS with a higher acidity and lower content of Hacac have a relatively high viscosity, more porous films must be formed from these FFS under the same conditions because of the hindrance to removal of products of FFS decomposition from the oxide skeleton. Analysis of the surface resistance *R* and transmittance *T* of the films (Table 3) obtained from these FFS confirms

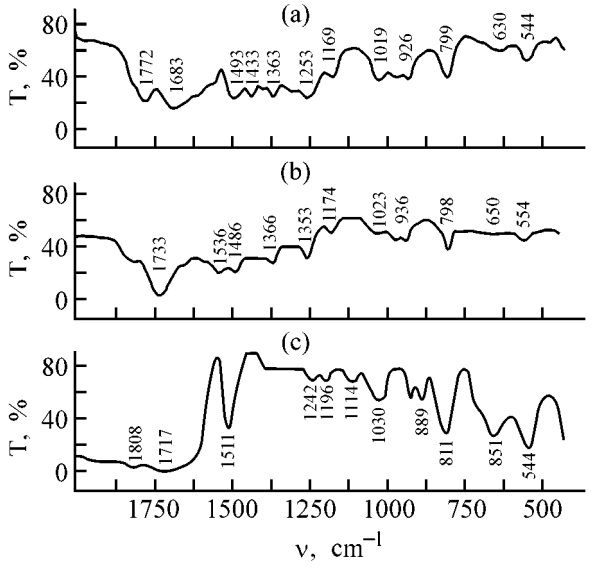
this assumption. As the acidity of FFS with Sn(II) or Sn(IV) increases, the resistance of the films obtained grows (the structure becomes more defective) and their transmittance decreases. In can also be seen from Table 3, that films obtained from FFS based on $SnCl_4$ are rather transparent (86.5 and 86.7%), but their resistance at this transparency exceeds 100 MΩ and 2000 kΩ, respectively. At the same time, films obtained from FFS based on $SnCl_2$ have a resistance of 11–12 and 5–10 kΩ at a transparence of 86.4 and 85.0%, respectively. This fact can be understood as follows: SnO is formed as an intermediate product in preparing oxide films from FFS based on Sn(II); this intermediate is involved at 380–1073 K in a disproportionation reaction, which yields SnO_2 and Sn [9]. An admixture of metallic Sn makes the conductivity of a film higher, and its transparence, lower. Because FFS with addition of Sn(IV) and high content of Hacac is to be used for obtaining films with lower resistance and high transparence, further study was aimed to prepare films from an FFS in which Hacac is both an organic ligand and a solvent.

The FFS was prepared by dissolving the salts $SnCl_2 \cdot 2H_2O$, or $SnCl_4$, $In(NO_3)_3 \cdot 4H_2O$, or $InCl_3$ in Hacac at 333 K in a thermostat or with a reflux condenser. The viscosity of these FFS reaches a constant value in 5 to 6 days and then remains constant for a long time. This enables a prolonged use of the solution for obtaining films with the same properties, in contrast to alcoholic FFS.

An analysis of the absorption bands in IR spectra of Hacac kept at 333 K with a reflux condenser and of FFS prepared from Hacac–In(III)–Sn(IV) at 333 K in a thermostat and with a reflux (see figure) demonstrated that complexation of In(III) in a Hacac solution is only observed after heating the FFS with a reflux condenser to red-brown color. Presumably, the rate of complexation of In(III) with ketone and undissociated enol forms of Hacac increases because the FFS passes into the gas phase.

Films were prepared from these FFS and the properties of these films were studied (Table 4). As can be seen from Table 4, the surface resistance of In_2O_3–Sn(II, IV) films prepared from FFS kept at 333 K with a reflux condenser (complex ions exist in these FFS) is more uniform over the surface. The presence of the complex of indium(III) with Hacac in the FFS with Sn(IV) leads to formation of uniform films because of the better adhesion of the π-system on the surface of the cyclic enol form of the complex ion with the glass surface [10], compared with the solvated In^{3+} ion. As the number of layers deposited on the substrate grows, the surface resistance *R* of the films decreases. According to published data [11], the crystallites in a film grow in size, and, simultaneously, the charge carrier concentration increases as the films become thicker. The oxidation state of tin in an FFS affects the properties of the films, whereas the nature



IR absorption spectra of (c) Hacac kept at 333 K with a reflux, (b) Hacac–In(III)–Sn(IV) kept at 333 K in a thermostat, and (a) Hacac–In(III)–Sn(IV) kept at 333 K with a reflux. (T) Transmission and (ν) wave number.

of the salt anion does not exert any significant influence. Films with a lower resistance are formed from Sn(II)-based FFS; however, the transparence of these films in the visible spectral range is lower than that of films obtained in FFS based on Sn(IV). A similar behavior was observed for films prepared from alcoholic solutions.

CONCLUSION

The influence exerted by the acidity, composition (concentration of acetylacetone and ethanol, oxidation state of tin), and thermal treatment of film-forming solutions on the electrical and optical properties of indium-tin oxide films was established. To obtain films with a relatively low resistance ($\leq$0.3 kΩ) and high transparence (up to 91%), it is necessary to use acetylacetone FFS prepared from Sn(IV), $In(NO_3)_3$, and $InCl_3$ and kept at 333 K with a reflux.

Abstract—Extraction of indium(III) from sulfuric acid solutions with di-2-ethylhexyl hydrogen phosphate and isododecylphosphethanic and diisooctylphosphinic acids was studied. The effect of H_2SO_4 and In(III) concentrations in the aqueous phase, type and concentration of the extractant in the organic phase, temperature, and time of phase contact on the extraction of In(III) and impurity metal ions was considered. The In(III) extraction constants were estimated.

Extraction is widely used for recovering and concentrating In(III) from multicomponent process solutions [1–3]. Di-2-ethylhexyl hydrogen phosphate (HDEHP) is usually used as an extractant [2–6], although it exhibits poor selectivity. Along with In(III), HDEHP recovers Ga(III), Fe(III), Sb(III), and any other multicharged metal ions. In addition, the extraction with HDEHP has a slow kinetics and is often irreversible. Backwashing is performed with strong backwashing agents, such as HCl, H_2SO_4 + HCl, H_3PO_4, and $H_2C_2O_4$. Effective ways to eliminate the above disadvantages are sought for. Certain authors suggest to use, instead of pure HDEHP, its mixtures with monocarboxylic acids [7–10] or alkylamines [8]. In this case, a certain improvement of the backwashing conditions due to a decrease in the concentration of chloride ions in the backwashing solution is accompanied by a noticeable worsening of In(III) recovery and separation. Other researchers look for a better extractant than HDEHP [2, 11–13]. Such an extractant, while preserving HDEHP advantages, should ensure selective extraction of In(III) under milder conditions. Presumably, phosphinic acids, which are weaked than HDEHP, should meet the above requirements.

In this study, we examined the possibility of using isododecylphosphetanic (HIDDP) and diisooctylphosphinic (HDiOP) acids for In(III) extractive recovery from weakly acidic sulfate solutions.

EXPERIMENTAL

The In(III) sulfuric acid solutions were prepared by dissolution of metallic indium in aqueous H_2SO_4. They contained about 50 g l^{-1} In(III) and 290–320 g l^{-1} H_2SO_4. Less concentrated solutions were prepared by dilution of the initial solution with chemically pure sulfuric acid and distilled water. Such solutions contained 1–1.7 g l^{-1} In(III) and 9–14 g l^{-1} H_2SO_4, which corresponded to the composition of the process solutions of zinc production used for In(III) recovery.

Preliminarily purified HDEHP, HDiOP, and HIDDP (RH) were used as extractants. The content of the main substance in these acids was no less than 96 wt %. As a rule, 20 vol % solutions of these acids in kerosene were used. The dependence of the extraction on the extractant concentration was studied within the 5–30 vol % extractant content in kerosene. The above solutions were prepared by dilution of the extractants with dearomatizated kerosene. The main properties of the extractants are described in [14, 15].

The extraction and backwashing were performed in separating funnels. A mechanical shaker was used for phase mixing. For extraction, phases (unless otherwise indicated) were brought in contact once for 15 min at $20 \pm 1°C$ and 1 : 1 volume ratio of the aqueous to organic phase. After mixing, the phases were separated

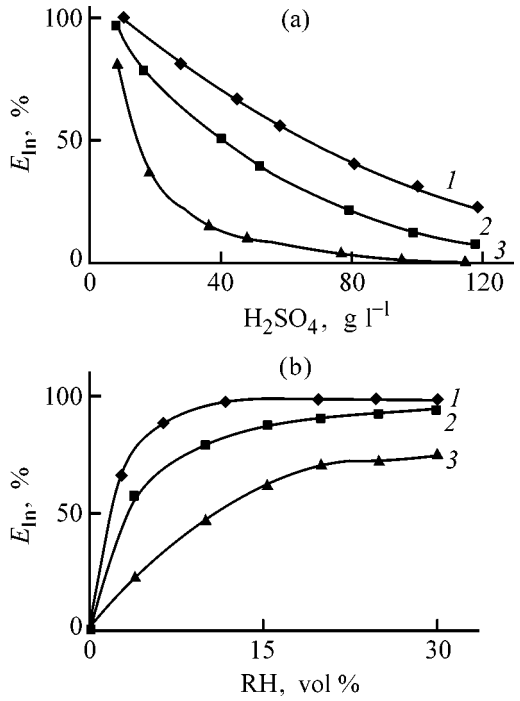

Fig. 1. Influence of the (a) H_2SO_4 concentration and (b) concentration of organophosphorus acids in kerosene on In(III) extraction E_{In}. Extractant: (*1*) HDEHP, (*2*) HIDDP, and (*3*) HDiOP; the same for Fig. 2.

by centrifuging. The initial and equilibrium aqueous phases were analyzed. The content of the metal ions and H_2SO_4 in the organic phase was found as the difference between their contents in the initial solutions and equilibrated aqueous phases, small changes in the phase volumes being neglected. A direct analysis of the backwashing solutions confirmed the validity of this procedure.

The effect of H_2SO_4 concentration in the aqueous phase, extractant concentration in the organic phase, time of phase contact, and temperature on In(III) extraction was studied. These parameters are the most important in evaluation of the process feasibility and in hardware design.

The In(III) extraction with phosphorus-containing acids proceeds by the cationexchange mechanism with the release of H_3O^+. Hence, the acidity of the aqueous phase should substantially affect the extraction.

It follows from the data obtained (Fig. 1a) that In(III) is well recovered from solutions containing approximately 10 g l^{-1} H_2SO_4: to 90–95% with HDEHP and HIDDP and to 70% with HDiOP. The recovery decreases as the acid concentration increases. The recovery of In(III) is virtually complete (>90%) with HDEHP and HIDDP at H_2SO_4 concentrations of up to 110 and 16 g l^{-1}, respectively.

As a rule, raising the extractant concentration leads to an increase in the metal ion recovery, but, at the same time, to a decrease in the rate of phase separation, which makes it necessary to use larger reactors, and, accordingly, a greater amount of the initially charged extractant.

The In(III) recovery is satisfactory with 20 vol % solutions of HDEHP and HIDDP and 30 vol % solution of HDiOP in kerosene (Fig. 1b). At extractant concentrations exceeding 30%, the phase separation substantially decelerates.

It is known that the extraction of M(III) ions, e.g., Fe(III), with HDEHP is slow [16]. Our data on In(III) extraction show that the equilibrium is virtually attained only after phase contact for >10 min (Table 1). The time in which the extraction equilibrium is estab-

* Initial aqueous phase: M(II, III) 1 g l^{-1}, H_2SO_4 10 g l^{-1}.

lished depends on the type of the extractant and shortens as the organophosphorus acid strength increases, in the order HDiOP < HIDDP < HDEHP.

The temperature can strongly affect the extraction through the structure of the extractable complexes. For instance, heating improves the Co(II) recovery but does not affect the Ni(II) extraction with organophosphorus acids.

Varying of the temperature within the 20–40°C range does not noticeably affect the In(III) recovery. At higher temperatures, the extraction somewhat increases (Table 2).

The extraction isotherms obtained with feed solutions containing 1 to 15 g l^{-1} In(III) are shown in Fig. 2. As can be seen, the metal ion is recovered with HDEHP and HIDDP with a high distribution ratio providing a complete recovery up to a metal concentration in the aqueous phase of approximately 13 g l^{-1}. In the process, unsaturated extracts are formed. Thus, it is feasible to concentrate In(III) in the extraction step.

The process solutions contain, in addition to the target metal ion, In(III), such impurities as Fe(III), Fe(II), Zn(II), Cu(II), Ni(II), Cd(II), Co(II), Sb(III), etc. These ions mainly occur in the solution in the form of hydrated and partially hydrolyzed cations, and their extraction with acid organophosphorus extractants substantially depends on the acidity of the aqueous phase. Our study shows that the above ions are not noticeably recovered from weakly acidic sulfate solutions (Table 3).

424	0.022	1.053	0.021	2.06

The most difficult-to-remove metal ion is Fe(III). Its distribution depends on the H_2SO_4 concentration (Table 4).

Thus, the recovery of admixtures, including Fe(III), increases in the order HDiOP < HIDDP < HDEHP.

The In(III) backwashing from the organic phase is an important factor in the assessment of the feasibility of using HDiOP and HIDDP as indium extractants. Table 5 shows that indium can be efficiently backwashed from an extract with 250–350 g l^{-1} H_2SO_4 solutions (without adding HCl), which is a substantial advantage over the system with HDEHP. This makes it possible to recommend HDiOP and HIDDP for extractive recovery and purification of In(III).

The mechanism of In(III) extraction from sulfuric acid solutions with HDEHP was considered in [13, 14]. With HDiOP and HIDDP, the mechanism is apparently similar:

$$In^{3+}_{(w)} + 3(RH)_{2(org)} \rightarrow InR_3 \cdot 3HR_{(org)} + 3H^+_{(w)},$$

where RH is HDEHP, HIDDP, and HDiOP.

Then, the extraction constant is given by

$$K = \frac{D_{In}[H^+]_{(w)} \cdot 2^3}{[(RH)_2]^3_{(org)}},$$

$$\log K = \log D_{In} + 3\log[H^+]_{(w)} + \log 8 - 3\log[(RH)_2]_{(org)}$$
$$= \log D_{In} + b,$$

where $b = 3\log[H^+]_{(w)} + \log 8 - 3\log[(RH)_2]_{(o)}$ is constant for all the extractants under the same conditions of the extraction.

This equation allows estimation of the extraction constants for different extractants at its known value for any one of these. From the data on the In(III) distribution between 0.1 M aqueous H_2SO_4 solution and 0.25 M RH solution in kerosene, we obtained the following extraction constants, K ($D_{In(III)}$): HDEHP 6.5×10^5 (99) [17], HIDDP 1.48×10^4 (2.45), and HDiOP 7.9×10^3 (1.31).

Taking into account the above results and the necessity for minimizing the alteration of the existing process scheme of In(III) recovery from sulfuric acid solution of zinc production, we can recommend the following basic operations:

(1) Fe(III) reduction to Fe(II);

(2) In(III) extraction with 20–30 vol % solutions of HIDDP or HDiOP in kerosene from sulfuric acid solutions containing Zn(II);

(3) Scrubbing of the organic phase with a 5–10 g l^{-1} aqueous solution of H_2SO_4;

(4) In(III) backwashing with H_2SO_4 (250–350 g l^{-1});

(5) In(III) recovery from backwashes by the existing process.

The basic process parameters of the process suggested for In(III) extractive recovery and concentration from sulfuric acid solutions are as follows:

Extraction

H_2SO_4 content in the aqueous phase	10–20 g l^{-1}
HIDDP or HDiOP concentration in kerosene	30 vol %
Organic-to-aqueous phase volume ratio (org : w)	1 : (1–2)
Time of phase contact	≥15 min
Temperature	20–40°C

Scrubbing of the organic phase

H_2SO_4 content in the scrubbing solution	5–10 g l^{-1}
org : w ratio	(10–15) : 1
Time of phase contact	10 min
Temperature	20–40°C

In(III) backwashing from the organic phase

H_2SO_4 content in the backwashing solution	350–400 g l^{-1}
org : w ratio	(10–15) : 1
Time of phase contact	≥10 min
Temperature	20–40°C

CONCLUSIONS

(1) A study of extraction of In(III) and concomitant metal ions with organophosphorus acids showed that HIDDP or HDiOP can be used instead of HDEHP as extractants for selective recovery and concentration of In(III), provided that Fe(III) is preliminarily reduced to Fe(II) and separated.

(2) The In(III) recovery increases in the order HDiOP < HIDDP < HDEHP. An increase in H_2SO_4 concentration in the aqueous phase leads to a decrease in the extraction of In(III).

(3) In(III) can be completely recovered from the resulting extracts by treatment with 2.5–3.5 M solutions of H_2SO_4.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Thermodynamics of Cerium(III) Extraction with Naphthenic Acids

D. E. Chirkst, T. E. Litvinova, P. N. Devyatkin, and I. T. Zhadovskii

St. Petersburg State Mining Institute, St. Petersburg, Russia

Received February 25, 2004

Abstract—Cerium(III) extraction from dilute aqueous solutions with naphthenic acids in decane was studied. The dependence of the distribution ratio on the pH of the equilibrium aqueous phase was determined, and the extraction equilibrium constant and Gibbs energy were calculated.

The steady rise in the industrial demand for individual lanthanide and yttrium metals and for their pure compounds requires that lean raw materials [1], including eudialyte ore concentrate of the Kola peninsula, should be involved in the processing; however, the known procedures for recovery and separation of lanthanides by extraction with tributyl phosphate from nitrate solutions have low separation coefficients, 1.1–1.5 [2, 3]. Therefore, multiple repetitions of the extraction–backwashing cycles and too large expenditures for the equipment and chemicals are required. This stimulates a search for hydrometallurgical systems that would ensure higher distribution and separation coefficients of lanthanides. This search is based on a thermodynamic simulation and study of the extraction mechanisms. In this study, we examined the extraction of cerium(III) from dilute aqueous solutions simulating the composition of filtrates from acid leaching of eudialyte concentrates.

The initial aqueous solutions contained approximately 0.65 g l^{-1} Ce(III); the precise concentration was found photometrically. A 0.5 N naphthenic acid solution in decane was used as an extractant. The naphthenic acid was prepared by distillation of technical-grade Acidol-1 from Baku petroleum refinery at 165–190°C and a residual pressure of 5–7 mm Hg. The average molar weight of this fraction was 226 g mol^{-1} and the concentration, 4.4 M. In accordance with elemental analysis, the mean formula of the acid is $C_{13}H_{27}COOH$, and mean pK_a, 5.1 [4]. The pH of the aqueous phase was ajusted with NaOH and HCl solutions and monitored with a pH-150M pH-meter with a combined electrode. Chemically pure chemicals were used. The Ce(III) concentration was determined photometrically (λ 670 nm) on a KFK-3 photocolorimeter with Arsenazo III in an acetate buffer solution with pH 3 [5].

The cerium(III) content in the organic phase was determined as a difference between the Ce(III) concentrations in the initial and equilibrium aqueous phases with regard to the difference in the phase weights:

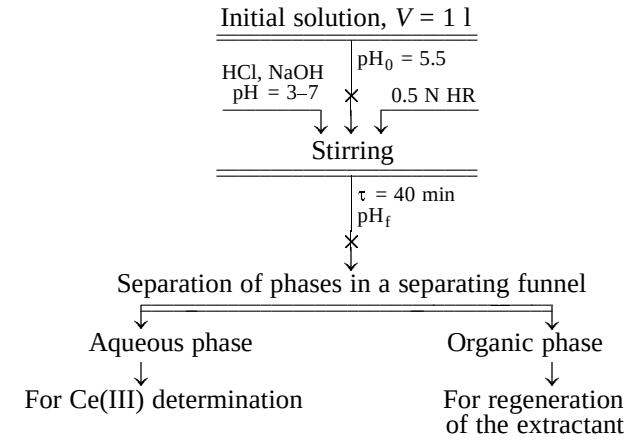
$$c_{org} = (c_0 - c_w)\frac{m_w}{m_{org}}, \quad (1)$$

where c_{org} is the equilibrium concentration of the metal in the organic phase (mol kg^{-1}); c_w, Ce(III) concentration in the equilibrium aqueous phase (mol kg^{-1}); c_0, initial content of cerium in the aqueous phase (mol kg^{-1}); and m_w/m_{org}, ratio of weights of the aqueous and organic phases (30 : 1 in our experiments).

The distribution ratio was calculated by the formula

$$D = c_{org}/c_w.$$

The liquid extraction of cerium(III) with the naphthenic acid solution in decane was studied within the pH 3–6.5 range (see scheme).



Scheme of the experiments on cerium(III) extraction.

* ε is the degree of Ce(III) recovery into the organic phase.

** Data for the HR expenditure of 3.6 and 2.4 mol mol^{-1} Ce(III) are given in the numerator and denominator, respectively.

The experiments were performed at various pH values and various expenditures of the naphthenic acid: at the expenditure equivalent to formation of neutral cerium(III) naphthenate in the extract, i.e., 3.6 mol of naphthenic acid per mole of cerium (20% excess), and at expenditure of 2.4 mol of naphthenic acid per mole of cerium, which corresponds to formation of basic cerium naphthenate. In the first case, an excess amount of free naphthenic acid was present, and in the second case, the acid was in deficiency and was fully bound into the solvate complex in the organic phase. Raisinh the pH to above 6.0 is not appropriate because of the precipitation of cerium(III) hydroxide, which begins at pH values close to 6 and is substantial at pH 6.5.

The experimental data are listed in Table 1. The dependence of the Ce(III) recovery into the organic phase on the pH of the equilibrium aqueous phase at various naphthenic acid expenditures is shown in Fig. 1. As can be seen, the maximum distribution ratio of cerium(III), 83.2 (degree of recovery 73.5%), is observed at pH equal to the pK_4 of naphthenic acid, 5.0–5.1. At the deficiency of the naphthenic acid with respect to the stoichiometry, the degree of Ce(III) recovery is lower by a factor of 1.5–2.

The dependences of the logarithm of the distribution ratio on the pH of the equilibrium aqueous phase

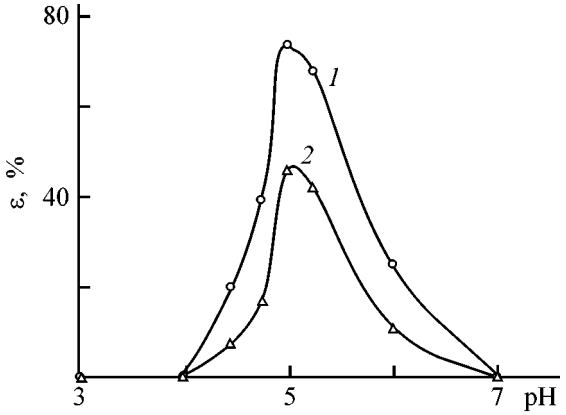

Fig. 1. Effect of pH on the degree of cerium(III) recovery ε. HR expenditure [mol mol^{-1} Ce(III)]: (*1*) 3.6 and (*2*) 2.4.

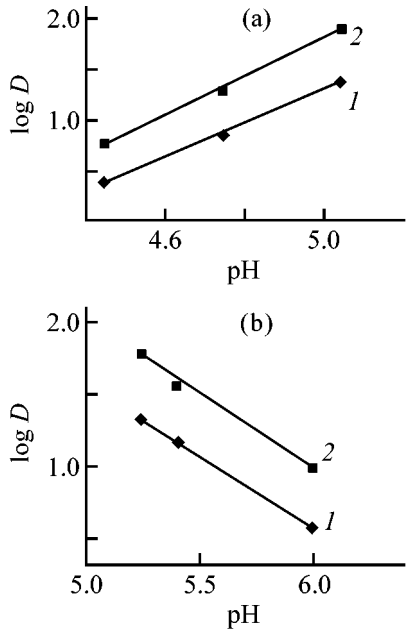

Fig. 2. Logarithm of the cerium(III) distribution ratio D vs. equilibrium pH of the aqueous phase at (a) pH < pK_a and (b) pH > pK_a.

were derived from the data of Table 1 (Figs. 2a, 2b). These dependences are described by the following linear equations with the confidence factors $R^2 > 0.99$:

$$\log D = 1.89\text{pH} - 7.654 \text{ (Fig. 2a, HR : Ce(III) = 3.6)}, \quad (2)$$

$$\log D = 1.67\text{pH} - 7.03 \text{ (Fig. 2a, HR : Ce(III) = 2.4)}, \quad (3)$$

$$\log D = -1.03\text{pH} + 7.16 \text{ (Fig. 2b, HR : Ce(III) = 3.6)}, \quad (4)$$

$$\log D = -1.00\text{pH} + 6.595 \text{ (Fig. 2b, HR : Ce(III) = 2.4)}, \quad (5)$$

It follows from the equation of formation of neutral cerium(III) naphthenate that the slope of these dependences should be 3. The experimental slopes [Eqs. (2)–(5)] are substantially lower, suggesting the extraction of cerium(III) hydroxo naphthenates. Hence, the following equations of extraction can be suggested:

$$\text{Ce(OH)}_{3-z}^{z+}\text{(w)} + z\,\text{HR(org)} \rightleftarrows \text{Ce(OH)}_{3-z}\text{R}_z\text{(org)} + z\,\text{H}^+\text{(w)}, \quad (6)$$

where z is the slope of straight lines described by Eqs. (2)–(5).

At pH < pK_a, this slope is positive, which means that, as the pH value increases, equilibrium (6) is shifted to the right, and at pH > pK_a, the slope is negative, and the equilibrium is shifted to the left. At pH = pK_a, the distribution ratio is at a maximum. The law of mass action for reaction (6) is

$$K = \frac{[\text{Ce(OH)}_{3-z}\text{R}_z\text{(org)}]a_{\text{H}^+}^z}{[\text{Ce(OH)}_{3-z}^{z+}\text{(w)}]\gamma_{z+}[\text{HR}]^z} = \frac{Da_{\text{H}^+}^z}{\gamma_{z+}[\text{HR}]^z}, \quad (7)$$

where the molal concentrations are denoted by brackets and γ_{z+} are the activity coefficients of cerium(III) hydroxo cations, calculated by the Davies equation [6]

$$\log \gamma_{z+} = -0.51z^2\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.2I\right), \quad (8)$$

where I is the ionic strength of the solution.

The ionic strength of the aqueous phase was 0.018 ± 0.009 mol kg^{-1}. The calculated logarithms of the activity coefficients are -0.06 ± 0.01 and -0.24 ± 0.04 for $[\text{Ce(OH)}_2]^+$ and $[\text{Ce(OH)}]^{2+}$, respectively. Equations (4) and (5) describe the backwashing $[\text{Ce(OH)}_2]^+$ complexes, and Eqs. (2) and (3), extraction of a mixture of $[\text{Ce(OH)}_2]^+$ and $[\text{Ce(OH)}]^{2+}$ complexes in a 1 : 4 ratio, which is indicated by the slope of 1.8 ± 0.1. Therefore, we used $\log \gamma = -0.20$ in the calculations. For neutral molecules and solvates, the activity coefficients were taken be unity.

The concentration of naphthenic acid in the organic phase at the HR : Ce(III) molar ratio of 3.6 and 2.4 was 0.5 and 0.33 mol kg^{-1}, respectively.

The logarithmic form of Eq. (7) is

$$\log D = \log K + \log \gamma_{z+} + z\log[\text{HR}] + z\,\text{pH}. \quad (9)$$

It corresponds to empirical Eqs. (2) and (3).

The thermodynamic equilibrium constant was calculated from the absolute terms of Eqs. (2), (3) (they were denoted by a):

$$\log K = a - \log \gamma_{z+} - z\log[\text{HR}]. \quad (10)$$

Equations (4) and (5) correspond to the backwashing reaction, whose constant is equal to the reciprocal constant of the direct reaction. Then, we obtain from Eqs. (2) and (4), respectively:

$$\log K = -7.654 + 0.20 - 1.89\log 0.5 = -6.88,$$

$$\log K = -7.16 + 0.06 - \log 0.5 = -6.80.$$

The average value of the extraction constant from two independent empirical dependences is $(1.4 \pm 0.2) \times$

Table 2. Constants and Gibbs energies of cerium salt extraction

Extractant	pH	D	K	ΔG^0_{298}, kJ mol^{-1}
Naphthenic acid [Eq. (11)]	5.1	83.2	623 ± 60	-16.0 ± 0.2
TABAS [8], $c_{MgSO_4} = 2$ mol kg^{-1}	1.6–4	35 ± 4	35 ± 4	-8.9 ± 0.3
TBP [3], $c_{MgSO_4} = 2.5$–3 mol kg^{-1}	3	26.4 ± 0.4	10.9 ± 0.1	-5.92 ± 0.03

10^{-7}. The corresponding Gibbs energy is 39.04 ± 0.2 kJ mol^{-1}. We obtain from Eqs. (3) and (5), respectively:

$$\log K = -7.03 + 0.20 - 1.67 \log 0.33 = -6.03,$$

$$\log K = -6.595 + 0.06 - \log 0.33 = -6.05.$$

The average value of the equilibrium constant is $(9.1 \pm 0.2) \times 10^{-7}$. The corresponding Gibbs energy is 34.47 ± 0.2 kJ mol^{-1}. The difference in the constants and Gibbs energies at an excess and a deficiency of naphthenic acid can be accounted for by different mechanisms of the process. At the acid deficiency, anions of the cerium(III) salt can be incorporated into the solvate. Hereinafter we will use the thermodynamic characteristics obtained at the molar ratio of naphthenic acid to Ce(III) equal to 3.6, i.e., at a 20% excess of the extractant.

Taking into account the independence of the extraction constant and Gibbs energy on z within the range studied, $1 < z < 2$, we can calculate the Gibbs energy of formation of the solvate from simple ions by the reaction

$$Ce^{3+}(w) + (3 - z)OH^-(w) + zR^-(org) \rightleftarrows Ce(OH)_{3-z}R_z(org). \quad (11)$$

Calculations were performed for $z = 2$. The Gibbs energy of solvation is given by

$$\Delta_{solv} G^0_{298} = \Delta_{extr} G^0_{298} + \Delta_{compl} G^0_{298} - \Delta_{dis} G^0_{298}. \quad (12)$$

Formula (12) includes the Gibbs energies of solvation, extraction, formation of the hydroxo complex from Ce^{3+} ions, and dissociation of naphthenic acid, respectively. $\Delta_{compl} G^0_{298}$ was calculated from the reference data [7] to be –25.9 kJ mol^{-1}, and $\Delta_{dis} G^0_{298}$, from the dissociation constant, to be 29.1 kJ mol^{-1}. The Gibbs energy of solvation (from ions), was obtained equal to -16.0 ± 0.2 kJ mol^{-1}. It corresponds to the equilibrium constant of 623 ± 60. Since the maximum distribution coefficient of Ce(III) is 83.2 (this indicates the shift of the equilibrium toward extraction), it is reasonable to use the constant and Gibbs energy of formation of the solvate from simple ions, in accordance with Eq. (11), as the thermodynamic characteristics of the extraction.

The thermodynamic constants of cerium(III) nitrate extraction with neat tri-*n*-butyl phosphate (TBP) [3], 0.5 M solution of naphthenic acid in decane, and extraction of cerium(III) sulfate with a 0.5 M solution of trialkylbenzylammonium sulfate (TABAS) in *o*-xylene [8] are compared in Table 2.

As can be seen, the efficiency of extractants increases in the order TBP < TABAS ≪ naphthenic acid. The extraction with naphthenic acid proceeds without a salting-out agent. This gives an additional benefit and diminishes the pollution of the environment. In addition, TBP was used neat, and TABAS and naphthenic acid, as 0.5 M solutions in organic diluents; also the cost of naphthenic acid is hundreds of times lower than that of TBP and TABAS.

CONCLUSIONS

(1) The distribution ratio in extraction of cerium(III) with a 0.5 M solution of naphthenic acid in decane is at a maximum, 83.2, at pH = pK_a = 5.1 and the molar ratio of naphthenic acid to cerium(III) equal to 3.6. Under these conditions, a mixture of cerium(III) hydroxodinaphthenate and dihydroxonaphtenate at 4 : 1 molar ratio is extracted. The equilibrium constant and Gibbs energy of this process are 623 ± 60 and -16.0 ± 0.2 kJ mol^{-1}, respectively.

(2) The efficiency of extraction increases in the order tributyl phosphate (100%) < 0.5 M solutions of trialkylbenzylammonium salts in *o*-xylene ≪ 0.5 M solution of naphthenic acid in decane.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Complexation of Sterically Hindered Cobalt Porphyrin with 1-Methylimidazole along the Axial Coordinate and the Reaction of Reversible Binding of Oxygen

A. B. Valiotti and R. A. Abakumova

St. Petersburg State University, St. Petersburg, Russia

Received December 19, 2003; in final form, June 2004

Abstract—The complexation of a sterically hindered cobalt porphyrin with 1-methyl imidazole and its reaction of reversible binding of oxygen was studied. Spectrophotometry and potentiometry were used to determine the equilibrium constant of the oxygenation process.

In the last decade, methods for synthesis and study of properties of model compounds of natural porphyrins reversibly binding oxygen have been developed successfully. Synthetic oxygen transporting agents of this kind find use as blood substitutes, gas sorbents, and materials for recovery of oxygen from liquid media [1–4].

Monitoring the partial pressure of oxygen in gases, liquids, and semi-liquid media is an important task in most of biochemical investigations and technological processes. It is of indubitable interest, in this context, to develop a potentiometric sensor for measuring the partial pressure on the basis of a redox system that contains cobalt porphyrin and reversibly binds oxygen [5]. A necessary stage in this case is a study of the properties of the cobalt porphyrin.

The goal of this study was to examine the complexation of sterically hindered cobalt(II) meso-tetra(α,α,α,α-*ortho*-pivalamidophenyl)porphyrin [Co(II)TPivPP] with 1-methylimidazole along the axial coordinate and the reaction of reversible binding of oxygen.

EXPERIMENTAL

The meso-tetra(α,α,α,α-*ortho*-pivalamidophenyl)-porphyrin was synthesized by the procedure suggested by Collman [6]. The compound [Co(II)TPivPP] was obtained by heating free porphyrin with $CoCl_2$ in a flow of argon under constant stirring in a solution of tetrahydrofuran [7]. The purity of the products synthesized was verified chromatographically and using spectra. The complexation with 1-methylimidazole was studied spectrophotometrically. In the experiments, the dependence of the optical density of [Co(II)TPivPP] solutions in propyl cyanide on the concentration of 1-methylimidazole was determined at a fixed wavelength and analyzed. Propyl cyanide was chosen as the solvent because it has a sufficiently high dielectric constant (ε = 20.3) and does not react with metal porphyrins. As supporting electrolyte served tetrabutylammonium perchlorate (TBAP), c(TBAP) = 0.1 M. All the measurements were performed in quartz cuvettes of thickness 0.1 and 1.0 cm on an SF-18 spectrophotometer. The titration with a solution of 1-methylimidazole was performed directly in the cuvette. The titrant was added dropwise to a solution of [Co(II)TPivPP] in the atmosphere of argon and a spectrum of the solution was recorded upon each addition. All the measurements were carried out at a temperature of 20 ± 0.5°C. Figure 1 shows the experimental data in the form of a dependence of the optical density $A(\lambda_{532})$ of the [Co(II)TPivPP] solution on the concen-

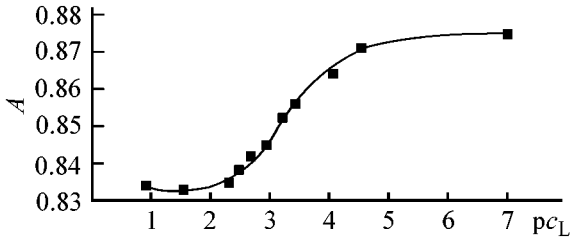

Fig. 1. Optical density A (λ = 532 nm) of the [Co(II)TPivPP] solution vs. the pc_L of 1-methylimidazole.

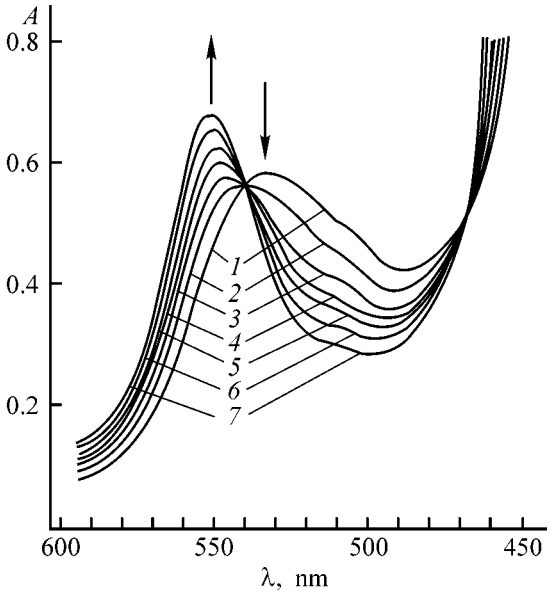

Fig. 2. Spectra of [Co(II)TPivPP] solutions in propyl cyanide in the presence of 1 M of 1-methylimidazole and 0.1 M of TBAP at different partial pressures of oxygen. (*A*) Optical density and (λ) wavelength. P_{O_2} (mm Hg): (*1*) 0, (*2*) 38, (*3*) 84, (*4*) 114, (*5*) 190, (*6*) 380, and (*7*) 760.

tration of 1-methylimidazole (pc_L). The first stage of the reaction of axial complexation of [Co(II)TPivPP] with 1-methylimidazole can be represented as

$$[\text{Co(II)TPivPP}] + \text{L} = [\text{Co(II)TPivPPL}], \quad (1)$$

where L is 1-methylimidazole.

Introduction of 1-methylimidazole into a porphyrin solution leads to a decrease in the optical density at λ = 532 nm. It can be shown, with account of this circumstance, that the dependence of the optical density of the solution on the ligand concentration c_L can be expressed as

$$A = \frac{A_0 + A_1 K_1 c_L}{1 + K_1 c_L}, \quad (2)$$

where A is the optical density measured in the experiment; A_0, optical density of a solution without ligand; A_1, optical density of a solution in which the complexation is complete; and K_1, complexation constant found from the equation

$$K_1 = \frac{[\text{Co(II)TPivPPL}]}{[\text{Co(II)TPivPP}][\text{L}]}.$$

The experimental dependence is described by a smooth single-step curve, which is due to the occurrence of the reaction of 1-methylimidazole addition by Eq. (1). The logarithm of the stability constant for [Co(II)TPivPP] with 1-methylimidazole, calculated by Eq. (2), is 3.3 ± 0.2. The data obtained suggest that, at a 1-methylimidazole concentration of 0.1 M, the complexation in the system constituted by porphyrin and 1-methylimidazole is complete. This result is of primary importance for a study of the reaction in which oxygen is reversibly bound in the presence of 1-methylimidazole.

The reversible binding of O_2 was studied by means of spectrophotometry in a hermetically sealed quartz cuvette. The partial pressure of O_2 was set by mixing argon and oxygen in various volume ratios at 1 atm in calibrated gas meters. Each mixture of gases, preliminarily dried over KOH, was bubbled through the cuvette for 20 min, and the spectrum of the solution was recorded after that. All the measurements were performed at a temperature of 20 ± 0.5°C.

It is known that, in the presence of an axial ligand, 1-methylimidazole, and O_2 in a [Co(II)TPivPP] solution, there exist the equilibrium

$$[\text{Co(II)TPivPPL}] + O_2 \rightleftarrows [\text{Co(II)TPivPPLO}_2], \left(K_{O_2}\right). \quad (3)$$

The fact that logarithm of the stability constant of [Co(II)TPivPP] with 1-methylimidazole has a value of 3.3 ± 0.2 shows that the complex [Co(II)TPivPPL] is formed to an extent exceeding 99% at a 1-methylimidazole concentration of 1 M. To determine K_{O_2}, spectra of a [Co(II)TPivPP] solution in propyl cyanide were recorded in the presence of 0.1 M of 1-methylimidazole and 0.1 M of TBAP at different partial pressures of O_2. Typical changes in the spectrum of a [Co(II)TPivPPL] solution in propyl cyanide in the presence of O_2 are shown in Fig. 2. It can be seen that, as the concentration of O_2 increases, the peak at 534 nm, associated with the deoxygenated form, is shifted to longer wavelengths, and a new peak associated with the oxygenated form appears at 552 nm.

Two clearly pronounced isobestic points are observed at 540 and 470 nm, which points to the presence of two interconvertible species in the solutions. In deoxygenation of the solution by bubbling of argon, the spectrum changes in the opposite direction and virtually coincides with the initial spectrum, i.e., the starting cobalt porphyrin is oxidized only slightly. It should be noted that the oxygenated form Co(II)TPivPPLO_2 and the oxidized species Co(II)TPivPPL^+ have the same spectrum. K_{O_2} was calculated using the Drago equation [6]

$$P_{1/2} = K_{O_2}^{-1} = P_{O_2}\left(\frac{[CoP]_{tot} l \Delta\varepsilon}{\Delta A} - 1\right), \quad (4)$$

where $[CoP]_{tot}$ is the total concentration [Co(II)TPivPP] in solution; l, cuvette thickness; $\Delta\varepsilon$, difference of the absorption coefficients of the oxygenated and deoxygenated species; and ΔA, difference of the optical densities at a certain P_{O_2} and in the absence of oxygen.

This equation is convenient in that it does not require any knowledge of the optical density of the oxygenated form, because the oxygenation is not complete even at P_{O_2} = 1 atm and 0°C. Transformation of Eq. (4) yields

$$P_{O_2} = [CoP]_{tot} l \Delta\varepsilon\left(P_{O_2}/\Delta A\right) - P_{1/2}. \quad (5)$$

The plot of P_{O_2} against $(P_{O_2}/\Delta A)$ is a straight line with a slope equal to $[CoP]_{tot} l \Delta\varepsilon$. This plot (Fig. 3) was used to determine K_{O_2}.

At a temperature of 20 ± 0.5°C in propyl cyanide in the presence of 0.1 M of TBAP, $P_{1.2}$ = 140 ± 7 mm Hg ($K_{O_2} = 7.2 \times 10^{-3}$).

The reversible binding of O_2 was also studied by means of potentiometry and, in particular, by the method of the oxidation potential [8]. The equation for the oxidation potential φ of the system Co(II)TPivPPL–Co(III)TPivPPL$^+$ can be written as

$$\varphi = \varphi^0 + \vartheta \log \frac{[Co(III)TPivPPL^+]}{[Co(II)TPivPPL]}, \quad (6)$$

where $\vartheta = 2.3RT/F$ and the concentrations of the oxidized and reduced forms of the redox system are given in the square brackets.

It was shown preliminarily that the oxidation potential of this system at a 1-methylimidazole concentration $c \geq 0.1$ M is independent of pc_L, which indicates the formation of complexes of the same composition for the oxidized and reduced forms. If reaction (1) is regarded as complexation of Co(II)TPivPPL with O_2, then the material balance equations can be written as

$$c^O = [Co(III)TPivPPL^+],$$

$$c^R = [Co(II)TPivPPL] + [Co(II)TPivPPLO_2]$$

$$= [Co(II)TPivPPL]\left(1 + K_{O_2}P_{O_2}\right), \quad (7)$$

where

$$K_{O_2} = \frac{[Co(II)TPivPPLO_2]}{[Co(II)TPivPPL]P_{O_2}},$$

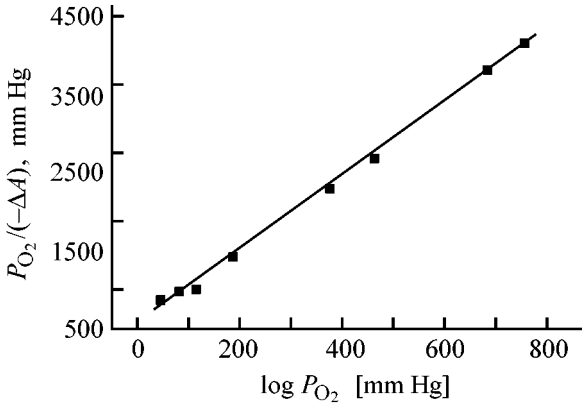

Fig. 3. $P_{O_2}/\Delta A$ vs. the partial pressure of oxygen, P_{O_2}. λ = 530 nm, c(TBAP) = 0.1 M, T = 25°C.

and c^O and c^R are the total concentrations of the oxidized and reduced forms of cobalt porphyrin.

With account of (7), the equation for the oxidation potential is transformed into

$$\varphi = \varphi^0 + \vartheta \log\left(c^O/c^R\right) + \vartheta \log\left(1 + K_{O_2}P_{O_2}\right),$$

and then, at constant concentrations c^O and c^R,

$$\varphi = \varphi_0 + \vartheta \log\left(1 + K_{O_2}P_{O_2}\right), \quad (8)$$

where $\varphi_0 = \varphi^0 + \log\left(c^O/c^R\right)$.

It follows from Eq. (8) that at high P_{O_2}, when $K_{O_2}P_{O_2} >> 1$, the dependence φ–log P_{O_2} must be linear with a slope equal to ϑ.

The experimental study consisted in finding the dependence φ–log P_{O_2}. The oxidation potential was determined by measuring the electromotive force of the galvanic cell Hg | Hg_2Cl_2, LiCl(sat.) || solution under study | Pt.

All the measurements were performed at 25°C. The concentration of 1-methylimidazole was 0.1 M. The ionic strength was maintained with 0.1 M of TBAP. The cobalt porphyrins Co(II)TpivPP and Co(III)TPivPP$^+$ were taken in a 1 : 1 molar ratio.

The experimental dependence E–log P_{O_2} is shown in Fig. 4. The oxidation potential φ is given relative to a saturated calomel electrode. It can be seen that this dependence is represented by a straight line at high P_{O_2}, in agreement with Eq. (8). At P_{O_2} = 0, φ = φ_0. The graphically found φ_0 made it possible to calculate, using Eq. (8), K_{O_2}($K_{O_2} = 1/P_{1/2}$) and, accordingly, $P_{1/2}$. The calculation was performed using the values of P_{O_2} falling within the range in which the dependence φ–log P_{O_2} is linear. The averaged value of

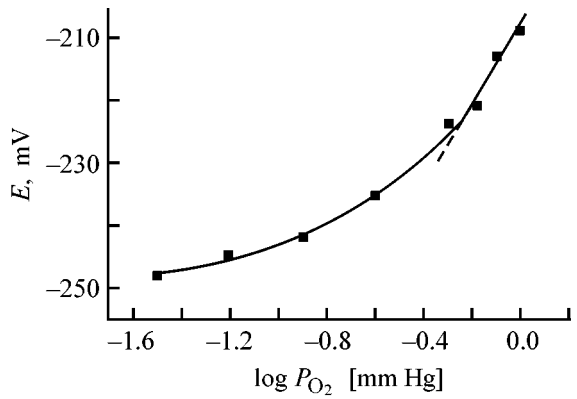

Fig. 4. Oxidation potential E of a solution of the redox system Co(II)TPivPPL–Co(III)TPivPPL$^+$ in propyl cyanide in the presence of 1-methylimidazole (1-MeIm) vs. log P_{O_2}. c(1-MeIm) = 0.1 M, c(TBAP) = 0.1 M, T = 25°C.

$P_{1/2}$ is 160 mm Hg, i.e., the results of spectrophotometric and potentiometric studies are in agreement within the experimental error.

CONCLUSION

The functional dependence of the oxidation potential of the redox system Co(II)TPivPPL–Co(III)TPivPPL$^+$ on the partial pressure of oxygen was determined on the basis of experimental data.

These results can be used to design a potentiometric sensor for molecular oxygen in aqueous solution and to assess the region and limits of its applicability.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Light Fullerenes C_{60} and C_{70} on NORIT-AZO Carbon

K. N. Semenov, V. I. Seregin, O. V. Arapov, and N. A. Charykov

St. Petersburg State University, St. Petersburg, Russia

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received April 29, 2004

Abstract—Sorption of fullerenes C_{60} and C_{70} from *o*-xylene, toluene, and dichlorobenzene solutions on NORIT-AZO carbons was studied.

Fullerenes can be regarded as a new form of hyperconcentrated carbon [1, 2]. Their molecules consist of five- and six-membered carbon rings forming balls. The ratio of hexagons and pentagons is determined by the isolated pentagon rule (IPR). Although the sp^2 orbitals are situated on a spherical surface, the fullerene molecules have a common π-electron system and are similar to aromatic compounds [3].

The fundamental parameters of fullerenes are the electron affinity *EA* and the ionization energy *IE*. For C_{60}, $EA = 2.667 \pm 0.001$ eV and $IE = 7.57 \pm 0.01$ eV [4]. It should be noted that the *EA* of fullerenes is higher than that of aromatic compounds, i.e., fullerenes are relatively strong electron acceptors. Since fullerenes have relatively high *EA* and low *IE*, they can be both donors and acceptors of electrons. In the solid state, C_{60} molecules are bound by van der Waals for us [5].

Isolation of pure fullerenes, i.e., by chromatographic separation of their mixtures is a problem of current interest [6]. The solution of this problem involves a study of fullerene sorption and development and synthesis of new sorbents. There are two types of sorption: physical sorption (van der Waals and electrostatic interactions between the adsorbate and adsorbent) and chemisorption (formation of chemical, usually covalent bonds between the adsorbent and adsorbate).

Apparently fullerenes C_{60} and C_{70} are physically sorbed from the solution on unmodified activated carbon. In this case, the adsorbent–adsorbate interaction is long-range and weak and the enthalpy of sorption is of the same order of magnitude as the enthalpy of condensation. The energy of separation can be transformed into vibrations of the sorbent lattice or released as a heat. Clearly, the first pathway prevails in our case.

The energy of intermolecular interaction consists of orientation, induction, and dispersion components

$$U(r) = U_{or} + U_{ind} + U_{disp}. \quad (1)$$

The dispersion forces are caused by fast fluctuations of the electron density in each atom which induce an electric moment in the nearest neighbor and thereby lead to interaction between atoms. The induction interaction is due to polarization of a molecule in the electrostatic field of another molecule. Since fullerene molecules (especially C_{60}) are relatively difficultly polarized, this interaction is weak. The orientation interactions are caused by permanent dipole moments of molecules. In our case, this interaction is absent, since all unsubstituted fullerene molecules are spheroids or quasiellipsoids of revolution and are nonpolar.

Sorption from solutions is a more complex process than sorption of gases. In this case, not only the force field of the solid phase but also intermolecular interactions in the liquid phase should be taken into account. In addition, sorption from the liquid phase is complicated by the competing sorption of the solvent [7, 8].

In this study, we examined the sorption of fullerenes C_{60} and C_{70} from oxylene, toluene, and dichlorobenzene solutions on NORIT-AZO carbon. This study was encouraged by the possibility of complete chromatographic separation of components of a fullerene mixture [9, 10].

EXPERIMENTAL

We used fullerene C_{60} containing 99.9 wt % main compound (0.1 wt % C_{70}) and C_{70} containing 99 wt %

1070-4272/04/7710-1627 © 2004 MAIK "Nauka/Interperiodica"

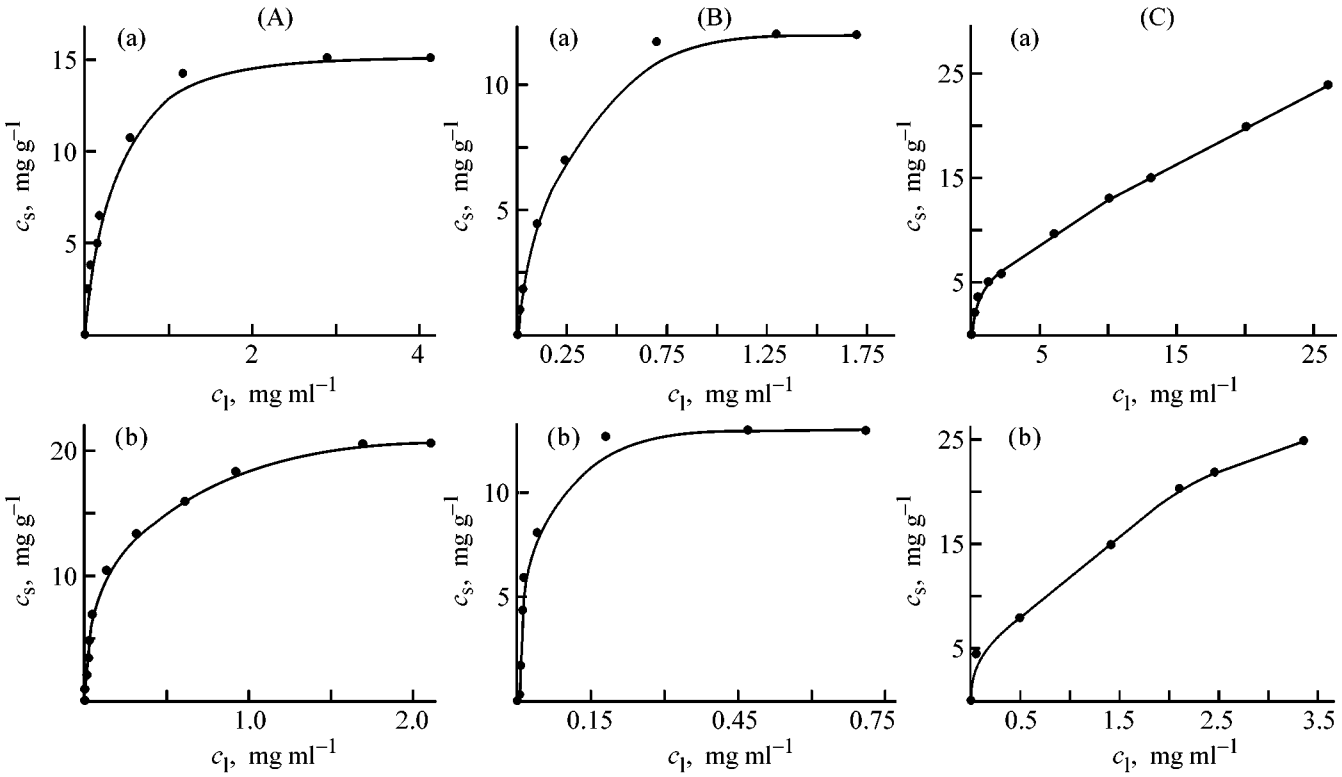

Fig. 1. Isotherms of adsorption of (a) C_{60} and (b) C_{70} from (A) *o*-xylene, (B) toluene, and (C) *o*-dichlorobenzene on NORIT-AZO carbon at 25°C. Sorbent weight $m \sim 1$ g, solution volume $V \sim 10$ ml. (c_s, c_l) Fullerene concentrations in the solid and liquid phases, respectively.

main compound (1 wt % C_{60}) (ILIP Joint-Stock Company). *o*-Xylene, *o*-dichlorobenzene, and toluene were of analytically pure grade. NORIT-AZO carbon (average grane size of the main fraction 75–90 μm, specific surface area ~250 m^2 g^{-1}).

To study the sorption properties of the carbon, concentrated stock solutions of the fullerenes in the above solvents were prepared by isothermal saturation at 25°C for 24 h. The concentration of C_{60} and C_{70} in *o*-xylene, toluene, and *o*-dichlorobenzene was 4.1 and 2.3, 1.3 and 0.46, and 26 and 3.3 g l^{-1}, respectively. Less concentrated solutions in all of these solvents were prepared by successive dilutions.

To weighed portions of the carbon (1 g) predried at 150°C for 3 h, 10 ml aliquots of the fullerene solutions of different concentrations were added. The mixture was magnetically stirred for 3 days at 25°C. This time is required for an equilibrium to be attained in the carbon–solution system. The mixture was filtered through a Schott filter (porosity 16) to remove the sorbent, and the fullerene content in the resulting solution was determined.

The content of C_{60} and C_{70} in the solutions before and after the sorption was determined spectrophotometrically on an SF-46 spectrophotometer operating at λ = 335.5 and 472.0 nm [11]. The concentrations were calculated by the following equations:

$$c(C_{60}) = 13.10(D_{335} - 1.808D_{472}), \quad (2)$$

$$c(C_{70}) = 42.51(D_{472} - 0.00810D_{335}), \quad (3)$$

where D_{335} and D_{472} are the optical densities of a 1-cm layer of the solution; $c(C_{60})$ and $c(C_{70})$ are the fullerene concentrations (g l^{-1}) [11].

The isotherms of fullerene sorption from *o*-xylene, toluene, and dichlorobenzene on ZORIT-AZO carbon are shown in Figs. 1A–1B.

In all the cases, except with *o*-dichlorobenzene solutions, the sorption isotherms exibit a sharp increase in sorption in the fist steps and smoother adsoption growth with further increase in the fullerene concentration in the solution. At fullerene concentrations $c < 0.1$ g l^{-1}, the slopes of the initial portions of the isotherms are approximately equal for both fullerenes, both in toluene and in *o*-xylene, and differences appear at higher concentrations.

It should be noted that the isotherms measured in toluene level of at lower fullerene concentration than the isotherms measured in *o*-xylene. The saturation of sorption isotherms in toluene is due to the physical sorption without specific adsorbate–adsorbent interactions. In *o*-dichlorobenzene, the sorbent is not saturated because of chemical interactions at high fullerene concentrations. In this case, fullerene association in the solution [19, 20] or layer-by-layer condensation of fullerenes on the sorbent surface is possible.

All sorption isotherms measured in toluene and *o*-xylene are of Langmuir type. This is not the case for *o*-dichlorobenzene solutions.

It should also be noted that adsorption of fullerenes depends on their solubility [12]. It is known [13, 14] that fullerenes dissolve by the cluster mechanism. Aggregation of fullerenes in a solution affects their thermodynamic parameters. As a result, the phase equilibrium is shifted and the fullerene solubility changes [15]. Fullerenes are almost insoluble in polar solvents [16]. The solubility of a fullerene is the highest if the ratio of the enthalpy of vaporization of the solvent to the volume of the solvent molecule is close to the similar ratio for the fullerene. The solubility of C_{60} and C_{70} in *o*-xylene, toluene, and *o*-dichlorobenzene at 25°C is 8.7 and 14.3, 2.8 and 1.4, and 27.0 and 36.2 g l^{-1}, respectively.

The effect of solubility on the sorption isotherms can be estimated by the height of the plateau (Figs. 1A–1C), which, in turn, characterizes the static sorption capacity of the carbon for the fullerenes. As can be seen from Figs. 1A–1C, the static sorption capacity for C_{60} and C_{70} in *o*-xylene, toluene, and *o*-dichlorobenzene (milligrams of fullerene per 1 g of the sorbent) is 15.5 and 21.3, 14.1 and 14.3, and >24 and >25, respectively. In *o*-xylene, the sorption capacity does not level off (Fig. 1C). These sorption capacities are appreciably higher than those of carbon sorbents studied previously [17–20].

The dependence of the distribution coefficients of C_{60} and C_{70} between NORIT-AZO carbon and *o*-xylene, toluene, and *o*-dichlorobenzene on the fullerene concentration in the liquid phase at 25°C is shown in Figs. 2a and 2b. The error of determination of the fullerene concentration in the solution and in the solid phase is 3 and 5 rel%, respectively. Hence, the determination error of the distribution coefficients is about 6 rel. %.

As can be seen from Figs. 2a and 2b, the distribution coefficients are only slightly dependent on the solvent (the curves almost coincide). The only difference is observed in dilute *o*-dichlorobenzene solution of C_{60}. In all cases, the distribution coefficients monotonically decreases with increasing fullerene concen-

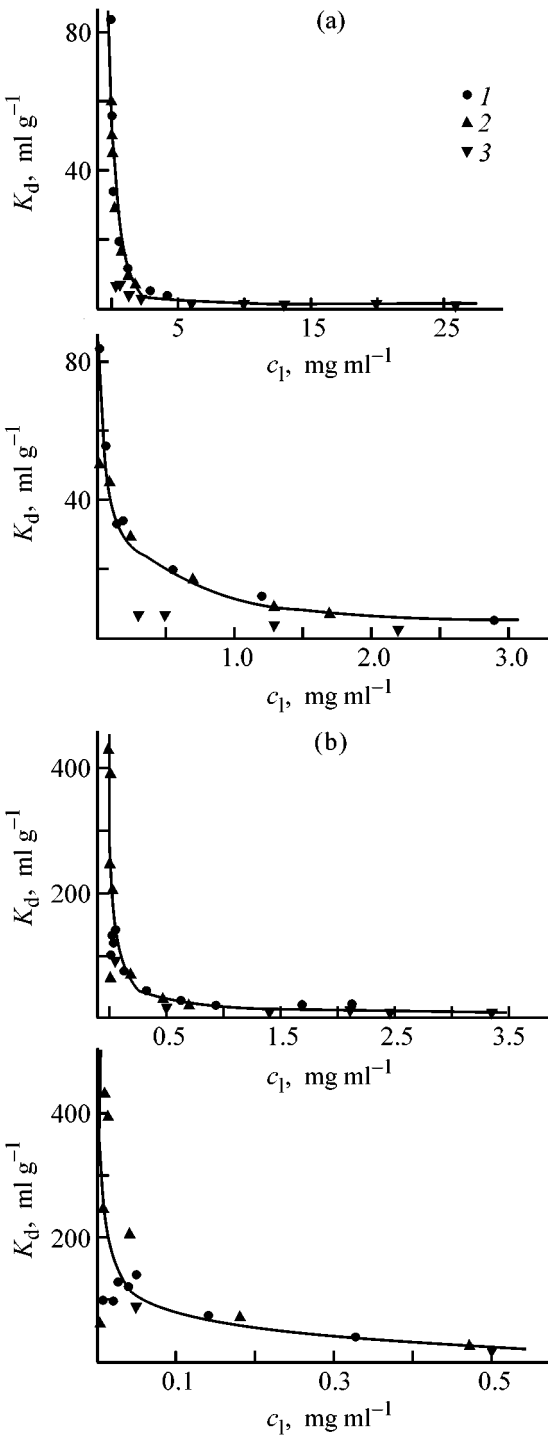

Fig. 2. Distribution coefficients $K_d = c_s/c_l$ of (a) C_{60} and (b) C_{70} fullerenes between NORIT-AZO carbon and (*1*) *o*-xylene, (*2*) toluene, and (*3*) *o*-dichlorobenzene vs. the fullerene concentration in the liquid phase c_l at 25°C.

tration in both phases. The distribution coefficients of C_{70} are almost always several times higher that those of C_{60}, which creates prerequisites for chromatographic separations of these fullerenes. The only exceptions are highly concentrated fullerene solutions (>5 g l^{-1}). In this case, the distribution coefficients of C_{60} and C_{70} become close, which makes chromatographic separation ineffective.

CONCLUSIONS

(1) Isotherms of fullerene adsorption from *o*-xylene, toluene, and dichlorobenzene solution at 25°C were measured and characterized.

(2) The sorption properties of NORIT-AZO carbons with respect to fullerenes are fairly good. The different sorption capacities of carbon for C_{60} and C_{70} fullerenes makes it promising for industrial separation of fullerenes.

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received December 17, 2003; in final form, April 2004

Abstract—Adsorption of nickel *N,N*-ethylenebis(salicylideneimine) complex from acetonitrile solution on expanded natural graphite powder at 273–313 K is studied.

The chemistry of conducting polymers and molecular modification of electrode surfaces are thriving branches of modern chemical science. In the last decade, a number of new complexes of transition metals with Schiff bases have been synthesized [1–4]. These polymeric compounds demonstrate high electron conduction, stability, and electrochromic and catalytic properties [3]. The polymerization is always accompanied by adsorption of monomers on the electrode surface. However, to our knowledge, there are no published data on the adsorption of the complexes indicated. Therefore, we examined in this study the adsorption of nickel *N,N*-ethylenebis(salicylideneimine) complex [Ni(SalEn)] on graphite.

Experimental data on adsorption of organic compounds on metal surfaces are often described by the Frumkin isotherm (1).

$$\frac{\Gamma}{\Gamma_{max}-\Gamma}\exp\left(-2a\frac{\Gamma}{\Gamma_{max}}\right) = Bc_{org} = BX_{org}\Sigma n, \quad (1)$$

where Γ and Γ_{max} are the current and limiting numbers of moles of a surfactant that can be adsorbed on unit surface area (mol); a and B, attraction and adsorption constants; c_{org} and X_{org}, concentration (M) and mole fraction of the surfactant; and Σn is the total number of moles contained in 1 l of the solution.

Since the common case is that $c_{org} \le 0.1$ M, it may be accepted that Σn is equal to the solvent concentration in the solution. It is known that

$$\ln(B\Sigma n) = -\Delta G_A^0/RT, \quad (2)$$

where ΔG_A^0 is the standard Gibbs energy of adsorption, corresponding to the asymmetric standard state in the bulk of solution [6]. At $a = 0$, the Frumkin isotherm transforms to the Langmuir isotherm [7]:

$$1/c_{org} = B\Gamma_{max}/\Gamma - B. \quad (3)$$

From experimental dependences of Γ on c_{org}, we can calculate the adsorption term B, and then, using Eq. (2), find the standard Gibbs energy of adsorption ΔG_A^0. In a previous communication [6], we suggested to calculate parameters Γ_{max}, a, and B of the Frumkin isotherm using the Origin software package.

If the symmetric standard state is chosen for the bulk of solution, the Frumkin isotherm should be represented as [6]:

$$\frac{\Gamma}{\Gamma_{max}-\Gamma}\exp\left(-2a\frac{\Gamma}{\Gamma_{max}}\right) = B'\gamma_{org}X_{org}. \quad (4)$$

Here $B' = \exp[-\Delta G_{ads}^0/RT]$ is the dimensionless parameter; ΔG_{ads}^0, standard Gibbs energy of adsorption, corresponding to the symmetric standard state; and γ_{org}, activity coefficient of the surfactant in the bulk of solution.

According to [6], if $c_{org} \le 0.1$ M, then

$$\Delta G_{ads}^0 \simeq \Delta G_A^0 + RT\ln\gamma_{org}^\infty, \quad (5)$$

where γ_{org}^∞ is the activity coefficient of the surfactant at infinite dilution.

The activity coefficient γ_{org}^∞ is the characteristic of the solution, which can range from unity to 10^3–10^5, depending on the nature of a surfactant and solvent [8]. The parameter ΔG_A^0 in Eq. (5) depends both on the properties of the surfactant solution and on the metal–surfactant binding energy, while the parameter

1070-4272/04/7710-1631 © 2004 MAIK "Nauka/Interperiodica"

$RT \ln \gamma_{org}^{\infty}$, only on the bulk properties of the solution. Therefore, the standard Gibbs energy of adsorption, ΔG_{ads}^0, characterizes the binding of the organic molecule to the metal.

If a surfactant is poorly soluble, the activity coefficient γ_{org}^{∞} can be approximately calculated by Eq. (6) [8].

$$RT \ln \gamma_{org}^{\infty} \approx -RT \ln X_{org}^{sat}, \quad (6)$$

where X_{org}^{sat} is the concentration of the saturated solution.

The standard enthalpy of adsorption can be calculated the using well-known equation [9]:

$$\Delta H_{ads}^0 = \Delta G_{ads}^0 + T\Delta S_{ads}^0, \quad (7)$$

where ΔS_{ads} is the standard entropy of adsorption.

Since the adsorption of a surfactant is always accompanied by displacement of ν solvent molecules from the metal or oxide surface to the bulk of the solution, we have

$$\Delta H_{ads}^0 = (\Delta H_{ads}^0)_{suf} - \nu(\Delta H_{ads}^0)_s. \quad (8)$$

where $(\Delta H_{ads}^0)_{sur}$ and $(\Delta H_{ads}^0)_s$ are the standard enthalpies of adsorption, related to adsorption of the surfactant and desorption of the solvent, respectively.

The goal of this study is to determine the parameters ΔG_{ads}^0 and ΔH_{ads}^0 characterizing the binding of Ni(SalEn) to the graphite surface. For this purpose it was needed to obtain the adsorption isotherms at various temperatures.

The numbers of moles of the adsorbed substance on the surface of the graphite powder was calculated by

$$\Delta n = (c_{org}^0 - c_{org})V, \quad (9)$$

where c_{org}^0 and c_{org} are the surfactant concentrations in the initial and equilibrium solutions, respectively; and V is the solution volume.

The Δn is accepted to be the surface concentration. Then we can write

$$\Gamma = \Delta n/A, \quad (10)$$

where A is the specific surface area of graphite.

The spectrum of monomeric Ni(SalEn) contains in its UV part three bands at 252, 325, and 420 nm. The optical density is a linear function of the monomer concentration, which allows determination of c_{org}^0 and c_{org} from Eq. (9). It was demonstrated in separate experiments that the band at 325 nm is best suitable for determining the monomer concentration in the solution bulk, and also that the time of contact of the solution with graphite can be reduced from 2 h to 10 min. The spectra were recorded on an SF-2000 spectrophotometer.

In the study, we used thermally expanded natural graphite of 99.9% purity.[1]

Above 150°C, the surface area of graphite increases dramatically. Incomplete removal of gases from the powder results in overestimation of the BET surface area of graphite. It is this circumstance that is responsible for such a low experimental value of A (0.4–1 $m^2 g^{-1}$; 0.7 ± 0.2 $m^2 g^{-1}$ on the average) determined by the BET method. For more exact determination of the specific surface area of the graphite powder, we studied the adsorption of β-naphthol from aqueous solutions at 19 ± 1°C. Then we calculated the parameters characterizing the adsorption of β-naphthol on graphite by Eqs. (1), (9), and (10) at $A_{ef} = 1$ $m^2 g^{-1}$ using the Origin software package. We obtained $\Gamma_{max}^{ef} = 2.65 \times 10^{-6}$ mol m^{-2}. The specific surface area of the graphite powder can be calculated by Eq. (11).

$$A = \frac{\Gamma_{max}^{ef}}{\Gamma_{max}} A_{ef}. \quad (11)$$

Our previous study of the adsorption of β-naphthol on the α-Fe_2O_3 surface [10] revealed that the surfactant molecules are oriented normally to the surface, since $\Gamma_{max} = 5.7 \times 10^{-6}$ mol m^{-2} and $\Delta G_A^0 = -24$ kJ mol^{-1} [Eq. (2)]. In studying the adsorption of β-naphthol on a smooth bismuth surface, Palm and Damaskin found [11] that $\Gamma_{max} = 3.1 \times 10^{-6}$ mol m^{-2} and $\Delta G_A^0 = -34$ kJ mol^{-1}. Changing the vertical orientation of the molecule for the horizontal orientation increases the absolute value of the Gibbs energy of adsorption. For the graphite powder, $\Delta G_A^0 = -28.8$ kJ mol^{-1}. Assuming the same type of orientation of β-naphthol as on bismuth and using Eq. (11), we obtain $A = 0.85$ $m^2 g^{-1}$. This value is somewhat overestimated, since $|\Delta G_A^0|_C < |\Delta G_A^0|_{Bi}$. Assuming the same type of orientation of β-naphthol as that on iron oxide, we obtain $A = 0.47$ $m^2 g^{-1}$. This value is underestimated, since $|\Delta G_A^0|_C > |\Delta G_A^0|_{\alpha\text{-}Fe_2O_3}$. The arithmetic mean $\bar{A} = 0.7 \pm 0.2$ $m^2 g^{-1}$. The results obtained suggest the following:

(1) The values of the true surface area of graphite $\bar{A}$, determined independently by two methods (BET and adsorption of β-naphthol) are well consistent. Therefore, we used in further study of Ni(SalEn) adsorption the value $\bar{A} = 0.7$ $m^2 g^{-1}$.

[1] Produced at the Unikhimtek.

Table 1. Parameters characterizing adsorption of Ni(SalEn) at different temperatures

T, K	Frumkin isotherm			Langmuir isotherm	
	B, M^{-1}	$2a$	$\Gamma_{max} \times 10^6$, mol m^{-2}	B, M^{-1}	$\Gamma_{max} \times 10^6$, mol m^{-2}
275	590 ± 220	~0	2.8 ± 0.6	540 ± 180	3.1 ± 0.5
283	890 ± 260	0.3	3.2 ± 0.3	690 ± 300	3.8 ± 1.0
293	250 ± 40	1.0	3.0 ± 0.4	240 ± 90	4.5 ± 0.5
304	220 ± 80	0.3	3.8 ± 0.8	350 ± 85	2.9 ± 0.3
313	150 ± 30	0.9	3.1 ± 0.3	200 ± 60	3.4 ± 0.4

(2) The porosity of graphite is small, since the specific surface area of the graphite powder is considerably lower than that of other materials. For comparison, A ($m^2\ g^{-1}$): α-Fe_2O_3 7–10, ZnO 6.8–9.4, W 2.7, graphitized carbon black (Vulkan 36-2700) 71.3 ± 2.7 [12], and activated carbon (Merck) 800–1000 [13].

To calculate the activity coefficients of Ni(SalEn) in acetonitrile by Eq. (6), it is necessary to have data on its solubility.[2] The solubility was measured over the temperature range 1–50°C. The saturated concentration of the monomer was determined using the optical density-vs.-concentration calibration curve. The dependence of the saturated concentration c^{sat} on t over the temperature range 0–50°C is described by Eq. (12).

$$c^{sat} \simeq 0.00624 - 0.000496t + 0.000049t^2 - 1.62 \times 10^{-6}t^3 + 2.33 \times 10^{-8}t^4 - 1.08 \times 10^{-10}t^5. \quad (12)$$

It follows from Eq. (12) that the solubility of Ni(SalEn) in acetonitrile is low. At 25°C, 1 l contains 19.024 moles of acetonitrile. Therefore, $\Sigma n \sim 19$ and $X_{org}^{sat} = c^{sat}/19$.

Acetonitrile (ultrapure grade) was used without further purification.

The adsorption parameters estimated by Eqs. (1) and (3) are listed in Table 1. As can be seen, the values of B and Γ_{max} are consistent within the errors indicated in the table, which is due to the fact that the attraction constant $a \leq 0.5$. Table 1 shows also that there is no clearly pronounced temperature dependence of Γ_{max}. Therefore, it may be accepted that Γ_{max} = constant over the temperature range 275–313 K. The arithmetic mean values of $\overline{\Gamma}_{max}$, corresponding to the Frumkin and Langmuir isotherms, are $(3.2 \pm 0.3) \times 10^{-6}$ and $(3.5 \pm 0.5) \times 10^{-6}$ mol m^{-2}, respectively. Then, the graphite surface area occupied by one Ni(SalEn) molecule is $(52 \pm 5) \times 10^{-20}$ m^2.

[2] Pure Ni(SalEn) was kindly provided by A.M. Timonov.

In the case of adsorption of the surfactant from the acetonitrile solution, Eq. (2) takes the form of Eq. (13).

$$\Delta G_A^0 = -RT \ln (19B). \quad (13)$$

The ΔG_A^0 values calculated this equation are listed in Table 2. The value of $RT \ln \gamma_{org}^{\infty}$ were calculated by Eqs. (6) and (12). The standard Gibbs energies of adsorption ΔG_{ads}^0 (symmetrical standard state) were found using Eq. (5). Table 2 shows that $|\Delta G_A^0| \gg |\Delta G_{ads}^0|$. Therefore, the coverage of the graphite surface with the Ni(SalEn) molecules is to a considerable extent determined by the effect of forcing-out of these molecules from the bulk of the solution to the interface. Since the parameter ΔG_{ads}^0 is small, the work expended for binding of monomer molecule to the graphite surface is close to that for breaking the bonds between ν acetonitrile molecules and the surface [ν is the number of acetonitrile molecules desorbed as a result of adsorption of one Ni(SalEn) molecule]. With decreasing temperature, the binding of Ni(SalEn) to the surface strengthens, since ΔG_{ads}^0 decreases.

It is commonly accepted [1–4, 14] that, in adsorption of Ni(SalEn), its molecule is horizontally oriented on the electrode surface. It can be found from

Table 2. Thermodynamic parameters of Ni(SalEn) adsorption

T, K	$-\Delta G_A^0$	$RT \ln \gamma_{org}^{\infty}$	ΔG_{ads}^0
	kJ mol^{-1}		
275	21.2 ± 0.4	18.4	2.8 ± 0.4
283	22.8 ± 0.7	19.9	2.9 ± 0.7
293	20.6 ± 0.4	19.6	1.0 ± 0.4
304	21.1 ± 0.7	19.1	2.0 ± 0.7
313	20.7 ± 0.4	19.7	1.0 ± 0.4

the structural formula of the monomer that, in the case of such an orientation, the Ni(SalEn) molecule covers about 70×10^{-20} m^2 of the surface, which noticeably exceeds the experimental value of $(52 \pm 5) \times 10^{-20}$ m^2 per molecule. Deviations from the horizontal arrangement of the adsorbed molecule may be due to the following factors.

(1) The larger the area occupied by a surfactant molecule on the surface, the greater the number of acetonitrile molecules to be transferred from the surface to the bulk of the solution, i.e., the higher the energy consumption.

(2) The experimental results obtained demonstrate that, in adsorption of Ni(SalEn), the prevailing effect is forcing-out of the molecules from the bulk to the surface, since $|\Delta G_A^0| >> |\Delta G_{ads}^0|$. The solvent tends to push out the maximum number of the molecules to the surface. This occurs at the vertical orientation of the molecule on the surface. In this case, the area occupied by the adsorbed molecule is the smallest. As a result of the simultaneous action of these two factors (interaction with the surface and forcing-out from the bulk of the solution), the adsorbed molecules can be differently oriented on the surface.

Finally, the thermal and vibrational-rotational motions of the adsorbed molecule can also alter its orientation.

Assuming that ΔS_{ads}^0 and ΔH_{ads}^0 are temperature-independent, we calculated these parameters by Eq. (7), using the experimental data for ΔG_{ads}^0 (Table 2). We obtain $\Delta S_{ads}^0 = -53 \pm 10$ J K^{-1} mol^{-1} and $\Delta H_{ads}^0 = -18 \pm 3$ kJ mol^{-1}.

Differentiation of Eq. (5) gives Eq. (14).

$$\Delta S_{ads}^0 = -\frac{d\Delta G_A^0}{dT} - R \ln \gamma_{org}^{\infty} - RT\frac{d\ln \gamma_{org}^{\infty}}{dT}. \quad (14)$$

Table 2 shows that, within the experimental error, $\Delta G_{ads}^0 \approx$ const, and, then, $\Delta S_A^0 = -d\Delta G_A^0/dT \approx 0$. Therefore, the change in ΔS_{ads}^0 is virtually totally accounted for by changes in the activity coefficients in the solution bulk. The high negative ΔS_{ads}^0 shows that the forcing-out of the Ni(SalEn) molecule from the bulk to the graphite surface results in ordering of the solution.

The observed negative ΔH_{ads}^0, corresponding to heat release in the course of adsorption, is virtually totally accounted for by the entropy factor.

CONCLUSION

The study of the adsorption of Ni(SalEn) on the graphite surface showed that the coverage of the surface with adsorbed monomeric molecules is controlled to a considerable extent by the effect of forcing-out of these molecules from the solution bulk to the interface. The observed high negative enthalpy of adsorption is accounted for by the entropy factor.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Oligomeric Polyamineimide Binder and Its Monomers on the Surface of Nonstoichiometric Compounds of Titanium

A. V. Ishkov and A. M. Sagalakov

Altai State University, Barnaul, Altai krai, Russia

Received July 6, 2004

Abstract—Adsorption of an oligomeric polyaminoimide binder, PAIS-104, and its monomers, diaminodiphenylmethane and dimaleimidodiphenylmethane, on the surface of nonstoichiometric titanium carbides, nitrides, and carbonitrides was studied. The dependence of the oligomer adsorption parameters and strength properties of composites on the nature, composition, and specific surface area of the adsorbent and presence of various additives in the binder was examined.

The adsorption processes occurring on the surface of fillers in solutions and melts of oligomers and polymers predetermine numerous technological features of manufacture of composites and their properties [1, 2]. As is known, the properties of composites depend not only on the properties of the starting components, but also on surface phenomena at the phase boundary (wetting, adsorption, adhesion, etc.). The adsorption interaction of the components of a polymer solution with the filler surface is a first stage of formation of the phase boundary in composites, and, therefore, studying the adsorption of polymers on the filler surface is of high theoretical and practical importance.

Electrically conducting materials (ECM) occupy a particular place among composites with special properties. ECM are used to fabricate current-lead coatings, heat and radiation shields, film and bulk resistive heaters, and other articles of this kind [3]. However, a number of difficulties are encountered in manufacture and operation of articles fabricated from such composites. These difficulties are associated with the interactions at the interface between the polymer and the conducting filler, which lead to instability of the electrical properties of the material. For example, oxidation of filler grains is observed in ECM based on metal powders, which causes a decrease in the electrical conductivity of the material [4]. Therefore, obtaining new ECM with stable characteristics is, undoubtedly, a matter of current interest.

Previously, materials in which the part of the conducting filler is played by nonstoichiometric titanium compounds of the type of an interstitial phase have been suggested [5, 6]. Use of nonstoichiometric titanium carbides, nitrides, and carbonitrides exhibiting a metallic conductivity and high chemical and thermal resistance (up to 3500 K) in materials with a polymeric matrix based on a polyaminoimide binder makes it possible to obtain ECM with stable electrical properties in the whole temperature range of application of modern polymers. In addition, the ECM mentioned above have a new property of interest, self-adjustment, which makes them promising materials for fabrication of low-temperature heating devices [7]. Therefore, a study of adsorption properties in systems constituted by a nonstoichiometric compound of titanium and a polyaminoimide binder is of particular interest.

The aim of this study was to analyze the adsorption of an oligomeric polyaminoimide binder and its monomers on the surface of such fillers as high-melting nonstoichiometric compounds of titanium of the type of interstitial phases.

EXPERIMENTAL

As oligomeric polyaminoimide binder served a commercial specimen of PAIS-104 resin [TU (Technical Specification) 6-05-231-192–79], which is a powdered oligomer with an average molecular weight of 3.5×10^3. Content of free amino groups in the polymer ≤5%, drop temperature 103°C, gelatinization time 180 s.

One of monomers of PAIS-104, diaminodiphenylmethane (DADPhM), was used after additional purification of the commercial chemically pure product by recrystallization from ethanol. Dimaleimidodiphenylmethane (DMIDPhM), the second monomer of PAIS-104, was obtained by reacting DADPhM with maleic anhydride in an ether solution in a 1 : 2 molar ratio, with the subsequent dehydration of the resulting diamide with a mixture Ac_2O : AcONa. The product thus obtained was purified by recrystallization from toluene to give a compound with a melting point of 155–156°C, which was identified by IR spectra [8, 9].

As nonstoichiometric compounds of titanium were used its carbides, nitrides, and carbonitrides obtained by means of a self-propagating high-temperature synthesis [10].

Titanium nitrides TiN_x ($0.5 \le x < 1$) were prepared by reacting powdered titanium of PTOM brand with nitrogen gas in a flow-through reactor under a nitrogen pressure of 0.2–0.5 atm at a controlled flow rate of the gas. Titanium carbides TiC_x ($0.5 \le x < 1$) were synthesized by burning mixtures of powdered titanium of PTK brand and carbon black of PM-50 brand, taken in 1 : 0.5, 1 : 0.6, 1 : 0.75, and 1 : 0.9 molar ratios, in argon. Titanium carbonitrides TiC_xN_y ($x + y < 1$) were obtained by reacting powdered titanium of PTK brand with technical-grade hexamethylenetetramine (urotropin) at 1 : 0.1 and 1 : 0.07 molar ratios of the reagents. The self-propagating high-temperature synthesis was initiated in all the systems with a thermit formulation.

The composition of the nonstoichiometric compounds was confirmed bu X-ray phase (DRON-2, Co_{K_α} radiation) and chemical analyses. Composites were prepared from titanium fractions with $d < 100$ μm. The specific surface area of the fillers was determined from the adsorption of surfactants.

The adsorption of PAIS and its monomers from solutions in DMF was performed in hermetically sealed volumetric flasks at a temperature of 20 ± 1°C and 10 : 1 mass ratio of the liquid and solid phases. Equilibrium solutions were separated from the adsorbent by centrifugation. The concentration of a polymer solution was determined by means of refractometry, using preliminarily obtained calibration plots. The concentration of DMIDDPhM solutions was determined using the procedure suggested in [11]. The content of DADPhM in solution upon adsorption was found photometrically, after combining the amine with β-naphthol [12].

Polymeric formulations for further studies were obtained by hot compaction of a mixture of powdered filler and binder at a pressure of 20–30 MPa and temperature of 200–220°C in the course of 1 h and at 240–250°C for additional 1 h.

The strength properties of the composites were determined on an R-0.5 tensile machine (rate of sample loading 10 mm min^{-1}, maximum load 500 kg) and a KM-0.5 pendulum impact testing machine by the standard procedures.

A specific feature of the compounds produced by self-propagating high-temperature synthesis is that their properties depend on various parameters of the technological process: powder dispersity, duration of agitation, and process temperature, and, therefore, any technological scheme of self-propagating high-temperature synthesis requires monitoring of the basic properties and the composition of the products obtained.

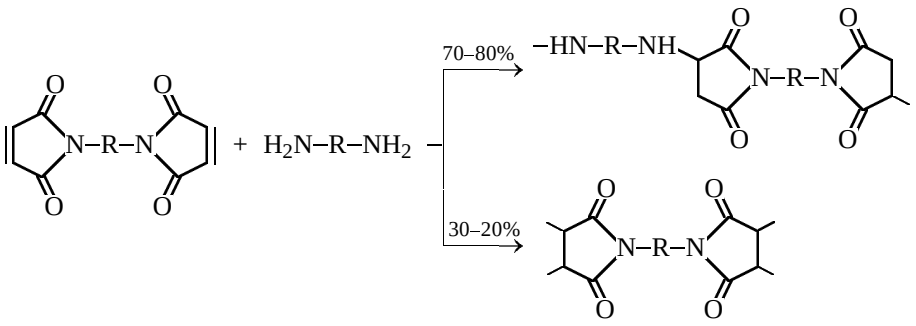
Table 1 lists the principal physicochemical parameters of the fillers synthesized. As can be seen from the data presented, the substances synthesized are nonstoichiometric and have a developed specific surface area, which predetermines their improved adsorption properties. With titanium nitrides and carbides, the prescribed compositions were well reproduced in synthesis. At the same time, the nonstoichiometric carbonitrides synthesized had a composition somewhat different from that expected. Presumably, this is due to sublimation and decomposition of a part of the organic substance at the temperature of synthesis and to different rates of assimilation of nitrogen and carbon by titanium in self-propagating high-temperature synthesis [10]. The nonstoichiometric titanium nitrides obtained have a 3.3–6.5 times greater specific surface area than the other compounds, which is accounted for by the higher dispersity of the starting titanium powder.

The attainment of the adsorption equilibrium in the systems under study was determined by measuring kinetic curves of adsorption. Figure 1 shows the kinetic curves of adsorption of the oligomeric polyaminoimide binder under study on the surface of some of the compounds in question. It was established that a constant value of the refractive index of the solution was observed during the first two to three days after solutions of PAIS-104 in DMF were brought in contact with the adsorbent, which indicates that the adsorption equilibrium was attained. Similar dependences were obtained for all the systems studied.

As is known, the rate at which the adsorption equilibrium is attained is determined by the nature of the adsorbent and by its dispersity and porosity. As the adsorbents studied have about the same dispersity and granulometric composition, the fact that the highest rate of adsorption is observed for the nonstoichiometric titanium nitrides $TiN_{0.5}$ and $TiN_{0.95}$ is accounted for by their larger specific surface area. The nature of adsorbent has a little effect on the kinetic parameters of adsorption of the polyaminoimide oligomer.

Similar studies were performed for systems constituted by a nonstoichiometric adsorbent and monomers of the polyaminoimide binder. It was established that the adsorption equilibrium is attained in this case during the first 1.5–2 h after DMIDPhM and DADPhM solutions are brought in contact with the surface of the adsorbent.

As the oligomer under study is a product obtained by reaction in a melt of DMIDPhM and DADPhM, it contains simultaneously amine and imide functional groups. In curing of PAIS-104, there simultaneously occur addition of amine groups to double bonds of imide rings and a competing reaction of autopolymerization of imide rings, which result in that structures of two types are formed in the polymer:



(I)

Therefore, a study of adsorption of the oligomeric polyaminoimide binder and its monomers could reveal the selective adsorption properties of the surface of the nonstoichiometric compounds with respect to amine and imide functional constituents of the oligomer.

As is known, adsorption by J. Gibbs is calculated as an excess amount of a solution component within the adsorption layer enveloping the surface of the adsorbent. However, the adsorption is calculated in actual practice as the amount of a substance adsorbed on a unit surface area of the adsorbent, using the formula

$$\Gamma_i = \frac{(c_0 - c_i)V}{mS_{sp}}, \quad (1)$$

where c_0 and c_i are the concentrations of the component in the initial solution and that in equilibrium with the adsorbent (mM); m, mass of the adsorbent (g); V, volume of the adsorption solution (l); and S_{sp}, specific surface area of the adsorbent ($m^2\ g^{-1}$).

Figure 2 shows adsorption isotherms of PAIS-104 and its monomers from diluted solutions in DMF on

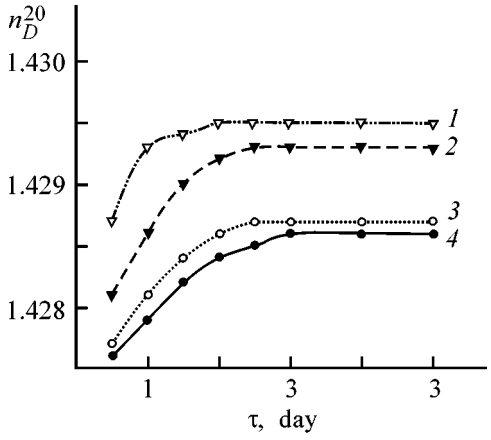


Fig. 1. Kinetic curves of PAIS-104 adsorption on the surface of fillers from solutions in DMF. (τ) Time. (*1*) $TiN_{0.5}$, (*2*) $TiN_{0.95}$, (*3*) $TiC_{0.5}N_{0.4}$, and (*4*) $TiC_{0.5}$.

the surface of a nonstoichiometric titanium carbide of composition $TiC_{0.75}$. Similar dependences were obtained for the other adsorbents.

As can be seen in Fig. 2, the adsorption isotherms of the monomers DMIDPhM and DADPhM have a typical shape with the adsorption approaching a limiting value. The adsorption isotherm of the polyaminoimide oligomer is S-shaped, which is typical of adsorption of sparingly soluble substances. Systems of this kind are commonly regarded as bulk-stratifying [13].

It is known [14] that all components of a mixture are sorbed simultaneously, but to varied extent, in adsorption of macromolecules from dilute solutions. Therefore, it is somewhat difficult to determine the limiting adsorption of the polymer. However, the adsorption isotherms of the polyaminoimide oligomer show a plateau with a nearly constant adsorption. If it is assumed that this part of the isotherm corresponds to dense filling of the surface of the adsorbents by macromolecules in a single layer, Langmuir's theory of monomolecular adsorption can be used to find the parameters of the adsorption equilibrium in systems of this kind. The equation describing the adsorption process is in this case as follows:

$$\Gamma = \Gamma_\infty[kc/(1 + kc)], \quad (2)$$

where Γ_∞ is the limiting surface concentration of the adsorbate (mmol m^{-2}); *k*, equilibrium constant equal to the ratio of the rate constants of desorption and adsorption; and *c*, volume concentration of the substance (mmol l^{-1}).

Equation (2) is linearized in the coordinates $c/\Gamma = f(c)$, which makes it possible to easily find values of its parameters.

Figure 3 shows linear anamorphoses of the adsorption isotherms of the polyaminoimide oligomer and its monomers on the surface of $TiC_{0.75}$. As can be seen from the plots shown in the figure, the experimental points fall with good precision on the theoretical straight line, which indicates that the model of monomolecular adsorption is adequate to the systems under study. Similar plots were constructed for the other adsorbents. The linear correlation factors found using the least-squares procedure were 0.985–0.998.

The linear form of Eq. (2) was used to find the limiting surface concentration of the components being sorbed and the adsorption equilibrium constants for all the nonstoichiometric compounds under study. The data on the limiting adsorption were used to calculate the thickness of the adsorption layer:

$$l = \Gamma_\infty M/d, \quad (3)$$

where Γ_∞ is the limiting adsorption (mg m^{-2}); *M*, molecular weight of the substance (g); and *d*, density of the substance (kg m^{-3}).

As can be seen from Table 2, the limiting adsorption depends not only on the specific surface area of the adsorbents, but also on the nature of a nonstoichiometric compound. Despite the large specific surface of nonstoichiometric titanium nitrides, the limiting adsorption of the polyaminoimide oligomer on their surface is lower than that on the surface of titanium carbonitrides and of the carbide of composition

Table 2. Parameters of adsorption of PAIS-104 and its monomers on the surface of fillers

Filler	PAIS-104			DADPhM		DMIDPhM	
	$\Gamma_\infty \times 10^7$, mg m^{-2}	k	l, Å	$\Gamma_\infty \times 10^7$, mg m^{-2}	k	$\Gamma_\infty \times 10^7$, mg m^{-2}	k
$TiC_{0.5}$	1.2	1.8	2.4	2.5	6.2	2.0	3.0

$TiC_{0.75}$	3.2	1.4	6.6	4.7	4.8	2.2	3.4
$TiC_{0.9}$	1.8	1.7	3.7	2.8	6.4	1.5	4.6
$TiN_{0.5}$	2.0	2.3	4.1	3.1	4.2	1.7	3.2
$TiN_{0.95}$	2.4	1.9	4.9	3.5	5.1	1.8	4.0
$TiC_{0.5}N_{0.4}$	2.5	1.2	5.1	4.2	3.8	2.0	3.7
$TiC_{0.4}N_{0.3}$	3.3	1.4	6.8	4.5	4.7	2.4	4.1

$TiC_{0.75}$. Another pattern is also observed: the farther the composition of a nonstoichiometric compound from the boundaries of the homogeneity region [15], the higher the limiting adsorption of the oligomer. The data of Table 2 also show that the adsorption of the amine functional constituents of the oligomer dominates over that of imide constituents. This is indicated by the values of the limiting adsorption of model compounds, monomers DMIDPhM and DADPhM. The low values of the equilibrium constants point to a comparatively weak interaction of binder molecules with the surface of the adsorbents, in agreement with published data [14]. The higher values of the constants for the model compounds indicate that desorption predominates over adsorption in the case of monomers. The thickness of the adsorption layer varies within the range 2–6 Å, which is due to orientation of oligomer molecules on the surface of the adsorbent in adsorption from dilute solutions and confirms once more the applicability of the monomolecular adsorption model to the systems studied.

As already noted, ECM based on a polyaminoimide binder and nonstoichiometric compounds are distinguished by stability of their electrical parameters, but also have some disadvantages: articles made of cured resins exhibit an increased brittleness, their processing by injection molding and extrusion is difficult [16]. These disadvantages can be obviated by modifying the polyaminoimide oligomer with various additives.

Oligooxypropylene glycol (OOPG), dioctyl phthalate (DOPh), and epoxydiane resin ED-20 were used as additives in this study. The adsorption equilibria in the systems constituted by a nonstoichiometric adsorbent, PAIS-104, and an additive were studied using the scheme described above. In this case, the adsorption isotherms were similar to those in Fig. 2. Their point-by-point linearization as far as the plateau region inclusive made it possible to determine the adsorption parameters for these systems.

Table 3 lists the parameters calculated similarly to those for the binary systems PAIS–filler: limiting adsorption, equilibrium constants, and thickness of the adsorption layer. As can be seen from the data presented, the adsorption of the polyaminoimide oligomer on the surface of the fillers studied is strongly affected by the composition of the binder. For example, introduction of a reactive additive OOPG and plasticizer additives DOPh and ED-20 raises the limiting adsorption by 40–60%, which is due to enhancement of the adsorption properties of the modified binder.

Noteworthy is the existence of a relationship between the limiting adsorption and the strength properties (adhesion strength and impact viscosity) of the

Table 4. Strength parameters of composites containing 50 wt % filler (n = 5)

Filler	Composite							
	no additive		2.5% OOPG		1.5% DOPh		3% ED-20	
	σ_{shear}, MPa	A, kJ m^{-2}	σ_{shear}, MPa	A, kJ m^{-2}	σ_{shear}, MPa	A, kJ m^{-2}	σ_{shear}, MPa	A, kJ m^{-2}
$TiC_{0.5}$	7	3.75	12	4.25	10	5.76	9	7.92
$TiC_{0.6}$	10	7.12	16	10.65	12	12.72	11	15.45
$TiC_{0.75}$	15	8.62	22	11.25	15	15.25	12	18.94
$TiC_{0.9}$	12	6.15	18	7.68	16	9.73	14	13.22
$TiN_{0.5}$	9	7.52	12	9.10	13	13.85	15	16.60
$TiN_{0.95}$	8	7.90	12	10.75	12	14.27	12	16.35
$TiC_{0.5}N_{0.4}$	10	7.24	12	12.15	18	13.88	20	16.30
$TiC_{0.4}N_{0.3}$	14	8.57	18	12.82	15	13.42	18	15.28

composite obtained. Table 4 lists the values of the adhesion strength in interlayer shear, σ_{shear}, and impact viscosity by Sharpy, A, for composites containing 50 wt % nonstoichiometric filler and similar composites with modifying additives. It can be seen that an increase in the limiting adsorption of PAIS-104 on a carbide of composition $TiC_{0.75}$ by a factor of 1.6 leads to an approximately 1.5 times higher strength in interlayer shear. A similar correlation is observed for other fillers and modifiers. The data in Table 4 can also be used to elucidate the relationship between the filler composition and the strength properties of the resulting composite. The increase in the strength of the composite can be attributed to a rise in the share of structures of the second type [Scheme (I)] in the cured polymer. These structures are formed upon blocking (as a consequence of specific adsorption) of radicals from the amine constituent of the oligomer on the surface of fillers, which enhances the process of autopolymerization of the imide.

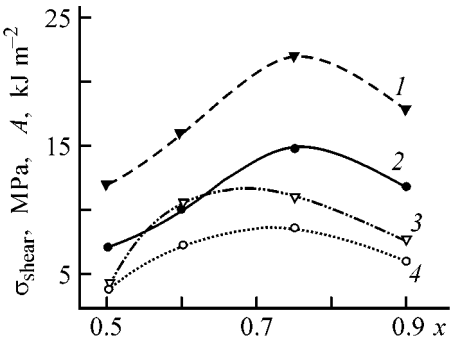

Fig. 4. Mechanical properties of composites vs. the composition of titanium carbide TiC_x: (*1*, *2*) adhesion strength σ_{shear} and (*3*, *4*) impact viscosity A. Material: (*1*, *2*) with 2.5% OOPG and (*3*, *4*) without additives.

Figure 4 shows how the strength properties of the composites obtained depend on the parameter x in the formula of nonstoichiometric titanium carbide. It can be seen that the maximum strength in interlayer shear and higher impact viscosity are observed for the material containing a carbide whose composition corresponds to the middle of the homogeneity region of the system Ti–C, i.e., $TiC_{0.75}$. This is in a good agreement with the previously established dependence of the adhesion strength of the material on the limiting adsorption of the polyaminoimide oligomer.

CONCLUSIONS

(1) Experimental data on adsorption of an oligomeric polyaminoimide binder PAIS-104 and its monomers on the surface of nonstoichiometric titanium carbides, nitrides, and carbonitrides were obtained for the first time.

(2) It was established that the adsorption of PAIS-104 on the surface of the fillers studied is adequately described by the monomolecular-layer model.

(3) It was found that the limiting adsorption of PAIS-104 is in the range $(1.2–5.1) \times 10^7$ mg m^{-2}, equilibrium constants are equal to 1.2–4.2, and the thickness of the adsorption layer is within 2.4–6.8 Å. The strength of the composites obtained, as well as the adsorption parameters of the binder, depend on the nature, composition, and specific surface area of the nonstoichiometric fillers and on the presence of modifying additives, oligooxypropylene glycol, dioctyl phthalate, and ED-20 resin.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

A Study of the Kinetics of Electrochemical Dissolution of Aluminum Alloys in Alkaline Electrolytes

A. V. Krasnobryzhii, A. I. Rusin, V. N. Varypaev, V. V. Nikol'skii, and S. B. Alekseev

Received April 17, 2004

Abstract—Electrochemical dissolution of aluminum alloyed with tin, indium, and lead in a NaOH solution in the concentration range 4.4–12.0 M at 75°C was studied by the method of chronopotential and current–voltage curves. The influence exerted by alloying elements on the electrochemical parameters of the process was revealed.

The high electrochemical activity of aluminum, especially in alkaline solutions, makes it an attractive anodic material for standby chemical power cells [1, 2, 3]. Aluminum has a low electrochemical equivalent (0.336 g A^{-1} h^{-1}) and, consequently, a sufficiently high theoretical specific capacity (2.98 A h g^{-1}), and well surpasses zinc (0.83 A h g^{-1}), widely used as anode material, and the promising magnesium (2.20 A h g^{-1}). As regards its bulk characteristics, aluminum has a capacity of 8.00 A h cm^{-3}, compared with 5.88 A h cm^{-3} for zinc and 5.58 A h cm^{-3} for magnesium [1]. In addition, aluminum is a readily available and relatively inexpensive metal.

Until recently, the electrochemical dissolution of aluminum and its alloys has been mainly studied in a diluted NaCl solution modeling seawater [2–4]. In the last years, the interest of researchers in the behavior of aluminum in an alkaline medium has increased. This is due to the fact that the half-system Al/NaOH seems to be rather promising owing to its high electronegative standard potential, equal to –2.30 V [5]. However, the high energy capacity of aluminum cannot be used in full measure because of the pronounced difference effect, which markedly diminishes the utilization factor of the electrochemically active substance. Moreover, a shift of the anode potential toward the potential of the hydrogen electrode, which is –0.83 V at pH 14, is observed in this case.

To suppress the negative influence of the difference effect and the shift of the electrode potential in the negative direction, it is suggested to use alloying of aluminum with other elements in order to depassivate the surface and extend the range of anodic current densities, with the hydrogen evolution overvoltage simultaneously increasing. Of interest are studies by Klochkova's *et al.* [6, 7], who examined the anodic dissolution of aluminum and its alloys in alkaline solutions and pointed out, following Purenovich *et al.* [4], that use of indium as depassivator of the electrode surface in an anodic alloy and introduction of tin compounds as corrosion inhibitors into the electrolyte are promising methods.

This area of research is promising, which is confirmed by the patent literature. A number of patents are known, which suggest use of aluminum alloys containing gallium, thallium, tin, lead, and other alloying components for fabricating the active part of the anode in a chemical power cell [8, 9].

The present study is concerned with the electrochemical behavior of some aluminum alloys in a NaOH solution in a wide range of concentrations (4.4–12.0 M) and current densities (100–500 mA cm^{-2}).

EXPERIMENTAL

As objects of study were used aluminum–indium, aluminum–indium–tin, and aluminum–tin–lead alloys. The content of the alloying metals in some of the alloys studied is listed in Table 1. The aluminum–indi-

Table 1. Composition of the alloys studied (aluminum the rest)

Alloy	Content of alloying component, %		
	Sn	In	Pb
K16	0.20	0.25	–
K17	0.10	–	0.10
K18	0.20	0.06	–
K19	0.10	0.33	–
K20	–	0.60	–

1070-4272/04/7710-1642 © 2004 MAIK "Nauka/Interperiodica"

um alloy is a mixture of a solid solution and an indium–aluminum eutectic [6, 7]. At a mass fraction of indium of up to 0.2%, its solid solution with aluminum is a major component of the alloy. At higher indium concentrations, the fraction of the eutectic increases.

The electrode had the form of a $1.0 \times 4.0 \times 0.04$-cm plate with a working surface area of 2.0 cm^2 and the rest of the surface insulated with an alkali-resistant lacquer. Prior to each test the electrode surface was trimmed, degreased, and washed with distilled water. A NaOH solution of concentration 4.4, 8.0, and 12.0 M served as electrolyte. The working temperature of the electrolyte, equal to $75 \pm 1.0°C$, was maintained with a water thermostat. The polarization measurements were performed in a three-section electrochemical glass cell. A graphite rod was used as an auxiliary electrode, and a saturated silver chloride electrode, as reference. The anode under study was polarized with a B5-47 dc power supply. The voltage in the circuit constituted by the anode and the reference electrode was measured with a Shch-1413 high-input-resistance digital voltmeter. The loss of mass by the anode was determined gravimetrically by weighing the electrode on a VLR-200 balance before and after polarization.

Pure aluminum of A95 brand served for comparison of characteristics.

The chronopotential E–τ curves were obtained for the anodic dissolution of the aluminum alloys studied at current densities of 100–500 mA cm^{-2} and a polarization time of 600 s. The E–τ curves measured at a current density of 300 mA cm^{-2} in a 4.4 M NaOH solution are shown in Fig. 1a. All the potentials in the study are given relative to a standard hydrogen electrode.

It follows from Fig. 1a that the E–τ characteristics of alloys alloyed with indium and tin are stable (curves *1*, *3*–*5*). The chronopotentiograms lie at potentials in the range –1.54…–1.59 V, which indicates that there are no transient side processes, such as local semi-passivation by products of electrooxidation of the anode. It is important to note that the potential is stabilized during the first seconds of the electrode polarization. This means that the anodic activation of the electrode surface is not the rate-limiting process.

By contrast, the potential of the K17 alloy containing 0.1% tin and 0.1% lead (curve *2*) demonstrates a certain instability in the course of time, i.e., changes from –1.65 to –1.52 V in 600 s. However, even in this case, the electrochemical dissolution of the anode proceeds at potentials that are 0.15–0.20 V more negative than the potential of pure A95 aluminum (Fig. 1a, curve *6*).

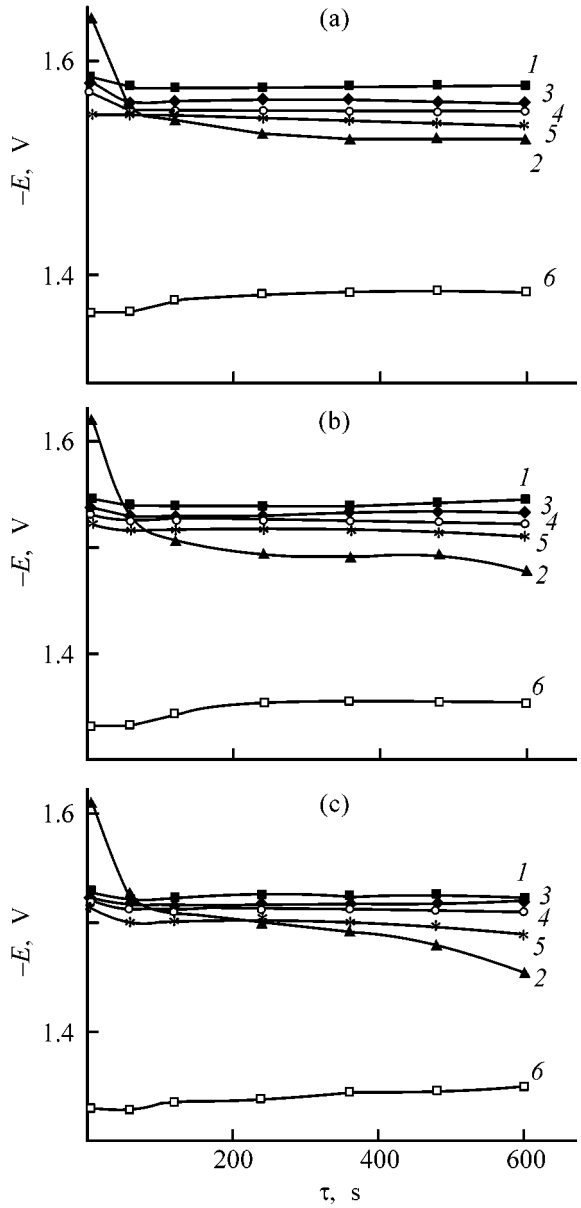

Fig. 1. Chronopotentiogram of anodic dissolution of aluminum alloys in a 4.4 M solution of NaOH. (*E*) anode potential and (τ) time. Current density (mA cm^{-2}): (a) 300, (b) 400, and (c) 500. Alloy: (*1*) K16, (*2*) K17, (*3*) K18, (*4*) K19, (*5*) K20, and (*6*) A95 aluminum.

The chronopotential curves obtained for the same alloys at current densities raised to 500 mA cm^{-2} (Fig. 1b, 1c) are not fundamentally different from the curves in Fig. 1a, except in the case of the lead-containing alloy K17 (curve *2*), which exhibits a stronger instability of the E–τ characteristics. For example,

Table 2. Potential of aluminum alloys at different concentrations of NaOH and current densities

c_{NaOH}, M	i, mA cm^{-2}	Potential $-E$, V, of indicated alloy			
		K16	K18	K19	K20
4.4	0	1.61	1.60	1.60	1.59
	100	1.60	1.59	1.59	1.56
	300	1.58	1.56	1.54	1.53
	400	1.57	1.55	1.54	1.52
	500	1.55	1.53	1.51	1.50
8.0	0	1.70	1.66	1.68	1.66
	100	1.65	1.63	1.64	1.62
	300	1.60	1.58	1.57	1.53
	400	1.56	1.54	1.53	1.50
	500	1.53	1.51	1.49	1.46
12.0	0	1.76	1.74	1.75	1.73
	100	1.70	1.67	1.69	1.63
	300	1.58	1.55	1.56	1.52
	400	1.55	1.52	1.53	1.48
	500	1.53	1.51	1.52	1.46

the change in the potential in 600 s at a current density of 500 mA cm^{-2} is as large as 0.17–0.20 V, whereas that for alloys with indium is 3–4 times smaller (curves *1*, *3–5*).

The chronopotential curves for the K16 and K18–K20 alloys are close, with the potential varying within the range ΔE not exceeding 0.05 V in each case. This confirms the decisive role of indium in the kinetics of electrochemical dissolution of the alloy, which has been noticed previously by Purenovich and coworkers [4]. The potential of each of the alloys in anodic polarization depends primarily on the relative rates of two processes, electrochemical dissolution of aluminum under the action of the external current by the reaction:

$$Al + 4OH^- \rightarrow AlO_2^- + 2H_2O + 3e \qquad (1)$$

and spontaneous dissolution of aluminum the electrochemical mechanism as a result of occurrence, on the anode surface, of two conjugate reactions

$$\left.\begin{aligned} Al + 4OH^- &\rightarrow AlO_2^- + 2H_2O + 3e, \\ 3H_2O + 3e &\rightarrow 3/2H_2 + 3OH^-, \end{aligned}\right\} \qquad (2)$$

which, combined, give the stoichiometric equation

$$Al + H_2O + NaOH \rightarrow NaAlO_2 + 3/2H_2. \qquad (3)$$

The anode potentials of the indium-alloyed aluminum (Fig. 1, curves *1*, *3–5*) are strongly shifted from the equilibrium potential of the hydrogen electrode in the negative direction with respect to the potential of pure aluminum. Therefore, the presence of indium as an alloying component makes lower the rate of spontaneous dissolution of aluminum by reactions (2). The mechanism of the influence exerted by indium is associated with the increase in the hydrogen evolution overvoltage on the surface of the indium-containing alloy. As regards pure aluminum (curve *6*), the side process (2) goes here at a noticeable rate, and, therefore, the E–τ curve is strongly shifted to less negative potentials.

Dependences similar to those plotted in Fig. 1 were obtained on raising the NaOH concentration to 12.0 M. The main results of these series of tests are listed in Table 2, which presents the average values of the potential in anodic polarization at a current density of 100 to 500 mA cm^{-2} for 600 s. The K17 alloy is omitted, as it has poorer characteristics than indium-containing alloys.

As the electrolyte concentration increases, the steady-state potential of the alloys shifts toward negative values and the variation of the potential with increasing current density becomes more pronounced. In a 4.4 M NaOH solution, the average potential at 100 mA cm^{-2} nearly coincides with the zero-current potential for all the alloys, whereas in a 12.0 M NaOH solution, E changes by 0.06–0.10 V, reaching a value of 0.23–0.27 V as the current density increases to 500 mA cm^{-2}. Most probably, the decrease in the anode potential is due to a rise in the concentration polarization as a result of an increase in the aluminum concentration in the near-anode layer, which is the more pronounced, the higher, the greater the current density. The increase in the electrolyte concentration is accompanied by a rise in the solution viscosity, which enhances the diffusion hindrance in the course of reaction (1). It should be noted, however, that the variation of the potential is, on the whole, quite acceptable. Also absent are any clearly pronounced indications of a partial passivation of the electrode surface, e.g., via formation of a sparingly soluble indium hydroxide.

The efficiency of the electrochemical dissolution of aluminum by reaction (1) can be conveniently evaluated by the utilization factor of the active substance, K_u, which is calculated by the formula

$$K_u = qi\tau S/\Delta m,$$

where q is the electrochemical equivalent of aluminum (g A^{-1} h^{-1}); i, current density (mA cm^{-2}); τ, duration of electrolysis (h); S, working surface area of the anode, (cm^2); and Δm, loss of mass by the anode through electrochemical and spontaneous dissolution (g).

The dependences of the utilization factor on current density in a 4.4 M NaOH solution are shown for the K16 and K18-K20 alloys and A95 aluminum in Fig. 2. When the current density increases from 100 to 500 mA cm^{-2}, the utilization factor clearly grows. The dependence is virtually linear within the range 200–500 mA cm^{-2}, which means that the rate of spontaneous dissolution of aluminum by reaction (3), accordingly, decreases. The deceleration of the spontaneous dissolution with growing current density in an alkaline electrolyte is typical of aluminum [10, 11].

As regards the data in Fig. 2, the K16, K18, and K19 alloys are indistinguishable (curves *1*–*3*) despite the different contents of indium (within the range from 0.06 to 0.33%). When the content of indium increases to 0.6% (K20 alloy, curve *4*), the utilization factor considerably grows (from 72 to 87% at a current density of 300 mA cm^{-2}). This is in agreement with the data obtained by Klochkova *et al.* [6, 7].

The utilization factor of A95 aluminum (curve *5*) exhibits a similar type of variation with increasing current density, but lies within 10–35%. This result agrees with the data in Fig. 1 (curve *6*).

At 8.0 M NaOH, the pattern of Fig. 2 is reproduced in every detail, and the utilization factors of all the four alloys change only slightly. A further increase in the electrolyte concentration to 12.0 M leads to a dramatic rise in the utilization factor of aluminum, K_u, in the alloys. At current densities of 300–500 mA cm^{-2}, the utilization factor is as high as 95–98%, with all the four alloys having closely similar characteristics. Thus, the rate of spontaneous dissolution of aluminum is at a minimum under these conditions.

CONCLUSION

A study of the electrochemical behavior of a number of the Al–Sn–In, Al–In, and Al–Sn–Pb alloys in a 4.4–12.0 M solutions of NaOH demonstrated that the efficiency of the anodic dissolution of aluminum largely depends on the nature and concentration of the alloying elements. The chronopotentiogram measured at current densities of 100–500 mA cm^{-2} is, as a rule, stable. The alloy containing 0.20% Sn and 0.25% In exhibits the most negative potentials of electrochemical dissolution, and that with 0.1% Sn and 0.1% Pb, the least negative anode potentials. The utilization factor of the active substance is the largest for the alloy with 0.60% In. As the electrolyte concentration increases, the efficiency of electrochemical dissolution of the alloys sharply grows.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Choice of Electrolyte Composition for Liquid-Absorption Concentration of Mercury from Air for Subsequent Inversion-Voltammetric Determination

S. S. Ermakov, E. O. Averyaskina, and L. N. Moskvin

St. Petersburg State University, St. Petersburg, Russia

Received May 20, 2004

Abstract—An electrolyte composition is suggested for absorption recovery and concentration of mercury from air and its subsequent inversion-voltammetric determination on a gold electrode in a solution of the same composition.

In spite of the extremely high toxicity, mercury and its compounds find wide application in various fields of human activity: research, chemical industry, manufacture of chemical power cells, agriculture (treatment of seeds with mercury-containing fungicides), medicine, and cosmetics [1–3]. As a result, mercury comparatively frequently finds its way into the environment. Taking into account the volatility of elemental mercury, the problem of monitoring the content of mercury in the atmosphere arises most frequently. The maximum permissible concentration of mercury in the air of a working area is 10 $\mu g\ m^{-3}$ [4]. Combined with the wide demand for methods that can be used to monitor its contents in air, this circumstance imposes contradictory requirements to these techniques, namely, high sensitivity and simultaneous ready availability.

At present, the method of atomic-absorption spectroscopy in "cold" vapor has found the widest use for determination of mercury [5]. The main drawbacks of this method are the insufficiently high reproducibility of analytical data and the necessity for use of a comparatively expensive equipment [6, 7]. A new variety [8] of differential atomic-absorption spectroscopy opened up additional opportunities for making lower the detection limit in direct determination of traces of mercury in air. However, the cost of the analyzer increases in this case to an even greater extent, which makes this method inaccessible for most of laboratories engaged in ecological analysis. At the same time, inversion voltammetry with a gold electrode is known to be one of the most sensitive methods for determining mercury in aqueous media [9]. However, to apply this method for determining mercury in air, it is necessary to solve the problem of its liquid-absorption recovery from air. The composition of the absorbing solution should be as close as possible to the optimal composition of the background solution used in inversion-voltammetric determination of mercury.

The aim of this study was to choose a universal composition of the solution, which simultaneously enables absorption recovery of all possible chemical forms of mercury from air and its inversion-voltammetric determination on a gold electrode.

EXPERIMENTAL

To determine mercury(II) in solutions, we used an AKV-07 voltammetric analyzer (AKVILON NPKF, Moscow) with a three-electrode transducer: a rotating-disc working electrode in the form of a gold rod pressed in a fluoroplastic sheath, with a disc 1 mm in diameter as the working surface and a surface area of 0.8 mm^2; an auxiliary electrode in the form of a glassy carbon crucible serving simultaneously as a measuring cell; and an EVL-1M4 silver chloride electrode as reference. We prepared the surface of the indicator electrode as follows: after mechanical polishing of its surface with a fine emery paper, we polished the electrode electrochemically using the technique described in [10] and then additionally activated it directly in a mercury(II) solution to be analyzed, on the background of 1 M $HClO_4$ + 0.1 M HCl by electrode polarization at a potential of +1.3 V (1 min) in an agitated solution. The surface of the working electrode was cleaned between the measurements electrochemically in a solution of the same composition. We monitored the extent of cleaning by recording background voltammograms.

1070-4272/04/7710-1646 © 2004 MAIK "Nauka/Interperiodica"

A reference solution of mercury(II) with a concentration of 10^{-3} M was prepared from $Hg(NO_3)_2 \cdot H_2O$ and the concentration of the solution was determined by precipitation titration [11]. Chemically pure reagents were used, the solutions were prepared with twice-distilled water. A 10^{-3} M iodine solution was prepared by dissolving crystalline iodine in ethanol.

To choose conditions for absorption recovery of mercury with the aim of its subsequent inversion-voltammetric determination, we assembled a setup with in-series connected compressor, flask of mercury vapor generator, and two Tishchenko flasks. Flask no. 1 was used to absorb mercury, and flask no. 2, to test the completeness of absorption in the first flask. We used a flask blown through with air, with a drop of mercury on the bottom, as a generator of mercury vapor. To obtain reproducible results, air was blown above mercury into an exhaust hood for 1 min before each measurement and then the air flow with mercury vapor was directed into the absorbing Tishchenko flasks. The measurements were made and the flow rate of air was controlled with an RM-25GUZ-K rotameter. Compressors manufactured by AND and Barnant companies were used to inject air.

When choosing a universal composition of the solution, we used as the starting assumption that the inversion-voltammetric determination of mercury is usually carried out on the background of a mixture of perchloric and hydrochloric acids. The optimal composition of the background solution is 1 M $HClO_4$ + 0.1 M HCl [12]. However, all attempts to use a solution of such a composition as an absorbent even for recovery of mercury present in air in the elemental state appeared to be ineffective. This was indicated by the fact that, even after blowing air through the absorbing installation at a rate of 1 l min^{-1} for 10 min, the concentration of mercury in the background solution placed in Tishchenko flasks was about the same.

To make the catching of mercury more complete by converting atomic mercury into a nonvolatile ionic form, we tested as absorbent a solution into which nitric acid was introduced as an oxidizing agent. The background curves obtained in the solutions with HNO_3 introduced in concentrations higher than 1×10^{-4} M show (Fig. 1) an anodic peak dependent on the concentration of HNO_3 ($E_{peak} = 0.68 \pm 0.01$ V) is observed at potentials close to those of mercury ionization. This peak virtually disappears at HNO_3 concentrations $\leq 1 \times 10^{-4}$ M. The introduction of 1×10^{-4} M of HNO_3 into the absorbing solution was insufficient for complete absorption of atomic mercury from air. However, the ratio between the mercury concentrations in Tishchenko flask nos. 1 and 2 was improved (no. 1, ~80%; no. 2, ~20%).

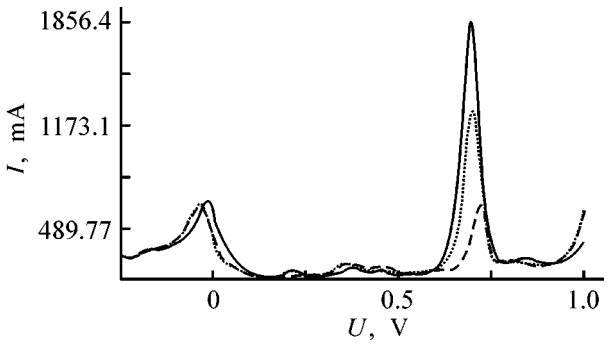

Fig. 1. Voltammogram obtained in a solution of composition 0.1 M HCl + 1 M $HClO_4$ + 1×10^{-3} M HNO_3 with addition of mercury. (I) Current and (U) voltage; the same for Fig. 2. Each curve corresponds to an increase in the concentration of nitric acid by an order of magnitude.

Therefore, we chose a solution of composition 0.1 M HCl + 1 M $HClO_4$ + 1×10^{-4} M HNO_3 for further experiments.

In our search for the conditions of absorption recovery of mercury, we took into account the known fact that virtually all forms of mercury are caught from air by activated carbon with elemental iodine absorbed on it [12]. By analogy, we studied the possibility of mercury absorption by a background electrolyte with addition of iodine. Molecular iodine was introduced into a solution of composition 0.1 M HCl + 1 M $HClO_4$ + 1×10^{-4} M HNO_3 by adding a solution of iodine in ethanol. The addition of iodine to the absorbing solution gave positive results. Mercury was found only in the solution contained in Tishchenko flask no. 1.

When choosing the optimal concentration of iodine, we started from the following. First, it was necessary to ensure a sufficient excess of iodine in the reaction mixture to effectively recover mercury from air and, second, the concentration of iodine should be not too high, because it is electrochemically active. In the presence of iodine, a peak is observed at +0.62 V in the voltammograms. Accordingly, at higher concentrations of mercury in air (>100 μg m^{-3}) and iodine in the absorbing solution (>10^{-5} M), an unresolved peak is observed in the voltammograms at 0.08–0.91 V (Fig. 2a). This peak corresponds to ionization of mercury with the formation of iodide complexes and to electrochemical conversion of iodine. In view of the fact that the mercury concentration range of practical interest for monitoring the content of mercury in air is in the range from several micrograms per cubic meter to tens of μg m^{-3}, we changed the conditions under which mercury vapor was generated. The area of the mercury mirror, over which the air was blown, was decreased from 400 to 16 mm^2. It was

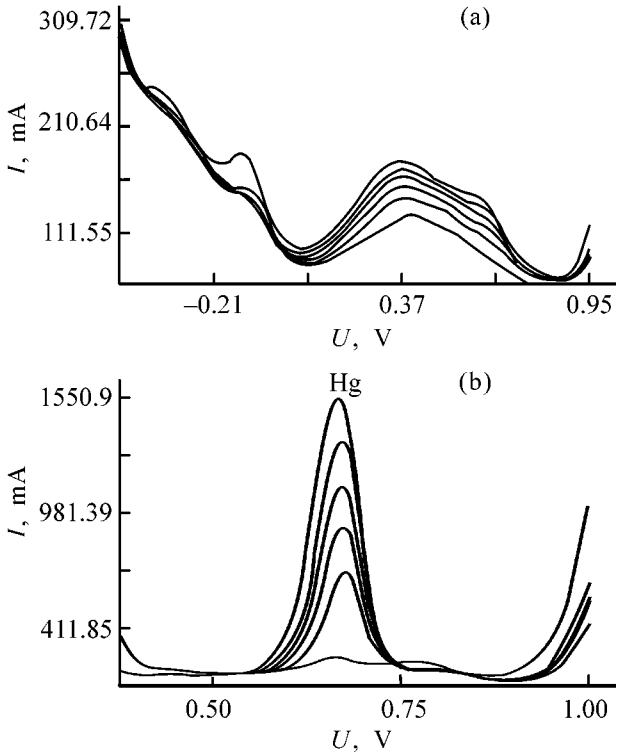

Fig. 2. Peak area in the voltammogram in bubbling air with a mercury vapor through a solution with a known concentration of Hg^{2+} ions. t_{acc} = 1 min. C_{I_2} (M): (a) 1×10^{-4} and (b) 1×10^{-6}.

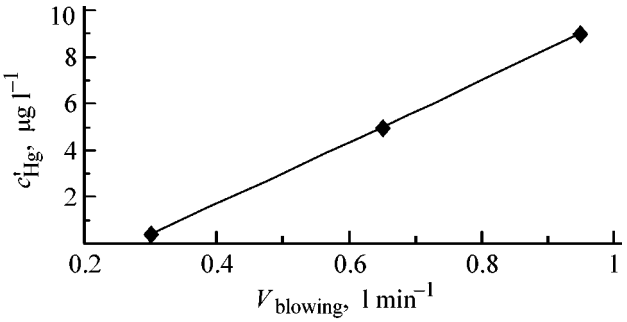

Fig. 3. Mercury concentration c'_{Hg} in a solution of composition 1 M $HClO_4$ + 0.1 M HCl + 2×10^{-4} M I_2 + 1×10^{-4} M HNO_3 vs. the rate of air blowing-through, $V_{blowing}$. t_{acc} = 60 s, flask no. 1.

found that the iodine concentration in solution, sufficient for complete recovery of mercury, is 1×10^{-6} M. No peak of iodine was observed in the voltammograms at this concentration (Fig. 2b).

A study of the concentration of mercury vapor in a solution at the outlet of the generator in relation to the blowing rate at a fixed volume of air (1 l) passed through the system gave the results presented in Fig. 3. It follows from the data obtained that the content of mercury at a blowing rate of 0.3–1 l min^{-1} varies in direct proportion to the blowing rate. Taking into account the experimentally confirmed completeness of mercury recovery with the solution of the chosen composition, we used a calibration plot constructed using data for reference solutions to determine the mercury concentration in air. This concentration, c'_{Hg}, was calculated by the equation

$$c'_{Hg} = c''_{Hg} \frac{V''}{V'},$$

where c''_{Hg} is the mercury concentration in the absorbate, found from the calibration plot; V'', volume of the absorbate; and V', volume of air blown through the system constituted by the generator and the absorbing vessel.

All the experimental data presented above suggest that the chosen solution composition provides for 100% mercury vapor catching in a wide range of mercury concentrations in air and allows inversion-voltammetric determination of mercury in a solution of the same composition.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Air Electrode of Chemical Power Cell as Oxygen Sensor

M. O. Danilov, G. Ya. Kolbasov, and N. V. V'yunova

Institute of General and Inorganic Chemistry, Ukrainian National Academy of Sciences, Kiev, Ukraine

Received February 21, 2003; in final form, April 2004

Abstract—The possibility of using the air electrode of a chemical power cell as an electrochemical oxygen sensor was studied.

The industrial development and ecological problems put forward, into a number of problems of current interest, the development of selective gas sensors for oxygen, hydrogen, and other gases [1, 2]. There exist two types of sensors: semiconductor [1, 2] and electrochemical [3, 4]. Semiconductor sensors have a semiconducting indicator element whose properties are changed under the action of a reagent to be determined. Electrochemical sensors intended for analysis of the gas composition of the atmosphere have the indicator electrode in which the electrode potential or the flowing current changes under the action of the reagent to be determined.

There exist electrochemical sensors of two types: potentiometric and amperometric. Amperometric sensors, in which the component to be determined is involved in a current-forming reaction, have the highest sensitivity among electrochemical sensors. Owing to the appropriate choice of catalysts for specific electrochemical reactions, amperometric sensors may have high selectivity and sensitivity. Electrochemical sensors based on a gas-diffusion electrode are preferable for analysis of gaseous media [4].

The goal of this study was to examine the possibility of using a porous gas-diffusion electrode, which is commonly applied in metal–air power cells and fuel cells, for analysis of oxygen-containing gaseous media. The prototype of such sensor is the air (oxygen) electrode of a chemical power cell.

The porous gas-diffusion electrode is a three-phase system electrode–electrolyte–oxygen [5]. The gas to be determined diffuses through a hydrophobic layer and enters into the current-forming reaction at the interface between three phases, gas–electrode–electrolyte.

As sensor for determining oxygen in the gas phase can serve a zinc–air chemical power cell or the oxygen electrode of a fuel cell working in a salt or acid electrolyte. The limitations associated with the use of an inert electrolyte are imposed in order to improve the selectivity of the sensor. This is because alkaline solutions can be carbonized in pores of the electrode by CO_2 present in the gas phase.

Let us consider the current-forming reaction at the air (oxygen) electrode in a neutral salt electrolyte:

$$O_2 + 4H^+ + 4e \rightarrow 2H_2O.$$

According to the data of [6, 7], where the kinetics of gas-diffusion porous oxygen electrodes is described, the current generated by this reaction is affected by the following factors: amount of fluoroplastic; electrode porosity; particle size of the catalyst, fluoroplastic, and carbon support; electrical conductivity of the electrolyte; and temperature. The electrode thickness and the dimensions of the current generation zone will also affect the current being generated. The dependence of the current on the electrode potential is determined not only by the Tafel slope but also by the relative values of the kinetic and transport coefficients of oxygen and the electrolyte.

Therefore, the oxygen sensor should have an inactive electrolyte, which poorly dissolves oxygen and does not enter into chemical reactions with possible impurities present in a gaseous medium. The indicator electrode should be composed of stable materials that are inert toward the gaseous medium. It should not include any oxygen-containing complexes and materials that can be involved not only in oxygen reduction, but also in a current-forming reaction, e.g., MnO_2.

As indicator electrode was used a combined matrix of the air electrode based on BAU activated carbon and

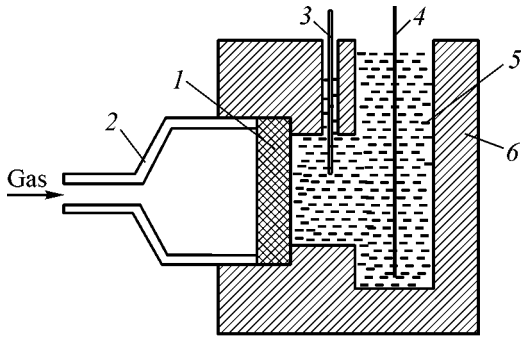

Fig. 1. Schematic of the electrochemical cell of the oxygen sensor: (*1*) indicator electrode, (*2*) gas-feeding chamber, (*3*) reference electrode, (*4*) auxiliary zinc electrode, (*5*) electrolyte, and (*6*) cell body.

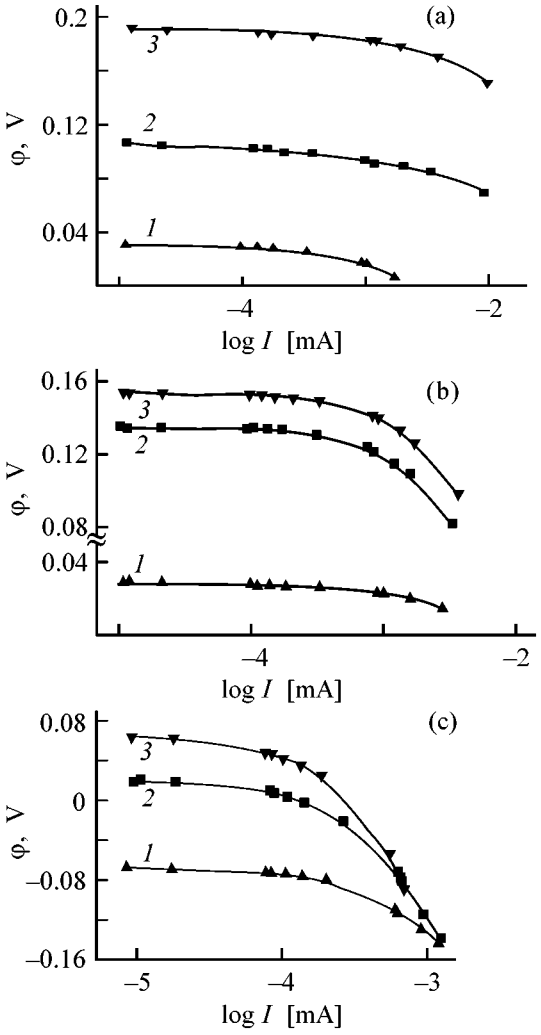

Fig. 2. Potential φ vs. current *I* for indicator electrode based on (a) BAU activated carbon, (b) polyaniline, and (c) combined matrix composed of polyaniline and BAU carbon in various gaseous media. (*1*) Argon, (*2*) air, and (*3*) oxygen.

electrochemically produced polyaniline. As shown previously [8], introduction of electrochemically produced polyaniline into the combined matrix gives a well-working air electrode. Therefore, a polyaniline matrix was used in the study. A salt electrolyte of composition 5 M NH_4Cl and 2 M $ZnCl_2$ was chosen. As auxiliary electrode served zinc, with the result that the sensor operated on the basis of an oxygen-zinc chemical power cell. The preparation of polyaniline and fabrication of the electrodes were described in [8]. All the potentials were measured relative to a silver chloride reference electrode. The indicator electrodes were fabricated from BAU activated carbon, pure polyaniline, and a combined matrix composed of polyaniline and BAU carbon.

The current–voltage characteristics of the oxygen sensor were measured in a three-electrode circuit in the current generation mode with a high-input-resistance voltmeter and microammeter.

The sensitivity of the air electrode based on the matrix was measured as follows. After the electrode was kept in argon, its potential (0.08 V relative to a silver chloride electrode) and the current at a load of 1×10^5 Ω were measured. Then, gaseous media were successively changed, the electrode was kept for 1 h, and the potential of the indicator electrode was adjusted to –0.08 V by making the load resistance lower. The current generated in the different media was recorded. The time of keeping in each medium was 1 h, although the potential varied noticeably only during the first 15 min.

The setup for testing the sensor is shown schematically in Fig. 1. The indicator electrode, composed of the matrix of the air electrode, was placed as a membrane between the gaseous medium and the electrolyte. The gas-feeding chamber, when tightened, firmly pressed the indicator electrode to the cell body. This chamber also served as a current lead.

The sensitivity of the oxygen sensor was tested in three gaseous media: oxygen-free atmosphere (argon), atmospheric air containing 21% oxygen, and a 100% oxygen atmosphere. The measurements were commenced in the oxygen-free atmosphere. Prior to a measurement, the electrode was kept for 2 h at a low pressure in the atmosphere to be analyzed. The excess pressure of the medium, created using an oxygen bag, was monitored with a gage.

The current–voltage characteristics of the indicator electrode in media with varied content of oxygen are shown in Figs. 2a–2c. Figure 2a demonstrates the cur-

rent–voltage dependence for the indicator electrode composed of activated carbon. As can be seen, at the minimum load of 300 Ω, on applying which the electrode is changed irreversibly, the potential corresponding to the argon atmosphere could not be reached in polarization with a flowing current in the atmosphere of air and oxygen. For the indicator electrode based on the electrochemically obtained polyaniline, it was possible to obtain rather close potentials at the minimum load (Fig. 2b, curves *2*, *3*) for air and oxygen, but it was impossible to reach the potentials corresponding to the atmosphere of argon (Fig. 2b, curve *1*).

The best coincidence of the potentials in argon, air, and oxygen (Fig. 2c, curves, *1*, *2*, and *3*, respectively) could only be achieved at the minimum possible load for the indicator electrode based on a combined matrix of activated carbon and polyaniline. As can be seen from Figs. 2a–2c, the current and potential of indicator electrodes respond to a certain extent to variation of the oxygen concentration in a gaseous medium. An analysis of Figs. 2a–2c demonstrated that the best suitable electrode for the oxygen sensor is a combined matrix composed of BAU activated carbon and polyaniline. With this electrode, a coincidence of the potentials in air and oxygen with the initial potentials in argon atmosphere was achieved at a load of 300 Ω and a polarization of 150 mV.

In this case, after switching off the polarization, the potentials of the matrix in different media returned to their initial values after a certain time at rest. This indicates that no irreversible changes occurred in the combined carbon-and-polyaniline matrix at a load of 300 Ω and a polarization of 150 mV.

The dependences of the potentials of the indicator electrodes composed of activated carbon, polyaniline, and a combined matrix on the oxygen concentration in the gaseous medium are shown in Fig. 3 (curves *1*, *2*, and *3*, respectively). As can be seen, the dependence is nonlinear for all the electrodes. This may be due to a change of the mechanism of oxygen diffusion in the hydrophobic layer toward the current generation zone on passing from a mixture of oxygen with the inert gas to pure oxygen.

The results obtained in measuring the sensitivity of the sensor with an indicator electrode based on a combined matrix composed of BAU activated carbon and electrochemically obtained polyaniline are presented in Fig. 4. An estimation of the sensitivity of this electrode from the dependence of the current on the oxygen concentration gives a rise in current by a factor of 180 on raising the oxygen concentration in air from 0 to 21%.

CONCLUSIONS

(1) Electrochemical oxygen sensors can be created on the basis of the air electrode of a chemical power cell. For this purpose, it is necessary to use a neutral salt electrolyte or an acid electrolyte that does not react with the medium to be analyzed.

(2) Owing to the use of electrocatalysts for oxygen reduction, these sensors possess a high sensitivity for oxygen in the gaseous medium to be analyzed.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Characteristics of Surface Microprofile of Electrolytic Copper Foil with High Adherence to Insulator

Abstract—The topography of a copper electrolytic foil with varied adherence to an insulator was studied by the methods of statistical analysis of profilograms, by optical and scanning electron microscopies, and by coherent optics. The morphology of the deposit surface was revealed, and the microprofile constants responsible for the adhesion were determined. A method for obtaining a foil with high adhesion strength was suggested.

One of requirements imposed on the copper foil used in radio engineering and microelectronics for metallization of insulators is the high strength of copper adhesion to the substrate. The adhesion of dissimilar materials depends on the physicochemical affinity of substances brought in contact [1] and on their mechanical interaction associated with the structure and topography of the foil [2, 3]. The highest adhesion strength is observed for a foil with two- or three-layered structure [4]. It is obtained by depositing an "adhesion layer" of powdered copper on films of compact copper (so-called "raw" foil). Rather frequently, powder particles are passivated or coated with a thin "reinforcing" layer of various metals to prevent their fall-off [5, 6].

The aim of this study was to analyze the adhesion properties of various samples of a multilayer foil to reveal the microgeometric structure of the surface of its separate layers and to develop a morphological factor and a method for obtaining copper that would provide a high adherence of metal to a nonconducting support.

EXPERIMENTAL

The parameters of the foil samples studied are listed in the table. All the samples, except sample no. 1, were coated with copper powder, and sample nos. 3, 6, 7, with additional reinforcing copper (no. 3) and brass (nos. 6, 7) layers. Differences in sample preparation are unknown because of the foreign origin of sample nos. 4–7 (Germany, Luxembourg, and USA).

The foil was attached to the insulator and the adhesion strength was estimated according to GOST (State Standard) 10316–78 and 262460–89. On a foil-clad fiber-glass plastic produced by the method described in [7], a pattern was etched in the form of four copper strips 74 mm long and 3 mm wide, spaced by 10 mm. The etching was performed in a solution of ferric chloride (density 1.4 g cm^{-3}) at 50°C. After washing and drying, the steady load at which no less than 25–30 mm of the foil was detached was determined for each strip with a RMU-0.005 tensile machine at a motion velocity of the mobile clamp of 50 mm min^{-1}. The minimum load determined by measurements on four strips described above was taken as the adhesion strength. Three parallel measurements were made on each sample. The average values of the thus determined adhesion strength are listed in the table.

The structure of cross sections of the foil was studied on an MMP-4 metallographic microscope. The surface microgeometry was examined on an ISM-U3 scanning electron microscope (SEM) and a Kalibr-201 profilograph, and analyzed by means of coherent Fourier optics. The combination of these methods allowed monitoring of the wide variety of geometric irregularities on the surface, from elements of growth of crystal faces and single grains of the deposit to their conglomerates and microscopic waves caused by microscopic nonuniformities of the foil thickness.

An LA-70 analog-to-digital converter connected to a profilographic amplifier (±5 V) was used to obtain data arrays with a 1-μm step along a 1–1.5-mm trace

* R_{am} and H_{rms}, the arithmetic mean and root-mean-square deviation of the profile, respectively; R_z and H_{max}, maximum height of irregularities; L_{av}, average width and α, average angle of inclination of the irregularities; l_{tr}, true length of the profile; S_{tr}, true surface area of the foil; and N_0, average number of iregularities per unit length of the trace.

** Transverse tracing.

of the microprofile in two mutually perpendicular directions, one of which coincided with the direction of motion of the foil in the electrolyte. The parameters characterizing the topography of the foil surface (see table) were determined by statistical processing of the data arrays, using a special software (based on formulas from [3, 8, 9]). The distribution of the metal along the height of the rough layer was characterized by plotting reference curves [8]. In addition, the distributions of the irregularities by height H, width L, and shape H/L were determined from the dependences of N/N_0 on H, L, and H/L, where N is the number of irregularities with the corresponding geometry.

A 35-μm-thick laboratory sample of foil was obtained by the method suggested previously [7] in pulsed electrolysis mode from an electrolyte of composition (M): $CuSO_4 \cdot 5H_2O$ 1 and H_2SO_4 0.5, on the polished steel cathode at 20°C. The current density was 6 A dm^{-2}, the pulse width, intervals between the pulses, and the total duration of electrolysis were 1 s, 5 s, and 2.7 h, respectively. To apply the adhesion layer, the electrode coated with raw copper was submerged in a 10^{-3} M solution of thiourea for 5 s. Then it was washed in distilled water and electrolysis was performed at 0.5 A dm^{-2} for 60 s at 18°C in an electrolyte containing (M): $CuSO_4 \cdot 5H_2O$ 0.02 and H_2SO_4 0.2.

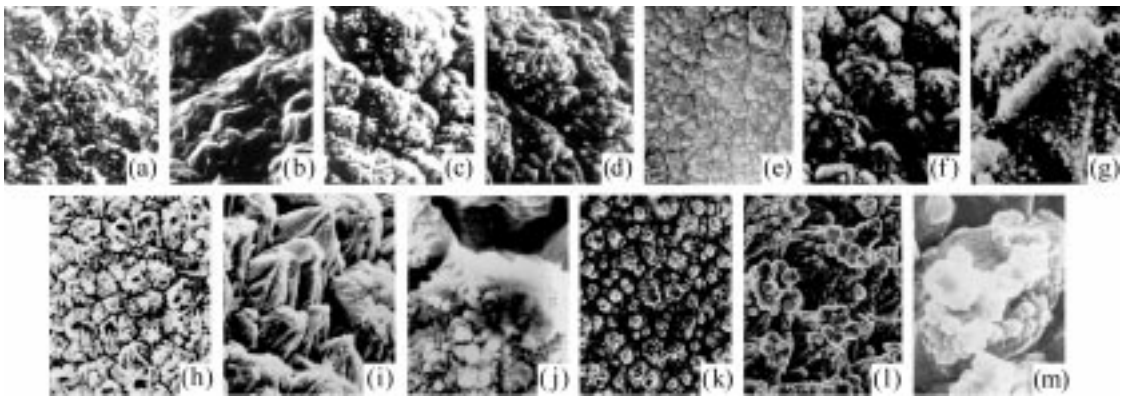

Fig. 1. Micrographs of the surface of the foil samples (a, b) no. 1, (c, d) no. 2, (e–g) no. 4, (h–j) no. 5, and (k–m) no. 6. Magnification: (k) 1500, (a, e, h) 2000, (c) 4000, (b) 4500, (f, i, l) 6000, (d, m) 12000, and (c, j) 20000. Measurement angle (deg): (a, e, h, j, k) 0 and (b–d, f, g, i, l, m) 45.

SEM micrographs of the foil surface are shown in Fig. 1. The surface of the raw foil with a low adhesion strength has loosely globular structure with a clearly pronounced nonuniformity of grains (grain size from 3 to 15 μm), which are speckled with Burgers dislocations and micropores (Figs. 1a, 1b). The layer of powdered copper, deposited on these structures, has the form of 0.3–0.4-μm grains of copper and copper oxide, which are uniformly distributed over the surface of flat crystals and somewhat decrease in size in going from projections to intergrain depressions (Figs. 1c, 1d). Deposition of a reinforcing layer of compact copper onto the powder has virtually no effect on structure of this foil.

Sample no. 4, like sample nos. 1–3, is not distinguished by high uniformity of the support grains (Figs. 1e–1g). At the same time, the scatter of their sizes, as also the size of the grains themselves (2.5–5 μm), considerably decreases. The powder layer has an extremely nonuniform distribution. The size of the powder particles is approximately 0.1–0.2 μm, i.e., a factor of 2–3 smaller than that of sample nos. 2, 3. At magnifications of about 20000, grains of raw copper in the form of faceted hexagonal pyramids with a conglomerate of powder particles at their vertices are clearly revealed (Fig. 1g). The insulator in which the foil is pressed may flow beneath such powder formations, with mechanical "locks" enhancing the adhesion produced as a result [3]. The adhesion strength is determined by the fraction of the surface, ν, occupied by the locks. This parameter can be evaluated by the ratio of the area under the lock to that occupied by a grain of the raw foil. Owing to the existence of a contact zone between the adhesion layer and the raw foil, the width of the lock is only a fraction of the width of a powder formation. This makes difficult finding the area under the lock, and, consequently, ν, too. We can roughly estimate ν by neglecting the above discrepancy and taking into account that the amount of the powder at the vertices and the zone of its contact with the grain grow simultaneously. In what follows, we name the powder formation the lock, thus emphasizing its function.

The minimum width of the lock for sample no. 4 is approximately 0.5–1 μm, i.e., 0.2 of the width of a raw foil grain, which corresponds to $\nu = 0.04$. As a base of the lock can serve any irregularity (projection or depression) making an acute angle with the visible surface of the foil [3]. In this case, even single particles of a uniformly distributed powder can act as locks if they are sufficiently large in size and have a granular structure similar to that in sample nos. 2, 3,. This seems to be a possible explanation of why the adhesion strength of the last two samples is better than that of sample no. 1.

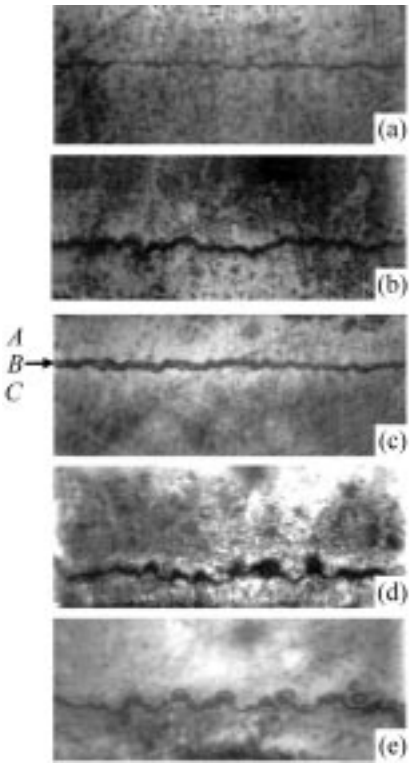

Fig. 2. Cross-sectional micrographs of the foil samples (a) no. 4, (b) no. 5, (c) no. 2, (d) no. 6, and (e) no. 7. Magnification: (a–c) 400 and (d, e) 600. (*A*) Raw foil, (*B*) powder, and (*C*) reinforcing copper sublayer.

A specific feature of sample nos. 5–7 (Figs. 1h–1m) is the pronounced uniformity of the substrate structure. The grains of the raw foil have a conical shape with the longitudinally folded facets. Their transverse dimensions are 4–6 μm (sample no. 5) or 5–7 μm (sample nos. 6–7). The copper powder is predominantly concentrated at projections of irregularities. The powder grain size of sample no. 5 is the same as that of sample no. 4 and five times less than that of sample nos. 6, 7. The micrographs of the foil clearly show the locks, each with small pits. The pits can enhance the adherence of the foil to the insulator, if their lateral faces make an acute angle with the bottom of a pit [3]. The minimum width of the lock is, similarly to sample no. 4, 0.2 of the grain width in the raw foil. The maximum width is markedly larger. It constitutes 0.3–0.5 of the width of the substrate grain.

Cross-sectional optical micrographs of foil samples (nos. 2, 4–7) are shown in Fig. 2. On sections prepared by the conventional procedure [10], two layers of compact copper with a dark layer of the powder in

between are clearly visible. One layer of compact copper is the raw foil, and the other, a the specially deposited reinforcing sublayer for preventing formation of roll-offs in polishing and finishing of the cross-sections of the samples to be studied. The surface of the raw foil is rough to a varied extent. The most pronounced roughness is observed for a foil with uniformly conical grains (sample nos. 6, 7), and the least rough surface, for a foil with extremely high size nonuniformity of grains of raw copper (sample no. 3). The adhesion layer reproduces the microprofile of the support, but its thickness and thickness uniformity vary between different samples. For example, a virtually uniform distribution of the powder over the irregularities of the raw foil is observed for sample nos. 2, 4, and 5, but the thicknesses of the powder layers are different. It is the same and equal to about 5 μm for sample nos. 2 and 5, and two times smaller for sample no. 4. A clearly pronounced nonuniformity in the distribution of the powder layer over microdefects of the substrate is observed for sample nos. 6, 7. In this case, globular formations of the powder with radius varying from 1 to 4 μm are present on microprojections of the raw foil. Apparently, they favor formation of locks. On the lateral edges and at microdepressions, the adhesion layer is, by contrast, virtually absent.

Thus, the results of our study of the surface morphology of a foil coated with a powder layer and of its cross-sections suggest that the adhesion strength is determined by the structure of the layers of both raw and powdered copper. The pointed crystals of the support ensure a reliable and deep penetration of the metal into the insulator. The nature of distribution of the powder particles over the grains of the raw foil provides formation of the mechanical locks of different shapes, from separate granular particles to conglomerates of various pointed irregularities. The highest adhesion is ensured by locks in the form of conical formations whose vertices are oriented toward vertices of raw copper grains and bases extend across voids of various sizes.

The microscopic study of the foil is mostly of descriptive nature. Obtaining the numerical parameters is limited to only the average size of structural elements. A more detailed quantitative description of the foil structure requires use of additional methods. In the study, the surface was examined by the method of contact profilography, with the subsequent statistical processing of the profilograms obtained.

The results of the statistical processing (see table) show that the parameters characterizing the height of the surface microprofile (R_{am}, H_{rms}, R_z, and H_{max}) are comparatively close for all the samples (R_{am} = 0.75–1, H_{rms} = 0.93–1.3, R_z = 3.5–6.1, and H_{max} = 3.9–7.9). Although no unambiguous correlation between the height of the microprofile and the adhesion strength can be revealed, a part of foil with an increased adhesion (sample nos. 5–7) has a somewhat more pronounced roughness (by 10–20%). No regular relationship is observed between the adhesion strength and the transverse dimensions of foil grains, which vary from 15 to 23 μm for different samples. For example, for foils with virtually the same average grain widths (sample nos. 1, 6) the strength of adherence to the insulator differs by more than a factor of 4. As indicated by the S_{tr}/S_0 ratio at S_0 = const, the true surface area of the foil coated with powder copper (sample nos. 2–7) steadily grows as their adherence capacity becomes higher. Only sample no. 1, which has no adhesion layer, falls out of the general trend. On the assumption that the irregularities have a triangular profile, it can be readily shown by a simple calculation that the ratio of S_{tr} to the apparent surface area S_0 is given by

$$S_{tr}/S_0 = (l_{tr}/l_0)^2 = (1/\cos\alpha)^2.$$

A similar result is obtained on the assumption of a spheroid shape of the irregularities.

$$S_{tr}/S_0 = (l_{tr}/l_0)^2 = [\alpha_1/2\sin(\alpha_1/2)]^2.$$

This means that the true surface area can be qualitatively characterized by the average angle of inclination of the irregularities, α, or by their curvature α_1. The greater α or α_1, the larger the true surface area, and statistical calculations do confirm this conclusion. As can be seen from the data in the table, the average angle of inclination of the irregularities varies similarly to S_{tr} as the adhesion increases. Another parameter indirectly characterizing the S_{tr} is the number of irregularities per unit length of the trace N_0 [3]. However, no correlation is observed between S_{tr} and N_0. This inconsistency may be due to the fact that profilography can give only a rough account of the true surface area of foil, which should be estimated [9] by considering simultaneously profilograhic data and those furnished by optical and scanning electron microscopies. Apparently, the method of contact profilography characterizes only that part of the surface which is formed by a conglomerate of grains. As to the true surface area of faces of grains themselves, coated with the powder, it can be qualitatively estimated from the secondary-electron emission spectra.

The secondary-electron emission spectra can be recorded simultaneously with sample surface imaging on a scanning electron microscope. These spectra are shown on the background of the surfaces studied in Figs. 3a, 3b. They look like profilographic traces on the surface of the samples at places indicated in the micrographs by solid lines. Special experiments on surfaces with undulate and steplike microprofiles showed that, unlike contact profilograms, the "optical profilograms" reflect neither areas with different heights, nor gently sloping waves. They are not affected by photographic magnification, either, and exhibit response solely to the angle of inclination of the irregularities and their curvature, i.e., to the true surface area of a foil. The stronger the average curvature of the irregularities, the larger S_{tr} and the higher the profile. This allows a qualitative estimate of the true surface area of crystals, which depends on the microgeometry and distribution of powder particles, by comparing the heights of optical profilograms.

The secondary-electron emission spectra, obtained from the surface of sample nos. 2–6 (Fig. 3), show that no unambiguous correlation exists between S_{tr} and the structure of the powder layer. Indeed, fine powder particles uniformly distributed over grains of raw copper (sample no. 3) exhibit a higher emission intensity than coarser particles irregularly covering the compact foil (sample no. 6). At the same time, sample nos. 2, 4, and 5 have, despite their different morphologies, spectra with virtually equal intensities, which is higher than those for sample nos. 3 and 6. Consequently, the true surface area associated with the powder structure and evaluated microscopically is not a factor determining the adherence of a foil to an insulator, unlike S_{tr}, which is found by profilography and takes into account profile elements with transverse dimensions of no less than 10 μm.

The results obtained in profilogram processing, which describe the distribution of the metal along the height of the rough layer and the distributions of the microprofile irregularities by size and shape are shown in Fig. 4.[1] The run of the reference curves (Fig. 4a) shows that the foil with higher adhesion strength (sample nos. 4–7) is distinguished by a steep drop of the deposit heights h at low and high fillings of the rough layer with the metal, l, at a length of the profile studied equal to l_0. This shows that high adhesion strength is typical of samples with roughness characterized by steeper projections and depressions. In this case, the size distribution of irregularities is uniform for all the foil samples, because the run of the reference curves is monotonic without sharp bends and inflections, which appear when microprofile elements of widely different sizes are present on the surface.

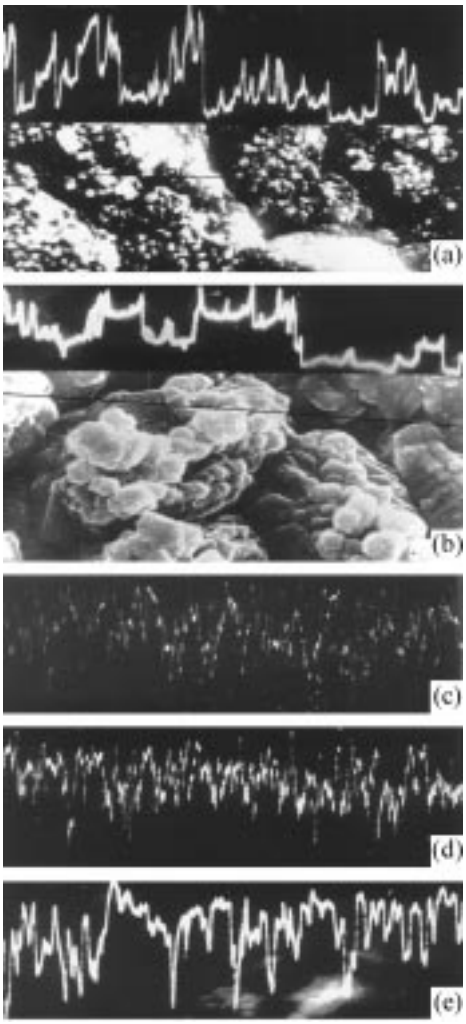

Fig. 3. Secondary-electron emission spectra of the foil samples (a) no. 3, (b) no. 6, (c) no. 4, (d) no. 5, and (e) no. 2 with (a, b) and without (c–e) the corresponding micrographs of the surface. Magnification: (c, d) 2000, (e) 10000, and (a, b) 12000.

The structural features of the foil roughness are the most clearly demonstrated by the curves of the height distribution of the irregularities (Fig. 4b). A foil with a high adhesion commonly has a larger fraction of higher irregularities (2.5–4 μm). Indeed, the foil with locks formed by copper powder (sample nos. 5, 7) has irregularities with a typical height of 2.5–3 μm, whereas on other samples (i.e., no. 2), the irregularities are lower.

[1] To make the perception of the statistical data in Fig. 4 easier, only selected curves clearly illustrating the conclusions based on the analysis of the whole body of the experimental data are presented of the whole variety of the dependences obtained.

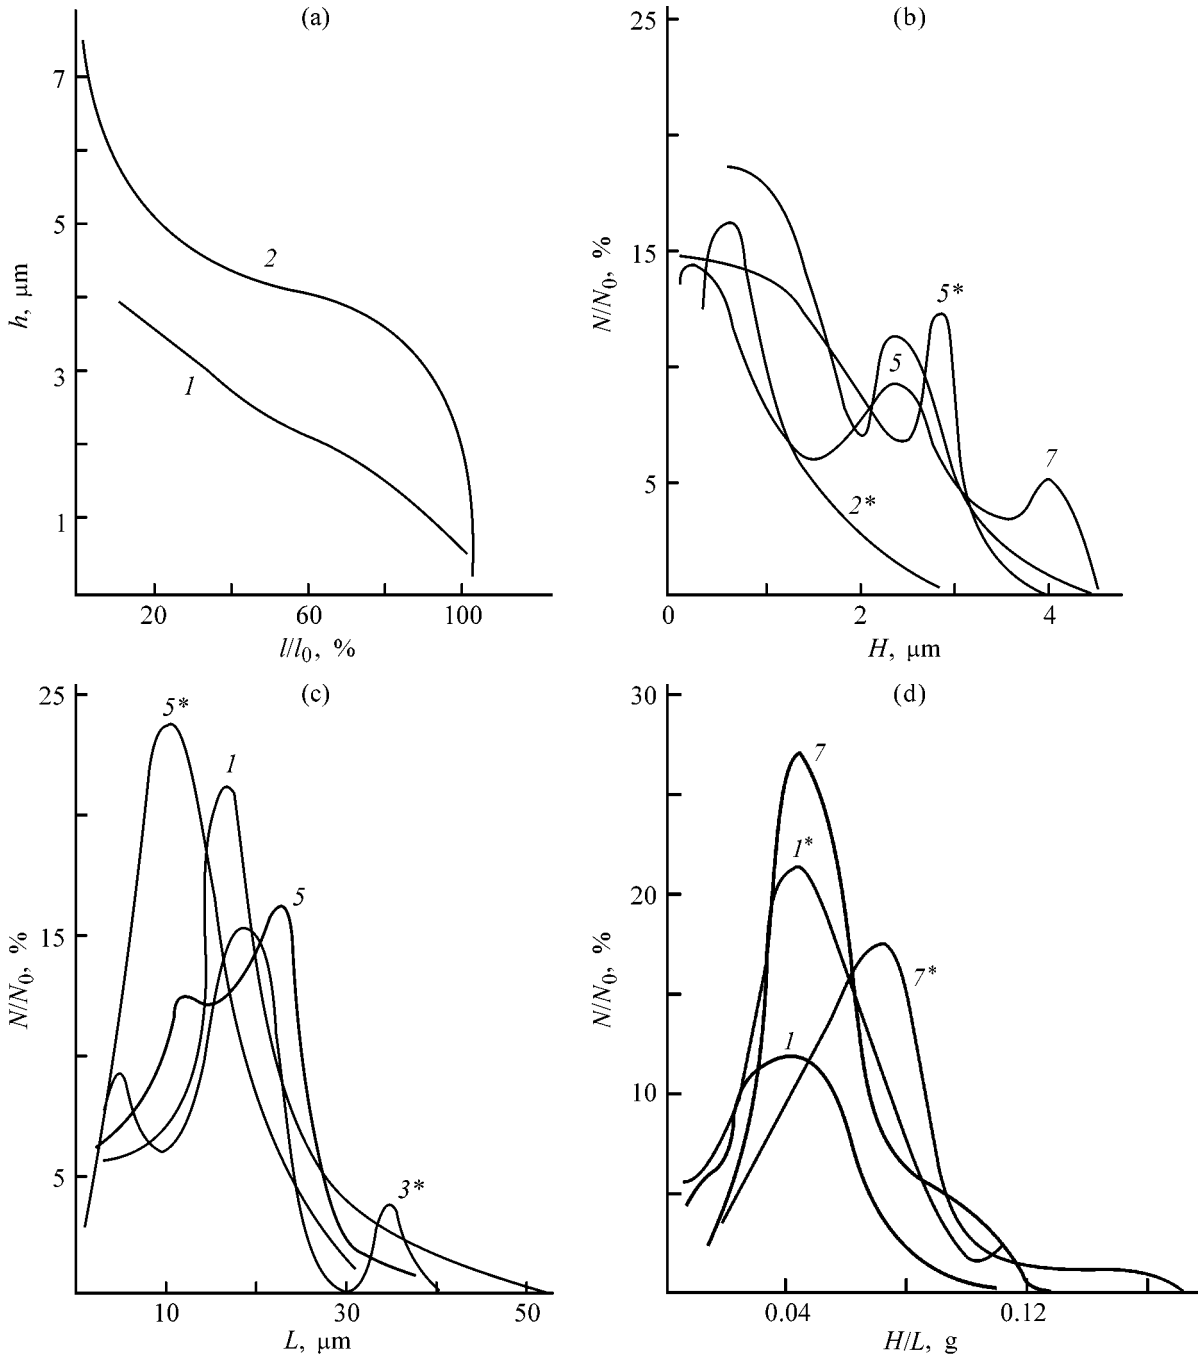

Fig. 4. (a) Reference curves h–l/l_0, the distributions of irregularities with respect to (b) height N/N_0–H, (c) width N/N_0–L, and (d) shape N/N_0–H/L. The *curve numbers* are the sample numbers [longitudinal and transverse (*) roughness].

The curves of the width distribution of the irregularities show a peak at around 10 μm for most of the foil samples (Fig. 4c). This indicates that, owing to the finite size of the probing tip of the profilograph, irregularities less than 10 μm in width are distorted or not recorded on the profilograms at all. This also confirms the predominance of small irregularities in the microprofile. Their dominating role in sample nos. 4–7 with a high adhesion strength is manifested as a clearly pronounced peak at L = 10 μm. This peak is always observed in transverse tracing of the foil surface with the profilograph tip. In longitudinal tracing, and also on foils with a lower adhesion strength, the peak is either broadened or shifted to larger L.

A study of the distribution of irregularities by sharpe (Fig. 4e) revealed a correlation between the adhesion strength and the profile structure. Indeed, the fraction of steep irregularities is commonly larger on the surface of foils with higher adhesion strength, compared with the other samples. For example, the number of irregularities with the ratio $H/L = 0.08$ is the following for sample nos. 4–7 (%): 27, 42; 24, 36; 9, 13; 7, 16, respectively; here the first and second figures in each pair corresponds to the longitudinal and transversal tracing of the foil surface, respectively. For the foil with an insufficiently high adhesion strength, the fraction of such irregularities constitutes only 2 and 9% for sample no. 1, 5 and 6% for sample no. 2, and 9% for sample no. 3 (transverse tracing). The percentage of even steeper irregularities with $H/L = 0.12$ varies from 2 to 22% on the surface of a foil with a high adhesion and does not exceed 1% of the total amount of defects in the profile for the foil with a low adhesion strength.

Notably, the surface of the foil studied is anisotropic. As can be seen from the data in the table, the anisotropy of the roughness parameters in the mutually perpendicular directions is small and does not commonly exceed 10–20%. This makes it possible to describe each parameter by only a single figure: the average of the values obtained in longitudinal and transverse tracings of the foil surface. The anisotropy also shows up in estimating the distributions of irregularities by height, width, and shape (Fig. 4). The anisotropy is an indication of the diffusion kinetics of formation of the majority of foils, which results in the appearance in their structure of heterogeneities caused by hydrodynamic flows in solution.

The profilographic method gives a notion of the anisotropy of the macroscopic elements of the microprofile. The method of coherent optics, which allows a study of the periodicities caused by growth of raw copper crystals and powder particles has great possibilities. An optical coherent spectral analyzer obtains information about the topography of a surface from its image on the photographic film in the form of a Fraunhofer diffraction pattern (FDP), which is a two-dimensional power spectrum of the frequencies present in the image [11]. The range of the periodicites recorded in FDP depends on the magnification of a photograph. With magnifications of 25 to 1500, the periodicites in the range from 40 to 0.1 μm can be studied.

The Fraunhofer diffraction pattern is a set of light spots of various shapes, whose brightness decreases from the center toward the periphery. Analysis of the shape of these spots reveals the anisotropy of the structure, its character, and orientation, indiscernible under visual inspection. It has been shown for electrolytic copper deposits that the spot is circular for an isotropic polycrystalline surface, [12]. Presence of clearly faceted crystals on the surface or similarly oriented profiles on the faces of these crystals (in the form of grooves or steps) leads to a redistribution of the light intensity in the directions that are normal to the structural elements and symmetric with respect to the FDP center. In the absence of a clearly pronounced faceting of the crystals, the surface anisotropy cannot be viewed visually, but is readily revealed by FDP, which acquires the shape of an ellipsoidal spot.

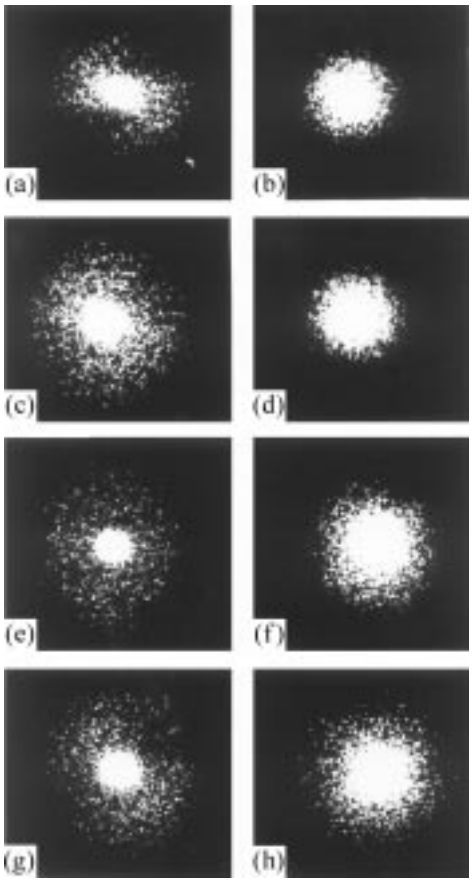

Fig. 5. Fraunhofer diffraction patterns and micrographs of the surface of the foil samples (a, b) no. 1, (c, d) no. 3, (e, f) no. 5, and (g, h) no. 6. Magnification: (e) 25, (g) 30, (a, c) 50, (b, d) 500, and (f, h) 1500.

The FDPs obtained in studying the surface of some foil samples are shown in Fig. 5. According to Fig. 5, the anisotropy is clearly manifested in all the samples at low magnifications. The anisotropy is the stron-

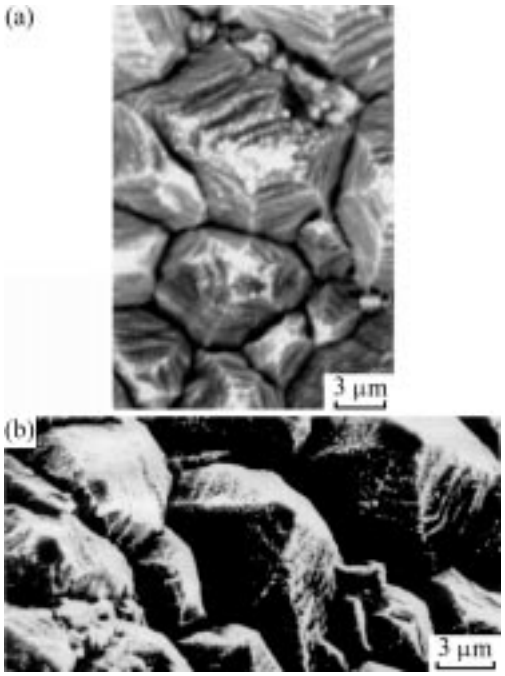

Fig. 6. SEM micrographs of the surface of a strongly adherent foil sample with a powder lock formed by preliminary modification of raw copper in an aqueous solution of thiourea. Measurement angle (deg): (a) 0 and (b) 5.

gest for the raw foil (sample no. 1), being less pronounced for sample nos. 3, 6 and, especially, sample no. 5. This indicates that the reason for the appearance of anisotropy is, for the most part, that coarse microstructural elements grow differently in the mutually perpendicular directions, in agreement with the profilographic data. Apparently, the anisotropy must impair the adhesion of the foil in certain directions. At the same time, it follows from the FDPs presented and from profilographic data that the anisotropy does not affect the adhesion by itself (within the limits recorded). Moreover, detailed analysis of the FDPs obtained from the photographs taken at large magnification shows that the ellipsoidal form is more clearly pronounced in samples with a high adhesion (Figs. 5f, 5h). This means that the ordered distribution of the powder particles over the coarse elements of the microprofile improves the adhesion strength of the foil.

Thus, to improve the adhesion strength of a foil, it is necessary, first of all, to ensure formation of conical or pyramidal grains of raw copper, which are uniform in size and have a width of 4–8 μm. In addition, a copper powder is to be deposited onto the foil to create mechanical locks that enhance the adhesion. The adhesion considerably increases in the case of a preferential deposition of the powder on tips of grains of the support. This occurs because the size of locks and the surface area occupied by them increase (ν changes from 0.04 to 0.15 in going from sample no. 4 to sample nos. 6, 7). The size of powder grains, which is not a crucial factor, varies within 0.1–1 μm. Spheroid granules are preferable. The reinforcing metallic layers must not make smoother the topography of the foil surface, formed upon powder deposition.

The pyramidal and conical structures of the raw foil can be easily formed if the sulfate copper plating electrolyte is purified to remove organic impurities and certain modes of pulsed electrolysis are used [13]. The copper powder is commonly obtained in the same electrolyte at the limiting current density, which is reached fast by making lower the concentration of Cu^{2+} ions, by intensifying the stirring of the solution, and by raising the concentration of sulfuric acid in the electrolyte [14]. The nonuniform distribution of the powder over the microirregularities of the cathode is favored by introduction of active depolarizing agents into the electrolyte [4, 6]. However, the incorporation of these additives into the deposit impairs its physicomechanical properties [8, 14], and their consumption in the course of electrolysis requires frequent corrections of the bath.

This stimulated a search for additional ways to control the distribution of powder copper over the electrode. The method suggested for production of foil is based on an unusual phenomenon in electrodeposition, which is associated with the ability of certain additives to rise to the surface of the deposit in the course of electrolysis, rather than being absorbed [15]. This ability is exhibited, in particular, by thiourea [16, 17]. This circumstance made it possible to separate the sorption and electrolysis processes and preliminarily modify raw copper having a pyramidal crystal structure in an aqueous solution of thiourea, with the subsequent deposition of the powder in a pure electrolyte, instead of introducing the additive into electrolyte [7]. In the course of sorption, thiourea decomposes to give Cu_2S [16]. Owing to the predominant diffusion of thiourea to the apices of microirregularities, copper(I) is preferentially formed there. When the amount of the sulfide present on the electrode surface constitutes a fraction of a monolayer, there occurs a prolonged (up to 10 min) depolarization of the subsequent electrodeposition of copper. As a result, the current density at apices of microirregularities is considerably higher during the above period, compared with that on the rest of the foil surface. Thereby, projections are formed at apices of the microirregularities to give locks in pressing of the foil in the insulator. When inspected under an electron microscope, these projections have the form of truncated pyramids (Fig. 6). The strength of adhesion

of such a foil to the insulator is 2160 N m^{-1}. Owing to the fact that additive is forced to the surface by the growing deposit [17], the concentration of sulfur incorporated in the deposit decreases [7], which makes lower the susceptibility of the foil to embrittlement and its possible corrosion activity.

CONCLUSIONS

(1) It was established that the highest adherence to the insulator is exhibited by a foil with uniform size and steep shape of conical or pyramidal grains of raw copper and extremely nonuniform distribution of copper powder particles over these grains. The powder, being concentrated at apices of microdefects, forms irregularities, and these irregularities give rise to mechanical locks in pressing of the foil in the insulator.

(2) A statistical study of the surface microprofile of the foil samples with a powder adhesion layer demonstrated that the strength of adhesion to the insulator increases when irregularities with an aspect ratio of 0.08–0.09 and an angle of inclination of no less than 7°–8° are present (in an amount of no less than 7%) in the microprofile and when the true surface area exceeds the apparent surface area by more than a factor of 1.048.

(3) An original method for obtaining copper foil with a high adhesion strength was suggested. This method is based on the prolonged influence exerted by thiourea preliminarily sorbed on the cathode on the copper electrodeposition from a sulfate solution. The forcing of the additive by the metal to the surface and its elimination from the electrolyte ensure that a lower amount of sulfur is incorporated in the deposit and improve the ecological conditions of the manufacture process.

Received April 18, 2003; in final form, September 2004

Abstract—A model of the process of filtration of the extracting agent in porous particles with entrapped gas was developed. This model takes into account pressure oscillations in the extractor.

The method of extraction with low-frequency pressure oscillations in the working volume of the apparatus finds increasing use for extracting target components from vegetable raw materials [1–6]. Compared with the conventional techniques, this method makes it possible to raise the mass-transfer rate, shorten the process duration, and diminish the energy expenditure. The available publications, as a rule, consider the hydrodynamics and mass exchange in separate capillaries [4–6]. The goal of the present study was to develop a model of filtration mass transfer in porous particles that would take into account pressure oscillations in the extractor.

Porous spherical particles, plates, and cylinders can serve as models of fruits and particles of a shredded raw material, leaves, and stalks, respectively. One or several zones of entrapped gas (as a rule, air), which are formed in impregnation of a vegetable raw material under the action of capillary forces, can be found within each particle in the initial stage of the process. Depending on how the pressure in the apparatus varies, the filtration of the extracting agent occurs in porous particles in different directions: from the periphery of a particle toward its center if the pressure in the apparatus increases, and vice versa. In the process, the gas in the entrapping zones is compressed or expands alternately. The difference between the maximum and minimum volumes of the zones with entrapped gas is equal (with account of the particle porosity) to the volume of the extracting agent entering a particle and exiting from it in a single cycle of variation of the external pressure.

Let us consider the filtration of the extracting agent in a spherical porous particle for the case when the zone of entrapped gas lies at its center. We assume that the particle and the extracting agent are incompressible, the structure of the particle is isotropic, and disregard the variation of the hydrostatic pressure along the particle height and the action of the gravity force on the filtration. The equations describing the filtration in a porous body in the spherical system of coordinates were presented in [7]. Taking into account the assumptions made and the symmetry of the spherical particles, we can transform these equations to obtain the following

$$\rho\varepsilon\left(\frac{\partial v_r}{\partial \tau} + v_r\frac{\partial v_r}{\partial r}\right) = -\varepsilon\frac{\partial p}{\partial r} - f_r s_V, \qquad (1)$$

$$\frac{\partial v_r}{\partial r} = -2\frac{v_r}{r}, \qquad (2)$$

where τ is time (s); r, running radius (m); v_r, velocity of filtration along the coordinate r (m s^{-1}); ρ, density of the liquid (kg m^{-3}); ε, volume fraction of pores; $\partial p/\partial r$, gradient of pressure along the coordinate r (Pa m^{-1}); f_r, specific force of interphase resistance, caused by friction of the liquid against the skeleton of a porous body (Pa); and s_V, specific internal volumetric surface area of the particle skeleton (m^2 m^{-3}).

In the laminar mode of motion of the extracting agent in a porous body, the specific resistance force is given by [7]

$$f_r = \frac{2\mu\xi^2 s_v}{\varepsilon} v_r, \qquad (3)$$

where μ is the dynamic viscosity coefficient (Pa s), and ξ is the tortuosity factor of the filtration path.

1070-4272/04/7710-1662 © 2004 MAIK "Nauka/Interperiodica"

On substituting Eqs. (2) and (3) into (1), we have

$$\frac{\partial v_r}{\partial r} - 2\frac{v_r^2}{r} + \frac{1}{\rho}\frac{\partial \rho}{\partial r} + Bv_r = 0, \quad (4)$$

where $B = 2\mu\xi^2 s_v^2/(\varepsilon^2\rho)$ is the coefficient characterizing the force of resistance to the motion of the liquid within a porous body (s^{-1}).

The filtration of a liquid within a porous particle is driven by the difference of pressures at the particle surface (external pressure P_{ext}) and inside a particle (in the zone of entrapped gas, P_{in}). Let us assume that the external pressure exerted by on the porous particle by the liquid varies by the law $P_{ext} = P_0 + \rho gh + \Delta P \sin\omega\tau$, where P_0 is the pressure at the initial instant of time or the average pressure in the extractor (depending on the principle of action of the extractor) (Pa); ρgh, hydrostatic pressure at a depth h at which a particle is situated (Pa); ΔP, amplitude of pressure oscillations around P_0 (Pa); and ω, angular frequency of pressure oscillations ($\omega = 2\pi f$) (rad s^{-1}).

The pressure within particles depends on the shape and diameter of pores, wettability of the particles with the solvent, and conditions of their impregnation. Let us designate the gas pressure within the porous particles at the initial instant of time (at the instant of impregnation with the extracting agent) as P_{in}.

In accordance with the Clapeyron equation, PV = const,

$$V_{pt}P_{in} = V_{tr}(P_{in} + P_c), \quad (5)$$

where V_{pt} and V_{tr} are the gas volumes in a dry porous particle in the entrapping zone of a wetted particle (m^3); $P_c = 4\sigma\cos\theta/\delta_c$, capillary pressure (Pa); σ, surface tension (N m^{-1}); θ, contact wetting angle (deg or rad); and δ_c, capillary diameter (m).

It follows from Eq. (5) that the volume fraction of entrapped gas at the instant of impregnation is given by

$$\alpha_0 = \frac{V_{tr}}{V_{pt}} = \frac{P_{in}}{P_{in} + P_c}. \quad (6)$$

If $P_{in} = P_0$, then

$$\alpha_0 = \frac{P_0 + \rho gh}{P_0 + \rho gh + P_c}. \quad (7)$$

If the particles are then placed in an apparatus with a pressure P_{ext}, the volume fraction of entrapped gas changes to

$$\alpha_{01} = \frac{P_{in}}{P_{ext} + P_c}. \quad (8)$$

If the shape of the gas entrapping zone gas is assumed to be the same as that of the particle itself, the radius of this zone can be found as

$$r_{01} = R\sqrt[3]{\alpha_{01}}, \quad (9)$$

where R and r_{01} are the radius of the particle and that of the gas entrapping zone at a pressure P_{ext} (m^3).

The gas pressure in the entrapping zone, P_{tr}, corresponds to the running radius r_0. By analogy with relation (5), $P_3 r_{01}^3 = (P_c + P_0 + \rho gh)r_0^3$, whence follows

$$P_{tr} = (P_c + P_0 + \rho gh)\left(\frac{r_0}{r_{01}}\right)^3, \quad (10)$$

where r_0 is the radius of the entrapping zone at the impregnation pressure (m).

The internal pressure exerted on the liquid in capillaries by the entrapped gas is lower than P_{tr} by the value of the capillary pressure P_c, which is oppositely directed:

$$P_{int} = (P_c + P_0 + \rho gh)\left(\frac{r_0}{r_{01}}\right)^3 - P_c. \quad (11)$$

Having integrated Eq. (2), we find how the velocity of the liquid being filtered varies along the particle radius:

$$\int_{v_R}^{v_r}\frac{\partial\omega_r}{\omega_r} = -2\int_R^r\frac{\partial\gamma}{\gamma}, \quad v_r = v_R\left(\frac{R}{r}\right)^2, \quad (12)$$

where ω_r and γ are auxiliary variables; v_r and v_R, velocities of filtration of the liquid across a spherical surface of radius r and on the particle surface (at $r = R$).

The velocities v_r and v_R are unknown functions; v_R is dependent only on time, and v_r, on time (via v_R) and radius [in accordance with formula (12)]. Substituting (12) into Eq. (4), we obtain

$$v_r'\left(\frac{R}{r}\right)^2 - 2v_R^2\frac{R^4}{r^5} + \frac{1}{\rho}\frac{\partial p}{\partial r} + Bv_R\left(\frac{R}{r}\right)^2 = 0. \quad (13)$$

Hence follows

$$\frac{1}{\rho}\frac{\partial p}{\partial r} = -\left[v_R'\left(\frac{R}{r}\right)^2 - 2v_R^2\frac{R^4}{r^5} + Bv_R\left(\frac{R}{r}\right)^2\right],$$

$$\frac{1}{\rho}\int_{P_{ext}}^{P_{int}}\partial p = -\int_R^{r_{01}}\left[v_R'\left(\frac{R}{r}\right)^2 - 2v_R^2\frac{R^4}{r^5} + Bv_R\left(\frac{R}{r}\right)^2\right]\partial r.$$

Upon integration and substitution of the values of P_{int} and P_{ext}, we obtain

$$v_R' R\left(\frac{R}{r_{01}} - 1\right) = (P_c + P_0 + \rho gh)\left[\left(\frac{r_0}{r_{01}}\right)^3 - 1\right]/\rho - \frac{\Delta P}{\rho}\sin\omega\tau + \frac{v_R^2}{2}\left[\left(\frac{R}{r_{01}}\right)^4 - 1\right] - Bv_R R\left[\left(\frac{R}{r_{01}}\right) - 1\right], \quad (14)$$

where $v_R' = \partial v_R/\partial\tau$.

Equation (14) involves an unknown quantity r_{01}, the running radius of the gas entrapping zone. As the velocity with which r_{01} changes coincides with the velocity of filtration at $r = r_{01}$, we obtain, taking into account formula (12) and introducing a dimensionless variable $z = R/r_{01}$, a system of two ordinary differential equations describing the process of filtration in a spherical porous particle with entrapped gas:

$$\begin{cases} \dfrac{\partial v_R}{\partial\tau} = \left[\Pi(Az^3 - 1) - \Delta\Pi\sin\omega\tau + \dfrac{v_R^2}{2}(z^4 - 1) - Bv_R R(z - 1)\right]/R(z - 1), \\ \dfrac{\partial z}{\partial\tau} = -\dfrac{v_R}{R}z^4. \end{cases} \quad (15)$$

The initial conditions are as follows: $\tau = 0$, $v_R = 0$, $z = R/r_0$.

The following designations are made in the system of equations (15): $\Pi = (P_c + P_0 + \rho gh)/\rho$, $\Delta\Pi = \Delta P/\rho$, $A = (r_0/R)^3$.

Equation (14) was numerically analyzed at different values of $\omega\tau$ and capillary diameters δ_c. The values of the physical variables appearing in Eq. (14) were taken to be as follows: $r_0 = 1 \times 10^{-3}$ m, $R = 4 \times 10^{-3}$ m, $\omega = 125.6$ rad s^{-1}, $\mu = 1 \times 10^{-3}$ Pa s, $\xi = 1.6$; $\varepsilon = 0.4$, $\theta = 0$; $\sigma = 73 \times 10^{-3}$ N m^{-1}, $\rho = 1000$ kg m^{-3}, $P_0 = 10^5$ Pa, $\Delta\rho = 0.25 \times 10^5$ Pa. s_v was calculated using the formula $s_v = 4\varepsilon/\delta_c$, which is valid for the case when the porous body is constituted by separate particles [8]. The hydrostatic pressure was neglected: $\rho gh = 0$; the capillary diameter was chosen in the range 10^{-3}–10^{-7} m. The contributions from the terms in Eq. (14) were evaluated with respect to that from the main terms $(P_c + P_0 + \rho gh)[(r_0/r_{01})^3 - 1]/\rho$ and $(\Delta P/P)\sin\omega\tau$.

It was established that, at different values of $\omega\tau$, the contributions of most of the terms are in the range 5×10^{-3}–5×10^{-7}% relative to the main terms and can be neglected. At capillary diameters $\delta_c \geq 1 \times 10^{-5}$ m, the term $Bv_R R[(R/r_{01}) - 1]$ can also be neglected. Then, formula (14) takes the form

$$(P_c + P_0 + \rho gh)\left(\frac{r_0}{r_{01}}\right)^3 = P_c + P_0 + \rho gh + \Delta P\sin\omega\tau, \quad (16)$$

whence follows, with account of (9),

$$r_{01} = R\left[\frac{(P_c + P_0 + \rho gh)\alpha}{P_c + P_0 + \rho gh + \Delta P\sin\omega\tau}\right]^{1/3}. \quad (17)$$

The relative (to the volume of liquid in the porous body at full impregnation) amount of the liquid drawn in and forced out of a porous particle in a cycle is given by

$$V_{rel} = \frac{\varepsilon V_{tr.max} - \varepsilon V_{tr.min}}{\varepsilon V_{pt}} = \frac{\alpha(P_c + P_0 + \rho gh)}{P_c + P_0 + \rho gh - \Delta P} - \frac{\alpha(P_c + P_0 + \rho gh)}{P_c + P_0 + \rho gh + \Delta P}, \quad (18)$$

where $V_{tr.max}$ and $V_{tr.min}$ are the maximum and minimum volumes of the gas entrapping zone, respectively; V_{pt}, volume of a porous particle; and ε, its porosity.

In a more compact form

$$V_{rel} = \frac{2\Delta P(P_c + P_0 + \rho gh)\alpha}{(P_c + P_0 + \rho gh)^2 - \Delta P^2}. \quad (19)$$

This relation can be used to calculate the maximum possible value of V_{rel}, which corresponds to a filtration mode without resistance to motion of the liquid in capillaries, i.e., is observed when equilibrium is attained at any instant of time between the gas pressures within the entrapping zone and in the bulk of the liquid. The same relations are obtained in solving the filtration equations for porous plates (model of leaves) and cylinders (model of stalks) at whose centers are situated gas entrapping zones.

The system of equations (15) was solved by the Runge–Kutta method. The values of the physical var-

iables corresponded to those presented above; the initial pressure in the apparatus was taken to be equal to the atmospheric pressure, P_0 = 0.1 MPa, and the magnitude of oscillations about this pressure, ΔP = 0.025 MPa. The actual relative amount of the liquid entering a porous particle and exiting from it in a cycle of pressure variation in the apparatus was found from the relation

$$V = \left(\frac{1}{z_{\min}^3} - \frac{1}{z_{\max}^3}\right), \qquad (20)$$

where $z_{\min}$ and $z_{\max}$ are the minimum and maximum values of z.

Figure 1 shows how the coefficient $K_v = V/V_{rel}$ depends on the diameters δ_c, angular frequency ω of pressure oscillations in the apparatus, and fraction α of entrapped gas. At low frequencies ω = 6.28 rad s^{-1} (f = 1 s^{-1}) and capillary diameters δ_c > 3 μm, V is comparable with V_{rel} and expression (19) can be used to calculate the relative amount of the liquid. ω = 251 rad s^{-1} (f = 40 s^{-1}), V is close to V_{rel} only for capillaries with a diameter δ_c > 50 μm. As δ_c decreases and ω increases, the coefficient K_v approaches zero. For example, this occurs at δ_c = 0.1 μm and ω = 6.28 rad s^{-1} or at δ_c = 1 μm and ω = 251 rad s^{-1}. The fraction of entrapped gas has only a little effect on the coefficient K_v, with V the closer to V_{rel}, the smaller α.

Data on the pore size distributions in particles of shredded vegetable raw materials of varied morphological structure were reported in [6, 8]. For saltwort, the fraction of pores of diameter exceeding 20 μm is 92%, and of those with diameters in the range from 100 to 600 μm, 63%. In the ginseng root, the fraction of >20 μm pores is 82.5%, and of those with diameters ranging from 100 to 2000 μm, 65%. Apparently, the loss of pressure is the same for motion of the extracting agent from the surface of a porous particle to the gas entrapping zone and in the opposite direction in capillaries of different diameters. Otherwise, the extracting agent would move along the path of least resistance and the flow rates through the capillaries would be redistributed until equalization of the pressure loss. In accordance with the Hagen–Poiseuille equation, the volumetric flow rates are proportional to capillary diameters raised to fourth power in a laminar motion of an incompressible liquid at equal resistances of the capillaries. Thus, the filtration of the extraction agent mainly occurs through coarse capillaries in extraction from vegetable raw materials under conditions of low-frequency pressure oscillations. These capillaries are formed in shredding of the raw material as a result of disintegration of its

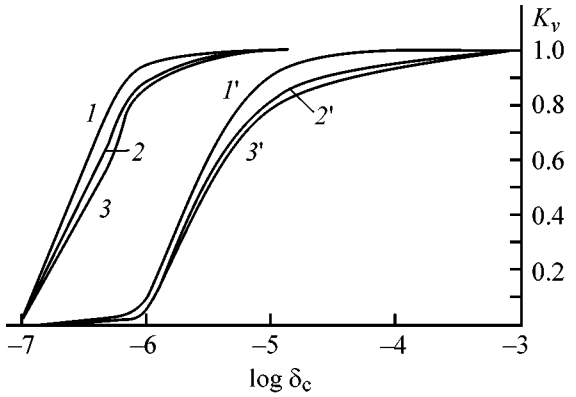

Fig. 1. Effect of the capillary diameter δ_c on the coefficient K_v. Curves *1*, *2*, and *3* are calculated for fractions of entrapped gas equal to 0.05, 0.15, and 0.25, respectively; unprimed for ω = 6.28 rad s^{-1} and primed for ω = 251 rad s^{-1}.

internal structure. In an unshredded vegetable raw material, coarse pores are virtually lacking, which is indicated by the closeness of the curves describing the kinetics of extraction of flavonoids from unshredded fruits of hawthorn, which contain entrapped air and are totally impregnated with the extracting agent (by their preliminary vacuum treatment and mixing with the solvent in a vacuum).

The experimentally found fractions of entrapped gas in capillary-porous bodies at the initial instant of time can be used to evaluate the capillary pressure P_c [formulas (6), (7)] in the gas entrapping zone (or zones) and the corresponding equivalent capillary diameter $\delta_{c.equiv} = P_c/4\sigma\cos\theta$. For various kinds of vegetable raw materials (unshredded fruits of hawthorn, leaves of birch, roots of licorice), $\delta_{c.equiv}$ = 0.8–1 μm, i.e., the capillary pressure in the gas entrapping zone is determined by the smallest diameters of pores in the raw material. This result is similar to the known results of experiments with impregnation from above of capillary-porous bodies with periodically narrowing and widening pores, in which the height of the capillary rise in the level of the liquid is determined by the diameters of the narrowest parts of the pores [9].

A solution of the system of equations (15) for filtration of an extracting agent in porous particles with capillary diameter exceeding 50 μm and gas pressure in the gas entrapping zone corresponding to P_c at $\delta_{c.equiv}$ = 1 μm demonstrated that formula (19) can be used to calculate V_{rel}. In the general case, when the magnitudes of drops ($\Delta P_{\min}$) and rises ($\Delta P_{\max}$) in the pressure in the apparatus relative to P_0 are not equal, formula (19) takes the form

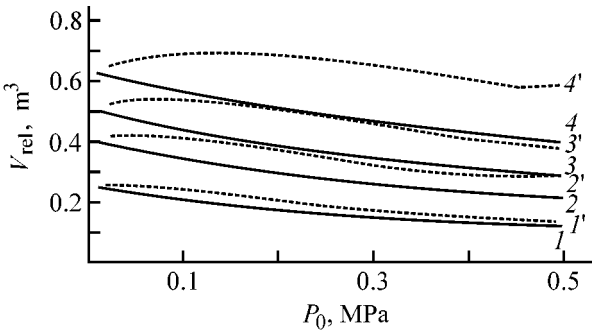

Fig. 2. V_{rel} in relation to the initial pressure P_0, total pressure difference, and way to produce pulsations. Curves *1*, *2*, *3*, and *4* correspond to pressure differences of 0.1, 0.2, 0.3, and 0.5 atm, respectively; unprimed, for apparatus with a pneumatic pulser, and primed, for those with piston pulser.

$$V_{rel} = \frac{(\Delta P_{max} + \Delta P_{min})(P_c + P_0 + \rho gh)\alpha}{(P_c + P_0 + \rho gh - \Delta P_{min})(P_c + P_0 + \rho gh + \Delta P_{max})}, \quad (21)$$

where P_c is the capillary pressure in the capillaries with the smallest diameter (MPa).

In accordance with Eq. (21), the volume of the extracting agent passing through porous particles is directly proportional to the fraction of entrapped gas, α, which steadily decreases in the course of time as a result of diffusion of the gas from a particle into the flow of the extracting agent. The magnitude ΔP_{min} may apparently fall within the range $0 \le \Delta P_{min} < P_0$. In apparatus with pneumatic pulsers, the minimum pressure is, as a rule, equal to the initial pressure P_0. When piston, plunger, bellows, or membrane pulsers are used, the pressure in the apparatus is related to the volume of the air cushion, following the law of adiabatic compression–expansion, by

$$(P_0 - \Delta P_{min})v_{max}^k = P_0 v_0^k = (P_0 + \Delta P_{max})v_{min}^k,$$

where v_{max}, v_0, v_{min} are the volumes of the air cushion in the apparatus at the minimum, initial, and maximum pressures, respectively (m^3); k is the adiabatic exponent.

Figure 2 compares the results of calculations of V_{rel} by formula (21) at $\alpha = 1$ for pneumatic and piston pulsers with equal values of $\Delta P_{min} + \Delta P_{max}$. The adiabatic exponent was taken to be $k = 1.4$, which is approximately equal to the adiabatic exponent of a vapor–air mixture over an aqueous solution (40%) of ethanol at 20°C. Depending on the initial pressure P_0 and the total pressure difference $\Delta P_{min} + \Delta P_{max}$, the values of V_{rel} for the piston pulser are 4–22% higher than the corresponding values for the pneumatic pulser. The volume of the extracting agent that has passed through porous particles grows as the initial pressure P_0 decreases and the total pressure difference increases. The highest values of V_{rel} can be obtained if the initial pressure in the apparatus is lower than the atmospheric pressure ($P_0 < 0.1$ MPa).

CONCLUSIONS

(1) The filtration of the extracting agent in porous particles, including those of vegetable raw materials, occurs only via coarse capillaries, which are for the most part formed as a result of shredding of the raw material.

(2) The volume of the extracting agent that passes through porous particles with entrapped gas in a single cycle of pressure variation in the apparatus is virtually independent of the frequency of pulsatory disturbances (at frequencies lower than 40 Hz), being determined by the volume of gas entrapped in particles, total pressure difference, initial pressure in the apparatus, and diameter of the narrowest pores in particles.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Substituted Ureas from Urea and Halohydrins

A. M. Magerramov, R. T. Abdinbekova, M. M. Kurbanova, A. V. Zamanova, and M. A. Allakhverdiev

Abstract—Substituted ureas were prepared by reactions of 1,2-halohydrins with urea and were tested as antimicrobial additives to motor oils.

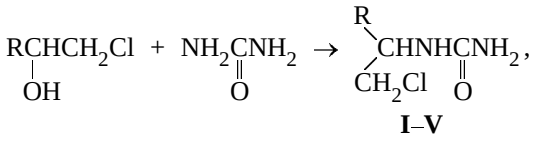
Substituted ureas attract researchers' attention thanks to a set of valuable properties allowing their use in industry, agriculture, and medicine. Substituted ureas are used as insecticides, as plant growth regulators, as effective additives of various purposes to hydrocarbon fuels, oils, and polymeric materials, as drugs, and as dyes [1].

Classical synthetic routes to substituted ureas are mostly based on reactions of amines with urea or with isocyanic acid derivatives, or on carbonylation of amino and nitro compounds [1]. These routes are diverse, but many procedures have certain drawbacks restricting their applicability. Development of new procedures is interesting from both scientific and practical viewpoints. In particular, synthesis of substituted ureas by direct reaction of aliphatic and aromatic alcohols with urea has been reported [2, 3]. However, there are no data on reactions of urea with alkoxy-substituted 1,2-halohydrins. These reactions are examined in our study.

Previously, we have studied the reactions of alkoxy- and alkylthio-substituted 1,2-chlorohydrins with thiourea in the presence of various acids [4–6]. Proceeding with analysis of the reactivity of ureas and thioureas [7], we prepared in this study *N*-substituted ureas by reactions of 1,2-halohydrins with urea in the presence of a mixture of H_2SO_4 and CH_3COOH.

The starting 1,2-halohydrins were prepared by reactions of appropriate alcohols with epichlorohydrin in the presence of $ZnCl_2$ at 65°C [8].

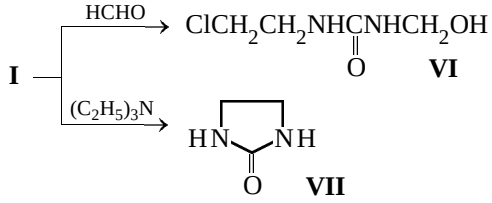
The yield of *N*-substituted ureas containing various functional groups (see table) can be optimized by varying the temperature (from 60 to 115°C), amount of H_2SO_4 (1–5 ml), and reaction time (4–8 h).



I–V

where R – H (**I**), CH_3OCH_2 (**II**), $C_2H_5OCH_2$ (**III**), $C_4H_9OCH_2$ (**IV**), $C_6H_5CH_2OCH_2$ (**V**).

By reactions of **I** with HCHO and $(C_2H_5)_3N$, we prepared *N*-hydroxymethyl-*N*'-chloroethylurea **VI** and cyclic urea **VII** (see table):



The compounds prepared were tested as antimicrobial additives to MS-11 lubricating oil [GOSTs (State Standards) 9.052–75 and 9.085–75]. The compounds showed a pronounced antimicrobial effect when present in low concentrations (0.5–1.0%); they are readily soluble in MS-11 oil and do not stimulate corrosion. Compounds **VI** and **VII** are more effective than the commercial antimicrobial additive, 8-quinolinol. With **VI**, the width of the suppression zone is 0.6–1.4 cm for bacteria and 1.0–1.9 cm for fungi. With 8-quinolinol, these parameters are 0.4–0.9 and 0.7–0.9 cm, respectively.

IR spectra were measured on a Specord 75-IR spectrometer (mulls in mineral oil).

The compound purity and reaction progress were monitored by TLC (Silufol UV-254 plates, eluent isopropyl alcohol–hexane, 3 : 5).

Ureas I–III. A mixture of 0.04 mol of an appropriate halohydrin and 16.2 g of urea in 30 ml of AcOH was heated to 80°C, and 5 ml of H_2SO_4 (ρ = 1.84 g cm^{-3}) was added with vigorous stirring over a period of 10 min. Then the mixture was heated at 80°C for 4 h and cooled; the precipitate was filtered off and recrystallized from DMF or C_2H_5OH.

Ureas IV and V. A mixture of 0.01 mol of an appropriate halohydrin, 0.06 mol of urea, 15 ml of AcOH, and 1 ml of H_2SO_4 (ρ = 1.84 g cm^{-3}) was heated with stirring at 115°C for 8 h. The resulting mixture was worked up as described above.

Urea VI. A 30% aqueous solution of formaldehyde (1 ml) was added at 18–20°C with stirring to a suspension of 0.01 mol of **I** in 5 ml of water. The color-

less precipitate that formed in 1 h was filtered off, washed with water, and dried in air.

Urea VII. Triethylamine (10 mmol) was added to a suspension of 10 mmol of **I** in 25 ml of ether. The mixture was stirred at 18–20°C for 12 h, the precipitate of triethylammonium chloride was filtered off, the solvent was removed, and the product was filtered off and dried in air.

CONCLUSION

N-Substituted ureas improving the antimicrobial properties of MS-11 motor oil were prepared in good yields (50–80%) by reactions of 1,2-halohydrins with urea in the presence of a mixture of sulfuric and acetic acids.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Copolymerization of Sulfolane-containing Acrylamido Sulfonic Acid with Acrylamide and Acrylonitrile in Water

K. V. Shirshin, O. K. Kazantsev, A. V. Igolkin, V. L. Krasnov, and A. P. Sivokhin

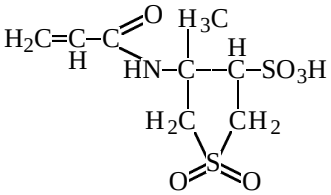
Received June 16, 2004

Abstract—Copolymerization of sodium 4-acrylamido-4-methyltetrahydro-1,1λ^6-dioxothiophene-3-sulfonate with acrylamide and acrylonitrile in water was studied. It was found the copolymer composition is mainly determined by association of the monomeric species.

Polymers derived from *N*-substituted acrylamides containing sulfo groups [primarily, copolymers of 2-acrylamido-2-methylpropanesulfonic acid (AMPSA)] are used in textile and paper industry, oil production, and wasterwater treatment [1]. A procedure for preparing a new monomer of this family, 4-acrylamido-4-methyltetrahydro-1,1λ^6-thiophene-3-sulfonic acid (ASA), has been developed recently [2].



ASA

This compound contains not only sulfonic acid but also a sulfolane fragment, which imparts new valuable properties to the polymer.

Some features of copolymerization of the potassium salt of ASA with acrylamide (AA) were studied in [3]. It was suggested that copolymerization of these monomers in concentrated aqueous solutions can be affected by strong intermolecular interactions and, in particular, by formation of charge-transfer complexes of sulfonic anions with protonated monomers. It is of interest to study the influence exerted by the intermolecular interactions on the copolymerization of ASA with AA and AN in more detail. In this study we examined the monomer conversion and the copolymer composition as influenced by the ratio of the monomers in the initial reaction mixture.

EXPERIMENTAL

Na–ASA was prepared by the procedure described in [2]. AA was recrystallized from benzene prior to use. AN was purified by distillation. The physical constants of the purified monomers agree with published data. Copolymerization of NaASA with AA and AN was performed in glass ampules at 70°C. In all experiments, the total initial concentration of the monomers was 1 M. The initial AA–AN ratio ranged from 1 : 9 to 9 : 1. An ampule was purged with nitrogen and was charged with disodium salt of 4,4'-azobis-4-cyaopentanoic acid (0.5 mol % relative to the sum of the monomers). The concentrations of Na–ASA and AA in the reaction mixture were estimated by liquid chromatography, and the concentration of AN, by gas–liquid chromatography. The liquid chromatographic analysis was performed on a Praha chromatograph equipped with a UV detector (λ = 254 nm) and a 150 × 4.6-mm steel column packed with modified silica gel (Silasorb C_{18}, 10 μm fraction). Acetonitrile was used as the eluent. Gas–liquid chromatrograpic analysis was performed on a Tsvet-100 chromatograph with a flame-ionization detector and a 2-m steel column 3 mm in diameter, packed with 10% PEGA on Chromaton N–AW. The flow rate of the carrier gas (nitrogen) was 2×10^{-3} m^3 h^{-1}. The temperature of the vaporizer and columns was 70 and 40°C, respectively. The specific viscosity of monomer solutions was measured at 25°C on an Ubbelohde viscometer with a capillary 0.34 mm in diameter. The conductivity of the solutions was measured on a PRL T57-21

1070-4272/04/7710-1670 © 2004 MAIK "Nauka/Interperiodica"

conductometer with graphite electrodes, operating at 3500 Hz.

The dependence of the copolymer composition on the initial ratio of the monomers is shown in Fig. 1. At excess of AA, the copolymer composition differs from that of the initial mixture by no more than 2%. As the Na–ASA fraction in the initial mixture increases, the copolymer is slightly enriched with the nonionic units. However, the difference between the copolymer composition and that of the initial mixture of the monomers does not exceed 3–5 %.

Thus, the copolymerization of Na–ASA with AA occurs in a nearly azeotropic mode. In addition, the copolymer composition, does not change up to a 70% conversion, except in experiments with a large excess of AA (Fig. 2, curves *5*, *6*). It is known that the copolymer composition may be close to that of the initial mixture of the monomers. However, this is usually the case for vinyl monomers with about the same distribution of the electron density and sterically accessible C=C bonds [4]. In our system, the induction effect and steric accessibility of the amide groups in the acrylamide monomers substantially differ. The steric constant R_S of the $-NH_2$ group of AA and –NHR group of Na–ASA, determined by the procedure described in [5] are –0.98 and –2.93, respectively. The induction constants of these groups, σ^*, determined by the procedures described in [6] and [7], respectively, are 0.87 and 0.53. The bond distances were calculated by the MNDO procedure, using HyperChem software. Thus, we deal in the given case with "azeotropic" copolymerization of a nonionic monomer (AA), which has a small substituent at the C=C bond, with an ionic monomer (Na–ASA), which has at the C=C bond the much bulkier subsituent with substantially stronger electron-with-drawing properties.

We compared the results obtained with the data on copolymerization of AA with other vinyl monomers with sulfonic acid groups in aqueous solutions. The AA–(Na–AMPSA) copolymer is slightly enriched in the nonionic amide units. The composition of this copolymer remains virtually the same up to deep monomer conversions [8]. Kurenkov and Utikeeva [9] reported that AA–(Na–AMPSA) copolymers are enriched in the AA units. They also found that the copolymerization is accelerated as the AA fraction in the initial mixture grows, and the content of the nonionic units in the copolymer becomes higher with increasing total initial concentration of the monomers. This is due to a decrease in the fraction of free ions in the solution with increasing ionic strength. As a result,

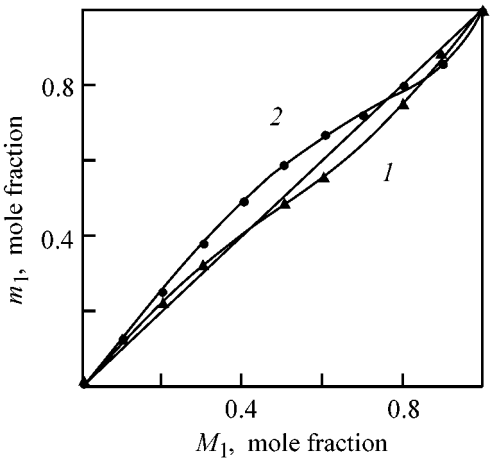


Fig. 1. Mole fraction of Na–ASA units m_1 in (*1*) Na–ASA–AA and (*2*) Na–ASA–AN copolymers prepared in water vs. the Na–ASA mole fraction M_1 in the initial reaction mixture.

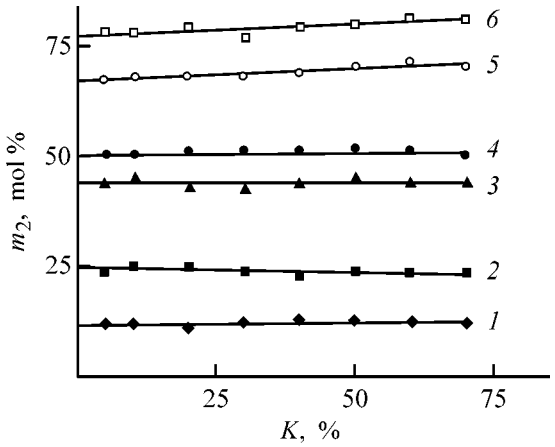

Fig. 2. Concentration of the AA units in Na–ASA–AA copolymer, m_2, vs. the monomer conversion K. Na–ASA : AA molar ratio in the initial mixture: (*1*) 90 : 10, (*2*) 80 : 20, (*3*) 60 : 40, (*4*) 50 : 50, (*5*) 30 : 70, and (*6*) 20 : 80.

the addition of the monomeric sulfonate to the macroradical with the terminal nonionic unit is accelerated. The composition of the AA–sodium vinylsulfonate copolymer remains constant up to approximately a 70% conversion [10]. In this case, the amide : sulfonate ratio in the copolymer exceeds by approximately a factor of 3 that in the initial mixture at all initial ratios of the monomers. Barabanova *et al*. [10] suggest that the copolymer composition of not only this copolymer but also all binary vinyl copolymers formed by homogeneous copolymerization in aqueous solutions should be almost independent of the monomer conversion and be determined by the ability of the monomers to penetrate into hydrophobic associates of the growing macroradicals. Since the penetration of charged sulfonate anions into these associates is dif-

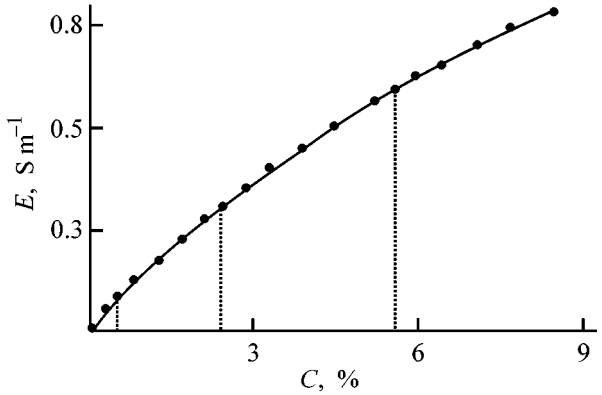

Fig. 3. Electrical conductivity E of aqueous Na–ASA solutions at 25°C vs. the Na–ASA concentration C.

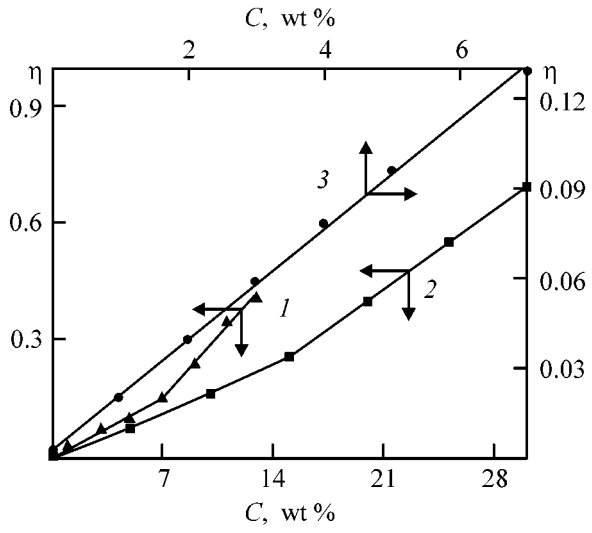

Fig. 5. Specific viscosity η of aqueous solutions of (*1*) Na–ASA, (*2*) AA, and (*3*) AN at 25°C vs. the monomer concentration C.

ficult, the reaction mixture in the vicinity of the reaction center is enriched with the nonionic amide.

It should be noted that these assumptions only partly account for the features of copolymerization of AA and vinyl sulfonic acid monomers. In particular, the copolymer composition markedly changes in some cases, e.g., in the AA–sodium sulfoethyl methacrylate system [8], in the course of copolymerization. Contrary to Kurenkov and Utikieva's hypothesis [9], the copolymer can be enriched in the nonionic units [see Fig. 1 or data on AA–(Na–AMPSA) copolymerization] or its composition may remain the same (AA–sodium vinylsulfonate system [10]) when the ionic strength of the solution becomes hidher, e.g., because of an increase in the fraction of the ionic monomer in the reaction mixture. In addition, the reaction orders with respect to the monomers in copolymerization of AA with potassium salts of ASA and AMPSA at the total monomer concentration of 20 wt % are abnormaly high (6.8 and 11.7, respectively) [3]. This fact cannot be understood in the framework of the above hypotheses.

The concentration effect and high reaction orders with respect to the monomers in copolymerization of Na–ASA with AA in water indicate that the monomer concentration is an important parameter of copolymerization. We suggest that the "prepolymerization" interaction of the monomers in aqueous solutions strongly affects the radical copolymerization. It is known [11] that vinyl monomers, which are not commonly classed with surfactants, i.e., contain no hydrophobic fragments with long hydrocarbon chain, along with polar hydrophilic groups, can be associated in aqueous solutions at the concentrations used in the copolymerization. In particular, association of acrylamide and some of its derivatives including AMPSA has been observed [12]. At the AA concentration in an aqueous solution exceeding 5.3 wt %, this monomer is associated to form mainly dimers [13]. Chapiro and Perec-Spritzer [14] suggest that AA forms dimers, trimers, and polymeric associates in aqueous solutions, with the polymer fraction increasing as the monomer concentration in the solution becomes higher.

Association of monomers can be judged from a nonlinearity of the concentration dependences of the viscosity, surface tension, electrical conductivity, and other physical properties of solutions. As can be seen in Figs. 3–5, Na–ASA and AA are associated in the solutions, with the structure of their associates changing with an increase in the concentration of these compounds. This is indicated by the "critical concentrations of association" (CCA), which are seen in the dependences of the electrical conductivity and vis-

cosity of solutions on the concentrations of Na–ASA and AA (Fig. 3, curve *5*). At these concentrations (about 1.0, 3.7, and 7.5 wt %), the dependence of the electrical conductivity on [Na–ASA] passes through inflection points (Fig. 3). At the concentration of 7.5 wt %, the concentration dependence of the viscosity (CDV) becomes nonlinear (Fig. 5, curve *1*).

The CDV of AA solutions (Fig. 5, curve *2*) has two inflection points at the monomer concentrations of 5% (in agreement with the data of [13]) and 15%. It should be noted that the concentration dependences of the physical properties of aqueous solutions of (meth)acrylate monomers that contain hydrophobic fragments (C_8 and longer) and, hence, exhibit surfactant properties also have several inflection points. These points are usually assigned to transformations of spherical micelles into anisotropic micelles and then into lamellas [15]. We suggest that the "critical concentrations" of AA solutions studied here are also due to transformation of AA associates with increasing monomer concentration.

Thus, copolymerization of ASA with AA should depend on the association of the monomers. It is known [11] that, in concentrated aqueous solutions of many monomers, their homopolymerization is sharply accelerated owing to close packing of molecules in the associates [11]. Probably, copolymerization in these associates is faster also. This mechanism accounts for the high total reaction order of copolymerization of K–ASA with AA [3]. The fact that the composition of Na–ASA–AA copolymer is close to that of the initial monomer mixture may be due to active formation of binary associates. As a result, although the individual capacities of pure monomers for association substantially differ, the composition of the binary associates is close to that of the initial monomer mixture. In such cases, the copolymer composition is similar to that of the coassociates. The constancy of the copolymer composition up to a high degree of monomer conversion can be explained as follows. Partial incorporation of monomers into hydrophobic polymeric chains stabilizes the monomer–polymeric associate. Hence, if the initial monomers readily associates, the process parameters will negligibly change with an increase in the conversion. Since AA monomers associate to a lesser extent than the sulfo monomer (Fig. 5), the total degree of the initial association at a low Na–ASA concentration (Fig. 2, curves *5* and *6*) starts to decrease and the copolymer composition slightly changes in the course of polymerization. This is due to a change in the composition of the monomer–polymer associates upon accumulation of the macromolecules (the total degree of association of the unchanged monomers gradually increases owing to hydrophobization).

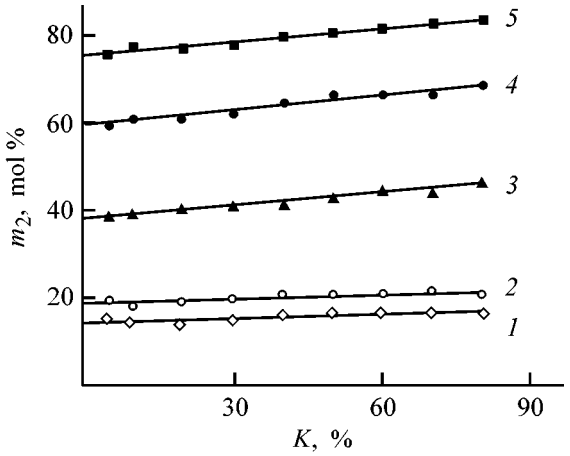

Fig. 6. Content m_2 of AN units in copolymers formed at the initial AN Na–ASA molar ratio of (*1*) 10 : 90, (*2*) 20 : 80, (*3*) 50 : 50, (*4*) 70 : 30, and (*5*) 80 : 20 vs. the monomer conversion K.

The formation of binary associates of the monomers is evident from the dependence of the electrical conductivity of the Na–ASA–AA–H_2O system on the monomer concentration. As in the case of a pure Na–ASA solution, three inflection points are observed (Fig. 4). However, the CCAs are shifted to lower concentrations, thus indicating the formation of Na–ASA–AA associates.

If Na–ASA copolymerizes with a monomer whose associating capacity is substantially lower than that of AA, the general aspects of the process will differ from those found for Na–ASA–AA system. We used AN as a such monomer. This compound does not associate in aqueous solutions (Fig. 5). The experimental data for the Na–ASA–AN system show that, unlike the first system, this system has a higher relative activity of Na–ASA. As can be seen from Fig. 1, the copolymer formed at the initial Na–ASA : AN ratios of 1 : 9 to 8 : 2 is enriched with the Na–ASA units. The copolymer composition changes in the course of copolymerization (Fig. 6).

Thus, copolymerization processes of Na–ASA–AA and Na–ASA–AN systems are strongly different. It is known that organic associates in aqueous solutions can both decompose and stabilize after introduction of substances of varied nature. We think that AN molecules, which do not form self-associates, are hydrophobic and can penetrate into Na–ASA associates. The stronger the hydrophobic properties of the associate, the higher the AN content in them. As the ini-

tial Na–ASA : AN ratio increases, the concentration of the readily associating Na–ASA monomer grows, and the molecules in the associates become more closely packed, which makes the aggregate more hydrophobic. As a result, a steadily increasing fraction of nitrile is incorporated into the associate (the degree of association increases), which leads to an increase in the content of the nitrile units in the polymer as compared to the systems with lower Na–ASA concentration in which the monomeric associates are "looser" and less hydrophobic.

CONCLUSIONS

(1) The composition of the Na–ASA–AA copolymer is close to that of the initial mixture of the monomers and remains the same up to high monomer conversions.

(2) The composition of the Na–ASA–AN copolymer changes in the course of the copolymerization. At the Na–ASA : AN ratio of 10 : 90 to 80 : 20 the copolymer is enriched with Na–ASA units, and at Na–ASA : AN = 90 : 10, with nitrile units.

(3) The capacity of Na–ASA, AA, and their mixtures for association revealed by analysis of the concentration dependences of the electrical conductivity and viscosity of their solutions.

Abstract—Radical copolymerization of derivatives of monoethanolamine vinyl ether and *o*- and *p*-chloranil with acrylic acid was studied. The parameter *p* for this system was determined by the Shtraikhman analytical graphic method; the copolymerization constants, Alfrey–Price specific activity and polarity parameters, probabilities of formation of various unit sequences in the macromolecular chain, lengths of sequences of similar monomeric units, and Harwood block structure parameters were calculated.

Although widely diverse synthetic ion exchangers are available today, improving their production processes and physicochemical characteristics and lovering of the production cost remain problems of current interest [1].

Previously, we have reported data on preparation of new quinoid derivatives of monoethanolamine vinyl ether (MEAVE) [2] and on their radical homopolymerization and copolymerization with available vinyl monomers [3–8]. In contrast to MEAVE, which shows virtually no tendency toward polymerization [9], and to quinones, which inhibit the polymerization, the redox monomers synthesized fairly readily enter radical homoand copolymerization. However, quinones differ in reactivity, depending on their structure.

The use of *o*- and *p*-chloranils for preparing redox ion exchangers is of large interest due to strong oxidative power of these compounds containing four chlorine atoms; the activity and redox potential of *o*-quinones are higher than those of their *p*-isomers [10].

In this study, we analyzed how the chemical structure (namely, position of carbonyl groups) affects the reactivity of redox monomers in copolymerization with acrylic acid (AA).

EXPERIMENTAL

3,4,5,6-Tetrachloro-1,2-benzoquinone (*o*-chloranil) (mp 125–130°C) was prepared as described in [11]. 2,3,5,6-Tetrachloro-1,4-benzoquinone (*p*-chloranil) (mp 289°C) was purchased from Aldrich and used without additional purification.

Redox monomers ($C_{10}H_8NCl_3O_3$) prepared according to [2] were cherry-lilac powders. The elemental composition and some physicochemical properties of derivatives of MEAVE and *o*- and *p*-chloranils (MEAVE–1,2-CA and MEAVE–1,4-CA), M 296.53, are listed in Table 1.

Azobis(isobutyronitrile) (AIBN) was recrystallized from absolute methanol, mp 102–103°C.

Table 1. Elemental composition and selected physicochemical properties of new redox monomers

Monomer	C	H	N	Cl	ρ, g cm^{-3}	mp, °C	Yield, %
	%

Monomer–copolymer composition diagrams. Content, mol %: (m_1) redox monomeric units in copolymers and (M_1) redox monomers in the monomer mixtures. (*1*) (MEAVE–1,2-CA)–AA and (*2*) (MEAVE–1,4-CA)–AA.

Acrylic acid had n_D^{20} = 1.421 after vacuum distillation.

The copolymerization of redox monomers (M_1) with AA (M_2) was performed in sealed ampules in DMF at 68°C in the presence of 6 wt % AIBN; the concentration of MEAVE–1,2-CA and MEAVE–1,4-CA was 20 g l^{-1}. The reaction was studied at the monomer ratio of 80 : 20 to 20 : 80. The conversion was evaluated by the concentration of the unchanged monomers, which was determined by polarography (redox monomers) and titration (AA).

Since it was difficult to record changes in the monomer concentrations in a short time, the first kinetic measurement was performed 30 min after the start of the reaction, and the experimental data were interpolated to 5 min from the start of the reaction.

The polarograms were measured in a temperature-controlled cell of a PU-1 polarograph at 25 ± 0.5°C using a mercury dropping electrode (capillary characteristic at open circuit $m^{2/3}t^{1/6}$ = 4.38 $mg^{2/3}$ $s^{1/2}$, with phosphate buffer solution (pH 7.4) in 25% DMF as supporting electrolyte. The reference electrode was a saturated calomel electrode. Prior to polarographic measurements, oxygen was removed from the solutions by bubbling of argon.

Viscometric studies were performed in Ubbelohde capillary viscometers in a temperature-controlled cell at 25°C in DMF.

The constants of relative activities of the monomers, which are important parameters of the copolymerization, characterize the relationship between the chemical structure of unsaturated compounds and their reactivity. The composition of the copolymers at various monomer ratios was determined by polarography and titration.

As seen from the figure, the systems do not form an azeotropic copolymer. In copolymerization of MEAVE–1,2-CA with AA, the composition curve lies above the azeotropic line, i.e., the copolymers are appreciably enriched in the units of the redox monomer ($r_1 > 1$, $r_2 < 1$) at any comonomer ratio. As the concentration of the redox monomer in the starting mixture is raised, the activities of both monomers become closer. In copolymerization of MEAVE–1,4-CA with AA, the composition curve lies below the azeotropic line, and the copolymer is enriched in the AA units ($r_1 < 1$, $r_2 > 1$).

Using the parameter p evaluated graphically by the Shtraikhman analytical method, we determined the copolymerization constants [12] and calculated from these data the Alfrey–Price specific activity and polarity parameters. For AA, we took Q_2 = 1.15 and e_2 = 0.77 [13]. The results are listed in Table 2.

As can be seen from Table 2, the *p*-chloranil-based copolymer shows a stronger tendency toward unit alternation, compared to the *o*-chloranil derivative, as indicated by the low product of the constants r_1r_2 and the large difference between the polarities of the two monomers, Δe (0.79).

For the monomeric system (MEAVE–1,2-CA)–AA, $r_1r_2 \approx 1$, i.e., "ideal" random copolymerization takes place, with low tendency toward alternation of the monomeric units. In such a copolymer, alternation of short blocks of the comonomers will be more typical. This system has a high specific activity Q_1; hence, MEAVE–1,2-CA is more reactive than MEAVE–1,4-CA.

The experimental data show that the reactivity of the redox monomers depends on the chemical structure of the quinones used for MEAVE modification. The mutual arrangement of carbonyl groups (*o*-, *p*-)

and chlorine atoms in the quinone ring affects the donor–acceptor properties of the molecule; as a result, the electron density redistribution and the change in the polarization of the vinyl double bond in MEAVE–quinone derivatives are different.

Copolymerization yields different structural units, depending on the reaction conditions and monomer ratio: M_1M_1, M_1M_2, and M_2M_2. We calculated the microstructural characteristics of the copolymers: probability of formation of various diads f, mean lengths of blocks of similar units L_{M_1} and L_{M_2}, and Harwood parameters of block structure [14, 15]. The Harwood coefficient R is equal to the number of sequences of similar units per 100 units of the chain. The results are listed in Table 3.

At different monomer ratios, copolymers of different compositions are formed. Table 3 shows that, at an excess of redox monomers, MEAVE–1,2-CA and MEAVE–1,4-CA add to the "like" radicals more actively. The higher the content of redox monomers in the starting mixture, the larger L_{M_1}. The Harwood coefficients are the largest in compolymers with short lengths of units.

In the system (MEAVE–1,4-CA)–AA, in the range of the monomer ratios $M_1 : M_2$ from 80 : 20 to 60 : 40, copolymers of a more regular structure are formed. In the redox polymers containing 1,2-CA, the alternation of the monomers is regular at the monomer ratios $M_1 : M_2$ of 45 : 55 to 39 : 61. Table 3 shows that the microstructure of the copolymers can be controlled by choosing appropriate monomer ratios.

CONCLUSION

New unsaturated redox monomers, derivatives of monoethanolamine vinyl ether and *o*- and *p*-chloranil, differ in reactivity because of the different arrangements of the carbonyl groups in the quinoid rings; copolymerization of these monomers with acrylic acid proceeds differently.

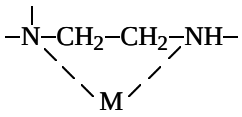
Received June 15, 2004

Abstract—Complexation of polymeric anion exchangers with transition metals was studied by polarographic and potentiometric titration techniques.

The wide use of ion-exchange sorption for recovering metals from process solutions and for solving various environmental problems stimulates studies of complexation of ion exchangers with metals. In choosing a sorbent suitable for efficient separation of metals with similar properties, data on the stability constants of sorbent–metal complexes, their composition, and factors influencing the complexation are required. These data are also taken into account in synthesis of sorbents selective for individual metal ions [1].

It is known that coordination compounds are mainly formed by transfer of an unshared electron pair from a ligand to a vacant orbital of a metal cation [2]. Sorbents containing amino groups (aliphatic or aromatic) are bound to metal ions via nitrogen atoms. Polymeric sorbents containing closely located amino groups can be coordinated to metals to give of strong five-membered chelate rings.



In this study, the complexation of polymeric polyfunctional anion exchangers with transition metal cations was examined by polarographic and potentiometric titration techniques. Anion exchangers were prepared by condensation of allyl glycidyl ether (AGE) with polyethylenimine (PEI) [AGE–PEI], AGE with poly(2-methyl-5-vinylpyridine) (PMVP) [AGE–PMVP], 4,4-isopropylidenediphenoldiglycidyl ether (ED-20) with PEI [ED-20–PEI], ED-20 with PVMP [ED-20–PVMP] and allyl haloides with PEI and PMVP.

EXPERIMENTAL

The polymeric anion exchangers used in this study were prepared by the methods reported in [3, 4]. A portion of the reaction mixture was taken in the precondensation stage and treated with diethyl ether to precipitate the polymeric sorbent. This sorbent was dried, and its solutions suitable for polarographic studies of its complexation with transition metals were prepared. The remaining reaction mixture was cured at 80°C to obtain an insoluble soild anion exchanger. The complexation of the cured sorbent with transition metals was studied by potentiometric titration.

The complexation of the anion exchangers obtained in the precondensation stage with transition metals was studied polarographically in 25% aqueous dimethylformamide (DMF) containing 0.01 N H_2SO_4. The anion exchanger concentration in these solutions was varied from 0.1 to 20 g l^{-1}. The concentration of transition metal salt ($CoSO_4$, $NiSO_4$, $CuSO_4$, and $ZnSO_4$) in these solutions was 2×10^{-3} M. A saturated calomel electrode was used as a reference electrode. The dropping mercury cathode had the following characteristic: $m^{2/3} t^{1/6} = 4.28$ mg$^{2/3}$ s$^{-1/2}$. The electrolytic cell was kept at 25 ± 0.1°C. The solutions used were deoxygenized by bubbling of argon for 10 min.

Table 2. Shift of the half-wave cathode reduction potential of transition metal cations due to complexation with AGE–PEI anion exchanger (c_{resin} = 10 g l^{-1}, $c_{salt} = 2 \times 10^{-3}$ M)

Cation	$E_{1/2}$	$\Delta E_{1/2}$	pH
	V		
Cu^{2+}(I)*	–0.12	0.06	4.77
Cu^{2+}(II)	–0.23	0.17	7.12
Ni^{2+}	–1.28	0.12	6.90
Co^{2+}	–1.44	0.13	6.90
Zn^{2+}	–1.21	0.17	7.35

* c_{resin} = 0.10 g l^{-1}.

The apparent dissociation constant pK_a of the anion exchanger, the Bjerrum formation function *n*, and the stability constant *K* of the complex were calculated from potentiometric titration data by the technique reported in [5].

Table 1 shows how the half-wave cathode reduction potential of transition metal cations is influenced by addition of anion exchanger.

It has been shown [6] that the kind of transition metal cation significantly affects the half-wave cathode reduction potential of the forming transition metal complexes and its shift $\Delta E_{1/2}$ relative to the reduction potential of free metal ion $E_{1/2}$. As can be seen from Table 2, on adding AGE–PEI to solutions of transition metal salt, the largest $\Delta E_{1/2}$ is observed for Cu^{2+} and Zn^{2+}, i.e., these cations form the strongest complexes with the resin.

To elucidate the stability and composition of complexes formed by the AGE–PEI anion exchanger with transition metals, the $E_{1/2}$ of these metals was studied as a function of the resin concentration in the range 0.1–10 g l^{-1}. Figure 1 shows that, for Ni^{2+}, Cu^{2+} and Zn^{2+}, $E_{1/2}$ is a linear function of the logarithm of the resin concentration, i.e., only one strong complex of the anion exchanger with these metals is formed [7]. In the case of Cu^{2+}, the plot of $E_{1/2}$ against log *c* consists of three linear portions separated by two breaks. This plot shows that two complexes of the anion exchanger with copper are formed at pH 4.77 and 7.12, respectively.

The coordination number *p* of metal cations bound to the anion exchanger was determined from the slope of the plot of $E_{1/2}$ against log *c*, using the equation reported in [6, 7].

$$p = \frac{n}{0.059}\tan\alpha,$$

$$\tan\alpha = \frac{(E_{1/2})_2 - (E_{1/2})_1}{\log c_2 - \log c_1},$$

where *n* is the number of electrons transferred to the transition metal cation during cathodic reduction.

We found that, for Ni^{2+}, Co^{2+} and Zn^{2+}, only one amino group of the sorbent is coordinated with the metal. For Cu^{2+}, one or three amino groups can be coordinated with the metal depending on pH.

The stability constants of AGE–PEI complexes with metal cations, calculated by the equation reported in [8]

$$\log K = \frac{n\left(\Delta E_{1/2} + p\frac{0.059}{n}\log c\right)}{0.059},$$

are listed in Table 3.

Table 3. Coordination numbers p and stability constants ($\log K$) of AGE–PEI complexes with transition metals, determined by the polarographic technique (c_{resin} = 10 g l^{-1}, c_{metal} = 2×10^{-3} M)

Salt	p	$\log K$	pH	Salt	p	$\log K$	pH

* Determined from the potentiometric titration curve.

Figure 1 and Table 3 show the stepwise character of AGE–PEI complexation with Cu^{2+}. At the sorbent concentration below 0.1 g l^{-1}, one amino group is coordinated with the Cu^{2+} cation. At the sorbent concentration above 0.1 g l^{-1}, three amino groups of the anion exchanger are bound to one Cu^{2+} cation. Our polatrographic experiments showed also that, among transition metal cations, Cu^{2+} is the most strongly bound to the AGE–PEI sorbent. The stability of AGE–PEI-transition metal complexes decreases in the order $Cu^{2+} > Zn^{2+} > Co^{2+} > Ni^{2+}$. The ionic radii of these cations decrease in the same order: 0.96, 0.74, 0.72, 0.69 A [9]. This correlation shows that, as the ionic radius increases, the coordination power of the transition metal ion toward the AGE–PEI amino groups grows.

The characteristics of complexation of a cured (insoluble) AGE–PEI sorbent with transition metals (stability constant, composition of complexes) was studied by potentiometric titration of an aqueous suspension of this resin in the absence and in the presence of transition metals, with simultaneous monitoring of the content of free metal cations and pH.

The physicochemical characteristics of the cured anion exchangers are listed in Table 4.

It is known [10] that the shape of a potentiometric titration curve is sensitive not only to the concentration of titrable functional groups, but also to both the ionic strength of solution and the type of a supporting electrolyte. With the ionic strength increasing from 0.1 to 1.0 M, the electron-donor power of unprotonated amino groups increases, and their hydrate shells become looser. As a result, the complexation of the anion exchanger with transition metals is enhanced. Therefore, our sorption experiments were performed at the ionic strength of 1.0 M.

Anion exchanger: (a) AGE–PEI, (b) AGE–PMVP, (c) ED-20–AB–PEI, (d) ED-20–AB–PMVP. Metal: (*1*) none, (*2*) copper, (*3*) nickel, (*4*) cobalt, and (*5*) zinc.

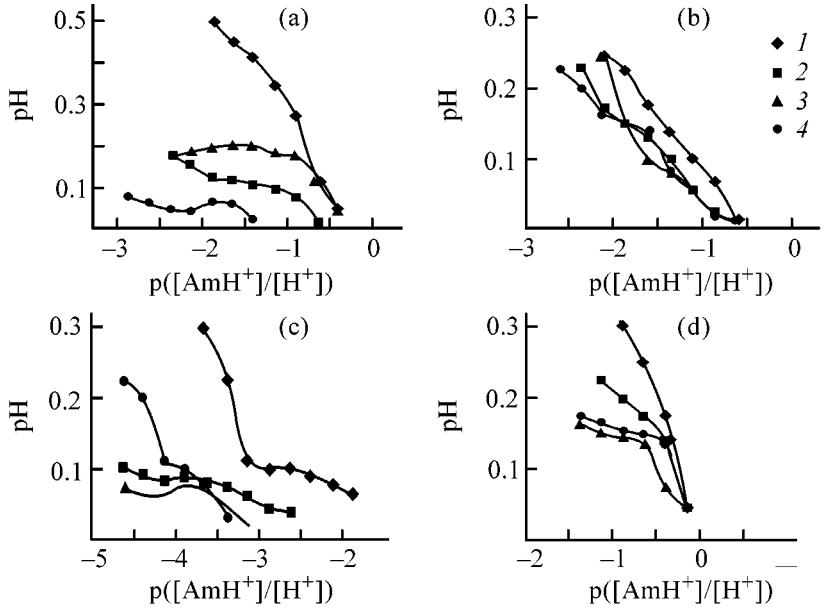

Fig. 3. Complexation functions. Metal cations: (*1*) copper, (*2*) nickel, (*3*) cobalt, and (*4*) zinc. Anion exchanger: (a) AGE–PEI, (b) AGE–PMVP, (c) ED-20–AB–PEI, and (d) ED-20-AB–PMVP.

Figure 2 shows the potentiometric titration curves of the cured anion exchanger based on AGE and ED-20 in an aqueous acid-containing suspension in the absence and in the presence of a transition metal. These curves show that both the complexation with metal and the protonation of the amino groups of the sorbent in the course of titration is accompanied by acidification of the liquid phase. The potentiometric titration curves obtained in the presence of metal are shifted to lower pH, compared to metal-free suspensions. This excess acidification becomes more pronounced with increasing metal concentration. The largest acidification in the presence of a metal is observed with AGE–PMVP and ED-20–PMVP anion exchangers. We believe that the excess acidification in the presence of metals is caused by a decrease in the sorbent basicity due to transfer of unshared electron pairs from the amino groups to metal cations. For all the sorbents under consideration, the sorption exchange capacity determined from the potentiometric titration curves at the equivalence point is less than the total exchange capacity. This difference can be caused by coordination of amino groups with metal cations and partial protonation of tertiary and secondary amino groups of the resin. The complexation curves of anion exchangers with copper, nickel, zinc and cobalt show (Fig. 3) that p tends to unity, i.e., the 1 : 1 complexes are predominantly formed. This means that one amino

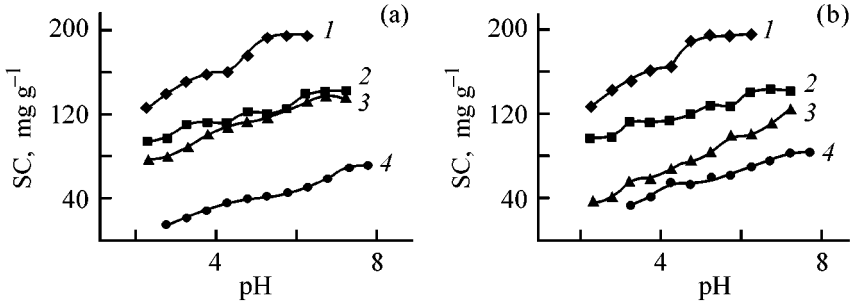

Fig. 4. Static exchange capacity SEC of anion exchangers as influenced by pH. Anion exchanger: (a) ED-20–AB–PEI and (b) AGE–PEI.

group, on the average, is coordinated with one metal cation. This stoichiometry is caused by the large excess of metal ions in the solution as compared with the content of sorbing sites in the sorbent. As the content of unprotonated amino groups in the sorbent becomes higher p increases to 1.5. This fact shows that the stoichiometry of complexation is sensitive to the content of sorbing sites in the resin. The chemical composition of sorbable metal complexes mainly depends on the ionic composition of the sorbing sites and on the metal cation speciation in the solutions. The higher the concentration of coordination-active ionic sites in the sorbent, the larger the amount of amino groups coordinated with metal cation.

Our calculations showed that the Bjerrum formation functions are too small for calculating the stability constants in our systems. In spite of this difficulty, we can suggest, based on published data [11], that in our systems the cross-linked anion exchanger complexation with transition metal decreases in the order: $Cu^{2+} > Zn^{2+} > Co^{2+} > Ni^{2+}$.

It is known [12] that sorption of cations on anion exchangers is dependent on the resin basicity. For example, zinc is sorbed on strongly basic anion exchangers only at the acidity exceeding 0.5 N, when anionic metal complexes are formed. By contrast, zinc is sorbed by weakly basic anion exchangers more strongly from weakly acidic aqueous solutions, and its sorption is enhanced when the acidity of the aqueous solution decreases. Therefore, to determine the pH ensuring the optimal metal sorption, we studied the transition metal sorption as influenced by pH. In these experiments, the distribution coefficients K_d and the degree of metal recovery, γ, were also determined (Table 5).

Table 5. Sorption of transition metal cations on AGE–PEI anion exchanger

Cation	Optimal pH	SEC_M, mg g^{-1}	K_d, ml g^{-1}	γ, %
Cu^{2+}	5–6	195	8203	94
Ni^{2+}	6–7	141	4976	91
Co^{2+}	7	126	3093	86
Zn^{2+}	7	72	2038	78

Figure 4 shows that, with increasing acidity of the aqueous phase, the sorption of metals decreases. This effect is caused by a decrease in the concentration of coordination-active (unprotonated) sorbing sites in the resin [13]. We found that the sorption of transition metals on the anion exchangers under consideration is the strongest at the following pH: Cu^{2+}, 5–6; Ni^{2+}, 6–7; and Zn^{2+}, 7.

CONCLUSIONS

(1) The complexation of polyfunctional anion exchangers based on polyimines and allyl and epoxy compounds with transition metals was studied by polarographic and potentiometric titration techniques. Copper was found to form the most stable sorption complexes.

(2) The distribution coefficients of transition metals between the aqueous phase and polymeric anion exchanger and the degrees of recovery of these metals were determined. The metal sorption was found to decrease with increasing acidity.

(3) Polyfunctional anion exchangers based on polyimine, allyl, and epoxy compounds can be recommended for industrial recovery of copper from aqueous solutions.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Water-Soluble Polymer-Colloid Complexes of Aluminum Polyhydroxochloride and Polyacrylamide in Separation of Model and Real Dispersions

I. A. Novakov, S. S. Radchenko, and F. S. Radchenko

Received March 1, 2004

Abstract—The activity of polymer-colloid complexes of aluminum polyhydroxochloride and polyacrylamide in separation of model kaolin dispersions and some real dispersions was studied under free and hindered particle sedimentation conditions.

The stability of dispersed systems is frequently controlled with flocculants, water-soluble macromolecular compounds, either natural or specially synthesized. Aluminum salts combined with certain polymers, above all polyacrylamide (PAA), have long been applied to water treatment [1, 2]. The main function of such components is to improve the flocculation in settlers and to reduce the water clarification time. However, the metal and the functional groups of the polymeric molecule of the flocculant can form ionic or coordination bonds. Schwartz and Francois [3] and Anufrieva *et al.* [4–6] studied reactions of a number of metals (Fe^{3+}, Ca^{2+}, Mg^{2+}, and rare-earth elements) with water-soluble polymers of various chemical structures and, in particular, with PAA. It was found that stable metal-containing polymeric complexes are formed in such systems via intramolecular complexation accompanied by a decrease in the conformational mobility of the macromolecules. Kudaibergenov *et al.* [7] studied the reaction between iron(IIII) chloride and nonionic and hydrolyzed PAA and showed that the coordination bond links the iron ions and the carbonyl groups of PAA. The resulting intramolecular ion-coordination cross-links are responsible for the compaction of the macromolecules: The hydrodynamic size of the particles of hydrolyzed PAA in water decreases from 2000 to 400 Å. At the same time, the conformation of the macromolecules and their hydrodynamic size in aqueous solutions are of primary importance in flocculation and sedimentation of dispersed particles. It has been shown [8–10] that the combined use of flocculants and inorganic coagulants in sedimentation of model kaolin and ocher dispersions can exert either synergistic or antagonistic effect, depending on the order in which the reagents are introduced.

More recent works [11–13] are concerned with formulations based on polyacrylamide and certain inorganic salts, whose high activity in flocculation and sedimentation of suspensions in potable water and wastewater treatment was noted by Gordeev-Gavrikov *et al.* [14]. Data on such formulations are scarce. These investigations are still in infancy, as suggested by the fact that the authors use terms like "alternative coagulants," "metal–polymer complexes," "composite organomineral coagulants," "inorganic polymeric flocculants," etc. [14, 15], which need to be defined more precisely.

We have shown previously [16] that mixing of aqueous solutions of PAA with aluminum polyhydroxochloride (APHC), as well as polymerization of acrylamide (AA) in an aqueous APHC solution, yields polymer-colloid complexes (PCCs) [16]. It was reasonable to test them both as flocculants for high-concentration dispersions and as coagulants for low-concentration aqueous dispersions (such as natural water).

EXPERIMENTAL

The poly complexes were prepared [16] by mixing aqueous solution of PAA (3 wt %) and APHC at room temperature or by polymerization of AA in an aqueous solution of APHC in the presence of an initiator, potassium persulfate. In both cases, the molar ratio of Al^{3+} to the PAA unit was varied from 0.25 to 10. The PCCs prepared were kept at room temperature for 2 days. The APBC obtained by the method described in [17] had the following characteristics: Al(III) content 12.8 wt %, Cl^{-1}/Al^{3+} atomic ratio 0.48, pH 4.5, ρ = 1330 kg m^{-3}, dry residue 46.5 wt %.

1070-4272/04/7710-1685 © 2004 MAIK "Nauka/Interperiodica"

Polyacrylamide was prepared by radical polymerization of AA (3% aqueous solution) in the presence of 0.1 wt % potassium persulfate at 45°C. The molecular weight of PAA was estimated viscometrically ($[\eta] = 6.8 \times 10^{-4} M^{0.66}$ [18]) at 520 000.

A kaolin dispersion (0.8 wt %) was prepared by swelling technical kaolin [GOST (State Standard) 19.608–84] in distilled water for 24 h. Before flocculation, we measured and, if necessary, adjusted pH to 7.4 by adding 5% $NaHCO_3$ or 0.1 N HCl solution. Before flocculation the dispersion was thoroughly mixed and poured into glass cylinders (V = 250 cm^3). A definite volume of a 0.1% solution of the flocculant was introduced into each cylinder, and the mixture was stirred for 1 min with a disk stirrer and allowed to stand for 20 min. The upper clarified layer was sampled with a pipet, and its optical density was measured on a Specol-10 spectrophotometer in a cell with a layer thickness of 1 to 5 cm at the wavelength of 460 nm. As flocculants served PCCs of various compositions, PAA and its copolymers (cation-active flocculants): Praestol-650, Zetag-92, and KF-99.

The flocculation of a concentrated kaolin suspension (5 wt %) was carried out in 100-cm^3 cylinders. A definite volume of the flocculant solution was introduced (0.1% solution) into each cylinder. After the cylinder was overturned 12 times, the time of migration of the interface between the clarified and thickened layers of the suspension was estimated using the graduation marks on the cylinders. Next, the kinetic plots were constructed in the distance (mm)–time (min) coordinates. The motion velocity of the interface was determined in the linear section of the curve at degrees of clarification within the range 20–60%.

To prepare a low-concentration kaolin dispersion, the previously prepared 0.8% kaolin dispersion was allowed to stand for 48 h. Then, the pH was measured and, if necessary, adjusted to 7.4. The upper clarified layer was decanted and filtered via a membrane filter to determine the content of the dispersed phase; it was estimated at 30–40 mg dm^{-3}. The coagulation was carried out by the same method as described above for a 0.8% dispersion. The settling time, after the reagent was added, was 40 min. Using the preliminarily constructed calibration plot [19], we recalculated the optical density into the turbidity (mg dm^{-3}). The flotation of the wastewater was carried out in a glass column (40 × 350 mm). The column bottom was a porous glass plate (Schott filter no. 4). Oil-containing wastewater (300 cm^3), preliminarily taken upstream of the process flotator, was poured into the column, whereupon a reagent dose was added; simultaneously, air was supplied via a porous plate. After a 20-min flotation, the sample was taken via the lower column cock, and the content of oil products in the sample was determined [20].

We studied poly complexes of PAA with APHC at various molar ratios of the reagents, prepared by mixing aqueous solutions of the reagents (PCMS) and by polymerization of AA in aqueous solutions of APHC (PCPs). Two particle sedimentation modes can be distinguished in flocculation, namely, free and hindered sedimentation at dispersed phase concentrations c_d under and over 1 wt %, respectively [21]. A number of parameters are used to quantitatively characterize the flocculation, among them the flocculation effect estimated from the rate of sedimentation of the particles and from accumulation of the precipitated mass on the pan of a torsion balance [9, 10]. However, the sedimentation rate was very high in the presence of PCCs and polycationic flocculants, which produced a strong scatter of the experimental data. Therefore, we studied the flocculation spectrophotometrically [22], by measuring the optical density of the supernatant liquid after the dispersion was allowed to stand a certain time with and without flocculant. Next, a dimensionless parameter, the clarification effect, was calculated:

$$E_{clar} = \tau_D^0/\tau_D - 1.$$

Here, τ_D^0 and τ_D are the optical turbidities of the supernatant liquid with and without the flocculant, respectively;

$$\tau_D = 2.3D/L,$$

where D is the optical density of the liquid; and L, length of the spectrophotometer cell.

The flocculation of the kaolin dispersion was carried out in the free sedimentation mode (dispersed phase concentration c_d = 0.8 wt %). Figure 1a presents the plots of the clarification effects for dilute kaolin dispersions as functions of the dose and composition of the poly complexes prepared by polymerization of AA in aqueous solutions of APHC. These dispersions are much more effective than PAA (Fig. 1a, curve *6*). The plots have peaks at the optimal content of the poly complex of 9–10 mg l^{-1}. At the poly complex concentrations above 10 mg l^{-1}, a secondary stabilization of the dispersion is observed, which is typical of all the flocculants. The poly complexes with the mole ratio of Al^{3+} to the PAA unit equal to 2 exhibit the maximum effect. Further increase in the content of aluminum in PCPs decreases the clarification effect (Fig. 1a, curve *5*). The poly complexes obtained by mixing

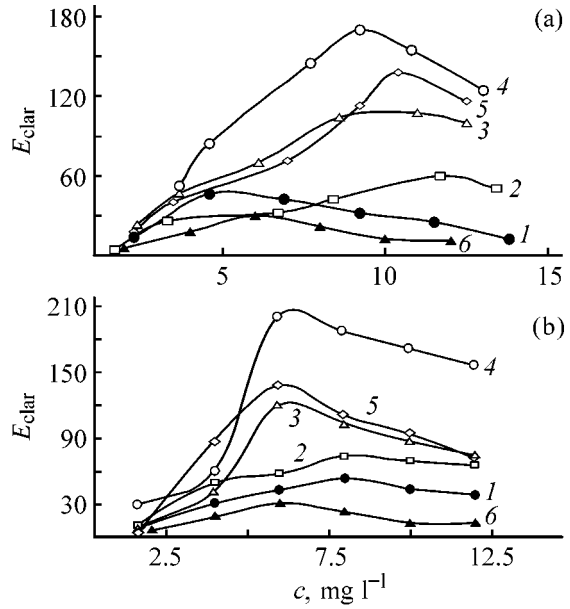

Fig. 1. Clarification effect E_{clar} for the kaolin dispersion (c_d = 0.8 wt %) vs. the concentration c and of the composition (Al^{3+} to PAA unit molar ratio, given below as hyphenated figures) of the poly complexes prepared by (a) polymerization of acrylamide (PCPs) and (b) mixing (PCMs).
