Abstract—The phase diagrams of a binary liquid system constituted by tetradecane and samarium(III) nitrate solvate with tri-*n*-butyl phosphate and a ternary system constituted by tetradecane, tri-*n*-butyl phosphate, and samarium(III) nitrate solvate with tri-*n*-butyl phosphate were studied at 298.15–355.15 K. The distribution of components between the phases was considered. The points of critical compositions of the ternary system at various temperatures and the upper critical temperature of mixing of the binary and ternary systems were estimated.

The phase diagrams of ternary liquid systems constituted by tetradecane, tri-*n*-butyl phosphate (TBP), and lanthanide(III) nitrate solvate with TBP at 298.15 K were studied in [1]. These diagrams consist of a field of homogeneous solutions and a field of separation into two liquid phases: phase I is enriched in tetradecane, and phase II, in $[Ln(NO_3)_3(TBP)_3]$. Quantitative data on the above binary and ternary phase diagrams in relation to the temperature are lacking, although such an information is of interest for the choice of diluent, component concentrations, and temperature of extractor operation. In this study, we examined the temperature dependences of the above binary and ternary systems with Sm(III).

The phase densities were measured pycnometrically. Vacuum-distilled TBP (density $\rho = 0.9727$ g cm^{-3} at 298.15 K) and tetradecane of chemically pure grade (0.7592 g cm^{-3}) were used. Samarium(III) nitrate solvate $[Sm(NO_3)_3(TBP)_3]$ (S) was prepared by threefold saturation of TBP with fresh portions of a saturated aqueous solution of samarium nitrate [2]. The "concentration" of $[Sm(NO_3)_3(TBP)_3]$ in the phase of pure S was 1.10 M, $\rho = 1.2755 \pm 0.0012$ g cm^{-3}. The binodals of the ternary system were measured with modified Alekseev's method [3] by titration of the binary system with different compositions with the third component under the temperature control. The S concentration in the organic phase was monitored complexometrically [4]. Nodes (compositions of the coexisting organic phases) were determined by the method described in [1, 3]. All the results are presented as phase diagrams in the form of the second Roozeboom's triangle: rectangular coordinates (component weight fractions) for two components of the ternary liquid systems (for the third component, $\omega_3 = 1 - \omega_1 - \omega_2$), depending on temperature. The errors in ω de-

termination did not exceed ±0.001–0.002, and those of temperature measurement, ±0.2 K.

The binary systems S–TBP and TBP–tetradecane are homogeneous at all the temperatures studied. By contrast, the S–tetradecane system exhibits solubility limits and has a field of separation into two liquid phases I and II. Phase I is enriched in tetradecane, and phase II, in S. With temperature rise, this field narrows (Fig. 1). The upper critical temperature of mixing lies at $T_{cr} = 351.15 \pm 0.2$ K. The compositions of the coexisting phases (nodes) at various temperatures are listed in Table 1. At the T_{cr} point, the component weight fractions are approximately equal (Table 1).

The phase diagram of the ternary liquid system S–TBP–tetradecane at various temperatures is shown in Fig. 2. It consists of the field of homogeneous solutions (Fig. 2, field *B*) and the field of separation into two liquid phases (Fig. 2, field *A*) bounded with binodals. The points of critical composition of the ternary system ω_{2cr} correspond to phases with approximately equal weight fractions of S and tetradecane and varied temperature-dependent TBP content (Table 2). The upper critical temperature of mixing for the binary and ternary systems is the same (Fig. 2). The temperature rise leads to narrowing of the separation field of the ternary system (Fig. 2). The dependence of ω_{2cr} on $1/T$ is shown in Fig. 3. It is virtually linear and can be described by the equation

$$\omega_{2\,cr} = -(0.980 \pm 0.042) + (344 \pm 13)/T. \qquad (1)$$

Dependence (1) allows prediction of the critical compositions of the ternary system at various temperatures.

The nodes of the ternary liquid system S–TBP–tetradecane (Table 2) show that, as in the case of the binary system S–tetradecane, two liquid phases I and II are formed. Phase I is enriched in tetradecane, and phase II, in S. TBP is also concentrated predominantly in phase II, while tetradecane is concentrated in phase I at all the temperatures studied (Table 2).

In practice, to use extraction systems based on TBP and hydrocarbon solvent, it is necessary to keep the TBP equilibrium content (weight fraction) no less than 0.17–0.20 at about 298.15 K, i.e., to operate with the organic phase unsaturated with respect to Ln(III). At 333.15 K, the equilibrium TBP weight fraction can be decreased to 0.05–0.06.

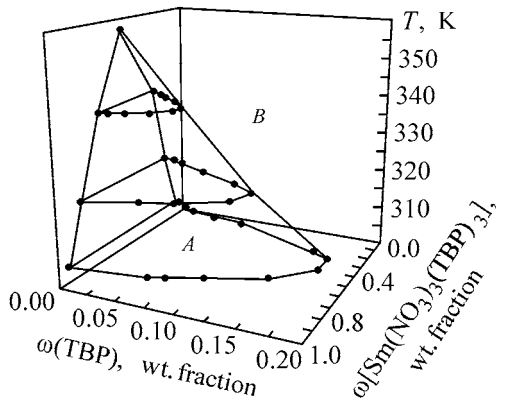

Fig. 2. Phase diagram of the ternary system $[Sm(NO_3)_3(TBP)_3]$–TBP–tetradecane in the 298.15–355.15 K range. $\omega[Sm(NO_3)_3(TBP)_3]$ and ω(TBP) are weight fractions of $[Sm(NO_3)_3(TBP)_3]$ and TBP, respectively; (*A*) field of separation into two liquid phases and (*B*) field of homogeneous solutions.

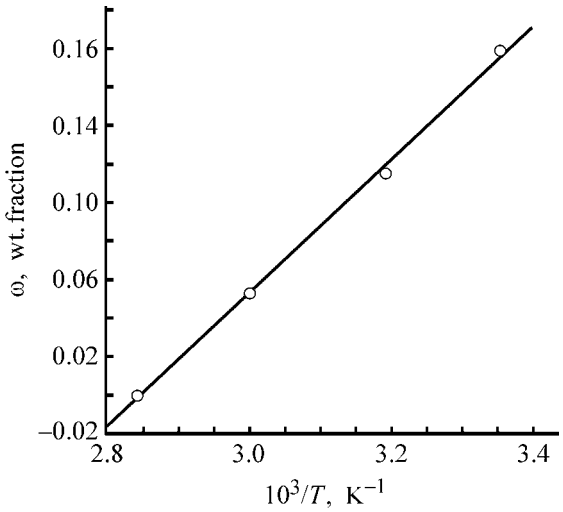

Fig. 3. Dependence of TBP weight fraction ω on the temperature *T* in the points of critical composition of the ternary system $[Sm(NO_3)_3(TBP)_3]$–TBP–tetradecane.

CONCLUSIONS

(1) The binary system S–tetradecane exhibits solubility limits and has a field of separation into two liquid phases I and II. Phase I is enriched in tetradecane, and phase II, in $[Sm(NO_3)_3(TBP)_3]$. With temperature rise, this field narrows (Fig. 1). The upper critical temperature of mixing is $T_{cr} = 351.15 \pm 0.2$ K.

(2) The phase diagram of the ternary liquid system $[Sm(NO_3)_3(TBP)_3]$–TBP–tetradecane at various temperatures consists of the field of homogeneous solutions and the field of separation into two liquid phases. The points of critical composition of ternary system ω_{2cr} correspond to phases with approximately equal weight fractions of $[Sm(NO_3)_3(TBP)_3]$ and tetradecane and varied temperature-dependent TBP content.

(3) Within the field of phase separation, $[Sm(NO_3)_3(TBP)_3]$ and TBP are predominantly concentrated in phase II, while tetradecane, in phase I, at various temperatures.

(4) In practice, to use extraction systems with TBP and hydrocarbon solvent, it is necessary to keep the equilibrium TBP content (weight fraction) no less than 0.17–0.20 at about 298.15 K. At 333.15 K, the equilibrium TBP weight fraction can be decreased to 0.05–0.06.

Abstract—Five-step countercurrent extraction of aromatic hydrocarbons from hydrofined diesel fraction with the 2-methoxyethanol–water–pentane extraction system was studied. The process was performed on a rotary-disk extractor.

In accordance with the demands proclaimed by the World-Wide Fuel Charter for Category 2 diesel fuels (for markets with stringent requirements for emission control or other market demands), the total content of aromatics should be no more than 25 wt % and that of polyaromatics, 5 wt %. The corresponding values for Category 3 diesel fuels (markets with advanced requirements for emissions control or other market demands) are 15 and 2 wt %. The sulfur content should not exceed 300 (Category 2) and 30 ppm (Category 3). Even more restrictions limits were imposed in such countries as the United States and Sweden. For example, the Swedish national standards for the quality of Grade 1 diesel fuel limit the content of total aromatics and polyaromatics to 5 and 0.02 vol %, respectively, and the content of sulfur, to 10 ppm [1].

Such very stringent requirements to the sulfur content are caused not only by undesirability of release of sulfur oxides to the atmosphere, but also by the fact that sulfur has a significant impact on vehicle emissions by poisoning the afterburning catalysts.

Pollution-free diesel fuels can be produced using hydrocracking of vacuum gas oils or hydroreforming of diesel fractions [1, 2]. However, these hydrogenation processes are performed at high pressure and require high specific investment, power consumption, and hydrogen consumption. For example, the consumption of H_2 per 1 vol % of arenes removed is 5–6 $nm^3\ m^{-3}$ raw material, and that per 0.1 wt % of sulfur and nitrogen removed, 2–3 and 4–6 $nm^3\ m^{-3}$ raw material, respectively [3].

The first industrial unit for refining of diesel fuel by solvent extraction was put into service in the United States in 2001 [4]. The extractant composition was not given, but it may be suggested from the reported process flowsheet that it is a high-boiling selective solvent, whose regeneration is performed by aqueous stripping, followed by removal of excess water by distillation. However, in this case, the water consumption for regeneration of the extractant from the extract phase should be high, requiring high power consumption for the subsequent removal of water.

Previously, we have suggested quite efficient extraction systems for refining of the diesel fraction to remove aromatic and organoelement compounds: acetonitrile–water–pentane [5–9] and dimethylformamide (or dimethylacetamide)–water–pentane [10–12]. These systems contain low-boiling polar and nonpolar solvents readily regenerable by distillation. Acetonitrile does not form azeotropic mixtures with components of the diesel fraction, and dimethylformamide and dimethylacetamide form heteroazeotropic mixtures only with saturated hydrocarbons contained in this fraction. Formation of such azeotropic mixtures improves the process selectivity: the major part of saturated hydrocarbons remaining in the extract phase is removed with a selective solvent in the course of its regeneration, and the arene content in the concentrate increases to 98–99.5 wt %.

Acetonitrile, dimethylformamide, and dimethylacetamide are characterized by fairly high selectivity with respect to aromatic hydrocarbons. Their draw-

1070-4272/04/7704-0566 © 2004 MAIK "Nauka/Interperiodica"

back is the hydrolytic instability in the course of regeneration at high temperatures (highly corrosive acetic and formic acids are formed as hydrolysis products). 2-Methoxyethanol is less selective with respect to arenes [13], but demonstrates higher hydrolytic stability and lower corrosive activity. The extraction system 2-methoxyethanol–water–pentane was successfully used for removal of aromatic hydrocarbons from dewaxed fractions 200–320°C [14, 15], for refining of liquid paraffin fractions to remove aromatic hydrocarbons [16], and also for manufacture of hydraulic and transformer oils from light oil fractions of the Troitsk-Anastasievsk oil field [17, 18].

The goal of this study was to check the possibility of manufacturing pollution-free diesel fuel by extraction refining of the hydrofined diesel fraction, using the 2-methoxyethanol–water–pentane extraction system.

As a raw material, we used hydrofined diesel fraction with the characteristics listed in Table 1.

EXPERIMENTAL

Five-step countercurrent extraction was carried out using a system of temperature-controlled separating funnels [20]. The raw material in pentane flowed countercurrent to aqueous 2-methoxyethanol. The experimental conditions are given in Table 2. The decision on five theoretical plates was caused by the fact that the efficiency of industrial extractors used for production of benzene, toluene, and xylenes from reformates corresponds to 6–7 theoretical plates, and that in selective refining of lube cuts, to 3–4 theoretical plates. It would be expected that the efficiency of similar extractors for selective refining of the diesel fraction with a viscosity intermediate between the gas oil and lube fractions corresponds to ca. five theoretical plates. Cycling by the scheme reproducing the operation of a fully charged column was performed until the steady state mode, under which the weights and compositions of the extract and raffinate phases become constant was established. Pentane was recovered from the extract and raffinate phases by distillation on a 15 TP column. 2-Methoxyethanol was entirely removed from the raffinate by multiple aqueous stripping. The most part of 2-methoxyethanol and water that remained after distillation of pentane were removed using the same column. Small residual amounts of 2-methoxyethanol (3–5 wt %) were removed from the extract and raffinate by aqueous stripping. The extract and raffinate were dried over calcined zeolite NaA. The material balance data for

the extraction refining of diesel fraction are listed in Table 3.

The process was then performed on a rotary-disk extractor (RDE). It has the form of a column (inner diameter 60 mm; height 1400 mm) with an axle drive shaft supported by a ball thrust bearing. Horizontal disks 40 mm in diameter are fastened on the shaft between the stator rings at a 15-mm spacing. The column consists of 50 sections with a total height of 800 mm. There are settling zones 300 mm high at the top and bottom of RDE. The extractor is equipped with a water jacket. The rotor speed can be finely adjusted within the range 200–1300 rpm. In this study, the extraction was carried out at a rotor speed of 400 rpm. The flows of the feed, extractant, and pentane were set with dosing piston pumps. Watered 2-methoxyethanol having a higher density as compared to the diesel fraction was fed to the top of RDE. The column was charged with the extractant and then the raw material with pentane was started to be fed through a sprayer producing fine droplets. The raffinate and extract phases were run off, respectively, from the top and bottom settling zones to tanks. The raffinate and extract were separated from the equilibrium phases by the procedure described above for the experiment with separating funnels.

The results obtained in the experiments on five-step countercurrent extraction with separating funnels and RDE with the use of the 2-methoxyethanol–water–pentane extraction system are well consistent. The yield of the raffinate in the experiments with separating funnels and RDE was 83.7 and 81.8 wt %, respectively; density of the raffinate at 20°C, 0.822 and 0.823 g cm^{-3}; refractive index at 20°C, 1.4599 and 1.4598; kinematic viscosity at 20°C, 5.98 and 5.72 mm^2 s^{-1}; and total content of aromatics, 11.3 and 10.4 wt %. Since the experiments on RDE were carried out at reduced temperature, a decrease in the solvency of the extractant was compensated for by increasing the extractant-to-feed ratio (Table 2). In the experiments on RDE, we achieved somewhat more exhaustive dearomatization of the diesel fraction at a lower (by 4.4 wt %) arene content in the extract. The similarity of the results obtained in both experiments suggests that the efficiency of RDE is about five theoretical plates.

The conclusions made upon a comparison of the results of this study with those obtained previously with the acetonitrile–water–pentane [6–8] and DMF–water–pentane extraction systems [10, 12] are as follows.

(1) Changing acetonitrile for 2-methoxyethanol in the extraction system allows more exhaustive and selective dearomatization of the diesel fraction. However, this requires an increase in the water content in the extractant from 1 to 5 wt % and in the volume ratio of the extractant to raw material from ca. 2.5 : 1 to (4.35 – 6.0) : 1.

(2) Changing DMF for 2-methoxyethanol provides the same degree of dearomatization, but at a volume ratio of 2-methoxyethanol to raw material, increased by 25–40%.

Despite the somewhat lower efficiency of the 2-methoxyethanol–water–pentane extraction system as compared to the system with DMF, a decision on a polar solvent for the industrial process should be made taking into account such important advantages of 2-methoxyethanol as its lower boiling point and, accordingly, milder temperature conditions required for its regeneration, and also higher thermal and hydrolytic stability of 2-methoxyethanol and, as a result, its lower corrosivity.

Characteristics of the raffinate obtained (Table 1) meet the requirements to summer diesel fuel. The flash point of the diesel fraction after dearomatization decreased, and the cloud and pour points slightly in-

Table 4. Characteristics of the extract from extractive refining of the diesel fraction with 2-methoxyethanol–water–pentane extraction system

Parameter	Five-step extraction	RDE	Parameter	Five-step extraction	RDE
Yield, wt %	16.3	18.2	Degree of recovery, %:		
Density ρ_4^{20}, g cm^{-3}	0.932	0.916	sum of aromatic hydrocarbons	62.0	66.0
Refractive index n_D^{20}	1.5179	1.5173	polycycloarenes	–	72.8
Arene content, wt %	95.0	90.6	sulfur-containing compounds	–	63.6
among them polycycloarenes	–	22.8			

creased. The content of aromatics in the extract was 90.6–95 wt % (Table 4).

The cetane index of the raffinate, which characterizes the ability of diesel fuel to self-ignition and depends on the group hydrocarbon composition, increased by 7 points as compared to the hydrofined diesel fraction. In this parameter (CI = 60) the raffinate meets the demands of the World-Wide Fuel Charter for Category 3 diesel fuels. The sulfur content in the raffinate decreased by a factor of 2.25 as compared to the hydrofined diesel fraction, which meets the requirements for Category 2 diesel fuels.

CONCLUSIONS

(1) Five-step countercurrent extraction of arenes from hydrofined diesel fraction at 5 : 1 weight ratio of aqueous (5% water) 2-methoxyethanol to raw material and 1 : 1 weight ratio of pentane to raw material allowed a decrease in the aromatics content from 25 to 10–11 wt % and in the content of organosulfur compounds from 0.045 to 0.02 wt %. In this case, the arene content in the extract approaches 90–95 wt %.

(2) Extractive refining of the diesel fraction with the 2-methoxyethanol–water–pentane extraction system can be successfully performed on an apparatus with a rotary-disk extractor.

(3) The use of extraction systems with 2-methoxyethanol provides more exhaustive and selective dearomatization of the diesel fraction as compared to that with acetonitrile. In this case, the results are similar to those obtained in refining with DMF–pentane. However, the system with 2-methoxyethanol requires an increased (by 25–40%) weight ratio of polar extractant to raw material. Such advantages of 2-methoxyethanol as higher thermal and hydrolytic stability and lower corrosivity, compared to acetonitrile and DMF, should be taken into account in making a decision on an extraction system for industrial implementation of the process.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Gallium(III) from Alkaline Solutions with a Polymeric Sorbent Impregnated with 1,2-Dioxyanthraquinone

Abstract—Distribution of Ga(III) among aqueous solutions of NaOH and a macroporous copolymer of styrene with divinylbenzene, impregnated with 1,2-dioxyanthraquinone in the presence of the trialkylmethylammonium cation, was studied.

The main source of raw materials for manufacture of gallium are alkaline solutions formed in production of alumina [1]. Pointing to the fact that extractive techniques are promising for processing of materials of this kind, the authors of reviews [2, 3] note that the choice of extracting agents for selective recovery of gallium is limited. Extraction of gallium(III) from alkaline solutions with solutions of alkylated 8-oxyquinolines [4–6], pyrocatechols [7, 8], and alkyl phenyl oligomers [9–11] in organic solvents has been reported. The use of hydrophobic reagents of this kind is associated with the decrease in their solubility in aqueous alkaline solutions in the course of extraction [12].

Recently, impregnated materials that combine properties of a sorbent and a selective extracting agent have been finding increasingly wide use in recovery, concentration, and separation of rare, trace, and nonferrous metals [13, 14]. Materials of this kind not only make it possible to eliminate organic solvents, which are frequently toxic, volatile, or fire-hazardous, from the technological scheme, but also ensure a substantial decrease in contamination of aqueous solutions with organic reagents [15]. The use of impregnated materials for recovery of gallium(III) from alkaline solutions has been the subject of a comparatively small number of studies [16]. In these studies, alkylated 8-oxyquinolines, which form with Ga(III) complex compounds in the sorbent phase, served as organic complexing agents. Presumably, the set of such reagents can be supplemented with other phenol derivatives, including those soluble in aqueous alkaline solutions.

For this purpose, the distribution of Ga(III) among aqueous solutions of NaOH and a macroporous polymeric sorbent impregnated with 1,2-dioxyanthraquinone in the presence of the trialkylmethylammonium cation was examined in this study.

EXPERIMENTAL

1,2-Dioxyanthraquinone (alizarin) of analytically pure grade and trialkylmethylammonium nitrate (TAMAN) with the content of the main product of no less than 98% were used in the study. As a matrix for preparing an impregnated sorbent served nonionogenic macroporous copolymer of styrene with divinylbenzene, Wofatite EP-60.[1] The parameters of the material [17] are close to those of similar products of domestic manufacture, polysorbs [18]. The polymeric matrix was impregnated with TAMAN by a procedure similar to that described previously [19] and then the sorbed TAMAN was converted into the OH^- form [20]. The resulting sorbent was mixed with a solution of 1,2-dioxyanthraquinone in a 1 M solution of NaOH, the mixture was agitated for 1 h, and then the sorbent was separated from the aqueous phase by filtration and used to recover Ga(III) from aqueous alkaline solutions.

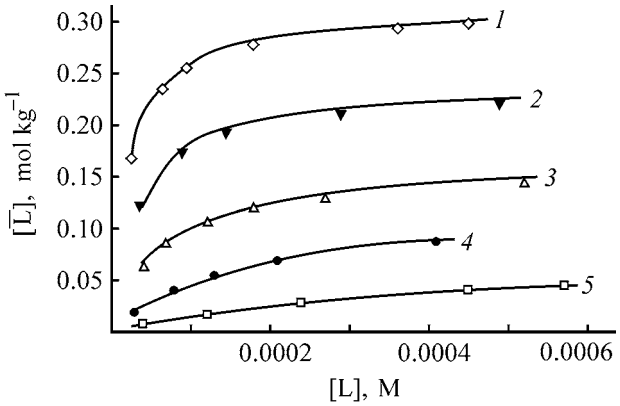

Fig. 1. Distribution of 1,2-dioxyanthraquinone among a 1 M solution of NaOH, [L], and a polymeric sorbent, [$\overline{L}$]. Concentration of ROH in the sorbent phase (mol kg^{-1}): (*1*) 0.75, (*2*) 0.5, (*3*) 0.25, (*4*) 0.1, and (*5*) 0.

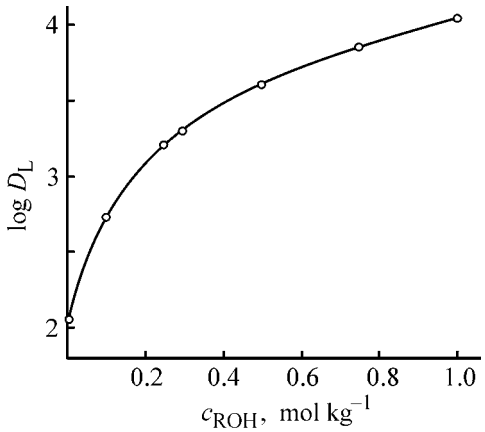

Fig. 2. Distribution coefficient of 1,2-dioxyanthraquinone, D_L, vs. the concentration of ROH, c_{ROH}, in the sorbent phase in sorption of from a 1 M solution of NaOH. Line: calculation by Eq. (5).

The starting aqueous solutions of Ga(III) were prepared by dissolving gallium oxide of pure grade in a 1 M solution of NaOH, with subsequent dilution with water or alkali. The concentration of Ga(III) in the starting solutions was 4×10^{-4} M.

Sorption experiments were performed under static conditions at 18±2°C. The mixture of an aqueous solution and the sorbent was agitated with a magnetic stirrer for 2 h, which is sufficient for constant distribution coefficients of gallium, D_{Ga}, and 1,2-dioxyanthraquinone, D_L, to be attained. The ratio between the volume V (ml) of the aqueous phase and the mass m (g) of the sorbent was 20 : 1.

The content of gallium(III) in the aqueous solutions before and after sorption was determined by mass spectrometry, with ionization of a sample in an inductively coupled plasma (ICP-MS), on a VG Elemental PlasmaQuad mass spectrometer (UK) by a procedure described previously in [21]. The concentration of 1,2-dioxyanthraquinone in the aqueous solutions was determined photometrically at λ = 590 nm on a KFK-2MP photocolorimeter.

The content of gallium(III) and 1,2-dioxyanthraquinone in the sorbent phase was calculated using material balance equations, and the distribution coefficients were found as the ratio of concentrations in the solid and aqueous phases. The concentration of NaOH in equilibrium aqueous solutions was determined by potentiometric titration with a 0.1 M solution of HCl.

Preliminarily, the distribution of 1,2-dioxyanthraquinone (H_2L) among aqueous solutions of NaOH and a polymeric sorbent impregnated with trialkylmethylammonium hydroxide (ROH) was considered. It is known that 1,2-dioxyanthraquinone is soluble in aqueous alkaline solutions because of the dissociation of phenol groups and virtually cannot be extracted with inert organic diluents. By contrast, the nonionogenic macroporous sorbent EP-60 sorbs 1,2-dioxyanthraquinone from solutions of this kind (Fig. 1, curve *5*), presumably as a sodium salt Na_2L. The sorption of 1,2-dioxyanthraquinone is markedly enhanced as the content of ROH in the sorbent phase grows (Fig. 1). This may be due to the formation in the sorbent phase of ionic associates RNaL and R_2L by the following ion-exchange reactions

$$L^{2-} + Na^+ + \overline{ROH} \rightleftarrows \overline{RNaL} + OH^-, \quad (1)$$

$$L^{2-} + 2\overline{ROH} \rightleftarrows \overline{R_2L} + 2OH^- \quad (2)$$

(the overline designates components in the solid phase) with the corresponding equilibrium concentration constants

$$K_1 = \frac{[\overline{RNaL}][OH^-]}{[L^{2-}][Na^+][\overline{ROH}]}, \quad (3)$$

$$K_2 = \frac{[\overline{R_2L}][OH^-]^2}{[L^2][\overline{ROH}]^2}, \quad (4)$$

The variation of the distribution coefficient of 1,2-dioxyanthraquinone with the concentration of ROH in the solid phase and with that of OH^- ions in the aqueous phase can be represented as

$$D_L = \frac{[\overline{RNaL}] + [\overline{R_2L}]}{[L^{2-}]} = \frac{K_1[Na^+][\overline{ROH}]}{[OH]} + \frac{K_2[\overline{ROH}]^2}{[OH]^2}. \quad (5)$$

The equilibrium constants calculated by the least-squares procedure with the use of the data in Fig. 2 are $K_1 = (4.7 \pm 0.2) \times 10^3$ and $K_2 = (6.3 \pm 0.3) \times 10^3$. It follows from these results that the sorbent for recovery of Ga(III), prepared by saturating with 1,2-dioxyanthraquinone a polymeric matrix impregnated with ROH, contains 1,2-dioxyanthraquinone in the form of the associates RNaL and R_2L. The concentration of the latter, relative to the total concentration of 1,2-dioxyanthraquinone in the sorbent phase, is expressed as

$$\alpha = \frac{K_2[\overline{ROH}]}{K_2[\overline{ROH}] + K_1[Na^+][OH]}. \quad (6)$$

Hence follows that raising the concentration of ROH in the solid phase and lowering the concentration of alkali in the aqueous phase favor an increase in the content of such a complex. The sufficiently high hydrophobicity of the associate R_2L ensures that it passes to only a slight extent into the aqueous phase in sorption recovery of Ga(III).

The data on saturation of the sorbent with gallium(III) (Fig. 3) indicate that Ga(III) is recovered into the solid phase in the form of a complex with a ratio Ga : L = 1 : 3, which is characteristic of extraction of this element in the form of intracomplex compounds [1]. It may be assumed that the C=O and OH groups of the molecule of 1,2-dioxyanthraquinone in the positions 9 and 1 of the anthraquinone ring are involved in complexation with Ga(III) [22], and the negative charge of the second phenol group of the reagent is neutralized by the trialkylmethylammonium cation.

Taking into account this fact, the interphase equilibrium of the process of recovery of Ga(III) from alkaline solutions in the form of an ionic associate $GaL_3^{3-} \cdot 3R^+$ can be described by the following equation of the exchange reaction

$$Ga(OH)_4^- + 3\overline{R_2L} \rightleftarrows \overline{Ga(RL)_3} + 3\overline{ROH} + OH^- \quad (7)$$

with an equilibrium constant

$$K_3 = \frac{[\overline{Ga(RL)_3}][\overline{ROH}]^3[OH^-]}{[Ga(OH)_4^-][R_2L]^3}, \quad (8)$$

and the dependence of the distribution coefficient of Ga(III) on the concentrations of components of the aqueous and solid phases can be expressed as

$$D_{Ga} = \frac{K_3[\overline{R_2L}]^3}{[\overline{ROH}]^3[OH]} \quad (9)$$

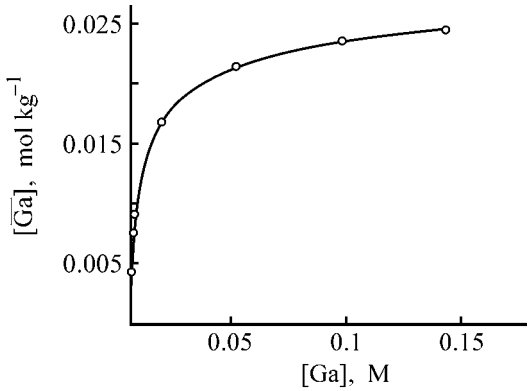

Fig. 3. Distribution of Ga(III) among a 1 M solution of NaOH, [Ga], and the impregnated sorbent, [$\overline{Ga}$]. c_L = c_{ROH} = 0.1 mol kg^{-1}.

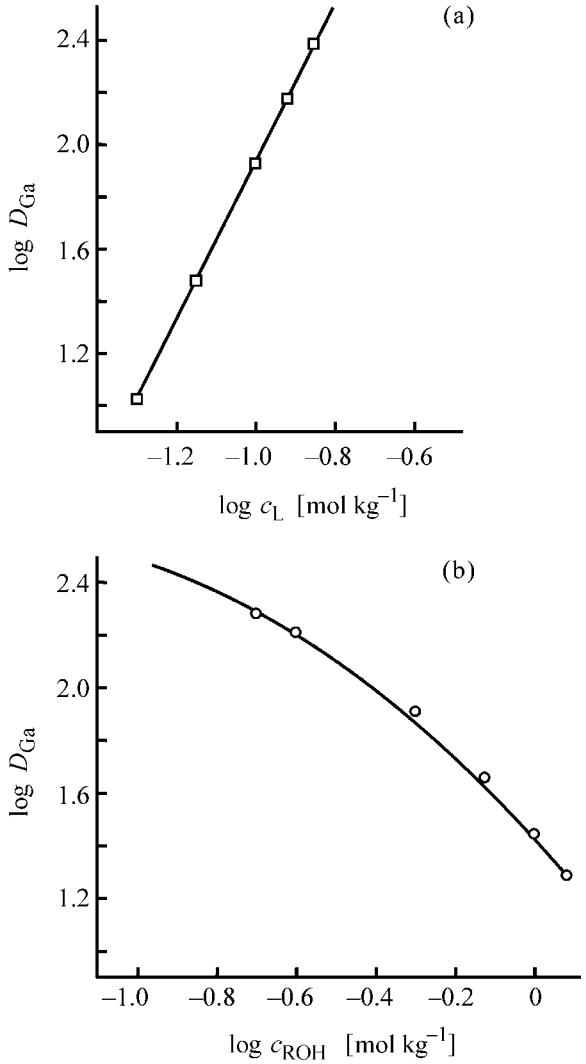

Fig. 4. Distribution coefficient of Ga(III), D_{Ga}, vs. the concentration of (a) 1,2-dioxyanthraquinone, c_L, and (b) ROH, c_{ROH}, in the sorbent phase in sorption from a 1 M solution of NaOH. (a) c_{ROH} = 0.1 mol kg^{-1}, (b) c_L = 0.1 mol kg^{-1}.

or, with account of relation (6),

$$D_{Ga} = \frac{K_3 K_2^3 (c_L - 3[\overline{Ga}])}{[OH](K_2[\overline{ROH}] + K_1[Na^+][OH])^3}, \quad (10)$$

where c_L is the initial concentration of 1,2-dioxyanthraquinone in the sorbent phase, and $[\overline{Ga}]$ is the equilibrium concentration of Ga(III) in the same phase.

The logarithmic dependence of the distribution coefficient of Ga(III) on the concentration of 1,2-dioxyanthraquinone in the solid phase (Fig. 4a) is represented by a straight line with a slope close to 3, which confirms the stoichiometric ratio Ga : L = 1 : 3.

It follows from expression (10) that D_{Ga} decreases as the concentration of ROH in the sorbent phase grows (Fig. 4b). At constant concentrations of NaOH in the aqueous solution and 1,2-dioxyanthraquinone in the solid phase, the dependence of $\log D_{Ga}$ on $\log(K_2[ROH] + K_1[Na^+][OH^-])$ is expressed by a straight line with a slope close to 3, which corresponds to the stoichiometric ratio Ga : R = 1 : 3 in the complex being sorbed. This points to the adequacy of the scheme suggested for describing the recovery of Ga(III) into the sorbent phase. At an invariable initial composition of the solid phase, the recovery of Ga(III) decreases with increasing concentration of NaOH in the aqueous phase, which is due both to the leftward shift of the equilibrium (7) and to a decrease in the fraction of the associate R_2L in the equilibrium solid phase as a result of an increase in the sorption of sodium ions into the sorbent phase.

The data presented here indicate that the macroporous copolymer of styrene with divinylbenzene, impregnated with 1,2-dioxyanthraquinone in the presence of the trialkylmethylammonium cation, effectively sorbs Ga(III) from alkaline solutions and can be used to recover and concentrate Ga(III).

CONCLUSIONS

(1) A sorbent based on a macroporous copolymer of styrene with divinylbenzene, impregnated with 1,2-dioxyanthraquinone (H_2L) in the presence of the trialkylmethylammonium cation (ROH), is suggested for sorption recovery and concentration of Ga(III) from alkaline solutions. The ionic associate R_2L is the active component of the sorbent.

(2) Gallium(III) is recovered from alkaline solutions in the form of the $Ga(LR)_3$ complex.

SORPTION AND ION-EXCHANGE PROCESSES

Exchange Isotherm of Strontium(II) and Iron(III) Ions on Clay

D. E. Chirkst, T. E. Litvinova, O. V. Cheremisina, and M. V. Ivanov

St. Petersburg State Mining Institute (Technical University), St. Petersburg, Russia

Received April 2, 2003; in final form, September 19, 2003

Abstract—Joint sorption of Sr^{2+} and Fe^{3+} ions on blue Cambrian clay was studied. A relationship between the isotherm of ideal ion exchange and the Langmuir sorption isotherm was revealed. The apparent constant and Gibbs energy of exchange of Sr^{2+} and Fe^{3+} ions on blue Cambrian clay were calculated.

Studying the ion exchange in soil makes it possible to prognosticate the behavior of ^{90}Sr on contaminated territories and to calculate the technological parameters of the process of soil decontamination by ion-exchange washing [1]. Previously, sorption isotherms of strontium(II) and iron(III) ions on clay, which binds most part of ^{90}Sr in soil, have been obtained [2, 3]. The present study is concerned with the exchange isotherm for the case of joint sorption of these cations.

A sample of Cambrian blue clay of composition $K_2Al_4[Al_2Si_6O_{20}](OH,F)_4$ had a specific surface area of 5.86 $m^2\ g^{-1}$ (found from sorption of Methylene Blue) [4]. The exchange capacity of the clay has been determined from the limiting sorption of Sr^{2+} and Fe^{3+} ions separately [2, 3]. The limiting amount of sorption was calculated from experimental data with the use of the Langmuir equation. The capacities of 69 and 78 mequiv kg^{-1} for the limiting sorption of Sr^{2+} and Fe^{3+} ions, respectively, have been obtained [2, 3], with the average value of 73 ± 5 mg-equiv kg^{-1}. A thermal analysis demonstrated that the clay is of the hydromicaceous type. A curve of potentiometric titration of a 0.5-g portion of air-dry clay soaked in 50 ml of water with a 0.01 N solution of NaOH was obtained (Fig. 1). The pH values were measured with a 150M pH-meter with a glass electrode upon addition of the alkali in 0.5-ml portions under agitation with a magnetic stirrer. Three pH jumps can be seen in the titration curve, which indicates that the clay has three functional groups. The equivalence point at pH 4.6 corresponds to an isoelectric state of kaolinite. The jump at pH 7.5–8.0 corresponds to the isoelectric point of hydrargillite and other minerals that are hydrates of aluminum oxide. The equivalence point at pH 9.0–9.2 is presumably due to dissociation of silanol groups.

Prior to determining the amount of sorption of cations, an air-dry sample of clay was ground and soaked in a 1 M solution of HCl for 1 day with agitation at regular intervals. Then the acid solution was replaced with its fresh portion and the soaking was repeated manyfold to negative reaction to iron ions in the aqueous phase. The presence of iron ions was determined by reactions with hexacyanoferrates (II) and (III) and with ammonium thiocyanate NH_4SCN. After that the clay was repeatedly washed with water to pH 3 in an aqueous extract. Then the clay was dried to the air-dry state and ground. The amount of sorption, Γ (mol kg^{-1}), was determined under static conditions at a ratio of the volume of the aqueous phase to the mass of the solid phase, $V/m = 10$ ml g^{-1}, with a 3-g weighed portion of the clay from the difference of concentrations of the initial (c_0) and equilibrium (c_{eq}) solutions by the formula

$$\Gamma = (c_0 - c_{eq})V/m.$$

A solution of a mixture of chlorides, $SrCl_2$ and $FeCl_3$ was acidified to pH 3, mixed with a weighed

portion of clay, and agitated to the equilibrium state. The time in which the equilibrium, which corresponded to a constant concentration of the solution, was attained was 5–6 h, the time of contact between the phases in the experiments performed was no less than 24 h. The initial and equilibrium pH values were 3 and 3.2 ± 0.3, respectively.

After an experiment, a 2- to 10-ml, depending on the content of strontium ions, portion of the solution was filtered through a blue ribbon filter and transferred into a 50-ml vessel. The necessary pH 2.8–3.0 was adjusted using an acetate buffer solution (10 ml). Then 25 ml of a 60% aqueous solution of acetone and 1 ml of a 0.1% solution of Nitroortanile C (nitrochromazo) were added. The content of strontium ions in the solution under study was determined from the intensity of the absorption band at a wavelength of 650 nm. This technique [5] makes it possible to find the content of strontium ions in the range from 2 to 20 μg in a 25-ml portion of a solution. Under these conditions there is no hindering effect by Na^+ and NH_4^+ ions to a 100-fold excess; K^+, to a 30-fold excess; Ca^{2+}, to a 1.5-fold excess; and Mg^{2+}, to a 5-fold excess. The content of iron(III) was determined from the intensity of the absorption band of a complex with thiocyanate at 480 nm. The table lists the following results obtained in the study: the initial and equilibrium concentrations of ions, c_0 and c_{eq}; amounts of sorption, Γ; and activity coefficients γ of cations, calculated using the Davis equation [6].

The exchange of strontium(II) and iron(III) ions was described thermodynamically on the assumption of an ideal solid phase, i.e., with the activity coefficients of ions in the sorbed state disregarded. The equation of the ion-exchange isotherm for the reaction

$$3Sr_s^{2+} + 2Fe_{aq}^{3+} \rightleftarrows 3Sr_{aq}^{2+} + 2Fe_s^{3+}$$

has, in this case, the form

$$K = \frac{\Gamma_{Fe^{3+}}^2 a_{Sr^{2+}}^3}{\Gamma_{Sr^{2+}}^3 a_{Fe^{3+}}^2}, \quad (1)$$

where K is the apparent exchange constant; $\Gamma_{Fe^{3+}}$ and $\Gamma_{Sr^{2+}}$, the amounts of sorption of jointly present ions (mol kg^{-1}); and $a_{Fe^{3+}}$ and $a_{Sr^{2+}}$, the activities of the ions in solution (mol kg^{-1}). It was shown in [7] that the ion-exchange isotherms can be described using equations of the type of the Langmuir isotherm. Now, this method will be applied to the equilibrium under study. The limiting amounts of sorption of the ions $\Gamma_\infty = 3\Gamma_{Fe^{3+}} + 2\Gamma_{Sr^{2+}}$, where Γ_∞ is the limiting amount of sorption of ions in equiv kg^{-1}, and the amounts of sorption of the ions are expressed in mol kg^{-1}. With account of this fact, Eq. (1) can be brought to the form

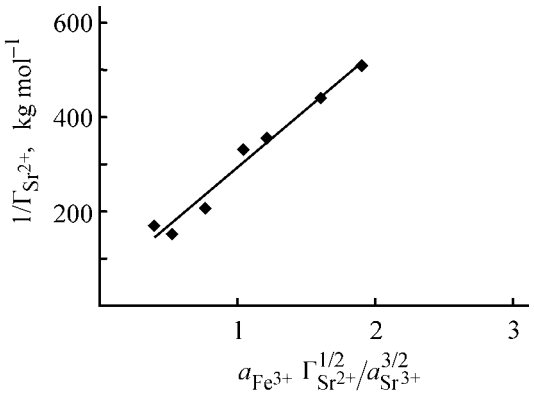

Fig. 2. Linear form of the ion exchange isotherm. (Γ) Amount of sorption and (a) activity of ions (mol kg^{-1}).

$$K = \frac{(\Gamma_\infty - 2\Gamma_{Sr^{2+}})^2 a_{Sr^{2+}}^3}{9\Gamma_{Sr^{2+}}^3 a_{Fe^{3+}}^2}. \quad (2)$$

Equation (2) is transformed into formula (3), which resembles the Langmuir isotherm equation $\Gamma = \Gamma_\infty K_a/(1 + K_a)$:

$$\Gamma_{Sr^{2+}} = \Gamma_\infty \frac{K^{-1/2} a_{Sr^{2+}}^{3/2}}{3a_{Fe^{3+}}\Gamma_{Sr^{2+}}^{1/2} + 2K^{-1/2} a_{Sr^{2+}}^{3/2}}. \quad (3)$$

The linear version of the equation has the form

$$\frac{1}{\Gamma_{Sr^{2+}}} = \frac{2}{\Gamma_\infty} + \frac{3a_{Fe^{3+}}(K\Gamma_{Sr^{2+}})^{1/2}}{\Gamma_\infty a_{Sr^{2+}}^{1/2}} \quad (4)$$

similar to the linear Langmuir equation

$$1/\Gamma = 1/\Gamma_\infty + 1/(\Gamma_\infty Ka).$$

A linear ion-exchange isotherm is shown in Fig. 2. The dependence of the inverse amount of sorption of strontium ions on the argument $\left(a_{Fe^{3+}}\Gamma_{Sr^{2+}}^{1/2}\right)/a_{Sr^{2+}}^{3/2}$ is described by the following linear equation $y = 246.01x + 47.08$, with a correlation factor $R^2 = 0.9744$. This equation was used to calculate $\Gamma_\infty = 42.5$ mg-equiv kg^{-1}, the apparent ion exchange constant $K = 12.14$, and the Gibbs energy of exchange of strontium(II) ions for iron(III) ions on the clay surface, $\Delta G_{298}^0 = -6.19$ kJ mol^{-1}.

The thermodynamic data indicate that the ion-exchange equilibrium is shifted toward displacement of strontium(II) ions from soil by solutions of iron(III) salts.

CONCLUSIONS

(1) The isotherm of ideal ion exchange of strontium(II) and iron(III) ions on blue Cambrian clay is described by a dependence of the type of the Langmuir equation and can be expressed in a linear form with a correlation factor $R^2 = 0.9744$.

(2) The linear Langmuir form of the isotherm was used to determine the apparent ion-exchange constant $K = 12.14$ and the Gibbs energy of exchange, $\Delta G_{298}^0 = -6.19$ kJ mol^{-1}. The exchange equilibrium is shifted toward displacement of strontium from the solid phase by iron(III) ions.

SORPTION AND ION-EXCHANGE PROCESSES

Dynamic of Exchange Sorption of Transition Metal Ions on Phosphate Cationite KFP-12

L. A. Pimneva

Tyumen State Academy of Architecture and Construction, Tyumen, Russia

Received December 30, 2003

Abstract—The dynamics of ion-exchange sorption of double-charged metal ions on a phosphate cationite KFP-12 was studied. Theoretical calculations of stationary fronts were carried out, the motion velocity of the stationary fronts was calculated, and the rate constant of sorption was evaluated.

The theory of sorption dynamics is a theoretical foundation of modern chromatography. The process of dynamic sorption can be regarded as continuous, and, therefore, all calculations are based on solution of Rachinskii's differential equations [1–5]. Methods for solving differential balance equations make it possible to perform a theoretical analysis of the dynamics of sorption in that stage of transfer, in which the uppermost layer of the sorption column is saturated.

One of the main points in the process of ion-exchange sorption is the equivalence law, according to which ions involved in the exchange are exchanged in equivalent amounts.

The aim of this study is to analyze the dynamics of ion-exchange sorption of double-charged ions on a phosphate cationite KFP-12 from chloride solutions.

EXPERIMENTAL

A phosphate cationite KFP-12 in the hydrogen form with porous structure was used in the study. The structure of the KFP-12 cationite contains phosphonic groups, which dissociate in two stages; the degree of their ionization is characterized by the parameters $pK_1 = 3.5$ and $pK_2 = 8.9$ and total exchange capacity of 7.5 mg-equiv g^{-1}.

The grain size was 0.25–0.50 mm (in the air-dry state). As starting solutions were used 0.2 M $CuCl_2$, $ZnCl_2$, $CdCl_2$, $MnCl_2$, $CoCl_2$, and $NiCl_2$. Two sets of experiments were carried out. In the first of these, output sorption curves were measured at different cationite charges (3.0, 6.0, 9.0, and 12.0 g in terms of absolutely dry resin) in a column with a cross-sectional area of 1.4 cm^2, which corresponds to a bed height of 8.3, 16.5, 24.75, and 33.0 cm, respectively, and constant filtration rate (1.0 ml cm^{-2} min^{-1}). In the second, the filtration rate of the solutions was varied (0.5, 1.0, 2.0, and 3.0 ml cm^{-2} min^{-1}) at an invariable height of the cationite bed (6.0 g) in the column.

The process of ion-exchange sorption of two differently charged ions under dynamic conditions is described by a system of differential material balance equations

$$\frac{\partial c}{\partial t} + \frac{\partial c}{\partial x} + \frac{\partial N}{\partial t} = 0, \quad (1)$$

an equation describing the kinetics of sorption

$$\frac{\partial N}{\partial t} = \beta(c - c_{eq}) \quad (2)$$

and an equation for the ion exchange isotherm

$$\frac{N_1^{1/z_1}}{N_2^{1/z_2}} = K_{1,2}\frac{c_1^{1/z_1}}{c_2^{1/z_2}}. \quad (3)$$

Here c is the concentration of ions being sorbed in a solution (mg-equiv cm^{-1} of column length) at an instant of time t; N, the concentration of ions in the ionite (mg-equiv cm^{-1} of column length) at an instant of time t; x, the distance counted off the inlet of the column packed with the ionite (cm); c_{eq}, the equilibrium concentration of ions being sorbed in the solution (mg-equiv cm^{-1}); β, the mass-exchange coefficient, which characterizes the broadening of the sorption front and depends on inner- and outersphere diffusion and on longitudinal transfer; and $K_{1,2}$, the ion-exchange constant for the ions being exchanged; and z_1, z_2, charges.

1070-4272/04/7704-0579 © 2004 MAIK "Nauka/Interperiodica"

On introducing dimensionless variables $\varphi = n/n_0$, $U\varphi' = n'/n_0$, $V = N/N_0$, $h = n_0/N_0$, the above system of equations takes the form

$$h\frac{\partial\varphi}{\partial t} + Uh\frac{\partial\varphi}{\partial x} + \frac{\partial V}{\partial t} = 0, \quad (4)$$

$$\frac{\partial V}{\partial t} = \beta h(\varphi - \beta'), \quad (5)$$

$$\frac{1 - V}{V^{\lambda}} = B\frac{1 - \varphi}{\varphi^{\lambda}}, \quad (6)$$

where N_0 and n_0 are the initial concentrations of ions in the ionite and solution, respectively; and $\lambda = z_1/z_2$ is the ratio of the charges of the exchanged ions.

This system should be solved with the following boundary conditions

$$\varphi(x, 0) = V(x, 0) = 0;\ \varphi(0, t) = 0;$$

$$V(0, t) = 1;\ \varphi(\infty, \infty) = V(\infty, \infty) = 0.$$

In the standard front, the following condition is satisfied

$$N/N_0 = n/n_0; \quad n = hN \text{ or } V = \varphi.$$

Analysis of the ion-exchange isotherm (6) shows that the shape of the isotherm depends on the constant B, which is the dimensionless exchange constant in a transformed Nikol'skii equation for the case of exchange of two differently charged ions [6]. Thus, the shape of the isotherm and, consequently, the sorbability in the exchange of differently charged ions depend not only on the exchange constant, but also on the ionic ratio (concentration of the solution introduced into the column) and the charge of the exchanged ions.

In the case of dynamics of ion-exchange sorption of differently charged ions, it is possible to select, by varying the ionic ratio, such operating conditions in which the constant $B < 1$, which is the necessary condition for formation of a stationary front of the sorption wave.

Let us introduce the parameter $S = V/\varphi' = \varphi/\varphi'$. Then the equation for the ion-exchange isotherm of differently charged ions takes the form

$$\varphi = \frac{1 - BS^{\lambda}}{S(1 - BS^{\lambda - 1})}, \quad (7)$$

$$(B\sqrt{S})^2 - (1 - \varphi)\sqrt{S} - \varphi B = 0 \quad (8)$$

or

$$\sqrt{S} = \frac{(1 - \varphi) \pm \sqrt{(1 - \varphi)^2 + 4\varphi B^2}}{2B}. \quad (9)$$

For a particular case at $\lambda = 1/2$, the equation of the stationary front has the form

$$x = \frac{h}{1 + h}Ut + \frac{U}{\beta}\frac{1}{1 + h}\left[\frac{B}{1 - B^2}\ln\frac{(\sqrt{S} - 1)^{1 + B}}{(\sqrt{S} + 1)^{(1 - B)}(\sqrt{S} - B)^{B}(1 - B\sqrt{S})^{1/B}} + C\right], \quad (10)$$

where

$$C = \frac{1}{1 + B}\ln(1 - B) + \frac{B}{1 - B}\ln(1 + B) + \frac{B^2 + B - 1}{1 - B^2}, \quad (11)$$

at $B < 1$, $c \approx -1$. From Eq. (10), the following calculational equations are obtained:

(a) equation for the elution curve

$$V = \frac{1 + h}{h}V_0 - \frac{U}{\beta}\frac{Q}{h}\left[\frac{B}{1 - B^2}\ln F(S) + C\right], \quad (12)$$

where V is the filtrate volume; Q, cross-section of the transfer front; V_0, the volume of solution retained within the sorbent column; and $F(S)$, the sublogarithmic function in Eq. (7);

(b) equation for the front width of the sorption wave in the column

$$\delta_V = \frac{U}{\beta}\frac{1}{1 + h}\frac{B}{1 - B^2}\ln\left[\frac{F(S_1)}{F(S_2)}\right], \quad (13)$$

where $F(S_1)$ and $F(S_2)$ are the values of the function $F(S)$ for two concentration points defining the front width;

(c) equation for the front width of the elution curve

$$\delta_V = \frac{U}{\beta}\frac{Q}{h}\frac{B}{1 - B^2}\ln\left[\frac{F(S_1)}{F(S_2)}\right]; \quad (14)$$

(d) equation for the volume passed till breakthrough (by analogy with the time of protective action)

$$V_1 = \frac{1 + h}{h}V_0 - \frac{U}{\beta}\frac{Q}{h}\left[\frac{B}{1 - B^2}\ln F(S) - C\right], \quad (15)$$

where S_1 is the value of the parameter S that corresponds to the breakthrough concentration recorded at the column outlet.

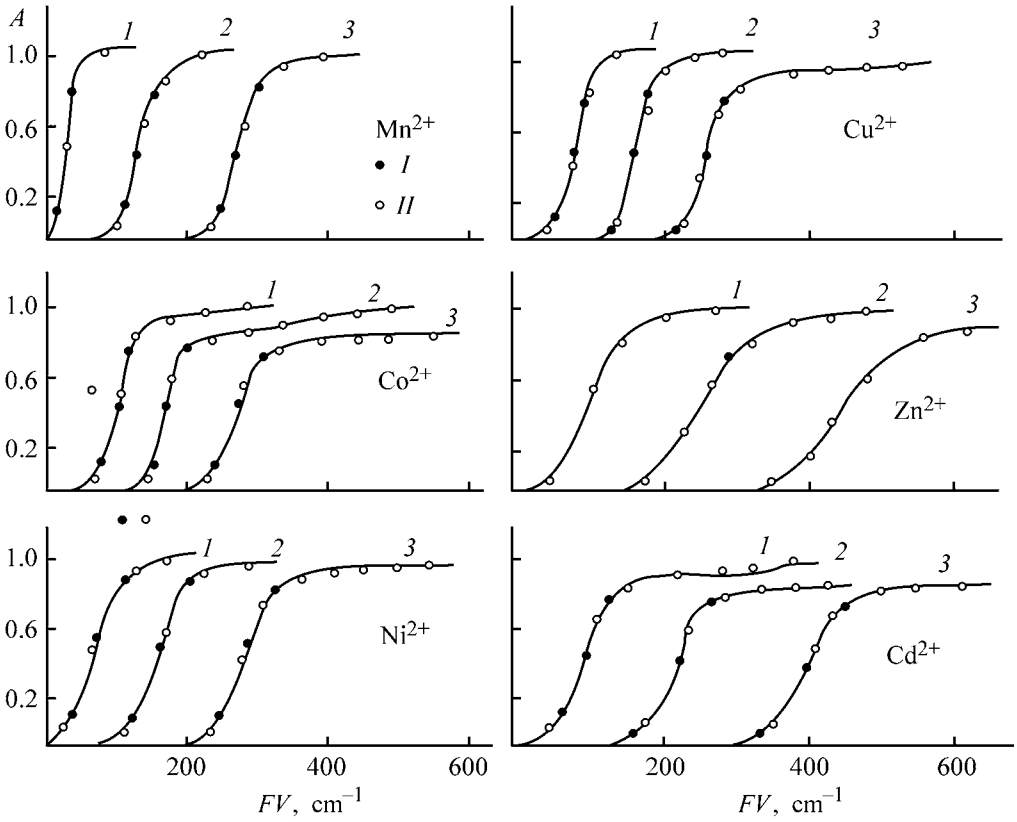

Fig. 1. Elution curves for sorption of double-charged cations from 0.2 M solutions of MCl_2 with a KFP-12 cationite. Filtration rate 1 ml cm^{-2} min^{-1}. Amount of ionite in the column (g): (*1*) 1.0, (*2*) 3.0, and (*3*) 6.0. (*A*) c/c_0 ratio and (*FV*) filtrate volume. Points: (*I*) theoretical and (*II*) experimental.

The experiments were performed at four filtration rates: 0.5, 1.0, 2.0, and 3.0 ml min^{-1}. Figure 1 shows elution curves for sorption of double-charged cations on a phosphate cationite KFP-12 for different column lengths, which were subjected to theoretical analysis. These are ordinary S-shaped frontal curves.

The theoretical analysis of the elution curves consisted in plotting the dependences of the shift of the concentration points at φ equal to 0.15, 0.30, 0.50, 0.70, and 0.85. These dependences confirm the theoretical prediction that stationary fronts are to be formed in the case of a convex isotherm. In all the experiments, the plots that describe the shift of the concentration points of the sorption front are straight lines parallel to one another. The shift plot for φ = 0.50 passes through the origin of the coordinates. Table 1 lists the results of a theoretical analysis of elution curves for sorption of double-charged metal ions. Elution curves for sorption of transition metal ions, constructed using experimental data, are shown in Fig. 1. Theoretical points are plotted on these curves.

To construct the theoretical elution curve for the stationary front, the dynamic constant u/β (where u is the flow velocity) was determined. Such a calculation was carried out using formula (14), and then the corresponding elution curve was calculated by Eq. (15). As can be seen from Fig. 1, the theoretically calculated points satisfactorily fall on the experimental elution curve, which also confirms that the dynamic sorption of double-charged metal ions occurs in this study in the stationary mode.

Calculation of the constant B gives values that are less than unity. According to the theory of sorption dynamics, such a value of the constant confirms the formation of a stationary front.

Let us evaluate the kinetic constant β. The dynamic constant by Todes–Bikson [6] is a sum of three terms:

$$\frac{u}{\beta} = \frac{u}{\beta^*} + \frac{u}{\beta^{**}} + \frac{D^*}{u}, \qquad (16)$$

where β^* is the rate constant of outer-sphere diffusion; β^{**}, that of the inner-sphere diffusion; and D^*

		1.0	0.83	55				1.10	
		2.0	1.67	60				1.20	
		3.0	2.50	70				1.40	

the effective constant of diffusion and quasi-diffusion longitudinal transfers.

Let us introduce the generalized rate constant of sorption

$$\frac{1}{\beta'} = \frac{1}{\beta^*} + \frac{1}{\beta^{**}}. \quad (17)$$

Then Eq. (16) takes the form

$$\frac{u}{\beta} = \frac{u}{\beta'} + \frac{D}{u}. \quad (18)$$

The rate constants of outer- and inner-sphere diffusion must be virtually independent of the flow velocity. The effective constant of longitudinal transport is proportional to the transport rate $D^* = \alpha u$. Consequently, we have in accordance with Eq. (18)

$$\frac{u}{\beta} = \frac{u}{\beta'} + \alpha. \quad (19)$$

where α = const and β = const.

Substituting Eq. (19) into (14), we obtain

$$\delta_V = \left(\alpha + \frac{u}{\beta}\right)\frac{Q}{h}\frac{B}{1 - B^2}\ln\left[\frac{F(S_1)}{F(S_2)}\right], \quad (20)$$

and then, assuming $u = V/Q$ and

$$G = \frac{\alpha Q}{h}\frac{B}{1 - B^2}\ln\left[\frac{F(S_1)}{F(S_2)}\right],$$
$$H = \frac{1}{\beta h}\frac{B}{1 - B^2}\ln\left[\frac{F(S_1)}{F(S_2)}\right], \quad (21)$$

we come to the equation

$$\delta_V = G + HV. \quad (22)$$

Having determined the experimental values of the coefficients G and H in Fig. 2, we calculated the coefficients α and β', using Eq. (21). Table 2 lists calculated kinetic and quasi-diffusion constants of ion exchange of double-charged metal ions.

The experimental values of the sorption constant β' exceed by an order of magnitude those for porous sorbents, such as silica gel or carbon [5]. This indicates that the mechanism governing the sorption kinetics in ion-exchange resins is different. The higher rate of sorption on the cationite is due to its developed porous structure.

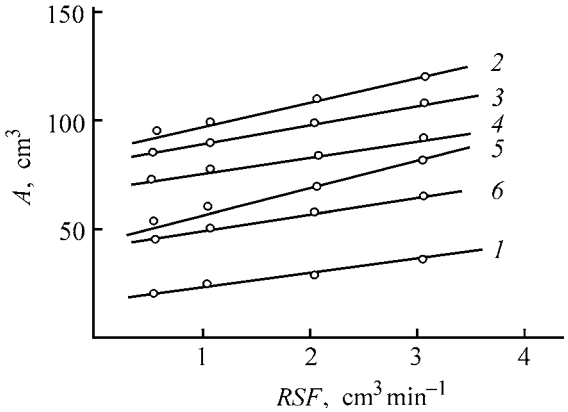

Fig. 2. Front width A of the elution curves for sorption of double-charged ions of (*1*) copper, (*2*) zinc, (*3*) cadmium, (*4*) manganese, (*5*) cobalt, and (*6*) nickel vs. the rate of solution filtration, *RSF*.

CONCLUSIONS

(1) The dynamics of exchange sorption of differently charged ions in the stationary mode was considered. The distribution of ions being sorbed in the stationary mode of dynamic sorption is described by the equation of the stationary front, used to obtain equations for calculating the elution curve and its front width.

(2) A satisfactory agreement between experimental elution curves and the theoretical equation of the elution curve was obtained.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Model of Hydrogen Sulfide Desorption in a Generator of Monodisperse Drops

S. V. Aniskin and I. O. Protod'yakonov

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received December 23, 2003

Abstract—Desorption of hydrogen sulfide in a generator of monodisperse drops from a weakly alkaline solution is considered. A mathematical model of the end effect is suggested. This model takes into account the specific features of formation of a diffusion boundary gas layer at the surface of a drop of increasing volume.

As is known, spraying of fluids is used to tackle with a wide variety of technological problems in chemical, paper-and-pulp, and other industries and, in particular, in purification of gases to remove undesirable impurities.

It should be noted that the mechanisms of substance transfer in spraying mass-exchange apparatus in the region of disintegration of a fluid jet into drops and in that of motion of the already formed drops are different.

When the transfer of the target component in these apparatus is described, an assumption is frequently made, in order to simplify the task of modeling, that the contribution, which comes from the region of disintegration of the fluid jet outflowing from a single-flare atomizer into drops, to the final result of the mass-exchange process can be disregarded because of the comparative smallness of this contribution. However, such an assumption is unjustified, e.g., for desorption in a spraying scrubber in the case when the main resistance to mass transfer is concentrated in the liquid phase.

When this contribution cannot be disregarded, it is said that there exists a pronounced end effect, which is, in the given case, the effect of intensification of mass exchange in the initial region of motion of the liquid phase.

It should be noted that studying the end effect, which is strongly dependent on the specific features of motion of the fluid in drop formation, is a rather complicated task.

Various experimental methods have been used to solve this problem. One of these is based on use of dropping bottles [1]. The main disadvantage of investigations of this kind is that the rate of drop formation with the use of dropping bottles is considerably lower than that from a fluid jet outflowing from an atomizer of a spraying apparatus. Therefore, the results obtained in studying the end effects with the use of dropping bottles are hardly applicable to description of end effects in spraying apparatus.

Studies of end effects with the use of a generator of monodisperse drops (GMD) are devoid of this disadvantage. A generator of this kind makes it possible to obtain a chain of drops of the same size with an outflowing velocity closer to that in the case of spraying of a fluid with atomizers.

The aim of this study is the provide a theoretical description of the end effect examined experimentally with the use of a GMD in desorption of hydrogen sulfide [2].

The way in which a chain of drops is formed when a fluid outflows from a needle-like nozzle of the GMD is shown schematically in the figure. The fluid outflows from a nozzle at a constant velocity v in the form of a jet of radius R_j and length l. Drops of radius R are formed at the end of the jet at intervals of time τ.

The experimental study was carried out at the following characteristic values of the parameters: $v = 1.1\ \mathrm{m\,s^{-1}}$, $R_j = 1.8 \times 10^{-4}$ m, $\tau = 1.045 \times 10^{-3}$ s, and $R = 3.07 \times 10^{-4}$ m. As fluid outflowing from the GMD served a weakly alkaline solution of hydrogen sulfide.

As is known, hydrogen sulfide partly dissociates at low pH to give hydrosulfide ions by the following chemical reaction

$$H_2S + OH^- \rightleftarrows HS^- + H_2O. \qquad (1)$$

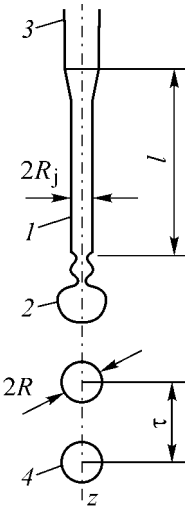
* x_0 is the total concentration of hydrogen sulfide and sodium hydrosulfide in the initial solution; η^0_{exp}, η^0_{calc}, and η^v_{calc}, the degrees of desorption: experimental, theoretically calculated for an immobile drop, and theoretically calculated for a drop that moves at a velocity v; and A, the concentration of hydrogen sulfide in the gas phase at the drop surface.

For this reason, the main forms of existence of sulfur in the alkaline solution mentioned above are the compounds H_2S and NaHS. The end effect in the GMD is manifested in this case as desorption of hydrogen sulfide. The degree of hydrogen sulfide desorption from a drop, before its detachment from the fluid jet, is as high as 40%, as follows from the table.

It was shown in [3] that such a strong desorption of hydrogen sulfide occurs in the conditions under consideration only when a drop is formed at the end of the jet in the GMD. In this case, the desorption of hydrogen sulfide from the surface of this jet can be disregarded.



Schematic of drop formation from a solution outflowing from the needle-like nozzle of the GMD. (*1*) Fluid jet, (*2*) forming drop, (*3*) needle-like nozzle of the GMD, and (*4*) formed drop.

With account of such a high degree of desorption and the short time of drop formation (10^{-3} s), it may be assumed that the desorption of hydrogen sulfide occurs during formation of a diffusion boundary layer in the gas phase.

To construct a theoretical model of the process in question, a simpler problem of determining the degree of hydrogen sulfide desorption from an immobile expanding drop will be considered first. The degree of hydrogen sulfide desorption, which is determined relative to the total amount of hydrogen sulfide and sodium hydrosulfide filling the drop volume, can be represented by the formula

$$\eta = \frac{3M}{4\pi R^3 x_0}, \quad (2)$$

where M is the amount of hydrogen sulfide (moles) and x^0 is the total concentration of hydrogen sulfide and sodium hydrosulfide (M).

To find M, it is necessary to formulate and solve a nonstationary boundary-value problem of diffusion from an immobile expanding drop.

The mathematical formulation of this boundary-value problem is as follows:

$$\left[\frac{\partial}{\partial t} - D\left(\frac{\partial}{\partial r} + \frac{2}{r}\frac{\partial}{\partial r}\right) + \frac{R^2}{r^2}\frac{\partial R}{\partial t}\frac{\partial}{\partial r}\right]c = 0, \quad (3)$$

$$0 < r < \infty, \ 0 < t < \infty,$$

$$c\big|_{r=R} = A(t), \quad c\big|_{r=\infty} = 0, \quad c\big|_{t=0} = 0, \quad R\big|_{t=0} = 0, \quad (4)$$

where c is the concentration of hydrogen sulfide (M); D, the diffusion coefficient of hydrogen sulfide in air ($m^2\ s^{-1}$); and r (m) and t (s), the running radius and time, respectively.

This problem has been solved by Koutetsky [4]. The solution is as follows:

$$J = 4\sqrt{\pi D}\left(\frac{3b}{4\pi}\right)^{2/3}\left[1.53t^{1/6} + 1.35\sqrt{\pi D}\left(\frac{4\pi t}{3b}\right)^{1/3}\right]A, \quad (5)$$

where J is the flow of hydrogen sulfide from the entire surface of the expanding drop at an instant of time t (mol s^{-1}), and b is the rate at which the drop volume increases ($m^3\ s^{-1}$).

The quantity b is defined by the formula

$$b = dV/dt, \quad (6)$$

where V is the drop volume (m^3).

To find the sought-for value of M, it suffices to integrate Eq. (5) over a time interval, having preliminarily determined the dependence of A and b on time for given particular conditions. In accordance with the model of fluid flow in drop formation [3], a fresh flow of the fluid with concentration x_0 and constant pH comes to the drop surface. This gives reason to consider that the concentration of hydrogen sulfide at the drop surface is constant during the entire time τ of drop expansion. The quantity b can be expressed by the formula

$$b = \pi R_j^2 v. \quad (7)$$

Then, integration of Eq. (5) with respect to time τ yields the following expression for M:

$$M = 4\sqrt{\pi D}\left(\frac{3b}{4\pi}\right)^{2/3}\left[1.31t^{1/6} + 1.012\sqrt{\pi D}\left(\frac{4\pi\tau}{3b}\right)^{1/3}\right]\tau A. \quad (8)$$

Substitution of (8) into Eq. (2) shows that the final expression for the degree of desorption depends on the ratio of A and x_0. This ratio is given by the formula

$$\frac{x_0}{A} = \frac{1}{\mathrm{He}} + K \times 10^{\mathrm{pH}}, \quad (9)$$

where K is the equilibrium constant defined by

$$K = \frac{[\mathrm{H}^+][\mathrm{HS}^-]}{A}, \quad (10)$$

and $[\mathrm{H}^+]$ and $[\mathrm{HS}^-]$ are the concentrations of hydrogen ions and hydrosulfide ions, respectively.

It follows from [5] that $K = 10^{-6.68}$ at 20°C. The η^0_{calc} calculated with $D = 1.47 \times 10^{-5}$ m^2 s^{-1}, He = 0.38, and $b = 1.159 \times 10^{-7}$ m^3 s^{-1} are listed in the table. The numerical values of these quantities correspond to the experimental conditions of [2]. Comparison of the calculated η^0_{calc} with the experimental η^0_{exp} shows that the actual intensity of desorption substantially exceeds the theoretical value in the conditions under consideration. This can be accounted for by a decrease in the thickness of the diffusion boundary layer because of the drop motion.

The process of formation of a chain of drops in the GMD is characterized by Reynolds numbers that correspond to transition modes of a flow around a drop. This circumstance gives no way of solving analytically the diffusion boundary-value problem formulated.

That is why the present study employs, in order to simplify the solution of the problem in constructing the model of the end effect, the semiempirical Fresling dependence for calculating the mass-transfer coefficient β for the gas phase in that form in which it was presented in [6] when solving the problem for an already formed drop of radius R. This dependence is as follows:

$$\beta/\beta_0 = 1 + 0.275\mathrm{Re}^{1/2}\mathrm{Sc}^{1/3}, \quad (11)$$

where β and β_0 are the mass-transfer coefficients at a drop motion velocity v under conditions of zero relative motion of the gas and fluid phases, respectively; $\mathrm{Re} = 2Rv/\bar{\nu}$, the Reynolds number; $\mathrm{Sc} = \bar{\nu}/D$, the Schmidt number; and $\bar{\nu}$, the kinematic viscosity of air.

The increase in the amount M_v of hydrogen sulfide desorbed from a moving and, simultaneously, expanding drop can be accounted for by the formula

$$M_v = M\beta/\beta_0. \quad (12)$$

The results of calculation of the degree of hydrogen sulfide desorption, η^0_{calc}, for the given case are listed in the table and confirm the good agreement between the theoretical values obtained in this study and experimental data.

CONCLUSIONS

(1) The mathematical model of hydrogen sulfide desorption from a moving drop, constructed in this study, is in agreement with experimental data.

(2) The high degree of hydrogen sulfide desorption from a moving drop is attributed to specific features of a nonstationary diffusion process in motion and simultaneous increase in the volume of a drop in the stage of its formation.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Theoretical Study of Desorption in Disintegration of a Fluid Jet Formed in a Single-Flare Atomizer into Drops

S. V. Aniskin and I. O. Protod'yakonov

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received December 23, 2003

Abstract—A model of desorption in the gas–fluid system for the region of disintegration into drops of a fluid jet outflowing from a single-flare atomizer is suggested.

An issue of current interest in working with black-liquor boilers in manufacture of sulfate pulp is how to make lower the amount of toxic components discharged with fume gases into the atmosphere. This problem is commonly solved by using spraying scrubbers with single-flare atomizers. In scrubber purification of fume gases to remove toxic components, absorption–desorption processes occur on the surface of sprayed fluid. The intensity of these processes predetermines the efficiency of purification of fume gases. As is known, in those cases when the main resistance to mass transfer is concentrated in the liquid phase, the intensity of adsorption and desorption is high in that relatively small region in which the fluid jet disintegrates into drops [1]. This phenomenon has been named the end effect in the scientific literature. By now, no theoretical description of the end effect in spraying of a fluid with single-flare atomizers has been provided.

The aim of the present study was to construct a model of this effect.

Let us consider the process of fluid disintegration in a single-flare atomizer in more detail. In [2], photographic images of various parts of a fluid jet outflowing from a single-flare atomizer were obtained.

The region studied in the jet included both its initial part and that in which the process of jet disintegration into separate parts is complete.

In accordance with the data of [2], despite the diversity and complexity of the process of disintegration of a fluid jet, it reduced to the follows: drops are finally formed by fine jets that appear on the surface of fragments of a disintegrating fluid jet.

In [3], formation of drops of the same size from a separate fine jet outflowing from the nozzle of a generator of monosdisperse drops was analyzed in detail. It was established that the fine fluid jet passes through a drop and comes to its front surface, with vortex flows formed within the drop. As a result, the drop size increases till the instant of drop detachment from the fine jet.

The pronounced end effect in this case is accounted for by mechanical transfer of the fluid to the surface of a growing drop, which leads to a dramatic decrease in the resistance to mass transfer in the fluid phase.

The contribution from the mechanism of diffusion transport in the fluid is negligible under these conditions. Comparison of the results obtained in experimental studies of the process of drop formation from fine jets outflowing from the surface of fragments of a disintegrating fluid jet formed by a single-flare atomizer in a spraying scrubber with the process of drop formation in a generator of monodisperse drops readily reveals a certain analogy between these processes. In this case, it seems natural to assume that the overall end effect that appears in disintegration into drops of a jet formed by a single-flare atomizer in a spraying scrubber is constituted by end effects that arise in the formation of separate drops from these fine jets. This overall end effect can be evaluated by the flux G of a substance, given by the formula

$$G = \Delta M/\Delta t, \quad (1)$$

where ΔM is the total mass of a substance sorbed by drops through the end effect in a certain period of time Δt.

1070-4272/04/7704-0588 © 2004 MAIK "Nauka/Interperiodica"

The quantities ΔM and Δt are found on the basis of the following considerations. Let us analyze a layer Δz in the region of motion of the already formed drops (Fig. 1). Apparently, all the drops in this layer are formed in region *2*. To these drops corresponds a certain value of the quantity G.

The quantity ΔM has the meaning of the characteristic of the overall end effect of drops with the volume ΔV of layer *4* in Fig. 2. The quantity Δt has the meaning of the time in which drops pass across the layer Δz. ΔM can be found from the formula

$$\Delta M = \int_0^\infty M \frac{\partial N}{\partial R} \mathrm{d}R, \quad (2)$$

where M is the value of the end effect for a separate drop of radius R, and N is the number of drops of radius R in the volume ΔV.

The quantity $\partial N/\partial R$ in this formula has the meaning of the numerical drop size distribution function. However, it is more convenient to use in this model the distribution function of drop volumes V over drop sizes

$$\varphi(R) = \frac{1}{\Delta V} \frac{\partial v}{\partial R}. \quad (3)$$

Then, with account of (3), formula (2) takes the form

$$\Delta M = \frac{3\Delta V}{4\pi} \int_0^\infty \frac{M}{R^3} \varphi(R) \mathrm{d}R. \quad (4)$$

Let us express ΔV in terms of the flow rate Q of a fluid emerging from the atomizer:

$$\Delta V = \Delta t Q, \quad (5)$$

where Δt is the time in which drops cross the layer Δz.

From formula (4) can be obtained, with account of (1) and (5), an integral expression for the flux of substance in disintegration into drops of a jet formed by a single-flare atomizer:

$$G = \frac{3}{4\pi} Q \int_0^\infty \frac{M}{R^3} \varphi(R) \mathrm{d}R. \quad (6)$$

An expression for M in (6) was obtained in [4]. This expression takes into account the nonstationary process of formation of a diffusion boundary layer at a drop moving relative to the ambient gas medium. In disintegration of a fluid jet formed by a single-flare atomizer, the density of the forming fluid flow is so high that the gas entrapped by the disintegrating fluid jet moves at virtually the same velocity as the fluid.

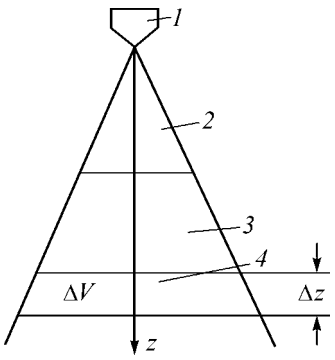

Fig. 1. Schematic of determining the volume ΔV of the fluid in a gas-fluid jet. (*1*) Single-flare atomizer, (*2*) region of disintegration of the fluid jet, (*3*) region of motion of the drops formed, and (*4*) elementary layer of volume ΔV.

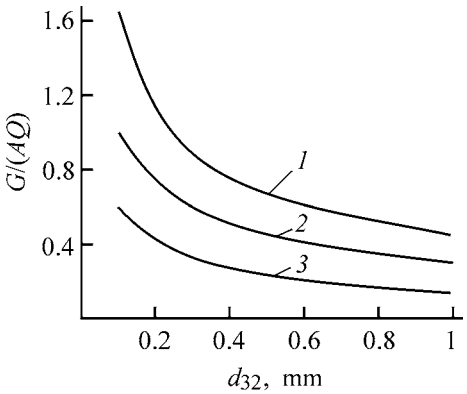

Fig. 2. Relative flux of substance being desorbed in disintegration of a fluid jet into drops vs. the Sauter diameter d_{32}. S = 6.35, D = 1.5–5 $m^2 s^{-1}$. v ($m s^{-1}$): (*1*) 5, (*2*) 10, and (*3*) 30.

Taking into account this circumstance, let us write down the expression for M, obtained in [4], with account of the assumption of the zero relative velocity of motion of the phases:

$$M = \sqrt{4\pi D} \left(\frac{3b}{4\pi}\right)^{2/3} \left[1.31\tau^{1/6} + 1.012\sqrt{\pi D} \left(\frac{4\pi\tau}{3b}\right)^{1/3}\right] \tau A. \quad (7)$$

Here A is the concentration of the substance being desorbed in the gas phase at the drop surface (kmol m^{-3}); D, the diffusion coefficient of the gas A in air ($m^2 s^{-1}$); b, the rate at which the drop volume grows ($m^3 s^{-1}$); and τ, the time in which a drop of radius R is formed (s).

The quantity A is considered to be constant at any instant of time during the formation of a drop of an arbitrary radius R, i.e.,

$$A = \text{const}. \quad (8)$$

The time of drop formation depends on the radius of the drop and on its growth rate:

$$\tau = \frac{4}{3}\pi\frac{R^3}{b}. \quad (9)$$

The rate at which the drop volume grows is a function of the radius R_j of a jet from which the drop is formed:

$$b = \pi R_j^2 v, \quad (10)$$

where v is the motion velocity of the fluid ($m\ s^{-1}$).

Since the motion velocity of the fluid varies only slightly in the region of disintegration of the fluid jet, it is assumed that the motion velocity of fine jets with different radii in the disintegrating fluid jet formed by the single-flare atomizer is the same and equal to the velocity v_n at which the fluid outflows from the nozzle:

$$v = v_n = \text{const}. \quad (11)$$

To integrate the right-hand part of Eq. (6), it is necessary to determine the type of the dependence of M on the final radius R of the drops. For this purpose, let us determine the relationship between the quantities R and R_j in formula (10).

It is known [5] that the wavelength λ of the most probable oscillations of a jet is determined by the radius R_j of this jet by the formula

$$\lambda = SR_j, \quad (12)$$

where S is a coefficient whose value depends on the viscosities of the fluid and gas, and also on the surface tension of the fluid.

For particular conditions of disintegration of a fluid jet, S is a constant:

$$S = \text{const}. \quad (13)$$

With account of the fact that the wavelength λ is that part of a jet of radius R_j, from which a drop is formed, the following equality is valid:

$$\pi R_j^2\lambda = \frac{4}{3}\pi R^3, \quad (14)$$

Comparison of (12) and (14) yields the sought-for relation

$$\frac{R}{R_j} = \sqrt[3]{\frac{4}{3}S}. \quad (15)$$

In accordance with (15), let us write down expressions (9) and (10) in the explicit form:

$$\tau = \left(\frac{4}{3}\right)^{1/3} S^{2/3}\frac{R}{v}, \quad (16)$$

$$\tau = \pi\left(\frac{4}{3}\right)^{2/3} vR^2. \quad (17)$$

The expressions obtained make it possible to find in the explicit form the function M:

$$M = \gamma R^2(\alpha R^{1/2} + \beta)A. \quad (18)$$

The quantities α, β, and γ are calculated using the following formulas:

$$\alpha = 1.33\frac{S^{1/3}}{v^{1/2}}, \quad (19)$$

$$\beta = 1.08\sqrt{\pi D}\,\frac{S^{4/9}}{v^{2/3}}, \quad (20)$$

$$\gamma = 4\sqrt{\pi D}\,\frac{S^{2/9}}{v^{1/3}}. \quad (21)$$

In integrating Eq. (6) with account of (18), we use the Rosin–Rammler distribution [5], which is the most frequently used when describing the dispersion composition of drops of the fluid being atomized. This distribution is described by the formula

$$\varphi(R) = \frac{n}{a}\left(\frac{R}{a}\right)e^{-(R/a)^n}, \quad (22)$$

where a and n are the distribution constants.

Then the sought-for expression for the flux of the substance being desorbed takes the form

$$G = \frac{3\gamma}{4\pi a}\left[\alpha a^{0.5}\Gamma\left(1 + \frac{1}{2n}\right)\right], \quad (23)$$

where Γ is the gamma function.

The constant a of the Rosin–Rammler distribution is uniquely determined in terms of the volume-surface drop diameter (Sauter diameter) by the formula [5]:

$$a = 1.3542d_{32}, \quad (24)$$

where d_{32} is the Sauter diameter.

The constant n of this distribution may be equal or close to 3 [6].

Therefore, the gamma function can be taken to be unity with high precision.

Taking into account the aforesaid and using for-

mulas (19)–(21), we transform expression (23) into the form convenient for analysis:

$$\frac{G}{AQ} = 1.95S^{5/9}\left(\frac{D}{vd_{32}}\right)^{1/2} + 2.39S^{2/3}\left(\frac{D}{vd_{32}}\right)^{1/2}. \quad (25)$$

Relation (25), obtained in the dimensionless form, shows that the relative flux of the substance being desorbed in disintegration of a fluid jet into drops depends mainly on the value of v and on the dispersion composition of the fluid being atomized, which is characterized by the Sauter diameter d_{32}. The calculated values of the function represented by expression (25) are shown in Fig. 2.

It is important to emphasize that G/AQ may exceed unity only in the case of chemisorption, when the substance being desorbed is present in drops in both free and chemically bound states.

It follows from the plots in Fig. 2 that the amount of relative desorption in disintegration of a fluid jet outflowing from a single-flare atomizer may be rather large. This conclusion has been confirmed experimentally, e.g., in [1]. In this study, with the nozzle of the atomizer mounted at a distance of 2 cm from the bottom of a spraying apparatus, the intensity of desorption was so high that the extent to which the equilibrium between the gas and fluid phases was attained exceeded 85%.

CONCLUSIONS

(1) A model of gas desorption in the region of disintegration into drops of a sprayed fluid was constructed with account of its polydisperse composition characterized by the Rosin–Rammler distribution.

(2) The model constructed can be used to evaluate theoretically the efficiency of desorption in spraying apparatus.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Oxidation of 2,4-Dinitrotoluene with an Ozone–Oxygen Mixture

P. Yu. Andreev, G. A. Galstyan, A. G. Galstyan, and I. S. Yakunina

Rubezhnoe Branch, Dal East-Ukrainian National University, Rubezhnoe, Lugansk oblast, Ukraine

Received August, 14, 2003

Abstract—Oxidation of 2,4-dinitrotoluene to 2,4-dinitrobenzoic acid with an ozone–oxygen mixture in glacial acetic acid was studied.

2,4-Dinitrobenzoic acid (DNBA) is an intermediate in production of roentgenocontrast agents [1] and is used as a component of light-sensitive materials in electrophotography [2].

2,4-Dinitrobenzoic acid is prepared by oxidation of 2,4-dinitrotoluene (DNT) with sodium dichromate or chromium trioxide in concentrated sulfuric acid at 40–60°C [3, 4]. The disadvantages of this method are the formation of large amounts of toxic and difficultly utilizable wastes and the low yield of the target product (50–70%). In this context, the study of DNT oxidation with ozone is of practical interest.

In this study, we examined the oxidation of DNT with an ozone–oxygen mixture in glacial acetic acid with the aim to develop a low-waste process for DNBA production.

As can be seen from Fig. 1, ozone reacts with the aromatic ring and methyl group of DNT to form peroxides and 2,4-dinitrobenzaldehyde (DNBAld), respectively. These reactions are parallel. As for aromatic products, DNBAld is accumulated in the first oxidation steps and DNBA, in the final steps.

At 30°C, the reaction of ozone with DNT is slow: in 3 h the conversion reaches ~20%, after which the oxidation stops (Fig. 2). The DNBA yield based on the reacted DNT is as low as 34%. The selectivity of oxidation of the methyl group increases on heating. At 100°C, the DNBA yield based on the reacted substrate reaches 48% (Fig. 2). On heating, the oxidation is accelerates and the DNT conversion increases, reaching 100% at 100°C.

It is known [5] that the ratio of alternative reaction pathways in this system is shifted to DNBA formation

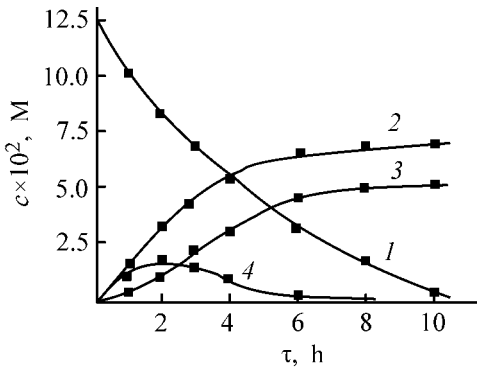

Fig. 1. Content *c* of (*1*) DNT, (*2*) peroxides, (*3*) DNBA, and (*4*) DNBAld in the course of DNT oxidation with an ozone–oxygen mixture vs. time τ. v_{O_2} = 8.3 × 10^{-3} l s^{-1}; $[ArCH_3]_0$ = 0.125, $[O_3]_0$ = 9.5 × 10^{-4} M; 50°C.

in the presence of catalysts based on salts of metal with variable oxidation state. In this study, we examined the catalytic oxidation of DNT in the presence of cobalt(II) acetate (Fig. 3). Previously, we found that oxidation of DNT with molecular oxygen at 100°C in the presence of cobalt(II) acetate is very slow: only traces of DNBA were detected after 15-h oxidation. Catalytic oxidation with an ozone–oxygen mixture is fast and yields mainly DNBA (Fig. 3). Oxidation at 100°C in the presence of 0.14 M cobalt(II) acetate is complete in 3.5 h; the DNBA yield is 87%.

Selective oxidation of the methyl group with ozone in the presence of cobalt(II) acetate is a two-step process. Under the experimental conditions, ozone oxidizes mainly Co^{2+} (k of $Co^{2+} + O_3$ reaction is 930 [6], and k of the $ArCH_3 + O_3$ reaction is 0.013 $l\,mol^{-1}\,s^{-1}$ at 30°C) to reactive Co^{3+} species which, in turn, rapidly and selectively oxidize the methyl group of DNT:

$$Co^{2+} + O_3 + H^+ \rightarrow Co^{3+} + HO^{\cdot} + O_2, \quad (1)$$

$$ArCH_3 + Co^{3+} \rightarrow Ar\dot{C}H_2 + Co^{2+} + O_2 + H^+. \quad (2)$$

Since $v_1 \gg v_2$ [v_1 and v_2 are the rates of reactions (1) and (2), respectively], cobalt is in the oxidized form throughout the process (Fig. 3). For reaction (1) to occur, ozone should be continuously fed to the system. If the ozone supply is interrupted, the reaction will decelerate and then stop. For the formation of 1 mol of DNBA is spent 95% of the theoretical amount of ozone. This indicates that DNT is mainly oxidized with ozone under the experimental conditions. The role of molecular oxygen is limited to the reaction with benzyl radical

$$Ar\dot{C}H_2 + O_2 \rightarrow ArCH_2O_2^{\cdot}. \quad (3)$$

The amount of oxygen liberated in ozone reduction by reaction (1) is sufficient for reaction (3) to occur. The fact that the rate and selectivity of oxidation of the methyl group are independent of the oxygen concentration in the ozone–oxygen mixture confirms the suggested scheme involving reactions (1)–(3).

Introduction of potassium bromide into the reaction mixture substantially accelerates the DNT oxidation with an ozone–oxygen mixture but has no effect on the selectivity of oxidation of the methyl group (Fig. 3). We suggest that potassium bromide reacts with cobalt(II) acetate to form $Co^{2+}Br^{\cdot}$

$$Co^{3+} + Br^- \rightarrow Co^{3+}Br^- \rightleftarrows Co^{2+}Br^{\cdot}. \quad (4)$$

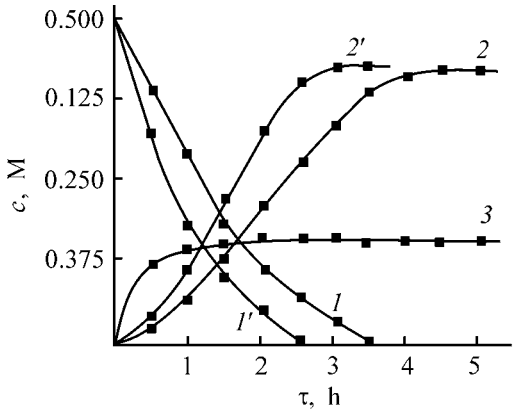

Fig. 3. Kinetic curves of (*1*–*1*′) DNT consumption, (*2*–*2*′) DNBA accumulation, and (*3*) Co^{3+} accumulation in oxidation of DNT with an ozone–oxygen mixture at 100°C. $v_{O_2} = 8.3 \times 10^{-3}$ $l\,s^{-1}$; $[ArCH_3]_0 = 0.5$, $[O_3]_0 = 9.5 \times 10^{-4}$, $[Co(AcO)_2 \cdot 4H_2O]_0 = 0.14$ M. (*1*′, *2*′) [KBr] = 0.1 M.

This complex is more reactive than Co^{3+} and oxidizes DNT by the reaction

$$ArCH_3 + Co^{2+}Br^- \rightarrow Ar\dot{C}H_2 + Co^{3+}Br^- + H^+. \quad (5)$$

EXPERIMENTAL

Dinitrotoluene was oxidized in a glass column with a fine-pore barrier for dispersion of the gas mixture. The reactor was charged with 15 ml of glacial acetic acid and a weighed portion of DNT of chemically pure grade. Then it was heated to the required temperature, and an ozone–oxygen mixture was fed at a rate of 8.3×10^{-3} $l\,s^{-1}$. The concentrations of unchanged DNT and of intermediate oxidation products were determined by gas–liquid chromatography on an LKhM-80 chromatograph with a flame-ionization detector, using a 2 m × 3 mm column packed with Chromaton N-AW with PNFS-6 stationary phase. The DNBA concentration was determined by titration with 0.01 N NaOH on an EV-74 ionometer.

CONCLUSIONS

(1) The reaction of 2,4-dinitrotoluene with ozone in acetic acid at 30°C occurs mainly via oxidation of the aromatic ring. The yield of the products of oxidation of the methyl groups does not exceed 34%. At 100°C, the selectivity of oxidation of the methyl group reaches 48%.

(2) The yield of 2,4-dinitrobenzoic acid in catalytic ozonation of 2,4-dinitrotoluene in the pres-

ence of cobalt(II) acetate is 87%. Introduction of potassium bromide into the oxidation system enhances the catalytic activity of cobalt(II) acetate. As a result, the oxidation of the methyl group is accelerated, but the selectivity of this reaction remains the same.

Kazan State Technological University, Kazan, Tatarstan, Russia

Received July 22, 2003; in final form, December 2003

Abstract—The surface activity of sodium, potassium and, ammonium salts of fatty acids [stearic, oleic, synthetic fatty acids (C_{13}–C_{15} fractions), higher fatty acids contained in bottoms after separation of volatile fatty acids from cotton oil] in aqueous solutions was studied and analyzed.

Surfactants are widely used in various branches of economy, mostly for improvement of materials and development of their new kinds.

In production of anionic surfactants, narrow fractions of synthetic fatty acids (SFA) (C_{13}–C_{15} and C_{10}–C_{16}) and also individual stearic and oleic acids are used as raw materials. This raw material is expensive and its production is complicated. Therefore, attempts have been made to find alternative sources of fatty acids and their mixtures. For example, anionic surfactant prepared from products recovered from tall oil (one of products of cellulose processing) has been used in emulsion polymerization [1, 2]. It is known also [3, 4] that sodium or potassium salts of higher fatty acids recovered from cotton oil efficiently stabilize bituminous emulsions [3, 4].

In this study, we prepared anionic surfactants from bottoms formed after separation of volatile fatty acids from cotton oil (FACB). These bottoms contain a fairly large amount of fatty acids and are an inexpensive natural raw materials for preparing surfactants. The surface activities of the new and commercial anionic surfactants are compared.

EXPERIMENTAL

The surface activity of fatty acid salts was studied by common technique [GOST (State Standard 20 216–74] [5–9]. The physicochemical features and chemical composition of FACB were determined by the standard method [GOST 5474–5478] [10]. FACB is a dark brown oily liquid with a specific odor, which contains 30 wt % monomeric (stearic, oleic, palmitic, linoleic) and 70 wt % oligomeric fatty acids. The moisture content is 10.2 wt %, ash content 0.6 wt %, the number-average molecular weight 1130, acid number 156.7 mg KOH g^{-1}, saponification number 192.0 mg KOH g^{-1}, and iodine number 76.1 g I_2/100 g.

The fatty acids were converted into their salts by saponification with 30% aqueous sodium, potassium and ammonium hydroxides at 90–100 °C for 2 h. Aqueous solutions of these surfactants have pH 10.0–11.4.

It is known that surfactant molecules have a large excess free energy at the interface between the aqueous solution and air. The specific interfacial excess free energy (σ) (surface tension) of a surfactant is a function of its molecular weight, molecular configuration, and intermolecular interaction features. In order to characterize the surface activity of surfactants based on FACB, we studied their surface tension isotherms (Figs. 1a–1b). The surface tension in these systems was measured by the Du Nouy technique.

The surface tension of aqueous anionic surfactants is dependent on both the molecular structure of the surfactants and the cation type. It is known that branched anionic surfactants exhibit a higher surface tension. As can be seen from the table, the lowest surface tension is exhibited by paraffinates (fraction C_{13}–C_{15}) used as emulsifiers in production of commercial butadiene-vinylidene-chloride latexes. The highest surface tension is exhibited by sodium stearate. We found that the surface activity of salts prepared from FACB containing a mixture of fatty acids is intermediate between the surface activities of particular fatty acid salts, i.e., the multicomponent FACB salt does not show synergism in the surface activity.

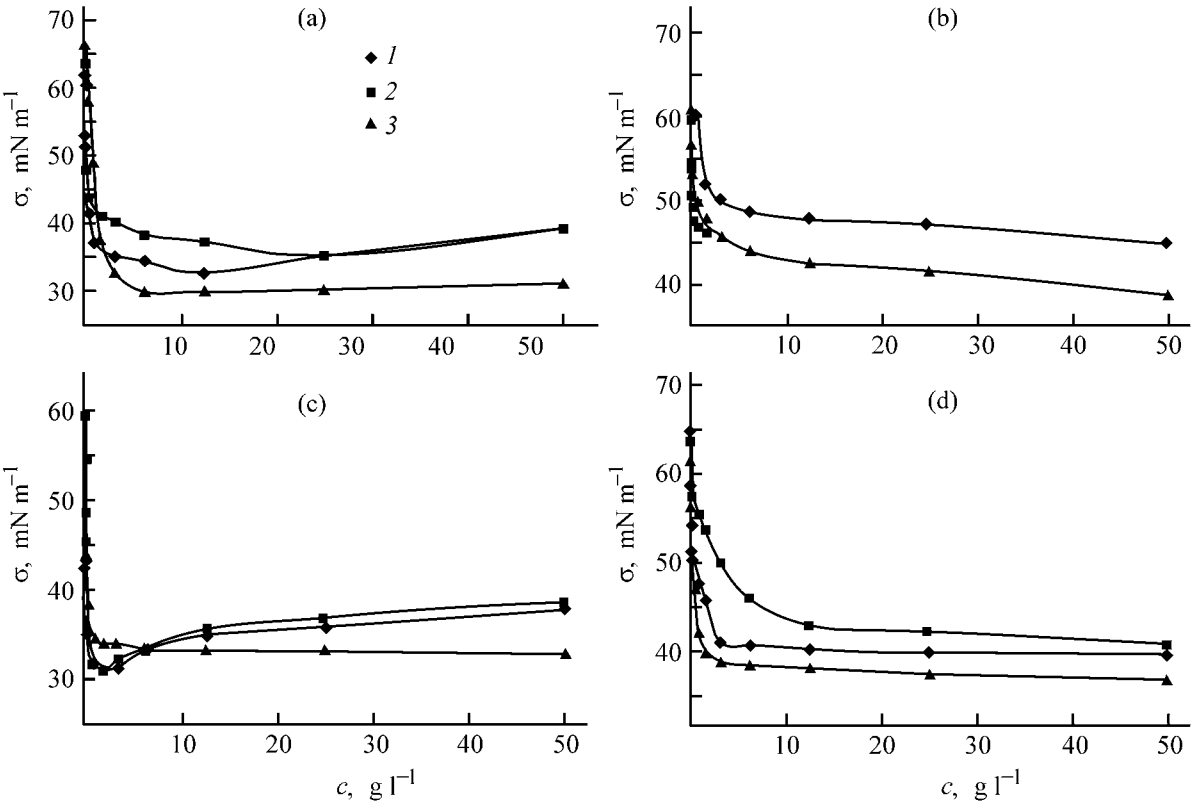

Fig. 1. Surface tension isotherms of aqueous solutions of (a) SFA ($C_{13–15}$ fraction), (b) stearic acid, (c) oleic acid, and (d) FACB salts. (σ) Surface tension and (*c*) surfactant concentration. (*1*) K^+, (*2*) Na^+, and (*3*) NH_4^+.

Along with the surface tension, the surface activity of surfactant can be characterized by the parameter pc_{20} (negative logarithm of the surfactant concentration at which the surface tension decreases by 20 mN m^{-1}). The table shows that this parameter is sensitive to the molecular structure of the hydrocarbon moiety in the surfactant molecule. The sodium SFA salt and sodium oleate have comparable pc_{20} values. In going to sodium stearate and then to FACB salts, this parameter appreciably increases. These data show that, although the multicomponent surfactants based on FACB do not exhibit synergism in surface tension, they are synergistic with respect to the pc_{20} value.

Both dispersing and stabilizing effects of surfactants are due to their interfacial sorption. Therefore,

Characteristics of aqueous surfactants

Surfactant	Cation	σ, mN m^{-1}	pc_{20}, g dm^{-3}	$\Gamma_\infty \times 10^6$, g m^{-2}	*n*	CMC, g dm^{-3}
SFA C_{13}–C_{15}	K^+	32.8	0.25	5.6	0.59	0.6
	Na^+	35.3	0.03	4.8	1.52	0.1
	NH_4^+	29.7	0.78	6.9	1.36	5.0
Stearic acid	K^+	43.2	3.98	3.3	2.18	6.3
	Na^+	47.2	0.32	3.8	1.38	0.8
	NH_4^+	38.7	0.32	2.5	1.76	6.3
Oleic acid	K^+	31.1	–	0.5	4.28	2.6
	Na^+	30.9	0.04	6.0	1.75	0.6
	NH_4^+	32.7	–	7.1	1.76	0.4
FACB	K^+	39.8	0.40	3.0	0.57	0.4, 4.2
	Na^+	41.0	3.16	2.5	1.19	7.9
	NH_4^+	36.9	0.25	2.8	2.54	1.8

the limiting interfacial surfactant sorption (surface concentration of the surfactant, at which its monomolecular surface layer is formed) can be used for characterization of its surface activity. The limiting sorption Γ_∞ of surfactants under consideration was determined from their sorption isotherms (see table). The highest sorption is exhibited by ammonium oleate, and the lowest sorption, by ammonium stearate. The surfactants based on FACB salts have Γ_∞ value close to that of stearates and are virtually insensitive to cation nature. The water solubility of surfactants is dependent on cation nature. The most soluble are potassium salts.The table shows that, irrespective of the cation kind, the stearates and FACB salts are less soluble than the SFA salts and oleates.

The surface activity of surfactants can be characterized also by the slope *n* of the plot of the surface tension against the interfacial sorption. The surfactants belonging to a certain type (water-soluble, nonionic, ionic), have approximately equal colligative parameter *n* irrespective of their molecular structure. Depending on the type of a surfactant, the *n* values vary as follows: water-soluble 1.5, nonionic 1, and ionic 2. The *n* value of ionic surfactants in electrolyte solutions is in the range 1–2. Most part of the surfactants tested by us, apart from their potassium derivatives, belong to the ionic type. Due to weak dissociation of SFA and FACB potassium salts, their *n* parameters are less than unity. At the same time, for completely dissociated potassium stearate and oleate, the *n* value exceeds 2.

The critical micelle concentration (CMC) is one of the most important characteristics of a surfactant. This parameter is sensitive to both the features of surfactant molecular structure and such factors as temperature, electrolyte content, presence of polar organic impurities, etc. The CMC decreases with lengthening of the hydrocarbon radical,[1] and depends on the number, kind, and position of ionic groups and presence of unsaturated functional groups. The surfactants with branched and, especially, cyclic hydrocarbon chains have lower CMC.

Our results (see table) do not show any relationship between the nature of a surfactant and its surface activity. However, these data show some features of FACB salts.

(1) There are two inflection points in the surface tension isotherm corresponding to two different CMC values. We suggest that the appearance of these two CMC values can be caused either by the multicomponent composition of FACB, hindering formation of uniform micelles, or by transformation of the initial spherical micelles into those of another kind. The second CMC can also be due the fact that FACB contains a large amount of oligomeric fatty acids. Their salts are associated at concentrations higher than the first CMC, and this is manifested in the sorption isotherm as the point of critical concentration of association.

(2) The FACB sodium salt has considerably higher CMC than FACB salts with other cations.

(3) The CMC of the FACB ammonium salt is intermediate between those of ammonium stearate (paraffinate) and ammonium oleate.

Thus, our experiments showed that the surface activity of FACB potassium, sodium and ammonium salts is intermediate between the surface activities of unsaturated and saturated acid salts contained in FACB salt. There is a synergistic effect in the slope of the concentration dependence of the surface tension, but the synergism is lacking with respect to other characteristics of surface activity.

CONCLUSION

Anionic surfactants prepared from higher fatty acids contained in bottoms formed after separation of volatile fatty acids from cotton oil are not inferior to commercial industrial surfactants. These surfactants can be applied as emulsifiers in emulsion polymerization, as plasticizers in production of concretes, and as dispersing agents in preparation of suspensions of solids.

Received October 9, 2003

Abstract—Previously unknown 2-methacryloyl-5-hydroxy-3,3,5-trimethylisoxazolidine was prepared by the reaction of 5-hydroxy-3,3,5-trimethylisoxazolidine with methacryloyl chloride. Homopolymers of this compound and its copolymers with *N*-vinylformamide and *N*-vinylpyrrolidone were obtained by radical polymerization.

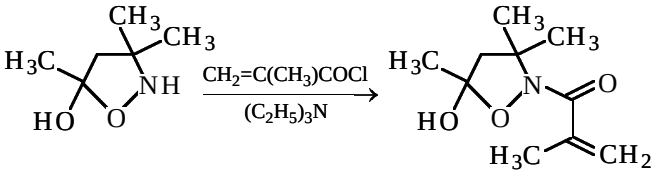
The targeted transport of a physiologically active substance to a definite organ or tissue of a living body is an important problem of modern pharmacology. Water-soluble copolymers derived from *N*-vinylamides and vinyl saccharides, which exhibit increased affinity for glycoproteins owing to the presence of similar amide and saccharide groups, may be efficient means for such a transport.

Previously, we have prepared polymers derived from *N*-vinylamides (*N*-vinylpyrrolidone; *N*-vinylacetamide and its *N*-alkyl derivatives) and vinylsaccharides (2-*N*-methacryloylglucosamine [1], 3-*O*-methacryloyl-1,2;5,6-di-*O*-isopropylidene-*O*-glucofuranose [2], and 6-*O*-methacryloylglucopyranose [3]).

The main problem arising in preparation of vinylsaccharides, which are the starting comonomers in synthesis of copolymers of vinylsaccharides with *N*-vinylamides, is associated with preliminary protection of hydroxy groups of the glucopyranose ring in regioselective acylation with unsaturated carboxylic acid anhydrides or chlorides [2, 3]. These synthetic limitations can be lifted by using, instead of pyranose and furanose units, oxygen-containing saturated rings (e.g., five-membered isoxazolidine structures) as alternative models of saccharide fragemnts. The presence of the cyclic hemiacetal fragment –O–C–OH suggests an enhanced affinity of these molecules for monosaccharides and thus opens up certain prospects for synthesis of isoxazolidine-containing polymers suitable as structural analogs of polymeric compounds based on vinylsaccharides. It is also known that isoxazolidine derivatives, the so-called "pseudonucleoitides," are used in medicine, e.g., as potential means for treating HIV infections [4–6].

In this context, our goal was to prepare 2-methacryloyl-5-hydroxy-3,3,5-trimethylisoxazolidine **II** by the reaction of readily accessible [7] 5-hydroxy-3,3,5-trimethylisoxazolidine **I** with methacryloyl chloride, and also to study copolymerization of **II** with hydrophilic comonomers, *N*-vinylformamide (VFA) and *N*-vinylpyrrolidone (VP).

It is known that acylation of **I** occurs by several pathways to yield a mixture of cyclic and linear products, 2-acyl-5-hydroxy-3,3,5-trimethylisoxazolidine and 4-(*O*-acylhydroxylamino)-4,4-dimethyl-2-butanone, respectively [8]. However, the reaction of 5-hydroxy-3,3,5-trimethylisoxazolidine **I** with methacryloyl chloride yields the cyclic product only (MAIS, **II**) (see Experimental).



I **II**

The criteria used to prove structure **II** were similar to those applied previously [9–12] to functionally substituted isoxazolidines and were based on NMR spectroscopy. In particular, the ^{1}H NMR spectrum of **II** in $CDCl_3$ contains a set of signals characteristic of a five-membered isoxazolidine ring. Diastereotopic methylene protons give a typical *AB* pattern with a

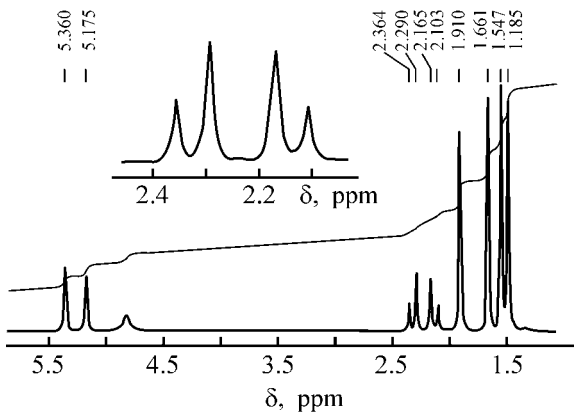

Fig. 1. ^{1}H NMR spectrum of **II** in $CDCl_3$. (δ) Chemical shift; the same for Fig. 2.

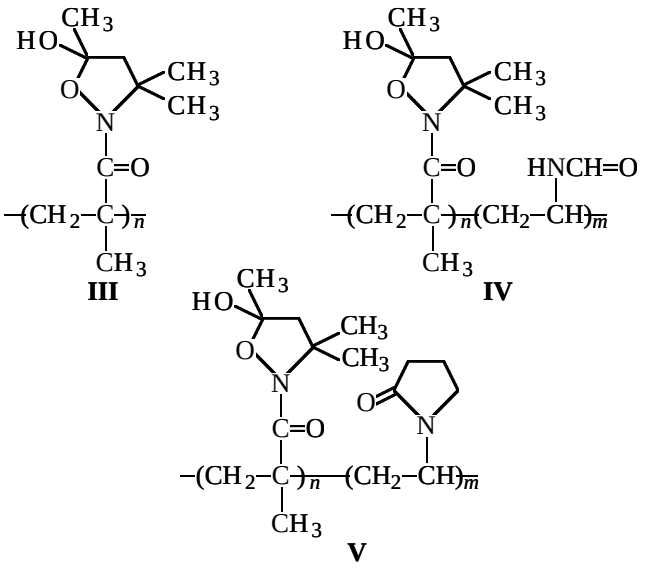
coupling constant of 12 Hz. Also, the spectrum contains a set of signals of the methacryloyl moiety, namely, those of the methyl group at 1.91 ppm and two vinyl protons at 5.17 and 5.36 ppm (Fig. 1). The ^{13}C NMR spectrum of **II** in $CDCl_3$ contains a set of signals at 55.7, 63.1, and 102.4 ppm, corresponding to the C^4, C^3, and C^5 atoms of the isoxazolidine ring, respectively (see Experimental). An additional fact confirming the formation of the *N*-acyl group is the violet coloration appearing upon treatment of **II** with an $FeCl_3$ solution, which is typical of cyclic hydroxamic acid derivatives.

Homopolymerization of **II** and its copolymerization with VFA and VP was performed in DMF at 60°C using azobis(isobutyronitrile) as initiator (1 wt % relative to the comonomers). We obtained soluble MAIS–VFA (**IV**) and MAIS–VP (**V**) copolymers, and also MAIS homopolymer, poly-2-methacryloyl-5-hydroxy-3,3,5-trimethylisoxazolidine (PMAIS, **III**):



The conditions under which **III**–**V** were prepared and the intrinsic viscosities [η] of these polymers are given in Table 1.

Homopolymer **III** is water-insoluble, which may be due to intrachain hydrophobic interactions of three methyl groups of the isoxazolidine ring. The ^{1}H NMR spectrum of **III** in DMSO-d_6 contains a typical set of signals at about 1.50 ppm, characteristic of the 3- and 5-CH_3 groups of the isoxazolidine ring, and also the signal of the C^4H_2 group at 1.80 ppm (Table 2). As

Table 1. Conditions of synthesis and properties of polymers **III**–**V**

IV	15	85	75	10	90	0.20
	20	80	70	22	78	0.16
V	30	70	85	30	70	0.33

* Determined in DMF.

Table 2. ^{1}H NMR spectra of **III**–**V** in D_2O

Compound	δ, ppm						
	MAIS				VFA or VP		
	CH_3	3-CH_3	5-CH_3	4-H	H–C=O or 3-H	4-H	5-H
III*	0.88	1.38; 1.49	1.66	1.88	–	–	–
IV	1.15	1.46; 1.53	1.76	2.29	7.98	–	–
V	1.19	1.53 (6H)	1.93	2.36	2.28	2.03	3.26

* Recorded in DMSO-d_6.

compared to the spectrum of **II**, these signals are appreciably shifted upfield, which is due to transformation of the methacryloyl fragment into the saturated isobutyryl unit of the polymer. The ^{1}H NMR spectra of MAIS–VFA (**IV**) and MAIS–VP (**V**) copolymers in D_2O contain a typical set of signals in the range 1.50–1.80 ppm, which are characteristic of the 3- and 5-CH_3 groups in the isoxazolidine ring. The ^{1}H NMR spectrum of **IV** also contains a formyl proton signal at 7.98 ppm (Fig. 2), and the spectrum of **V**, signals of lactam ring protons (4-H, 3-H, 5-H) at 2.03, 2.28, and 3.26 ppm, respectively.

Thus, acylation of 5-hydroxy-3,3,5-trimethylisoxazolidine with unsaturated carboxylic acid anhydrides or chlorides may be a convenient route to new isoxazolidine monomers; their polymers show promise as carriers of biologically active substances.

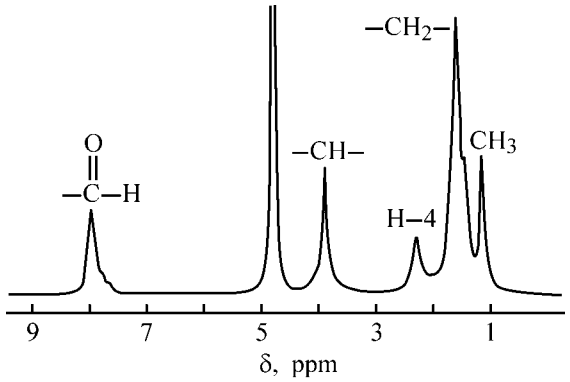

Fig. 2. ^{1}H NMR spectrum of **IV** in D_2O.

EXPERIMENTAL

The ^{1}H and ^{13}C NMR spectra were measured on a Bruker AC 200 spectrometer at 200 and 50 MHz, respectively. The compositions of copolymers **IV** and **V** were determined from the relative intensities of the characteristic ^{1}H NMR signals. The reaction progress was monitored, and the product purity checked, by TLC on Silufol UV 254 plates (eluent benzene : acetone, 2 : 1). The intrinsic viscosity [η] was measured with an Ubbelohde viscometer in 0.1 M sodium acetate solution at 25°C. Compound **I** was prepared as described in [7].

2-Methacryloyl-5-hydroxy-3,3,5-trimethylisoxazolidine II. To a solution of 13.1 g (0.1 mol) of **I** and 15.2 g (0.15 mol) of triethylamine in 250 ml of ether, cooled to 5°C, we added dropwise with stirring 15.7 g (0.15 mol) of methacryloyl chloride. The resulting precipitate was separated, and the ether solution was washed with a saturated $NaHCO_3$ solution. The solvent was removed in a vacuum, and the residue was recrystallized from benzene–hexane, 2 : 1. Yield of **II** 12.9 g (65%), mp 109–111°C.

CONCLUSIONS

(1) Reaction of 5-hydroxy-3,3,5-trimethylisoxazolidine with methacryloyl chloride yields a new monomer, 2-methacryloyl-5-hydroxy-3,3,5-trimethylisoxazolidine.

(2) Homopolymers of 2-methacryloyl-5-hydroxy-3,3,5-trimethylisoxazolidine and its copolymers with *N*-vinylformamide and *N*-vinylpyrrolidone, containing 10–30 mol % isoxazolidine units, were prepared. The structures and compositions of the copolymers were confirmed by ^{1}H NMR spectroscopy.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Copolymerization of *N*-Vinylsuccinimide with Butyl Methacrylate in Pyridine

N. A. Lavrov, A. G. Pisarev, and E. V. Sivtsov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received January 23, 2004

Abstract—The kinetics of radical copolymerization of *N*-vinylsuccinimide with *n*-butyl methacrylate in pyridine was studied, and the previously unknown copolymerization constants of the monomers were determined. The calculations were performed using appropriate software and a new procedure for approximation of the experimental data, which allow determination of the kinetic parameters at high conversions with the minimum error. The copolymerization kinetics were compared for the reaction systems constituted by *N*-vinylsuccinimide and *n*-butyl methacrylate and by *N*-vinylsuccinimide and *n*-butyl acrylate.

Copolymers of *N*-vinylsuccinimide (VSI) with *n*-butyl acrylate (BA) were suggested as materials for preparing films for medicobiological purposes [1–3]. The acrylic comonomer acting as internal plasticizer makes it possible to prepare elastic films recommended for protection and treatment of skin wounds. However, copolymers containing more than 80–90% BA are sticky liquids incapable of film formation. This drawback can be eliminated by introducing one more comonomer, i.e., by partially replacing BA with *n*-butyl methacrylate (BMA). Papers on preparation of VSI polymers and copolymers, published in the last 50 years [4], contain no data on binary copolymerization of VSI with BMA. In this study, we examined the copolymerization of VSI with BMA in pyridine.

The monomers and initiator, azobis(isobutyronitrile) (AIBN), were purified as described in [5]. Analytically pure pyridine was double-distilled. The copolymerization of the monomers was performed in glass ampules under Ar at 60°C. The total concentration of the monomers in pyridine was 0.7, and that of AIBN, 0.0165 M. The reaction kinetics was studied gravimetrically, as in [5]. After the copolymerization was complete, the ampule contents were poured into distilled water. The precipitated copolymer was filtered off and dried to constant weight at 20°C (660 Pa). The copolymer compositions (Table 1) were determined by IR spectroscopy from the ratio of the optical density at 1700 cm^{-1}, D_{VSI}, to that at 1725 cm^{-1}, D_{BMA}, using a calibration plot constructed according to [6]. The IR spectra of copolymers were recorded on a Perkin–Elmer spectrophotometer. Samples were prepared as films cast on KBr plates or as free films.

Copolymerization of VSI with both BMA and BA [5] in pyridine is relatively fast, which does not always allow isolation of the copolymers at low conversions. With increasing conversion, the viscosity of the reaction mixture grows, thus complicating a quantitative isolation of the product. Copolymerization occurs under homogeneous conditions and yields copolymers soluble in organic solvents, which allows preparation of films by casting.

Comparison of the kinetics of VSI–BMA copolymerization with that of VSI–BA copolymerization and with the results given in [5] shows that the initial rate of VSI–BMA copolymerization is higher as compared to the VSI–BA system (Table 1). This is due to the higher activity of BMA, compared to BA. However, the rate of copolymerization of VIS with BMA decreases with increasing conversion (Table 1). This may be due to changes in the solution viscosity and in conformations of macromolecules in the course of polymerization, and also to steric factors.

The high viscosity of the reaction system may be responsible for the fact that the gravimetric method used to monitor the copolymerization kinetics gives a certain scatter of experimental points. As a result, the error in calculation of the copolymerization constants increases. Therefore, in studying the kinetics of copolymerization of VSI with BMA, we used the approximation procedure [7] allowing correction of

data on the monomer conversion and copolymer composition by the least-squares method; the error in calculation of the copolymerization constants is thus decreased.

Detailed analysis of the applicability of this procedure to treatment of experimental data obtained at various conversions of the monomers, using computer programs for calculation of the polymerization constants by the Ezrielev–Brokhina–Roskin (EBR) [8] and Kelen–Tüdös (KT) [9] methods, shows that reliable results can be obtained even at conversions exceeding 50%. Using this procedure, we also refined the constants of copolymerization of VSI with BA [5]; the results are listed in Table 2.

In calculation of the VSI–BMA copolymerization constants in pyridine by the EBR and KT methods, the minimum error factor was 0.001. In the system VSI–BA, the copolymerization constants in pyridine could be calculated with an even lower error factor of 0.0001. Calculation of r_1 and r_2 by both methods gives virtually coinciding results (Table 2).

The constants of copolymerization of VSI with BA in pyridine, calculated in [5] ($r_1 = 0.26 \pm 0.05$, $r_2 = 1.86 \pm 0.11$), were determined at a 3–8% conversion of the monomers. However, measurements at low (≤10%) conversions do not always ensure a low error of the copolymerization constants. For example, the error factor was 0.5 in [5].

The use of experimental data for low conversions is quite justified if the methods used for calculating the copolymerization constants are based on solution of differential equations for the copolymer composition. With more up-to-date calculation methods and computer facilities, there is no need to restrict artificially the experimental data. Therefore, we refined in this paper the constants of copolymerization of VSI with BA in pyridine using the approximation treatment of experimental data for <50% conversion (Table 2). The error factor was 0.0001.

The constants of copolymerization of VSI with BMA in pyridine (Table 2) were determined similarly with an error factor of 0.001. Hence, the procedure of approximation of the experimental data on the monomer conversion and copolymer composition allows determination of the copolymerization constants r_1 and r_2 with a minimum error even at conversions exceeding 50% (Table 1). This confirms the conclusion made in [10] that the Kelen–Tüdös method is quite suitable for calculating the copolymerization constants at high conversions. In turn, the copolymerization constants calculated from the approximated experimental data with a very low error factor furnish more reliable information on the reaction kinetics and microstructure of the copolymers.

Using the copolymerization constants for the systems VSI–BMA and VSI–BA (Table 2), we calculated the probability *f* of diad formation and the statistical-mean block lengths *L* in the chains of VSI–BMA and VSI–BA copolymers by the formulas from [11, 12]

Table 3. Probability f of diad formation and statistical-mean block length L in chains of VSI–BMA and VSI–BA copolymers (copolymerization in pyridine, AIBN initiator, 60°C)

		70	0.246	0.085	0.334	1.74	1.25

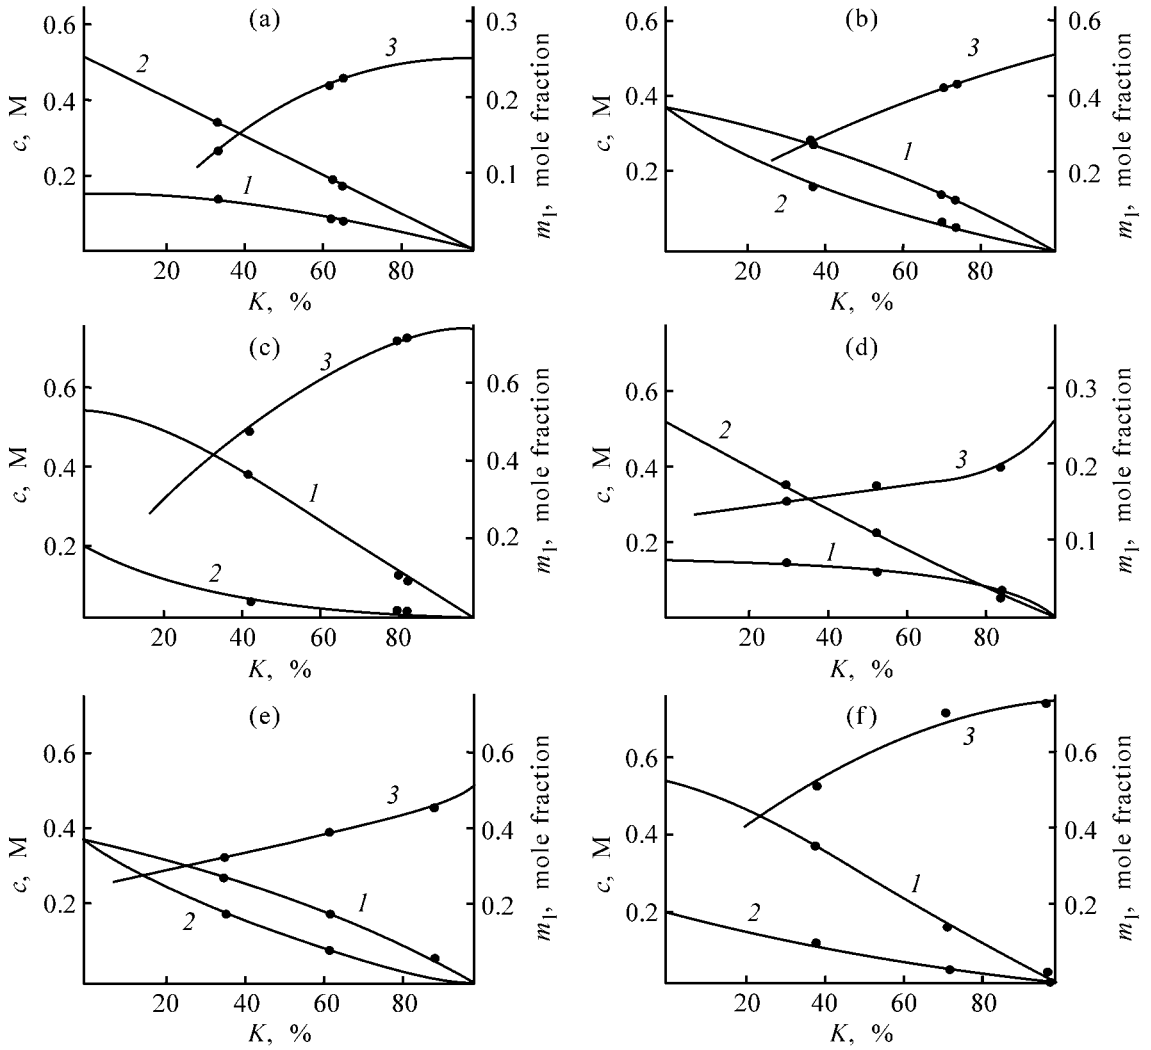

Fig. 1. Concentrations *c* of (*1*) VSI and (*2*) BMA or BA in the reaction mixture and (*3*) the mole fraction of VSI units in the copolymer m_1 vs. the conversion *K*. Solvent pyridine; total monomer concentration 0.7 M; AIBN concentration 0.0165 M; 60°C. VSI mole fraction in the monomer mixture: (a, d) 0.25, (b, e) 0.50, and (c, f) 0.75. Copolymerization: (a–c) VSI + BMA and (d–f) VSI + BA.

using the appropriate software [13]. The results obtained (Table 3) show that the tendency toward formation of alternating copolymers in copolymerization of VSI with BMA in pyridine appears at the VSI mole fraction in the monomer mixture equal to 0.80–0.90, and in the system with BA in the same solvent it appears at the VSI mole fraction of 0.70–0.80.

Taking into account changes that occur in the VSI content in the monomer mixture as the conversion grows from 0 to 70% (Table 4), we determined, according to [14], the probability of diad formation and the statistical-mean block length in the chains of VSI–BMA and VSI–BA copolymers prepared in pyridine at various conversions (Table 5), using the diagrams shown in Fig. 1.

Table 4 shows that the high reactivity of BMA and BA, which determines higher rate of their consumption in the reaction mixture, results in an enrichment of the monomer mixture with the less active monomer, VSI. Therefore, with increasing conversion, the probability of formation of M_1M_2 and M_2M_2 diads ($f_{12} = f_{21}$) grows, and that of formation of diads consisting of BMA or BA units (f_{22}) decreases. Also, with increasing conversion, the statistical-mean block lengths L_1 and L_2 approach each other (Table 5).

Tables 3–5 show that the highest probability of unit alternation, f_{12} = 0.349, in VSI–BA copolymers prepared in pyridine is observed at the VSI mole fraction in the monomer mixture equal to 0.7–0.8. The maximum probability of cross addition of units, f_{12} =

0.349, is attained at the VSI mole fraction of 0.79 and a 20–40% conversion.

The microstructure of VSI–BMA copolymers prepared in pyridine was analyzed similarly. The highest probability of unit alternation, f_{12} = 0.406, is observed at the VSI mole fraction in the monomer mixture equal to 0.7–0.9. The maximum probability of cross addition of units, f_{12} = 0.406, is attained at the VSI mole fraction of 0.87 and a 50–70% conversion.

The BSI–BMA copolymers prepared in pyridine are characterized by better alternation of units than the VSI–BA copolymers prepared in the same solvent. The maximum probability of unit alternation, $f_{12} = f_{21}$, is 0.406 for VSI–BMA copolymers and 0.349 for VSI–BA copolymers. The minimum difference between the mean block lengths L_1 and L_2 (ΔL) for the VSI–BMA copolymers is 0 at VSI mole fraction of 0.88–0.89 and $K \approx 70\%$ (Table 5). For the VSI–BA copolymers, the minimum ΔL is 0.01 at the VSI mole fraction of 0.79–0.80 and $K \approx 20\%$ (Table 5). This fact confirms the conclusion made in [5] that pyridine as a solvent ensures a better compositional uniformity of copolymers, compared to other solvents, e.g., dimethyl sulfoxide.

Our experimental results can be used in planning and simulation of ternary copolymerization of VSI with BA and BMA with the aim to obtain elastic films for medical and biological purposes.

CONCLUSIONS

(1) The kinetics of copolymerization of *N*-vinylsuccinimide with *n*-butyl methacrylate was studied for the first time, and the constants of copolymerization in pyridine were determined: $r_1 = 0.03 \pm 0.04$ and $r_2 = 1.79 \pm 0.04$.

(2) Application of the approximation procedure to data on monomer conversion and copolymer composition made it possible to determine the constants of copolymerization of *N*-vinylsuccinimide with *n*-butyl methacrylate and *n*-butyl acrylate in pyridine with an error factor of 0.0001–0.001.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Molecular Structure of Comb-Shaped Photochromic Copolymers on Photoinduced Birefringence

E. B. Barmatov, A. V. Medvedev, and S. A. Ivanov

Lomonosov Moscow State University, Moscow, Russia

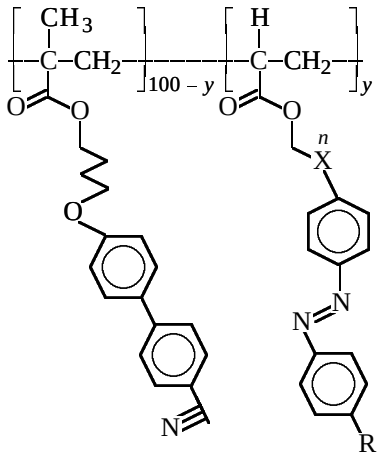
Received October 31, 2003; in final form, February 2004

Abstract—A series of mesomorphic and amorphous photochromic copolymers containing azobenzene groups were prepared. The emergence of induced birefringence in films of these copolymers under the action of plane-polarized laser light was studied.

Comb-shaped photochromic mesomorphic polymers (MPs) show promise as media for information recording and storage, as well as for application in various optical elements, including filters, polarizers, switches, etc. [1–3]. Photosensitive MPs are usually obtained from compounds comprising two basic structural elements, photochromic and mesogenic. The primary role in photoorientation of photochromic MPs under linearly polarized laser light belongs, undoubtedly, to photochromic moieties. Mesogenic groups in the mesomorphic copolymers (MCs) not only participate in photoorientation but also perform the following important functions. First, they are responsible for mesomorphic ordering, which in many cases allows significant improvement of the photoinduced order (birefringence enhancement effect [4, 5]). Second, the mesomorphic order substantially enhances the thermal stability of the photoinduced birefringence [6]. This allows preparation of photochromic MCs suitable as advanced information carriers.

Much progress has been achieved in physical chemistry of MPs comprising azobenzene photochromic moieties, but the influence of the chemical structure of photochromic and mesogenic groups on the photooptical properties of copolymers still remains to be elucidated. There are scarce published data on homologous series of comb-shaped MPs with varied length of the aliphatic spacer and invariant structure of the mesogenic units [7, 8]. At the same time, specifically studies of homologous series can provide quantitative information on how the chemical structure of comb-shaped MPs affects the magnitude and kinetic features of photoinduced birefringence.

The aim of this study was to elucidate how the molecular structure of comb-shaped photochromic MPs affects the kinetic features and magnitude of photoinduced birefringence. To this end, we synthesized comb-shaped mesomorphic and amorphous copolymers (ACS) P-1–P-6 with varied photochromic unit polarity and distance separating the azobenzene fragment and the polymer chain:



with no X, R = H , n = 0 (P-1); X = O, R = H, n = 4 (P-2); X = O, R = H, n = 10 (P-3); no X, R = CN, n = 0 (P-4); X = O, R = CN, n = 4 (P-5); and X = O, R = CN, n = 10 (P-6); and y = 21 ± 1 mol%.

EXPERIMENTAL

The copolymers were prepared by radical copolymerization from appropriate monomers in absolute tetrahydrofuran with azobis(isobutyronitrile) (AIBN) as initiator. The resulting copolymers were refluxed in ethanol for a long time to exhaustively remove oligomers and low-molecular-weight products. Microcalorimetric studies were carried out on a Mettler differen-

1070-4272/04/7704-0608 © 2004 MAIK "Nauka/Interperiodica"

tial scanning calorimeter (heating rate 10 deg min^{-1}), and microscopic examinations, on a POLAM-P-211 polarization microscope equipped with a Mettler FP-82 heating system. The molecular weight characteristics of the P-1–P-6 copolymers were determined by gel-permeation chromatography on a GPC-2 Waters instrument equipped with an LC-100 column and a Data Modul-370 data processing system. The measurements were made with a UV detector (solvent THF, 1 ml min^{-1}, 25°C; 100, 500, and 10^3 Å columns; calibration against polystyrene).

The kinetic features of the photoinduced birefringence were studied on the photooptical installation described in [9]. The vertically polarized "recording" beam from an argon laser (λ_{rec} = 488 nm, intensity I_0 = 0.035 W cm^{-2}) was directed toward the selected segment of the polymer film. To record the photoinduced alterations in the polymer film, the same segment of the sample was simultaneously illuminated with the probing laser beam from an He–Ne laser (λ_{sens} = 633 nm). The intensity of the probing beam that passed through the sample and analyzer was measured with a photodiode and a special recording system. The photoinduced birefringence Δn_{ind} was estimated from the phase shift $\varphi(\tau)$ between the probing beam components polarized in parallel and perpendicularly to the polarization direction of the recording beam. The absorption of the probing beam passing through the polymer was measured using the monitor channel.

The samples for photooptical measurements were prepared in a glass sandwich cell; the polymer layer thickness was adjusted with Teflon spacers (30 μ). We used amorphous or amorphized samples prepared by rapid cooling of the isotropic melt to the glassy state.

Phase characteristics of P-1–P-6 copolymers. Figure 1 shows the differential-scanning calorimetric (DSC) curves of the copolymers. The P-1 and P-4 copolymers are amorphous, as suggested by the absence of melting peaks of the mesomorphic phase in the DCS curves, as well as by the lack of optical anisotropy of the samples. Copolymer P-5 forms a nematic mesomorphic phase, and P-2, P-3, and P-6 copolymers, a smectic mesophase. The DCS curves of the MCs, recorded in the heating mode, exhibit an endothermic peak with the enthalpy of melting of 1.1–2.1 J g^{-1}. The glass transition points for P-1–P-6 copolymers lie within 61–74°C and are weakly dependent on the nature of the substituent in the azobenzene moiety. Table 1 summarizes the molecular-weight characteristics and phase characteristics of the copolymers.

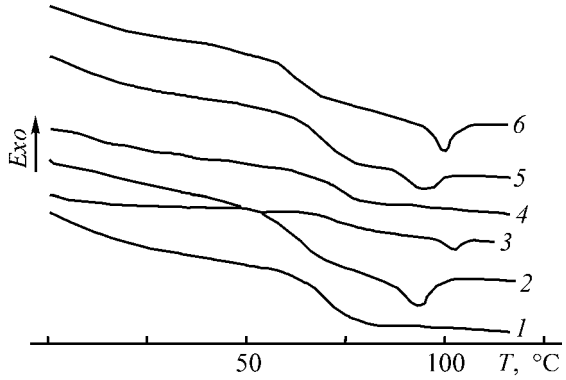


Fig. 1. (*1*–*6*) DCS curves of P-1–P-6 copolymers, recorded in the heating mode. (*T*) temperature.

Photooptical characteristics of the copolymers. To study the photooptical characteristics of the photochromic copolymers P-1–P-6, we recorded the curves of build-up of the photoinduced birefringence in the course of laser irradiation. Specifically, we recorded the time dependence of the phase shift φ/π between the probing beam components polarized parallel and perpendicular to the electric vector of the recording beam. Figure 2 shows a typical dependence of the phase shift on the irradiation time for the P-6 copolymer. For all the copolymers studied, the φ/π phase shift growth curves are typical of photochromic copolymers [1, 9, 10]. Laser irradiation is responsible for the emergence and build-up of the phase shift. Upon termination of irradiation, the birefringence decreases by 15–20% within 1000–3000 s, whereupon it remains unchanged for a long time.

Two segments are distinguishable in the birefringence build-up curves, namely, those corresponding to fast and a slow rise in birefringence (Fig. 2, curves *1*

Note. The birefringence Δn is given for the irradiation time of 2400 s.

and *2*). The first segment (Fig. 2, curve *1*) can be closely approximated by the exponential curve [9]

$$\varphi(\tau) = \frac{2\pi}{\lambda_{sens}} \frac{\Delta n_{max}}{\alpha} \left\{ \ln K - \int_1^K \exp\left[-\left(\frac{\hat{\tau}}{z} \right)^{\beta} \right] \frac{dz}{z} \right\}, \quad (1)$$

$$\hat{\tau} = \tau / t_0, \; C = t_g I,$$

where λ_{sens} = 633 nm is the probing beam wavelength; t_g, characteristic time of birefringence growth on the sample surface; α, absorption coefficient of the polymer film for the probing beam ($\ln K = \alpha d$); d, sample thickness; and β, constant in the Kohlrausch–Williams–Watts function

$$\Delta n = \Delta n_{max} \{ 1 - \exp[-(\tau/t)^{\beta}] \}. \quad (2)$$

We described the second segment of the birefringence build-up curve, corresponding to slow, linear, build-up of φ/π (Fig. 2, curve *2*), by the same function (1) for $\hat{\tau} \ll 1$:

$$\varphi/\pi = B\tau^{\beta}, \quad (3)$$

where B is a constant.

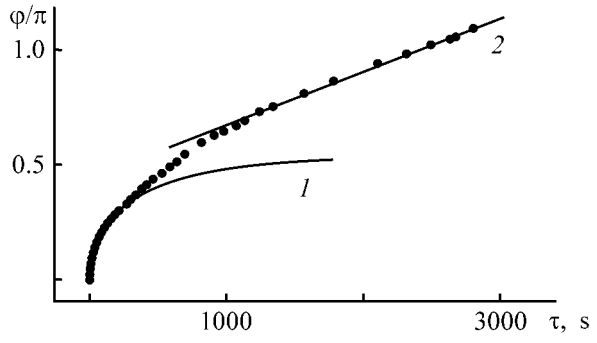

Fig. 2. Variation of the phase shift φ/π for P-6 copolymer in the course of laser irradiation (0.025 J cm^{-2} power). (τ) Time. Approximation of the segments corresponding to (*1*) slow and (*2*) fast birefringence build-up.

Table 2 summarizes the kinetic parameters of P-1–P-6 copolymers, calculated by Eqs.(1)–(3).

Data in Table 2 allow certain conclusions about the kinetic features of the photooptical behavior of the copolymers studied.

It is seen that, for copolymers whose molecules contain the cyano group (R = CN) of the azobenzene moiety (P-4–P-6), the rates in the fast and slow build-up segments of the birefringence curves exceed those of the copolymers with the substituent R = H (P-1–P-3). For example, the constant C [Eq. (1)] for P-3, which is inversely proportional to the birefringence build-up rate, was estimated at 0.22 J cm^{-2}. At the same time, for P-6 containing a polar substituent the constant C is much lower (0.08 J cm^{-2}). Similar trends were observed for the rates B in the slow build-up segments of the kinetic curves of the birefringence. The constants B of copolymers P-4–P-6 exceed those of P-1–P-3, for example, fivefold in the case of P-4 vs. P-1.

Broadening of the spectrum of the relaxation time β in the slow build-up stage suggests gradual complication of the photoorientation process with lengthening of the methylene spacer n. At the same time, β in the fast build-up stage is independent of n, which suggests only one birefringence build-up process in the initial stage of irradiation (up to 100 s). Most probably, this is photoorientation of the dye molecules in defective domains of the sample.

Let us discuss how the polarity of the terminal group R, as well as the length of the aliphatic spacer between the polymer chain and azobenzene moiety, affect the birefringence Δn. Notably, for both fast and slow build-up processes, the photoinduced birefringence of P-4–P-6 copolymers passes through a maximum. The largest birefringence is characteristic of

P-5. This unambiguously suggests a strong influence of the steric factor on the photoorientation process.

To explain the relationships revealed in this study, we will refer to papers by Ho *et al.* [11] and Meng *et al.* [12]. These authors noted that the polarity of the photochromic and mesogenic moieties of macromolecules strongly affect the parameters of the photoorientation process. This influence is the strongest when both the mesogenic and photochromic moieties in the copolymer contain polar cyano groups. Strong Coulomb interaction of the polar fragments increases the efficiency of transfer of the orienting action from the azonbenzene to mesogenic moiety, which suggests cooperativity of the motions of the photoactive groups of the dye and inert mesogenic moieties. At the same time, the birefringence of comb-shaped photochromic copolymers containing both polar and nonpolar side moieties was not enhanced. This allowed Natansohn *et al.* [11, 12] to conclude that, in the copolymer series studied, the deciding influence on the photoinduced birefringence is exerted by specifically dipole interactions between the side groups of the copolymer. The contribution from the cooperativity of the motions of these moieties is less significant.

As mentioned above, our results agree with the conclusions made in [11, 12] and also suggest the importance of dipole interactions between polar photochromic and mesogenic groups. Indeed, the strength of interaction of dipoles is inversely proportional to the cubed distance. Thus, with increasing distance between the photochromic and mesogenic moieties, the strength of their interaction and, hence, the efficiency of transfer of the orienting action from the photochrome to the mesogene will sharply decrease. Therefore, for P-5 copolymer comprising spacers with $n = 4$, the cooperative interaction between the photochromic azobenzene and mesogenic cyanobiphenyl moieties is the strongest, and P-5 is characterized by the largest birefringence. A decrease in the efficiency of interactions because of the less favorable steric arrangement of the interacting polar groups is responsible for much smaller birefringences in the case of P-4 and P-6 copolymers.

For another series of copolymers, P-1–P-3, containing a nonpolar azobenzene moiety we obtained unexpected results. In these copolymers, photoorientation is also strongly affected by the spacer length. However, in contrast to the above-mentioned relationships, the birefringence for P-2 ($n = 4$) copolymer is the smallest for both fast and slow build-up processes. This once again suggests the importance of dipole interactions and the predominance of the dipole factor over the steric factor. Moreover, we found that the maximum birefringence can be achieved for P-5 copolymer in which both factors are favorably combined.

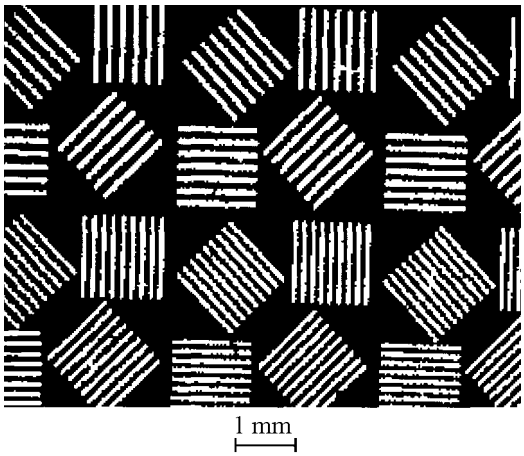

Fig. 3. Image of a standard array recorded on the copolymer P-3 film.

Let us discuss whether the mixtures studied by us are suitable, in principle, as media for optical recording and storage of information. Figure 3 shows as an example the image of a standard test-array obtained upon irradiation of the P-3 copolymer film with unfiltered light from a mercury lamp through a template. The image exhibits reasonable contrast and stability at room temperature.

CONCLUSIONS

(1) A series of comb-shaped photochromic copolymers were synthesized, which contain cyanobiphenyl mesogenic and azobenzene groups differing in the polarity and length of the aliphatic spacer ($n = 0, 4, 10$) between the azobenzene moiety and the polymer backbone.

(2) Kinetic parameters of the birefringence build-up depend on the mutual arrangement of the azobenzene and mesogenic groups, which is manifested in a noticeable influence of the spacer length n on the induced birefringence. For copolymers containing 4-cyanoazobenzene photochromic moieties, the greatest birefringence is achieved for a copolymer in which the mesogenic and photochromic groups are equidistant from the polymer backbone.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Statistical Analysis of the Microstructure and Mechanical Properties of Rolivsans in the Course of Thermal Curing

S. V. Bronnikov, B. A. Zaitsev, and T. E. Sukhanova

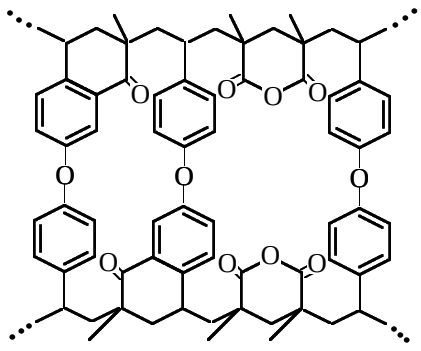
Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received August 8, 2003; in final form, November 10, 2003

Abstract—The reversible aggregation model was applied to analyze the electron-microscopic data for statistical ensembles of Rolivsan microdomains in the course of thermal curing. The experimentally established correlation between the average size of the microdomains in the ensembles and the dynamic Young modulus of the Rolivsan samples cured at different temperatures was interpreted in terms of the kinetic strength concept.

Rolivsans are polyfunctional monomeric–oligomeric systems whose molecules contain styrene-like and/or methacrylate terminal groups [1, 2]. In the course of curing, they form thermally stable cross-linked polymers of a new type, which find various engineering applications [3, 4].

As known [5–7], the polymer network yielded by three-dimensional copolymerization of the monomeric and oligomeric components of Rolivsan at 100–170°C is converted upon further heating (≥180°C) to a network with a much greater thermal stability. It fundamentally differs from the original (essentially, trivial) network both chemically and topologically; also, their supramolecular structure is different. The main structural unit of the new network of exhaustively cured Rolivsans can be represented as follows:



Naturally, rearrangement of such specific densely cross-linked methacrylates under the action of 4,4'-divinyldiphenyl oxide (analogue of *n*-divinylbenzene) into cross-linked polyether-ketones of the Tetralone type affects the properties of new thermosetting binders. In particular, cured Rolivsans surpass the known binders in thermal (softening point 270–330°C and over) and thermooxidative stability.

EXPERIMENTAL

Samples for studies were prepared by open pouring of MV-1 commercial Rolivsan [1–5] into 50 × 50 × 10 mm metallic or Teflon molds, followed by heating at a rate of 5 deg min^{-1} to the end curing temperatures T_0 (150, 160, 180, 200, and 250°C) in the following modes, °C/h: 150/5, 160/5, 170/5, 180/4, 200/4, and 250/9.

Prior to microstructural studies, the Rolivsan samples were cleaved at liquid nitrogen temperature to minimize the plastic deformation at failure. Then, the surfaces of low-temperature chips were etched in a high-frequency oxygen discharge plasma for 15–40 min, depending on T_0. Next, two-stage replicas were prepared by alternately depositing at an angle of 45° to the chip surface (oblique shadow-casting) [8] platinum (Pt) and carbon (C) layers. The Pt/C replicas were detached from the sample surface with an aqueous solution of polyacrylic acid, which was subsequently removed by placing the replicas in distilled water. Next, the Pt/C replicas in the form of thin (30–40 nm) films were deposited onto a copper grid, dried, and examined in a Tesla (Czech Republic) BS-500 transmission electron microscope at the ×20 000 magnification.

The dynamic Young modulus of the cured Rolivsan samples in the form of 34 × 20 × 8-mm parallel-

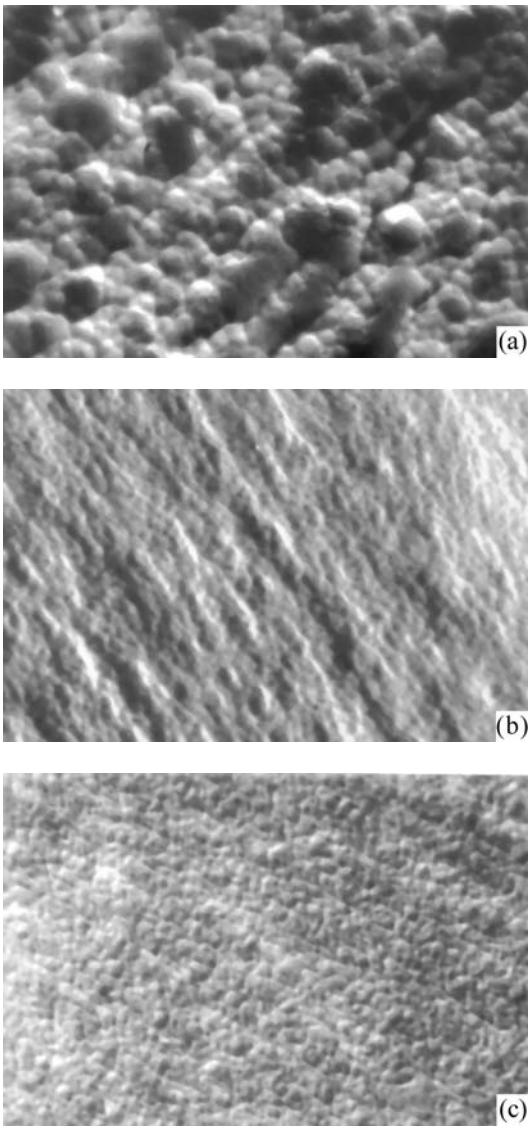

Fig. 1. Electron micrographs of the platinum-carbon replicas from the surface of the Rolivsan samples heated to (a) 150, (b) 190, and (c) 250°C.

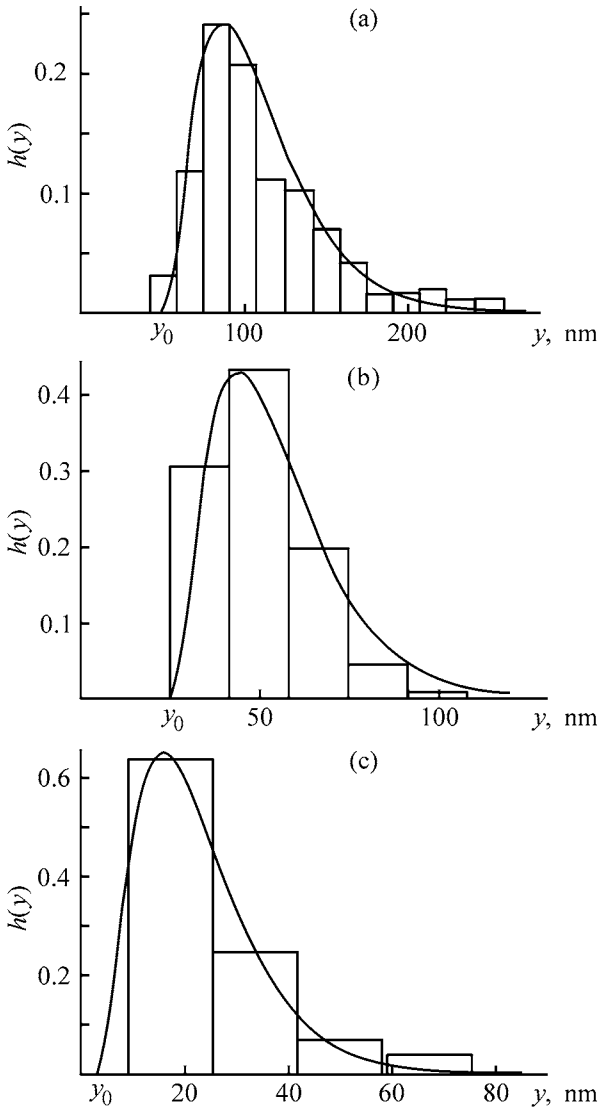

Fig. 2. Statistical distribution $h(y)$ of microdomains over the diameter y, on the surface of Rolivsan samples heated to (a) 150, (b) 190, and (c) 250°C.

epipeds was determined on a facility described in [9] at 20°C at the exciting vibration frequency of 72 Hz.

Figure 1 shows the electron micrographs of the Pt/C replicas from the etched surface of the low-temperature chips of the Rolivsan sample cured at T_0 = 150, 190, and 250°C. It is seen that, like for other cross-linked polymers [5, 6, 10], the surface microstructure of the samples is formed by a set of densely cross-linked microdomains (polymer grains, globules, microdomains) and intergranular layers characterized by a looser polymer network [11–13]. The domains have a close-to-spherical shape, and their linear size (diameter) varies with T_0.

Figure 2 shows the histograms derived from a statistical analysis of the microdomain diameters. From 500 to 4500 microdomains were analyzed in each micrograph. It is seen that, for each T_0, the statistical size distribution patterns for microdomains form common statistical ensembles. For analytical description of these ensembles, we used the reversible aggregation model.

Based on the general principles of chemical kinetics and equilibrium thermodynamics of irreversible processes, we obtained in terms of the reversible aggregation model an expression describing the statistical size distribution $h(y)$ of the structural formations, aggregates [14, 15]:

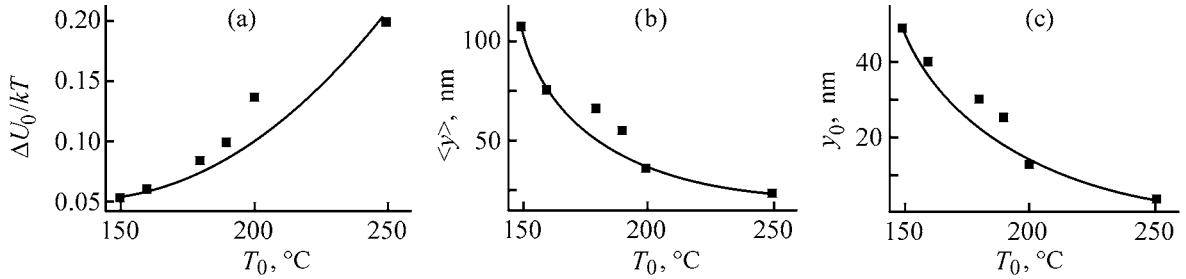

Fig. 3. (a) Reduced aggregation energy $\Delta U_0/kT$ and (b) average $\langle y \rangle$ and (c) nucleation y_0 diameters of microdomains in the Rolivsan samples vs. the heating temperature T_0.

$$h(y - y_0) = A(y - y_0)^m \exp\left[-\frac{(y - y_0)\Delta U}{kT}\right]. \quad (1)$$

Here, A is the normalizing coefficient; $(y - y_0)\Delta U_0$, J, aggregation energy which is a product of the reduced size of an aggregate in the ensemble $(y - y_0)$ by the standard aggregation energy ΔU_0, J m^{-1}; y_0, size of the smallest aggregate; k, Boltzmann constant; T, absolute temperature; and m, dimensionality of the space in which the aggregate grows (for the surface, $m = 2$).

The key role in expression (1) is played by the ΔU_0 parameter determining the equilibrium size distribution of the aggregates.

The lines in Fig. 2 represent the experimental statistical data obtained using Eq. (1). Our results suggest the applicability of the reversible aggregation model to the objects of study. Notably, this model has been successfully applied earlier to derive statistical size distributions for microdomains yielded by solid-phase intramolecular chemical transformations of polyamido acids of various chemical structures to polyimides [16–19]. Our results suggest that this model is suitable for describing the kinetics of various solid-state chemical reactions.

A practically important characteristic of the statistical distribution is the average size of an aggregate in the ensemble, which is defined as the normalized expectancy:

$$\langle y \rangle - y_0 = \frac{\int_0^\infty (y - y_0)\, h(y - y_0)\mathrm{d}y}{\int_0^\infty h(y - y_0)\mathrm{d}y} = \frac{(m + 1)kT}{\Delta U_0} = \frac{3kT}{\Delta U_0}. \quad (2)$$

Figure 3 shows how the reduced standard aggregation energy $\Delta U_0/kT$, as well as the average ($\langle y \rangle$) and nucleation (y_0) diameters of the microdomains, vary with T_0. It is seen that, upon high-temperature heating, the supramolecular structure of cured Rolivsan gets more uniform: $\Delta U_0/kT$ increases approximately fivefold with temperature raized from 150 to 250°C, which means that the statistical distribution of the diameters of the microdomains narrows, and $\langle y \rangle$ and y_0 decrease ten- and fivefold, respectively.

The fact that the size of the polymer grains diminishes in the course of high-temperature curing of Rolivsans is evidently due to chemical and topological rearrangements in the polymer networks constituting these grains. These rearrangements involve scission of polymer chains and cross-links, accompanied by (poly)cyclization, cross-linking, and degradation reactions [5–7]. These processes are responsible for decreased size and denser packing of the polymer grains and forthe resulting optimization of the supramolecular structure.

The optimization of the structure of Rolivsan in the course of thermal curing is confirmed by the results of dynamic mechanical measurements, shown in Fig. 4. It is seen that, with rising T_0, the dynamic Young modulus E' of the Rolivsan samples tends to increase, most steeply at temperatures corresponding to formation of the primary network (T_0 = 150–170°C). To establish the practically important correlation between the microstructure and the macroscopic characteristics, we examined the $\langle y \rangle(T_0)$ and $E'(T_0)$ dependences.

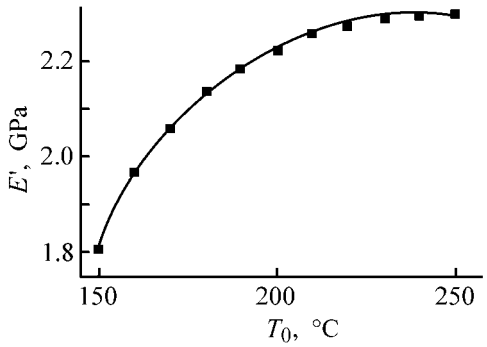

Fig. 4. Dynamic Young modulus E' of the Rolivsan samples vs. the heating temperature T_0.

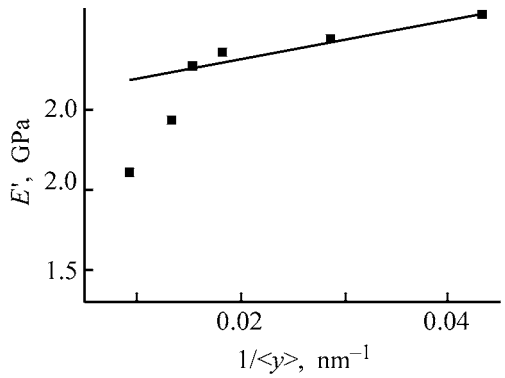

Fig. 5. Dynamic Young modulus E' of Rolivsan samples vs. the inverse average diameter $1/\langle y\rangle$ of microdomains in the course of curing.

In terms of the kinetic failure concept, the strength of a solid, σ, is determined by the characteristics of the interatomic bonds (elasticity E, equilibrium length r_0, and ultimate strain ε^*), free path length of phonons Λ, failure activation energy ΔU_0, and the time before failure τ [20–22]:

$$\sigma = \frac{Er_0\varepsilon^*}{\Lambda}\left(1 - \frac{kT}{U_0}\ln\frac{\tau}{\tau_0}\right), \quad (3)$$

where $\tau_0 \approx 10^{-13}$ s. It can be suggested that, in amorphous substances, including polymers, phonons are scattered at the boundaries of structural (supramolecular) formations, i.e., that the parameter Λ is determined by the average diameter of the microdomains $\langle y\rangle$:

$$\Lambda \cong \langle y\rangle. \quad (4)$$

Vettegren' *et al.* [23, 24] found that the failure and the relaxation of stresses have a common thermal-fluctuation nature, which is manifested in identical kinetic equations describing the temperature and time dependences of the strength and the Young modulus. The common nature of the processes of interest is reflected by the known empirical equation, which relates the dynamic Young modulus E' and the strength [25]:

$$E' = A\sigma + C, \quad (5)$$

where $A \cong 0.1$ and C are empirical parameters. Taking into account Eqs. (3) and (4), we write Eq.(5) as

$$E' = \frac{0.1Er_0\varepsilon^*}{\langle y\rangle}\left(1 - \frac{kT}{U_0}\ln\frac{\tau}{\tau_0}\right) + C = \frac{B}{\langle y\rangle} + C, \quad (6)$$

where

$$B = 0.1Er_0\varepsilon^*\left(1 - \frac{kT}{U_0}\ln\frac{\tau}{\tau_0}\right).$$

Equation (6) was tested in the E'–$1/\langle y\rangle$ coordinates, as illustrated by Fig. 5. It is seen that the experimental data can be fitted with a linear dependence represented by Eq. (6). The fact that the first two points (corresponding to T_0 150 and 160°C) fall out of this dependence is evidently due to the lower ductility (Er_0 parameter) of the polymer chain in the primary network of a weakly cured Rolivsan, compared to that in the final stage of high-temperature curing (densely cross-linked network).

CONCLUSIONS

(1) In the course of thermal curing, microdoamins in Rolivsan form statistical ensembles which can be described in terms of the reversible aggregation model.

(2) With increasing curing temperature, the statistical size distribution parameters of the domains in Rolivsan exhibit the following trends: The aggregation energy tends to grow, and the average and nucleation sizes of the microdomains, to decrease.

(3) A weak inverse proportionality was revealed between the average size of the microdomains and the dynamic Young modulus of thermally cured Rolivsan samples; it was explained in terms of the kinetic strength concept.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Chemical Modification of Polypropylene with Isocyanate–ε-Caprolactam Mixtures

A. M Gafarov, S. S. Galibeev, A. M. Kochnev, and V. P. Arkhireev

Kazan State Technological University, Kazan, Tatarstan, Russia

Received October 3, 2003; in final form, February 2004

Abstract—Modification of polypropylene with isocyanate–ε-caprolactam mixtures was studied. The effect of these mixtures as influenced by the sequence of introduction of their components was examined.

Physical and chemical modification of polypropylene (PP) is performed to obtain PPs with required performance and process properties, to improve their chemical and supramolecular structure formed under uncontrollable production conditions, and to restore or change the properties of spent articles for their repeated use [1].

In some cases, polypropylenes are modified with mixtures of reactive compounds, as modification with individual additives does not ensure the required result. Previously [2], we have shown that isocyanate (IC)-epoxide (EP) binary mixtures used as modifiers for polyolefins (PO) synergistically affect both the heat resistance and the strength of the samples. This is due to grafting of homo- or copolymers of IC and EP to the terminal unsaturated bonds of PO [3–5].

Thus, a search for other binary systems capable of copolymerization under conditions of PP reprocessing is a topical problem. Among these systems are mixtures of aromatic and aliphatic diisocyanates with ε-caprolactam (ε-CL). Our previous studies have shown that these substances can copolymerize by the anionic mechanism in the presence of sodium organic compounds. The strength and thermal properties of the resulting copolymer can be varied in a wide range [6].

The aim of this study was to examine modification of PP with mixtures of IC [tolulene-2,4-diisocyanate (TDI), diphenylmethane-4,4'-diisocyanate (MDI), and product of reaction of polyoxymethyleneglycol with TDI (SKU-PFL)] with ε-CL, to determine the optimal concentrations, and to develop an efficient procedure for introduction of these modifiers.

EXPERIMENTAL

The IR spectra of PP modified with ε-CL-TDI mixture contain a new band at 3400–300 cm^{-1}, assigned to the N–H bonds of amide and urethane groups formed in opening of the lactam ring; and also the band at 1680–1620 cm^{-1} [–C(O)–N< in the ternary imide group, formed by the rupture of the N=C bond in isocyanate] (Fig. 1). In addition, the band of terminal unsaturated bonds of PP at 888 cm^{-1} is weakened owing to the reaction with isocyanate (Table 1).

The reaction of PP with the binary mixtures probably involves two steps. The first is copolymerization of IC with ε-CL by the anionic mechanism to form

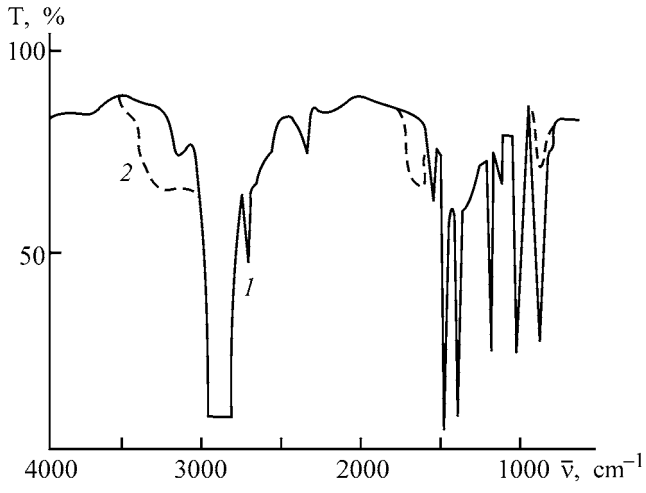

Fig. 1. IR spectra of (*1*) initial PP and (*2*) PP modified with 3 wt % of ε-CL–TDI mixture (1 : 1 weight ratio). (T) Transmission and ($\bar{\nu}$) wave number.

1070-4272/04/7704-0618 © 2004 MAIK "Nauka/Interperiodica"

amides, and the second is grafting of the resulting copolymers via unreacted isocyanate groups to unsaturated bonds of PP.

We studied three sequences of modifier introduction: (1) IC is added to a PP melt, a sample is rolled for 5 min, and ε-CL is added; (2) ε-CL is introduced and then IC is introduced in 5 min; and (3) IC and ε-CL are added simultaneously. Anionic copolymerization of IC and ε-CL was catalyzed by sodium caprolactam.

Since the activities of the modifiers with respect to PO differ, different polymeric structures grafted to PP should be formed at different introduction sequences of the modifier components.

In the first case, IC homopolymerizes to form relatively high-molecular-weight fragments consisting of tertiary polyamides units that can be added via unreacted functional groups to multiple bonds of PP. Introduction of ε-CL enlarges the grafted fragments by reaction with free iocyanate groups to form amide structures.

Since ε-CL ring is not opened in the presence of Na-CA [8], chemical reactions occurring in PP in the case of the second and third introduction sequences are relatively complex. Intense homopolymerization of ε-CL is activated by diisocyanates or *N*-acetylcaprolactam [9]. Hence, ε-CL does not change in the course of the second sequence until diisocyanate is added. In the presence of diisocyanate, ε-CL copolymerizes with lactam to form copolyamides capable of addition via free isocyanate groups to unsaturated bonds of PP.

Thus, the polymer grafted to PP with the first sequence of modifier introduction has mainly the block structure (it consists of tertiary polyimide units bound with the macromolecule via amide groups), whereas the structure of the polymer grafted with the second and the third sequence consists of alternating amide and tertiary imide units.

As can be seen from Table 2, samples with the best performance and process properties were obtained by simultaneous addition of the modifiers.

The ultimate stress σ_u of the samples modified by simultaneous addition of the modifiers is higher than that of the samples prepared by the separate addition of the components. Modification with MDI does not change σ_u and that with ε-CL even decreases σ_u from 34 to 31 Mpa, whereas introduction of a mixture of these compounds increases σ_u to 38 MPa. When MDI is replaced with TDI in the mixture, σ_4 increases to 42.5 MPa (Fig. 2). Introduction of a modifier mixture increases the melt flow index of a polymer (MFI). However, the viscosity of the melt also decreases

Table 1. Change in the content of terminal vinylidene bonds in PP after modification with IC–ε-CL* system

Modifier	log I_{888} : log I_{1380}

97	2.8	0.2	12.4	35.9
97	3	0	11.6	36.1

after introduction of IC in amount from 1 to 2 wt % (Table 3).

Modification with the binary mixtures improves also the following thermal properties of PP: induction period τ_{ind} and rate v_{ox} of autooxidation, temperature of 5 and 50% weight loss T_5 and T_{50}, oxidation onset temperature T_{onset}, and equilibrium oxidation temperature T_{ox} (Tables 4, 5). Introduction of a mixture of 1 wt % MDI and 1 wt % ε-CL increases τ_{ind} by 21 min, whereas introduction of 1 wt % MDI increases τ_{ind} by only 10 min. Addition of 1 wt % ε-CL has no effect on this parameter.

The most prominent result of modification with the binary mixtures is a decrease in v_{ox}. The oxidation rate is determined from the slope of the oxidation curve. Oxidation of PP modified with almost all the mixtures examined is slower than that of initial PP and PP modified with IC and ε-CL taken separately (Table 4).

Previously, we have shown that the structure and properties of IC–ε-CL copolymer prepared in the presence of anionic initiators substantially depend on the monomer ratio [7, 10]. In this study, we modified PP with IC–ε-CL binary mixtures with different weight ratios of the components.

As can be seen from Table 5, the flexibility of the macromolecules (estimated from the change in the activation barrier of failure U_0) decreases, and hence the ultimate stress increases.

This is due to the fact that the content of tertiary imide units (which are more rigid than the amide units) in the grafted copolymer increases with increasing IC concentration in the modifying system. In addition, since IC is a bifunctional compound, a more branched copolymer is formed with increasing IC concentration. As a result, the mobility of the grafted macromolecule decreases owing to steric hindrance.

A slight decrease in the ultimate stress after modification with the mixtures with a high IC content (Table 5) is due to a strong acceleration of copolymerization of IC with ε-CL upon PP reprocessing. Clearly, in this case, the number of steps of addition of the isocyanate groups to the double bonds of PO decreases, which deteriorates the modification efficiency.

CONCLUSIONS

Polypropylene was modified with isocyanate–ε-caprolactam mixtures. A synergistic increase in the strength, viscosity, and thermal stability of the modified polymer was observed. We suggest that this is due to the reaction of isocyanate–ε-caprolactam copolymers with unsaturated bonds of polypropylene.

Abstract—Precipitation of a model kaolin suspension and dehydration of the excess active sludge were studied as influenced by copolymers of 2-(*N*,*N*-dimethyl-*N*-benzylammonio)ethyl methacrylate chloride and its copolymers with acrylamide and 2-(*N*,*N*,*N*-trimethylammonio)ethyl methacrylate methyl sulfate.

Hydrophilic cationic polyelectrolytes based on aminoalkyl (meth)acrylates and their ammonium salts are promising reagents for water treatment [1–3]; among them, poly-2-(*N*,*N*,*N*-trimethylammonio)ethyl methacrylate methyl sulfate, poly-2-(*N*,*N*,*N*-trimethylammonio)ethyl methacrylate chloride and their copolymers with acrylamide are the most widely used compounds. The flocculation power of copolymers simultaneously containing ionic groups and bulky hydrophobic fragments is also of particular importance. It is expected that the flocculation power will increase with enhancement of the polymer-polymer hydrophobic interactions.

In this study, we examined the flocculation power of poly-2-(*N*,*N*-dimethyl-*N*-benzylammonio)ethyl methacrylate chloride (poly-DMAEMA · BC) and copolymers of DMAEMA with nonionic acrylamide (AA) and cationic 2-(*N*,*N*,*N*-trimethylammonio)ethyl methacrylate methyl sulfate (DMAEMA · DMS) using model and real dispersed systems.

EXPERIMENTAL

Poly-DMAEMA · BC and poly-DMAEMA · DMS were synthesized by the ampule procedure (2 M monomer concentration) in aqueous solution at 25 ± 0.5°C. The monomers were prepared by alkylation of dimethylaminoelthyl methacrylate with benzyl chloride and dimethyl sulfate at 0–3°C in acetone with subsequent recrystallization from acetone-acetonitrile mixture; acrylamide was additionally purified by recrystallization from acetone. Copolymerization of DMAEMA · BC with DMAEMA · DMS and AA was performed in aqueous solution at 25 ± 0.5°C at various initial monomer ratios. Polymerization was carried out to 96–98% conversion. *tert*-Butylperoxy-2-propanol initiator was prepared by the procedure described in [4], with subsequent vacuum sublimation. According to the data of potentiometric titration for chloride ions, the copolymer composition corresponded to that of the monomeric mixture. The viscosity of dilute solutions was measured using an Ubbelohde viscometer at 30°C in the presence of sodium chloride (0.1–0.6 M). The intrinsic viscosity was determined by extrapolation of η_{sp}/c to $c \to 0$.

As model dispersion, we used an aqueous kaolin suspension (KSD brand, 7×10^{-6} m particle size) with the concentration of the dispersed phase of 0.8 wt %, which eliminates the effect of hindered sedimentation [5]. The flocculant concentrations were varied in the 0–40 mg g^{-1} range. The flocculation was carried out in 250-ml glass cylinders. The suspensions after polyelectrolyte addition were mixed in sealed vessels with disc stirrers for 2 min (0.3 s^{-1} frequency). After storage for 60 min, the optical density *D* of the supernatant was measured on a KFK-3 device at λ = 490 nm (distilled water reference). The supernatant turbidity τ was calculated from the following expression:

$$\tau = 2.3Dl^{-1}, \quad (1)$$

where *l* is the cell length (cm).

Using the results of measurements, we calculated the optimal polyelectrolyte concentrations c_{opt}, provid-

ing the greatest decrease in the supernatant turbidity, and evaluated the clarification effect D_τ from Eq. (2)

$$D_\tau = \tau_0/\tau - 1, \quad (2)$$

where τ_0 and τ are the supernatant turbidities in the absence of additives and after polyelectrolyte addition, respectively.

The flocculant activity was determined from the following expression:

$$\lambda = D_\tau/c_p^{-1}, \quad (3)$$

where c_p is the polymer concentration.

To study the precipitate dehydration, we used the active sludge from installations for biological treatment of household wastes (Volgogradvodokanal Municipal Unitary Enterprise). The flocculant solution (0.1% concentration) was added to the active sludge (100 ml), and the mixture was stirred by tenfold overflow. After settling for 30 s, the precipitate was filtered off and additionally squeezed for 1 min under a 5-kg load. The water content in the cake was determined by gravimetry [6]. The efficiency of the active sludge dehydration, D_w, was determined as follows:

$$D_w = W_0/W - 1, \quad (4)$$

where W_0 and W are the contents of water in the initial sludge and in the squeezed precipitate upon addition of a certain portion of the polyelectrolyte, respectively.

The approximate intensity of the intermolecular hydrophobic interactions can be evaluated from the behavior of the polyelectrolyte in aqueous salt solutions. The viscometric data (Fig. 1) showed that, with increasing salt concentration in the 0.1–0.6 M range, the thermodynamic quality of the solvent becomes worse, which is confirmed by a nonlinear decrease in the intrinsic viscosity of poly-DMAEMA · BC. According to the modern concepts, this is accompanied by a decrease in the effective charge of macroions and in the number of the polymer–solvent contacts and by an increase in the number of intramolecular contacts, which results in compaction of macromolecular globules. As for poly-DMAEMA · DMS, its intrinsic viscosity also decreases in the above concentration range, but the [η]–C_{NaCl} dependence is characterized by the minimum viscosity of 3.25 dl g^{-1}, corresponding to the conformation of the uncharged globules. In con-

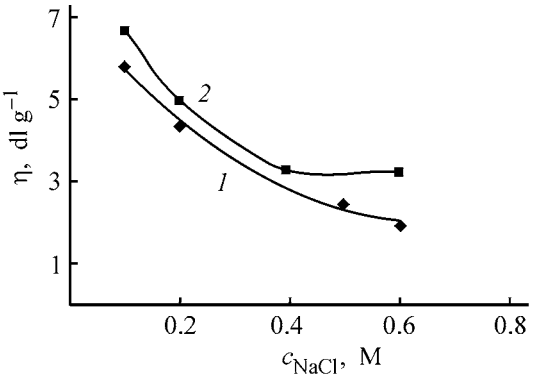

Fig. 1. Intrinsic viscosity of polyelectrolyte η as influenced by the inorganic salt concentration c_{NaCl} in solution. (*1*) PE-7 and (*2*) PE-6.5.

trast to hydrophilic poly-DMAEMA · DMS and poly-1,2-dimethyl-5-vinylpyridinium methyl sulfate (poly-1,2-DM-5-VPMS) [7] soluble even in concentrated aqueous salt solutions (2 M), the solubility of poly-DMAEMA · BC decreases at NaCl concentration of 0.8 M. The phase separation in the system is probably due to intense hydrophobic interactions between the chain units, which become predominant at shielding of the macroion charges. Since no phase separation is observed with poly-DMAEMA · DMS, we assumed that specifically the benzyl substituents in the DMAEMA · BC chain promote the chain association. The hydrophobic interactions can also affect the adsorption of macroions on the particles and formation of interparticle bridges during flocculation.

The flocculation of the kaolin suspension was studied in the presence of DMAEMA · BC homo- and copolymer samples, whose characteristics are listed in Tables 1 and 2.

The experimental dependences of the supernatant turbidity on the flocculant concentration in the system are shown in Figs. 2a–2c. As can be seen, the flocculation of the kaolin suspension with cationic polyelectrolytes based on DMAEMA · BC and DMAEMA · DMS

* Data taken from [6].

proceeds in accordance with classical dependences in the liquid–solid–polyelectrolyte systems. The dependence of the supernatant turbidity on the flocculant concentration is nonmonotonic and consists of three portions. At low flocculant concentrations (>0.08 mg g^{-1}), the supernatant turbidity gradually decreases, which corresponds to destabilization of the dispersed system. In the 0.08–1.00 mg g^{-1} concentration range, the degree of the suspension clarification is the highest. At higher polymer concentrations, the supernatant turbidity sharply increases due to the protective effect of the flocculant. Stabilization is determined by sorption conditions of the excess macromolecules on the solid phase surface; this phenomenon is observed upon recharging of the disperse particle surface as a result of electrostatic repulsion or steric hindrance.

As can be seen from Fig. 1 and Table 3 describing the optimal conditions of kaolin flocculation, the flocculation effects of homopolymers based on DMAEMA · BC (PE-4, PE-7) are similar in the given concentration range, and greater by a factor of 1.1–1.7 than that of PE-6.5. It was found that DMAEMA · BC surpasses poly-1,2-DM-5-VPMS [6] in both the flocculation effect (by a factor of 1.2–1.5) and flocculation activity.

The copolymers of DMAEMA · BC with AA and DMAEMA · DMS also exhibits a fairly high flocculation power (Figs. 2b, 2c). The best results of coagulation of kaolin suspensions with the copolymers are listed in Table 4.

According to the experimental data, the flocculation effect of the kaolin suspension with DMAEMA ·

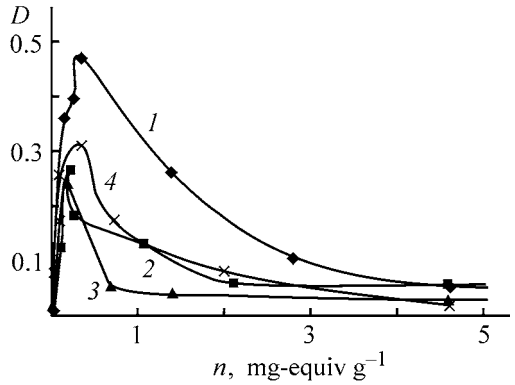

Fig. 3. Flocculation effect *D* of a 0.8% kaolin suspension as influenced by the reduced density of the total charge of macroions *n*. (*1*) PE-4, (*2*) 25-AA, (*3*) 50-AA, and (*4*) 75-AA.

BC · AA copolymers is 50–155 and does not exceed the optimal values for homopolymers. At the same time, the range of the optimal flocculation conditions becomes narrower and shifts toward higher flocculant concentrations (0.1–1.0 mg g^{-1}). This is probably due to the smaller number of cation-exchange centers in the copolymer (as compared to the homopolymer) involved in sorption of macromolecules on the surface of dispersed particles, whereas the optimal flocculation conditions correspond to the certain and constant ratio of the surface particle charge and total charge of macroions.

Actually, the dependence of the flocculation effect on the total charge of macroions in homo- and copolymers per unit weight of the dispersed phase (Fig. 3) shows that the highest flocculation effect for homopolymers and copolymers of DMAEMA · BC with AA for all the compositions studied corresponds to a rather narrow range of charge densities *n* from 0.176 to 0.350 mg-equiv g^{-1}. A decrease in the flocculation effect of copolymers suggests that the process efficiency is determined by conditions of sorption and fixation of macromolecules on the surface of dispersed particles, which changes as the number of macromolecule chain units containing a bulky hydrophobic fragment and a salt group decreases. The insignificant increase in the flocculation power of 75-AA (Fig. 3) is probably due to the relatively high molecular weight of the sample, which is indirectly confirmed by its intrinsic viscosity.

In the case of DMAEMA · BC–DMAEMA · DMS copolymers (as also for homopolymers), destabilization of the kaolin suspension is observed in the 0.01–1.00 mg g^{-1} concentration range, and the flocculation effect amounts to 55–150, which is comparable with the effect of PE-6.5 and DMAEMA · BC · AA copolymers, but smaller by a factor of 1.8–2.3 than that for poly-DMAEMA · BC.

As can be seen from a comparison of the flocculation parameters of DMAEMA · BC · AA copolymers with a highly active flocculant based on 1,2-DM-5-VPMS (Table 4, [6]), the flocculation effect of acrylamide copolymers based on DMAEMA · BC only slightly exceeds that of the corresponding pyridinium flocculants (by a factor of 1.2–1.3), but, if account is taken of the concentration range studied, their activity is higher than that of the pyridinium analogues by a factor of 1.6–1.9.

The efficient water purification in treatment of household wastes is impossible without use of biological methods employing active sludge. To maintain the operation status of the aeration tanks, the excess sludge biomass should be regularly removed, with subsequent flocculation and filtration. Since the hydrophilic sludge particles strongly retain water in their hydration shells, dehydration of the sludge suspension on the filter is an important problem.

Taking into account the promising data on the flocculation of the model kaolin suspension, the DMAEMA · BC (co)polymers were tested in dehydration of the excess active sludge formed at the sewage treatment plants. The residual water content in the cake was used as a criterion of the flocculant efficiency.

Analysis of the flocculant effect on the water content in the sludge on the filter (Fig. 4) shows that the minimum water content in the cake reaches 83–88%, and it is attained at the polyelectrolyte concentration in the suspension of 2–3 mg g^{-1}. Subsequent increase in the polyelectrolyte charge does not noticeably affect the cake moisture content, and in the presence of PE-7 it even slightly increases. The optimal concentration range of the polymer in flocculation of the active sludge is 2–4 mg g^{-1}, and further increase in the polyelectrolyte concentration is not appropriate. As can be seen from Fig. 4, the minimum water con-

tent of 83.5–85.0% in the cake is attained on adding to the sludge suspension PE-6.5 and PE-7 homopolymers containing hydrophobic benzyl and methyl groups. Addition of hydrophilic AA units to the macromolecular chains, apparently, decreases the number of hydrophobic polymer-sludge contacts, which hinders the sorption of macromolecules on the sludge particles. As a result, the hydrophobicity of the surface layer decreases, which increases the residual water content in the cake to 90% in the sample containing 75 mol % AA.

Since the initial water content in the industrial sludge samples varies in a wide range, the effect of DMAEMA · BC (co)polymers was evaluated with a dimensionless parameter (dehydration power). The data on the sludge dehydration listed in Table 5 show that all the polymers based on DMAEMA · BC are highly active, and the greatest effect on the active sludge dehydration was observed for PE-7 sample (which is greater by a factor of 1.4 than that that for poly1,2-DM-5-VPMS) and for the copolymer of 1,2-DM-5-VPMS and vinylpyrrolidone (1-VP) containing 10% nonionic comonomer. The effect of PE-7 on the active sludge dehydration is also greater by a factor of 1.1 as compared to 1-VP(AA) terpolymer containing 1 mol % AA and 9 mol% vinylpyrrolidone [6].

Our experimental data showed the higher activity of poly-DMAEMA · BC in the dehydration of the active sludge and in flocculation of kaolin suspensions as compared to hydrophilic AA copolymers. This is probably due to different conformation states of homo- and copolymer macromolecules at the phase boundary and conditions of bridging interactions at flocculation. We believe that the hydrophobicity of amphiphilic poly-DMAEMA · BC macromolecules strongly increases due to charge shielding in the course of sorption. In flocculation, new polymer–polymer interactions arise along with the polymer–particle contacts. These interactions can provide additional contacts between the particles with sorbed macromolecules and thus promote flocculation. A similar phenomenon was observed for 1,2-DM-5-VPMS copolymers containing nonionic vinylpyrrolidone units [8]. The efficiency of the active sludge dehydration in the presence of hydrophobic aggregates is greater as compared with that for hydrophilic copolymers.

The sorption of copolymers containing nonionic AA units is probably accompanied by the formation of polymeric bridges in which the content of hydrophobic units is relatively small. As a result, they strongly retain the solvent molecules by Van der Waals interactions. The aggregates that are not stabilized by the polymer-polymer interactions and contain solvent molecule in the interparticle space, are readily broken. As a result, the flocculation with copolymers is less efficient as compared to that with homopolymers.

Table 5. Activity of cationic flocculants in dehydration of excess active sludge

Flocculant	c, mg g^{-1}	W, %	$D_w \times 10^3$
Poly-1,2-DM-5-VPMS*	1.5	87.4	137
1-VP*	2.5	87.5	139
1-VP(AA)*	3.4	84.9	174
PE-7	2.0	83.5	190
PE-3.56	1.0	85.0	169
PE-6.5	3.0	84.9	171
25-DMS	2.0	86.6	148
25-AA	2.0	88.9	117

* Data take from [6].

CONCLUSIONS

(1) The data on the flocculation of model kaolin suspension and dehydration of excess active sludge in the presence of cationic flocculants show that the flocculation performance of poly-2-(*N*,*N*-dimethyl-*N*-benzylammonio)ethyl methacrylate chloride is better than that of copolymers of 2-(*N*,*N*-dimethyl-*N*-benzylammonio)ethyl methacrylate chloride with nonionic acrylamide and cationic 2-(*N*,*N*,*N*-trimethylammonio)ethyl methacrylate methyl sulfate.

(2) The greater flocculation power of homopolymer of 2-(*N*,*N*-dimethyl-*N*-benzylammonio)ethyl methacrylate chloride is probably due to the formation of additional bridges and more complete involvement of the particles in the flocculation, owing to the hydrophobic polymer–polymer contacts.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Temperature on Formation of Structure and on Mechanical Properties of Plasticized Polyether–Urethane–Urea

V. V. Tereshatov, E. N. Tereshatova, and M. A. Makarova

Institute of Technical Chemistry, Ural Division, Russian Academy of Sciences, Perm, Russia

Received December 9, 2003

Abstract—The influence exerted by temperature and time of curing on the strength and deformation properties of plasticized polyether–urethane–urea was examined. Addition of a plasticizer ensures the optimal rheological properties, and the resulting material cured at a low temperature exhibits high mechanical characteristics.

Polyurethane–ureas (PUUs) derived from polyethers exhibit high strength and deformation properties and resistance to oil, benzine, and many aggressive media. Therefore, articles made of these materials find wide application. The rheological properties and mechanical characteristics of PUUs can be controlled by adding various plasticizers [1–3]. In preparation of PUUs, plasticizers can also act as solvents for powdered diamines whose vapors and dusts are toxic [4].

The elastomers under consideration belong to microheterogeneous polymer systems with incomplete phase segregation of flexible polyether and rigid urethane–urea segments. The structure and properties of PUUs may appreciably depend on the history of their preparation. As a rule, these materials are prepared at temperatures of 80 to 140°C [3–6]. It is believed that the strength of PUUs can appreciably grow when the temperature at which the reaction mixture is cured increases [4]. However, it is impossible to find from the available data any regular trends in the influence of the curing temperature and time on the mechanical properties of plasticized polyurethane–ureas.

In this study, we examined the influence of the curing temperature on the mechanical properties of plasticized PUU and compared the results obtained with those for the nonplasticized samples. Our goal was to find the temperature conditions under which the resulting material exhibits high strength and deformation characteristics. We took into account the fact that, as the curing temperature is increased, the thermal shrinkage of the polymeric material after its cooling to the service temperature grows. This is especially undesirable for big items used for cleaning of oil and gas pipelines.

EXPERIMENTAL

Experiments were performed with PUU derived from SKU-PFL-100 prepolymer ($M \sim 1400$) plasticized with readily available di(2-ethylhexyl) phthalate (DEHP). The prepolymer was prepared by the reaction of oligo(tetramethylene oxide)diol ($M \sim 1000$) with toluene 2,4-diisocyanate taken in a twofold excess. The prepolymer was preliminarily subjected to a vacuum treatment for 20 min in a mixer at 50 ± 1°C. Then a weighed portion of aromatic diamine, 3,3'-dichloro-4,4'-diaminodiphenylmethane (Diamet Kh), dissolved in the plasticizer (or as a melt, in preparing a nonplasticized material) was added. The components were stirred for 3 min at 50 ± 1°C. The resulting mixture was poured into molds, which were subsequently kept at different temperatures. After keeping for the required period, the cured samples were unloaded, and their mechanical properties were determined under equal conditions.

All the experiments were performed at the ratio of the NCO (prepolymer) and NH_2 (diamine) groups less than unity (0.95), taking into account the published data that the dense chemical network negatively affects the mechanical properties of segmented polyurethane materials [4]. This allowed us to decrease the probability of formation of biuret cross-links.

The rheological properties of the reaction mixture were studied with a Rheotest-2 viscometer (cone–plate working unit) at a shear rate of 180 s^{-1}. The mechan-

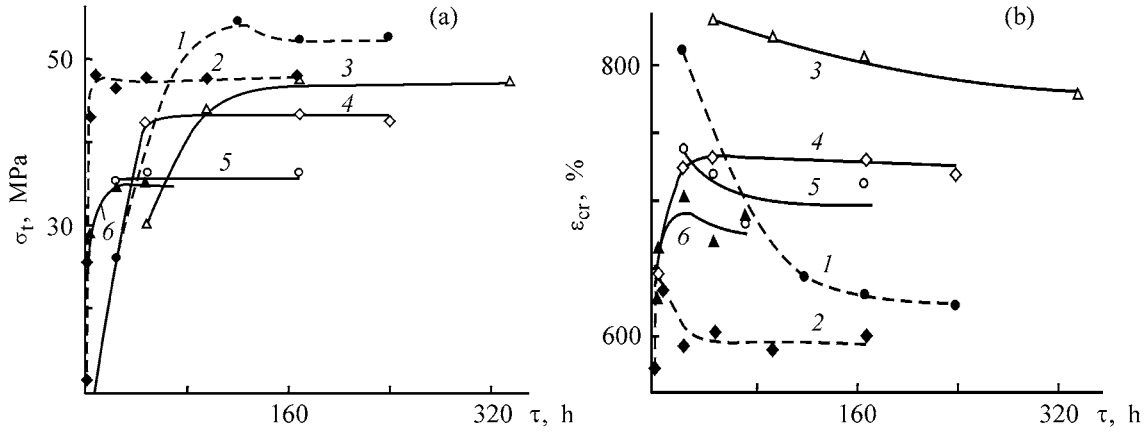

Fig. 1. (a) Strength σ_t and (b) relative critical strain ε_{cr} of (*1*, *2*) nonplasticized and (*3*–*6*) plasticized PUUs vs. the curing time τ. Curing temperature, °C: (*1*, *3*) 35, (*4*) 50, (*2*, *5*) 80, and (*6*) 100.

ical characteristics of PUU {tensile strength σ_t (ultimate stress for the initial cross section of a sample), relative critical strain ε_{cr}, and breaking stress

$$f_b = \sigma_t[(\varepsilon_{cr} + 100)/100],$$

(calculated for the actual cross section of the sample)} were determined at 23 ± 2°C, at the extension rate of 0.28 s^{-1}.

The effective density of the chemical network of PUU, N_c, was calculated with samples subjected to equilibrium swelling in tributyl phosphate, using the procedure described in [7].

The spectroscopic study of association of urea and urethane groups in the PUUs prepared at different temperatures was performed with a Bruker IFS 66/S Fourier spectrometer. The samples were prepared as films without solvents. The amide I band (C=O vibrations, ν 1620–1750 cm^{-1}) was used as analytical band.

The assignment of the components of the amide I band was made in accordance with [8, 9]. For convenience of comparison, the spectral curves were normalized with respect to the band at ν 1575 cm^{-1}. The spectra were compared at complete conversion of the isocyanate groups, as judged from the disappearance of absorption at ν 2275 cm^{-1}.

Figure 1 shows the dependences of the strength and deformation characteristics of PUU samples plasticized with 10% DEHP on the time of their curing at different temperatures (from 35 to 100°C). The corresponding curves for the nonplasticized samples are also shown (curves *1*, *2*). These results indicate that, as the temperature of curing of the plasticized samples is lowered from 80–100 (curves *5*, *6*) to 35–50°C (curves *3*, *4*), the strength and deformation characteristics of PUU are enhanced to a greater extent than in the absence of the plasticizer. Although constant values of σ_t and ε_{cr} are attained in essentially different times, the final mechanical properties of the nonplasticized samples cured at 35 and 80°C differ insignificantly (Fig. 1, curves *1*, *2*).

Comparison of the IR spectra (region of amide I band) of the samples cured at 80°C for different times shows that, as the curing time is increased from 1 to 9 h, the band at ν 1640 cm^{-1} grows in intensity (Fig. 2a). This indicates that the strongest structural formations, self-associates of the urea groups localized in domains of rigid urethane–urea segments [9], grow in amount; accordingly, the elastomer strength increases.

Longer curing at this temperature does not appreciably affect the association of rigid segments and the mechanical properties of the material, as can be clearly seen from comparison of the IR spectra and mechanical characteristics of nonplasticized PUU samples cured for 9 and 168 h at 80°C (Figs. 1, 2a). The results are consistent with the generally accepted views that microphase segregation is the decisive factor affecting the properties of segmented polyurethane materials [10, 11]. In curing of nonplasticized PUUs at 35°C, high mechanical properties are achieved at weakly pronounced microphase segregation. The IR spectra of these samples (Fig. 2b) exhibit in the range 1665–1670 cm^{-1} a well-defined shoulder originating from formation of a large amount of disordered H-bonds between the urea groups of rigid segments mixed with flexible polyether segments, with the intensity of the band at 1640 cm^{-1} being low. The above shoulder is preserved upon prolonged curing.

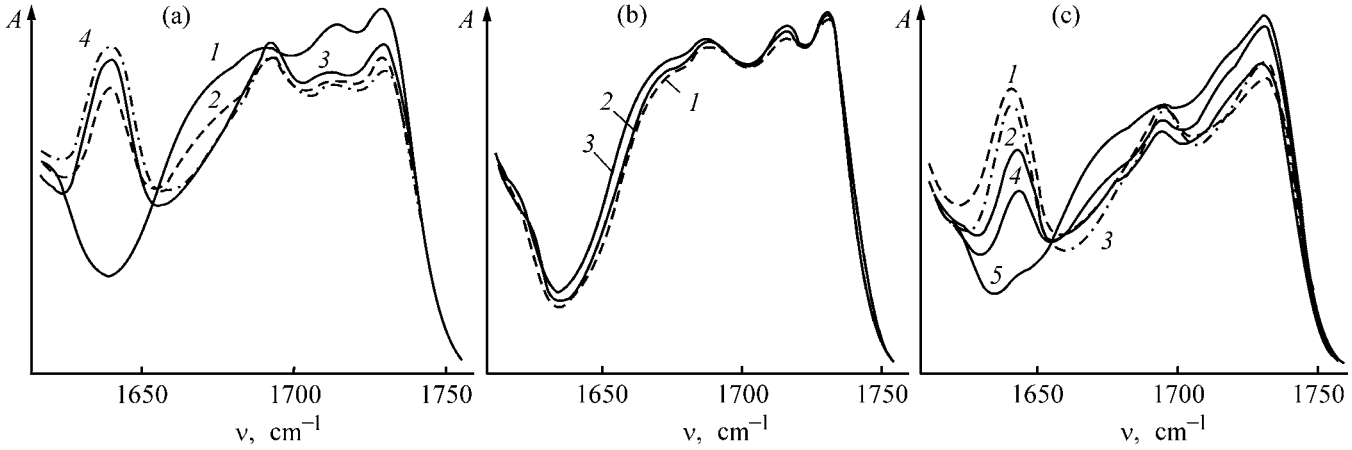

Fig. 2. IR spectra of nonplasticized PUU samples cured at different temperatures. (*A*) Absorption and (ν) wave number. Temperature, °C: (a) 80; (b) 35; (c) (*1*) 80, (*3*) 50, and (*2*, *4*, *5*) 35. Curing time, h: (a) (*1*) 1, (*2*) 2, (*3*) 9, and (*4*) 168; (b) (*1*) 48, (*2*) 120, and (*3*) 240; (c) (*1*, *3*, *4*) 168, (*2*) 336, and (*5*) 48.

The strength of plasticized PUU samples cured for the same time at different temperatures does not grow with the curing temperature but, by contrast, decreases, despite an increase in the amount of associated rigid segments in the material (Fig. 1a, curves *3–5*; Fig. 2c, curves *1*, *3*, *4*).

In curing of plasticized PUU samples at the same temperature, e.g., 35°C, the high strength and deformation properties of the material are achieved when the extent of segregation of rigid blocks is far from the maximum. This is clearly seen from comparison of curves *2* and *4* in Fig. 2a with each other and with curve *1* at $\nu = 1640$ cm^{-1}.

Thus, there is generally no unambiguous correlation between the mechanical propreties of segmented PUU samples prepared under different conditions and the microphase segregation of the flexible and rigid blocks. This may be due to increased defectiveness of the material prepared at elevated curing temperatures when microphase segregation is fast. This effect should be stronger in the presence of a plasticizer enhancing the mobility of flexible and rigid blocks of the polymer.

The enhancement of the interchain interaction in the flexible polymeric matrix due to mixing of flexible polyether segments and rigid urethane–urea blocks acting as proton acceptors positively affects the material strength. Therefore, microphase segregation in a segmented polyurethane material is not undoubtedly the major factor affecting its properties as stated in monographs [10, 11] and many other papers. Our conclusion directly follows from the experimental results shown in Figs. 1 and 2a–2c.

It is known that, under conditions of storage at room temperature, the structure of segmented polyurethanes becomes "frozen," i.e., it can remain in the virtually unchanged state for a long time [12]. The properties of the material should not appreciably

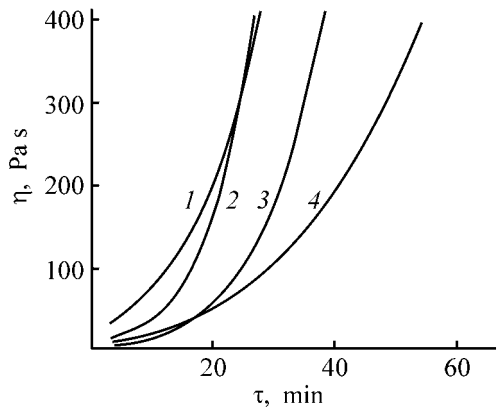

Fig. 3. Dynamic viscosity η of the reaction mixture in curing of (*1*, *2*) nonplasticized and (*3*, *4*) plasticized PUUs vs. time τ. Temperature, °C: (*1*, *4*) 35 and (*2*, *3*) 50.

change in this case. The table shows that, indeed, the mechanical characteristics of PUU samples change insignificantly after storage for 120 days at 20 ± 3°C.

The density of the chemical network, N_c, was low in all the samples (which was preset by the deficiency of the NCO groups in the reaction mixture) and did not noticeably change in storage of the material. The table shows that the trend toward an increase in the strength of the plasticized material with decreasing curing temperature is preserved in prolonged storage of the samples. The strength and deformation characteristics (f_b, ε_{cr}) of plasticized PUU prepared at 35°C exceed those of the nonplasticized material cured at both 35 and 80°C.

The high strength characteristics of the plasticized material obtained under these conditions are combined with the considerably better rheological characteristics of the plasticized reaction mass, compared to the nonplasticized mass (Fig. 3). As a result of plasticization, the shear viscosity of the compound becomes several times lower and the working life of the compound grows, which favors production of block items of higher quality.

CONCLUSIONS

(1) Lower curing temperatures ensure better strength and deformation characteristics of the plasticized material.

(2) Plasticized polyurethane–urea prepared at relatively low temperatures compares well with the nonplasticized material in strength and surpasses it in the deformation and processing characteristics.

(3) There is no unambiguous correlation between the strength of the segmented polymer and microphase segregation in it. The high strength can be achieved at a low extent of microphase segregation of the flexible and rigid blocks.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of Compounds of Epoxy Resins with Low-Molecular-Weight Carboxyl-containing Rubbers by Activating Mixing

V. P. Britov, V. V. Bogdanov, O. O. Nikolaev, A. E. Tubolkin, and T. M. Lebedeva

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 4, 2003

Abstract—A process was developed for preparing adhesives from a low-molecular-weight carboxyl-containing rubber and an epoxy resin with different oligomer ratios. The process involves the chemical reaction of the components under conditions of activating mixing.

To develop a process for preparing and modifying compounds under conditions of activating mixing, we chose as objects to be studied epoxy oligomers (EOs) and low-viscosity carboxyl-containing rubbers. This choice was governed by the following facts.

(1) Mixing of epoxy oligomers and low-viscosity carboxyl-containing rubber can initiate their chemical reaction.

(2) These materials have low viscosity, and, in this case, it is especially difficult to provide the strain energy density required to initiate a chemical reaction.

(3) Blends of epoxy polymers with rubbers are of large practical interest as adhesives.

Epoxy oligomers exhibiting high adhesive power are still important for practice, despite the development of new types of adhesives. However, the properties of the existing epoxy adhesives, in particular, their shock resistance and elasticity, do not fully meet the requirements of modern engineering. These characteristics are improved by modifying EOs with liquid rubbers [1–4]. The modification process is based on the high reactivity of carboxy group toward epoxy groups.

Modification of EOs with liquid rubbers is performed by the following procedures: (1) addition of a curing agent to a blend of EO with a rubber, prepared by mechanical mixing; (2) copolymerization of epoxy and rubber oligomers, which occurs simultaneously with curing of the epoxy resin at 120 or 150°C (hot curing); (3) preliminary reaction (esterification) between epoxy groups of the resin and carboxy groups of the rubber, followed by curing of the resulting copolymer at room temperature [5].

In preparation of compounds by the first procedure, there is no chemical reaction of the rubber with the epoxy matrix, which does not allow high mechanical characteristics of the compound to be attained. However, prolonged heating enhances the cracking resistance owing to changes in the phase interaction of the components.

In preparation of compounds by the second procedure, important factors are the selectivity and activity of the functional groups of the rubber, which are necessary for formation of chemical bonds between the components.

Of particular interest is the third procedure for EO modifcation. On mixing of epoxy and rubber oligomers, followed by heating for 2 h at 150°C, a noncatalytic reaction of the carboxy and epoxy groups occurs to yield a hydroxy ester.

The other procedures ensuring the required properties of the materials are more difficult to perform in practice because of the sophisticated equipment required and prolonged process.

Analysis of these methods from the process viewpoint reveals the following contradiction: Mechanical mixing is the simplest and the most convenient procedure, but it does not ensure the required properties of the compound because of the absence of a chemical reaction between the components. Irrespective of a particular procedure of compound preparation, mixing is

an inherent step of the process. In this case, we speak just of activating mixing, since the chemical reaction of the components under consideration requires initiation. We examined the possibility of initiating the chemical reaction of EO with rubber in mechanical-type apparatus.

Scheme of an installation for preparing epoxy–rubber compounds: (*1*) RPA, (*2*) static mixer, (*3*) thermostat, (*4*) tank, (*5*) power meter, (*6*) rotameters, (*7*) gear-type pump, (*8*) universal rate control unit, (*9*) motor, (*10*) sensor, (*11*) frequency meter, (*12*) disc, and (*13*) hydraulic pump.

EXPERIMENTAL

As objects of study served compounds based on EO (oligoether–epoxide) and liquid rubbers with terminal carboxy groups (butadiene–acrylonitrile and butadiene rubbers); also, we studied compounds of EO and liquid butadiene–acrylonitrile rubber with terminal carboxy groups, diluted with furfuryl glycidyl ether (FGE).

The compounds were cured with hardeners traditional for epoxy resins. We studied the materials obtained from blends of EO and liquid rubbers with terminal carboxy groups and those prepared with preliminary esterification of EO with carboxy groups of the rubbers.

Component characteristics: SKN-10KTR oligobutadiene–acrylonitrile rubber with terminal carboxy groups, 10% acrylonitrile units, 2.9% carboxy groups, molecular weight MW 2900 [TU (Technical Specifications) 000-31-24–60]; SKD-KTRA oligobutadiene rubber with terminal carboxy groups, 2.9% carboxy groups, MW 2800 (TU 38-103-327–46); ED-20 oligoether–epoxide, MW 410 [GOST (State Standard) 10597–76); FGE (furfuryl 2,3-epoxypropyl ether), 27% epoxy groups, MW 154.16 (TU 6-09-5208–85); xylylenediamine (XD), MW 150 (pilot product), hardener for ED-20; diethylenetriaminomethylphenol (UP-583), MW 210, hardener for ED-20 (TU 6-05-241-331–82). The compositions of the compounds studied are listed in Table 1.

The compounds were prepared both on traditional equipment (rollers, blade mixer) and on a specially contructed installation with a rotary pulsation apparatus (RPA). Previously, [6] we have formulated common requirements to preparation and modification of compounds under conditions of mechanochemical transformations controlled by mixing: concentration of a definite quantity of energy and its proper utilization in the working volume of the apparatus (creating high shear rates and stresses and controlling them within wide limits; uniformity of the strain action parameters in each elementary volume of the material being processed). We noted that effective small-volume mixers, RPAs, meet these requirements.

The experimental installation is shown schematically in Fig. 1. The installation includes an RPA, a hydraulic drive, a system for flow and pressure head control, and measuring devices. The rotary pulsation apparatus with a vertical shaft was a one-step device with the possibility provided for enhancement of re-

placeable rotors and stators (Fig. 2). This allowed the working clearance to be varied from 0.5 to 6 mm; the number of slits, from 0 to 32; the slit width, from 2 to 12 mm; and the cylinder thickness, from 3 to 12 mm.

The rotor and startor are mounted in a casing. The rotor is fixed on the vertical shaft, and the stator is mounted on a stationary vertical axle with an outlying support with two precision bearings. The outlying support is fixed on the frame of the installation, and on the upper end of the axle there is a horizontal cantilever with the attached system of a rope and a pulley.

Removable weights were fastened at the rope end. The apparatus was driven by an electric motor. We also used another version of the RPA working unit, based on the design from [7] and allowing finer dispersion of the components (Fig. 3).

In the installation scheme, we also used the RPA design from [8], in which the inlet tubes were replaced by a static mixer with screw parts. The installation was equipped with systems for flow and pressure head control for fluids of different viscosities. With low-viscosity fluids, the installation included a tank, a centrifugal pump, two pneumatic rotameters RP-1.6 and RP-10, cut-off and control valves, and a system of pipelines. With more viscous media, the system for flow and pressure head control consisted of the same tank and a gear-type pump with the drive equipped with a universal rate control unit.

The installation worked as follows. The working medium from the tank was withdrawn with a centrifugal (for low-viscosity media) or gear-type (for high-viscosity media) pump. When working with low-viscosity media, the material was fed with the pump through one of rotameters used to set and monitor the required flow rate. After passing through the rotameter, the fluid arrived at the internal volume of RPA and then, after passing through the rotor and stator slits, to the external volume of the apparatus and then moved through the discharge tube to the tank from which, if necessary, it was fed into the RPA again. Thus, the fluid continuously circulated in a closed loop. When working with highly viscous media, the fluid from the apparatus was fed with a gear-type pump preliminarily calibrated with respect to the flow rate. The fluid supply was finely controlled with a universal rate control unit in the pump drive.

Prior to being fed into the RPA, two (or more) polymeric materials were mixed in a static mixer with screw parts. In the experiments, we varied the system of component supply to the static mixer, the number

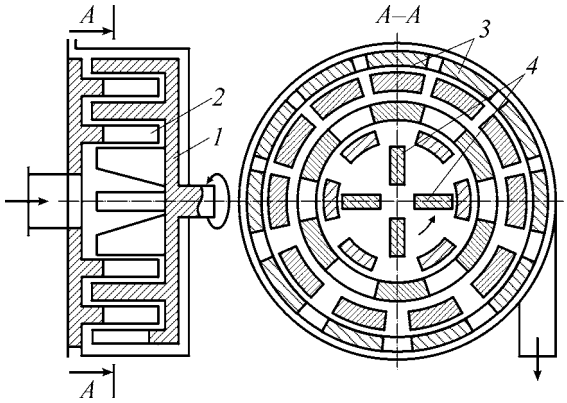

Fig. 2. Scheme of RPA: (*1*) rotor, (*2*) stator, (*3*) teeth, and (*4*) blades.

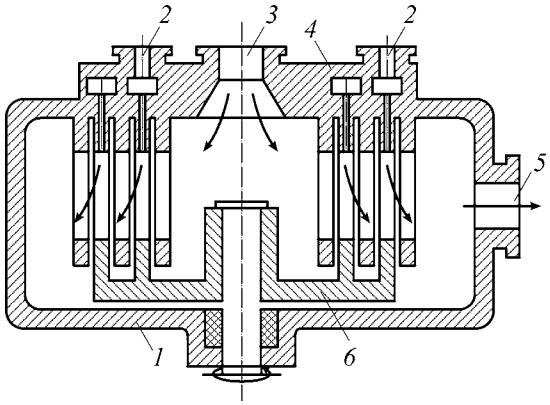

Fig. 3. Rotary pulsation apparatus for fine dispersion of components: (*1*) casing, (*2*, *3*) inlet tubes, (*4*) stator, (*5*) outlet tube, and (*6*) rotor.

of screw parts, the angle of their twisting, etc. This allowed us to analyze how mixing in RPA is affected by the initial interface area.

The power-measuring installation consisted of a stator and a rotor with a rope. The rotor rotation frequency was measured with a frequency meter, which was connected to a magnetic sensor mounted near the disk with slits, with a narrow clearance. The disk was fastened on the rotor shaft. When the disk moved near the sensor, the magnetic flux in it changed in proportion to the number of slits on the disk and frequency of rotor rotation. The induction voltage changed, and this change was transmitted to the frequency meter through the coil in the sensor.

To provide the constancy of the fluid temperature, the tank was equipped with a jacket through which, if necessary, brine (≥15°C) or cold water was passed to maintain the required temperature (20 ± 0.5°C).

The rheological properties of the components and their mixtures were determined with a Rheotest rotary

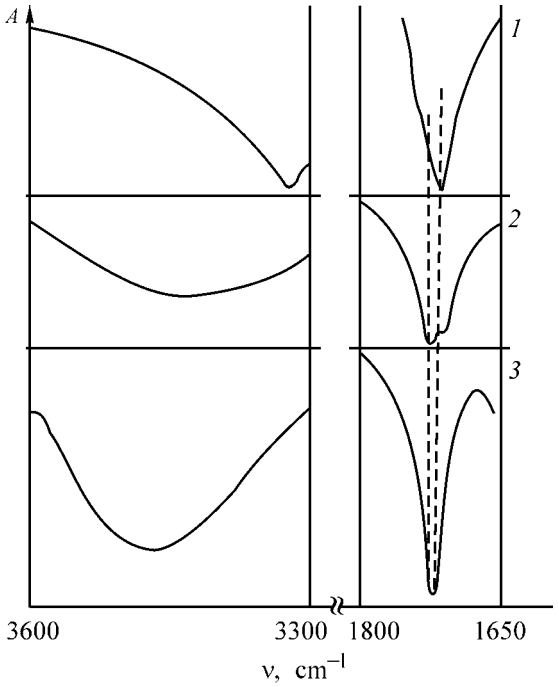

Fig. 4. IR spectra of (*1*) SKN-10KTR rubber, (*2*) blend of SKN-10KTR with EO, and (*3*) product of preliminary esterification. (*A*) Absorption and (ν) wave number.

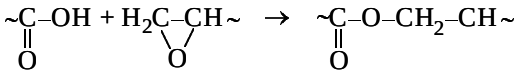
viscometer. The structure of the uncured compounds was studied with an optical microscope, and that of cured compounds, with an electron microscope (REM-100, V8-500). The chemical and physical transformations of the components were monitored as follows: formation of chemical bonds between the functional groups of rubber and EO, by IR spectroscopy; consumption of EO functional groups, by acid–base back-titration; and the curing kinetics, by the procedure involving evaluation of the temperature effect of curing. The quality of mixing was estimated by optical and dielectric methods.

To elucidate the mechanisms of processes occurring at different compounding procedures, we studied the structure and chemical reactions of the component polymers.

The preliminary esterification product is initially a homogeneous material, but after curing it becomes a two-phase system similar to that obtained from the mechanical mixture.

The following reaction occurs between the carboxy groups of rubbers and epoxy resin [5]:

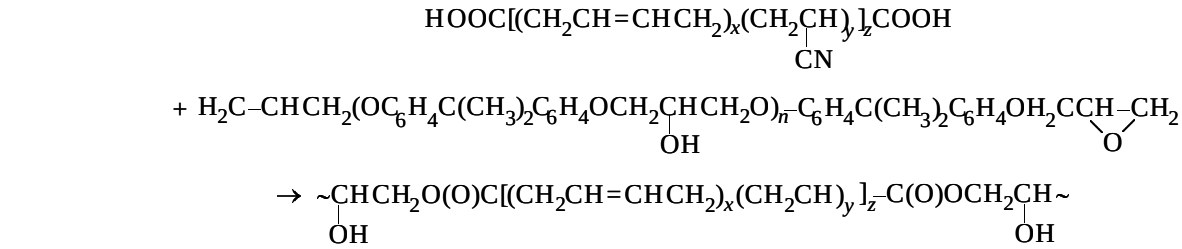


The reaction proceeds until all the carboxy groups are consumed. In the process, intermolecular hydrogen bonds undergo redistribution. Comparison of the IR spectra of SKN-10KTR rubber (Fig. 4, spectrum *1*), its mechanical mixture with EO (spectrum *2*), and product of preliminary esterification shows the following. In the spectrum of SKN-10KTR, the absorption at 1710 cm^{-1} is more pronounced (C=O bonds in hydrogen-bonded carboxy groups). On mixing with EO, the band at 1740 cm^{-1} (free C=O groups) becomes more intense owing to redistribution of hydrogen bonds upon interaction of the hydroxy groups of rubber with proton-acceptor groups of ED-20. The absorption at 1710 cm^{-1} becomes less intense. The IR spectrum of the product of preliminary esterification exhibits a single strong band at 1740 cm^{-1}, suggesting the existence of free carbonyl groups, as all the carboxy groups of the rubber have reacted with the epoxy groups, so that the hydrogen bonds between the rubber molecules have been broken. A strong band at 3300–3600 cm^{-1} in the spectrum of the product of preliminary esterification indicates that all the OH groups are involved in hydrogen bonding.

Thus, in contrast to mechanical mixtures, there is chemical bonding between the phases in the compound prepared by preliminary esterification.

The IR data show that, after the cleavage of the hydrogen bonds with C=O groups, all the OH groups of SKN-10KTR molecules form hydrogen bonds with acceptor groups of ED-20, i.e., a redistribution of intermolecular hydrogen bonds occurs.

The reaction of oligobutadiene–acrylonitrile rubber (SKM-10KTR, $x = 5$, $y = 1$, $z = 10$) with ED-20 resin can be represented as:



As will be shown below, the occurrence of the chemical interaction determines the difference between the compounds prepared by preliminary esterification and by other procedures in the strength, elastic, and adhesion properties.

Numerous studies have shown that the properties of polymeric systems can be appreciably changed by varying the dispersity of one of the components in the medium of another component in preparation of compounds from polymer blends. One of such properties is the stability of the system (resistance to phase separation). In the first step of this study, we examined the possibility of preparing stable epoxy–rubber systems in an RPA in which it is possible to attain high shear stress by varying the shear rate, and thus to attain fine dispersion of one of the components in the medium of the other component.

Depending on the viscosity and component ratio, it is possible to obtain stable systems in RPA by varying the rotation rate of the working parts or the clearance between the rotor and stator (variation of the shear rate), and also by varying the number of passages through the working zone of the apparatus and the flow rate (variation of the residence time in the treatment zone). In this study, as expected, we obtained the most stable systems at equal amounts of the components. With an RPA of the standard design (without static mixer), a threefold treatment of the SKI-10KTR : ED-20 = 1 : 1 blend yielded a system that did not undergo phase separation in 14 days.

In the second step of our study, we examined the possibility of performing a chemical reaction between the functional groups of the oligomers being mixed. In the first step, we prepared a homogeneous system stable in time and hence provided the most favorable conditions for the reaction between the functional groups; whereas in the second step, we promoted the chemical reaction between the oligomers by making the stirring conditions more "severe." Upon sixfold passage of the components through the working zone of the apparatus (without static mixer), we obtained a system whose analysis suggested the occurrence of the chemical reaction between the components.

As already noted, the spectrum of the blend obtained mechanically without RPA contains two bands at 1710 and 1740 cm^{-1}. In the spectrum of the product of preliminary esterification, the first band is absent. The spectrum of the product obtained in RPA also has an absorption band at 1740 cm^{-1}, but it is less intense than in the previous case. After repeated passages of the blend through the working zone of the mixer, the spectra of the products of preliminary esterification and RPA treatment became virtually identical. The formation of a chemical compound was also confirmed by other methods and by the results of physicomechanical and service tests of the compounds (Table 2).

Table 2. Physicomechanical and service properties of compounds prepared by different procedures

Parameter	Product of RPA treatment	Product of preliminary esterification	Mechanical blend
Tensile strength, MPa	14.0	13.2	4.3
Relative elongation, %	58.0	66.0	10.0
Adhesion strength, MPa	12.2	11.5	4.0

Table 3. Optimal parameterts $\tau\gamma$ for compounds with varied rubber content *c*

c, %	$\tau\gamma$, kJ mol^{-1}	
	ED-20 + SKN-10KTR	ED-20 + SKD-KTRA
10	590–620	600–630
20	650–750	700–800
30	850–950	850–950
40	900–1000	900–1050
50	950–1050	1000–1100

In practice, to obtain a chemical compound, there is no need in repeated passage of the raw materials through the working zone of RPA. On setting the energy of the bond ruptured in chemical modification, it is necessary to estimate the criteria $\tau\gamma$ and $\mu y'$, required for mechanochemical cracking, and to calculate appropriate process modes.

Analysis of the reaction between a carboxyl-containing rubber and an epoxy resin to give a chemical compound, shows that, first, it is necessary to break the C–O bond (according to different sources, its energy varies from 314 to 322.6 kJ mol^{-1}). Thus, $\tau\gamma$ should exceed this value. It is also necessary to take into account the energy consumption for dispersion of one of the components in the other one, their homogenization, etc., which, in turn, depends on the ratio of the component viscosities and concentrations in the two-phase system.

The optimal values of $\tau\gamma$ for compounds with varied rubber content are given in Table 3.

Using the procedure for RPA calculation [6] and knowing the required $\tau\gamma$, we can calculate the appropriate process modes. At the same time, in some cases, a single passage of the material through the RPA working zone is insufficient to perform the process. In this case, the most acceptable way is to improve the apparatus design (e.g., to combine RPA with a static mixer [8]).

CONCLUSIONS

(1) Treatment of blends of low-molecular-weight carboxyl-containing rubbers and epoxy resins in a rotary pulsation apparatus at a definite value of the external energy effect ensures a chemical reaction between the components and preparation of high-quality adhesives.

(2) It is appropriate to use as a criterion of the external energy effect the strain energy density and strain intensity; this allows calculation of process modes for efficient treatment of blends in a rotary pulsation apparatus, depending on the component ratio.

Abstract—Thermal carbonization of nitrogen-containing cellulose derivatives (chitin, chitosan, cyanoethyl chitosan, cyanoethyl cellulose, copolymers of allyl carboxymethyl cellulose with polyacrylonitrile) as models of probable products of thermal reaction of cellulose with polyacrylonitrile was studied. The quantitative characteristics of carbonization of the model compounds are influenced by the nitrile group.

Polycarylonitrile (PAN) and a number of cellulose derivatives are the most widely used precursors of carbonized products [1]. Numerous materials based on their carbonizates are commercially produced for chemical industry, power engineering, and medicine. It has been shown previously [2–5] that joint carbonization of PAN with other nitrogen-containing polymers, mainly with polyheterocycles, involves thermal reactions between the starting macromolecules. In various steps of these reactions, new compounds are formed, whose carbonization yields products of a polycarbon structure with a number of specific properties. An analysis of these thermal reactions revealed a particular role of nitrogen atoms in formation of the carbonizate structure in the initial step of the reactions of PAN with the polymers examined; nitrogen atoms present in the starting polymers affect the properties of the final carbonization product [6–8]. Since these effects were mainly observed in reactions of PAN with various nitrogen-containing polyheteroarylenes, we examined in this study thermochemical reactions of PAN with nitrogen-containing polysaccharides and their derivatives.

To record changes in the kinetics of thermal reactions of the starting compounds depending on their structure and ratio and on the heat treatment conditions, we used various methods of thermal analysis in the dynamic and isothermal modes in the temperature range 20–1000°C. The reaction products were studied by elemental analysis, pyrolytic gas chromatography (PGC), and spectroscopy.

As nitrogen-containing polysaccharides, we used chitin (CT) and chitosan (CTS), substances with virtually unlimited resources of raw materials, showing much promise as precursors of carbonized products. It should be noted that there are no papers focused on the carbonization of CT and CTS, and also of their blends with other compounds. Certain aspects of thermal degradation of CT, CTS, and their blends with other compounds were considered in [9–16]; according to these papers, their degradation, as that of PAN, involves formation of reactive intermediates which can react by intra- and intermolecular pathways.

The goal of this study was to determine the conditions and mechanism of carbonization of chitin and chitosan and of their blends with PAN. CT and CTS were prepared and pretreated according to [17, 18]; PAN was synthesized using radical (r-PAN) and anionic (c-PAN) catalysts [19].

The kinetics of thermal degradation in a vacuum was studied by thermovolumetric analysis (TVA); the thermal oxidative degradation was monitored by TGA and DTA. The results (Figs. 1, 2) show that the thermal reactions are the most intense in the range 150–350°C.

Thermal degradation in a vacuum (Fig. 1, curve *1*) follows the mechanism of transformation of r-PAN into the cyclic analog of PAN, considered in [19]. At 200°C, vigorous release of volatiles is observed, with a maximum at 215°C and weight loss of 21.5%. These products mainly consist of nitrogen-containing

compounds, such as HCN, NH_3, acrylonitrile, and acetonitrile.

On further heating, at 500–600°C, the rate of the release of volatiles and their amount appreciably decrease, with hydrogen and ammonia becoming prevalent. Under these conditions, degradation prevails over carbonization, and the weight loss of r-PAN reaches 80% at 900°C.

In the case of partially cyclized polyacrylonitrile (c-PAN), the kinetics of gas release under the same heating conditions is appreciably different throughout the temperature range studied (Fig. 1, curve *2*). The gas release occurs with several peaks, but separate steps cannot be distinguished, in contrast to the case of r-PAN.

Unexpectedly, the pattern of thermal degradation of CT and CTS samples, despite the quite different structure of the starting polymers, is qualitatively similar to that of r-PAN as regards the release of low-molecular-weight degradation products. The major amount of volatiles is released in the ranges 150–315°C from CT and 200–260°C from CTS. These effects are related to the breakdown of acetamide- and amine-containing glucopyranose rings, accompanied by the formation of a wide variety of low-molecular-weight oxygen- and nitrogen-containing compounds. The main of these are water, methanol, pyridine, acetamide, levoglucosan, and a number of picoline derivatives. On heating to 320–350°C, CT and CTS lose about 70% of their weight, and at 900°C the amount of the carbonized residue does not exceed 8–10%. According to PGC, whose qualitative aspects will be considered later, the gas release peaks in isothermal heating of CT and CTS samples are shifted to 300–450°C. Thus, the fairly close coincidence of the temperature ranges in which the release of volatile thermal degradation products from PAN, CT, and CTS reaches a maximum suggests that the reactive compounds released from PAN and the polysaccharides may react with each other when these compounds are thermolyzed in a blend.

When these polymers are subjected to thermal oxidative degradation in a self-generated atmosphere, the temperature of intense thermal reactions occurring on heating is still narrower (Figs. 2a, 2b). According to DTA data (Fig. 2b), the peaks of the exothermic reactions of all the four samples are observed at 260 ± 5°C. Hence, this temperature seems to be the best for performing thermal reactions of the intermediate degradation products. Also, curves in Fig. 2 can be considered as reference characteristics of the polymers from which it is possible to evaluate the thermal characteristics of the cocarbonization products. In particular, from the viewpoint of relative heat resistance,

r-PAN is the most stable, showing no weight loss up to almost 300°C; at 800–900°C, its coke residue varies within 40–50%. Contrastingly, c-PAN starts to release low-molecular-weight gaseous products of thermal oxidative degradation even at 150°C; however, its coke residue at 800–900°C is almost equal to that of r-PAN. In addition to these characteristics, recording of thermal effects by DTA reveals differences in intensities of thermal reactions and, in some cases, allows characterization of the reactivity of the intermediates formed in the course of the heat treatment. The DTA curve of r-PAB exhibits a strong exothermic effect at approximately 300°C, accompanied by a 30% weight loss in 5–7 min, whereas the thermal effect observed with c-PAN in the same temperature range is considerably weaker. The endothermic effects observed in the DTA curves for both PAN samples in the range 450–600°C deserve particular consideration with spectroscopic examination of the transformation products. These effects (peaks at 455 and 545°C for r-PAN and at 530 and 550°C for c-PAN) can be assigned to certain partially ordered domains formed at temperatures of PAN precarbonization.

As for the kinetics of thermal degradation of CT and CTS (Fig. 2, curves *3*, *4*), the highest rate of the release of volatiles is observed in the same temperature range as with PAN and is comparable with the rate of thermal oxidative degradation of c-PAN. The values of the total thermal effects of degradation of CT, CTS, and c-PAN are also comparable. It should be noted, however, that the weight loss in degradation of CT and CTS in this temperature range is 45–55%, and on further heating the weight loss in carbonization is almost equal to the rate of carbonization of PAN; at 850–900°C the samples almost fully burn out.

Thus, the results of a thermal analysis of all the samples in hand suggest that, first, all the intermediate degradation products of these polymers can enter thermal reactions with each other and, second, PAN can initiate carbonization of CT and CTS; the specific synergism in cocarbonization with polysaccharides can be manifested through formation of precarbonizates, with a simultaneous increase in the coke residue.

To confirm this conclusion, we prepared a series of polysaccharides whose structure can simulate, to a certain extent, the intermediates formed in reactions of cellulose derivatives, CT, and CTS with PAN and its degradation products. Of particular interest among these compounds are cellulose derivatives containing a nitrile group, in particular, cyanoethyl cellulose (CEC) and cyanoethyl chitosan (CECTS) as products of the initial step of the reaction between the above

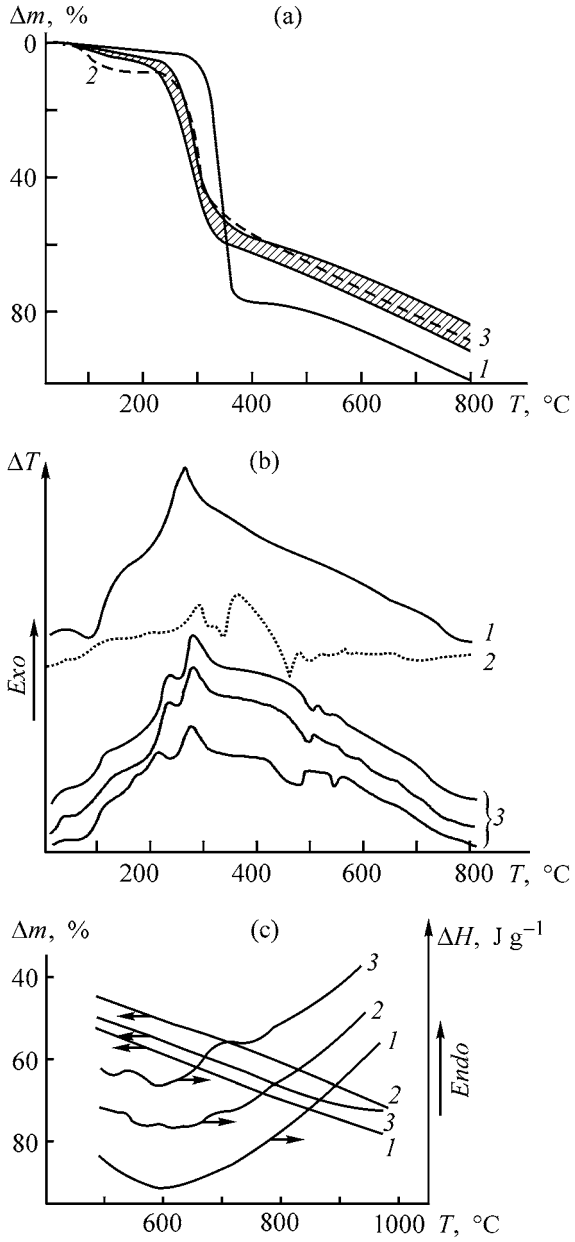

Fig. 3. (a) TG, (b) DTA, and (c) TG + DSC curves of polymers: (Δm) weight loss, (ΔT) temperature difference, (ΔH) heat of reaction, and (T) temperature. (a, b) (*1*) CEC, (*2*) chitosan, and (*3*) CECTS samples with γ = 154–191 (cross-hatched area in Fig. 3a). (c) (*1*) Chitosan; (*2*) CECTS, γ = 166; and (*3*) CECTS, γ = 191.

polymers. For thermochemical studies, we chose several samples of CECTS with the degree of substitution γ, from 51 to 191 and, for comparison, a CEC sample with γ = 280 [18].

Figure 3 shows as examples the TG and DTA curves of CEC and CECTS samples, recorded in a self-generated atmosphere. A comparative kinetic study

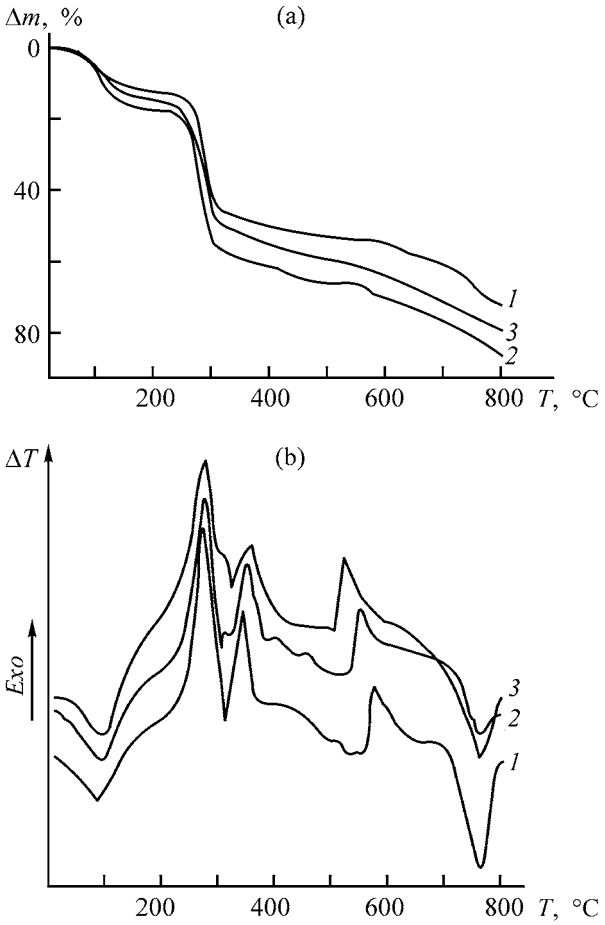

Fig. 4. (a) TG and (b) DTA curves of polymers: (*1*) CMC; (*2*) ACMC, γ = 6; and (*3*) ACMC, γ = 25.

of the thermal oxidative degradation of these compounds demonstrated that the coke residue of CECTS is within 10–18% and grows with increasing degree of substitution. The coke residue is similar to that obtained with unsubstituted CTS; appreciable differences are observed only in the initial step of degradation, corresponding to the release of sorbed water. As for CEC, although it fully burns out at 800°C, it considerably surpasses CECTS in the heat resistance, being comparable with PAN at temperatures below 300°C. This fact shows that the nitrile groups noticeably enhance the heat resistance of cellulose derivatives and affect the carbonization mechanism.

The effect of cyanoethylation of hydroxy groups in the glucopyranose unit of chitosan is still more pronounced when the thermal effects accompanying thermal oxidative degradation of CTS and CEC are considered (Fig. 3b). The degree of substitution in CECTS exerts a certain effect on the shape of the DTA curves (Fig. 3b, curve *3*). These curves noticeably differ from those obtained with CTS and CEC (Fig. 3b, curves *1*, *2*). It should be noted that, with substituted CTS samples, we revealed for the first time noticeable differences in the thermal effects of carbonization above 500°C. A similar pattern is observed in thermal degradation of the same CEC and CECTS samples in a vacuum. Such differences were observed, according to DSC, even in carbonization of small samples in a nitrogen atmosphere (Fig. 3c). It is clearly seen that the CECTS samples with γ = 191 show endothermic effects at 571 and 703°C. The rate of the weight loss in this step of carbonization remains the same for all the samples.

The other compounds simulating the possible products of thermal reactions of PAN with polysaccharides are graft copolymers of PAN with cellulose derivatives. These include copolymers of allyl carboxymethyl cellulose (ACMC) with PAN, prepared using radical catalysts, with the degree of substitution with allyl groups, γ_A = 6, and degrees of grafting, *C*, from 130 to 670. To reveal the role of allyl groups in ACMC and the influence of their content, we studied the samples with γ_A = 20 and 25, and also a CMC sample. According to the TG and DTA curves recorded in the self-generated atmosphere, the course of degradation of these compounds is qualitatively similar to that of cellulose under similar conditions [20], but quantitative differences in the heat resistance are noticeable. The CMC sample is more stable than ACMC with γ_A = 25 but less stable than ACMC with γ_A = 6.

Similar trends were observed in a comparative study of cellulose allyl and sulfoethyl ethers [21]. The allyl groups exert a dual effect. On the one hand, allyl groups form primary cross-links on heating the samples to 120–200°C. On the other hand, these groups are readily oxidized, which results in an accelerated weight loss on heating. Figure 4a shows that, at a higher degree of substitution of ACMC (γ = 25), cross-linking prevails, enhancing the heat resistance of the sample as compared to that with γ = 6. As for CMC (Fig. 4a, curve *1*), this ether degrades to a lesser extent in the initial steps of heat treatment, approaching in the heat resistance unsubstituted cellulose. This is confirmed by comparison of thermal effects observed in thermal oxidative degradation of the samples (Fig. 4b).

As for thermal degradation of ACMC–PAN copolymers (Figs. 5, 6), grafting of PAN to the allyl groups of ACMC appreciably affects the course of the reactions occurring in the samples on heating.

The curves of thermal degradation in a vacuum (Fig. 5) show that the pattern observed with the graft copolymer is a superposition of the patterns characteristic of ACMC and r-PAN. As the degree of PAN grafting to ACMC is increased from 130 to 670, the relative intensities of the corresponding peaks are redistributed. For example, the characteristic peak of thermal transformation of PAN into the cyclic state (peak at 215°C) has almost the same intensity in the case of the PAN–ACMC copolymer with C = 670 and is ill-defined at C = 130. At the same time, the sample with C = 130 (curve *2*) exhibits a well-defined peak of thermal degradation of ACMC (maximum at 182°C). On further heating of the copolymer, certain characteristic features of PAN degradation in the range of low-temperature carbonization are seen (broadened peaks at 450–500°C), but the peaks at 340 and 535°C characteristic of ACMC are fully absent. In the range 750–870°C, the copolymer exhibits gas-release peaks characteristic of high-temperature degradation of the carbonized ACMC residue, but these peaks are somewhat shifted to higher temperatures. A similar pattern is observed with the other copolymer samples with C in the range from 130 to 670.

The TG curves in Fig. 6, recorded under conditions of limited thermal oxidation (self-generated atmosphere), show how the coke residue depends on the degree of PAN grafting to ACMC. As the degree of grafting grows, the coke residue noticeably increases: from 13 for ACMC without grafted PAN to 52 for the copolymer with C = 670. The grafting of PAN to ACMC also enhances the heat resistance of the copolymer in the low-temperature range (75–250°C). It is particularly interesting that, at high degrees of PAN grafting (from 470 to 670) (Fig. 6, curves *5–7*), the coke residue of the copolymers is 10–14% higher, compared to PAN homopolymer. These observations suggest that the carbonization of the graft copolymers above 400°C occurs by the mechanism differing from that observed with PAN and ACMC. This is indicated by the pattern of thermal effects accompanying the carbonization of the homopolymer and copolymers with a high PAN content (Fig. 7). These results suggest the occurrence of a directional carbonization of ACMC, with blocking of the reactive groups of cellulose; this process may occur simultaneously or successively with intramolecular cyclization of PAN side chains in the graft copolymer. Our results show that the bonding of cellulose macromolecules with acrylonitrile (CEC) or polyacrylonitrile (PAN–ACMC) appreciably increases the carbonizate yield under optimal cocarbonization conditions.

CONCLUSIONS

(1) In cocarbonization, the carbonized structures of cellulose ethers and polyacrylonitrile affect each other, so that the coke residue becomes higher than that obtained with polyacrylonitrile under the same conditions.

(2) Pathways of thermal reactions of chitin and chitosan with polyacrylonitrile were determined in experiments with the model compounds (cyanoethyl cellulose, cyanoethyl chitosan, and graft copolymers of cellulose ethers and polyacrylonitrile).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Oxidative Ammonolysis of Vegetable Raw Materials

M. V. Efanov, D. V. Dudkin, and M. V. Popova

Altai State University, Barnaul, Russia

Received September 10, 2003

Abstract—The influence of the composition of lignocarbohydrate vegetable raw materials, process duration (15–120 min), amount of hydrogen peroxide (0.1–0.9 g per gram of raw materials), and amount of ammonia (0.25–1.5 g per gram of raw materials) on the yield of the target product and on the nitrogen content and the content of functional groups in it in mechanochemical treatment of vegetable wastes with hydrogen peroxide in aqueous ammonia (oxidative ammonolysis) was studied. Sorption and agrochemical testing of the resulting samples as nitrogen-containing ion exchangers and fertilizers was performed.

In treatment of wood and other vegetable raw materials, significant amounts of wastes (bark, sawdust, straw, etc.) are formed. At present, these wastes are not utilized. The promising way of utilization of these wastes is their use as raw materials for production of fertilizers and sorbents [1, 2].

For production of nitrogen-containing fertilizers from wood bark, a procedure involving treatment of raw materials with oxygen in aqueous ammonia (oxidative ammonolysis) has been suggested [1, 3]. The main drawbacks of this procedure are elevated temperature (75–200°C), oxygen pressure of up to 8 MPa, and rather low content of nitrogen in the resulting fertilizer (1–3.5%).

A mechanochemical procedure for production of nitrogen-containing fertilizers and sorbents based on wood by oxidation with ammonia solution of ammonium persulfate at 20°C and atmospheric pressure has been developed previously [4]. However, practical implementation of the procedure is limited by the high cost of ammonium persulfate and its relatively high expenditure. Publications on oxidation of vegetable raw materials with hydrogen peroxide in aqueous ammonia are virtually lacking.

In this study, we examined the influence of the conditions of oxidation with hydrogen peroxide in aqueous ammonia on the yield and characteristics of nitrogen-containing derivatives of lignocarbohydrate materials produced by mechanochemical oxidative ammonolysis.

EXPERIMENTAL

As the raw materials we used air-dry sawdust (0.5-mm fraction) of the following lignocarbohydrate materials (LCHM): birch wood, aspen wood, pine wood, flax shive, and sunflower and buckwheat husk. The raw materials were analyzed by the procedure described in [5]. The data obtained are listed in Table 1. The target product of oxidative ammonolysis is the sol-

id residue insoluble in the reaction mixture and containing nitrogen atom and carboxy groups. The process was carried out as follows. A 3.0-g weighed portion of the 0.5-mm fraction of sawdust of vegetable raw materials was placed in a cylindrical reactor of a 300 cm^3 vibrational mill (IV-98B vibrator, frequency 2800 min^{-1}) with 15 steel rods (10 × 100 mm).

Into a temperature-controlled reactor, a 30% solution of hydrogen peroxide (0.1–0.9 g H_2O_2 per gram of the raw materials) and a 25% solution of ammonia (0.25–1.5 g of NH_3 per gram of the raw materials) were introduced, and the mixture was subjected to intensive mechanical grinding at 25°C for 15–120 min. Then, the reaction mixture was discharged from the mill and separated from the milling bodies. The products were washed with distilled water to pH 6–7 and dried in a desiccator to constant weight, and the yield was determined (percent relative to the weight of the raw materials).

The content of bound nitrogen in the product was determined by the Kjeldahl procedure [6]; the content of carboxyl groups, by conductometric back-titration [7]; and the amount of methoxyl groups, by the Zeisel method using gas–liquid chromatography [7]. The agrochemical testing of the resulting products as nitrogen-containing fertilizers for peas was carried out by the method of vegetation experiments, in which the plant height, the weight of the dry substance, and the chlorophyll content in the plant were determined as the growth index [8]. The sorption capacity of nitrogen-containing derivatives of pine wood for cations of some *d* elements was determined under equilibrium conditions, using the p°rocedure described in [2].

As can be seen from Table 1, the ammonolysis products are obtained from various types of wood in a somewhat higher yield than from other lignocarbohydrate materials (nonwood vegetable raw materials), which may be due to oxidative degradation of lignin and polysaccharides contained in these raw materials during mechanochemical oxidation in aqueous ammonia.

It was found that lignocarbohydrate materials containing greater amount of lignin undergo ammonolysis more efficiently. The products of ammonolysis of nonwood vegetable raw materials contain a lower amount of methoxy groups than the products based on various types of wood, excluding pine wood. This may be due to the structural features of lignins of annuals and pine, high content of nonmethoxylated *p*-hydroxyphenylpropane and guaiacyl structures [5], an also their high reactivity in ammonolysis (Table 1). Variation of the functional composition of vegetable raw materials was considered for pine wood as an example. The influence of the duration of mechanochemical treatment on the composition of the products of oxidative ammonolysis of pine wood is illustrated by Table 2.

Table 2 shows that, with increasing duration of mechanical milling of wood in the presence of hydrogen peroxide in the ammonia medium, the content of bound nitrogen and carboxy groups steadily increases, i.e., the oxidative binding of nitrogen takes place. Oxidation of wood in the ammonia medium results in demethylation with the loss of approximately 25–55% of methoxy groups of their initial content. Within 90 min from the beginning of the reaction, up to 3.7% N is incorporated into the wood composition. With increasing process duration, the yield of the resulting products decreases, apparently, due to growing extent of mechanochemical degradation of wood in the ammonia medium (Table 2).

The influence of the amount of oxidizing agent (hydrogen peroxide) on the functional composition of nitrogen-containing derivatives of pine wood was studied. The results obtained (Table 3) show that, with increasing amount of hydrogen peroxide per gram of raw materials, the product yield decreases. This is apparently caused by oxidative mechanochemical degradation of wood. With the content of oxidizing agent increasing from 0.1 to 0.6 g per gram of raw materials, the content of carboxy groups increases from 2.9 to 7.1%, i.e., oxidation of wood is enhanced with parallel binding of nitrogen.

Further increase in the amount of hydrogen peroxide to 0.9 g per gram of raw materials does not result in a significant oxidation of wood. In this case, an in-

crease in content of the hydrogen peroxide results in oxidative demethylation of wood with the loss of 10–65% of methoxy groups relative to their initial amount (Table 3).

The influence of the amount of ammonia on the characteristics of nitrogen-containing derivatives of pine wood is shown in Table 4. With increasing amount of ammonia per gram of raw materials, the yield of nitrogen-containing derivatives of wood somewhat decreases due to degradation.

Raising the ammonia content results in a steady increase in the content of bound nitrogen and carboxy groups in the products of oxidative ammonolysis of pine wood (Table 4). The demethylation of the resulting products is caused by a rise in the degree of ammonolysis with increasing content of ammonia.

To establish the nature of bound nitrogen, the resulting products were hydrolyzed by boiling with 1 M sodium hydroxide [7]. It was found that approximately 15–35% of bound nitrogen (ammonium and amide) is eliminated in hydrolysis, and the remaining amount of nitrogen (65–85%) is firmly bound in organic structures (amine and heterocyclic), in good agreement with published data on oxidative ammonolysis of lignin [7].

The product containing 3.7% bound nitrogen was tested as a nitrogen-containing fertilizer for peas of the "Sakharnyi" variety. It was shown that nitrogen-containing derivatives of pine wood stimulate the pea plant growth by 25–30%, increasing the total biomass by 45–60% and the chlorophyll content in the plants by 58–113%.

Hence, nitrogen-containing derivatives of pine wood stimulate pea growth and can be used as nitrogen-containing organic fertilizers for crops.

Data on sorption capacity of nitrogen-containing derivatives of pine wood with respect to Zn^{2+}, Cd^{2+}, and Cu^{2+} cations are given in Table 5.

As the experimental results show, the sorption capacity of the products of oxidative ammonolysis of wood with respect to the series of the cations studied depends on the content of nitrogen and COOH groups in these products.

The static exchange capacity (SEC) of nitrogen-containing derivatives of wood is fairly high for all the cations studied, which is caused by the high content of carboxy groups (Table 5).

The high sorption capacity of the products of oxidative ammonolysis of wood with a high content of COOH groups, which contain up to 3.7% nitrogen, for multicharged cations is due to their chelating properties.

Thus, the products of oxidative ammonolysis of pine wood can be used as effective sorbents transition metal cations in their recovery from dilute solutions.

Table 3. Influence of the amount of hydrogen peroxide on the characteristics of nitrogen-containing derivatives of pine wood (milling duration 60 min, 0.25 g of NH_3 per gram of raw materials)

Initial	0.5	2.4	0.7	0.8	1.0
1	1.9	3.5	2.5	3.2	3.8
2	3.7	6.7	3.6	4.4	4.7

CONCLUSIONS

(1) In oxidative ammonolysis of various vegetable raw materials with an ammonia solution of hydrogen peroxide, samples of lignocarbohydrate materials containing a larger amount of lignin are oxidized to a greater extent.

(2) Depending on the oxidation conditions, the products of oxidative ammonolysis of pine wood contain up to 6.2% organic bound nitrogen and up to 7.8% carboxy groups. Nitrogen-containing derivatives of wood contain 15–35% weakly bound (ammonium and amide) and 65–85% firmly bound (amine and heterocyclic) nitrogen relative to its total amount.

(3) Oxidative ammonolysis of pine wood with hydrogen peroxide in ammonia medium is accompanied by demethylation with loss of up to 65% of OCH_3 groups of their total amount.

(4) The resulting nitrogen-containing products have a high sorption capacity for Zn^{2+}, Cd^{2+}, and Cu^{2+} cations (SEC 2.5–4.7 mg-equiv g^{-1}) and can also be used as organic fertilizers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of Water-Soluble Sulfur-containing Derivatives of Wood

M. V. Efanov, E. S. Filina, and M. V. Popova

Altai State University, Barnaul, Russia

Received September 30, 2003

Abstract—The influence of conditions of alkaline activation on xanthation of pine wood with mechanochemical preactivation was studied. It was shown that the duration of alkaline preactivation and the amount of sodium hydroxide exert a decisive effect on the degree of conversion of wood. The resulting macromolecular compounds are soluble in aqueous alkaline solutions and form viscous solutions.

Xanthation of cellulose, aimed at production of viscose fibers and films, is based on preparation of cellulose esters by the reaction of alkaline cellulose with carbon disulfide and is widely used in production of chemical fibers [1]. There are published data on the reaction of individual carbohydrate components of wood (cellulose, oligosaccharides, and hemicelluloses) with carbon disulfide in the presence of sodium hydroxide [2]. However, published data on direct xanthation of lignin, wood, and other lignocarbohydrate materials are virtually lacking.

A mechanochemical procedure for xanthation of wood and other lignocarbohydrate materials for production of water-soluble surfactants and fertilizers has been developed previously [3]. Here we describe how the conditions of alkaline pretreatment of pine wood affect the characteristics of water-soluble sulfur-containing polymers produced by its xanthation.

EXPERIMENTAL

A 0.5-mm fraction of air-dry sawdust of pine wood was used as the raw material. Composition of the raw materials (%): lignin determined by the Komarov method, 26.1; cellulose determined by the Kürschner method, 53.8; hemicellulose determined by the Wise method, 17.6. The content of hydroxy groups determined by the Werley acetylation method in the presence of pyridine [4] was 23.5%.

The sulfur content in the resulting products was determined by the Schoeniger method using the procedure described in [5] (error 0.1%). The degree of conversion of hydroxy groups in xanthation, α, was evaluated as the ratio of the content of bound sulfur, determined analytically, to the theoretical content (20.5%) evaluated from the content of hydroxy groups.

The xanthation procedure has been described previously [3]. Xanthation of wood involves mechanochemical activation in the presence of sodium hydroxide with and without addition of water, followed by xanthation proper. The reaction products were washed to remove thio salts with 5% solution of acetic acid in ethanol (50–100 ml) to pH 3–4 an then with ethanol to negative reaction for S^{2-} ion with lead(II) nitrate. The presence of thio salts in the filtrates was tested spectrophotometrically on an SF-46 spectrophotometer at λ = 335 nm (absorption of sodium trithiocarbonate).

The influence of the following factors on the characteristics of products of pine wood xanthation was studied: duration of alkaline pretreatment, amount of reactants, and duration of xanthation. In particular, we determined the solubility of these products in 5% solution of sodium hydroxide and the specific viscosity of the resulting solutions on an Ubbelohde viscometer (d = 0.65 mm) at 20°C according to the procedure described in [6].

The influence of duration of pine wood xanthation on the sulfur content in the resulting products, their solubility in aqueous alkali solution, and specific viscosity of solutions η_{sp} is illustrated in Table 1.

With increasing duration of pine wood xanthation from 10 to 30 min, the sulfur content in the result-

1 : 2.5	2.7	0.14	40
1 : 3	1.9	0.09	39

ing products and the degree of conversion of wood increase. The maximum solubility was observed for the product containing 3.5% S (Table 1).

Further increase in xanthation duration to 40–50 min results in a certain decrease in the content of bound sulfur and in the solubility. This trend is accounted for by side process of formation of thio salts and mechanochemical degradation, disturbing the xanthation equilibrium.

Data on the influence of duration of mechanochemical alkaline pretreatment on the sulfur content, solubility of the resulting products, and degree of conversion of pine wood in xanthation are presented in Table 2.

With the duration of alkaline preactivation increasing from 5 to 30 min, the content of bound sulfur in the xanthation products increases. The degree of conversion of wood varies insignificantly and is 18% after alkaline treatment for 30–40 min. These data show that, with increasing duration of alkaline preactivation, the solubility of the products decreases, which is apparently caused by alkaline degradation occurring upon prolonged mechanochemical action. Therefore, we selected for further studies the optimum duration of alkaline treatment of pine wood equal to 10 min.

Data on the influence of the amount of sodium hydroxide added in the stage of alkaline preactivation on the degree of conversion, solubility, and sulfur content in the xanthation products are presented in Table 3.

It was found that the increase in the molar ratio from 0.5 to 1.5 results in a higher content of bound sulfur in the xanthation products and a higher degree of conversion of wood. Further increase in the amount of sodium hydroxide to 2–3 mol per mole of OH groups of wood is accompanied by a certain decrease in the sulfur content.

An increase in the sodium hydroxide concentration decelerates xanthation of wood, which can be accounted for by binding of free NaOH to form thio salts by the reaction

$$6NaOH + 2CS_2 \rightarrow Na_2S + Na_2CO_3 + Na_2CS_3 + 3H_2O. \quad (1)$$

The optimal molar ratio OH : NaOH is 1 : 1. The influence of the content of water in the reaction mixture, added in the stage of alkaline preactivation, on the xanthation of wood is illustrated by Table 4.

An increase in the amount of water from 1 to 4 mol results in that the content of bound sulfur and the solubility grow, apparently, due to enhancement of hydration. Further increase in the water content in the reaction mixture to above 4 mol is accompanied by a certain decrease in the sulfur content and also in the solubility of the products, apparently due to partial saponification of the resulting wood xanthates and formation of thio salts. The maximum amount of reacted hydroxy groups is 34%.

Table 4. Influence of water content on the characteristics of products of pine wood xanthation (molar ratio OH : $NaOH : CS_2$ = 1 : 1 : 1, duration of alkaline activation 10 min, xanthation duration 30 min)

1 : 3	8.7	0.44	75
1 : 3.5	8.8	0.44	70
1 : 4	8.8	0.44	68

Data on the influence exerted by the amount of carbon disulfide added on the sulfur content and the solubility of the products of wood xanthation in aqueous alkaline solution are listed in Table 5.

With the amount of carbon disulfide increasing from 1 to 2.5 mol, the content of bound sulfur in the products of wood xanthation grows. Further increase in the amount of this reactant to 3–4 mol per mole does not result in variation of the sulfur content, which is apparently caused by side reactions, namely, by saponification of xanthates and their mechanochemical degradation, and also by formation of thio salts. The degree of conversion of wood in xanthation, evaluated from the sulfur content, suggests that, under the conditions studied, 5–44% of the hydroxy groups of wood had reacted (Tables 1–5).

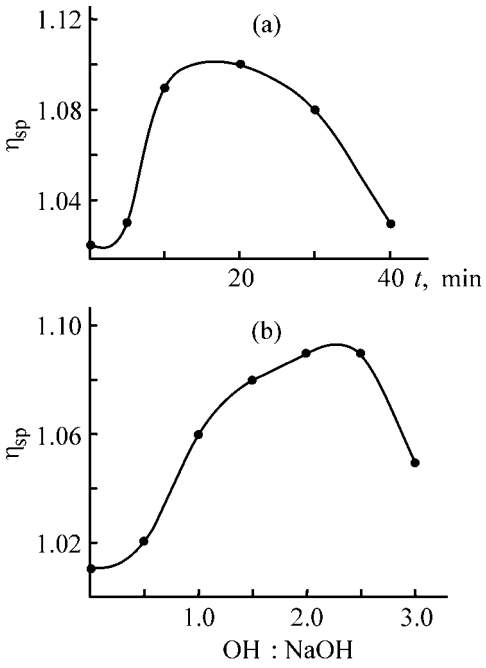
The influence of various process conditions can be estimated from variation of the specific viscosity of the products of wood xanthation. In prolonged alkaline activation and at high ratios of the reactants, the specific viscosity decreases (figure), which is caused by the prevalence of alkaline and mechanochemical degradation of the main components of wood under these conditions.

As can be seen from the figure, the dependences of the specific viscosity of alkaline solutions of wood xanthate on the main parameters of alkaline activation pass through a maximum. This is apparently caused by the competition of two parallel processes occurring in wood xanthation: formation of xanthates and their degradation with partial dissolution of the main components of wood in the reaction medium with variation of the process conditions.

Thus, the products of wood xanthation have 30–75% solubility in aqueous alkaline solutions and form highly viscous solutions. Alkaline activation of wood significantly affects the characteristics of the xanthation products. The resulting products can be used as polymeric surfactants.

CONCLUSIONS

(1) Macromolecular products containing up to 8.8% bound sulfur and having solubility in aqueous-alkaline solutions of up to 75% were obtained by xan-



Specific viscosity of the products of pine wood xanthation η_{sp} vs. (a) duration of alkaline pretreatment t and (b) molar ratio OH : NaOH.

thation of pine wood with mechanochemical preactivation.

(2) The stage of alkaline preactivation of raw materials exerts the decisive influence on wood xanthation and characteristics of the resulting products. Within 30 min of xanthation, up to 44% of hydroxy groups of wood react with carbon disulfide.

CHEMISTRY OF FOSSIL FUEL

Identification of Oxygen-containing Compounds in Benzine and Kerosene Oil Fractions and Determination of Sulfur and Halogen Content in Them

O. Yu. Begak and A. M. Syroezhko

Received April 8, 2003

Abstract—A procedure based on X-ray fluorescence and inductively coupled plasma with mass spectrometric recording was developed for express determination of the content of sulfur and halogen-containing compounds in benzine and kerosene oil fractions. Oxygen-containing compounds in gasolines and reforming products were identified by chromatography-mass spectrometry.

The requirements to the quality of motor fuels (in particular, to gasoline) become increasingly stringent [1]. Heteroatomic compounds (S-, O-, N-, and chlorine-containing products) strongly affect the gasoline quality. The major part of these compounds is removed by hydrofining, but their certain fraction is retained in the final product.

In this study we developed reliable procedures for quantitative determination of heteroorganic compounds in raw materials and benzine components, and also in reforming products from the Ryazan Oil Refining Plant, Joint-Stock Company (RORP).

EXPERIMENTAL

The samples of the initial raw materials, catalyzates, and stable and unstable hydrogenizates were taken from installations for primary (AT-6) and secondary oil refining [hydrofining of benzine, kerosene, diesel oil, and other reforming products, namely, L-35/8-300 (benzene), L-35/5-300 (xylene), L-35/11-300 (12/1, benzine)] and for hydrofining of kerosene (24/600) at the Ryazan Oil Refining Plant. The contents of sulfur and organic chlorine were determined by X-ray fluorescence analysis (RF) [2] using a Spectroscan spectrometer and by the method of inductively coupled plasma with mass spectrometric recording (ICP-MS). The comparative study of products from the entire cycle of production of high-octane gasolines was performed by IR Fourier spectrometry (IR-FS) [3] on an FSM 1201 unit.

The oxygen- and nitrogen-containing compounds in the samples were identified by gas chromatography-mass spectrometry (GC-MS) according to the procedure given in [4], using the MassLab and Amdis software and databases.

The highest content of sulfur was determined in the feed of the 24/600 installation. The 105-140 (feed of L-35/5-300) and 115–180°C fraction contain 0.0353 and 0.0487 wt % sulfur, respectively. The feed of the installation for benzene reforming, (62–85°C, L-35/8-300) and 85–105°C fraction (feed of L-35/6-300) contain 0.0128 and 0.0184 wt % sulfur, respectively.

The content of sulfur in the wide benzine fraction, 85–180°C, supplied to benzine reforming and in benzine from the K-8 fractionating column (AT-6 installation) varies from 0.054 to 0.062 wt %.

Due to hydrofining, the content of sulfur in stable hydrogenates and catalyzates obtained from the above installations decreases to 0.0005 wt%, whereas in imported gasoline, its content is as high as 0.0098 wt %.

The IR spectrum of the straight-run naphtha from the K-8 column (AT-6) exhibits a broad strong absorption band of the methylene groups of alkanes and naphthenes at 2850–2980 cm^{-1}. The presence of methylene groups in alkanes and in paraffins and cyclic compounds (C_5–C_6) is confirmed by a doublet at 1365–1395 and a singlet at 750 cm^{-1}, respectively. The content of arenes in naphtha is low, which is confirmed by a weak band at 1580 cm^{-1}. The carboxy and hydroxy

Table 1. Content of chlorine, bromine, and iodine in feed, hydrogenizates, and catalyzates from various installations at the RORP Join-Stock Company

Installation, product	Cl	Br	I
	$c \times 10^{-4}$, wt %		
AT-6, desalinated oil	16.0	3.9	6.4
24/600, feed	13.0	1.8	5.5
24/600, hydrofined kerosene	1.8	0.7	2.4
Å™-6, naphtha from K-8	11.0	2.5	5.6
L-35/5-300, feed	10.0	2.1	5.8
L-35/5-300, catalyzate	2.1	0.75	3.2
L-35/5-300, unstable hydrogenizate	1.5	0.6	3.0
L-35/5-300, stable hydrogenizate	1.2	0.5	2.9
L-35/11-300, feed	9.0	1.8	4.6
L-35/11-300, stable catalyzate	3.0	1.0	3.2
L-35/11-300, unstable hydrogenizate	1.7	1.0	0.9
L-35/11-300, stable hydrogenizate	1.3	0.75	0.84
L-35/8-300, feed	8.0	2.5	5.1
L-35/8-300, catalyzate	1.7	1.0	0.9
L-35/8-300, unstable hydrogenizate	1.3	0.65	2.2
L-35/11-300, stable hydrogenizate	1.0	0.6	2.1
12/1, 62–70°C fraction	1.1	0.8	0.9
12/1, 70–115°C fraction	5.0	1.8	1.3
L-35/11-1000, feed	8.0	1.3	1.4
12/1, 115–180°C fraction	7.0	2.0	1.6

groups in naphtha are almost absent; the absorption bands corresponding to these groups are very weak.

As can be seen from the IR spectrum of the catalyzate (L-35/11-300 installation), it is enriched in arenes (1580 cm^{-1}), whereas the content of alkanes is smaller than that in the initial naphtha (180°C dry point).

According to the IR spectra, there are no arenes in light benzine from the E-201 tank (L-35/11-300 installation). The intensity ratio of the absorption bands in the IR spectra of unstable catalyzate sampled from the S-1 separator (L-35/11-300 installation) and hydrogenizate differ from that in the feed. The IR spectrum of the stable catalyzate from this installation exhibits strong absorption bands of arenes at 700–740, 1580, and 3080 cm^{-1}.

The IR data indicate that the 62–70 and 70–115°C fractions contain almost no arenes; these fractions predominantly consist of alkanes, isoalkanes, and naphthenes (strong absorption band at 750 cm^{-1}).

Organic halogens were determined by combustion of the oil product sample, with subsequent absorption of the combustion products with soda and analysis by ICP-MS.

As can be seen from Table 1, the content of organic halides in the feed supplied for secondary oil processing is higher than that in the final products from installations for hydrofining and reforming. The content of chlorine in unstable hydrogenizate is higher than that in the stable product. The chlorine content increases with increasing dry point of the fraction.

It should be noted that, in some cases, the iodine content is much greater than that of bromine. Organic compounds of iodine, bromine, and chlorine strongly accelerate corrosion of installations and pipelines, especially in the presence of water.

The data on the content of organic chlorine in oil and some petroleum products from installations for benzene and benzine reforming at the KINEF Limited Liability Company processing West-Siberian crude oil well agree with the results of an analysis of the feed and products from the RORP installations using the same crude oil.

A typical chromatogram of the 85–180°C fraction, used as the feed at the L-35/11-300 reforming installation, consists of 42 peaks; most of them belong to the compounds listed in Table 2. Nearly 40 and 10 oxygen-containing compounds were iden-

tified in the straight-run naphtha sampled from K-8 column (AT-6 installation) and in hydrogenizate of benzine reforming (L-35/11-300), respectively (Table 2).

The data on the content of oxygen-containing compounds in three samples taken from L-35/11-300 and AT-6 installations are also listed in Table 2. According to GC-MS data, the feed supplied to

the L-35/11-300 installation (85–180°C) contains 42 compounds [41 oxygen-containing compounds and insignificant amounts of 2,2,4-trimethyl-1,2-dihydroquinoline (0.05 wt %)]. Aliphatic alcohols and ketones (C_4–C_9) were mainly identified, and the content of ketones is greater than that of alcohols by a factor of 3. The content of alicyclic alcohols is smaller by a factor of 32.4 – 48.0 than that of acyclic compounds. Similar trend is observed for ketones: the acyclic to alicyclic ketone ratio in the samples studied varies from 140 to 205.

As can be seen, aliphatic ketones with methyl substituents at different distance from the carbonyl group are predominant in the samples studied. The fraction of linear ketones C_6–C_8 is smaller. Among alcohols, the major fraction belongs to linear (primary and secondary) aliphatic alcohols.

CONCLUSIONS

(1) The content of sulfur and halogen-containing compounds in benzine and kerosene oil fractions from the RORP Joint-Stock Company was determined using the methods of X-ray fluorescence and inductively coupled plasma with mass spectrometric recording; oxygen-containing compounds were also identified. It was found that the content of ketones is greater than that of alcohols by a factor of 3.

(2) X-ray fluorescence procedure is the best method for express determination of sulfur in benzines and their components and in kerosene. For control of hydrofining and reforming (aromatization) of the benzine and kerosene fractions, the IR Fourier spectrometry is preferable. The method of inductively coupled plasma with mass spectrometric recording is the best for express analysis of halogens in organic compounds contained in oil and petroleum products.

(3) The higher the dry points of the fraction, the greater the content of bromine and iodine in it; in some cases the iodine content is much higher than that of bromine.

CHEMISTRY OF FOSSIL FUEL

Relationship between Group Composition of Tars and Asphalts Produced from Various Crude Oils and Their Performance Characteristics

A. M. Syroezhko, O. Yu. Begak, and V. V. Fedorov

Received October 28, 2003; in final form, January 2004

Abstract—A comparative study is made of the thermodynamic stability of asphalts produced from various crude oils differing in their density, in the content of sulfur, resin, and asphaltene, and in the yield of top paraffins (fraction <350°C). The relationship between the group composition of tars and asphalts produced from these oils and their performance characteristics is analyzed.

It is known that the presence of a fairly large amount of the naphtheno-aromatic rings in the oil fraction of asphalts imparts a colloidal stability and desirable physicochemical characteristics (penetration P_{25} and ductility D_{25}) to bitumens. In the case of an insufficient content of the oil fraction, or when this fraction is of essentially naphtheno-paraffinic nature, the colloidal stability of bitumen decreases, as also do its ductility and mechanical characteristics. Therefore, we examined in this study the effect of the group composition of petroleum tars and asphalts on their performance characteristics.

We examined four petroleum tars (nos. 1–4 in Table 1) and asphalts obtained by their oxidation (nos. 5–9 in Table 1). Tar sample no. 1 was produced at the Kirishi refinery (hereinafter, manufacturer I)

BND 60/90 (no. 9, Yaroslavl refinery, T_s 48°C)	81.3	18.7	20.2	80.0

* Numbering of samples is the same as in Table 1; the same for text below.

from West-Siberian crude oil; sample no. 2, at the Yaroslavl refinery (II) from West-Siberian crude oil; sample no. 3, at the Norsi Joint-Stock Company (III) from crude oil extracted by the Tatneft' Joint-Stock Company; and sample no. 4, at the Ukhta refinery (IV) from Yarega crude oil.

Tar nos. 1–4 and asphalt nos. 5–9 were deasphalted in a Soxhlet apparatus.

The polar fraction (PF) was extracted from malthenes of the tars and asphalts with DMF. Group separation of polar and nonpolar fractions (NPF) was performed on a silica gel [1, 2].

EXPERIMENTAL

The yields of asphaltenes, malthenes, and polar and nonpolar components, and also the group composition of tars and asphalts under study are listed in Table 2. The yields of malthenes from the tar samples are very close (88.6–89.6%) (Table 2). The yields of polar and nonpolar fractions are about the same (to within 1.5 wt %).

After oxidation of tars into BDUS 70/100 and BDUS 60/90 asphalts, the yield of malthenes from the oxidized samples decreased to 79–80.7%, and that of asphaltenes increased [3].

In the initial tar samples, the asphaltene content is 10.5–11.4 wt %, whereas in the corresponding asphalts (from West-Siberian oil) it ranges from 19.3 to 21 wt %. The yield of the polar fraction from asphalts is higher by 4.3–6.3 wt %, compared to the corresponding tars. Note that tar sample no. 2 [P_{25} 390 (here and hereinafter, 0.1 mm units), RV_{80} 92 s] was oxidized deeper (asphalt sample no. 6, T_s 49°C) than tar no. 1 (P_{25} 305, RV_{80} 89 s). The content of polar components in asphalt no. 6 with a higher softening point increased by 1.8 wt % [3].

Asphalt from Yarega oil differs noticeably in the asphaltene content (22.1 wt %) produced from asphalts from other crude oils. It is also characterized by a high content of the polar component (25.7 wt %). Tar nos. 8 and 9 from the Yaroslavl and Nizhni Novgorod refineries differ from tar nos. 5 and 6 from the Kirishi refinery to a considerably lesser extent.

Tables 3 and 5 shows that the content of oils and resins is essentially different in both the polar and nonpolar fractions of the tars studied and of the corresponding asphalts. In particular, the oils/resins ratio in the nonpolar fraction (NPF) of tar no. 1 (P_{25} 305) is 2.06, whereas that in BDUS 70/100 asphalt (no. 6) is considerably lower (1.73). The resin content in the polar fraction of tar no. 1 and the corresponding asphalt (no. 5) increases, and this ratio is 1.37 and 1.25, respectively.

Tar no. 2 with an increased penetration (P_{25} 390) is distinguished by higher oil content in both polar and nonpolar components.

The oils/resins ratio in the nonpolar fraction of this tar is 2.46, whereas that in tar with P_{25} = 305 is 2.06, and in the polar fraction of the tars under comparison, 1.60 and 1.37, respectively.

It should be pointed out that tar nos. 1 and 2 from West-Siberian oil differ each from other not only in the penetration, but also in the relative viscosity. From tar with P_{25} = 305, BDUS 70/100 quality asphalt was obtained, having the desired T_s, P_{25}, D_{25} and thermal stability (P_{25} and D_{25} after heating). At the same time, from tar no. 2 with higher relative viscosity (92 s), P_{25}, and oils/resins ratio, we were able to obtain only harder BND 60/90 asphalt (no. 6), having not only an increased softening point, but also a lower thermal stability.

It is worth noting that BND 60/90 asphalt (no. 6) obtained from tar with P_{25} = 390 0.1 mm units and then oxidized into asphalt with higher T_s is characterized by a higher oils/resins ratio in both the nonpolar and polar fraction as compared to BDUS 70/100 quality asphalt no. 5.

It is known that the thermal stability of asphalts strongly depends on the degree of aromaticity of the starting tars and resulting asphalts. In this case, the thermal stability (defined as the permissible temperature range of variation of the softening point, penetration, ductility, and brittle point) is influenced not only by the deepness of oxidation, but also by the content of oils, resins, asphaltenes, and aromatic compounds.

Not only the total content of these compounds, their ratio, composition (molecular weights and content of polar components depending on the concentration of heteroatoms and paramagnetic centers in the system), and degree of association of the indicated components and their aromaticity are of importance, but also the concentration and nature of trace com-

pounds (metal complexes). It was noted in the literature that, if polycycloarenes dominate among aromatic hydrocarbons of the oil fraction, the packing density of the micellar structures of tars and asphalts is higher, and, correspondingly, such asphalts are characterized by increased thermal stability [3].

According to our results, not so much the content of BCACs and PCACs is important as the degree of aromaticity of these compounds. To obtain thermally stable asphalt, it is also important to meet a desired oils/resins ratio. Because of the increased content of resins in tar no. 2 with $P_{25} = 390$, the resulting asphalt no. 6 also contains undesired excess of resins, compared to asphalt no. 5, so that its degree of structurization (third-type structure of colloidal aggregates by Kolbanovskaya) is lower. With increasing solvency of malthenes and decreasing asphaltenes/resins ratio, the strength of the asphalt structure decreases.

The presence of NPCs in the polar fraction and also of heteroatomic compounds (Tables 3, 4) suggests that the extraction of group components of tar and asphalt proceeds not at the molecular level, but at a level of associates. Evidently, both asphaltenes and malthenes are associated in black oil, the latter forming smaller associates. Dimethylformamide extracts NPCs associated with other more polar molecules. Compounds of hybrid structure (containing both naphthenic and aromatic rings) with long linear alkyl chains can also be extracted, which then behave as NPCs.

Asphalt is a typical dispersion. Its dispersed phase (associates) is distributed throughout the oil fraction, which is the dispersion medium. Because of the strongly different polarities of components, lyophobic dispersions are characterized by weak phase interaction, being thermodynamically unstable. By contrast, lyophilic dispersions are characterized by strong interaction and considerable mutual solubility of components only slightly different in their nature. Such systems are spontaneously formed as abnormally finely dispersed systems (colloid solutions), to which primarily belong emulsions.

The observed deviations in the behavior of tar or asphalt from ideality can be attributed to molecular interactions occurring between numerous compounds contained in structural units. The nature of intermolecular interactions depends on the properties of hydrocarbons (primarily those of hybrid structure) and heteroatomic compounds and on their reactivity.

It is difficult to characterize the chemical organization and to predict properties of such a complex system as tar or asphalt. However, attempts have been made to predict the structure–property trends in a series of polycyclic compounds [4].

The compounds constituting tars and asphalts can be arranged in order of decreasing dipole moment as follows: nitrogen-containing aromatic components of asphaltenes and resins > oxygen-containing components > sulfur-containing components > hybrid-structure condensed PCACs > BCACs > MCACs. The most common and universal forces causing intermolecular interactions are the dispersion forces controlled by the ionization energy and polarizability of molecules.

At an intermolecular distance considerably exceeding the molecular diameter ($r \gg d$), the relative dipole–dipole, induction, and dispersion contributions to the intermolecular interaction energy γ can be determined from comparison of $r^6\gamma_{\text{dip–dip}}$, $r^6\gamma_{\text{ind}}$, and $r^6\gamma_{\text{disp}}$.

For weakly polar molecules, the first two values are lower by several orders of magnitude than $r^6\gamma_{\text{disp}}$. For molecules with higher dipole moment (≥1.5 D), $r^6\gamma_{\text{dip–dip}}$ starts to dominate over the dispersion term.

At an intermolecular distance comparable with the size of molecules, the energy of interaction is no longer an additive value, but, by virtue of electrostatic repulsion, it is lower than it would be if the law $\gamma \approx 1/r^6$ were valid down to these distances.

Brief consideration of certain reactivity issues for representatives of various classes of organic compounds composing tars and asphalts reveals an ambiguity of their predicted contributions to the overall state of aggregation of the system. However, there is no doubt that it is affected by Coulombic interactions between molecules of group components of black oil, association through hydrogen bonding, and π–π interaction between aromatic rings in asphaltenes, resins, PCACs, BCACs, and MCACs.

Furthermore, tars and asphalts contain 3*d* elements capable of forming chelates with heteroatomic (sulfur-, oxygen-, and nitrogen-containing) ligands. Formation of mixed-ligand complexes is also possible, as well as that of donor–acceptor complexes with heteroatoms of resins and asphaltenes, and π complexes with polycycloaromatic compounds.

For a binary mixture consisting of, e.g., resins (r) and asphaltenes (a), we can write

$$\delta_{ra} = \sqrt{\delta_r \delta_a},$$

where δ_r and δ_a are the attractive interactions between unitypical molecules of resins and asphaltenes, respectively; and δ_{ra} is the attractive interaction between resin and asphaltene molecules.

At $\delta_{ra} > \delta_r$ and δ_a, mixing of resins with asphaltenes liberates potential energy, which results in an increase in the temperature and a decrease in the volume and vapor pressure of the mixture. In this case, molecules interact each with other more strongly, and their separation requires higher temperature.

The above considerations are valid for multicomponent systems also. However, in tars and asphalts, asphaltenes occur as associates. Components of oils (arenes) and resins are most likely associated too, but their intermolecular interactions are weaker than those of asphaltenes. Associates of oils and resins are very sensitive to external factors and, in particular, to temperature.

Additionally, to obtain an energetically favorable structure, it is necessary to have the optimal type of interaction between components of the system. Association of complex hybrid structures of BCACs, PCACs, resins, and asphaltenes at ambient temperature results in a slow establishment of the thermodynamic equilibrium in asphalts. To a first approximation (by Hildebrand), the bonding strength between molecules of different types is controlled by the force field of the molecules [$\delta = f(\Delta H_{vap}/V)$, where V is the molar volume]. This parameter is known as the cohesion energy density. The closer the force fields of molecules, the higher the mutual solubility of the compounds. The δ value increases in the order NPCs < MCACs < BCACs < PCACs < TRs < ATRs < asphaltenes, weakly associated polar compounds.

Data on the group composition of BDUS 70/100 thermostable quality asphalt (no. 5) and BND 60/90 substandard asphalt (no. 6) show that they differ in that the resins/total aromatics ratio is higher in the quality asphalt.

Let us compare the group compositions of tars studied and the corresponding asphalts obtained from them. In quality tar no. 1 (P_{25} = 305), the content of NPCs in NPF and PF is 22 and 10.6 wt %, respectively. At the same time, for tar no 2 (P_{25} = 390) the corresponding values are 20.1 and 10 wt %, i.e., both samples are only slightly different in this parameter.

In the corresponding BDUS 70/100 quality asphalts (no. 5) and less thermostable BND 60/90 (no. 6), these values are 14.2 and 7.2 wt %, and 15.8 and 7.2 wt %, respectively. Therefore, although the total content of NPCs in asphalts decreases relative to that in tars, the ratio between the contents of NPCs in NPF and PF remains nearly the same.

There is a tendency toward an increase in the contents of arenes and resins in the polar fraction of both the initial tars and resulting asphalts. The total of MCACs + BCACs in the nonpolar and polar fractions of tar no. 1 and BDUS 70/100 quality asphalt (no. 5) is 45.3–46.9 and 48.7–49.2 wt %, respectively, i.e., the content of aromatic structures increases after oxidation. In less thermostable BND 60/90 (no. 6), the total of MCACs + BCACs is nearly the same as in the initial tar. It ranges from 50.4 to 51.6 wt % in both polar and nonpolar fractions of the tar and asphalt. Note that the MCACs/BCACs ratio in thermostable BDUS 70/100 asphalt (no. 5) is higher than that in less thermostable BND 60/90.

Table 5. Group composition of asphalt no. 9 from West-Siberian oil (Yaroslavl refinery)

Fraction	NPF	PF
	wt %	
NPCs	16.2	8.2
MCACs	20.5	18
BCACs (PCACs)	22.0	24.8
TRs	19.0	19.8
ATRs	22.3	29.2
Oils	58.7	51.0
Resins	41.3	49.0
Oil/Resin	1.40	1.04
Resin/Σ[MCACs + BCACs (PCACs)]	0.97	1.14
TRs/ATRs	0.85	0.68
MCACs/BCACs (PCACs)	0.93	0.73

Finally, the most noticeable differences in the group composition of thermostable (quality) and less thermostable asphalts and the corresponding initial tars are reflected in the resins/total arenes ratio in the oil fraction. This ratio is higher in BDUS 70/100 quality asphalt and the corresponding tar in both polar and nonpolar fractions, compared to less thermostable BND 60/90 asphalt.

The polar fractions of tars and the corresponding asphalts are characterized by higher resins/total arenes ratio, compared to the nonpolar fractions. Furthermore, the TRs/ATRs ratio and, as indicated above, the MCACs/BCACs (PCACs) ratio in the nonpolar and polar fractions are higher in quality asphalt.

Thus, the thermal stability of asphalts depends on the group component ratio in the initial tar and resulting asphalt and also on their structure (structural types 1–3 by Kolbanovskaya). As noted above, the asphalts studied are classified with the third-type structures. Evidently, the presence of a fairly large amount of

the oil fraction characterized by a high carbon content in cyclic structures and a high aromaticity imparts the colloidal stability to asphalts. The distribution of atoms plays an important role also [3].

The optimal capacity of asphaltenes and resins for structurization should be combined with the optimal MCACs/BCACs (PCACs) ratio, to obtain the most aggregatively stable and, therefore, less temperature-sensitive structure, in which changes in the penetration and ductility, initiated by the effect of heating (aging) or addition of a mineral ballast, will be at a minimum.

For comparison, Tables 5, 6 show the group composition of asphalts obtained at the Yaroslavl, Norsi, and Ukhta refineries from West-Siberian oil, oil extracted by the Tatneft' Joint-Stock Company, and Yarega oil, respectively (sample nos. 9, 8, and 7). In the group composition, asphalt from the Yaroslavl refinery is close to BDUS 70/100 quality asphalt from the Kirishi refinery, as demonstrated by the oils/resins and resins/Σ[MCACs + BCACs (PCACs)] ratios in the nonpolar and polar fractions, respectively. The most noticeable differences between the asphalt samples are found in the MCACs/BCACs (PCACs) ratio. The increased content of MCACs in BDUS 70/100 asphalt from the Kirishi refinery, i.e., the lower aromaticity, makes this asphalt less thermostable, compared to the asphalt from the Yaroslavl refinery.

In asphalt no. 8 from the Norsi Joint-Stock Company (Table 6), we found increased content of TRs, ATRs, and heavy aromatics (BCACs, PCACs), but lower content of NPCs and MCACs, compared to the quality asphalt from the Kirishi refinery. Therefore, the thermal stability of asphalt from Norsi will be higher.

The most pronounced differences were found between BDUS 70/100 asphalt from Kirishi and BDU 70/100 asphalt from Ukhta (Table 7). The content of MCACs in the nonpolar and polar fractions of asphalt from Yarega oil, manufactured at the Ukhta refinery, is lower by a factor of 2.03 and 2.27, respectively. At the same time, asphalt from Ukhta contains more BCACs (PCACs), TRs, ATRs, and asphaltenes (Table 7). Furthermore, BDU 70/100 from Ukhta contains less naphtheno-paraffinic compounds in NPF and PF. The aromaticity of asphaltenes of asphalts under comparison is 0.395 and 0.5, respectively. Asphalt from Ukhta is characterized by increased concentration of heteroatomic compounds (*O*-, *S*-, *N*-) in both HPF and PF compared to BDUS 70/100 quality asphalt from Kirishi. Asphalts under comparison (nos. 5–7) are obtained from different oils (paraffin-base and asphalt-base oils), which is reflected in the remarkably different group composition of the initial

tars (Table 2). Tar no. 3 from Yarega oil contains more asphaltenes and resins as compared to tars from West-Siberian oils (nos. 1, 2). These tars also differ in the content of the oil fraction. Our results suggest that the performance characteristics of asphalts studied increase in the order West-Siberian paraffin-base oils < oils extracted by the Tatneft' Joint-Stock Company < Yarega oils.

It is obvious that the major factors controlling the aggregative stability of the 3*D* coagulation structure of asphalts are the concentration of asphaltenes in the dispersed phase and its chemical affinity for oils and resins composing the dispersion medium. The formation of a kinetically stable fluctuation state of the asphalt structure is completed in the first several days after it was mechanically or thermally distorted.

It follows from a numerical analysis of small-angle X-ray diffraction patterns that the structure of the asphalt dispersion is characterized by the occurrence of first- and second-order microinhomogeneities. According to [5], the size of these microinhomogeneities does not depend on the group composition of asphalts, which is rather questionable in our opinion. In the cited work, first-order microinhomogeneities are interpreted as primary structural units containing nuclei of the asphaltene phase 2–6 nm in size, and second-order microinhomogeneities, as asphaltene aggregates about 10 nm in size, formed in the course of condensation structurization in the bulk of a complex structural unit.

The aggregative stability of the 3*D* coagulation structure not only depends on the concentration of asphaltenes forming the dispersed phase, but also is caused by the absorption factor, specifically, by the chemical affinity of asphaltenes for oil and resinous components composing the dispersion medium. As a parameter characterizing this affinity, the lyophobicity index *L* is suggested, which is defined as the difference between the aromaticity (fraction of aromatic carbon) of asphaltenes and oils, since it is the presence of condensed aromatic structures in black oil that is the necessary condition for their association into lamellar structures. Posadov *et al.* [6] have demonstrated that *L* is independent of the degree of oxidation of asphalts, but is controlled by the chemical composition of the initial petroleum tars, being 0.18, 0.28, and 0.31 for asphalts obtained by oxidation of tars from West-Siberian, Romashkino, and Arlan oils, respectively. Therefore, the 3*D* coagulation structure of asphalts from Romashkino and Arlan oils should be more stable, and these asphalts, naturally, will be more thermostable, compared to those obtained from West-Siberian oils.

Table 8. Group composition of tars from the AVT-60 plant of the Kirishi refinery

Sample no.	Paraffins (NPCs)	Arenes (BCACs + MCACs)	Resins	Asphaltenes
	wt %			
5	10.3	54.2	24.4	11.1
6	9.8	54.6	22.7	12.9
7	11.4	50.9	26.2	11.5
8	11.9	54.9	20.5	12.7
9	11.9	52.4	24.2	11.5
10	7.6	61.7	20.1	10.6
11	10.5	54.8	23.0	11.7

The correlation between the lyophobicity index and rate constant of condensation structurization *K* can be approximated by the linear relationship

$$K = K_0(L - 0.13),$$

where $K_0 = 8.5 \times 10^{-3}$ yr, suggesting that petroleum disperse systems are thermodynamically stable at $L > 0.13$.

For comparison, we present in Tables 8 and 9 the group composition for an extended sample of tars and asphalts from the Kirishi refinery. The tars were taken from the AVT-6 plant, and the asphalts, from the Bitumnaya-2 plant in May 2000. These data show that the group composition of tars and asphalts only slightly varies samples. In asphalts, the arene content (MCACs + BCACs) decreases and the content of resins and asphaltenes increases as compared to the initial tars.

A higher thermostability, which can be judged from the increase in the softening point (Table 9) and a less pronounced decrease in the penetration and ductility after heating, is observed at the optimal resins/Σ(MCACs + BCACs) ratio from 0.65 to 0.67. Asphalts with $D_{25} < 100$ have a substandard quality after heating for 5 h at 160°C.

In the penetration after heating, all the asphalts from Kirishi (Tables 1 and 9), except sample nos. 5 (Table 1) and 13 (Table 9), meet the requirements only for BND 40/60 hard asphalt, falling outside the range acceptable for the initial BDUS 70/100 and BND 60/90 grades.

Table 9. Characteristics of asphalt nos. 10–16 (Kirishi refinery) obtained by oxidation of tar nos. 5–11 (see Table 8)

Parameter	Sample no.						
	no. 10	no. 11	no. 12	no. 13	no. 14	no. 15	no. 16
T_s, °C	45	45	48	43.5	48.5	48	48.5
Ash content	1.0188	1.023	1.0235	1.0196	1.0218	1.019	1.021
P_{25}, 0.1 mm units	79	76	67	123	84	78	85
D_{25}, cm	150	146	126	118	31	138	128
P_{25} after heating, 0.1 mm units	66	67	71	57	71	60	70
T_s after heating, °C	49	49.5	50	49	52	54	54.3
D_{25} after heating, cm	132	118	54	94	56	81	102
Content, wt %:							
NPCs	10.3	10.0	11.1	10.4	9.4	7.8	9.8
MCACs + BCACs	44.6	43.4	39.1	46.8	46.2	46.44	46.4
resins	29.8	28.3	30.6	28.5	27.1	23.80	23.3
asphaltenes	15.2	18.3	19.2	14.3	16.9	21.95	20.5

Table 9 shows that asphalt nos. 10–16 manufactured from hot charge of West-Siberian crude at the Kirishi refinery (Table 9, tar nos. 5–11) do not demonstrate high thermostability, since their penetration after heating decreases by 29–43%, the softening point increases by 2–6°C, and the ductility decreases considerably. According to requirements for asphalts, the ductility after heating should be no less than 100 cm. Only sample nos. 10, 11 (Table 9), and 5 (Table 5) meet this requirement. Nevertheless, all the asphalts from Table 9 fully meet the requirements of GOST (State Standards) for paving asphalts of BND grade. Asphalts from Yaroslavl, Ukhta, and Nizhni Novgorod refineries correspond to the initial grade after heating. To conclude, we thoroughly studied the group composition of the polar and nonpolar fractions of malthenes of tars from West-Siberian crude and asphalts (thermostable BDUS 70/100 and less thermostable BND 60/90) obtained from them by oxidation at the Kirishi refinery. These tars and asphalts contain virtually equal amounts of dispersed asphaltenes (10.5 and 11.4%, and 19.3 and 21.0%, respectively). The stability of the colloidal structure of asphalts decreases with increasing solvency of malthenes and decreasing asphaltenes/malthenes ratio. Comparison of the compositions of asphalts from West-Siberian oils (Kirishi and Yaroslavl refineries), asphalt from oil extracted by the Tatneft' Joint-Stock Company (Norsi refinery), and asphalt from Yarega oil (Ukhta refinery) shows that asphalt from the Norsi Joint-Stock Company contains heavier aromatic compounds, TRs, and ATRs, compared to asphalts from West-Siberian oil. Asphalt from Yarega oil is characterized by the highest aromaticity of asphaltenes, and the polar and nonpolar fractions of this asphalt contain the largest amount of heteroatomic compounds.

BDUS 70/100 quality asphalt contains more aromatic structures as compared to BND 60/90. In BDUS 70/100 quality asphalt and the corresponding initial tar, the resins/total aromatics ratio is higher in both the polar and nonpolar fractions than that in less thermostable BND 60/90.

The polar components of tars and the corresponding asphalts are characterized by a higher resins/total aromatics ratio as compared to nonpolar components. The quality asphalt is characterized by higher TRs/ATRs and MCACs/BCACs (PCACs) ratios in both polar and nonpolar fractions.

The stability of colloidal structures is the highest if the oil fraction contains a sufficient amount of aromatic carbon in monocycloaromatic compounds and in the toluene fraction of resins, and also if the naphthenic structures have a sufficient carbon content. Factors controlling the aggregative stability of the 3*D* coagulation structure of asphalts are the concentration of the dispersed phase (asphaltenes) and its chemical affinity for oils and resins composing the dispersion medium (lyophobicity index).

Our results revealed no distinct correlation between the group composition of asphalts and their performance characteristics, since the latter depends on a great number of factors.

CONCLUSIONS

(1) The performance characteristics of oxidized petroleum asphalts increase in the order West-Siberian oils < oils extracted by the Tatneft' Joint-Stock Company < Yarega oils.

(2) Heat-resistant quality asphalt (BDUS 70/100 grade) from West-Siberian oil is characterized by a higher content of aromatic structures as compared to the less heat-resistant BND 60/90 asphalt produced from the same raw material. In quality asphalt and the corresponding tar, the resin to total aromatics ratio is higher in both polar and nonpolar components as compared to less heat-resistant BND 60/90 asphalt.

(3) Factors controlling the aggregative stability of the 3D coagulation structure of asphalts are the concentration of the dispersed phase (asphaltenes) and its chemical affinity for oils and resins composing the dispersion medium (lyophobicity index).

BRIEF COMMUNICATIONS

Influence of Enamel Composition and Calcination Conditions on the Corrosion of Steel under a Layer of Enamel Melt

L. G. Protasova and I. G. Kosnyreva

Ural State Technical University, Yekaterinburg, Russia

Received April 16, 2003

Abstract—The influence exerted by introduction of some oxides into the sodium–borosilicate enamel and by calcination conditions on the rate and mechanism of corrosion and on the structure and properties of enamel coatings was studied by thermogravimetric, X-ray phase, and microscopic analyses.

At present, sodium–borosilicate enamels are used as protective coatings on steel pipes for pump-and-compressor stations, oil pipelines, and water lines. Protective enamel coatings are applied onto the inner surface of a pipe by a wet or dry procedure and are calcined at 800–820°C in tunnel-type furnaces for 20–60 min [1]. The calcination is accompanied by iron oxidation, dissolution of iron oxide in the enamel melt, and formation of a transition layer. The corrosion of steel under the layer of an enamel coating was analyzed in [2, 3].

In this study, we examined the corrosion of steel under a layer of a model sodium–borosilicate enamel with a constant component ratio $Na_2O : B_2O_3 : SiO_2 = 1 : 0.5 : 0.48$. The composition of this enamel was made increasingly complex by adding Fe_2O_3, FeO, MnO, CaO, MgO, Li_2O, CaF_2, Al_2O_3, CuO, and ZnO. The compositions of the enamels studied are listed in Table 1. The enamels were synthesized by the method suggested in [4].

EXPERIMENTAL

Samples for study were prepared by the following procedure. An enamel powder (14 mg) with a grain size of 0.8 mm was placed on a 10 × 10 mm 08 KP steel plate. The sample was mounted onto a balance-beam in a derivatograph cell (MOM, Hungary) and heated from 20 to 820°C in the course of 90 min at a rate of 5 deg min^{-1}. Also, a sample was inserted into a furnace preheated to 820°C and kept there for 60 or 90 min. The DTG scale was 200 mg. The temperature

of the enamel spreading and the wetting angle for the melt on the steel surface were determined by the lying-drop method. An X-ray phase analysis (XPA) was made on a DRON-2 instrument (Cu_{K_α}-radiation), and the composition of the corrosion products was identified using the ASTM file. The structure of the enamel coating was studied on an UEMV-100K electron microscope with a resolution of 30 Å (magnification 24000) on carbon replicas of the etched surface of the samples.

The thermogravimetric technique was used to obtain and to process curves describing the change of mass as a function of the temperature and time of the experiment. The characteristic parameters of steel corrosion under a layer of the enamel melt: τ, time; T, temperature; Δm, change in mass; and α, corrosion rate, are listed in Table 2. The corrosion rate was calculated by the formula:

$$\alpha = \Delta m/m_0 \tau S, \quad (1)$$

where m_0 is the initial mass of the sample, and S is the surface area of the metallic plate.

The data in Table 2 show that the corrosion of a steel plate without a coating starts after 29 min of heating at 780°C and proceeds in a single stage: with a gain in mass of 98%. In this case, according to [1], metal oxidation to give scale proceeds by the reactions

$$2Fe + O_2 = 2FeO, \quad (2)$$

$$3Fe + 2O_2 = Fe_2O_3. \quad (3)$$

Except in the case of formulation 7, the corrosion of a steel plate under a layer of enamel melt occurs in two stages. Reactions (2) and (3) proceed in the first stage, before spreading of the enamel; in the second stage, scale starts to dissolve in the enamel melt. Since the diffusion of oxygen to the metal surface is hindered upon spreading of the enamel, the corrosion decelerates. This is indicated by the fact that the corrosion rate in the first stage, α_1, is higher than that in the second stage, α_2. The only exception is formulation 9, for which $\alpha_2 > \alpha_1$ (Table 2).

The composition of the enamel coating affects the corrosion properties of the metallic plate. Under melts of formulations 4–6, metal corrosion starts after 16 min of heating at 665°C (gain in mass, Δm, 41–43%); under melts of formulations 2, 3, and 7–11, it starts after 22–27 min of heating at $T \geq 780$°C (Δm = 36–75%), and under a melt of formulation 1, after 52 min of heating at 820°C (Δm = 71%). As was shown in [3], water dissolved in the enamel melt affects the oxidation of the metal. Apparently, the amount of water in formulation 1 is sufficient for the following reactions to proceed

$$2Fe + 2(OH^-) = 2FeO + H_2, \quad (4)$$

$$2(=B–OH) + Fe = FeO + H_2 + =B–O–B=. \quad (5)$$

As can be seen, these groups of formulations differ mainly in the time and temperature of the onset of corrosion, whereas their remaining parameters (Δm, α) are close. However, the metal corrosion in the second stage depends on the temperature and time of enamel spreading (Table 2). It can be seen that the enamel formulations strongly differ in the onset temperature of spreading, T_{os}. Formulations 2, 3, 10, and 11 are higher-melting (T_{os} = 800–850°C), and the remaining, lower-melting (T_{os} = 700–790°C). On spreading,

Table 3. Results of an X-ray phase analysis of enamel coatings

Enamel	Crystals		
	thermogravimetry	calcination at 820°C	
		60 min	10 min
3	–	α-Fe_2O_3	–
5	$CaMn(SiO_3)_2$, β-$Ca_3Si_3O_9$, Fe_3O_4, α-Fe_2O_3, Fe_2SiO_3	Fe_3O_4	–
8	Fe_3O_4, $MgFe_2O_4$, $(MgFe)SiO_3$	Fe_3O_4	–
9	Fe_3O_4, $MgFe_2O_4$, $(MgFe)SiO_3$	–	–
10	–	$MnLiBO_3$	Fe_3O_4
11	–	Fe_3O_4	Fe_3O_4

all the enamels exhibited good wetting of the metal surface (θ = 44–57°C). Only for formulations 1, 2, 10, and 11, the onset temperature of enamel spreading was the same as the onset temperature of corrosion.

After the experiments, the samples of enamel coatings were markedly different in outward appearance. Solid, uniform, smooth, and shining enamel coatings of green, brown, and black color, respectively, were observed for formulations 1, 3, 10, and 11. For the other formulations, the coatings were uniform, but without shine, more resembling a glass ceramic than a glass. The outward appearance of samples 2 and 5–9 after a thermogravimetric analysis suggests that the corrosion products in these samples are crystallized. Their phase composition, as indicated by XPA, is listed in Table 3.

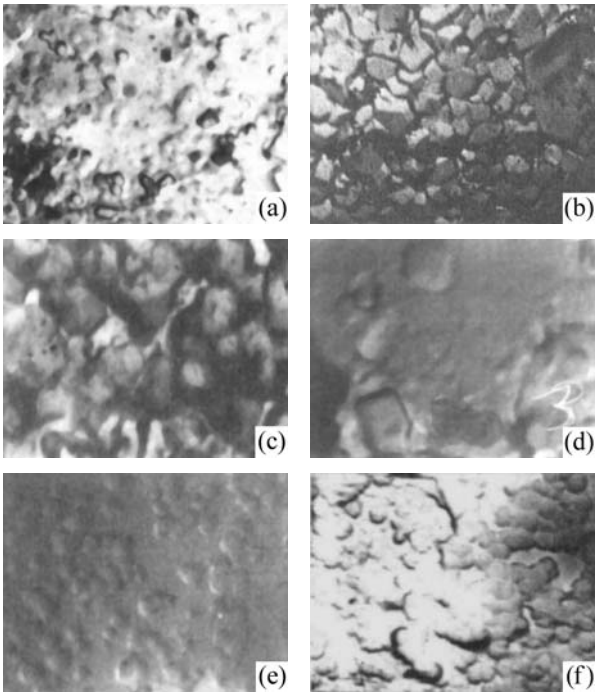

Fig. 1. Electron micrographs of the enamel coatings. Enamel (see Table 1): (a) 1, (b) 2, (c) 3, (d) 7, (e) 9, and (f) 10.

Crystals were revealed only in formulations 5, 8, and 9. Apparently, their concentration in other formulations is low. It is noteworthy that the phase composition is complex: along with the corrosion products, a number of silicates also crystallize.

To reveal the influence exerted by calcination conditions on the composition of corrosion products, samples placed in a muffle furnace preheated to 820°C and kept there for 60 min were subjected to XPA.

The outward appearance of the enamel samples was as follows: coatings of formulations 1, 2, 5–7, and 9 were smooth, shining, light green to black; in coatings of formulations 2 and 4, a great number of pinholes was observed; coatings of formulations 10 and 11 were nonuniform, shining, and black, with small brown inclusions. The results of XPA are presented in Table 3. It can be seen that corrosion products crystallize in coatings of formulations 3, 5, 8, and 11, and, presumably, a binary manganese-lithium borate, in formulation 10. The XPA data in Table 3 refer to enamel coatings on steel plates after calcination at 820°C for 10 min.

The data obtained show that the calcination conditions directly affect the type and amount of corrosion products in enamel coatings. The presence of a great number of crystalline phases in the coatings of formulations 5, 8, and 9, revealed by thermogravimetric analysis in a gradual heating in the course of 90 min, points to a deeper interaction of metal-corrosion products with the enamel melt. Moreover, these phases become crystallization centers, on which silicates crystallize from the melt. Only corrosion products are present in enamel coatings heated for 60 min. Consequently, this time is the optimal for a transition layer to be formed and strong adhesion between a coating and metal ensured. The concentration of the corrosion products in the enamel coating heated for 10 min is too small for a transition layer to be formed in formulations other than 10 and 11.

Electron micrographs of the surface layer of enamel coatings suggest that the microstructure of the coatings is nonuniform (see Fig. 1). However, the degree of nonuniformity is not the same, being at a maximum for formulations 1–3, 9, and 10 and at a minimum for

formulation 7. It may be assumed that the crystals revealed by XPA in formulations 5 and 8–10 are concentrated near the zone of contact between an enamel coating and the metal, rather than on the surface of the coating.

CONCLUSIONS

(1) It was established that the corrosion of the metal under a layer of an enamel melt occurs in two stages, and its parameters are determined by the composition of the enamel, including the concentration of dissolved water, and also by the temperature and time of its spreading.

(2) The extent to which processes of metal corrosion under a layer of Na_2O–B_2O_3–SiO_2 enamels with addition of various oxides are complete depends on calcination conditions. The optimal time of calcination at 820°C is 60 min.

(3) An X-ray phase analysis demonstrated that, in the course of interaction of the enamel melt with the metal, iron oxides dissolve in the enamel coating, which leads, in some cases, to crystallization of α-Fe_2O_3 and F_3O_4 in the coating.

(4) Not only the composition, but also the structure of enamel coatings vary in the course of interaction of an enamel coating with the metal. According to the results of electron microscopic studies, the surface of the coatings is nonuniform at the microscopic level.

Received June 26, 2003; in final form, December 2003

Abstract—An equation for predicting the normal temperature depression in boiling of complex aqueous solutions of nonvolatile substances is considered. The constants of the equation are tabulated. The equation is compared with experimental data for a binary solution of caustic soda and sodium chloride.

In the theory and practice of calculations of evaporation installations, the difference in the boiling temperatures of a solution of nonvolatile substances and a pure solvent is commonly referred to as the temperature depression in boiling of solutions. This is because it is a measure of the extent to which the driving force of the heat transfer (i.e., the difference between the temperature of the heating vapor and the boiling point) in boiling of a solution is lower than that in boiling of a pure solvent, all other conditions being the same. The temperature depression in boiling of solutions at an arbitrary pressure is expressed in terms of the normal temperature depression, i.e., the temperature depression at normal pressure [1, 2].

To predict the normal temperature depression for simple aqueous solutions of separate nonvolatile substances, the following equation has been suggested [3]

$$\Delta_n = \frac{327.9}{\dfrac{11.693}{Az + Bz^2 + Cz^3} - 1}, \qquad (1)$$

where $z = x/(1 - x)$ is the relative mass concentration of the solute: x, its mass concentration (kg kg^{-1}); and A, B, and C, tabulated coefficients dependent on the nature of the solute.

However, the importance of Eq. (1) is diminished by the fact that, commonly, complex solutions, i.e., solutions of two or more nonvolatile substances, are used for evaporation in the engineering practice.

We suggest that the normal temperature depression of complex solutions can be predicted using the equation

$$\Delta_n = \frac{327.9}{\dfrac{11.693}{\sum_{i=1}^{n} A_i z_i + \sum_{i=1}^{n} B_i z_i^2 + \sum_{i=1}^{n} C_i z_i} - 1}, \qquad (2)$$

where

$$z_i = \frac{x_i}{1 - \sum_{j=1}^{n} x_j}. \qquad (3)$$

Here i and j are the ordinal numbers of solutes, n, the number of different types of solutes; and z_i, the ratio of the concentration of a given solute to that of water in the complex solution.

In a particular case of simple solutions, i.e., at $n = 1$, Eq. (2) transforms into Eq. (1), whose adequacy as applied to simple solutions was convincingly demonstrated in [3].

It is possible to verify the applicability of Eq. (2) for the example of a solution of two substances, namely, caustic soda and sodium chloride.

According to the data of [3], $A_{NaOH} = 0.7853$, $B_{NaOH} = 1.5828$, and $C_{NaOH} = -1.0365$ at $x > 0.5$, i.e., $z_{NaOH} < 1$; $A_{NaOH} = 1.6272$, $B_{NaOH} = -0.29721$, and $C_{NaOH} = 0.009015$ at $x > 0.5$, i.e., $z_{NaOH} > 1$; $A_{NaCl} = 0.47309$, $B_{NaCl} = 1.02646$, and $C_{NaCl} = -0.7679$ at $z_{NaCl} \le 0.35$.

Table 1 lists the values of the normal temperature depressions in boiling of a binary solution of caustic soda and sodium chloride, calculated using Eq. (2), and compares them with the experimental values from [4].

It can be seen that the maximum deviation of the calculated values from those obtained exper-

imentally is –1.34°C, and the average deviation is approximately –0.5°C. Such deviations seem to be acceptable, the more so as they can be attributed to insignificant systematic inaccuracies in determining the concentrations of a complex solution being prepared.

In [3], the constants *A*, *B*, and *C* for solutions of various substances were given together with the conditions for their applicability in the case of Eq. (1). To avoid confusion, the values of these constants in Table 2 are given, with the conditions for their applicability in the case of Eq. (2) specified.

In the case when the constants for a certain substance under consideration are unknown, they can be found from the experimental normal depressions of the corresponding simple solutions of various concentrations, using the formulas presented in [3].

CONCLUSIONS

(1) An equation for analytical prediction of the normal temperature depression in boiling of complex aqueous solutions is suggested.

(2) A table of constants is presented, with the conditions for their applicability in the case of the equation suggested in this study specified.

BRIEF COMMUNICATIONS

Study of Fusion Diagrams of Two-Component Systems *n*-Tricozane–Pentadecane and *n*-Tricosane–Hexadecane by Low-Temperature Differential Thermal Analysis

I. P. Kalinina, A. Yu. Kopnina, and I. K. Garkushin

Samara State Technical University, Samara, Russia

Received September 16, 2003; in final form, December 2003

Abstract—The two-component systems *n*-tricozane–pentadecane and *n*-tricozane–hexadecane were studied by low-temperature differential thermal analysis. The characteristics of the eutectic compositions were determined.

To predict and study the phase diagrams, the authors analyzed a number of two-component systems formed by *n*-tricosane and *n*-alkanes and determined the specific enthalpies of fusion of the eutectic compositions.

The main method used in the study was low-temperature differential thermal analysis (LDTA) [1–4]. The heating and cooling curves for the compositions studied were measured on an LDTA installation with a TZ 4620 double-line flat self-recorder. As a source of the thermoelectromotive force served a Chromel–Copel thermocouple, with one of its junctions immersed into the mixture under study and the other placed in a test tube filled with a reference indifferent substance (calcined powdered aluminum oxide). The cold junction of the thermocouple was in a Dewar flask filled with a mixture of water and ice, which had a temperature of 0°C. The thermoelectromotive force of the differential thermocouple was amplified with an F 116/1 photoamplifier. The sensitivity of the differential recording was attenuated with an MSR-33 resistance box. The zero line of the differential curve was shifted with an IRN-64 source of variable voltage. The temperature was determined to within ±0.2°C. The compounds studied were cooled and heated in a TK-1 thermal chamber. The study was performed in the temperature range 233–333 K. The rate of cooling and heating of the compounds was 1–2 deg min^{-1}. The starting components were weighed on a VLR-2000 analytical balance with an accuracy of 0.3 mg. The characteristics of the individual substances corresponded to the reference data [5, 6].

n-Tricosane **I** containing 98 wt % pure substance, *n*-pentadecane **II**, and commercial *n*-hexadecane **III** of pure grade were used in the study. The purity of the reagents was confirmed by liquid-phase chromatography (Tsvet-100 chromatograph, 50-m × 0.25-mm and 25-m × 0.25-mm capillary columns). The evaporator temperature was 623 K. As a solvent of solid hydrocarbons served toluene.

To perform a preliminary theoretical analysis of the **I**–**II** and **I**–**III** systems, we calculated the hypothetical eutectic compositions by Schroeder's equation, which is commonly used to describe ideal systems [7]:

$$\ln X_1 = \frac{-\Delta H_{\text{fus},i}(T_{\text{mel},i} - T_\text{e})}{RT_{\text{mel},i}T_\text{e}}, \quad (1)$$

where X_i is the mole fraction of *i*th substance in a mixture; $\Delta H_{\text{fus},i}$ the molar enthalpy of fusion of *i*th component (J mol^{-1}); $T_{\text{mel},i}$, the melting point of *i*th substance (K); T_e, the eutectic temperature (K); and R = 8.314 J mol^{-1} K^{-1}, the universal gas constant.

To confirm the accuracy of determination of the experimentally found specific enthalpies of fusion of the systems, they were calculated by formulas [1, 2]

$$\Delta H_{\text{fus,e}} = x_1 \Delta H_{\text{fus},1} + x_2 \Delta H_{\text{fus},2}, \text{ kJ kg}^{-1}, \quad (2)$$

$$\frac{\Delta H_{\text{fus,e}}}{T_\text{e}} = \frac{x_1 \Delta H_{\text{fus},1}}{T_{\text{mel},1}} + \frac{x_2 \Delta H_{\text{fus},2}}{T_{\text{mel},2}}, \text{ kJ kg}^{-1}, \quad (3)$$

where x_1 and x_2 denote the composition of the eutectic

The experimental enthalpies of fusion of the systems under study were determined using the equation [1]:

$$\Delta H_{\text{fus, e}} = \frac{\Delta H_{\text{fus},1} T_{\text{e}} S m_1}{T_{\text{mel},1} S_1 m}, \quad (4)$$

where ΔH_{fus} is the enthalpy of fusion of the reference substance (*n*-tetradecane), whose melting point is close to that of the eutectic composition (kJ kg^{-1}); T_{mel}, the melting point of the reference substance (K); S_1 and S, the half areas under the peak in the cooling curve of the pure reference substance and a mixture of eutectic composition, respectively (mm^2); m_1 and m, the weighed portions of the pure reference substance and the eutectic mixture, respectively (kg); T_{e}, the melting point of the eutectic composition in the system (K).

The calculated and experimental data obtained are listed in Tables 1 and 2 and shown in Figs. 1a, 1b.

The liquidus curves are represented by three crystallization branches α-**I**, β-**I**, and **II** [**III**]. The minimum crystallization branch corresponds to the compounds **II** [**III**]. The eutectic compositions found experimentally and those calculated by Eq. (1) are listed in Table 1.

The phase equilibria for points and lines of the given diagrams are indicated in Table 3.

CONCLUSION

The phase diagrams of the two-component systems constituted by *n*-tricosane and pentadecane and by *n*-tricosane and hexadecane were studied. The characteristics of their eutectic compositions were determined: mp 273.5 and 279.6 K, eutectic composition 3.0–97 and 5.0–95.0 wt %, and specific enthalpy of fusion 30 and 72 kJ kg^{-1}, respectively.

Abstract—IR and electronic absorption spectroscopies were applied to a study of the mechanism of extraction of vanadium(V) with di-2-ethylhexylphosphoric acid from sulfuric acid solutions.

Di-2-ethylhexylphosphoric acid (D2EHPA) is an extracting agent widely employed in radiochemistry, analytical chemistry, and chemical engineering. It is used to extract such elements as Nb(V), Ta(V), Ti(III), and V(IV). In [1], it was demonstrated for the first time that D2EHPA can also extract vanadium(V) from weakly acidic solutions by the hydrate-solvate mechanism. Investigations in this area have been continued. The present communication reports the results obtained in studying the mechanism of V(V) extraction with D2EHPA from concentrated sulfuric acid solutions.

EXPERIMENTAL

Extraction of vanadium(V) and spectroscopic measurements were performed at 25 ± 0.5°C. Di-2-ethylhexylphosphoric acid was preliminarily purified to remove mono-2-ethylhexylphosphoric acid. The extraction was carried out with undiluted D2EHPA at $V_o : V_a = 11$ and multiple contact (~4 min) with a sulfuric acid solution of V(V). The working solutions were prepared using sodium metavanadate $NaVO_3$ of chemically pure grade. The concentration of V(V) in aqueous solutions was determined titrimetrically [2]. The content of V(V) in the organic phase was calculated from the difference of concentrations in the aqueous solution before and after extraction.

IR spectra were recorded with a Specord 75-IR spectrometer in the range 400–4000 cm^{-1}. The solutions studied were placed between KRS-6 plates. Electronic absorption spectra of V(V) extracts were recorded with a Specord UV-VIS spectrophotometer in the range 13000–30000 cm^{-1} in cuvettes with the thickness of the absorbing layer $l = 0.1$ cm. Electronic absorption spectra of V(V) solutions in H_2SO_4 were recorded in cuvettes with $l = 1.0$ cm. In this case, the concentration of V(V) was 4×10^{-4} M. ^{51}V NMR spectra were recorded with a Bruker MSL-400 spectrometer at a frequency of 105.24 MHz. The chemical shift δ was determined relative to $VOCl_3$ as external reference.

Of high importance in choosing the conditions of V(V) extraction from sulfuric acid solutions is the stability of the extracting agent. It is known that D2EHPA is stable in acid solutions [1]. It was shown in [2] that, on bringing this extracting agent in contact with sulfuric acid solutions, it is hydrolyzed only slightly. As shown by the investigations performed, D2EHPA is not decomposed, either, in the presence of V(V) up to a concentration of 0.20 M in a 12 M solution of H_2SO_4. The intensity of hydrolysis of D2EHPA increases upon prolonged contact with a 11 M solution of HF, and especially with a mixture of HF and H_2SO_4 [2]. The aforesaid indicates that, in selecting the optimal conditions of V(V) extraction with D2EHPA from solutions with higer H_2SO_4 concentrations. In doing so, however, account should be taken of the fact that the ionic state of V(V) in H_2SO_4 solutions is determined by the concentrations of V(V) and H_2SO_4. At high V(V) concentrations ($c_V \geq 0.12$ M), dimeric complexes of the oxovanadium(V) cation, $[V_2O_3(H_2O)_{8-2x}(SO_4)_x]^{(4-2x)+}$, are formed in concentrated H_2SO_4 solutions [3]. Therefore, it is preferable to extract V(V) from solutions with H_2SO_4 concentrations at which V(V) exists in the form of the above dimeric complexes and no decomposition of D2EHPA occurs.

To establish the concentration range of the monomer–dimer transition, the ionic state of V(V) was studied in H_2SO_4 solutions at the concentrations $c_{H_2SO_4}$ of 1.0–16.8 M.

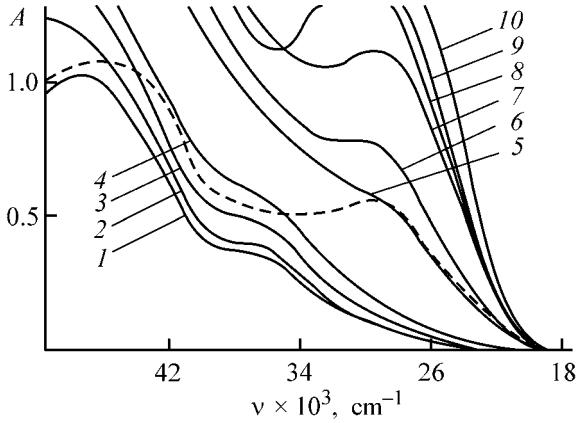

Fig. 1. Electronic absorption spectra of V(V) solutions in H_2SO_4 at l = 1.0 cm. $c_V = 4 \times 10^{-4}$ M; the same for Fig. 2. (*A*) Optical density and (ν) wave number. $c_{H_2SO_4}$ (M): (*1*) 1.0, (*2*) 3.0, (*3*) 5.0, (*4*) 7.0, (*5*) 9.0, (*6*) 10.0, (*7*) 11.0, (*8*) 13.0, (*9*) 15.0, and (*10*) 16.8. *Dashed line*: $c_{H_2SO_4}$ = 12.0 M, $c_V = 1.2 \times 10^{-4}$ M.

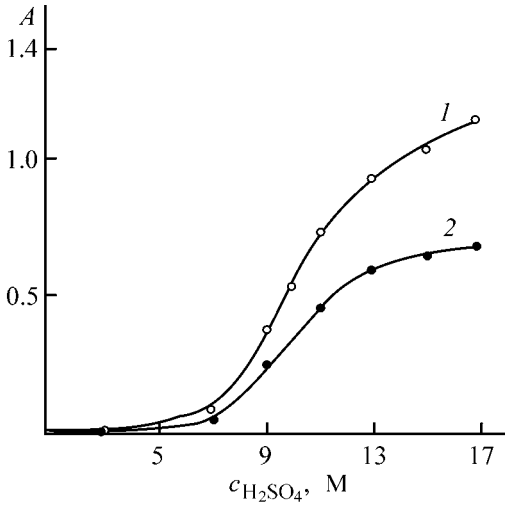

Fig. 2. Optical density A of V(V) solutions vs. the concentration c of H_2SO_4 at l = 1 cm. ν (cm^{-1}): (*1*) 26000 and (*2*) 23000.

Figure 1 shows electronic absorption spectra of V(V) solutions in H_2SO_4. At sulfuric acid concentrations in the range 1.0–7.0 M, absorption bands at 48000, 44000, and 36000 cm^{-1} are observed in the electronic spectra of V(V) solutions, which indicates that V(V) exists under these conditions in the form of complexes in which the dioxovanadium(V) cation is the central group [4]. Raising the concentration of H_2SO_4 further leads to a dramatic increase in the optical density and to a change of the shape of the spectrum. Beginning with a H_2SO_4 concentration of 9.0 M, a new absorption band at 29000 cm^{-1} appears in the electronic spectra of V(V) solutions.

Such a variation of the shape of the spectrum with the H_2SO_4 concentration is probably due to the appearance of another ionic form of V(V). Indeed, beginning with a H_2SO_4 concentration of 7.0 M, the molar absorption coefficients grow abruptly as the concentration of H_2SO_4 or V(V) increases. This is presumably due to the formation of polynuclear forms of V(V).

To confirm these conclusions, ^{51}V NMR spectra of V(V) solutions in H_2SO_4 were recorded. With the concentration of V(V) in the range from 1×10^{-3} to 5×10^{-1} M, a singlet signal with a chemical shift δ = –650 ppm was observed in ^{51}V NMR spectra in H_2SO_4 ($c_{H_2SO_4}$ = 16.0 M), which indicates that dimeric complexes of the oxovanadium(V) cation are formed under these conditions [3] (see table).

At low H_2SO_4 concentrations, ^{51}V NMR spectra of V(V) solutions show a singlet signal with a chemical shift δ = –541 ppm, which indicates that V(V) complexes with the dioxovanadium(V) cation as the central group exist under these conditions [5]. It can be seen from Fig. 2 that the optical density of V(V) solutions increases abruptly at $c_{H_2SO_4} \geq 7.0$ M.

At $c_{H_2SO_4}$ of 11.0 M the optical density starts to level off, which is presumably due to formation of dimeric complexes of dioxovanadium(V) cations in this range of H_2SO_4 concentrations. In the electronic absorption spectrum of the dimeric complex of the dioxovanadium(V) cation in a 12.0 M solution of H_2SO_4 (Fig. 1), two absorption bands at ν 46000 and 29000 cm^{-1} were observed. These bands can be identified as charge-transfer bands. On the basis of the data obtained in analyzing the ionic state of V(V) in H_2SO_4 solutions, and with account of the results of a previous study [6], the optimal conditions of V(V) extraction with D2EHPA are $c_{H_2SO_4} \geq$ 11.00 M.

The extraction of V(V) with D2EHPA from H_2SO_4 solutions was studied using IR and electronic absorption spectroscopies. In the IR spectrum of the extract

5×10^{-1}	16.0	–650
5×10^{-2}	16.0	–650
1×10^{-3}	16.0	–648
5×10^{-2}	11.0	–626
1×10^{-3}	1.0	–541

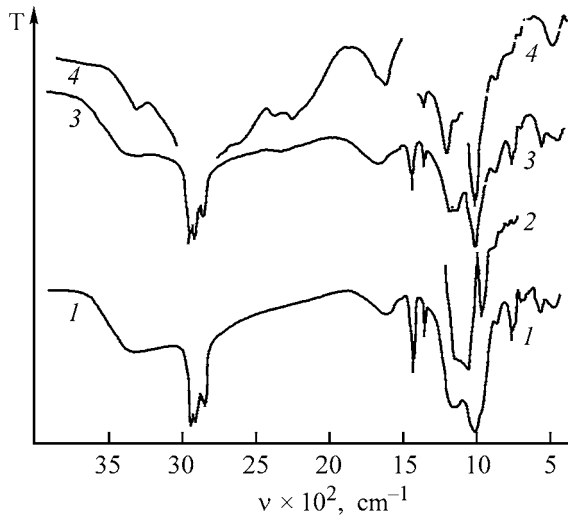

Fig. 3. IR spectra of the system V(V)–H_2SO_4–D2EHPA. (T) Transmission and (ν) wave number. (*1*) V(V) extract with D2EHPA (c_V^{in} = 0.1381 M), (*2*) V(V) extract with D2EHPA after compensation of D2EHPA, (*3*) H_2SO_4 extract with D2EHPA, and (*4*) D2EHPA.

of V(V) with D2EHPA (Fig. 3), the component of the ν_{P-OH} band at 1680 cm^{-1} is shifted to 1630 cm^{-1} as compared with a similar component in the IR spectrum of the H_2SO_4 extract with D2EHPA. The components of the ν_{P-OH} band at 2260 and 2660 cm^{-1} disappear. This indicates that P–OH groups are involved in the coordination of V(V) [7]. Presumably, protons of the extracting agent are replaced with V(V) cations, which exist in concentrated H_2SO_4 solutions. The same behavior is observed in extraction of Sc(III) from concentrated HCl solutions [8]. In this case, the cation-exchange mechanism of extraction predominates up to a HCl concentration of 10 M. In addition, the IR spectra of V(V) extracts with D2EHPA contain absorption bands at 1170 and 1070 cm^{-1}, which are identified as ν_{POO}^{as} and ν_{POO}^{s}, respectively [7]. The shift of the band associated with the POO group, ν_{POO}^{as} in the spectrum of the V(V) extract with D2EHPA, compared with the IR spectrum of the H_2SO_4 extract with D2EHPA, indicates that POO groups are also presumably involved in the coordination of vanadium(V).

An analysis of IR spectra of a V(V) solution in 11 M H_2SO_4 and a V(V) extract with D2EHPA made it possible to identify ions in whose form D2EHPA extracts V(V). As shown above, V(V) exists in 11 M H_2SO_4 solutions in the form of dimeric complexes of the dioxovanadium(V) cation. A band at 988 cm^{-1} and a shoulder at 750 cm^{-1} appear in the IR spectrum of a V(V) solution in 11 M H_2SO_4, measured after the compensation of the acid. The IR spectrum of the V(V) extract with D2EHPA shows a doublet at 970–990 cm^{-1} on the background of the bands associated with D2EHPA and sulfate ions. A strong band at 985 cm^{-1} appears in the IR spectrum of the V(V) extract with D2EHPA after the compensation of D2EHPA. By analogy with the data of [3], this band can be attributed to ν_1-type vibrations of the dimeric oxovanadium(V) cation. The band at 750 cm^{-1} could not be observed because it is, presumably, overlapped with a stronger band of D2EHPA.

The aforesaid shows that D2EHPA extracts V(V) from concentrated H_2SO_4 solutions in the form of a dimeric complex of the oxovanadium(V) cation. The presence of absorption bands at 3450 and 570 cm^{-1} and a shoulder at 600 cm^{-1} in the IR spectrum of the V(V) extract with D2EHPA indicates that the complex being extracted also contains molecules of water and sulfate ions [9]. To confirm the possible formation of mixed-ligand complexes of V(V) in its extraction with D2EHPA, electronic absorption spectra of V(V) solutions in 12 M H_2SO_4 and V(V) extracts with D2EHPA were recorded. The electronic absorption spectrum of a V(V) solution in 12 M H_2SO_4 contains an absorption band at 29 000 cm^{-1}. The electronic absorption spectrum of the V(V) extract with D2EHPA shows a shift of the absorption band to the higher-energy part of the spectrum.

The shift of the absorption peak from 29 000 to 25 000 cm^{-1} on passing from a sulfate dimeric complex if the oxovanadium(V) cation to the V(V) complex with D2EHPA, being extracted, is due to the appearance of upper occupied molecular orbitals, which reflect the π-bond in the PO group. This conclusion follows from an analysis of molecules of the type Alk_3PO (Alk stands for an alkyl radical). It has been established for molecules of this kind that their electronic configuration in the ground state has the form $(1a_1)^2(2a_1)^2(1e)^4(3a_1)^2(2e)^4$, where the high-energy occupied molecular orbital $2e$ is the orbital involved in the π-bonding between oxygen and phosphorus atoms [10].

CONCLUSION

A study of the ionic state of V(V) in H_2SO_4 solutions in the concentration range 1.0–16.8 M resulted in that the optimal conditions of V(V) extraction with di-2-ethylhexylphosphoric acid were determined. It was established that the extraction occurs by the cation-exchange mechanism to give mixed-ligand complexes of the dimeric oxovanadium(V) cation with

anions of sulfuric and di-2-ethylhexylphosphoric acids in the organic phase.

BRIEF COMMUNICATIONS

Influence Exerted by H_2SiF_6 on Extraction of Titanium(IV)

V. G. Maiorov, A. I. Nikolaev, V. K. Kopkov, and G. V. Korotkova

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received November 4, 2003

Abstract—Extraction of titanium(IV) with octanol and tributyl phosphate from fluoride solutions that contain H_2SiF_6 or H_2SO_4 was studied.

Previously, a significant enhancement of the extraction of Ta(V) and Nb(V) with tributyl phosphate (TBP) from fluoride solutions with high content of impurity ions, Ti(IV), Si(IV), Sn(IV), etc., which form fluoroelement acids, has been observed [1, 2]. These acids can replace mineral acids (sulfuric and others), which are commonly added to improve the efficiency of recovery of Ta(V) and Nb(V) fluorides [3]. The fluoroelement and sulfuric acids can be arranged in order of increasing influence on the extraction of Ta(V) as $H_2TiOF_4 > H_2SiF_6 \geq H_2SO_4$ and in order of increasing effect on the extraction of Nb(V) as $H_2SiF_6 \geq H_2SO_4 \geq H_2TiOF_4$. Of interest is a study of the influence exerted by the acids under consideration, present in the extraction system, on the distribution of fluorides of elements other than Ta(V) and Nb(V).

This study is concerned with the influence exerted by the acid H_2SiF_6 on the recovery of Ti(IV). Naturally, Ti(IV) must also affect the distribution of Si(IV). It has been established that Ti(IV) is extracted from fluoride solutions considerably better than Si(IV) [3], which creates prerequisites for a clearer manifestation of the effect expected. In addition, the content of Ti(IV) in fluoride solutions is more easily determined by chemical analysis than Si(IV). A study of the effect of Si(IV) on the distribution of Ti(IV) is also of practical interest for obtaining pure compounds of Ta(V) and Nb(V) from raw materials with high content of these impurities.

As extracting agents were used octanol-1 (OCL; content of main product ~98%) and TBP of pure grade. The physicochemical properties of OCL were reported in [4], and methods for working with aggressive fluoride solutions and for analytical monitoring, in [1, 2]. The extraction was performed from a solution containing 1 M of Ti(IV) and a varying amount of H_2SiF_6 or (for comparison purposes) H_2SO_4 at two different concentrations of HF_{free}. The designation HF_{free} is adopted for the conditional calculated concentration of HF, which exceeds that necessary for the complexes H_2TiOF_4 and H_2SiF_6 to be formed, since just these complexes are predominant in the system under study [1, 3, 5]. The experimental data obtained are presented in Figs. 1, 2 and in the table ($V_o : V_a$ is the volume ratio of the organic and aqueous phases before extraction).

It has been noted previously [4] that the extracting capacity of OCL for fluoride systems with Ta(V) and Nb(V) is approximately twice lower than that for TBP. Accordingly, the extraction with OCL was performed, in studying the influence exerted by H_2SiF_6 on the distribution of Ti(IV), at $V_o : V_a$ exceeding by a factor of 2 that for TBP. As also in the case of Ta(V) and Nb(V) fluorides, H_2SiF_6 exerts a considerably stronger influence on the extraction of Ti(IV) than

Influence exerted by the concentration of HF on the extraction of Ti(IV) with TBP ($V_o : V_a = 1 : 1$) and OCL ($V_o : V_a = 2 : 1$) from a solution of 1 M of Ti(IV)

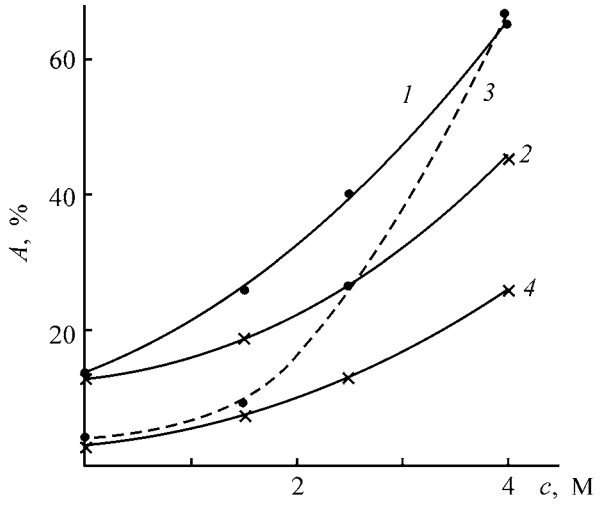

Fig. 1. Effect of (*1*, *3*) H_2SiF_6 or (*2*, *4*) H_2SO_4 on the extraction of Ti(IV) with (*1*, *2*) TBP and (*3*, *4*) OCL from a solution that contains 0.5 M of HF_{free} and 1 M of Ti(IV). (*A*) Recovery of Ti(IV) and (*c*) concentration of H_2SiF_6, H_2SO_4. $V_o : V_a$: (*1*, *2*) 1 : 1 and (*3*, *4*) 2 : 1.

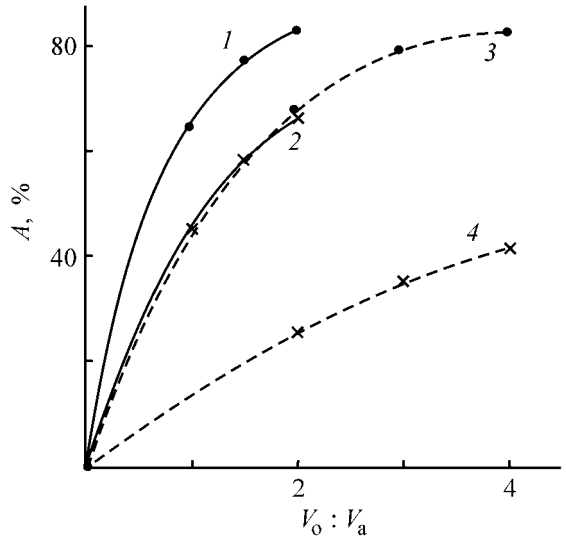

Fig. 2. Effect of the $V_o : V_a$ ratio on the extraction of Ti(IV) with (*1*, *2*) TBP and (*3*, *4*) OCL. Content (M): HF_{free} 0.5, Ti(IV) 1; (*1*, *3*) Si(IV) 4 and (*2*, *4*) H_2SO_4. (*A*) Recovery of Ti(IV).

H_2SO_4 does. The analogy with the data for Ta(V) and Nb(V) is also manifested in that the above effect of enhancement of Ti(IV) extraction from H_2SiF_6 solutions (compared with H_2SO_4 solutions) for OCL at high content of H_2SiF_6 is substantially stronger than that in the case of TBP. For example, replacing H_2SO_4 with H_2SiF_6 in extraction from a 4 M acid solution leads to an increase in the recovery of Ti(IV) with OCL by a factor of 2.6, and that with TBP, by only a factor of 1.4. This indicates that the effect of acids, which supply H^+ ions, on the distribution of H_2TiOF_4 depends not only on the type of an acid, but also on the nature of an organic solvent. This circumstance should be taken into account in studying the influence exerted by fluoroelement acids on the distribution of Ti(IV) and fluorides of other elements present in the extraction system.

Raising the ratio $V_o : V_a$ makes it possible to achieve a Ti(IV) recovery from H_2SiF_6 solutions in a single stage of 80% and more with both OCL and TBP. This value is sufficient for virtually complete extraction of Ti(IV) into the organic phase in the mode of a continuous counterflow extraction. At the same time, complete recovery of Ti(IV) with TBP (and the more so with OCL) from H_2SO_4 solutions under the conditions studied is hardly achievable. It should be noted that the extracting capacity of OCL approaches that of TBP in extraction of Ti(IV) from solutions with high concentration of H_2SiF_6 and large values of $V_o : V_a$, as also in the case of extraction of Ta(V) and Nb(V) [4].

Raising the concentration of HF leads to a decrease in recovery of Ti(IV), presumably, because of the competing extraction of HF (see table). Rather unexpected was the absence of any effect of HF in the concentration range studied on the distribution of Ti(IV) in extraction with OCL from H_2SiF_6 solutions.

The data obtained lead to practically important conclusions. If the objective of a researcher is to ensure complete recovery of Ti(IV) in order to obtain its high-purity compounds [6], then presence of Si(IV) in the extraction system is desirable because this makes it possible to lower the ratio $V_o : V_a$ and, accordingly, to diminish the material flows in the extraction technology. In obtaining high-purity compounds of Ta(V) and Nb(V), the recovery of Ti(IV) should be at a minimum and presence of Si(IV) in solutions is undesirable. To work efficiently with fluoride extraction sys tems, it is necessary to know and take into account the mutual influence of fluoroelement acids of all elements that are present in solutions and can form fluoride complexes that dissociate by the acid type.

CONCLUSIONS

(1) H_2SiF_6 exerts substantially stronger influence on the extraction of Ti(IV) with octanol and tributyl phosphate than H_2SO_4 does.

(2) Conditions are found under which the recovery of Ti(IV) from H_2SiF_6 solutions in a single stage exceeds 80%.

Abstract—Synthesis of a mordenite-like zeolite from reaction mixtures of composition $2.5R \cdot (2.2–7.3)Na_2O \cdot Al_2O_3 \cdot (12–40)SiO_2 \cdot (300–1200)H_2O$, where R is monoethanolamine, was studied. The crystallization conditions under which mordenite with a SiO_2/Al_2O_3 ratio of 13 to 22 can be synthesized were determined.

Raising the SiO_2/Al_2O_3 ratio in a zeolite improves its thermal stability and resistance to an acid medium [1]. It has been suggested to obtain high-ratio mordenites (with SiO_2/Al_2O_3 molar ratio > 13) by dealumination of low-ratio mordenites (SiO_2/Al_2O_3 = 8–10) [1] or by high-temperature synthesis in the presence of organic additives (templates) [2]. Commonly, quaternary alkyl ammonium bases are used for this purpose. In [3], it was suggested to synthesize mordenite with a ratio of about 20 from reaction mixtures of composition $(10–29)R \cdot (2–20)Na_2O \cdot Al_2O_3 \cdot (30–100)SiO_2 \cdot (600–2500)H_2O$, using a more accessible organic base monoethanolamine (MEA) as a template [3]. As starting reagents served solutions of Na_2SiO_3, $Al_2(SO_4)_3$, and H_2SO_4.

In this study, we made an attempt to synthesize high-ratio mordenite in the presence of MEA from reaction mixtures of another composition, prepared by mixing other types of Si- and Al-containing raw materials, carbon white or wastes produced in manufacture of crystalline silicon (WMSC) [4], with solutions of sodium silicate and aluminate. Not only MEA, but also isobutyl alcohol (IBA), were used as templates.

EXPERIMENTAL

The experiments were performed in an autoclave with a stirrer and a sampling device. The degree of crystallinity and the type of a forming zeolite were determined by X-ray phase analysis. The procedures used to synthesize and study the zeolites were described in more detail in [4].

Reaction mixtures of composition $2.5R \cdot (2.2–7.3)Na_2O \cdot Al_2O_3 \cdot (12–40)SiO_2 \cdot (300–1200)H_2O$ were used for synthesis.

Silica-alumina hydrogels of the above compositions were obtained by mixing a carbon white or WMSC with solutions of sodium silicate and aluminate. To these gels was added MEA or IBA. The crystallization was performed at 130–170°C under continuous agitation.

Preliminary experiments demonstrated that mordenite with a ratio exceeding 13 can be synthesized under the conditions chosen. Further, we studied the kinetics of crystallization of high-ratio mordenites.

The kinetic curves of crystallization of a mordenite-like zeolite at 150°C from the reaction mixtures containing MEA and IBA are plotted in Fig. 1.

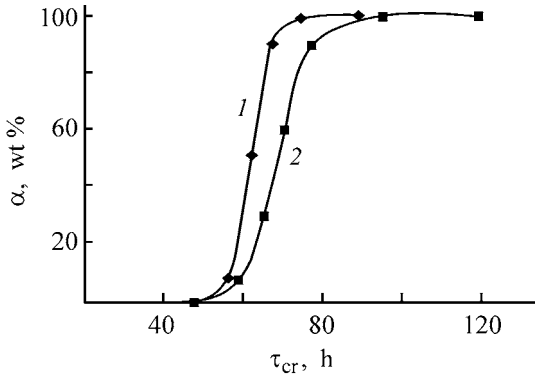

Fig. 1. Crystallinity α of a mordenite-like zeolite vs. the time of crystallization τ_{cr} of a reaction mixture of composition $2.5R \cdot 7.3Na_2O \cdot Al_2O_3 \cdot 40SiO_2 \cdot 1200H_2O$ at 150°C. Organic compound: (*1*) MEA and (*2*) IBA.

Physicochemical properties of high-ratio mordenites

R	τ_{cr}, %	λ, wt %	Static capacity of a zeolite for an indicated vapor, $cm^3\ g^{-1}$			Composition, wt %		SiO_2/Al_2O_3
			H_2O	C_6H_6	C_7H_{16}	SiO_2	Al_2O_3	
MEA	72	100	0.11	0.07	0.08	88.6	7.1	21.4
IBA	96	100	0.10	0.08	0.08	77.9	7.7	17.2

The duration of the induction period of crystallization is independent of the type of an organic compound, and the period of exponential growth of crystals is longer in the case of IBA. The higher crystallization rate in the case of MEA can be accounted for by its higher basicity as compared with IBA. It should be noted that the crystallinity and adsorption capacity are high for all the zeolites synthesized (see table).

The synthesis of mordenite-like zeolite in the presence of MEA was studied in more detail. The region of crystallization of the zeolite at 150°C from reaction mixtures of composition $2.5\ MEA \cdot (2.2–9.0)Na_2O \cdot Al_2O_3 \cdot (12–50)SiO_2 \cdot (300–1200)H_2O$ is shown in Fig. 2.

The region of crystallization of mordenite-like zeolites, found in this study, corresponds to the following range of compositions of the reaction mixtures: $2.5MEA \cdot (2.2–7.3)Na_2O \cdot Al_2O_3 \cdot (12–40)SiO_2 \cdot (300–1200)H_2O$.

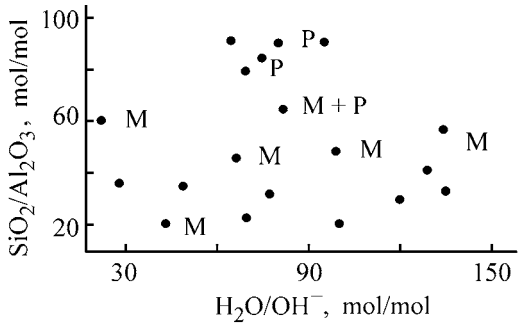

Fig. 2. Regions of crystallization of zeolites from reaction mixtures of composition $2.5MEA \cdot (2.2–9.0)Na_2O \cdot Al_2O_3 \cdot (12–50)SiO_2 \cdot (300–1200)H_2O$. Zeolite: (M) mordenite-like and (P) pentasyl-like.

With the SiO_2/Al_2O_3 ratio raised to 45, two zeolite phases, pentasyl and mordenite, crystallize simultaneously. Crystallization of reaction mixtures with $SiO_2/Al_2O_3 > 50$ yields a pentasyl-like zeolite.

Thus, the results obtained made it possible to develop a procedure for synthesis of mordenite-like zeolites with a ratio of 13–22. This procedure is based on hydrothermal crystallization of silica-alumina hydrogels obtained by mixing a carbon white or WMSC with solutions of sodium silicate and aluminate in the presence of an organic compound, MEA or IBA, at 130–160°C in the course of 72–96 h. The zeolites synthesized have an adsorption capacity of 0.10–0.11 for water vapor and 0.08–0.09 $cm^3 g^{-1}$ for *n*-heptane.

CONCLUSION

A procedure for synthesizing mordenite of high phase purity with a ratio of 13–22 and nearly 100% crystallinity was developed. This procedure is based on crystallization of a silica-alumina hydrogel of composition $2.5MEA \cdot (2.2–7.3)Na_2O \cdot Al_2O_3 \cdot (27–7.30)SiO_2 \cdot (300–1200)H_2O$ at 130–160°C.

Abstract—The flocculating power of calcium-containing polyacrylate was studied. The optimal dose of this flocculant and the velocity of clarification of a model process water were determined.

Due to growing hydrosphere pollution, the requirements to wastewater decontamination become increasingly stringent. The commonly used methods for decontamination of wastewater are based on its treatment with coagulating and flocculating agents.

The wastewater treatment with flocculants is more efficient. Their specific consumption in decontamination of process water ranges from 0.5 to 40 g m^{-3}. The consumption of cationic flocculants is in the range from 3 to 8 g kg^{-1} of clay. For anionic flocculants, this parameter varies from 1.0 to 1.5 g kg^{-1}. The clarification efficiency of reused water with flocculants reaches 96–100%.

There are various methods for preparation of polymeric flocculants based on sodium polyacrylate (PA) and polymethacrylate, copolymers of acrylamide with alkali metal acrylates [1, 2] and other cationic and anionic polymers [3–10].

The aim of this study was to elucidate how partial substitution of single-charged Na^+ cations in sodium polyacrylate with double-charged Ca^{2+} cations affects its flocculation characteristics. This problem is important because Ca^{2+} is the main component of wastewater from plants for lime and chalk production. We failed to prepare water-soluble calcium-containing polyacrylate by adding $CaCl_2$ to aqueous sodium polyacrylate. Under these conditions, insoluble calcium polyacrylate is formed. Water-soluble calcium-containing polyacrylate can be prepared by treatment of polyacrylic acid (PAA) ($M = 150 \times 10^3$) with aqueous $CaCl_2$ (0.162–0.625 g Ca^{2+} l^{-1}) at 25–35°C for 16–24 h. At the same time, in treatment of PAA with 400 ml of concentrated $CaCl_2$ (>0.625 g Ca^{2+} l^{-1}) at 50–80°C, insoluble compound is formed.

It is known that several cationic flocculants bind metal cations (Ca^{2+}, Mg^{2+}, Al^{3+}, Sn^{2+}, etc.) from aqueous solution to form poorly soluble complexes. Therefore, the calcium-containing polyacrylates prepared by us were tested in this respect.

Taking into account that introduction of sodium cation into calcium-containing polyacrylates strongly affects their flocculating power, we also tested the polymers with varied Na^+ content. We found that, in complete or half saturation of the carboxy groups of polyacrilic acid with Na^+ cations, stable water-soluble flocculants are formed. However, after replacement of even 0.5% of Na^+ with Ca^{2+} in this flocculant, its viscosity, refractive index, and density significantly increase. The calcium-containing sodium polyacrylate sorbs Ca^{2+}, Mg^{2+}, Al^{3+}, Fe^{2+}, Fe^{3+}, and other cations to form unidentified poorly soluble complexes.

The flocculation performance of water-soluble calcium-containing polyacrylate was tested on a model industrial wastewater contaminated with suspended montmorillonite (Wyoming, USA) (1.0, 5.0, 8.0, 25.0, 60.0, and 100.0 g l^{-1}).

The water clarification velocity W (mm s^{-1}) was determined as the ratio of the height of a clarified water layer S (mm) to the sedimentation time τ (s):

$$W + S/\tau. \quad (1)$$

The approximate flocculant dose D in our experiments was established in accordance with recommendations published in [2]. This dose was then op-

* (R_f) flocculant consumption (per 1 gram of clay suspension).

EXPERIMENTAL

The sedimentation velocity was measured in 1-l volumetric cylinders with scale divisions on strips of graph paper glued on their walls along a height of 250–300 mm below the water level.

Equal volumes of the model industrial water contaminated with clay suspension were poured into several cylinders, the mixture was stirred and a prescribed dose of the flocculant was added. To randomize the mixture, the cylinders were turned upside down many times. After settling, 100-ml samples of clarified water were taken from a depth of 10 cm, and the amount of suspended matter was determined. After that, the heights of both the clarified water and the sedimented clay layers were measured.

The effect of flocculation on the sedimentation velocity was determined from the time required for sedimentation of the main part of suspended clay, measured with a stopwatch. The clarification velocity was calculated by Eq. (1) (Table 1). The flocculant consumption was calculated by Eq. (2) (Table 2).

The calcium-containing polyacrylate was prepared as follows. Potassium peroxodisulfate [15.5 g (0.057 mol)] was dissolved in distilled water (150 ml) at 30 or 45°C with stirring for 0.4 h. After that, acrylic acid purified by distillation [130.860 g (1.816 mol, 124.5 ml] was added and stirred for 0.5 h. Then 400 ml of aqueous $CaCl_2 \cdot 2H_2O$ (chemically pure grade) (0.375 g ml^{-1}) was added, and this mixture was stirred for 3 h. The resulting solution was diluted with water (1.5 l) and its pH was checked with indicator paper. The pH of this solution was adjusted to 8–9 by adding 1.55 M aqueous NaOH.

The aqueous calcium-containing polyacrylates were kept for 24 h and then dried in a vacuum at 95°C at a residual pressure of 1300 Pa until a solid film of constant weight was formed. The IR spectrum of this film (KBr pellets) contains absorption bands assigned to vibrations of the following groups (cm^{-1}): C–C (800, 850, 900); C–O (1100, 1200, 1250); CH_2, =C(OH)–O (1300, 1410,1470); CH (2920, 2950); and OH (3400, 3500). In the ^1H NMR spectra (working frequency 68.797 MHz) of calcium-containing polyacrylate in D_2O, the following signals were detected (δ, ppm): 1.54 (1H, –C(OH)–CH–), 1.91 (2H, =CH–CH_2–), 4.3 (1H, COOH), and 4.73 (1H, OH).

An elemental analysis of two parallel samples showed the following chemical composition of the calcium-containing polyacrylate films (%): C 21.15, 21.19; H 1.76, 1.80; S 9.40, 9.44; K 11.47, 11.51; Ca 11.76, 11.80; and Na 6.73, 6.77. This elemental composition is close to that of the compound with the stoichiometry $C_6H_6SO_8KCaNa$, %: C 21.17; H 1.78; S 9.42; K 11.49; Ca 11.78; Na 6.75; and O 37.61.

The osmometrically determined molecular weight of the calcium-containing polyacrylate was $(100–125) \times 10^3$.

CONCLUSIONS

(1) Calcium-containing polyacrylate can be used as a flocculant for clarification of process water contaminated with suspended clay.

(2) Partial replacement of Na^+ cations in sodium polyacrylate with Ca^{2+} does not noticeably change its flocculating power.

Rheological and Adhesion Properties of Aqueous Solutions of Corn Dextrin

T. G. Klimets, E. V. Grinyuk, and L. P. Krul'

Research Institute of Physicochemical Problems, Belarussian State University, Minsk, Belarus

Received October 17, 2003; in final form, January 2004

Abstract—Rheological and adhesion properties of aqueous solutions of corn dextrin at widely varied concentrations, obtained at different mixing temperatures, were studied.

Aqueous solutions of natural polysaccharides (ASPs), especially starch and its derivatives, such as, e.g., dextrin, are widely used as adhesives [1]. Dextrin adhesives find extensive application for gluing paper and paper labels [1–3].

Despite the wide use of aqueous solutions of dextrin as adhesives, there are virtually no published data on their rheological and adhesion properties, which specifically determine the main process characteristics of adhesives. Preparation of dextrin glues consists in heating a dextrin–water mixture or in dissolving dextrin in hot water [4]. These operations resemble the pasting stage in preparation of starch paste [5], However, there are no published data on how pasting affects the rheological and adhesion characteristics of dextrin adhesives.

The aim of this study was to examine the rheological and adhesion properties of solutions of corn dextrin (CD) of different concentrations, prepared in hot and, for comparison, in room-temperature water.

EXPERIMENTAL

We studied aqueous solutions of acidic corn dextrin, GOST (State Standard) 6034–74. The solutions were prepared at room temperature or at $65 \pm 5°C$ under continuous stirring for 30 min. The concentration of the solutions was varied from 15 to 70%.

The viscosity of the resulting solutions was measured on a Rheotest 2 rotary viscometer with a coaxial-cylinder working unit at $20 \pm 0.1°C$.

The adhesive properties of ASPs in the glass–adhesive–paper system were studied in an RMU-0.05.-1 tensile-testing machine with the stress measurement range $(0–10) \pm 0.02$ kgf and the rates of motion of the guide rod of the machine from 0 to 100 mm min^{-1} [6, 7].

To keep the glass surface at a constant temperature, we placed it in a metallic flow-through cell whose dimensions were adjusted to those of the glass shell, a fragment of a bottle.

As substrate served samples of KYMULTRA COPY writing paper, A4, 80 g m^{-2}–500, which were cut into 150×10 mm strips. A 100-mm long adhesive layer was manually applied to each strip. The samples were glued to the surface of the bottle fragment kept at $20 \pm 0.5°C$. The free end of the strip was fixed in the stationary clamp of the tensile machine.

Figure 1 presents the log-log flow curves for aqueous solutions of dextrin with different concentrations, prepared by mixing at room temperature. Figure 1a shows that all the aqueous solutions of CD, studied by us, are non-Newtonian liquids. The pseudoplasticity is the most pronounced in the case of 50–70% solutions (Fig. 1a, curves *4*–*6*).

Figure 1b shows the flow curves for the same solutions prepared by mixing at $65 \pm 5°C$. It is seen that pseudoplasticity is characteristic of only 50–70% CD solutions, and 15–30% solutions are virtually Newtonian liquids (Fig. 1b, curves *4*–*6* and *1*–*3*, respectively).

Comparison of the results shows that, at low shear rates ($0.3333–9$ s^{-1}), the CD solutions obtained at $65 \pm 5°C$ are less viscous than those obtained at room temperature, while at high shear rates ($48.6–1312$ s^{-1}) this difference is partly eliminated. Also, heating yields less pseudoplastic solutions.

1070-4272/04/7704-0688 © 2004 MAIK "Nauka/Interperiodica"

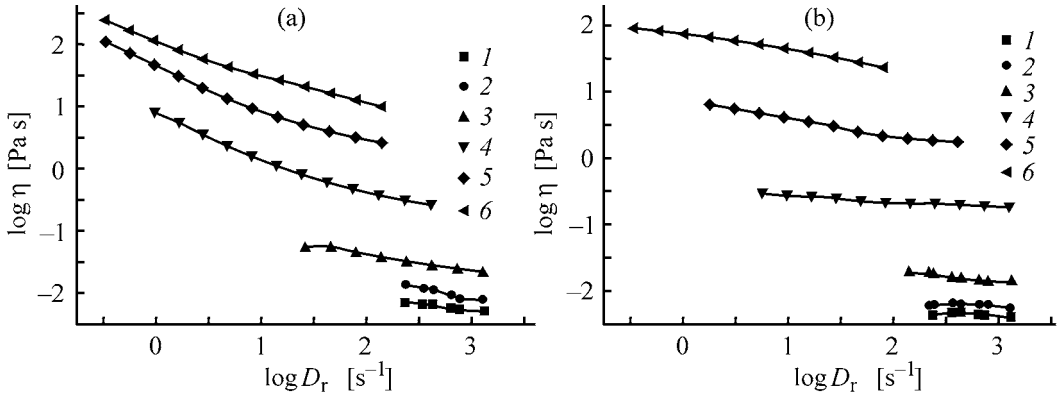

Fig. 1. Log-log plots of the viscosity η, vs. shear rate D_r for aqueous solutions of CD, prepared by mixing at (a) 20 and (b) 65 ± 5°C. Concentration of the solution, %: (*1*) 15, (*2*) 20, (*3*) 30, (*4*) 50, (*5*) 60, and (*6*) 70.

Higher viscosities, as well as lower shear rates and more pronounced pseudoplasticity, of aqueous solutions of CD prepared at room temperature suggest an increased, relative to solutions prepared at 65 ± 5°C, concentration of the points of contact in the fluctuation network [8]. A similar decrease in the concentration of the points of contact in the fluctuation network in aqueous solutions has also been observed for many other water-soluble polymers (polyacrylamide, polyvinyl alcohol, etc.) [9].

As known, the concentration of the points of contact in the fluctuation network in starch (whose hydrolysis yields dextrin) tends to increase with rising temperature. This is usually attributed to degradation of the shells of the natural polymer grains and to the corresponding increase in the effective concentration of macromolecules in solution [6]. Evidently, the starch–dextrin conversion involves grain shell degradation as well. Therefore, with the mixing temperature of dextrin and water rising from room temperature to 65 ± 5°C the viscosity and pseudoplasticity tend to decrease (as in the case of water-soluble polar synthetic polymers), rather than increase (as in the case of starch solutions).

Preliminary studies of the adhesion characteristics of aqueous solutions of CD with concentrations of up to 30 wt % in the glass–adhesive–paper system showed that these solutions are virtually incapable of providing a paper–glass joint. With a 50% aqueous solution of dextrin, the paper can be glued to glass, but this glue joint is so weak that even after 3 min the paper exfoliates from the glass upon attempted application of a load. Figure 2 illustrates the adhesion properties of 60–70% CD solutions. For these solutions, the glue joint strength σ increases with increasing keeping time and approaches in the limit the value corresponding to the breaking strength of a dry paper strip. As can be seen from Fig. 2, the setting time is 2–3 min, which is smaller than that for imported adhesives for gluing labels (4–7 min). The temperature mode of preparation of aqueous solutions of CD only slightly affects their adhesion properties. Evidently, the lack of a direct correlation between the rheological and adhesion properties of aqueous solutions of CD prepared at different temperatures is due to the specific mechanism of glue joint formation. Lower viscosities of the aqueous solution of CD, prepared at 65 ± 5°C, are responsible for the accelerated water removal from the glue joint and, thereby, for an increase in the viscosity of solution to that characteristic of the dextrin solution prepared at room temperature.

Notably, aqueous (especially concentrated) solutions of CD prepared at 65 ± 5°C have better keeping qualities. For example, a 50% solution prepared at room temperature grew moldy even after 3 weeks of keeping in a dry cool place, while the solution prepared at 65 ± 5°C did so only after 2 months of keeping.

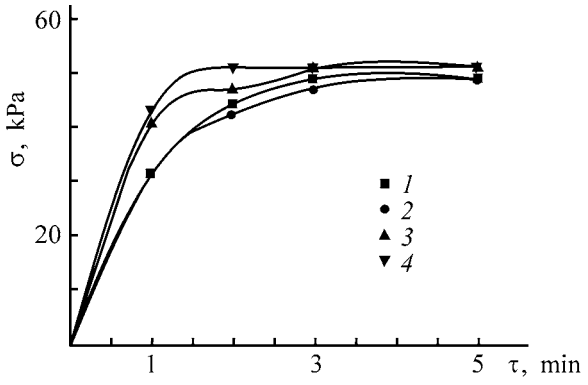

Fig. 2. Variation of the shear strength of glue joint, σ, with the time of keeping τ for aqueous solutions of CD with different concentrations. Concentration of the solution, %: (*1*, *2*) 60 and (*3*, *4*) 70. Mixing temperature, °C: (*1*, *3*) 20 and (*2*, *4*) 65 ± 5°C.

CONCLUSION

Aqueous (60–70%) solutions of corn dextrin are suitable as adhesives for gluing labels. Moreover, they surpass imported analogs in adhesion properties. These properties of aqueous solutions of corn dextrin are virtually unaffected by increase in the temperature of preparation from room temperature to $65 \pm 5°C$, but solutions prepared at $65 \pm 5°C$ are preferable because of better keeping qualities.

Ural Wood Chemical Plant Open Joint-Stock Company, Kirovgrad, Sverdlovsk oblast, Russia

Received November 10, 2003

Abstract—Oxidation of tall pitch with atmospheric oxygen was studied as influenced by the oxidation initiator and temperature. Conditions for preparing tall pitch with required physicochemical properties were determined.

Tall pitch (TP), meltable distillation residue of tall oil, is a large-tonnage waste of sulfate cellulose production. This substance contains fatty and resin acids, their esters, and the so-called oxidized compounds and unsaponifiables [1].

Tall pitch is a relatively low-cost renewable phytogenic raw material with valuable properties. However, the major portion of accumulated TP is not used and is burnt in a mixture with mazut. Practical use of TP is prevented by its variable chemical composition and low softening point (T_s = 19–25°C).

Oxidation of TP with atmospheric oxygen at 200–280°C [2–4] improves its physicochemical properties and processing characteristics. The oxidized product with T_s 45–60°C is used in building [4]; that with T_s 60–90°C in metallurgy and in tire and rubber industry [3, 5]; and that with T_s 90–105°C in paint and varnish industry [6].

Clearly, T_s of oxidized TP determines the field of its practical application and depends on the oxidation conditions. In this study, we examine the influence of conditions of TP oxidation on the physicochemical properties of the resulting product.

Tall pitch was oxidized with atmospheric oxygen at 220–280°C in the absence and in the presence of the oxidation initiator. Under these conditions, a brittle dark brown solid product with T_s = 98–102°C was formed in 80–85% yield. Oil, water, and gaseous products with odor of sulfur-containing compounds were liberated, presumably owing to thermolysis of TP components. In addition, the acid number of oxidized TP (38–45 mg KOH g^{-1}) was lower than that of the initial TP (55 mg KOH g^{-1}). Hence, one of the possible pathways of thermolysis can be decarboxylation of resin and fatty acids to form the corresponding hydrocarbons. If this is the case, carbon dioxide should be liberated. Liberation of gaseous products containing CO_2 and sulfur compounds in the course of TP thermolysis has also been observed by Shmidt [2]. Decarboxylation of resin acids in their liquid-phase oxidation was described in [7].

Since the T_s of TP depends on the extent of its oxidation, oxidation of TP was monitored by its T_s. The dependence of T_s of TP oxidized with atmospheric oxygen at different temperatures on the oxidation time is shown in Fig. 1.

As can be seen from Fig. 1, autooxidation of TP by atmospheric oxygen is similar to liquid-phase oxidation of hydrocarbons and their derivatives [8]. As the reaction temperature increases from 220 to 260°C, the induction period shortens and fully disappears at 280°C. The maximum oxidation rate increases. The activation energy of TP oxidation, determined

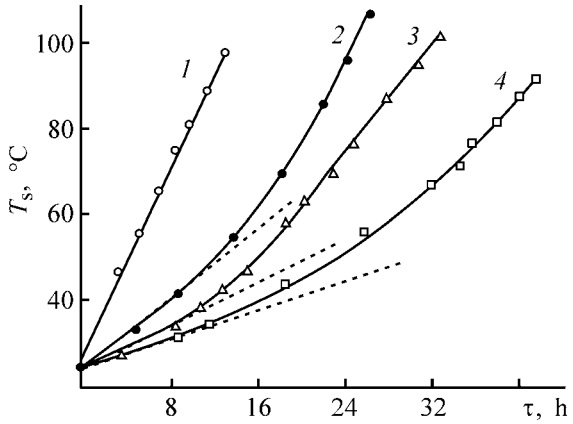

Fig. 1. Softening point T_s of TP oxidized at (*1*) 280, (*2*) 260, (*3*) 240, and (*4*) 220°C vs. the oxidation time τ.

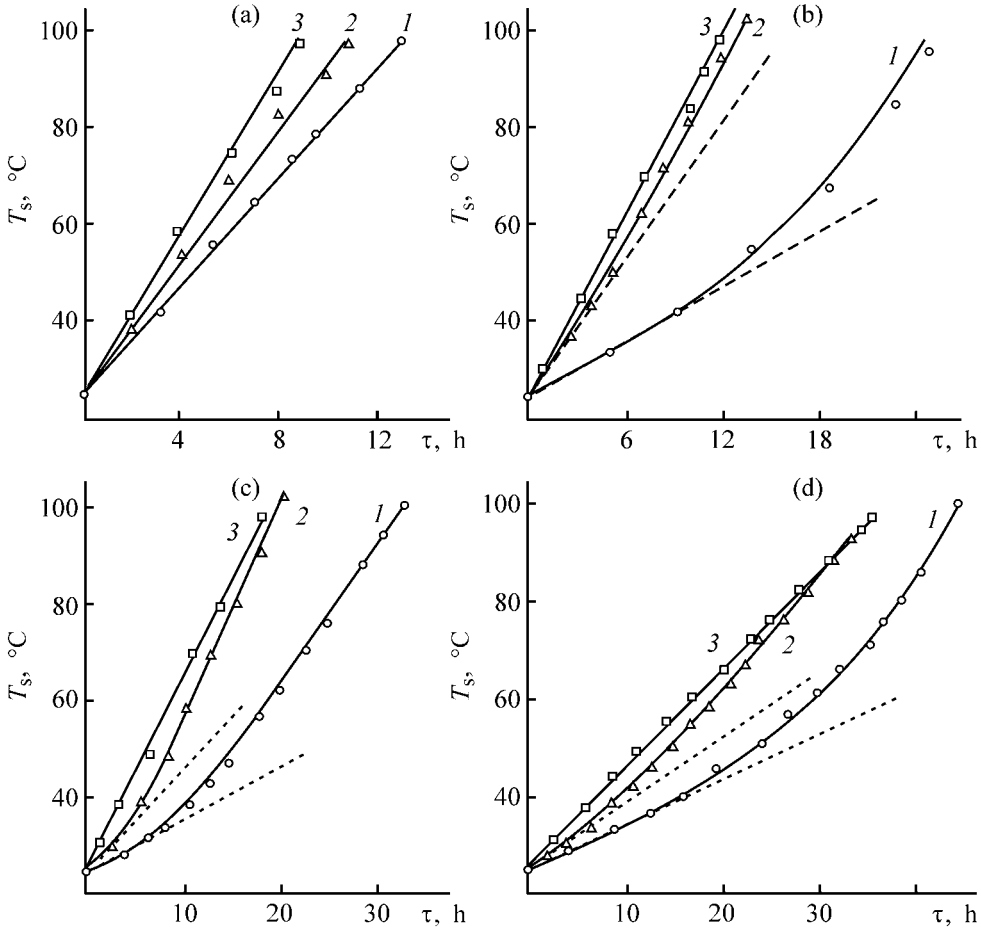

Fig. 2. Softening point T_S of TP oxidized at (a) 280, (b) 260, (c) 240, and (d) 220°C in the presence of (*1*) 0, (*2*) 5, and (*3*) 10 wt % of the initiator vs. the oxidation time τ.

from the slope of the temperature dependence of the initial reaction rate, plotted in the Arrhenius coordinates, is 68.6 ± 0.5 kJ mol^{-1}.

Oxidation of TP is strongly affected by the initiator concentration. As can be seen from Fig. 2, the oxidation substantially accelerates and the induction period of the reaction at 220–260°C shortens with increasing initiator concentration. At the initiator concentration of 10 wt %, the induction period in this temperature range is absent and the dependence of T_s on the oxidation time τ is linear, as that at 280°C (Fig. 2, curve *3*).

The activation energy of TP oxidation in the presence of 5 and 10 wt % initiator, calculated from the slope of the temperature dependence of the initial oxidation rate, plotted in the Arrhenius coordinates, is 62.0 ± 0.5 and 48.6 ± 0.4 kJ mol^{-1}, respectively.

As noted above, the field of practical application of oxidized TP depends on its T_s. The dependence of T_s of oxidized TP on the oxidation conditions (Table 1) can be used for preparing TP with required properties.

Table 1. Oxidation conditions of tall pitch

T_s of oxidized pitch, no less than indicated value, °C	T, °C	Oxidation time at c_{in}^* (wt %) no less than indicated value (h)		
		0 (no initiator)	5	10
45	280	4	3	2.5
	260	10.5	3.5	3
	240	14.5	7.5	5
	220	20	13	10
60	280	6.5	5	4
	260	15	6.5	5
	240	19	11	9
	220	28.5	19.5	17
90	280	11	9	7.5
	260	23	11	10
	240	29	18	16
	220	41.5	31.5	31

* c_{in} is the initiator concentration.

Oxidation of TP was performed at Ural Wood Chemical Plant Open Joint-Stock Company.

EXPERIMENTAL

We used TP [TU (Technical Specification) 13-0281078–84, revision no. 1, Tall Pitch for Road-Building] with T_s 24°C and acid number 55 mg KOH per gram of the product.

Partially oxidized TP containing peroxides was used as the oxidation initiator. It was prepared by oxidation of TP with atmospheric oxygen at 220°C for 10–12 h with subsequent stopping of the air supply and rapid cooling.

Oxidation of TP with atmospheric oxygen was performed in a reactor with a heating jacket. The reactor was equipped with a bubbler for air supply, a descending condenser, and a turbine-type stirrer. The reactor was charged with a weighed portion of TP preheated at ~80°C in the absence or in the presence of the oxidation initiator. The reactor temperature was kept constant (±2°C) by circulating high-temperature heat carrier (organosilicon liquid) between a thermostat and the jacket. When the reactor was heated to the required temperature, the stirrer was switched on and purified air was fed at a rate of 35–36 l h^{-1} per 1 g of the pitch. The air flow rate was measured with a rotameter. The liberated water and oil were removed through a descending condenser into a receiver, and gaseous reaction products were fed into a trap filled with a 15% aqueous solution of NaOH. Samples of the reaction mixture were taken at definite intervals. Their AN and T_s were measured in accordance with GOST (State Standard) 23863–79. The average of three replicate measurements was calculated.

CONCLUSIONS

(1) Oxidation of TP is characterized by an induction period typical of liquid-phase oxidation of hydrocarbons and their derivatives. The induction period shortenes on heating from 220 to 280°C.

(2) Oxidation in the presence of 10 wt % initiator (partially oxidized TP) is substantially faster and is characterized by the absence of the induction period at 220–260°C. The dependence of T_s of oxidized TP on the oxidation time is linear.

(3) The process for production of oxidized tall pitch with different T_s was developed and applied at the Ural Wood Chemical Plant Open Joint-Stock Company.

BRIEF COMMUNICATIONS

Effect of Polycaprolactam Fiber on Coagulation of Rubbers and on Properties of Rubbers, Rubber Stocks, and Vulcanizates

S. S. Nikulin and I. N. Akatova

Voronezh State Academy of Forestry Engineering, Voronezh, Russia

Received March 7, 2003

Abstract—The effect of polycaprolactam fiber on the coagulation of butaidene–styrene rubber from the latex was studied.

Large amounts of wastes of fibers and fibrous materials are formed at textile and clothing factories. Utilization of these wastes is a topical problem [1–4].

In industry, fibrous fillers are introduced into polymers on rollers in the course of preparation of rubber stocks [5, 6]. The fillers impart the required rigidity and enhance the strength of rubber items. However, introduction of a fibrous filler on rollers does not ensure its uniform distribution in the bulk of the rubber stock, which negatively affects the physicomechanical parameters of the vulcanizates.

Hence, it is necessary to ensure, with minimum expenditure, a uniform distribution of a fibrous filler in the bulk of a polymeric compound. One of the ways to achieve this goal is introduction of a fibrous filler into a polymer in the latex step in production of emulsion rubbers.

In this study, we analyzed how the polycaprolactam fiber affects the coagulation of a latex of SKS-30 ARK butadiene–styrene rubber (BSR) and the properties of rubbers, rubber stocks, and vulcanizates.

First we considered several modes of pretreatment of a fibrous filler, polycaprolactam, before its mixing with BSR latex. The size and dosage of the filler were kept constant: 2 mm and 0.5 wt % relative to the rubber. The fibrous filler was introduced without pretreatment (dry) and after wetting with various agents: water, tallow soap solution, 24 wt % NaCl solution (coagulant), and 2% H_2SO_4 solution (acidifying agent).

Introduction of the fibrous filler without pretreatment (in the dry form) or after wetting with water does not ensure the desired effect. Better results are obtained after pretreatment of the fiber with a tallow soap solution. However, this involves additional material and economic expenditures. Introduction of the fibrous filler in combination with the coagulating agent does not noticeably affect the coagulation.

Treatment of the fiber with sulfuric acid slightly increases the coagulum yield. This may be due to the fact that the amide groups of polycaprolactam macromolecules react with sulfuric acid molecules. Appearance of quaternary ammonium groups in the macromolecules should stabilize the coagulation process. The possibility of using quaternary ammonium salts for coagulation of rubbers from latexes has been shown previously [7, 8].

Therefore, apparently, the best choice will be introduction of the fibrous filler with an acidifying agent in the final step of coagulation.

Further experiments on the influence exerted on the coagulation by the dosage and length of a polycaprolactam fiber were performed with simultaneous addition of the fiber and the acidifying agent. The fiber length was 2, 5, and 10 mm, and the dosage, 0.1, 0.3, 0.5, 0.7, and 1.0 wt % relative to the rubber. The influence of the fiber length (at a dosage of 0.3 wt % relative to the rubber) and NaCl dosage on the coagulum weight is illustrated by the figure. Similar dependences of the coagulum weight on the NaCl

Tear resistance, kN m^{-1}	53.0	89.0	90.0	81.0	85.0	66.0	73.0
Resistance to multiple extension, thousands of cycles	69.550	66.700	62.000	93.200	73.100	76.200	77.700
Aging coefficient (100°C, 72 h):							
for strength	0.44	0.65	0.67	0.72	0.69	0.80	0.96
for relative elongation	0.33	0.46	0.40	0.40	0.41	0.45	0.54

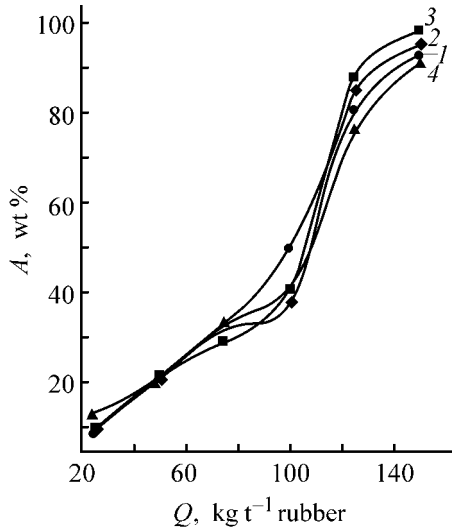
dosage were obtained at other dosages of the polycaprolactam fiber.

The experimental data show that addition of the fibrous filler in the course of rubber coagulation from the latex increases the coagulum yield. This is probably due to reduction of losses associated with the removal of a fine rubber crumb with serum and wash waters [9] and to additional introduction of the fibrous filler taken up by the coagulum.

The best results were obtained with the fiber dosage within 0.3–0.7 wt % relative to the rubber and fiber length of about 5 mm. The fiber length affects the coagulum yield insignificantly.

In the second step of our study, we examined the effect of polycaprolactam fibers on the properties of rubber stocks and vulcanizates. The rubber samples filled with polycaprolactam fibers were tested according to GOST (State Standard) 15627–79 for BSR in comparison with a commercial BSR sample.

The table shows that the physicomechanical characteristics of vulcanizates get slightly worse with increasing content and length of polycaprolactam fibers in rubbers. For example, the nominal tensile strength of the rubber containing 0.3 wt % 2-mm-long fibers is 28.6 MPa, and that of the sample containing 0.7 wt % 10-mm-long fibers is 20.0 MPa. By contrast, the rebound elasticity at 20°C slightly increases: from 38 to 43%, respectively. The resistance to thermal aging of vulcanizates and the tear resistance of the filled samples throughout the examined range of fiber dosages are higher than those of the control sample.



Influence of the polycaprolactam fiber length (dosage 0.5 wt % relative to rubber) and NaCl dosage Q on the coagulum yield A: (*1*) no fiber added; fiber length, mm: (*2*) 2, (*3*) 5, and (*4*) 10.

CONCLUSIONS

(1) Addition of polycaprolactam fiber and an acidifying agent (2% H_2SO_4) in the step of coagulation of butadiene–styrene latex before the final step enhances the tear resistance and resistance to thermal aging of the vulcanizates. The optimal length of the polycaprolactam fibers is 5 mm at the dosage of 0.3–0.7 wt % relative to the rubber.

(2) Introduction of polycaprolactam fibers in the step of latex coagulation ensures its uniform distribution in the bulk of the rubber.

Professor Yurii Konstantinovich Delimarskii (To Centennial Anniversary of His Birthday)

Yu.K. Delimarskii, a known Ukrainian scientist and pedagogue, full member of the Academy of Sciences of the Ukrainian SSR, made a major contribution to the organization and development of research in the field of physical chemistry and electrochemistry of ionic melts in our country; during many years he headed the Scientific Council of the Academy of Sciences of the USSR for physical chemistry of ionic melts and solid electrolytes.

Yurii Konstantinovich Delimarskii was born on April 23, 1904, at Krasnopolka village of Kamenets-Podol'sk Province (now Vinnitsa oblast) into the family of a village teacher. He received his elementary education at Bar nonclassical secondary school (1913–1920) and then at the mechanical school (town of Bar), which he finished in April 1922. Delimarskii started his working activities as metalworker at a machining workshop and then worked as a teacher at a labor school. In 1924–1928, he was a student of Kiev Institute of people's education (physicochemical department). Having graduated from the Institute, Delimarskii became a postgraduate student at Kiev Polytechnic Institute at the chair of the technology of mineral substances, headed by professor D.A. Chernobaev. During the period of time from 1928 till 1934, Delimarskii carried out an extensive series of investigations in the field of synthesis and analysis of physicochemical properties of aluminosilicates of the zeolite type. In 1936, he successfully defended his candidate (Chem. Sci.) dissertation devoted to this research area. From 1932 till 1934, the young scientist worked as a docent at Kiev Polytechnic Institute at the chair of inorganic chemistry, headed by professor V.A. Izbekov (1881–1963, corresponding member of the Academy of Sciences of the Ukrainian SSR since 1939), a prominent scientist in the field of electrochemistry of nonaqueous solutions, including low-melting salt systems.

Beginning in 1934, Delimarskii's scientific activities had been associated with the Academy of Sciences of the Ukrainian SSR and, in particular, with the Institute of General and Inorganic Chemistry, Academy of Sciences of the Ukrainian SSR (IONKh AN USSR, Institute of Chemistry before 1945), where the scientist worked till his dying day, with the exception of the time from September 1941 till March 1944. During this time interval, he headed the laboratory of mineral technology at the Chemical Institute, Uzbek branch of the Academy of Sciences of the USSR, in Tashkent. In 1944, Delimarskii was appointed deputy director of IONKh AN UkrSSR and head of laboratory (department) of electrochemistry of molten salts at the same Institute. In 1949, the scientist completed a large series of investigations, commenced in 1936, of the electrode potentials of metals in molten media and defended his doctoral (Chem. Sci.) dissertation "Electrode Potentials and Electrochemical Series of Metals in Molten Salts." In 1950, he became a professor.

During the period of time from 1938 till 1941, Delimarskii occupied a position of docent at the chair of inorganic chemistry at Kiev State University (KGU). In 1944, he resumed his teaching activities at the University; from 1951 till 1959, he headed the chair of inorganic chemistry at KGU, and in 1960–1964, was a professor of this chair [1].

In January 1957, Delimarskii was elected an academician of the Academy of Sciences of the Ukrainian SSR and chairman of the Bureau of the Department of chemical and geological sciences. He occupied the latter position till March 1960. Since that time, and till March 1973, Delimarskii was director of IONKh AN UkrSSR and, simultaneously, headed (till No-

1070-4272/04/7704-0697 © 2004 MAIK "Nauka/Interperiodica"

vember 1987) the department of electrochemistry of molten salts. Since the end of 1987 he was a councilor of the board of directors of IONKh AN UkrSSR.

The Kiev school of electrochemistry, one of whose brilliant representatives was Delimarskii, owes its origin to a known physical chemist V.A. Plotnikov (1873–1947, academician of the Academy of Sciences of the Ukraine since 1920, corresponding member of the Academy of Sciences of the USSR since 1932). A graduate from Moscow University, he taught from 1899 till 1941 at Kiev Polytechnic Institute, as a professor since 1910. Simultaneously, in 1931–1941, he was director of the Institute of Chemistry, Academy of Sciences of the Ukrainian SSR. The main Plotnikov's investigations were devoted to nonaqueous solutions and, in particular, to their electrochemistry. Among Plotnikov's pupils were such prominent scientists as V.A.Izbekov, Ya.A. Fialkov (1895–1958, corresponding member of the Academy of Sciences of the Ukrainian SSR since 1945), M.I. Usanovich (1894–1981, academician of the Academy of Sciences of Kazakh SSR), and many others [1].

Delimarskii carried out his first studies in the field of electrochemistry of molten salts as early as in 1934–1935 under the supervision of Izbekov. Having graduated from Yur'ev (Tartu) University in 1909, Izbekov commenced his teaching and scientific activities at Kiev Polytechnic Institute and, simultaneously, taught inorganic, physical, and analytical chemistry at other higher school institutions of Kiev. In particular, he taught inorganic chemistry at Kiev University from 1933 till 1950. Already the first joint study by Izbekov and Delimarskii (1936), in which the electrode potentials of metals in molten aluminum bromide were determined, confirmed the phenomenon, previously discovered by Izbekov, that the electrochemical series of metals is specific to each particular solvent. Further investigations by Delimarskii in this area markedly extended the knowledge of the influence exerted by the nature of a solvent on the position of metals in the electrochemical series and revealed the effect of temperature and some other factors. It was established that the difference between electrochemical series in molten electrolytes is primarily due to complexation and to the influence exerted by the nature of anions present in the melts (1955). In the subsequent years, Delimarskii and co-workers paid considerable attention to voltammetric measurements in molten salts (polarography with solid electrodes). Voltammetric measurements were used to study the reduction of cations of the overwhelming majority of metals and to refine their deposition potentials, diffusion coefficients, activation energies of processes, and their reversibility under stationary conditions. Later, pulsed and ac investigation techniques were suggested. A major contribution to the development of stationary and nonstationary methods for studying ionic melts was made by leading staff members of IONKH AN UkrSSR A.V. Gorodyskii (1930–1992; academician of the Academy of Sciences of the Ukrainian SSR since 1978), V.I. Shapoval (1933–1999), corresponding member of the National Academy of Sciences of the Ukraine since 1995), E.V. Panov, N.Kh. Tumanova, and V.F. Grishchenko.

In 1960, a monograph by Delimarskii and Gorodyskii *Elektrodnye protsessy i metody issledovaniya v polyarografii* (Electrode Processes and Investigation Methods in Polarography), largely based on studies of its authors, was published. Delimarskii and B.F. Markov (1912–1992) carried out extensive studies in the field of thermodynamics of molten salts, which were reflected in the monograph *Elektrokhimiya rasplavlennykh solei* (Electrochemistry of Molten Salts, 1960), translated in the United States. Investigations in the field of coordination chemistry in ionic melts were summarized in the monograph *Koordinatsionnaya khimiya solevykh rasplavov* (Coordination Chemistry of Salt Melts) (in co-authorship with S.V. Volkov and V.F. Grishchenko, 1977). The book had no analogues in the domestic and foreign literature.

The research conducted by Delimarskii was of applied nature and promoted the solution of specific technological problems. In particular, considerable attention was given by the scientist to intermetallide electrode processes of refining of heavy nonferrous metals. The main results of these studies were reflected in an original monograph *Elektrolitichеskoe rafinirovanie tyazhelykh metallov v ionnykh rasplavakh* (Electrolytic Refining of Heavy Metals in Ionic Melts) (in co-authorship with O.G. Zarubitskii, 1975). The research in the field of utilization of lead-containing secondary raw materials and separation of lead alloys, conducted under Delimarskii's supervision about 50 years ago, have remained topical and scientifically important up to now. To solution of important technological problems were devoted Delimarskii's monographs *Electrolitichеskoe luzhenie iz solevykh rasplavov* (Electrolytic Tinplating from Salt Melts) (in co-authorship with A.I. Vitkin, A.A. Kolotii, et al., 1967) and *Elektrokhimicheskaya ochistka otlivok v ionnykh rasplavakh* (Electrochemical Cleaning of Castings in Ionic Melts (in co-authorship with I.R. Fishman and Zarubitskii, 1976). Delimarskii supervised numerous investigations of electrolytic recovery of beryllium, titanium, zirconium, silicon, germanium, and carbon from molten salts. The scientist paid prime attention to extending the range of application of ionic liquids in various branches of technology. These issues were

the subject of a special monograph *Ionnye rasplavy v sovremennoi tekhnike* (Ionic Melts in Modern Technology, 1981). The modern state of the theory and practice of electrolysis was considered in a broader sense in Delimarskii's book *Electroliz. Teoriya i praktika* (Electrolysis: Theory and Practice, 1982). There is no escape from mentioning other, widely known monographs by the scientist: *Electrokhimiya ionnykh rasplavov* (Electrochemistry of Ionic Melts, 1976), *Khimiya ionnykh rasplavov* (Chemistry of Ionic Melts, 1980), *Teoreticheskie osnovy electroliza ionnykh rasplavov* (Theoreticval Foundations of Electrolysis of Ionic Melts, 1986), and *Prikladnaya khimiya ionnykh rasplavov* (Applied Chemistry of Ionic Melts, 1988).

The scientific legacy of Delimarskii is immense. The published list of his scientific works, in which the last item is dated by the beginning of 1988 [2], includes 761 titles. Among these, studies in at least three priority areas can be distinguished: electrochemical recovery, separation, and refining of heavy nonferrous metals (18.3% of all the publications); voltammetric (polarographic) studies (15.8%); and studies of the potential series and reference electrodes in molten media (11.2%). A large number of publications were devoted to general problems of electrochemical kinetics in salt melts, methods for study of kinetic characteristics, and techniques for electrodeposition of coatings from melts. A separate series of investigations was devoted to an analysis of the structure of molten salts by measuring their Raman spectra. It was demonstrated for the example of a number of nitrate melts that the ion–ion interactions in these melts are determined both by the crystal structure of the corresponding solid phases and by the nature of the first coordination sphere of the anion.

As already noted, Delimarskii was engaged in pedagogical activities at the chair of inorganic chemistry at KGU during many years. In this connection, he wrote an original textbook *Neorganicheskaya khimiya. Izbrannye glavy* (Inorganic Chemistry: Selected Chapters, 1973), which pays a considerable attention to the Periodic Law. To the centennial anniversary of this law was devoted a monograph by Delimarskii (in coauthorship with G.V. Shilina, in Ukrainian, 1969).

Rather prominent is Delimarskii's contribution to the organization of research in high-temperature inorganic chemistry and physicochemical and electrochemical studies in our country. He initiated the organization in 1969 of the Scientific Council of the Academy of Sciences of the USSR for physical chemistry of ionic melts and solid electrolytes and was its permanent chairman for 20 years.

By the early 1980s, the Council coordinated investigations that involved about 130 research institutions, and higher school institutions as well. All-Union and regional symposia and seminars and scientific workshops were held regularly. At that time, the Soviet Union occupied the leading position in world's science as regards the scale and level of the research in this field.

Delimarskii was also engaged in a variety of other kinds of public activities. He was chairman of the Scientific Council of the Academy of Sciences of Ukrainian SSR for kinetics and thermodynamics of electrode processes from 1967 till 1978, Editor-in-chief of *Ukrainskii Khimicheskii Zhurnal* (Ukrainian Chemical Journal) from 1968 till 1988, and chairman of the Ukrainian republican directorate of the Mendellev All-Union Chemical Society from 1970 till 1983. Delimarskii was a member of a number of international scientific organizations and represented our country at numerous congresses and conferences abroad. During a number of years he headed the Section of high-temperature chemistry of the International Electrochemical Society.

Scientific achievements of Delimarskii were honored with Pisarzhevskii Prize of the Academy of Sciences of Ukraine (1972), Mendeleev gold medal (1980), and a State Prize of the Ukrainian SSR in science and technology (1988). In 1974, Delimarskii was awarded an honorary title of Honored Science Worker of the Ukrainian SSR; he was decorated with a number of State awards.

Yurii Konstantinovich Delimarskii died on June 2, 1990. His pupils and colleagues preserve thankful memory of this remarkable scientist, who had done so much for the development of domestic high-temperature electrochemistry. To the life and activities of Delimarskii were devoted an issue concerned with the biobibliography of scientists of the Ukrainian SSR [2], articles by Gorodyskii [3] and Zarubitskii [4], and other numerous publications listed in [2].

Received July 8, 2003; in final form, December 2003

Abstract—The data on formation of solid, liquid, and dust–gas wastes in various stages of titanium sponge production were generalized and systematized. To prevent environmental contamination by secondary production wastes, the procedures and flowsheets providing solidification of the waste products using gypsum or magnesia binding materials were offered.

The commercial process for production of metallic titanium as titanium sponge consists of three basic stages [1, 2]: (1) reductive ore smelting (ROS) of ilmenite ($FeTiO_3$) and(or) ilmenite–rutile ($FeTiO_3 \cdot TiO_2$) concentrates at 1600–2000°C, which yields titanium slag (80–86% TiO_2) and pig iron alloyed with nonferrous, rare, and scattered metals; (2) chlorination of titanium slags in melts of chlorides of alkali and alkaline-earth metals, mainly in a melt of a spent electrolyte from magnesium production. Thus technical-grade $TiCl_4$ is obtained, which is further purified to remove impurities, in particular, V(V) compounds, to obtain purified $TiCl_4$ and $VOCl_3$ (and/or V_2O_5) as commercial products; and (3) magnesium-thermal reduction of $TiCl_4$ yielding titanium sponge and $MgCl_2$ melt.

Waste products are formed in each of these stages, with the dust from ROS and waste products from the chlorination shop being the most toxic and difficult-to-process. In the course of ROS, almost all micro- and macrocomponents belonging to ilmenite and ilmenite–rutile concentrates are redistributed. Up to 90–96% of Ti, more than 80% of V, Nb, and Ta, and also a significant part of Mn, Cr, Al, Sc, Zr, Hf, Th, and U pass into the slag, whereas Fe mainly passes into pig iron, which is sold as a commercial product. A part of the initial furnace charge and of the products of redox reactions proceeding in the furnace is carried away from the melt surface as a dust–gas mixture to form waste products. The "yield" of the dust is up to 100 kg per ton of commercial titanium sponge [1, 2]. Therefore, production of, e.g., 10000 t/year of spongy titanium involves formation of up to 1000 t/year of the dust in the ROS process.

The composition of the dust in off-gases essentially depends on the operating mode (open, half-closed, and closed), temperature, and time from the beginning of the furnace operation to the end of a cycle. Usually the ROS dust contains (wt %) TiO_2 20–40, Fe_2O_3 30–60, Al_2O_3 1–2, SiO_2 6–7, Cr_2O_3 4–5, V_2O_5 0.2–0.3, MnO_2 1–2, sum of MgO and CaO 2–3, C 2–3, and a small amount of oxides of rare, scattered, and radioactive metals. The size of particles varies within very wide limits from 0.01 to 50 μm. Coarsely dispersed (10–50 μm) dust is entrapped in cyclones and goes then to the process "head" for the preparation of the initial charge for ROS, and finely dispersed dust ("behind-cyclone dust") is caught in bag filters or is ejected into the atmosphere.

It was shown in [3, 4] that the powder is essentially enriched with volatile components Pb, Zn, As, etc., which are evaporated owing to high temperature of the process (up to 2000°C) and are then condensed on dust particles. The degree of their concentration in comparison with the initial raw material ilmenite reaches 25–100%, and their content in the dust is 0.3–0.9%, with the higher degree of concentration of volatile metals being observed in the finely dispersed fraction. At the same time, we note that similar phenomena were also observed [5] when studying various high-temperature processes: gasification of fossilized coal, gaseous fuel and pig iron production, operation of thermal power stations, etc. In view of these facts, we could expect that the secular radioactive balance in the series of uranium and thorium, which are present in the initial ilmenite concentrates, would be disturbed.

1070-4272/04/7705-0701 © 2004 MAIK "Nauka/Interperiodica"

To study the distribution of natural radionuclides among industrial products of ore smelting of ilmenite concentrates, we selected appropriate samples of the initial concentrate, coke, slag, pig iron, dust caught in cyclones, and behind-cyclone dust. The determination of the specific activity of ^{226}Ra, ^{228}Ra, and ^{228}Th has shown that the main γ-emitting radionuclides do not get to a noticeable extent into the smelted pig iron and pass into the slag [3, 4]. The behavior of lead and polonium radionuclides in the ROS process essentially differs from that of their parent radionuclides: both Pb and Po almost completely sublime and are concentrated in the fine fraction. The activity of Pb and Po reached 3000–6000 Bq kg^{-1} in the dust caught in cyclones and 8000–20 000 Bq kg^{-1} in the behind-cyclone dust, which is much higher than the levels prescribed by NRB-99 and OSPORB-99 regulations [6, 7]. The high α-activity of the radionuclides of the behind-cyclone powder essentially complicates its recovery from the dust–gas mixture and subsequent utilization. The concentration of Po and Pb radionuclides in fine dust fractions reaches so high values that, according to the established regulations, the behind-cyclone dust should be classed with radioactive substances, and handling it requires special safety measures.

Thus, it follows from the aforesaid that even in the first stage of the general flowsheet of the spongy titanium production a significant amount of highly toxic radioactive waste products such as ROS dust is formed. Its recovery from a dust–gas mixture and subsequent utilization are of importance for the titanium production as a whole and are pressing problems to be solved urgently. Preliminary study and comparative tests of various ways and devices for the recovery of behind-cyclone dust have shown that, among all the known and commercially available types of dust-removing facilities, the most efficient for the behind-cyclone ROS powder are filters with powdery sintered filter cartridges (PSFCs).[1] The tests have shown that the efficiency of ROS dust removal from gases is more than 99.9%, and the residual concentration of the dust in off-gases does not exceed 0.20–0.34 mg dm^{-3} [8, 9].

In SIOT-type cyclones, only up to 40–50% of ROS dust is trapped. It should be noted that, in this case, the problem of radiation safety of dust recovery under conditions of sealed apparatus does not arise basically. However, this problem inevitably arises further when unloading the dust from the apparatus and when transporting it. According to the existing regulations [6, 7], formation of radioactive aerosols on workplaces during unloading, transportation, dosing, and packaging should be excluded.

The utilization of the trapped dust, especially of the behind-cyclone dust, involves still more problems. Obviously, the direct use of ROS dust, e.g., in formulations of paint-and-varnish materials, as suggested earlier, does not stand up under scrutiny owing to the fact that the powder contains α- and β-emitting radionuclides of Po, Bi, and Pb, volatile daughter products of ^{232}Th and ^{238}U decay. The return of the dust to the process "head," to the stage of charge preparation for ROS, also does not solve all questions concerning the emission of radionuclides into the atmosphere. In this case, radionuclides and stable isotopes of Pb, will inevitably accumulate in the system, and the trapped dust will become richer in Po, Bi, and Pb radionuclides from one cycle to another, being also enriched in stable Pb. We suggest two ways to solve the problem of utilization of the ROS dust [9].

The first way is "burdening up," i.e., addition of a small amount of the dust to the titanium slag to be chlorinated. However, in this case it should be expected that the composition of technical $TiCl_4$ would change, and salt wastes (of spent melt and sublimates from titanium chlorinators) would form. This requires special measures and technical decisions to be undertaken to ensure the necessary purity of $TiCl_4$ and neutralization of waste products.

The second way is mixing of ROS powder with other toxic waste products of titanium production: with the insoluble residue from hydraulic removal of a melt in which Th and Ra are concentrated, or with an oxyhydrate precipitate containing Fe, Cr, Mn, Ti, V, Th, etc., formed upon local neutralization of solutions and(or) pulps from the hydraulic washout of spent melts and sublimates from titanium chlorinators. Then the resulting composition should be solidified using gypsum or predominantly magnesia binding materials [10, 11], in particular, those based on serpentine raw materials, waste products from asbestos production [12]. The chlorination of slags from ROS of ilmenite concentrates enriched in TiO_2 (up to 80–86%) results in the formation of large amounts of waste products in salt chlorinators: spent melt, fusible and "dry" sublimates from titanium chlorinators, acid drains from washing of process equipment, and spent solutions from gas purification. As much as 0.25–0.30 t of the spent melt and up to 0.05–0.10 t of sublimates from titanium chlorinators are formed per ton of $TiCl_4$ (Table 1).

pH	1.1	2.1	2.1	1.3

In the accepted process, these waste products are discharged into water, with the resulting acidic wastes (pulps) forming three independent streams.

The first stream is an acid chloride solution formed directly from hydraulic washout of spent melt: 8–12 m^3 of water per ton of melt. Every day the melt is poured out 5–7 times (per chlorinator), each time in the amount of 2–3 t. Thus, 10–20 t of the melt is poured out from one chlorinator (correspondingly, 20–40 t when two chlorinators work), and 200–450 $m^3\ day^{-1}$ of wastewater is formed. The volume of such dumping reaches 50 $m^3\ h^{-1}$ at the total pouring duration of 9 h.

The second stream from chlorinators is a weakly mineralized solution from hydraulic removal baths. When water is fed to a bath in the flow-through mode, the dumping volume from two chlorinators is up to 150 $m^3\ day^{-1}$ (up to 10 $m^3\ h^{-1}$ at 15 h of the flow).

The third stream is formed by discharges from hydraulic removal baths for sublimates of smelting chambers. Every day 1.5–3.0 t of the sublimate from two chlorinators is discharged, and up to 480 m^3 of water (up to 20 $m^3\ h^{-1}$) is consumed to remove it, with water being fed continuously in the flow-through mode.

The average composition of the above-mentioned solutions, and also the composition of discharges from hydraulic washout buckets with "dry" sublimates are shown in Table 2. Calculations based on the averaged results of the inspection of the wastewater formation

system show that up to 230 000 m^3 of acidic chloride wastewater is formed in the chlorination process stage directly from chlorinators (80 000, 60 000, and 90 000 m^3 per year for the first, second, and third streams, respectively) at the annual output of 10 000 t of spongy titanium.

The discharges from the chlorination stage amount to less than 10% of the total amount of wastewater from the AVISMA Titanium–Magnesium Combine, Joint-Stock Company. At the same time, this wastewater contains the greatest amount of rather toxic metals: nonferrous, rare, scattered, and radioactive (Tables 1, 2).

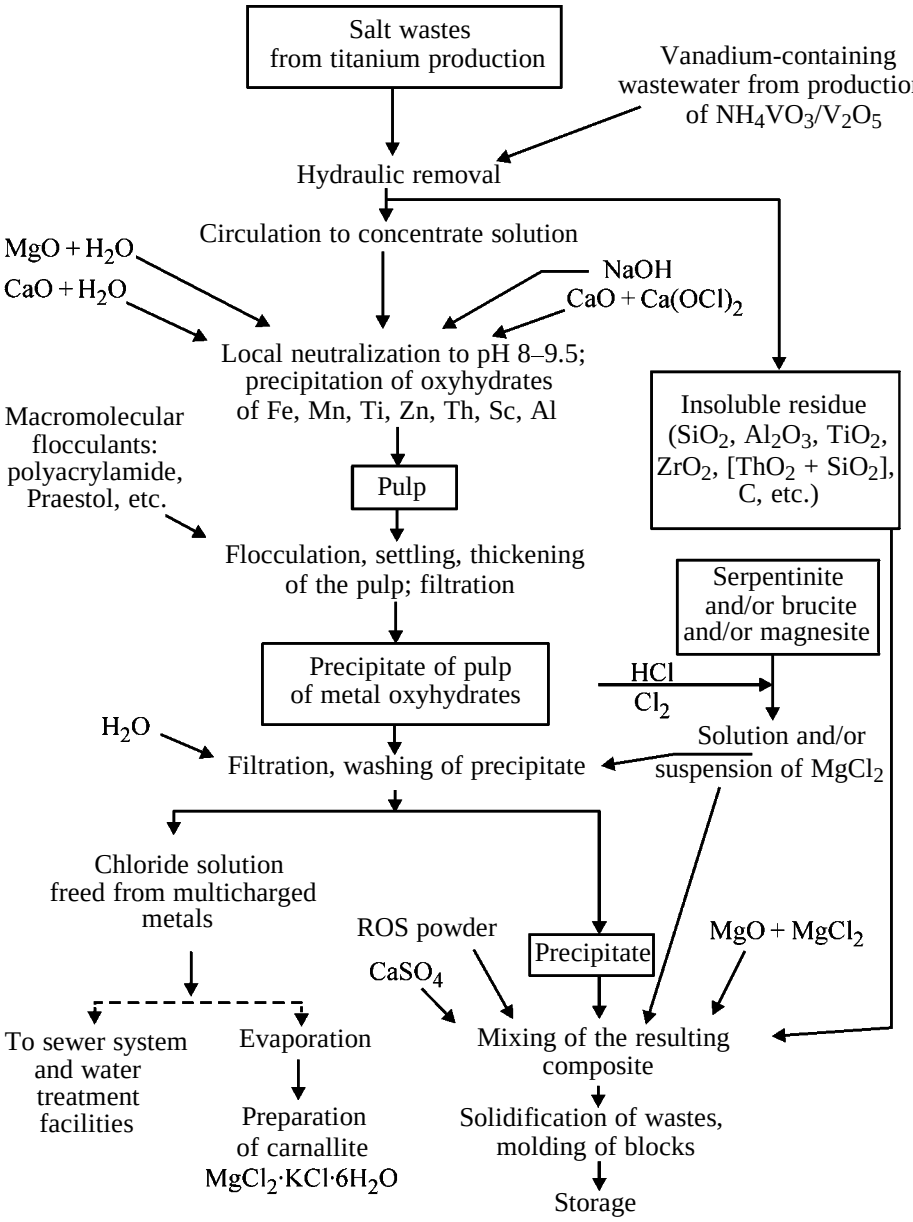
According to the existing technology, wastewater from the hydraulic washout of spent melt and sublimates of $TiCl_4$ production is discharged into the sewer system, combined with the other wastewaters, and fed to the wastewater treatment facilities (in total, up to 3×10^6 m^3/year and more). The combined discharges are treated with lime milk and Praestol flocculant, settled, and discharged into the so-called "industrial channel" (where practically the whole amount of wastewater from industrial enterprises of the city is discharged) and then into the Kama river.

The scheme accepted for processing wastewater from titanium–magnesium industry has a number of essential drawbacks, the main of which is unsatisfactory removal of Mn(II) and Fe(II) ions and suspended substances. This results in that significant amounts of harmful substances are discharged from the wastewater treatment plant into the industrial channel and then into the Kama river, thus giving rise to secondary environmental pollution. One of the principal causes of the existing situation is that the accepted concept of processing wastewater from the combine is inefficient as a whole. Namely, a relatively small volume of wastewater from chlorinators (up to 10% of the total amount), containing chlorides of polyvalent metal ions, is combined with other wastewaters, mainly those from gas purification units, which are suspensions of solid CaO, $CaCO_3$, SiO_2, etc. in liquid solutions of $CaCl_2$ and $Ca(ClO_3)_2$.

Combining acidic wastewaters from the chlorination stage and alkaline wastewaters from gas purification units results in formation of difficultly settling colloidal and semicolloidal oxyhydrates of metals present in the wastewater from hydraulic washout of spent melt and sublimates of titanium chlorinators. As a result, conditions for the flocculation of all polydisperse suspensions present in the combined pulp get worse, the clarification of solutions becomes unsatisfactory, and hydrophilic precipitates saturated with water (the sum of metal oxyhydrates, hydroxides, oxides, and carbonates) are formed. Their dehydration and utilization is an independent and difficult problem. The results of [13–15] show that these problems can be largely solved by separate processing of wastewaters from chlorinators and those from magnesium production and gas purification as a whole, in particular, by local neutralization of solutions and pulps formed from hydraulic washout of sublimates and especially of spent melt from titanium chlorinators. In this case, the load on wastewater treatment plants is significantly reduced, and the problem of the isolation of suspended substances will consist only in settling of coarsely dispersed phases ($CaCO_3$, "sand" fractions of limy milk, etc.) and the part of solid CaO particles that remained unchanged during removal of Cl_2 and HCl from off-gases owing to relatively large size of the particles, their decreased hydrophilicity, and low chemical activity.

It should be noted that the initial wastewaters from the $TiCl_4$ production are relatively dilute as compared to the maximum possible concentration of the sum of metal chlorides (Table 2). It was found experimentally that 1.8–2.0 m^3 of water per ton of the melt is necessary to obtain solutions saturated with metal chlorides, i.e., when 20–40 $m^3\ day^{-1}$ of the melt is discharged, it is possible to obtain 40–80 $m^3\ day^{-1}$ (instead of 200–450) of the concentrated solutions. To obtain concentrated solutions from the sublimate of melting chambers, 4–5 m^3 of water per ton of the sublimate is necessary. In this case, 15 m^3 of a solution (instead of 480 $m^3\ day^{-}$) is formed daily upon processing 1.5–3.0 t of fusible sublimates. As to water passing through the baths for the hydraulic removal in the flow-through mode, this water should be replaced with recycled solutions to reduce the volume of the forming wastewater. Taken together, these measures will reduce the volume of concentrated chloride solutions discharged from chlorinators from 800–1200 to 50–100 $m^3\ day^{-1}$.

To implement this approach, a flowsheet [13] (see figure) was developed and an installation was constructed, providing for the circulation of solutions obtained from the hydraulic washout of spent melt in a system. The installation consists of a bath for the hydraulic removal: a 40 m^3 water-cooled circulating tank. The experience of the installation operation has shown that, on the one hand, the developed technology significantly reduces the volume of "fresh" water consumed, and, on the other hand, after 4–6-fold circulation it yields solutions concentrated with respect to metal chlorides. These solutions are fairly convenient



Flowsheet for processing of titanium production wastes.

for subsequent processing, in particular, for the local neutralization [14, 15] and(or) for the complex processing with extraction of valuable components and production of various commercial items [16, 17].

To gain insight into the processes occurring upon neutralizing and rendering harmless acidic wastewaters from chlorination of titanium slags, we studied in detail how the composition of the initial solutions, their concentration, pH, temperature, types of precipitating agents (alkaline reagents) and flocculants, their concentration and amount, and certain specific features of processing and preliminary preparation of a pulp affect the degree of the precipitation of the sum of metal oxyhydrates, the rate of pulp clarification, the aggregative stability, the weight of the forming precipitate, the efficiency of its dehydration, etc. As initial solutions for the experiments and comparative tests we took the initial solutions and pulps from hydraulic washout of the melt and sublimates obtained according to traditional technology, various mixtures of these solutions, and concentrated solutions formed upon their 4–6-fold circulation. These solutions were neutralized with limy milk (100–150 g dm^{-3} of CaO), NaOH solution (40–120 g dm^{-3}), $MgCO_3$, brucite

$Mg(OH)_2$, serpentinite, and(or) their aqueous suspensions. These studies allowed us to develop, test, and run several versions of a process for locally neutralizing and rendering harmless wastes from titanium production, differing in the type of applied alkaline reagents and, correspondingly, in the composition of the resulting precipitates and solutions (filtrates) and in the ways of their further utilization.

The results of the tests and the experience of running the process have convincingly shown that the use of this technology for processing of the whole volume of the forming wastes make it possible to exclude discharge of polyvalent metals to wastewater treatment plants of the combine and creates prerequisites for utilization of wastes as commercial products: concentrates and individual compounds of nonferrous, rare, and scattered metals, in particular, of iron oxide pigments of various color and purpose, selective inorganic sorbents, and commercial scandium compounds [17]. However, in the first stage of the work, it is appropriate to restrict the consideration to local neutralization of acidic wastewater from titanium production by the precipitation of the sum of metal oxyhydrates.

It is doubtful that these precipitates will be claimed by potential consumers because of their relatively poor consumer properties. At the same time, the presence of toxic metals in the precipitates does not allow their open dumping. To utilize secondary waste products of titanium production, including wastes with the increased content of natural radionuclides (Th, Ra, ..., Po, Bi, and Pb), we developed procedures and flowsheets [18] in which the precipitates of metal oxyhydrates are combined with ROS dust and insoluble residue from hydraulic washout of the melt from titanium chlorinators, and the resulting mixture of waste products is treated with gypsum [$CaSO_4$ and(or) $CaSO_4 \cdot 0.5H_2O$] or magnesia ($MgO + MgCl_2$) binders, solidifed, and molded in "blocks" (see scheme). It allows highly toxic wastes to be incorporated into a water-insoluble, nondust-forming matrix, stable to atmospheric precipitates, soil and subsoil waters, fluctuations of the ambient temperature, and wind and water erosion. Storage of such wastes will prevent emission of radioactive dust into the atmosphere and pollution of the environment.

CONCLUSIONS

(1) The processes of formation of solid, liquid, and dust–gas wastes in various stages of titanium sponge production were considered. A significant amount of finely dispersed dust in which toxic metals and radionuclides of the thorium series are concentrated is formed in the course of ore smelting of the ilmenite concentrates.

(2) According to the accepted technology, when titanium slag is chlorinated, the concomitant metals (Fe, Cr, Mn, Zr, Al, Th, Sc, etc.), which are accumulated in the spent melt and sublimates from titanium chlorinators, are discharged into water, and the resulting pulp is discharged to the sewer system and fed to the wastewater treatment facilities. However, owing to the formation of colloidal and semicolloidal metal oxyhydrates upon the neutralization, the pulp does not settle and is not clarified.

(3) To prevent environmental pollution, we suggested and tested a process involving pulp circulation when the spent melt and sublimates from titanium chlorinators are removed. The process yields concentrated solutions and pulps, which are then locally neutralized. The resulting oxyhydrate precipitate is mixed with other toxic wastes from titanium production and with gypsum or magnesia binder for solidification and then molded in blocks in an environmentally safe form.

ACKNOWLEDGMENTS

The study was made within the framework of the 2000–2003 Interbranch Program of Cooperation of the Ministry of Education of the Russian Federation and the Ministry of Atomic Energy of the Russian Federation, Scientific-Innovation Cooperation direction.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Possibility of Integrated Processing of the Baddeleyite Concentrate

V. N. Lebedev, E. P. Lokshin, N. A. Mel'nik, T. E. Shchur, and L. A. Popova

Received August 21, 2003; in final form, December 2003

Abstract—Main procedures used in integrated processing of baddeleyite, including sintering with calcium carbonate or oxide, decomposition of the cake with hydrochloric acid, and recovery of zirconium in the form of zirconium oxochloride, were studied.

The baddeleyite concentrate (BC) from the Kovdor deposit, which contains no less than 97.5–98.5% ZrO_2 + HfO_2, is used without chemical processing in many fields of technology. Its use for production of zirconium compounds is considered to be inexpedient since the cost of ZrO_2 in the concentrate is nearly twice that in zircon. In view of the decreasing demand for BC because of the saturation of the market with zircon-based synthetic materials [1], a necessity arises for deeper processing of the concentrate. The profitability of such a processing can be substantially improved by recovery of Sc(III), Ta(V), and Nb(V), which are present in the BC in amounts whose cost, at the world prices, is comparable with that of the concentrate. Previously, the distribution of rare and radioactive elements in various flowsheets of BC processing has been studied, and it was shown that simultaneous synthesis of pure zirconium compounds and recovery of rare and radioactive elements into separate concentrates is the most efficient in processing by sintering with CaO or $CaCO_3$ and subsequent transfer of chlorides or nitrates into solution. Here we studied methods for recovery of rare elements into concentrates by sintering of BC with $CaCO_3$ and recovery of zirconium(IV) in the form of an oxychloride.

EXPERIMENTAL

A baddeleyite concentrate conforming to TU (Technical Specification) 48-0572–91 was used in the study. Rare and impurity elements in precipitates were analyzed by X-ray fluorescence and spectral methods, and those in solution, by the emission and atomic-absorption techniques. The specific radioactivity and the content of U and Th were determined by radiometry and γ-ray spectrometry.

The baddeleyite concentrate was ground in a ball mill to grain size of less than 0.054 mm, mixed with $CaCO_3$ and $CaCl_2$ in weight ratio of 10 : 8.2 : 1.2, and sintered at 1150°C for 4 h. The cake was dissolved in hydrochloric acid, and the $ZrOCl_2$ precipitate was separated and washed with counterflow repulpations to required purity. The acid consumed for washing was used to decompose the cake. The degree of concentrate decomposition was 95–97%, which considerably exceeds the value in sintering with CaO [2, 3]. The yield of the mother liquor after isolation of $ZrOCl_2$ was 150–250 ml per 100 g of BC (~150 g of cake) at a composition (g l^{-1}): 40–60 HCl, 120–180 CaO, 2–5 Fe_2O_3, 4–8 ZrO_2, 1.5–3.5 TiO_2, 1.7–3.0 Nb_2O_5, 0.25–0.4 Ta_2O_5, 0.08–0.18 Sc, 0.15–0.6 SiO_2, 0.06–0.12 U, and 0.05–0.1 Th. Iron finds its way into the BC mainly during grinding and is present in solution as Fe(III), with other elements also oxidized to the highest oxidation state.

Rare elements were primarily recovered using extraction techniques. It is known that Sc(III) is best recovered with organophosphorus acids [4, 5]. The possibility of its recovery with a 0.3 M solution of di-2-ethylhexyl hydrogen phosphate (HDEHP) in dodecane was studied. It was found that 99% of Sc(III) is extracted at a phase ratio o : a = 1 : 10, and 92%, at o : a = 1 : 50, in the case of agitation for 5 min and settling for 1 h. The results of a large-scale experiment are listed in Table 1.

The extract was twice washed with a 6 N solution of HCl at o : a = 1 : 1. Zr(IV) and Sc(III) were not noticeably washed out; U(VI), Ti(IV), and Fe(III)

Table 2. Composition of precipitates formed in thermal hydrolysis

Run no.	*A*, kBq kg^{-1}	Content of oxides, wt %					
		Nb(V)	Ta(V)	Ti(IV)	Zr(IV)	Fe(III)	Si(IV)
1	52.9	19.7	3.9	26.6	25.6	0.3	6.8
2	570	14.6	2.7	20.8	31.2	1.1	4.7
3	490	15.6	2.9	24.3	32.9	0.01	1.8

were washed out incompletely; all the other elements passed into the aqueous phase. The concentration of Sc(III) in the extract exceeded that in baddeleyite by a factor of nearly 100, and that in solution, by a factor of 10. Use of NaF for back extraction has been recommended [6]. An advantage of such a technique is that the most valuable element is recovered in the first stage; to its disadvantages belong difficult back extraction and distribution of radioactivity among phases.

An experiment on extraction of elements with the most readily available solvents, octanol and tributyl phosphate (TBP), showed that iron(III) can be selectively recovered from solution and the separation factors for other impurities are low.

It would be expected that, at a high concentration of the salting-out agent, $CaCl_2$, the distribution coefficients of Sc(III) should be greater [4, 5]; however, these coefficients were found to be lower and close to those for the other components monitored. Raising the acidity fails to improve the selectivity of the system. Quite the opposite, the distribution coefficient of Sc(III) becomes smaller because of the competing influence of other ions.

We examined the possibility of separating the components using the difference in the pH values of hydroxide precipitation and the tendency for multicharged cations to undergo hydrolysis. In the case of neutralization with ammonia, the pH of the onset of Sc(III) precipitation is 4.8–4.9, whereas Ti(IV), Zr(IV), Nb(V), and Ta(V) precipitate in the pH range from 0.5 to 2.0 [4, 7]. It was established that, upon neutralization to pH 0.5–2.5, virtually unfilterable slurries are formed. At pH 3.5 the precipitate can be filtered off, and not only Ti(IV), Zr(IV), Nb(V), Ta(V), and Fe(III) completely precipitate, but also U(VI), Th(IV), and Sc(III). The coprecipitation of Sc(III) and the radionuclides is due to the sorption properties of the hydrogels of multicharged cations and iron(III).

When thermal hydrolysis is performed in an acid medium, 5–15% of Sc(III) is precipitated, depending on the conditions (acidity, time of thermal treatment, nucleating and other additives). This mainly occurs via capture of the mother liquor. In order of their precipitation, the elements can be ranked as follows: Ta(V) > Nb(V) > Ti(IV) > Zr(IV) > U(VI), Th(IV). By changing the precipitation conditions, it is possible to selectively leave in solution radioactive elements and part of Zr(IV). However, taking into account the separation of Sc(III) and difficulties in filtration, it is advisable to isolate these elements into a collective precipitate. The yield of dry residue is 15–25 g l^{-1} of solution. The compositions of the precipitates obtained by neutralization of the solution with 10 g l^{-1} of HCl, introduction of H_2SO_4 to 1 mol mol^{-1} of ZrO_2, and keeping at 90°C for 2 h are listed in Table 2. In run

no. 3, hydrolysis was performed in solution after separation of Fe(III) by extraction, and in run nos. 1 and 2, before separation of Fe(III). The content of Sc(III) in the washed precipitates was below the detection limit of the X-ray fluorescence analysis (<0.01 wt %). The precipitation was fairly complete: the residual content of Ti(IV) and Nb(V) in solutions formed in run nos. 2 and 3 was less than 0.01 g l^{-1} for each of these components, and that of Zr(IV), less than 0.3 g l^{-1}. Thus, the separation of Sc(III) from multicharged cations was achieved in the experiments, with the only difficulty consisting in the poor filterability of the precipitates formed by hydrolysis.

Further processing of the precipitates can be done using the standard methods in an $HF–H_2SO_4$ medium in order to perform extractive recovery and separation of Ta(V) and Nb(V) [8], with preliminary removal of U(VI) on anion-exchange resins in a sulfuric acid medium [9].

From a solution that contains $CaCl_2$, 85% of Sc(III) is extracted with TBP in a single stage in the absence of competing ions at o : a = 1 : 1. In a counterflow process, 98% recovery was achieved in three stages at o : a = 1 : 2. After backwashing with water and neutralization of the backwash with ammonia, the hydroxides isolated were treated with oxalic acid. The content of Sc_2O_3 in a precipitate calcined at 900°C was 16.5 wt %, with the rest constituted by Ca(II), Fe(III), Mg(II), and Zr(IV). The yield of the precipitate was 0.8–1 g l^{-1} of solution at a direct recovery of Sc(III) from BC in the range 65–78.5%.

CONCLUSION

The study demonstrated the possibility of processing of the baddeleyite concentrate to produce zirconium compounds with recovery of scandium(III), niobium(V), and tantalum(V) into separate concentrates. The process includes sintering with calcium oxide or carbonate in the presence of a modifying agent, breakdown of the cake with hydrochloric acid, recovery and purification of zirconium oxychloride, thermal hydrolysis of the mother liquor, and transfer into a precipitate of basic salts of multicharged cations. Scandium(III) is recovered from solution via extraction with di-2-ethylhexyl hydrogen phosphate or is accumulated in a raffinate in extraction of iron(III) with tributyl phosphate.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Recovery of Thorium(IV) in Utilization of Solutions Formed in Sulfuric Acid Breakdown of Perovskite

V. G. Maiorov, A. I. Nikolaev, V. K. Kopkov, L. A. Safonova, and G. V. Korotkova

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received August 21, 2003; in final form, December 2003

Abstract—Extraction of thorium(IV) with di-2-ethylhexyl hydrogen phosphate, octanol, and tributyl phosphate in sulfuric acid processing of perovskite was studied. The main stages of utilization of waste hydrochloric acid solutions were considered.

Russia suffers from permanent shortage of compounds of titanium(IV), niobium(V), and tantalum(V), which is due to the lack of readily available resources of conventional raw materials (ilmenite, columbite–tantalite, pyrochlore, and microlite ores). At the same time, Russia possesses a considerable part of world's mineral resources of titanium-and-rare-metal raw materials; more than half of the domestic resources can be found in the Kola Peninsula. The largest amounts of titanium-and-rare-metal raw materials are contained in loparite ores of the Lovozero deposit and perovskite ores of the Afrikanda and Vuoriyarvi deposits. The loparite concentrate is produced in limited amounts and actually serves as the only important exploited source of raw materials in Russia for manufacture of niobium, tantalum, and rare-earth products. Deposits of perovskite ores deserve closer attention because of the shortage of materials based on titanium and rare metals.

The total amount of ores only at the Afrikanda deposit (the best prepared for industrial use) is 626.2 million tons (52.2 million tons of TiO_2) [1–3]. A characteristic feature of perovskite is its complex multicomponent composition. For example, the perovskite of the Afrikanda deposit contains (wt %) 0.64–2.50 $(Nb,Ta)_2O_5$, 50.8–56.8 TiO_2, 0.12–1.93 SiO_2, 0.15–1.30 Al_2O_3, 0.43–2.00 Fe_2O_3, up to 1.44 FeO, 2.18–10.7 Ln_2O_3 (here and hereinafter, Ln_2O_3 is a sum of oxides of rare-earth elements), 26.3–38.1 CaO, 0.10–2.35 Na_2O, and 0.07–0.14 ThO_2. The complex composition of the raw materials necessitates their integrated processing with recovery of all the valuable components. Various techniques have been developed for processing of perovskite [1]. These techniques make it possible to obtain 0.41–0.47 t of TiO_2 pigment, up to 100 kg of a rare-earth concentrate, 7.7–9.3 kg of Nb_2O_5, and 0.42–0.50 kg of Ta_2O_5 from 1 t of the concentrate. Rather promising is breakdown of perovskite with hydrochloric acid, with Ca(II), La(III), and Th(IV) passing into solution, and Ti(IV), Nb(V), and Ta(V), into the precipitate, which is further processed into commercial products by the known schemes [1–3].

This study is mainly concerned with recovery of Th(IV) in the hydrochloric acid processing of perovskite. The perovskite concentrate contains as undesirable impurities such radionuclides as Th(IV), U(VI), and Ra(II), with Th(IV) predominant among these. A suggestion that Th(IV) compounds can be used in the future in nuclear power engineering has been made in the literature [4]. Naturally, recovery of Th(IV) is also necessary from the standpoint of the environmental safety. Hydrochloric acid solutions obtained by breakdown of perovskite contained, after precipitation of Ti(IV), Nb(V), and Ta(V) by hydrolysis, the following compounds ($g\ l^{-1}$): 100–200 HCl, 100–150 $CaCl_2$, 0.1–0.2 ThO_2, 6–10 Ln_2O_3, 6–10 Fe_2O_3 [Fe(II) + Fe(III) in terms of Fe_2O_3], and 1–10 TiO_2. In addition, Mn(II), V(V) (the perovskite concentrate contains an impurity of titanomagnetite), and Zn(II) [Zn(II) was used in the hydrolysis stage to obtain pigment-grade titanium dioxide] were present in solutions. The system has a complex multicomponent composition, the properties of its constituent elements are strongly different, and it has been poorly studied. All these factors predetermine the complexity and great number of different processes in the scheme to be used for utilization of these solutions, the more so as one of important tasks was to minimize the mass of radioactive products to be disposed of. The solutions

* Extraction with OCL containing 153 g l^{-1} of HCl.
** With account of HCl input with OCL.
*** Preliminarily, Fe(II) was oxidized to Fe(III) by addition of H_2O_2.

used in the experiments were either taken immediately after the precipitation of Ti(IV), Nb(V), and Ta(V), or (for the most part) after their evaporation to $CaCl_2$ content of 300 g l^{-1} and more. The evaporation was carried out in order to diminish the process flows, to regenerate HCl [5], which is recycled into the perovskite breakdown stage, and to improve the extraction of Th(IV) and some other components [6].

The distribution of Th(IV) and Ln(III) was monitored by chemical analysis: the sum Th(IV) + Ln(III) was isolated and Th(IV) was determined photometrically; Fe(III) was determined by atomic absorption spectroscopy, and Ca(II), by flame photometry; also, emission spectral, X-ray fluorescence, and X-ray phase analyses were employed. The error in determining the concentrations of the components did not exceed 3–7%, depending on an analytical technique, a chemical element to be determined, and (primarily) the content of this element.

The main method used for recovery of Th(IV) is extraction. As extracting agents we used di-2-ethylhexyl hydrogen phosphate (HDEHP) manufactured by Bayer (content of the main product >98%), octanol (OCL, content of the main product ~98%), and tributyl phosphate (TBP) of pure grade, the diluent was RED-1 (paraffin hydrocarbons C_{12}–C_{16}). The extraction was performed at room temperature (18±2°C); the solutions were kept before extraction (in the case when reagents were introduced into the solutions in order to vary their composition) for no less than 24 h. The extraction time was 10 min. When the precipitation technique was used, neutralization was performed with lime milk containing 20 wt % CaO (CaO containing no less than 97.5 wt % main component was used) or with a solution of 300 g l^{-1} NaOH of pure grade; the pH values were monitored with a standard I-120.2 ion meter with an ESL-45-07 electrode.

Tables 1–3 list the main experimental results obtained in studying the extraction of Th(IV) and concomitant components ($V_o : V_a$ is the ratio of the organic and aqueous phases before extraction). With HDEHP, good results were obtained in recovery of all the components under study; Th(IV), Fe(III), and Ti(IV) could be extracted in a wide range of acidities of the system. Nevertheless, the most complete transfer of the components into the organic phase is ob-

* Degree of dilution of the starting solution by adding concentrated HCl (467 g l^{-1} of HCl).
** Extraction with TBP containing 147 g l^{-1} of HCl.
*** Taking into account income of HCl with TBP.
**** Degree of recovery of other elements: Ln(III) ≤10%, Fe(III) >90%, and Ti(IV) about 50%.

served at a low content of HCl, especially for Ln(III). It should also be noted that replacing RED-1 with OCL improves the recovery of Th(IV) and (strongly) Ln(III). However, a disadvantage of HDEHP as an extracting agent is the low selectivity and poor phase separation in the system under study. Moreover, rare-earth elements are easily backwashed from HDEHPA with solutions of acids, whereas backwashing of Th(IV) and Ti(IV) requires use of fluoride or alkaline solutions, which leads to precipitation and gives rise to additional technological problems. Therefore, main attention was focused on neutral organic solvents, OCL and TBP. In the case of extraction with these solvents from the chloride system under study, the distribution of elements is the most strongly affected by changes in the concentrations of HCl and $CaCl_2$ [6].

The use of OCL as an extracting agent for recovery of Th(IV) was found to be inefficient (Table 2): in a wide range of HCl and $CaCl_2$ concentrations and $V_o : V_a$ ratios (including the case when HCl-containing OCL was used), the transfer of Th(IV) into the organic phase did not exceed 2%, presumably as a result of the low basicity of OCL and competition with HCl, which is well extractable with alcohols [7]. However, OCL selectively extracts Fe(III), which was used for its extraction from process solutions in order to simplify their utilization and to diminish the mass of subsequently recovered radioactive precipitates to be disposed of. Preliminary studies demonstrated the possibility of virtually complete extraction of Fe(III) with OCL under conditions of a continuous counterflow process at $V_o : V_a \approx 0.3 : 1$. It should be noted that up to 20 wt % of Fe is present in solutions as Fe(II). Since Fe(II) is not extracted in the system chosen [6], it is necessary to oxidize Fe(II) to Fe(III), e.g., by adding a minor amount of H_2O_2. After washing [mostly performed to remove Ti(IV) and trace amounts of Th(IV)] and back extraction with water ($V_o : V_a$ of 10 : 1 and 3 : 1, respectively), a high-quality concentrate of Fe(III) can be isolated. Further processing of this concentrate by the technique described in [8] yields high-purity compounds of Fe(III), which are used, e.g., in battery industry and for obtaining various types of ferrites [8].

The extraction of Th(IV) with TBP was analyzed in detail. Preliminary studies demonstrated that the transfer of Th(IV) into the organic phase was in the range 40–62% in the case of extraction of Th(IV) from a solution containing 182 g l^{-1} of HCl and 125 g l^{-1} of $CaCl_2$ (the content of other components is give above) immediately after the precipitation of Ti(IV), Nb(V), and Ta(V). This was done in a wide range of concentrations of HCl (182–372 g l^{-1}; concentrated HCl was added to the solution) and $CaCl_2$ (42–125 g l^{-1}; the content of $CaCl_2$ was varied on adding HCl) and varied $V_o : V_a$ ratios [(1–2) : 2; including the case when HCl-containing TBP was used]. The highest degree of Th(IV) extraction was 62% at $V_o : V_a$ = 1 : 1 and a threefold dilution of the solution of con-

centrated HCl to a concentration of 372 g l^{-1} of HCl. These parameters are insufficient for complete recovery of Th(IV) under conditions of an industrial counterflow extraction.

Good results were obtained in extraction of Th(IV) from solutions evaporated to $CaCl_2$ content exceeding 300 g l^{-1} (Table 3). Addition of concentrated HCl to an evaporated solution (run nos. 1–3) made it possible to raise the recovery of Th(IV) in a single stage to 70.6%, despite the decrease in the concentration of $CaCl_2$. Additional "saturation" of the system with HCl because of the use of HCl-containing TBP leads to a further rise in the degree of Th(IV) transfer into the organic phase to 80.8% (run nos. 4–9).

However, the introduction of considerable amounts of HCl into the system has an important disadvantage: HCl itself is rather well extracted with TBP (Table 3) [6], so that the acid binds the extracting agent and successfully competes with Th(IV). This approach, i.e., addition of HCl, can be considered to a certain extent acceptable (or, rather, forced) for systems that contain virtually only HCl, e.g., in processing of solutions in the hydrochloric acid technology of loparite. In the system under study, which contains $CaCl_2$ in high concentrations, it is more appropriate (and more advantageous economically) to extract Th(IV) from solutions with the highest possible (because of the preliminary evaporation) content of $CaCl_2$ (run nos. 10, 11). Even at $V_o : V_a = 1 : 1$, the recovery of Th(IV) is 85.8%, which makes it possible to virtually quantitatively recover Th(IV) from process solutions under the conditions of counterflow extraction. It would be expected that further evaporation of the solutions to a $CaCl_2$ content of, e.g., 450 g l^{-1} will create conditions for even more complete passing of Th(IV) into the extract, with the $V_o : V_a$ ratio simultaneously decreased to less than 1 : 1.

The study also demonstrated that extraction of Th(IV) under the conditions determined, with the subsequent scrubbing and backwashing with water, can be used to obtain a concentrate with the Th(IV) content of up to 10 wt %. Since U(VI) present in a minor amount in perovskite is recovered with TBP from hydrochloric acid solutions better than Th(IV) [6, 9, 10], it passes into the concentrate together with Th(IV). Scrubbing of the Th(IV) extract is necessary for separating such impurities as Ca(II), Ln(III), Ti(IV), Mn(II), etc., because, without scrubbing, the content of oxides of these impurities in the concentrate may be as high as >20, >25, 10–20, and 5–10 wt %, respectively.

Additional purification of Th(IV) to remove impurities can be performed by partial neutralization of its backwash. It is known that the pH of precipitation of element hydroxides strongly depends on the composition of a particular solution and on the type of a precipitating agent. It can be considered that, in the system under study, Ti(IV), Fe(III), Th(IV), U(IV), and U(VI) are completely or fairly completely precipitated at pH 5–6; Ln(III) and Fe(II), at pH ~9; and Mn(II), at pH ~10 [9–13]. Since Fe(III) is readily removed by extraction with OCL before recovery of Th(IV) with TBP, it would be expected that neutralization of the Th(IV) backwash to pH 5–6 will create conditions for the maximum possible purification of Th(IV) to remove Ln(III), Mn(II), and Ca(II), with the content of Th(IV) in the concentrate markedly increasing to values considerably higher than 10 wt %.

The results obtained in this study and published data [1–14] suggest the following scheme for utilization of solutions formed in breakdown of perovskite with hydrochloric acid and precipitation of Ti(IV), Nb(V), and Ta(V), with a Th(IV) concentrate produced: (1) evaporation of a solution (with distillation of HCl) to a $CaCl_2$ content exceeding 300 g l^{-1}; (2) extraction of Fe(III) with OCL, with preliminary oxidation of Fe(II) to Fe(III); (3) extraction of Th(IV) to give its concentrate containing 10 wt % ThO_2 and more [U(VI) is recovered together with Th(IV)]; (4) coprecipitation of Ra(II) on $BaSO_4$; (5) neutralization of the resulting solution to pH 5–6 with the formation of a precipitate that contains mostly Ti(IV); this precipitate is recycled into the stage of perovskite breakdown with hydrochloric acid; (6) neutralization of the solution to pH ~9 to give a commercial product, concentrate of rare-earth elements(III) (with Ln_2O_3 content of up to 90 wt %), which is processed further using the known procedures [1–3, 7].

It should be noted that it is preferable to recover Th(IV) and U(VI) by extraction, rather than by precipitation, since neutralization of solutions may yield soluble carbonate complexes [9, 10, 13] (because of the absorption of atmospheric CO_2), with the resulting distribution of radionuclides over the flowsheet and radioactive contamination of the concentrate of rare-earth elements(III).

According to preliminary data, the recovery of Th(IV) and Ln(III) into the corresponding concentrates exceeds 99%. The $CaCl_2$ solution obtained by neutralization is utilized by its evaporation to dry $CaCl_2$ or processed into gypsum (by addition of H_2SO_4 with evaporation of HCl) [3]. Calcium chloride is widely used as, e.g., a de-icing salt for roads

or a component of drilling muds in petroleum production; gypsum can be potentially used for manufacture of cement clinker and other building materials [1, 3].

The scheme described can be used with minor modifications to recover Th(IV) and Ln(III) in the hydrochloric acid technology of another rare-earth titanoniobate, loparite [15], mainly in utilization of solutions formed in nitric acid breakdown of perovskite and loparite, and also to process other kinds of rare-earth raw materials containing radionuclides.

CONCLUSIONS

(1) The conditions were studied under which thorium(IV) and other valuable components are recovered from hydrochloric acid solutions formed in breakdown of perovskite, after hydrolytic precipitation of titanium(IV), niobium(V), and tantalum(V).

(2) A flowsheet for utilization of hydrochloric acid solutions to give concentrates of thorium(IV), iron(III), and rare-earth elements(III) was suggested.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

New Sensory Materials Based on Chalcogenide Glasses Containing Zinc, Cadmium, and Manganese Sulfides

K. A. Legin, A. M. Bolotov, A. V. Legin, and Yu. G. Vlasov

St. Petersburg State University, St. Petersburg, Russia

Received April 12, 2004

Abstract—New chalcogenide glasses of the system $0.5AgI–(0.5 – x)Sb_2S_{3-x}MS$ containing cadmium, manganese, and zinc sulfides were obtained. The high purity of these materials and their glassy state were proved by X-ray analysis and X-ray fluorescence energy-dispersive spectroscopy. The impedance of the glasses obtained was measured within a wide range of frequencies, and the dependences of the conductivity on the composition of glasses were studied. New potentiometric sensors based the new glasses were developed, and an electrochemical experiment was carried out.

Glassy materials have a number of important advantages when used as chemical sensors [1, 2], in particular, high chemical stability in a number of liquid media and increased sensitivity and selectivity. Furthermore, modification of the glass composition allows their properties to be controlled within wide limits. The development of potentiometric sensors based on glassy systems and sensitive to inorganic ions is an urgent problem. Incorporation of transition metal chalcogenides in various glassy matrixes strongly affects the transport properties, e.g., conductivity parameters [3, 4], surface characteristics, and electrochemical behavior of new glasses [5, 6].

A wide region of glass formation is known to exist in the pseudobinary system $AgI–Sb_2S_3$ [7], and this chalcogenide system is mainly an ionic conductor with respect to silver. Furthermore, such glasses have a sufficiently "flexible" structure allowing their composition to be modified over a wide range, so that glassy materials considerably differing in their properties from the initial glasses can be prepared.

The aim of this work was to study glass formation in the system $0.5AgI–(0.5 – x)Sb_2S_{3-x}MS$ (MS = ZnS, CdS, and MnS), transport characteristics of these glasses, and also their electrochemical sensory properties in aqueous solutions of inorganic salts.

EXPERIMENTAL

The initial substances for the synthesis of glasses of the system $0.5AgI–(0.5 – x)Sb_2S_{3-x}MS$ were cadmium(II) sulfide (99.995%) and manganese(II) sulfide (99.9%) (Aldrich), analytical grade elemental sulfur and metal zinc (Merck), and also silver iodide and antimony sulfide, which were synthesized by standard techniques from chemically pure or ultrapure grade chemicals.

The glasses were synthesized by vacuum melting in quartz ampules evacuated to 0.01–0.1 Pa. The weight of samples for the synthesis was 3 g. The ampules were kept in a furnace at 900°C for a week with daily stirring of the melt, quenched by cooling from 900°C in water with ice, and then annealed for 24 h at 110°C. The amorphous structure of the glasses obtained was checked visually in the case of the compositions containing low amounts of ZnS, CdS, and MnS, and by X-ray phase analysis (XRPA) in the case of the compositions with the mole fraction of these sulfides exceeding 0.05.

To prepare samples for the X-ray phase analysis, they were polished to obtain pellets with the diameter not exceeding 10 mm and thickness, 2 mm. The glasses were washed with double-distilled water and spectroscopic-grade acetone. Samples were prepared just before taking X-ray diffraction patterns in order to prevent surface oxidation.

To control the glassy state, we used a Rigaku GeigerFlex–D/max–RC diffractometric system (Japan). A rotating cobalt anode (radiation wavelength λ = 1.789 Å) with a secondary monochromator on a diffracted beam served as an X-ray source. The current in the tube was 50 mA, and the accelerating voltage, 40 kV. The scanning rate was 1.5 deg min^{-1}, and the scanning step was 0.01°. The crystal phases

1070-4272/04/7705-0716 © 2004 MAIK "Nauka/Interperiodica"

were identified using the Powder Diffraction File, Alphabet Index of Inorganic Phases.

To check the presence of impurities in Sb_2S_3 and in $0.5AgI–0.5Sb_2S_3$ glasses, we analyzed them using X-ray fluorescence energy-dispersive spectroscopy. Weighed samples of Sb_2S_3 and of $0.5AgI–0.5Sb_2S_3$ glasses (2 g) were ground in an agate mortar and pressed in pellets on a boric acid support in a Herzog HTP-40 press. To take the spectra in air, we used a Tracor X-ray Spectrace-5000 X-ray fluorescent energy-dispersive spectrometer equipped with an X-ray tube with an Rh anode. The voltage across the tube was 30 kV, and the current in the tube, 0.10 mA.

Samples for the measurements were polished with an abrasive powder to obtain plane-parallel (with the accuracy of ±0.01 mm) plates 0.08–1.5 mm thick. We deposited contacts of the greatest possible diameter made from Sigma Carbon Paste (up to 40% of black lead in isopropanol + binding agent) on the parallel sides. The deposited contacts were dried for 0.5 h. The error of measuring the surface areas of the contacts did not exceed ±10%. Then the sample was clamped between two gold contacts and placed in a thermostat–cryostat cooled with liquid nitrogen, with a temperature control unit connected. The impedance was measured on alternating current using an Agilent Technologies 4285A LCR electrochemical measuring system controlled with a computer, which allowed us to obtain and accumulate all data in the digital form. The impedance spectra were taken in the temperature range 220–310 K and frequency range from 20 Hz to 1 MHz.

The charge-transfer activation energy E_a (eV), preexponential factor σ_0 (S cm^{-1} K), and also electrical conductivity at 25°C σ_{25} (S cm^{-1}) were calculated by the least-squares method from the dependence

$$\sigma T = \sigma_0 \exp[-E_a/(kT)]. \quad (1)$$

The choice of the calculation formula was determined by the fact that the glasses under study are mainly ionic conductors and the dependence of type (1) adequately describes their characteristics. The error in the determination of E_a was ±0.005 eV on the average, that of the preexponential factor, ±0.1–0.2 $\log\sigma_0$ units, and that of the conductivity at 25°C, ±0.06 $\log\sigma_{25}$ units.

The electrode properties of membranes for sensors with a solid contact were studied by measuring emf of the voltaic cell with transfer

Cu | Ag | AgCl, KCl_{sat} | Solution under study | Glass membrane | Ag | Solid contact | Cu.

For sensors with liquid contact, we used the cell

Cu | Ag | AgCl, KCl_{sat} | KNO_3, 0.1 M | Solution under study | Glass membrane | $AgNO_3$, 0.01 M | Ag | Cu.

An EVL 1M3 saturated silver chloride electrode served as a reference electrode. To measure pH of solutions, we used an ESL-43-07 glass electrode preliminarily calibrated with standard buffer solutions.

All measurements were carried out on a multichannel electronic digital voltmeter with a high input resistance (10^{12} Ω), with computer control and data collection. Standard solutions with the concentration of ions to be determined of 10^{-3} M and more were prepared by successive tenfold dilution of the initial 1 M solutions prepared gravimetrically. The dilution was carried out using a 0.1 M KNO_3 solution. Calibrating solutions were prepared directly before measurements in a Teflon measuring cell by adding fixed small volumes of standard solutions to 100 ml of a 0.1 M solution of a supporting electrolyte, potassium nitrate.

For all the experiments reported here, we have prepared and studied no less than three samples of each composition.

Repeated synthesis of compositions containing zinc, cadmium, and manganese sulfides has shown that the compositions with the mole fractions of ZnS, CdS, and MnS of 0.025, 0.05, and 0.1 had glassy appearance. At the mole fraction of the sulfides of 0.15, the samples are inhomogeneous, and at the mole fraction of zinc, cadmium, or manganese sulfide of 0.2, they apparently contain crystalline inclusions.

The results of the X-ray phase analysis of the glasses and the compositions of the crystallizing phases are given in Table 1. According to the X-ray data, the samples with the CdS mole fraction of 0.025, 0.05, and 0.1 and those with the MnS and ZnS mole fractions of 0.025 and 0.05 are X-ray amorphous.

Comparison of the crystal phases detected in non-X-ray-amrophous samples of all the systems under study shows that the main crystallizing phases are ZnS, CdS, and MnS, and also AgI. The crystallization of AgI at a metal sulfide concentration of 15 mol % and more is attributable to the fact that, when the sulfide of the second metal is introduced in significant amounts, the glass formation limit in the pseudobinary system $AgI–Sb_2S_3$ is approached (the limiting composition in this system is $0.66AgI–0.34Sb_2S_3$).

The analysis of Sb_2S_3 and $0.5AgI–0.5Sb_2S_3$ samples revealed the presence of Fe, Cu, and Ni impuri-

ties. Their amount is insignificant (no more than several ppm in total). Certain starting reagents, in particular antimony, seem to be the basic source of the impurities. Thus, the physical and chemical properties of the glasses described in this work are determined not by the presence of foreign elements and casual contaminants, but by specific features of structure and properties of the materials.

The results of studying conductivity of the glasses are given in Figs. 1–3 and Table 2. A typical impedance hodograph for the samples under study is shown in Fig. 1. The polarizing branch observed in the hodograph (Warburg's impedance) at low frequencies points to the presence of polarizing phenomena on the glass|graphite boundary and hence proves predominantly ionic character of conductivity in the glasses.

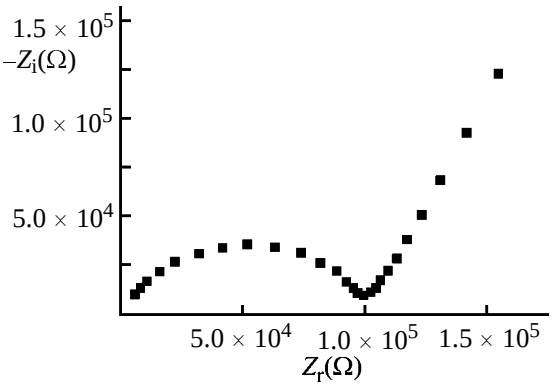

Fig. 1. Impedance hodograph for a sample of the composition $0.5AgI–0.475Sb_2S_3–0.025ZnS$.

The temperature dependences of the electrical conductivity for several glasses with the mole fraction of metal sulfides of 0.05 are given in Fig. 2. These dependences are adequately described by the Arrhenius equation of type (1) in the entire temperature range of the conductivity measurements.

The conductivity parameters of the alloys obtained are summarized in Table 2. The dependences of $\log\sigma_{25}$ on the content of the transition metal sulfide in all the three systems are presented in Fig. 3. The conductivity of glasses containing manganese, cadmium, or zinc sulfide is as high as approximately 10^{-4} S cm^{-1}, exceeding by almost two orders of magnitude that of the initial glass $0.5AgI–0.5Sb_2S_3$ [7]. When the mole fraction of a sulfide is increased to 0.1, the conductivity of the glasses at room temperature tends to increase (Fig. 3). This trend is the most pronounced in the case of the manganese-containing samples.

The preexponential factors and activation energies are virtually independent of the composition for the glassy materials (at the mole fraction of the sulfide in the systems with MnS and CdS of up to 0.1 and in the

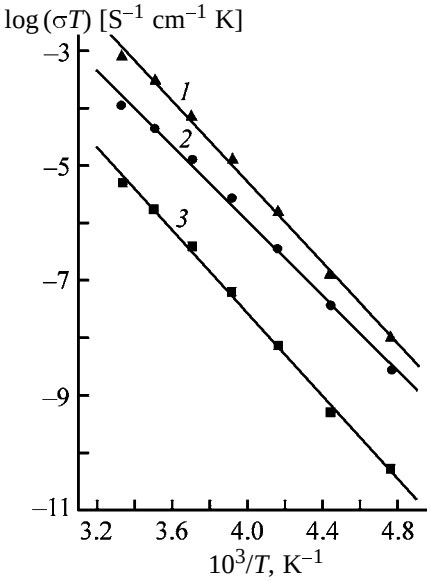

Fig. 2. Temperature dependence of the electrical conductivity σT for certain glasses of the system $0.5AgI–0.45Sb_2S_3–0.05MS$. (*1*) $0.5AgI–0.45Sb_2S_3–0.05ZnS$, (*2*) $0.5AgI–0.45Sb_2S_3–0.05MnS$, and (*3*) $0.5AgI–0.45Sb_2S_3–0.05CdS$.

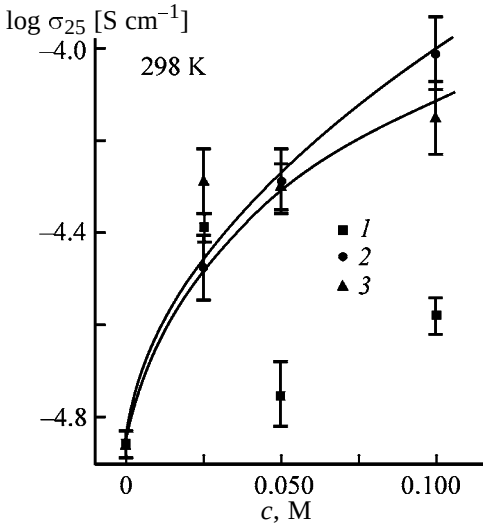

Fig. 3. Conductivity σ_{25} as a function of concentration c of a transition metal sulfide for glasses of various compositions: (*1*) $0.5AgI–(0.5 – x)Sb_2S_3–xCdS$, (*2*) $0.5AgI–(0.5 – x)Sb_2S_3–xMnS$, and (*3*) $0.5AgI–(0.5 – x)Sb_2S_3–xZnS$.

system with ZnS, up to 0.05). At the same time, it should be noted that, as compared to glassy materials, a decrease is observed in the activation energies (by up to 0.1 eV) and preexponential factors (by up to two orders of magnitude) of alloys containing a crystalline phase. This trend is especially pronounced in the case of the alloys containing ZnS and MnS, and is somewhat less pronounced in the cadmium-containing samples. A sharp reduction of E_a and $\log \sigma_0$ in comparison with homogeneous glasses is typical for inhomogeneous glasses and especially for glass–crystals [8], which is attributable to the appearance of additional paths of the facilitated charge transport along grain or phase boundaries.

We have carried out calibrating measurements with solutions of ammonium iodide NH_4I in the concentration range 10^{-6}–10^{-2} using potentiometric sensors manufactured from the glasses obtained. The results of these experiments for sensors of typical composition $0.5AgI–0.4Sb_2S_3–0.1MnS$ are given below:

Membrane	Slope, mV/pI	E^0, mV
I	–51.5 ± 1.4	–16.7 ± 5.6
II	–51.3 ± 1.6	–37.5 ± 2.4
III	–52.8 ± 1.1	–10.7 ± 2.6

The calibration plots are given in Fig. 4.

We have found that the sensors containing manganese sulfide have a good sensitivity to I^- anions with the anionic slope S = 50–57 mV/pI. The electrode functions for halide anions were observed previously only for crystalline sensors or glass–crystal compositions [1, 2]. The iodide function of a homogeneous glassy sensory material was observed here for the first time.

We also found that the sensitivity of chalcogenide glass sensors (the slope of the electrode function),

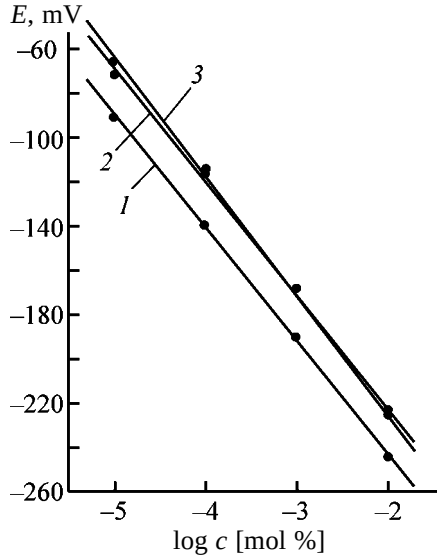

Fig. 4. Typical shape of the calibrating dependence of the sensor potential E on the concentration c of iodide ion in ammonium iodide solutions for potentiometric sensors of the composition $0.5AgI–0.4Sb_2S_3–0.1MnS$. Membrane: (*1*) I (S = –51.5 ± 2.1 mV), (*2*) II (S = –51.3 ± 0.9 mV), and (*3*) III (S = –52.8 ± 0.9 mV).

which was measured twice a day within a week, gradually decreased to S = 40–50 mV/pI. The standard potentials of the electrodes also changed to the side of more negative values as compared to the initial values.

The detection limit for each $0.5AgI–0.4Sb_2S_3–0.1MnS$ sensor was determined by a technique recommended by IUPAC. In this case, measurements were carried out in solutions with the concentrations from 10^{-8} to 10^{-4} M:

Membrane	Detection limit, M
I	8×10^{-7}
II	9×10^{-7}
III	8×10^{-7}

The results obtained show that the sensors containing manganese sulfide and manufactured from the glasses under study have a relatively low detection limit (on the average, 8.5×10^{-7} M).

We found in the course of the work that all the glasses under study containing sulfide of a second metal tend to cracking with time, practically irrespective of the glass composition. The cracking was observed visually after polishing of the glass surface. The glasses were stable during the synthesis and some time after it. Probably, the cracking occurred faster when the glasses were in contact with aqueous solutions. These phenomena could be due to sharp quenching of the glasses or insufficient annealing [9], which is proved by the fact that the mechanical instability of the glasses under study was manifested differently. Rather slow quenching of the glasses during synthsis and the subsequent annealing at temperatures close to T_g enhance their stability, but the causes of the observed cracking are not quite clear. The presence of internal stresses in the glasses obtained, which relax gradually, seems to be the most probable cause. Presumably, especially long and careful annealing is required for these compositions after the synthesis; however, we could not carry out it in this work because of time limitation.

CONCLUSIONS

(1) The study of the glass formation region in the systems $0.5AgI–(0.5 – x)Sb_2S_3–xMS$ (M = Zn, Cd and Mn) has shown that amorphous materials are obtained when the mole fraction of manganese, cadmium, or zinc sulfide is from 0 to 0.1.

(2) The conductivity parameters for all the compositions of the alloys were obtained by the electrochemical impedance spectroscopy, and it was found that introduction of the sulfide of the second transition metal into the glasses increases the conductivity to approximately 10^{-4} S cm^{-1}, which exceeds by two orders of magnitude the conductivity of the initial pseudobinary glass of the composition $0.5AgI–0.5Sb_2S_3$.

(3) The study of sensory characteristics of the synthesized materials in ammonium iodide solutions has shown that the sensors with glassy membranes of the composition $0.5AgI–0.4Sb_2S_3–0.1MnS$ have high sensitivity to iodide ions in aqueous solutions (electrode function slope 50–57 mV/pI) with the detection limit of 8.5×10^{-7} M.

ACKNOWLEDGMENTS

The authors are grateful to John Mortensen (Roskild University, Denmark) for the invaluable organizational help in carrying out the research. This work was financially supported in part by the Council of Ministers of Northern Countries (grant no. 2003-8003-2) and by Russian Foundation for Basic Research (project no. 02-03-32740).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effects of Potassium Polysilicates on Formation of Hydrogels from Stabilized Silica Sols

S. S. Airapetyan and A. G. Khachatryan

Yerevan State University, Yerevan, Armenia

Received June 27, 2003; in final form, February 2004

Abstract—The effect of introduction of potassium polysilicates with different SiO_2/K_2O ratios (silicate ratios *M*) on the rate of gelation of stabilized silica sols and on the quality parameters of the forming hydrogels was studied.

The problem of gelation of stabilized silica sols is a key issue as regards the formation of porous and other structural characteristics of porous silicas synthesized on their base. Such structural characteristics as the matrix rigidity, pore volume, and pore size distribution are formed in the sol–gel transition.

Occasionally, and in particular when obtaining microspherical silica gels, it is necessary to perform fast gelation. In this case, the high gelation rate is a decisive factor for preservation of the regular shape of the forming microspherical particles of a silica hydrogel. Fast gelation of water-soluble polysilicates (liquid glasses) is not unachievable. It occurs in their neutralization with various acids. However, it is difficult to achieve fast gelation of stabilized silica sols by neutralization, since the gelation processes that occur in this case may take a rather long time (5–6 days).

Fast gelation of stabilized silica sols can be achieved if the pH of the silica sol is preliminarily raised before the gelation. However, only raising the pH of the system fails to ensure fast formation of rigid homogeneous gels. As a rule, silica sols with increased pH yield in gelation inhomogeneous hydrogels or precipitates, i.e., more resemble hydrogels obtained from soluble polysilicates. Raising the pH value of a stabilized silica sol with, e.g., NaOH leads to precipitation of the silica sol before its gelation and fails to ensure the required concentration of the silicate fraction of silica because of the partial dissolution of colloid particles of silica sol. In fast gelation of silica sols to produce homogeneous rigid gels, the presence of such a silicate fraction becomes necessary, as demonstrated below.

Among alkali metal silicates, potassium silicates are the best compatible with stabilized silica sols: in contrast to sodium silicates, they do not cause precipitation of silica sols.

It is known [1, 2] that stable potassium polysilicates have a silicate ratio *M* 3–6 and 11–24. Potassium polysilicates can be obtained by addition of colloid silica to potassium silicate with a smaller silicate ratio (*M* = 3–4) under agitation and heating. As shown by electron microscopy, in synthesis of potassium polysilicates with silicate ratios *M* = 4–20, the particle size of the initial sol falls from 22 to 9–14 nm, which corresponds to a 4–12-fold decrease in the degree of polymerization. In addition, particles 1–7 nm in diameter were found in polysilicate solutions. For solutions with silicate ratios *M* = 4–40, the content of soluble silica is 20–50% of the total silica.

The problem of fast gelation is also associated with reinforcement of the structure of the forming gel, because addition of potassium polysilicate not only raises the pH of the system before its gelation, but also ensures the presence in the system of a reinforcing additive in the form of an active silica formed in gelation of potassium silicate. In the absence of such an additive of silicate origin, the gelation, as a rule, lasts for a considerably longer time (10–15 min), compared to the case when potassium silicate is present in the system (no more than 3 min). This indicates that active silica provides fast "setting" of colloid particles and leads to rapid structurization.

EXPERIMENTAL

As an object of study was used a stabilized silica sol obtained using the procedure described in [4], with

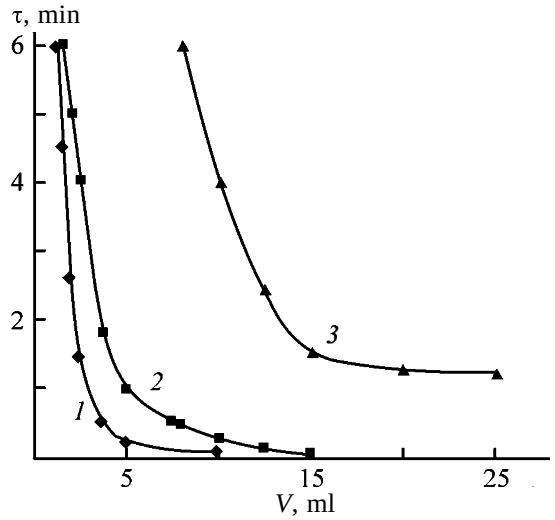

Fig. 1. Duration τ of gelation of stabilized silica sol vs. volume V of potassium polysilicate introduced. M = 15, V_{tot} = 100 ml. Content of SiO_2 in potassium polysilicate (wt %): (*1*) 30, (*2*) 15, and (*3*) 5.

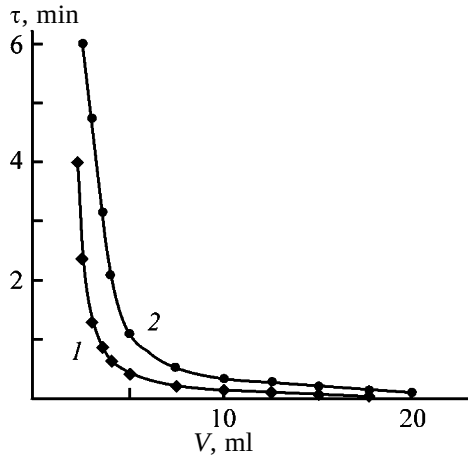

Fig. 2. Duration τ of gelation vs. volume V of potassium polysilicate introduced. M = 6.0, V_{tot} = 100 ml. Concentration of the gelling agent NH_4NO_3 (M): (*1*) 3.0 and (*2*) 1.5.

a particle size of 10 nm (as determined by the Sears method).

Potassium polysilicates with silicate ratios $M > 4$ were obtained from a potassium polysilicate with M = 4 by addition of polysilicic acid (PSA) synthesized according to [5]. The feeding rate of PSA was equal to the rate of moisture removal from the system. Potassium polysilicates with $M < 4$ (M = 3.2) were obtained by adding a certain amount of KOH to potassium polysilicate with M = 4.

Potassium polysilicate with the silicate ratio M = 4 was synthesized in a 1000-ml beaker. A 400-ml portion of distilled water was introduced into the beaker, and 42 g of KOH was dissolved in this water. Then, 100 g of silica gel was introduced in portions into the KOH solution at its boiling point under continuous agitation. The process was continued until silica gel completely dissolved, after which the heating was switched off, the system was allowed to cool under agitation, and the volume of the system was brought to 500 ml by adding distilled water.

As the gelling agent served NH_4NO_3 solution (1.5 or 3 M).

In all the experiments, a silica sol with a volume of 100 ml and concentration of 20 wt % (in terms of SiO_2) was used.

Figure 1 shows how the duration of gelation of a stabilized silica sol depends on the amount of potassium polysilicate with the silicate ratio M = 3.2, introduced into its composition. It can be seen that, as the amount of the potassium polysilicate introduced is increased, the gelation of the silica sol dramatically accelerates. The gelation duration mainly depends on the total amount of potassium polysilicate.

The table lists the basic parameters of the process in which hydrogel samples are prepared and the gelation duration τ. It is seen that, to obtain a rigid gel, the content of active silica (of silicate origin) in the system should exceed 3 wt %. In this case, the gelation duration does not exceed 1.5 min. The final content of silica sol (in terms of SiO_2) upon addition of the gelling agent is 14.5–19.0 wt %, which cannot affect the gelation processes. As a rule, low-strength hydrogels are obtained in systems that contain less than 2.5–3.0 wt % active silica, and the gelation takes a relatively long time.

Figure 2 shows how the duration of silica sol gelation depends on the amount of potassium polysilicate added (with the silicate ratio M = 6.0). It can be seen that, with more concentrated (3 M) NH_4NO_3 solutions used as gelling agents, the gelation is faster than with less concentrated (1.5 M) solutions. The gelation duration mainly depends on the total amount of the electrolyte in the system at the instant of gelation.

The table also shows that, if potassium silicate with M = 6.0 is used, high-strength gels start to form at its content in the silica sol as low as 5.9 wt % in terms of SiO_2.

As the silicate ratio of polysilicates increases (up to M = 15), the amount of colloidal silica, not involved in reinforcement of the hydrogel structure, grows. With increasing silicate ratio of potassium polysilicate, the minimum amount of polysilicate to be introduced to ensure the rigidity of the resulting hydrogel

also grows. At M = 3.2, this amount does not exceed 3 wt %, whereas at M = 15 it exceeds 24 wt % in terms of SiO_2. This indicates that, to reinforce the gel structure by addition of active silica into the composition of silica sol before its gelation, it is the most appropriate to use as potassium polysilicates those with silicate ratios M = 4–10. As the silicate ratio increases, the amount of silica of nonsilicate nature grows, i.e., when colloid silica is dissolved to obtain potassium polysilicate with a higher silicate ratio, its particles do not dissolve completely. In all probability, silica of nonsilicate nature is not involved in reinforcement of the hydrogel structure. It may be assumed that soluble silica of silicate nature is the main agent for fast gelation and reinforcement of the hydrogel structure.

In these terms, the mechanism of fast gelation can be understood as follows: At high pH values, soluble silicas are not deposited onto the surface of colloid

particles of the sol; it is soluble silicas that primarily respond to a decrease in pH in gelation. In such a system, a gel network is rapidly formed between colloid particles and the number of contact points between separate particles of the colloid silica grows. This yields a rigid and elastic hydrogel. In the process, silica gels with more open structure are produced.

CONCLUSIONS

(1) Raising the silicate ratio of potassium polysilicates introduced into the composition of stabilized silica sols prior to their gelation leads to an increase in the amount of polysilicates necessary for strengthening of hydrogels in a comparatively short time.

(2) The gelation duration increases as the silicate ratio of the potassium polysilicates used is made higher.

(3) The primary role in the processes of strengthening and fast gelation is played by silica of silicate nature. With increasing silicate ratio, the silicate nature of potassium polysilicates becomes less pronounced and the content of colloid particles grows. These particles are not involved in fast gelation and strengthening of the hydrogel structure.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Activity of Components in the Surface Layer of Ternary Mutual Melts

B. V. Patrov

St. Petersburg State Polytechnic Institute, St. Petersburg, Russia

Received January 28, 2004

Abstract—The activity of components in the bulk and in the surface layer, considered as individual phase, was calculated from the experimental surface tension values and in terms of the model of regular solutions. The ternary mutual chloride–fluoride, chloride–carbonate, and fluoride–carbonate systems were examined.

Study of the surface tension in ternary mutual systems, which can be used in electroslag remelting as flux and for welding of nonferrous metals, is of practical and theoretical significance. Determination of the activity of melt components is very important for thermodynamic calculations of salt systems [1]. The model of regular solutions is the most commonly used in study of metallurgical systems.

Calculation of the component activity in the bulk of mutual melts from the experimental surface tension values was described previously [2]. For the exchange reaction MA + NB = NA + MB at $\Delta G_T^0 > 0$, the stable diagonal section is the melt MA–NB. The mole fractions x and $(1 - x)$ of MA and NB in the initial mixture become in equilibrium $(x - y)$ and $(1 - x - y)$, i.e, they decrease by the mole fraction y of the reaction products. In terms of the model of regular solutions [3, 4], one can write

$$\ln\gamma_1 = \frac{A}{RT}(1 - x - y)^2, \quad (1)$$

$$\ln\gamma_2 = \frac{A}{RT}(x - y)^2, \quad (2)$$

where γ_1 and γ_2 are the activity coefficients of components along stable diagonals MA and NB and A, the interaction parameter.

The interaction parameter A was determined from experimental data on surface tension described by the Burylev equation [5] for regular solutions:

$$\sigma = \sigma_1 x_1 + \sigma_2 x_2 + C x_1 x_2, \quad (3)$$

where x_1 and x_2 are the mole fractions of MA and NB components, and σ_1 and σ_2 are their surface tensions.

The constant C includes the ion-exchange energy [5] and is related to the interaction parameter A by

$$A = C\omega, \quad (4)$$

where ω is the molar surface area of the component:

$$\omega = V_{\text{mix}}^{2/3} N^{1/3}, \quad (5)$$

N is the Avogadro number, and V_{mix}, the molar volume of the mixture.

To a first approximation, V_{mix} was calculated from the additivity equation $V_{\text{mix}} = xV_{\text{MA}} + (1 - x)V_{\text{NB}}$, and in equilibrium it was calculated as

$$V_{\text{mix}} = xV_{\text{MA}} + (1 - x - y)V_{\text{NB}} + yV_{\text{NA}} + yV_{\text{MB}}.$$

The necessary data on the density of components in the exchange reaction were taken from a reference book [6].

Since the content of the components along unstable diagonal did not exceed 6 mol %, their activities a_{NA} and a_{MB} were accepted equal to mole fraction y. The mole fraction was derived from the equation for the equilibrium constant of the exchange reaction.

$$K_a = y^2(x - y)^{-1}\{\exp[A(1 - x - y)^2(RT)^{-1}]\}^{-1} \times (1 - x - y)^{-1}\{\exp[A(x - y)^2(RT)^{-1}]\}^{-1}. \quad (6)$$

Comparison of the component activities in LiF–NaCl and LiF–KCl systems, as calculated by Fellner method [4] and by the method proposed in [2], showed that the maximal difference between them is 0.008 at the mole fraction $x = 0.5$ and does not exceed 2%, i.e., the activities are the same. Consequently,

1070-4272/04/7705-0725 © 2004 MAIK "Nauka/Interperiodica"

the suggested method of calculating the component activity from data on surface tension furnishes reliable data for the ternary mutual systems.

The activities of components in the surface layer of the solutions were calculated by assuming equilibrium of the component in the surface layer of the solution and in its bulk [7].

$$\mu_i^\omega - \mu_i = \sigma\omega_i, \quad (7)$$

where μ_i^ω are the chemical potentials of the component in the surface layer of the solution and in its bulk, and ω_i is the molar surface area of the ith component.

For a binary solution at the equal molar surface areas,

$$\sigma = \sigma_1 + \frac{RT}{\omega}\ln(a_1^\omega/a_1) = \sigma_2 + \frac{RT}{\omega}\ln(a_2^\omega/a_2). \quad (8)$$

From this relationship, we can derive the component activities in the surface layer of mutual melts:

$$\ln a_1^\omega = \frac{\sigma - \sigma_1}{RT}\omega + \ln a_1, \quad (9)$$

$$\ln a_2^\omega = \frac{\sigma - \sigma_2}{RT}\omega + \ln a_2. \quad (10)$$

The component activities a_1 and a_2 of the systems studied are given in [8, 9]. The surface layer, as the melt bulk, was assumed to be a regular solution. For regular solutions, the activity coefficients of components along the stable diagonal in the surface layer were determined from the equations

$$\ln\gamma_1^\omega = A(a_2^\omega)^2[RT(\gamma_2^\omega)^2]^{-1}, \quad (11)$$

$$\gamma_2^\omega = \exp\{A(a_1^\omega)^2[RT(\gamma_1^\omega)^2]^{-1}\}. \quad (12)$$

where A is the interaction parameter.

After expression for the activity coefficient of the second component in the surface layer is substituted in Eq. (11), we obtain

$$\ln\gamma_1^\omega = \frac{A(a_2^\omega)^2}{RT\{\exp[A(a_1^\omega)^2(RT)^{-1}(\gamma_1^\omega)^{-2}]\}^2}. \quad (13)$$

Consequently, the activity coefficients of components along the stable diagonal in the surface layer can be calculated by Eqs. (13) and (12), and the mole fractions, by the equations

$$x_1^\omega = a_1^\omega/\gamma_1^\omega, \quad x_2^\omega = a_2^\omega/\gamma_2^\omega. \quad (14)$$

The chloride–fluoride systems Ba^{2+}, Na^+ // F^-, Cl^-, and Ba^{2+}, K^+ // F^-, Cl^- were studied first. The stable diagonal sections in these systems are the melts $BaF_2 \cdot BaCl_2$–Na_2Cl_2 and $BaF_2 \cdot BaCl_2$–K_2Cl_2 [10]. Their characteristics (Gibbs energy of exchange reaction, Burylev constant, molar surface area, and interaction parameter) are given below:

System	T, K	ΔG_T^0, J	$-C$, mJ m^{-2}	ω, m^2 mol^{-1}	$-A$, J mol^{-1}
$BaF_2 \cdot BaCl_2$–Na_2Cl_2	1273	47 250	43.4	195 200	8472
$BaF_2 \cdot BaCl_2$–K_2Cl_2	1273	95 240	91.6	219 340	20 092

For these systems, as for simpler chloride–fluoride melts [11], the change in the Gibbs energy is related to the surface activity of chlorides by the interaction parameter. The results of calculation of the component activities in the surface layer of the melts are presented in Table 1.

As seen, the activity of the first component, equimolar compound of barium fluoride and chloride, is considerably lower than its mole fraction in the surface layer. The activity of sodium and potassium chlorides was also less than the mole fraction at their content x_2 in the melt of up to 0.5 and equal to the mole fraction in the surface layer at higher concentrations: $a_2^\omega \sim x_2^\omega$.

The second group of mutual systems comprised chloride– and fluoride–carbonate melts Na_2CO_3–K_2Cl_2 and K_2CO_3–Na_2F_2 [12]. The Gibbs energy, Burylev constant, molar surface area, and the interaction parameter for the given systems are presented below:

System	T, K	ΔG_T^0, J	$-C$, mJ m^{-2}	ω, m^2 mol^{-1}	$-A$, J mol^{-1}
Na_2CO_3–K_2Cl_2	1123	31 300	131.6	153 265	20 170
K_2CO_3–Na_2F_2	1273	55 073	6.72	127 570	857

The second system in this group differs from the above chloride–fluoride melts by the second component, sodium fluoride, which is not surface-active in this system. The interaction parameter A = –857 J mol^{-1} was lower by an order of magnitude,

compared to the chloride–fluoride and chloride–carbonate melts.

The results of calculation of the component activities in the surface layer of the second-group melts are presented in Table 2. As seen, in the Na_2CO_3–K_2Cl_2 system the activity of the first component, sodium carbonate, in the surface layer is also considerably lower than the mole fraction. As for the first-group melts, the activity of potassium chloride in the surface layer is virtually equal to the mole fraction at the chloride content x_2 more than 0.5.

Of interest are data on the activity, mole fraction, and the activity coefficient of components in the surface layer of the system K_2CO_3–Na_2F_2. The activity of the first component, potassium carbonate, and of the second component, sodium fluoride, is equal to the mole fraction: $a_1^\omega \sim x_1^\omega$, $a_2^\omega \sim x_2^\omega$. The coefficients of component activity are virtually equal to unity. This agrees with the above value of the interaction parameter.

Consequently, for surface-inactive components (sodium carbonate or equimolar compound of barium fluoride and chloride) in more complex chloride–fluoride and chloride–carbonate melts studied, the calculation equation (8) takes the form

$$\sigma = \sigma_1 + \frac{RT}{\omega}\ln(a_1^\omega/a_1). \quad (15)$$

For surface-active components (chlorides), the calculation equation is applicable in the narrower concentration range, $x_2 = 0.5$–1:

$$\sigma = \sigma_2 + \frac{RT}{\omega}\ln(x_2^\omega/a_2). \quad (16)$$

The surface tension of fluoride–carbonate mutual melts K_2CO_3–Na_2F_2 is described by the equations

$$\sigma = \sigma_1 + \frac{RT}{\omega}\ln(x_1^\omega/a_1), \quad \sigma = \sigma_2 + \frac{RT}{\omega}\ln(x_2^\omega/a_2). \quad (17)$$

CONCLUSIONS

The equations for calculating the surface tension of mutual chloride–fluoride, chloride–carbonate, and fluoride–carbonate melts were derived, depending on the content of chlorides, fluorides, and carbonates in the surface layer.

Received April 17, 2003; in the final form, November 2003

Abstract—The phase diagrams of ternary liquid systems tetradecane–*n*-octanol (or *n*-butanol)–neodymium(III) nitrate solvates with tri-*n*-butyl phosphate [$Nd(NO_3)_3(TBP)_3$] at T = 298.15 K were studied. These diagrams contain the fields of homogeneous solutions and the field of separation into two liquid phases (I, II). The distribution of components between these phases is analyzed.

In this work we studied the phase diagrams of ternary liquid systems tetradecane-*n*-octanol (or butanol)–neodymium(III) nitrate solvates with tri-*n*-butyl phosphate in the field of phase separation.

In our experiments we used *n*-octanol (ρ = 0.8220 g cm^{-3}) and *n*-butanol (ρ = 0.8075 g cm^{-3}, T = 298.15 K). The solvate $Nd(NO_3)_3(TBP)_3$ was prepared by triple contact of TBP with saturated aqueous solutions of Ln(III) nitrates [1]. The solvate concentration in the organic phase was 1.12 M (ρ = 1.2755 ± 0.0012 g cm^{-3}). The binodal curves were obtained by the visual technique reported in [2].

The phase diagrams (Fig. 1) and the data listed in the table show that the components of the binary systems $Nd(NO_3)_3(TBP)_3$–*n*-$C_8H_{17}OH$ (*n*-C_4H_9OH) and *n*-$C_8H_{17}OH$–$C_{14}H_{30}$ have infinite mutual solubility. The $Nd(NO_3)_3(TBP)_3$–$C_{14}H_{30}$ mixtures separate into two liquid phases (I, II). Phases I and II are enriched in $C_{14}H_{30}$ and $Nd(NO_3)_3(TBP)_3$, respectively.

The phase diagrams of the systems $Nd(NO_3)_3 \cdot (TBP)_3$–*n*-$C_8H_{17}OH$ (*n*-C_4H_9OH)–$C_{14}H_{30}$ (Fig. 1) contain field *B* of homogeneous solutions and two-phase field *A*. These fields are separated by the binodal curves. Ternary mixtures related to field *A* separate into two liquid phases (I, II) like the binary system $Nd(NO_3)_3(TBP)_3$–$C_{14}H_{30}$. Phases I and II are enriched in $C_{14}H_{30}$ and $Nd(NO_3)_3(TBP)_3$, respectively. For all the systems, the critical point in the binodal curve (ω_2, crit) corresponds to a solution with approximately equal weight fraction of $Nd(NO_3)_3 \cdot (TBP)_3$ and $C_{14}H_{30}$ and different content of alcohol. As seen from table, in the critical point the $C_8H_{17}OH$ content somewhat exceeds the *n*-butanol content.

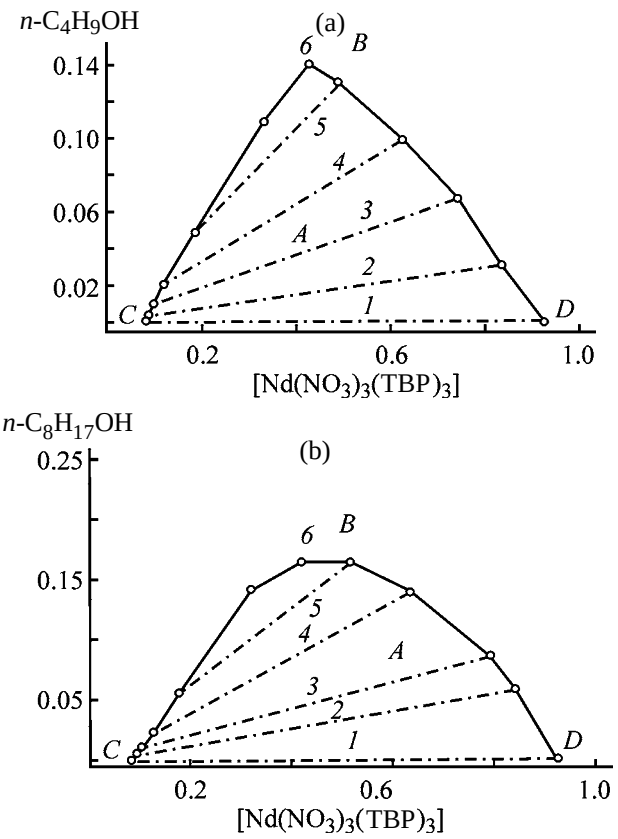

Fig. 1. Phase diagrams (weight fraction scale) of the ternary systems $Nd(NO_3)_3(TBP)_3$–*n*-$C_8H_{17}OH$ (*n*-C_4H_9OH)–$C_{14}H_{30}$ at T = 298.15 K. (*A*) Field of coexistence of two liquid phases, (*B*) field of homogeneous solutions, and (*CD*) binodal curve. (*1*–*5*) Nodes (see table); (*6*) point of the critical composition of the ternary system. Alcohol: (a) *n*-C_4H_9OH and (b) *n*-$C_8H_{17}OH$.

Figure 2 shows the distribution coefficient of $Nd(NO_3)_3(TBP)_3$ between phases I and II as a function of $Nd(NO_3)_3(TBP)_3$ weight fraction in phase II. As seen from these plots, with increasing $Nd(NO_3)_3 \cdot (TBP)_3$ concentration in phase II, the distribution coefficient decreases, i.e., $Nd(NO_3)_3(TBP)_3$ is accumulated in the phase II. This accumulation is virtually independent of the kind of alcohol.

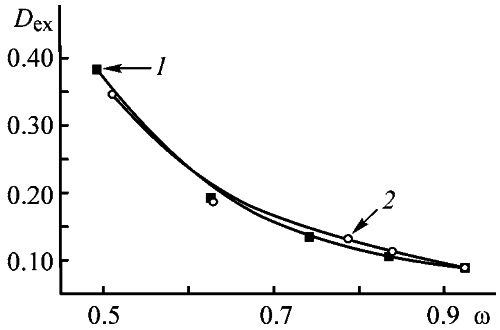

Fig. 2. Distribution coefficient D_{ex} of $Nd(NO_3)_3(TBP)_3$ between phases I and II as a function of the weight fraction ω of $Nd(NO_3)_3(TBP)_3$ in phase II. Alcohol: (*1*) *n*-C_4H_9OH and (*2*) *n*-$C_8H_{17}OH$; the same for Figs. 3 and 4.

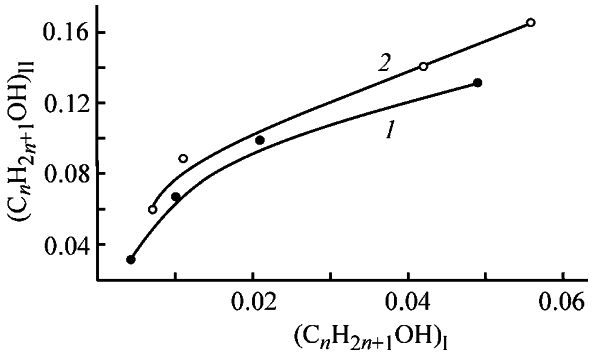

Fig. 3. Distribution of alcohols between phases II and I.

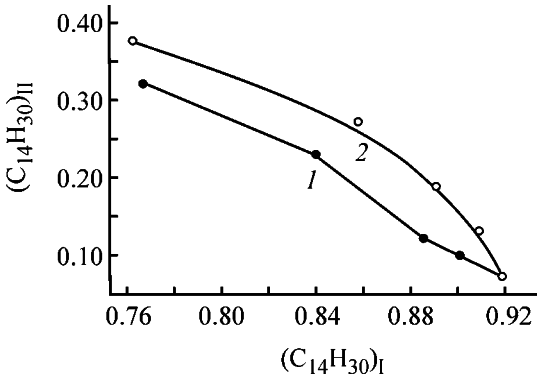

Fig. 4. Distribution of $C_{14}H_{30}$ between phases II and I.

Figure 3 shows the distribution of *n*-octanol (*n*-butanol) (weight fraction) between phases II and I. It is seen that the alcohols are predominantly concentrated in phase II and this tend is more pronounced for *n*-octanol.

Figure 4 shows the distribution of $C_{14}H_{30}$ (weight fraction) between phases II and I. It is seen that $C_{14}H_{30}$ is predominantly concentrated in phase I. The extent of enrichment of phase I with $C_{14}H_{30}$ is dependent on the kind of alcohol and is larger in the *n*-butanol-containing system.

Our results show that, in extraction of neodymium(III) nitrates with TBP in tetradecane–*n*-octanol (or *n*-butanol) mixture, the phase separation of the extracts saturated with neodymium(III) can be prevented if the weight fraction of *n*-octanol or *n*-butanol is no less than 0.15–0.17.

CONCLUSIONS

(1) The phase diagrams of the systems $Nd(NO_3)_3 \cdot (TBP)_3$–*n*-$C_8H_{17}OH$ (*n*-C_4H_9OH)–$C_{14}H_{30}$ contain the

field of homogeneous solutions and the two-phase field. Phases I and II are enriched in $C_{14}H_{30}$ and $Nd(NO_3)_3(TBP)_3$, respectively. The size of the two-phase field is dependent on the kind of alcohol; it somewhat decreases in going from *n*-octanol to *n*-butanol.

(2) In all the systems, the critical point in the binodal curve (ω_2, crit) corresponds to a solution with approximately equal weight fraction of $Nd(NO_3)_3 \cdot (TBP)_3$ and $C_{14}H_{30}$ and different content of alcohol. The *n*-$C_8H_{17}OH$ content in the critical point somewhat exceeds the *n*-butanol content.

(3) In phase separation, both $Nd(NO_3)_3(TBP)_3$ and *n*-octanol (*n*-butanol) are accumulated in phase II. The accumulation of $Nd(NO_3)_3(TBP)_3$ in phase II is virtually independent of the kind of alcohol. $C_{14}H_{30}$ is predominantly concentrated in phase I. This trend is more pronounced in the *n*-butanol-containing system.

(4) In extraction of neodymium(III) nitrates with *n*-TBP in tetradecane–*n*-octanol (*n*-butanol) mixture, the phase separation of the extracts saturated with neodymium(III) can be prevented if the weight fraction of *n*-octanol (*n*-butanol) in the extractant is no less than 0.15–0.17.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Dehydration Kinetics of Sodium Tetraborate Decahydrate

A. I. Sokol'skii, T. V. Basova, S. A. Sokol'skii, and V. Yu. Prokof'ev

Ivanov State University of Chemical Engineering, Ivanovo, Russia

Received April 3, 2003

Abstract—The kinetics of the dehydration of sodium tetraborate decahydrate was studied. The Topley–Smith effect was observed. The dehydration kinetics was described by an equation of contracting sphere. The mass conductivity coefficients were determined, and an empirical equation for calculating them is given.

In thermal decomposition of crystal hydrates, the dependence of the reaction rate on the water vapor pressure in the air supplied for the heat treatment is abnormal [1]. The influence exerted by the product phase on the water removal process is the important feature of the dehydration reaction. The abnormal behavior consists in that the thermal decomposition of crystal hydrates at pressures below equilibrium pressure decelerates with an increase in the deviation of the system from the equilibrium. This phenomenon is known as the Topley–Smith effect. The understanding of specific features of dehydration of crystal hydrates, sodium tetraborate decahydrate (STD) in particular, allows control of the process and preparation of the product of prescribed composition.

Sodium tetraborate decahydrate $Na_2B_4O_7 \cdot 10H_2O$ is obtained by crystallization from aqueous solution. Then, the powder is heat-treated in a heat carrier flow with formation of pentahydrate and anhydrous sodium tetraborate. In this case, it is necessary to obtain the resulting product containing either pentahydrate or anhydrous salt. When two forms of sodium tetraborate are present in the system, the powder tends to rapidly cake, and its consumers' properties get worse.

The kinetics of the topochemical reaction of thermal decomposition is described on the basis of combined solution of the kinetic equation and nonstationary mass-conductivity equation [2]. Thus, the thermal decomposition of dispersed materials in the region of diffusion-kinetic control is described within the nonstationary mass-conductivity boundary-value problem with an internal volume source of mass determined by the kinetics of chemical reaction. The mathematical description of the thermolysis of a spherical particle has the form

$$\frac{\partial c(r,\tau)}{\partial \tau} = k\left[\frac{\partial^2 c(r,\tau)}{\partial \tau^2} + \frac{2}{r}\frac{\partial c(r,\tau)}{\partial \tau}\right] + q, \qquad (1)$$

where c is the concentration of gaseous products (kg m^{-3}); r, particle radius (m); τ, time (s); q, internal volume source of mass (kg m^{-3} s); and k, the mass-conductivity coefficient (m^2 s^{-1}).

EXPERIMENTAL

Technical-grade sodium tetraborate is a white powder having, according to chemical analysis, the formula $Na_2B_4O_7 \cdot 10H_2O$. The dehydration was performed in a flow-through installation. The humidity and temperature of the heat carrier fed into the installation was maintained constant during one test. The flow rate of the heat carrier was chosen so as to eliminate external diffusion hindrance:

$$\mathrm{Bi} = \frac{\beta r}{k} \to \infty,$$

where Bi is the Biot criterion; β, mass-transfer coefficient (m s^{-1}); k, mass-conductivity coefficient (m^2 s^{-1}); and r, particle radius (m).

Fulfillment of this condition ensures constancy of the water vapor pressure over a sample during the whole test.

The change in the sample mass and the material temperature were recorded in the course of the experiment. The content of the main substance was calculated according to the reaction

$$Na_2B_4O_7 \cdot 10H_2O \to Na_2B_4O_7 + 10H_2O. \qquad (2)$$

Zonal method [3, 4] was used to calculate the mass-

conductivity coefficient by the equation

$$k = \frac{m_0[(\alpha_i)^{-1} - (\alpha_f)^{-1}]r}{F\Delta\tau\rho_v}, \quad (3)$$

where m_0 is the mass of the main substance, i.e. $Na_2B_4O_7$, in the weighed portion (kg); F, the surface area of particles of the sample (m^2); ρ_v, water vapor density (kg m^{-3}); α_i and α_f, initial and final contents of the main substance in the sample (%); and $\Delta\tau$, the time interval (s) in which the main substance content changes from α_i to α_f.

The partial water vapor pressure affects, according to the experimental data (Fig. 1), the content of the main product in the heat carrier depending on time. These dependences were obtained at a heat carrier temperature of 150°C and water vapor pressures of 10–20 and 145 mm Hg. Similar curves were also obtained for other temperatures. The rates of the $Na_2B_4O_7 \cdot 10H_2O$ dehydration as functions of water vapor pressure P_w are plotted in Fig. 2. As seen, with increasing water vapor pressure, the rate of reaction (2) first decreases, then increases, and after that passes a maximum at $P_w \cong 15$ mm Hg for all the temperatures. Thus, the Topley–Smith effect is clearly observed in thermolysis of sodium tetraborate decahydrate.

The kinetics of STD decomposition is most adequately described by a contracting volume equation whose integral form [1] is

$$k_0'\tau = 1 - (1 - \alpha)^{1/3}, \quad (4)$$

where k_0' is the rate constant (s^{-1}).

The values of the rate constant for different conditions are given in the table. The data obtained, when treated using the Arrhenius equation (Fig. 3), show that the pre-exponential factor k_0' and activation energy E as functions of water vapor pressure vary similarly with several extrema. The first and the second maxima in the curves correspond to the minimal and maximal dehydration rates, respectively. Thus, a decrease in k_0', rather than increase expected from Fig. 2, is observed for water vapor pressures above 18 mm Hg, with the minimal and maximal values differing by a factor of 3. An increase in the pre-exponential factor is compensated by the growth of the activation energy.

First of all, such phenomena are associated with thermodynamic properties, namely, with the ratio between the water vapor pressure in the heat carrier, its equilibrium pressure in reaction (2), and partial pressure of water vapor over the crystal hydrate.

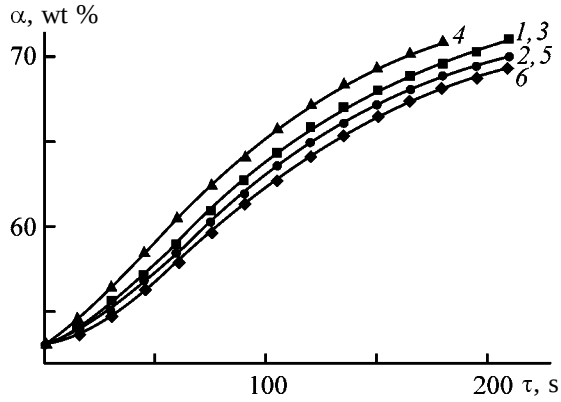

Fig. 1. Content of main substance, $Na_2B_4O_7$, α vs. time τ at 150°C. Partial water vapor pressure in air (mm Hg): (*1*) 10, (*2*) 11.36, (*3*) 13.97, (*4*) 15.26, (*5*) 18.04, and (*6*) 20.145.

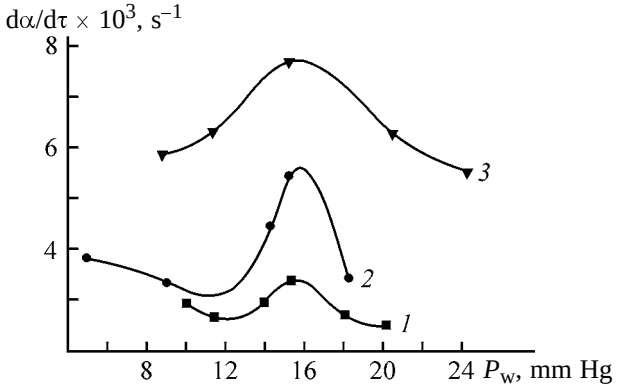

Fig. 2. Dehydration rate of sodium tetraborate decahydrate $d\alpha/d\tau$ vs. water vapor pressure P_w at various temperatures. Temperature (°C): (*1*) 150, (*2*) 200, and (*3*) 250.

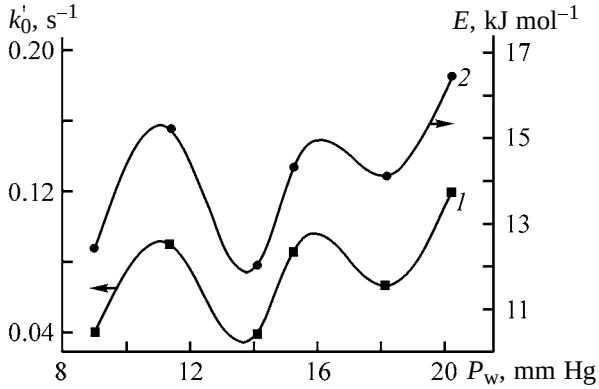

Fig. 3. Pre-exponential factor k_0' and activation energy E vs. water vapor pressure P_w. The parameters are calculated by Eq. (4).

The experimental data (Fig. 4) show that the dependences of the mass-conductivity coefficient k on the conversion α^* pass through a maximum at $\alpha \cong 0.2$, corresponding to the empirical formula $Na_2B_4O_7 \cdot$

	24.26	2.45	151.0	86.2

* The values are given at the conversion $\alpha^* = 0.2$.

$8H_2O$. Comparison of the above dependences with the character of variation of the material temperature t_m with conversion (Fig. 4) suggests that the increase in k at $\alpha^* < 0.2$ occurs in parallel with a considerable growth of the material temperature. Consequently, in this period, STD dehydration is accompanied by warming of the material.

With process at $\alpha^* > 0.2$ continued, k decreases gradually and the temperature of the powder grows insignificantly.

As noted above, the dehydration kinetics is described by an equation of contracting volume, i.e., the reaction starts from the outer layers of STD particles and then moves toward the grain centers. Evidently, a layer of the product impedes diffusion of water to the particle surface. As a result, the mass-conductivity coefficient decreases. It should also be noted that the mass-conductivity coefficients as functions of water vapor pressure in the heat carrier correlate with the corresponding rate constants calculated by Eq. (4).

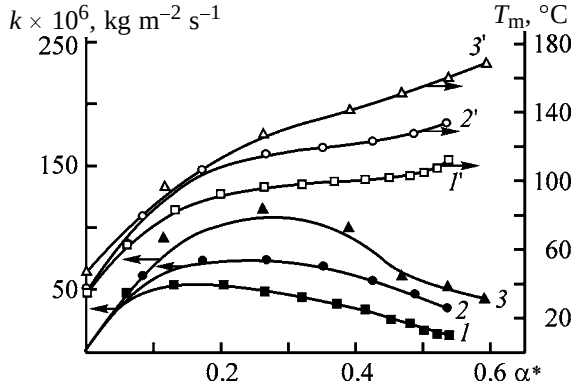

Fig. 4. Mass-conductivity coefficient k and the material temperature T_m vs. conversion α^* at the water vapor pressure of 15.26 mm Hg. Air temperature (°C): (*1*, *1'*) 150, (*2*, *2'*) 200, and (*3*, *3'*) 250.

A slight temperature growth at $\alpha^* > 0.2$, with an appreciable temperature gradient between the material and heat carrier preserved, is assigned to the fact that dehydration is an endothermic process, i.e., the heat supplied with a heat carrier is mainly spent for the chemical reaction.

The mass-conductivity coefficient is a function of many variables, with all these dependences having extrema (see table; Fig. 4). The noticeable effect on the mass-conductivity coefficient is exerted by the degree of dehydration α^*, water vapor pressure P_w, and heat carrier temperature T. Therefore, for analytical description of k, we choose the functional dependence

$$K = f(\alpha^*, P_w, T). \quad (5)$$

The mass-conductivity coefficient can be calculated most accurately by the equation

$$k = a + b\alpha^* + c\alpha^{*2} + d\alpha^{*3} + e\alpha^{*4} + f\alpha^{*5} + gP_w + hP_w^2 + iP_w^3 + jP_w^4 + mP_w^5, \quad (6)$$

where α^* is the degree of conversion by reaction (2); P_w, water vapor pressure (mm Hg); a, b, c, d, e, f, g, h, i, j, and m, the coefficients dependent on the heat-carrier temperature; and T, the heat-carrier temperature (°C):

$$a = \frac{-6297.72}{1 + \exp[(T - 164.17)/14.84]} + 345.91,$$

$$b = 1018.67 - 6.52 \times 10^{-6} T^3,$$

$$c = -7643.67 + 51.38 \exp(T/18.03),$$

$$d = (1.082 \times 10^9 - 68.49T^3)^{1/2},$$

$$e = -49\,398.28 + 69.28 \exp(T/10.18),$$

$$f = 45\,688 - 0.0025T^3,$$

$$g = -113.18 + 1703.02 \exp[-(T - 150)/21.94],$$

$$h = 10.08 + \frac{-332.10}{1 + \exp[(T - 162.79)/12.23]},$$

$$i = 17.10 \exp[-(T - 150)/1.77],$$

$$j = 31\,997.08 \exp[-T/13.79],$$

$$m = -0.0071 - (331.17/T),$$

where T is the heat carrier temperature (°C).

CONCLUSIONS

(1) Dehydration of sodium tetraborate decahydrate is characterized by the Topley–Smith effect, i.e., an irregular dependence of the dehydration rate on the water vapor partial pressure. The optimal content of water vapor in the gas phase is about 15 mm Hg.

(2) The mass-conductivity coefficients were determined. An empirical equation for calculating the coefficients as functions of dehydration conditions was suggested.

(3) The data obtained and the equations suggested for the kinetics of thermal decomposition of sodium tetraborate decahydrate can be used in calculating installations intended for preparation of pentahydrate or anhydrous sodium tetraborate.

Abstract—Glucose enthalpies of solution in binary systems *N*-methylmorpholine *N*-oxide monohydrate–aprotic solvent at 75°C are measured.

Since cellulose is the most abundant steadily renewable native polymer, the problem of its dissolution is topical for more than 150 years all over the world. Numerous works in this area are stimulated by the need in processing cellulose fibers through dissolution, to manufacture fibers and films of various purposes. The difficulty of the problem of cellulose dissolution originates from complexity of the structure of its elementary unit bearing hydroxy groups of various natures, and also from the structure of the cellulose macromolecule consisting of crystalline and amorphous regions of different reactivities.

To understand the mechanism of interaction of cellulose macromolecules with solvents, it is advisable to study the reactivity of functional groups of its elementary unit (α-*D*-glucose) under various conditions. In this case, it is rational to perform the study with solvents that dissolve cellulose to form solutions suitable for subsequent processing [1–3]. The capability of individual or mixed solvents to dissolve cellulose can be predicted using the calorimetric method. Not disclosing the nature of interparticle interaction, thermochemical data reveal whether or not components of a mixture are involved in chemical interaction.

The goal of this work is to study dissolution of α-*D*-glucose as a model for the cellulose unit in solvents based on *N*-methylmorpholine *N*-oxide monohydrate (MMO). The decision on the solvent was caused by the fact that MMO is of great practical interest in view of cellulose dissolution [3]. Also we used binary mixtures of MMO with co-solvents. The use of such binary mixtures allows preparation of cellulose solutions suitable for manufacture of speciality fibers and films, making these processes more cost-efficient [4–7].

The enthalpies of solution were determined at 75°C on a Calvet adiabatic calorimeter (calorimetric vessel volume 75 ml) to within 2.5%. As co-solvents for MMO we used dimethyl sulfoxide (DMSO), dimethylformamide (DMF), and dimethylacetamide (DMAA) (all of chemically pure grade). The solvents were dried over a zeolite. The composition of MMO was controlled by the melting point (72–73°C) and also using Fischer titration. In experiments we used glucose (chemically pure grade) with mp 146°C.

The solvency of DMSO, DMF, and DMAA at 75°C with respect to glucose amounts to 15–20%. The solubility of glucose in pure MMO is about 2% at 75°C. Therefore, in this work we studied solutions of glucose in binary mixtures with a concentration no more than 2%.

Our results (Table 1) showed that the enthalpy of glucose solution in DMSO, DMF, and DMAA at 75°C is independent of the glucose concentration.

Table 1. Glucose enthalpies of solution in aprotic solvents at 75°C

Solvent	Glucose concentration, wt %	ΔH_s, J g^{-1}

Table 2. Glucose enthalpies of solution in binary mixtures MMO monohydrate–aprotic solvent at 75°C

Solvent	ΔH_s, J g^{-1}, at indicated solvent concentration, wt %							
	0	20	40	60	70	80	90	100
DMSO	–10	–26	–67	–96	–95	–88	–75	60
DMF	–10	–20	–59	–81	–83	–82	–47	100
DMAA	–10	–39	–82	–109	–110	–107	–73	115

The glucose enthalpies of solution in binary solvents are given in Table 2 as functions of the solvent composition. In straight MMO, glucose dissolves with heat liberation, which can be attributed to hydrogen bonding between the NO group of MMO and OH groups of glucose (specific solvation). The specific solvation contributes significantly to the total enthalpy of solution ΔH_s

$$\Delta H_s = \Delta H_l + \Delta H_{solv}, \quad (1)$$

where ΔH_l is the crystal lattice energy of glucose and ΔH_{solv}, enthalpy of solvation. The observed negative enthalpy of solution is caused by strongly negative value of ΔH_{solv}.

In turn,

$$\Delta H_{solv} = \Delta H_{cav} + \Delta H_{sp} + \Delta H_{nonsp}, \quad (2)$$

where ΔH_{cav} is the enthalpy of cavity formation in a solvent (a positive value) and ΔH_{sp} and ΔH_{nonsp} are the contributions of specific and nonspecific interactions (negative values), with ΔH_{sp} prevailing.

In aprotic dipolar solvents such as DMSO, DMF, and DMAA, solvation occurs through essentially dipole–dipole interactions, whose energy is considerably lower than that of hydrogen bonding (ΔH_{nonsp} is considerably lower than ΔH_{sp}), and solvation appears to be an endothermic process. As a result, dissolution of glucose in aprotic solvents proceeds with heat consumption. The corresponding endothermic effect increases in the order DMSO < DMF < DMAA, being, respectively, 60, 100, and 115 J g^{-1} (Table 2). Therefore, the dominant effects in dissolution of glucose are fusion of the crystal lattice of glucose and cavity formation in a solvent, i.e., break of its structure. It is known [8] that, among the solvents used, DMSO is characterized by the strongest intermolecular interaction. Since ΔH_l is a constant, the contribution of nonspecific interactions between an aprotic solvent and glucose decreases in the order DMSO > DMF > DMAA, which correlates with the order of variation of the dipole moments (4.3, 3.86, and 3.8 for DMSO, DMF, and DMAA, respectively).

In binary solvents, the exothermic effect of glucose dissolution is considerably higher as compared to the individual components (Table 2). This can be attributed to the fact that the aprotic solvents studied have a strong structure-breaking effect on MMO, thus facilitating cavity formation [positive value of ΔH_{cav} in Eq. (2) considerably decreases]. As a result, dissolution of glucose becomes more exothermic. The break of MMO structure by adding an aprotic solvent should increase its solvency with respect to cellulose also.

Comparison of ΔH_s in various binary solvents at the compositions corresponding to the maximal exothermic effect of dissolution shows that the order of decrease in the interaction energy observed for the straight solvents changes: the strongest interaction with glucose is found in the system DMAA–MMO. This is inconsistent also with the results reported in [9] on dissolution of cellulose in the same binary systems. This inconsistency is probably due to specific structural features of cellulose and glucose. The glucose molecules occur in solutions in the cyclic and open forms, the latter containing the aldehyde group [10]. We have demonstrated the presence of the open conformation of glucose in DMSO, DMF, and DMAA. We compared the Ag^0 deposition efficiency upon adding the same amount of $AgNO_3$ to 5% glucose in the indicated aprotic solvents. The lowest deposition was observed in the DMAA solution, and the highest, in DMSO, suggesting that the fraction of glucose with free aldehyde groups increases on passing from DMAA to DMSO. Since the oxygen atom of the C=O group is more polarized and sterically accessible as compared to the oxygen of the ether group C–O–C in the cyclic conformation of glucose, the aldehyde group can produce a repulsive electrostatic effect when a glucose molecule approaches the oxygen atom of the NO group of MMO in a binary solvent. This effect should be reflected in the strength of intermolecular interaction of MMO with glucose and, correspondingly, in ΔH_{sp} and ΔH_{nonsp}, resulting in changing order of the decrease in the exothermic effect of glucose dissolution in the binary solvents.

On the contrary, cellulose does not form open conformations upon dissolution, which explains the results obtained in [9].

CONCLUSIONS

(1) The enthalpies of solution of glucose are determined in DMSO, DMF, DMAA, *N*-methylmorpholine *N*-oxide monohydrate, and their binary mixtures at 75°C.

(2) The observed differences in the thermal effects of solution of cellulose and glucose in binary systems *N*-methylmorpholine *N*-oxide monohydrate–aprotic solvent can be attributed to the occurrence of the open aldehyde conformation of glucose molecules in solutions.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Hydrocarbon Vapors on Activated Carbons Obtained from Vegetable Raw Materials

T. V. Anurova, V. N. Klushin, V. M. Mukhin, V. E. Myshkin, S. A. Anurov, and M. A. Suare

Mendeleev Russian University of Chemical Engineering, Moscow, Russia

Received July 22, 2003; in final form, December 2003

Abstract—The equilibrium adsorption of vapors of benzene, toluene, *o*-xylene, and gasoline in the temperature range 25–100°C and adsorbate content of 0.01–1.80 vol % on activated carbons obtained from plum stones and shells of peanut, walnut, and coconut was studied. The effect of temperature on the adsorption properties of the absorbents were analyzed. The isosteric heats of adsorption were calculated.

The protection of the atmosphere from pollution is an important and complicated environmental problem. Among the most global contaminants discharged into the atmosphere are various hydrocarbons. The most dangerous of these are, because of their prevailing mass, vapors of volatile organic solvents and light petroleum products, such as benzene, toluene, xylenes, gasolines, etc. The negative consequences of discharge of these toxic compounds are well known [1]. However, the economical factor, associated with the loss of valuable chemical compounds so much needed by modern industry, is to be taken into account in addition to the environmental aspect of the problem. According to the available estimates [2], the annual Russia's discharge from only stationary industrial sources is 1.6 million tons of volatile organic compounds and 2.6 million tons of other hydrocarbons even during the period of recession.

The diversity of conditions under which organic solvents and motor fuels are vaporized requires that different methods should be developed for their recovery. Among the rather wide variety of methods of this kind [1], processes of carbon-sorption purification are virtually unrivaled in processing of flows with relatively low content of these components. However, their use is only economical if low-cost and readily available carbon adsorbents can be used.

A technique for obtaining activated carbon from vegetable wastes in the form of plum stones and nutshells has been developed. This method yields microporous adsorbents with an effective half-width of micropores of 0.5–0.7 nm, which is comparable with the size of molecules of the organic compounds mentioned above. This suggests that these adsorbents can serve as rather active absorbents of hydrocarbons from vapor–gas mixtures.

To confirm the efficiency of this approach, it is necessary to study the adsorption properties of these carbons with respect to a number of characteristic hydrocarbons and light petroleum products. This was the aim of our study.

EXPERIMENTAL

As adsorbents served activated carbons obtained by carbonization in a nitrogen atmosphere of plum stones (PS) and shells of peanut (SP), walnut (SW), and coconut (SC) at 800°C for 1 h, followed by steam–gas activation of the carbon matrices under similar temperature and time conditions. The carbonizates of PS and SW were oxidized with water vapor, and those of SP and SC, with a nitrogen–oxygen mixture (2 vol % O_2). As reference were chosen activated carbons of SKT and ART-1 brands, which are recommended as adsorbents for catching vapors of organic solvents [3, 4]. The main technical characteristics of the carbon adsorbents are listed in Table 1.

As adsorbates were used benzene, toluene, *o*-xylene, and gasoline (motor fuel of the AI-95 brand). A number of physical constants of these hydrocarbons are listed in Table 2 [5–7]. It is difficult to specify the physical properties of gasolines because they are mixtures (boiling out at 40–195°C) of cyclic (20–65%), aromatic (2–12%), saturated (25–80%), and unsaturated (1–2%) hydrocarbons whose content in the final product is determined by the composition of the

raw materials used and the conditions of their processing [5]. The average molar mass of gasoline M = 109 g mol^{-1} was evaluated using the following empirical equation, which relates this parameter to the average temperature T_{av} of boiling-out of a mixture of hydrocarbons [5]:

$$M = 60 + 0.3T_{av} + 0.001T_{av}^2. \quad (1)$$

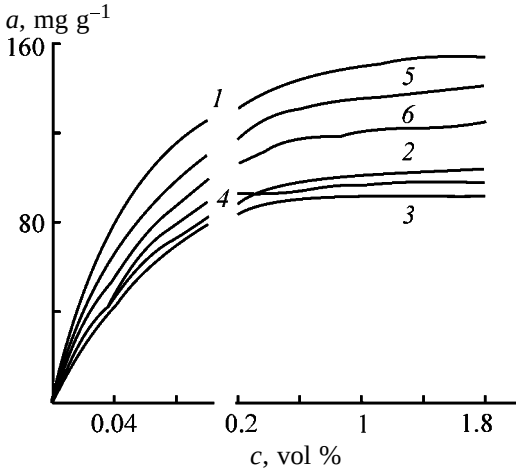

Fig. 1. Isotherms of benzene adsorption on activated carbons: (*a*) adsorbent activity and (*c*) benzene content. Type of carbon: (*1*) KU-1, (*2*) SKT, (*3*) AK-1, (*4*) AA-1, (*5*) ART-1, and (*6*) KU-2.

The adsorption measurements were performed in an evacuated setup with a McBain quartz spring balance in the temperature range 25–100°C. To remove moisture prior to adsorption, the carbons were dried at 120°C to constant weight. The adsorbate concentration was chosen with account of the requirement that, under the real conditions, the content of a hydrocarbon in the gas flow should be at the lower explosive limit in order to ensure explosion and fire safety. If the content of an adsorbate in a flow to be treated exceeds this limit, the technique envisages that it is diluted in an appropriate way with nitrogen or air. As seen from Table 2, these values for the substances used are within the range 0.9–1.7 vol %, and, therefore, the study was performed, irrespective of the nature of the hydrocarbons, at their contents in the range 0.01–1.8 vol %.

One of the most important characteristics used for comparative evaluation of the adsorption properties of solid absorbents and, consequently, for assessment of their suitability for specific processes is the adsorption isotherm. The results obtained in studying the static adsorption of hydrocarbon vapors at 25°C on the activated carbons under study are illustrated by Figs. 1 and 2. These figures show that, virtually in all cases, the isotherms correspond to the first type by Brunauer's classification: the adsorption capacity

grows with increasing content of adsorbates in the gas flow [8]. The highest adsorption capacity for all the systems is exhibited by the KU-1 adsorbent obtained from SW and by industrial carbon SKT. The static adsorption capacity of these adsorbents at a content of benzene, toluene, xylene, and gasoline in the gas mixture equal to 1.0 vol % is 151, 262, 295, 343 and 136, 238, 265, 312 mg g^{-1}, respectively. Less active are the KU-2, ART-1, AA-1, and AK-1 carbons, although their adsorption capacities for these hydrocarbons are rather close to the adsorption capacities of KU-1 and SKT and equal to 75–80% of these.

Also noteworthy is the fact that all the isotherms have a portion of steep initial rise, suggesting that these carbons will efficiently absorb the target components mentioned above from weakly concentrated gas flows.

A mathematical approximation to the adsorption equilibrium in question was made using the classical single-term equation for uniformly porous adsorption, which is derived in the theory of volume filling of micropores (TVFM) by Dubinin and Radushkevich (DR) [9]:

$$a = (W_0/V)\exp[(A/\beta E_0)^2], \quad (2)$$

where a is the amount of an adsorbed substance at a temperature T and relative pressure p/p_s; V, molar volume of the adsorbate; $A = RT\ln(p_s/p)$, differential molar work of adsorption; $\beta = E/E_0$, coefficient of similarity of the substance under study to a reference substance; E_0, characteristic energy of adsorption of the vapor of the reference substance (benzene); E, characteristic energy of adsorption of the vapor of the substance under study; p, partial pressure of the adsorbate; p_s, saturated vapor pressure of the adsorbate; and W_0, volume of micropores.

As shown by the calculations performed, the points characterizing the adsorption of each adsorbate on the activated carbons under study are approximated with a satisfactory accuracy with straight lines in the coordinates of the equation $\log a = f(\log p_s/p)^2$. This confirms unambiguously that the application of TVFM to description of the adsorption equilibrium in the systems under consideration is well justified.

The DR equation makes it possible to determine the volume of micropores in the adsorbents, the characteristic energy of adsorption of a reference substance in the micropores, and their effective half-width, the radius x_0 related to E_0 by

$$x_0 = k/E_0, \quad (3)$$

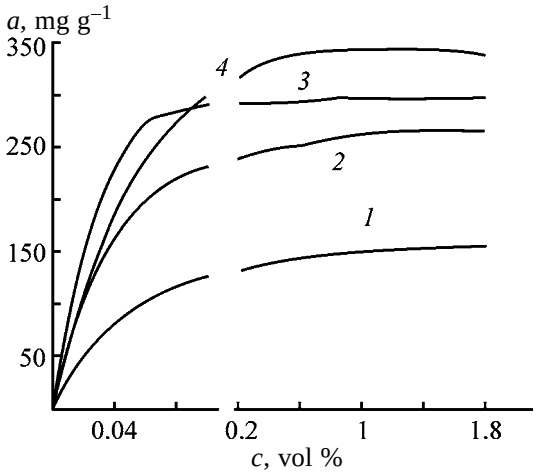

Fig. 2. Isotherms of hydrocarbon vapor adsorption on KU-1 activated carbon: (*a*) Adsorbent activity and (*c*) adsorbate content; the same for Fig. 4. Adsorbate: (*1*) benzene, (*2*) toluene, (*3*) xylene, and (*4*) gasoline; the same for Figs. 3–5.

where k is a coefficient equal to 10–12 kJ mol^{-1} [10, 11].

The volume of mesopores, V_{me}, was found as the difference

$$V_{me} = V_s - W_0, \quad (4)$$

where V_s is the limiting volume of the adsorption space (amount of adsorbed substance at the saturated vapor concentration).

The specific surface area was found from the BET equation [8].

Table 3 lists characteristics of the pore structure of the adsorbents, which were found from isotherms of adsorption–desorption of a benzene vapor using the single-term DR equation. Analysis of these data suggests that all the microporous adsorbents obtained compare well with the industrial activated carbons used as reference. For example, the microporosity of

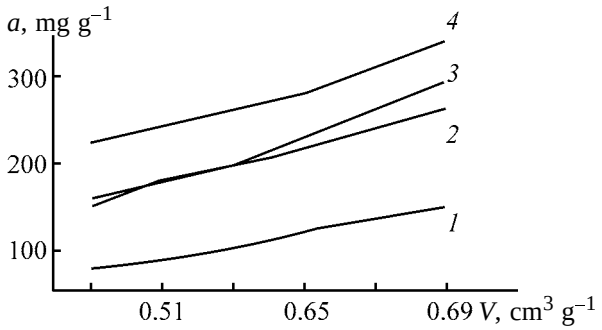

Fig. 3. Activity *a* of the carbons vs. the volume *V* of sorbing pores.

the adsorbents prepared from PS and SW is virtually the same and equal to 0.42–0.48 $cm^3 g^{-1}$. The volume of micropores in the adsorbents prepared by activation with oxygen (AA-1 and AK-1) is somewhat lower, but, nevertheless, quite sufficient: 0.26–0.30 $cm^3 g^{-1}$. The volume of mesopores is virtually the same for all of the adsorbents (0.19–0.22 $cm^3 g^{-1}$).

Comparison of the adsorption capacities of the adsorbents for the hydrocarbons with the parameters of their pore structure shows that this structure governs the adsorption properties. As seen in Fig. 3, the equilibrium activities are directly proportional to the volume of the sorbing pores in the carbons. This fact indicates that the absorption of vapors of aromatic and gasoline hydrocarbons by the carbon adsorbents proceeds in accordance with, exclusively, the laws of physical adsorption, i.e., the binding of adsorbate molecules to the carbon surface is due solely to the van der Waals forces.

The effect of temperature on the equilibrium adsorption capacity of the carbon adsorbents for vapors of the hydrocarbons under study was studied in the temperature range 25–100°C. As an illustration of the results obtained, Fig. 4 shows the isotherms of adsorption of aromatic hydrocarbons and gasoline on an activated carbon prepared from SW. For the other adsorbent–adsorbate systems, the effect of temperature

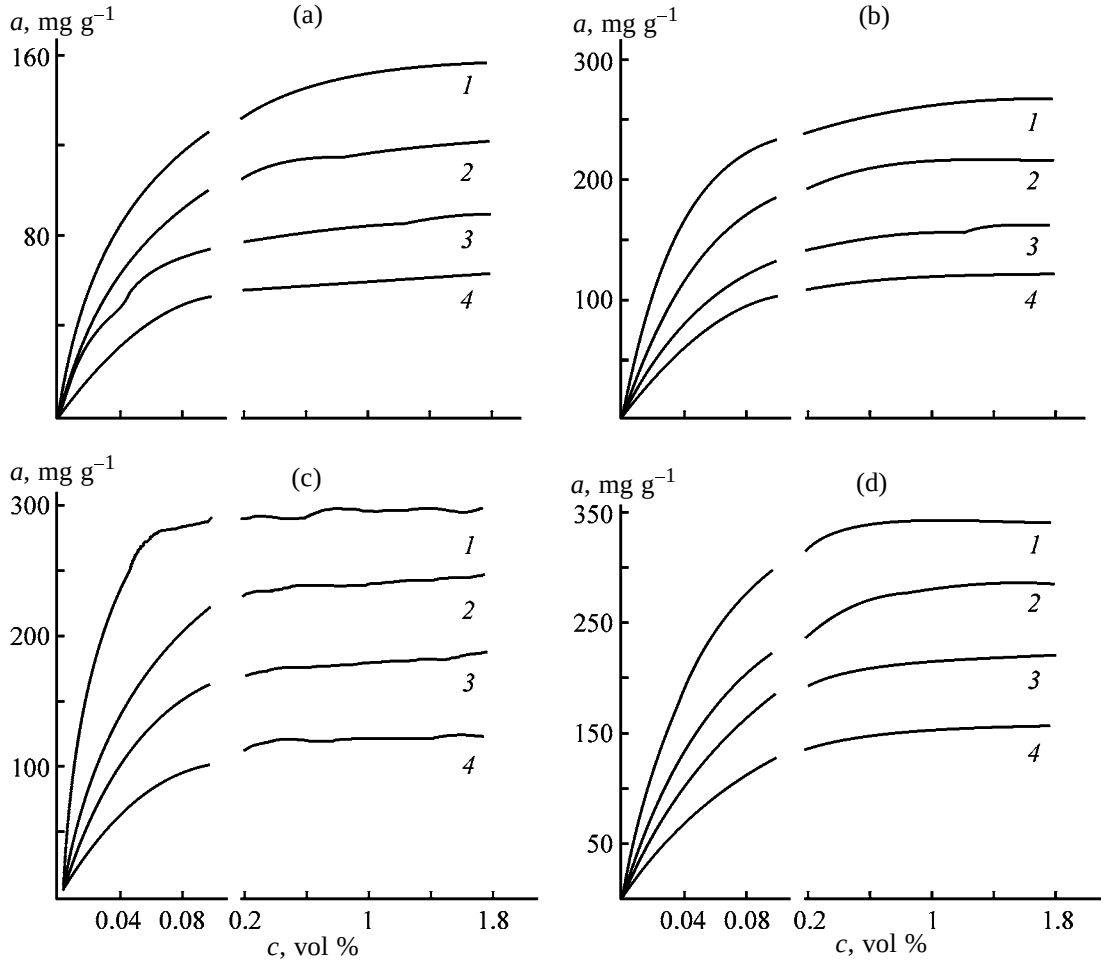

Fig. 4. Effect of temperature on the adsorption of hydrocarbons on KU-1 activated carbon. Temperature (°C): (*1*) 25, (*2*) 50, (*3*) 75, and (*4*) 100. Adsorbate: (a) benzene, (b) toluene, (c) *o*-xylene, and (d) gasoline.

on the activity of the adsorbents is similar. Apparently, an increase in temperature adversely affects in all cases the total amount of adsorbed hydrocarbons: with the temperature increasing in the range studied, the capacity of the adsorbents falls by 50–80% at a content of adsorbates in the vapor–gas mixtures higher than 1 vol %. However, at a low content of the hydrocarbons (<0.005%) the activity of the carbons is little dependent on the temperature, which indicates that their use for purification of low-concentrated gas flows at elevated temperatures without preliminary cooling is advisable.

The adsorption of vapors and gases is an exothermic process. Together with the equilibrium activity, the heat of adsorption is a parameter that is to be known in a calculation of adsorption processes. One of the simplest methods for calculating the heats of adsorption is based on the Clapeyron–Clausius equation, used in the form [12]

$$q = RT^2(\partial \ln p/\partial T)_{a=\text{const}}. \quad (5)$$

Figure 5 shows how the nature of an adsorbate and the degree of filling of the adsorption capacity affect the heat of adsorption of hydrocarbons on the activated carbons prepared from PS and SW. Analysis of these calculated data shows that, in all cases, the dependences $q = f(a)$ are decsending functions, which indicates that there is no specific interaction in the systems. For degrees of filling that are close to the limiting values, the heats of adsorption are approximately equal to the heats of condensation of the adsorbates, which is also evidence in favor of the physical nature of the adsorption of the hydrocarbons under study on microporous adsorbents. And finally, it should be noted that the isosteric differential heat of adsorption grows as the molecular mass of an adsorbate increases.

The average values of the differential heats of adsorption of benzene, toluene, *o*-xylene, and gasoline vapors on the carbon adsorbents under study are 42, 46, 51, and 57 kJ mol^{-1}, respectively.

CONCLUSION

The activated carbons obtained from waste agricultural vegetable raw materials can be successfully used for purification of vapor–air mixtures to remove vapors of benzene, toluene, *o*-xylene, and gasoline. The absorption of the hydrocarbons obeys the laws of physical adsorption, not complicated by any specific interaction, and the adsorption equilibrium is approximated with a sufficient accuracy with the single-term equation of the Dubinin–Radushkevich theory of volume filling of micropores, which can be used in simulation of purification processes.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Oil by Swollen Graphite: Contributions of Specific Surface Area and Specific Volume

Litvinenko Institute of Physical Organic Chemistry and Coal Chemistry, National Academy of Sciences of Ukraine, Donetsk, Ukraine

Received May 13, 2002; in final form, February 2004

Abstract—Sorption of heavy oil by swollen graphites obtained from residual graphite hydrosulfate at 300–900°C was studied. The dependence of the sorption capacity for oil on the specific surface area and specific volume of the swollen graphite sorbent was analyzed.

It has been shown previously that swollen graphite is an extremely effective sorbent for oil and oil products [1–11]. Despite the relatively low specific surface area, its sorption capacity for oil is up to 80 g g^{-1} [12–16]. It was demonstrated in [15] that, to a first approximation, there exists a hyperbolic dependence of the sorption capacity on the bulk density of a sorbent and a directly proportional dependence of the sorption capacity on the total pore volume of the sorbent. No dependence of the sorption capacity on the specific surface area was revealed. On this basis, a conclusion was made that the main contribution to sorption comes from the specific volume of a sorbent, with pores 1–400 μm in size responsible for sorption.

Here we have shown that the sorption determined by the specific surface area of a sorbent makes, together with the sorption governed by the specific volume, an important contribution to sorption of oil by swollen graphite. To distinguish these contributions to the total sorption, a number of sorbents obtained by swelling of the same residual graphite hydrosulfate at 300–900°C [17] were studied. It was found that, for all the samples studied, there exists a strong correlation between the specific surface area S_{sp} and specific volume V_{sp}, which makes impossible any separation of the contributions of these parameters to the total sorption of oil. To diminish the correlation between S_{sp} and V_{sp}, samples of swollen graphite were subjected to a mechanical treatment. This was done on the assumption that such a treatment will not affect S_{sp}, but will strongly diminish V_{sp}, thus making it possible to separate the contributions from the specific surface area and specific volume of the sorbent to the total sorption.

EXPERIMENTAL

The sample of residual graphite hydrosulfate (product formed in hydrolysis of graphite hydrosulfate) used in our study was prepared as follows [17]. Natural flaky graphite of the GT-1 brand (A^d = 5.68 wt %) from the Zaval'evskoe deposit (Ukraine) was used. The initial graphite contained two fractions; 74.3 wt % particles 0.630–0.315 mm in size and 22.1 wt % particles 0.315–0.200 mm in size. As reagents were used a CrO_3 solution in distilled water (50 wt %, d = 1.50 g dm^{-3}) and concentrated H_2SO_4 of chemically pure grade (95.8 wt %). To 25 g of graphite was added with stirring 3.0 cm^3 of the aqueous solution of CrO_3, and the reaction mass was agitated for 10 min. Then, 9.0 cm^3 of H_2SO_4 was introduced into the reactor, and the agitation was continued for 10 min. Further, the contents of the reactor were poured over with 500 cm^3 of water, and the resulting mixture was blended by agitation and allowed to stand for 24 h for hydrolysis to occur. After that, the solid phase was filtered off and washed on the filter with 2 dm^3 of water. The residual graphite hydrosulfate was obtained by drying the moist product at 105°C for 2 h.

Sorbent samples were obtained by heating the residual graphite hydrosulfate in a muffle furnace in the heat-shock mode in the temperature range 300–900°C. The samples were kept in the furnace for 5 min at 300–500°C and for 2 min at 600–900°C. The mechanical treatment of the resulting samples was carried out under the standard conditions by agitation of dry sorbent samples with a T-shaped glass stirrer in a glass vessel at 200 rpm for a time from 0 to 45 min. The values of S_{sp} and V_{sp}, as well as the

sorption capacity for oil at 20°C, W_{sp}, were determined for all the initial and mechanically treated samples.

The BET specific surface area S_{sp} was determined by low-temperature adsorption of argon in accordance with GOST (State Standard) 13144–79. The specific volume was calculated as a reciprocal of the bulk density of the sorbent, which was determined in accordance with GOST 14922–77. The sorption capacity of a sorbent was determined for heavy oil from Lisichansk oil refinery, with a density of 0.873 $g\ cm^{-3}$ at 20°C. The sorption capacity for oil was determined as follows [18]. To a 0.2–0.6-g weighed portion of the graphite sorbent was added 25 g of oil, the resulting mixture was blended by careful agitation, and, after keeping for 1 h, the unsorbed oil was removed in the course of 24 h using a filter made of a metallic mesh. The swollen graphite sorbent with sorbed oil was weighed and the sorption capacity (g of oil per g of sorbent) was calculated.

The parameters of the untreated sorbents obtained at different swelling temperatures T_{sw} in the range 300–900°C are listed in the table.

Figures 1a–1c show how the specific surface area, specific volume, and sorption capacity for oil depend on the temperature at which swollen graphite sorbents are obtained, before their mechanical treatment.

It is seen that all the three parameters studied for the swollen sorbents depend on the swelling temperature in a similar way; below 300°C, the values of the parameters vary only slightly; beginning with 400°C, a steep rise is observed; and in the range 700–800°C all the three curves tend to level off. An attempt to estimate the contributions from the specific volume and specific surface area to the sorption capacity of swollen graphite sorbents on the basis of the data

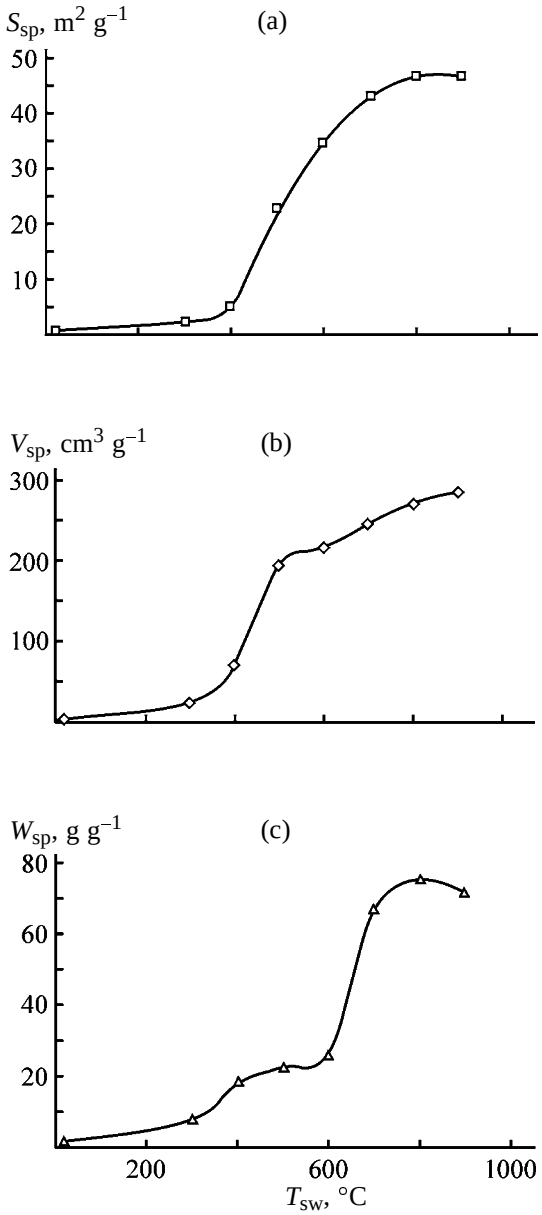

Fig. 1. (a) Specific surface area S_{sp}, (b) specific volume V_{sp}, and (c) sorption capacity of swollen graphite for oil W_{sp} vs. the temperature T_{sw} at which it was obtained.

presented in the table and Figs. 1a–1c by the method of a multiple linear regression failed. This is due to the fact that the presumably independent regression parameters S_{sp} and V_{sp} are actually not independent. As seen from Figs. 1a and 1b, both these parameters depend on the swelling temperature in a similar way, which results in a high coefficient of linear correlation between them: $r = 0.96$.

To diminish the correlation between the parameters S_{sp} and V_{sp}, the sorbent samples obtained at different

temperatures were subjected to a mechanical treatment. It was demonstrated that V_{sp} remains virtually unchanged upon such a treatment of the swollen graphite samples obtained at 300 and 400°C, and steadily decreases by, to a first approximation, a hyperbolic law for samples obtained at 500–900°C. At the maximum time of the mechanical treatment of 45 min, V_{sp} of these samples decreases 2–3-fold. As expected, mechanical treatment does not change the specific surface area of all the samples studied in the whole range of treatment times used. Typical dependences of the specific volume of swollen graphite on the time of its mechanical treatment are shown in Fig. 2.

Figure 3 shows how the sorption capacity for oil depends on the specific volume for samples obtained at 300–900°C and subjected to a mechanical treatment. For the samples prepared at 300 and 400°C, mechanical treatment does not change significantly their sorption capacity for oil, which is indicated by the compact arrangement of the points for these samples. This fact is in agreement with the invariability of the parameters S_{sp} and V_{sp} for these swollen graphite samples in the course of their mechanical treatment. For the samples obtained at higher temperatures (500–900°C), the situation changes dramatically. To a first approximation, the dependences of W_{sp} for oil on V_{sp} can be represented for these samples by straight lines, around which lie, with a significant scatter, experimental points. The slopes of these straight lines are positive, close to zero, and negative for the samples obtained at 700–900, 600, and 500°C. It is noteworthy that the intercepts on the *y*-axis fall within the range 30–40 g g^{-1} for all these straight lines.

For the samples obtained at 700–800°C, the straight lines with a positive slope can be readily accounted for by a decrease in V_{sp} of these samples in the course of a mechanical treatment (Fig. 2), which makes lower their sorption capacity for oil. Unexpectedly, it was found that for the samples obtained at 500 and 600°C the run of these curves is anomalous. For the samples synthesized at 600°C, V_{sp} decreases in the course of a mechanical treatment, but the sorption capacity for oil remains virtually unchanged. For the samples obtained at 500°C, mechanical treatment even raises their sorption capacity for oil.

The anomalous dependences of W_{sp}, observed for the swollen graphite samples obtained at 500 and 600°C, can presumably be accounted for as follows. Heating of the residual graphite hydrosulfate yields

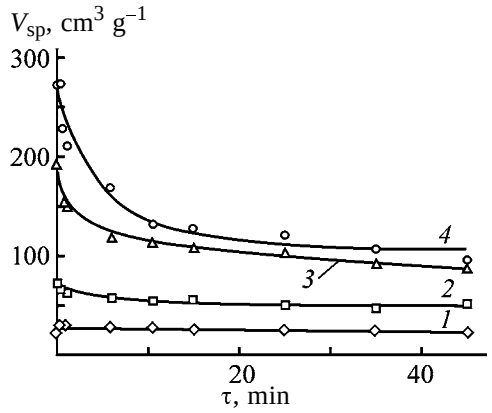

Fig. 2. Specific volume V_{sp} of swollen graphite samples obtained at different temperatures vs. the duration τ of their mechanical treatment. Preparation temperature (°C): (*1*) 300, (*2*) 400, (*3*) 500, and (*4*) 800.

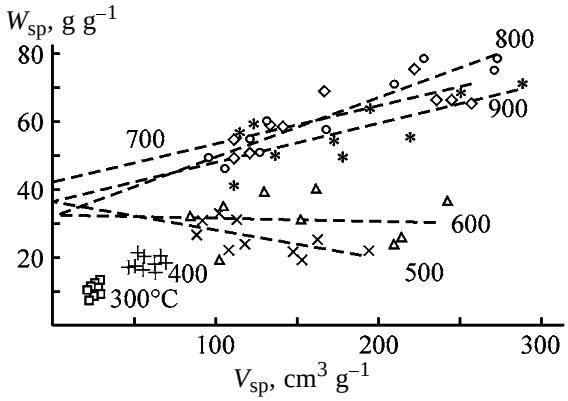

Fig. 3. Sorption capacity for oil, W_{sp}, vs. the specific volume V_{sp} for swollen graphite samples obtained at 300, 400, 500, 600, 700, 800, and 900°C and subjected to a mechanical treatment.

a swollen graphite with a characteristic honeycomb structure [19]. In all probability, this structure is poorly developed at 300–400°C and is mainly composed of closed pores, which are inaccessible to oil. At a swelling temperature of 500–600°C, the honeycomb structure of the swollen graphite is already well developed; however, a considerable fraction of closed pores inaccessible to oil is still present. At swelling temperatures of 700–900°C, virtually all pores in the structure of swollen graphite are open and accessible to oil. It is noteworthy that raising the temperature at which swollen graphite is obtained leads not only to the development of the honeycomb structure, but also to a decrease in its mechanical strength.

Mechanical treatment of swollen graphite obtained at 700–900°C only diminishes the specific volume of the sorbent and, as a consequence, leads to a decrease in its sorption capacity for oil. In the case of swollen

graphites obtained at 500–600°C, mechanical treatment also diminishes the V_{sp} of the sorbent, which leads to a decrease in the W_{sp} of swollen graphite for oil. However, closed pores are, presumably, also opened in this case and, as a result, become accessible to oil. This effect compensates for the decrease in the W_{sp} of the sorbents, which is associated with the lowering of their specific volume. An evidence in favor of this conclusion is the following experimental fact. As regards their behavior in isopropyl alcohol, all the untreated sorbent samples can be divided into two groups: those obtained at 300–500°C float on the alcohol surface, and those prepared at 600–900°C drown. After 45 min of mechanical treatment, the behavior of the samples obtained at 300–400 and 600–900°C remains unchanged. By contrast, the sample prepared at 500°C drowns in the alcohol virtually completely. In the untreated sample obtained at 600°C, all the pores are presumably already opened, but the size of their mouths allows only comparatively small molecules, e.g., those of isopropyl alcohol, to penetrate into the pores. Molecules of substances contained in oil (average molecular mass is about 1000) cannot penetrate through so narrow apertures into the pores. Presumably, the mechanical treatment used makes the pore mouths wider, with the result that pores become accessible to oil.

The honeycomb structure of the swollen graphites obtained at 300–400°C is so strong that the mechanical treatment used neither makes smaller the V_{sp} of the sorbent, nor opens up the closed pores present in its structure. As a result, mechanical treatment leaves virtually unchanged the W_{sp} of these sorbents.

The fact that, upon a mechanical treatment of swollen graphite, its V_{sp} decreases and S_{sp} remains unchanged made it possible to diminish the correlation between these parameters. For the untreated samples of graphites swollen at 300–900°C, the coefficient of linear correlation between the parameters S_{sp} and V_{sp} is $r = 0.96$. At the same time, after a mechanical treatment it decreases to $r = 0.76$. It is noteworthy that, if the samples obtained at 300 and 400°C (whose mechanical treatment does not change the parameters S_{sp} and V_{sp}) are excluded from consideration, the correlation coefficient falls to $r = 0.27$.

Such a weakening of the correlation between these parameters made it possible to estimate, to a first approximation, their separate contributions to the sorption of oil by swollen graphite. An estimate of the regression dependence of the sorption capacity W_{sp} of swollen graphite on the parameters S_{sp} and V_{sp} by means of the method of linear multiparameter regression for the whole body of experimental data yields the equation $W_{sp} = 3.946 + 0.807S_{sp} + 0.0812V_{sp}$ ($r = 0.88$). In this case, the estimate by the *t*-test (at confidence probability of 95%) shows that the coefficients at the parameters S_{sp} and V_{sp} in this equation are significant. Reducing this equation to the standard scale, which makes it possible to compare the absolute values of the regression coefficients, yields the equation $W_{sp} = 0.648S_{sp} + 0.277V_{sp}$. It follows from this equation that both the contributions to the sorption of oil, associated with the specific surface area and the specific volume of swollen graphite, are significant, with 70% of the sorption capacity governed by the specific surface area of swollen graphite, and only 30%, by its specific volume.

CONCLUSIONS

(1) Swollen graphite obtained by heating of the residual graphite hydrosulfate in the thermal-shock mode is a highly effective sorbent of oil. The sorption capacity of swollen graphite grows with increasing swelling temperature to become 70–75 g g^{-1} for the sorbents obtained at 800–900°C.

(2) The strength of the honeycomb structure of the swollen graphite sorbent, which is responsible for sorption of oil, is low. Even a simple mechanical agitation of dry sorbents obtained at 700–900°C leads to a decrease in their specific volume and, as a consequence, makes lower their sorption capacity for oil.

(3) The sorption capacity for oil is determined both by the specific surface area and the specific volume of swollen graphite, with the contribution of the sorption governed by the specific surface area equal to about 70%, and that associated with the specific volume, to about 30%.

Received November 25, 2003

Abstract—Changes in sapropelite structure at room temperature in the course of modification with HNO_3, HNO_3–Ac_2O, SO_3–H_2SO_4, and H_2SO_4 were studied. The effect of chemical modification on the development of the specific surface area at thermolysis in the presence of acid (H_3PO_4) or base (KOH) activators was analyzed.

Natural coals are widely used raw materials for preparing carbon sorbents (CS), whose properties are largely determined by the chemical structure and reactivity of the precursor [1]. The fossil coal structure can change under the conditions of chemical modification and, in turn, strongly affect the processes of further physical or chemical activation at the sorbent preparation [2–9].

The most widely used procedures for chemical modification of natural coals involve treatment with various oxidants, e.g., O_2 [2, 4], HNO_3 [3–5], $HClO_4$ [6, 7], acetyl nitrate [8], and others [9]. Conditions of oxidative modification (OM) are chosen on the basis of only two principally different approaches: (1) partial oxidative degradation of the coal organic matter with formation of functional groups (FGs) and (2) reorganization of the steric and molecular structure under the conditions similar to those of graphite intercalation [10].

As a typical heterogeneous process, oxidative degradation starts in the near-surface layer and spreads inside the coal particle; it is accompanied by low-temperature burning-out of organic compounds. Intercalation conditions provide rapid diffusion of the modifying agent into the coal, uniform distribution of the reacting species in the coal matrix (as in formation of solid solutions), and the occurrence of the modification reaction not only in the near-surface layer, but also in the coal bulk, i.e., under the "pseudohomogeneous" conditions.

It should be mentioned that the intercalation method is yet under development. Various procedures and reagents are tested, optimal conditions of intercalation of the natural coals (which are quite different from the conditions for preparing graphite intercalation compounds [11]) are sought for, and data on the reactivity of carbons of various histories are accumulated. The positive effect of intercalation has been shown, but its further development seems promising [5–7, 9].

In this work we studied modification of sapropelite (Sp) under the intercalation conditions and analyzed changes in its structure and their effect on the development of the specific surface area at activation.

The following modifying agents were used.

(1) Fuming HNO_3 (≥99%) is a traditional reagent for preparing graphite nitrate [10], which yields one-electron oxidant (nitronium cation NO_2^+) and intercalating agent (NO_3^- anion) in the course of dissociation: $2HNO_3 = NO_2^+ + HNO_3^- + H_2O$. As reagent, it was tested with anthracite (Donets Coal Fields, Ukraine) [9].

(2) Equimolar HNO_3–acetic anhydride (Ac_2O) mixture, which yields the same oxidant NO_2^+, but different intercalating agent (acetate anion) by the reaction $HNO_3 + Ac_2O \rightarrow NO_2AcO + AcOH \rightarrow NO_2^+ + AcO^- + AcOH$. This reaction was studied using humus coals [12] and tested with sapropelite [8].

(3) Oleum (20% SO_3 in H_2SO_4), containing oxidant (SO_3) and intercalating agent (hydrosulfate anion).

(4) Sulfuric acid (96%) was taken for comparison with oleum.

The first two reagents are nitrating agents [5, 12], and the last two are sulfonating agents [13].

These reagents were selected so as to transform the structural fragments of sapropelite into carbocations

1070-4272/04/7705-0750 © 2004 MAIK "Nauka/Interperiodica"

with subsequent compensation of the positive charge by intercalation of anions (A = NO_3^-, AcO^-, HSO_4^-) in the coal skeleton; as a result, modification reactions can be transferred from the particle surface into the bulk.

EXPERIMENTAL

We studied an Sp sample from the Taimylyr deposit (Lena coal field): particle size $d \le 0.2$ mm, water content $W^a = 1.1\%$, ash content $A^d = 3.5\%$; elemental composition of the organic matter (% daf): C 82.6, H 9.5, S 0.3, N 0.7, O_d 6.9. The contents of alginite and vitrinite was 87 and 13%, respectively.

Preliminarily dried (105°C, 2 h) coal sample was modified at room temperature (20 ± 1°C). The Sp sample (1 g) was contacted with a required amount of reagent R, given in moles of HNO_3 (or H_2SO_4) per kilogram of dry coal. In certain time τ, the reaction mixture was filtered, and the solid product was washed with benzene (30 cm^3) and diethyl ether (30 cm^3) and dried in a vacuum (~2 kPa, 20°C).

The modified coal was isolated by triple washing with water (hydrolysis) and decantation (250 cm^3 H_2O per gram of Sp) with subsequent filtration and drying. We assume that this treatment provides removal of molecules and ions that are not bound with the carbon skeleton by covalent bonds, i.e., the intercalated "guest" species are removed from the coal skeleton. For the coal samples prepared by this procedure, we studied changes in the molecular structure. Coals modified with various reagents are designated as follows: Sp(HNO_3), Sp(NO_2AcO), Sp(SO_3), and Sp(H_2SO_4).

Activated sapropelites (ASps) were prepared by thermal treatment of the modified coals in the presence of various activators (KOH or H_3PO_4) in two steps. The first step involves impregnation of the carbon sample (10 g) with a 50% aqueous solution of KOH or H_3PO_4 in the amount providing the required activator/coal weight ratio R_a (g g^{-1}), where a = KOH or H_3PO_4, storage at 20°C for 20 h, and drying for 3 h at 150 (KOH) or 170°C (H_3PO_4). In the second stage, the impregnated sample (2 g) is heated in a horizontal tubular furnace (heating rate 10 ± 2 deg min^{-1}) in an argon flow (~1 dm^3 h^{-1}) to the activation temperature T_a, kept at this temperature for 2 h, cooled in argon to 50 ± 10°C, washed with water to pH ~ 7, and dried at 105°C for 2 h.

In the course of modification, the relative changes in the coal weight m and volume V were monitored:

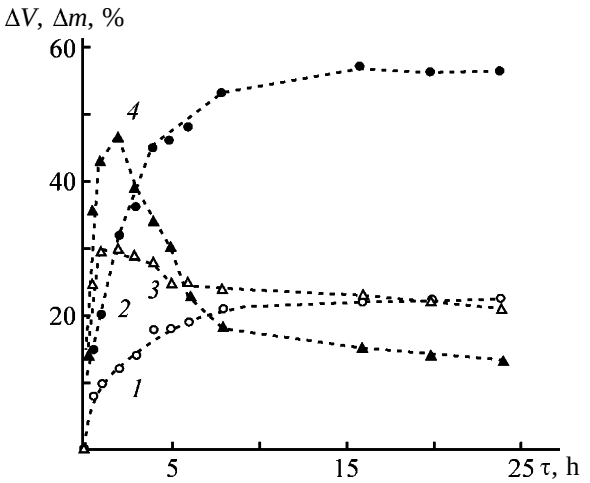

Fig. 1. Changes in the coal (*1*, *3*) weight Δm and (*2*, *4*) volume ΔV in the course of modification with HNO_3–Ac_2O mixture as functions of the reagent/coal ratio R. (τ) Time. R, mol kg^{-1}: (*1*, *2*) 20 and (*3*, *4*) 100.

Δm (%) = $100(m - m_0)/m_0$ and ΔV (%) = $100(V - V_0)/V_0$, where m_0 and V_0 correspond to the initial dry sample.

The IR spectra of coal–KBr (5 : 95 weight ratio) mixture were recorded on a Mattson 3000 FTIR apparatus in the 4000–400 cm^{-1} range (2 cm^{-1} resolution, 500 scans). The absorption bands were assigned by comparative analysis of the IR spectra of individual compounds [14], natural organic compounds [15], and coals [16]. The thermogravimetric analysis was performed on a Setaram TGDTA 92 analyzer (sample weight 50 mg, heating rate 10 deg min^{-1}, argon atmosphere). The IR spectra of the volatile thermolysis products were recorded *in situ* using a Bio-Rad FTS 165 spectrophotometer connected by a tube with the Setaram TGDTA 92 analyzer. The specific surface area S (m^2 g^{-1}) was determined by low-temperature (77 K) sorption of argon and by small-angle X-ray scattering (SAXS) [8].

Irrespective of the reagent type, modification is accompanied by swelling of the coal, changes in its weight, and release of gaseous NO_2 or SO_2. We also recorded exothermic effects, which (in the first 45–60 min) increase the temperature of the reaction mixture to the following values (R = 20 mol kg^{-1}): 63 (HNO_3), 59 (HNO_3–Ac_2O), 73 (oleum), and 67°C (H_2SO_4).

In the examined range of R, the weight and volume of the coal first increase and then reach a plateau (Fig. 1) or pass through a maximum and subsequently decrease to certain constant Δm or ΔV. All the modification reactions are complete in 16–20 h: ΔT values

Table 1. Change in the elemental composition of sapropelite at modification with HNO_3–Ac_2O mixture; R = 20 mol kg^{-1}, isolation by hydrolysis

τ, h	Composition, %				
	C	H	N	S	O_d
0	82.6	9.5	0.7	0.3	6.9
0.5	72.0	8.7	2.3	0.3	16.7
1.0	69.1	8.3	3.2	0.2	19.2
2.0	67.4	7.9	3.8	0.2	20.7
3.0	66.7	8.0	4.7	0.2	20.4
6.0	65.3	8.1	4.6	0.2	21.8
16	64.2	8.1	4.6	0.2	22.9
20	64.4	8.2	4.5	0.2	22.7

tend to zero, gas liberation is terminated, Δm and ΔV values are stabilized, and the elemental composition becomes constant (Table 1). In all the further tests, the modification time was constant (τ = 20 h). The degree of modification (evaluated as Δm and ΔV) depends on the reagent/coal ratio (Fig. 2): with increasing R, the weight and volume of the coal increase, reaching maximal values at R = 20 mol kg^{-1}. In the R = 20–100 mol kg^{-1} range, Δm values either remain constant or decrease after passing a maximum, which is caused by partial oxidative degradation of the organic matter at the reagent excess [8, 12]. The oxidative degradation is the most pronounced in modification with HNO_3 and less pronounced with the HNO_3–Ac_2O mixture; with H_2SO_4 and oleum at 20 ± 1°C, no degradation is observed. Thus, from the viewpoint of maximal weight and volume of the resulting coal, R = 20 mol kg^{-1} is the optimal value. This conclusion can be confirmed by the following facts.

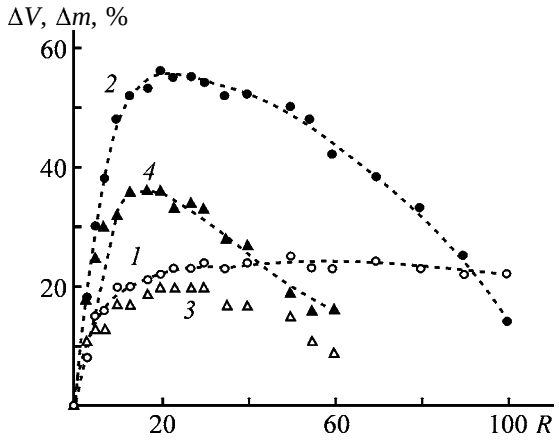

Fig. 2. Changes in the coal (*1*, *3*) weight Δm and (*2*, *4*) volume ΔV as functions of the reagent/coal ratio R. Modifying agent: (*1*, *2*) HNO_3 and (*3*, *4*) HNO_3–Ac_2O.

(1) According to the data of chemical analysis, the main fraction (0.90–0.95) of the covalently bound O, N, and S atoms appear at R = 20 mol kg^{-1}. In the R = 20–100 mol kg^{-1} range, the content of O, N, and S remains nearly constant (±0.1%). The intensity of the IR absorption bands, in particular, those of nitrate (1555 and 1375 cm^{-1}) and sulfate (1060 cm^{-1}) groups remain constant within the measurement error (±10 rel. %).

(2) The DTA data (Table 2) show that the total yield of the solid products and its dependence on the temperature (heating rate 10 deg min^{-1}) of thermolysis of the modified carbons only slightly change with increasing R from 20 to 100 mol kg^{-1}, but strongly differ from those observed in thermolysis of the initial sample.

(3) At small R (≤20 mol kg^{-1}), sapropelite seems visually dry (especially in the case of HNO_3 and HNO_3–Ac_2O reagents). Liquid modifying agent is almost completely absorbed by the coal skeleton, i.e., the modification reactions proceed in the carbon bulk. Moreover, R = 20 mol kg^{-1} was found to be the optimal value in modification of coals of the aromatic nature (humolites) in HNO_3–Ac_2O [17].

In the case of HNO_3-containing reagents, the coal organic matter is nitrated; the IR spectra exhibit the absorption bands of the antisymmetric (1555 cm^{-1}) and symmetric (1375 cm^{-1}) stretching and bending (850 cm^{-1}) vibrations of aliphatic nitro groups (Alk–NO_2). By deconvolution of the IR spectra [8], the fragments with C–N bonds (1580 cm^{-1}) and nitroso and aromatic nitro groups (1530 and 1348 cm^{-1}) were identified, but their amount is small because of small content of aromatic structures in sapropelite [16]. The carboxy groups and ketones with open chain were also detected (increase in the absorption intensity at 1725–1700 cm^{-1}).

Functional groups are formed in reactions with aliphatic sapropelite chains; as a result, the intensity of the absorption bands of the stretching (2926 and 2853 cm^{-1}) and bending (1465 cm^{-1}) vibrations of methylene groups decreases. The IR spectrum of Sp(NO_2AcO) exhibits a strong broad band at 1100 cm^{-1}, typical of dialkyl ethers –CH_2–O–CH_2– [15] and absent in the spectra of Sp and Sp(HNO_3). The bending vibrations of the alcohol hydroxy groups are also observed in this region, but simultaneously with the stretching vibrations of the alcoholic C–O groups (1350–1260 cm^{-1} [14]). In our case, the intensity of the absorption bands of the alcoholic C–O groups is low, and thus the content of alcoholic groups

Table 2. Yield of solid products of thermolysis of the initial and modified sapropelites

Sample	Yield, %, on heating to the indicated temperature, °C							
	200	300	400	500	600	700	800	900
Sp	96	92	84	28	24	19	13	9
$Sp(NO_2AcO)$, R, mol kg^{-1}:								
20	82	64	54	30	28	27	26	25
100	74	55	49	26	24	23	22	20
$Sp(HNO_3)$, R = 20 mol kg^{-1}	83	61	52	29	27	26	25	25

in $Sp(HNO_3)$ and $Sp(NO_2AcO)$ is insignificant. Moreover, these C–O groups can be parts of acetoxy (Alk–OAc) and other ester groups identified by the C=O absorption at 1750–1730 cm^{-1} in the IR spectra of $Sp(NO_2AcO)$. Thus, modification with the HNO_3–Ac_2O mixture probably yields ester groups between the neighboring alkane chains in the carbon skeleton.

If the increase in the nitrogen content after Sp modification (Table 3) is due to the nitration, then the content of the nitro groups comprises 3 and 2.7 mol kg^{-1} for $Sp(HNO_3)$ and $Sp(NO_2AcO)$, respectively. However, the corresponding content of oxygen in the NO_2 groups is 9.6 and 8.6% of the total 23.0 and 22.7%, respectively (Table 3). Thus, nitration of Sp in the course of modification is accompanied by other reactions, primarily, by formation of coal radicals at one-electron oxidation of the sapropelite fragment due to the electron transfer on the nitronium cation. Evolution of gaseous NO_2 directly confirms the occurrence of this reaction.

The oxidative degradation effect of the sulfuric acid reagents is lower. The increase in O_d (Table 3) is close to the oxygen content in the sulfo groups (calculated from S^{daf}), though in $Sp(SO_3)$ the oxygen content is higher. Appearance of new bands in the IR spectra of $Sp(SO_3)$ and $Sp(H_2SO_4)$ confirms formation of the sulfo groups (1225 and 1055 cm^{-1}), sulfones Alk–SO_2–Alk (1310 cm^{-1}), and probably sulfonates Alk–O–SO_2Alk (1360–1170 cm^{-1}). The oxidation and polymerization (dehydropolycondensation), often proceeding at sulfonation of alkanes, are also possible [13].

Our data on the effect of modification on the surface development in the course of sapropelite activation show that the ASp properties depend on the nature of the modifying and activation (KOH or H_3PO_4) agents. The initial sapropelite poorly reacts with aqueous solutions of KOH and H_3PO_4 at impregnation, and its activation yields only low-porous materials (S = 40–60 $m^2\ g^{-1}$). All the modified sapropelites are much more active than the initial substance.

The temperature dependences of the specific surface area S of modified sapropelites at activation with H_3PO_4 are shown in Fig. 3a. With increasing temperature (from 350 to 700°C), the specific surface area increases, whereas at T_a = 700–850°C it tends to decrease. The highest value of $S = 500 \pm 20$ $m^2\ g^{-1}$ is attained at T_a = 700°C; however, the samples with almost the same specific surface area (up to 440 $m^2\ g^{-1}$) can be prepared even at 500°C at activation of $Sp(H_2SO_4)$. A similar pattern is observed with $Sp(NO_2AcO)$; the greatest $S = 390 \pm 20$ $m^2\ g^{-1}$ is reached at T_a = 500°C, and on heating to 850°C it remains constant (within the experimental error). As seen from Fig. 3, H_2SO_4 is the best modification agent to convert sapropelite into porous carbon materials, but the other modifying agents are also effective. The acid activation agent (H_3PO_4) reacts at fairly low temperatures (≤500°C), but it is ineffective for preparing highly porous materials from modified sapropelites.

The activation effect of KOH is more pronounced (Fig. 3b); at T_a = 850°C [R(KOH) = 1.1 g g^{-1}] all

Table 3. Chemical compositions of modified sapropelites; R = 20 mol kg^{-1}, isolation by hydrolysis

Sample	Elemental composition, % daf				
	C	H	N	S	O_d

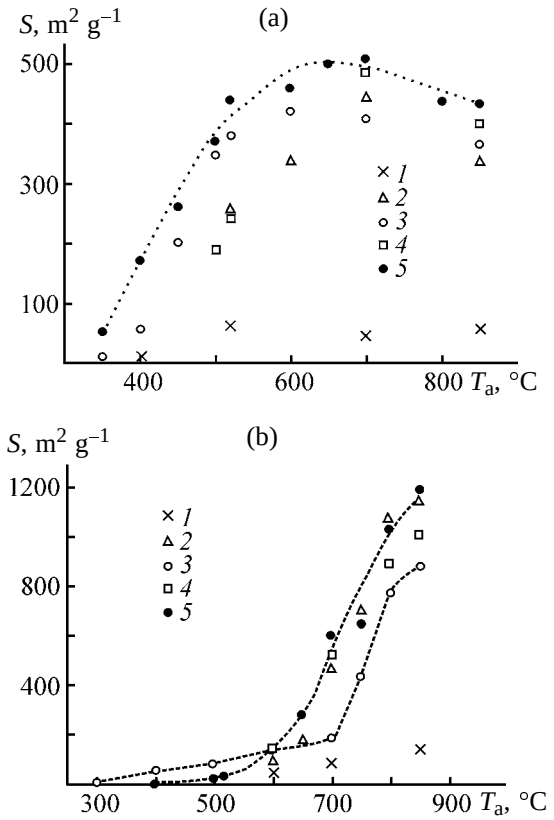

Fig. 3. Specific surface area *S* of sapropelites as influenced by the activation temperature T_a. Activating agents: (a) H_3PO_4 and (b) KOH; $R(H_3PO_4) = R(KOH) = 1.0$ g g^{-1}. Sapropelite: (*1*) Sp, (*2*) Sp(HNO_3), (*3*) Sp(NO_2AcO), (*4*) Sp(SO_3), and (*5*) Sp(H_2SO_4).

the modified sapropelites yield the materials with highly developed surface (S = 900–1200 m^2 g^{-1}). In the 650–850°C range, *S* almost linearly increases with temperature for all the samples, but with Sp(NO_2AcO) this increase is the least, and with Sp(H_2SO_4), the most pronounced, as in activation with H_3PO_4.

High activation temperature (800–850°C) levels off the differences caused by modification with different reagents. Under milder conditions [T_a = 700°C, R(KOH) = 1.0 g g^{-1}], the effect of the modifying agents on the specific surface area changes in the following order [*S* values, m^2 g^{-1}, for ASp (Fig. 3b) are given in parentheses]: HNO_3–Ac_2O (190) < HNO_3 (480) < SO_3–H_2SO_4 (520) < H_2SO_4 (600).

Table 4. Specific surface area as influenced by KOH/coal ratio,* T_a = 800°C, τ = 2 h

Sample	*S*, m^2 g^{-1}, at indicated *R*(KOH), g g^{-1}				
	0.25	0.50	1.0	1.5	2.0
Sp(H_2SO_4)	105	510	1030	1460 (1600)**	1590
Sp(NO_2AcO)	90	360	770	1130 (1200)	1230

* *S* determined by SAXS method [8].
** Measurement error ±8 rel %.

It should be noted that the same order is observed with H_3PO_4, but the *S* values (410, 450, 490, 510 m^2 g^{-1}; Fig. 3a) vary in a narrower range, i.e., the functional groups formed at modification are more sensitive to alkali than to H_3PO_4 (acid activator). With increasing KOH/coal ratio, *S* values increase (Table 4) virtually linearly to R(KOH) = 1.5 g g^{-1}; with further increase in *R*, variations in the specific surface area are negligible. Similar *S*–*R*(KOH) dependences were found previously for humus coals [18]. For two ASp samples (Table 4) we obtained similar *S* values by two independent methods: low-temperature (77 K) sorption of argon and SAXS procedure [8].

As seen, alkali strongly affects the development of the specific surface area in activation of modified sapropelites, which is due to the additional reactions of KOH with functional groups formed by modification. Even in the course of impregnation, various processes occur simultaneously, namely: ion-exchange reactions with acidic functional groups R–OH + KOH → R–O–K$^+$ + H_2O, where R = Alk–, Alk–C(O)–, Alk–SO_2–, formation of *aci*-nitro compounds Alk–CH_2NO_2 + KOH → Alk–CH=$NO_2^-K^+$ + H_2O, saponification of esters, etc.

These reactions promote penetration of KOH into the coal bulk, which is accompanied by swelling of the coal and distribution of KOH (or K^+ and OH^- ions) in the coal skeleton, which is similar to the formation of solid solutions. Upon heating to the activation temperatures, potassium compounds decompose, e.g., R–$NO_2^-K^+$ → R–OK + NO (≤400°C); R–SO_3K → R–OK + SO_2 (300–500°C); R–COOK → ROK + CO (≤500°C). Several new reactive intermediates arise, which form the secondary ASp network due to the polycondensation processes. Free alkali distributed in the coal skeleton also participates in the thermally initiated reactions, e.g., in cleavage of ethers (at 300–400°C [19]) and dehydrogenation CH_2 + KOH → C(H)OK + H_2 (500–700°C) [20].

Reactions involving KOH and various functional groups yield a porous carbon material with highly developed surface (S = 1000–1600 m^2 g^{-1}). The acidic groups do not promote penetration of H_3PO_4 into the coal bulk; as a result, certain fraction of the coal material is converted without H_3PO_4, yielding a more compact three-dimensional secondary lattice

with less developed surface ($S \leq 500$ $m^2 g^{-1}$). It should be noted that the greatest effect was found in modification with H_2SO_4, which exhibits only the sulfonation power at minimal oxidative degradation of the coal. We assumed that, along with formation of the corresponding functional groups, H_2SO_4 promotes low-temperature polycondensation of the alkane chains in sapropelite through the intermediate generation of carbocations [13]. Such reactions prepare the aliphatic carbon skeleton for thermally initiated conversion into the aromatic AC lattice.

CONCLUSIONS

(1) The data on structural changes in the course of sapropelite modification with HNO_3, HNO_3–Ac_2O, SO_3–H_2SO_4, and H_2SO_4 at room temperature showed that the steric structure changes owing to the penetration of reactive species in the coal skeleton and their binding with ionic and covalent bonds. The molecular structure changes as a result of nitration or sulfonation of the alkane chains, transformation of the aliphatic fragments into oxygen functional groups, and cleavage of a part of C–C and C–O bonds of the organic skeleton.

(2) At properly chosen temperature and activator/coal ratio, modified sapropelites transform into porous carbon materials with highly developed surface (1200–1600 $m^2 g^{-1}$).

SORPTION AND ION-EXCHANGE PROCESSES

Determining the Mechanism of Formaldehyde Adsorption from an Aqueous Medium on the Basis of the Diffusion Criterion

L. I. Bel'chinskaya and O. A. Tkacheva

Voronezh State Forestry Academy, Voronezh, Russia

Received April 16, 2003; in final form, October 2003

Abstract—Adsorption of formaldehyde from an aqueous medium on acid-treated clayey minerals was studied under conditions of natural convection and under stirring of the solution.

One of important unsolved environmental problems of the woodworking industry is removal of formaldehyde from liquid wastes of furniture factories. The aim of this study was to establish the mechanism of formaldehyde adsorption from an aqueous medium on the basis of the diffusion criterion and to use this parameter to determine ways to intensify the process.

EXPERIMENTAL

Three systems constituted by formaldehyde and clayey microporous minerals (montmorillonite, palygorskite, and clinoptilolite) and having different types of structure [1, 2] were studied.

To determine the specific features of the behavior of the systems under study under conditions of natural convection and under stirring, equilibrium and dynamic processes were studied.

The adsorption of formaldehyde was carried out on 1-g mineral samples (grain size 0.025 cm) from 0.025 l of 0.03 M formaldehyde solution. The time of equilibration was 20 min. The samples were pretreated with a 15% solution of H_2SO_4 to improve their adsorption characteristics [3].

The adsorption value, a (mg g^{-1}), was calculated by the equation [4]

$$a = (c_0 - c)/m, \quad (1)$$

where c_0 and c are the concentrations of the formaldehyde solution before and after adsorption, respectively (mg l^{-1}); m is the adsorbent mass (g l^{-1}).

The values of a were obtained with a high correlation factor ($r = 0.98$).

Typical dependences which supposedly reflect processes of the rate-determining stage of diffusion were analyzed: θ–τ and θ–$\tau^{1/2}$, where $\theta = a/a_{max}$ is the fraction of adsorption in a certain interval of time τ; a and a_{max} are the running and maximum adsorption values, respectively (mg g^{-1}).

The adsorption rate is determined by inner diffusion if the dependence θ–τ is initially linear and then gives way to the linear dependence $\theta = f(\tau^{1/2})$, with the straight lines emerging from the origin of coordinates [5]. The obtained linear dependence $\theta = f(\tau^{1/2})$ assumes that the inner diffusion is the rate-determining factor in adsorption of formaldehyde on palygorskite, montmorillonite, and clinoptilolite.

When the rate of the process is determined by outer diffusion, the dependence $\ln(1 - \theta)$–τ from the equation

$$\ln(1 - \theta) = -\beta\tau, \quad (2)$$

where β is the rate constant (s^{-1}), should be linear [6], which was found to be the case in an analysis of formaldehyde adsorption on the minerals under study. The value of β was determined graphically from the slope of the straight line in the coordinates $\ln(1 - \theta)$–τ.

The bounds of the outer- and inner-diffusion regions were discussed on the basis of an analysis of the Bi criterion with the use of the rate constant β of the adsorption process [4] and the inner-diffusion constant $\bar{D}$. The Bi criterion (ratio of the inner resistance to mass transfer within an adsorbent grain to the outer resistance to mass transfer from the bulk of the liquid to the grain surface) was found from the equation

$$Bi = \beta r^2/\bar{D}, \quad (3)$$

* τ is the time of adsorption.

where r is the effective radius of sorbent particles (cm) and $\bar{D}$ is the inner-diffusion coefficient $\bar{D}$ (cm^2 s^{-1}) calculated graphically using the Crank equation [4]

$$\ln(1 - \theta) = \ln(6/\pi^2) - (\bar{D}\pi^2\tau/r^2), \quad (4)$$

The values of D, obtained for the systems under study (Table 1), are comparable with published values for natural minerals [6, 7].

On the basis of the values obtained for β and $\bar{D}$, the Bi criterion was calculated (Table 1). This criterion establishes the boundary between the outer and inner types of diffusion: Bi $\leq$ 0.1 corresponds to rate-determining outer diffusion, and at Bi $\geq$ 30, the control is by the inner diffusion. If Bi is within the range from 0.1 to 30, the process may occur by the mixed-diffusion mechanism [4]. For modified minerals, Bi is approximately 10 (Table 1).

The operation of the mixed mechanism of adsorption is confirmed by the fact that the outer-diffusion limitations are partly lifted in the case of formaldehyde adsorption on montmorillonite in the hydrodynamic mode. The solution was agitated at fixed rates V of 6, 20, 50, and 60 rpm.

The free molar energy $-\Delta F^0$ (kJ mol^{-1}) was calculated by the equation

$$-\Delta F^0 = RT\ln K_{se}, \quad (5)$$

where K_{se} is the sorption equilibrium constant found from adsorption isotherms; R, universal gas constant (J mol^{-1} K^{-1}); and T, temperature (K).

The values of $-\Delta F^0$ for palygorskite and montmorillonite (Table 1) differ only slightly, but exceed that for clinoptilolite.

Montmorillonite was chosen as a sorbent of formaldehyde because it shows promise as a material for environmental technologies owing to the presence in Voronezh oblast of rather large and accessible deposits of bentonite enriched in montmorillonite.

The results of a comparative analysis of equilibrium, kinetic, and thermodynamic parameters (Tables 2, 3) under the conditions of natural convection and under stirring indicate that, in the latter case, adsorption of formaldehyde on a modified montmorillonite is intensified. The adsorption capacity grows with increasing rotational speed of the stirring rod

Table 3. Comparative diffusion and thermodynamic characteristics of the process of formaldehyde adsorption on montmorillonite under the conditions of natural convection and under stirring

v, min^{-1}	$\beta \times 10^3$, s^{-1}	$\bar{D} \times 10^8$, $cm^2\ s^{-1}$	$-\Delta F^0$, $kJ\ mol^{-1}$
0	2.9	4.6	31.2
6	2.8	4.4	33.0
20	3.7	5.9	33.3
50	9.3	14.7	34.3

(Table 2). However, the extent of this influence decreases at $\tau > 300$ s, as it becomes probable at n = 60 rpm that the adsorption equilibrium can be disturbed and desorption processes can occur owing to the possible turbulent nature of motion of the solution [8]. Consequently, stirring of the solution enhances sorption (Table 2) and makes higher the rate constant of adsorption and the inner-diffusion coefficient (Table 3).

To partly lift the outer-diffusion limitations, it is suggested to agitate the solution at a rate of 6 to 50 rpm. The stirring raises the adsorption rate and the adsorption value, with only a slight increase in the free molar energy, which makes it possible to identify stirring as a factor that intensifies formaldehyde adsorption from an aqueous medium and to use it to develop promising technologies for wastewater purification to remove formaldehyde.

CONCLUSIONS

(1) Equilibrium, kinetic, and thermodynamic parameters of formaldehyde adsorption on clayey microporous minerals, montmorillonite, clinoptilolite, and palygorskite, were determined.

(2) Under the conditions of natural convection, the adsorption of formaldehyde occurs by the mixed-diffusion mechanism.

SORPTION AND ION-EXCHANGE PROCESSES

Extraction of Molybdenum(VI) from Aqueous–Peroxide Solutions of Sodium Tungstate with Trialkylamine

L. A. Voropanova and N. G. Barvinyuk

North-Caucasian State Technological University, Vladikavkaz, North Ossetia, Russia

Received August 8, 2003; in the final form, January 2004

Abstract—The extraction of molybdenum(VI) from aqueous–peroxide solutions of sodium tungstate with a trialkylamine–isooctyl alcohol mixture in kerosene was studied in relation to the ratio of the organic and aqueous phases, hydrogen peroxide and hydrogen chloride consumption, and the ratio of molybdenum(VI) and tungsten (VI) in the aqueous phase. A method for additional purification of the raffinate to remove molybdenum was developed.

In recovery of tungsten from its ore concentrates, along with the target metal, arsenic(V), phosphorus(V), silicon(IV), and molybdenum(VI) impurities also pass into the solution. This solution can be efficiently purified to remove As(V), P(V), and Si(IV) impurities by well-known methods widely used in industry [1]. In contrast to As(V), P(V), and Si(IV), the purification of W(VI) to remove molybdenum is a more difficult problem, especially at high W : Mo ratios. In order to meet the consumers' requirements, the Mo content in tungsten must not exceed 0.02%. A common technique for tungsten purification to remove molybdenum is based on Mo(VI) precipitation as sulfide MoS_3. However, this procedure does not ensure preparation of tungsten meeting the requirements with respect to molybdenum content. Furthermore, with this technique, 0.2–0.3% of WS_3 is lost due to the coprecipitation of MoS_3 and WS_3. One more drawback of this technique is the hydrogen sulfide liberation. The most efficient tungsten purification to remove molybdenum can be carried out by solvent extraction or ion exchange.

It is known that, in acidification of aqueous solutions containing Mo(VI) and W(VI), mixed polyoxyanions of these metals are formed. When the molybdenum content in these polyanions becomes considerably lower than the tungsten content, the species similar to W(VI)-containing polyanions are formed. The mixed Mo(VI)–W(VI) polyanions can be decomposed with H_2O_2. This agent is relatively cheap and does not contaminate solution with any impurities [2]. Since aqueous–peroxide solutions of W(VI) and Mo(VI) are stable at pH < 2, they can be processed by solvent extraction. For example, in extraction of W(VI) and Mo(VI) from aqueous–peroxide–nitric acid solutions at pH 0.4–0.9 with tributyl phosphate, W(VI) is separated from Mo(VI) with the separation factor $\beta_{Mo/W}$ of about 40 [3]. Currently the most efficient purification of tungstates to remove Mo(VI) is achieved by selective solvent extraction of thio species $[MoS_4]_2^-$ [4–6].

In this work we studied the solvent extraction of Mo(VI) from aqueous–peroxide solutions of Na_2WO_4–Na_2MoO_4 mixture with the Mo(VI) content not exceeding 1% relative to the W(VI) content.

The extraction system used in our experiments contained trialkylamine R_3N [R = $CH_3(CH_2)_6CH_2$, TAA, 7 vol %], isooctyl alkohol $C_8H_{17}OH$ (14 vol %), and kerosene as diluent. This extraction system is used for industrial recovery of W(VI) from aqueous solutions preliminarily decontaminated from impurities, among them from Mo(VI) [7].

The aqueous solutions of W(VI) and Mo(VI) were prepared from chemically pure grade sodium tungstate and molybdate $Na_2MO_4 \cdot 2H_2O$ (M = W, Mo). Immediately after preparation, 33% H_2O_2 was added to the solution and the resulting mixture was acidified with concentrated HCl to the required pH (0–0.7). The HCl amount required for acidification is dependent on the initial tungstate concentration. In the course of extraction, the required pH was maintained at a constant level. The extraction was carried out at continuous stirring of the organic and aqueous phases to attain the equilibrium. The W(VI) and Mo(VI) content in both the initial solution and raffinate was determined colorimetrically. Before analysis, the aqueous solution was boiled to decompose H_2O_2. The metal content in the extract was determined as the difference between its content in the initial solution and raffi-

nate. The efficiency of extraction of the metals was characterized by their distribution factors D (the ratio of the metal concentration in the organic and aqueous phase), degree of Mo and W separation $\beta = D_{Mo}/D_W$, and degree of recovery ε (wt % relative to the initial content).

The experimental results were statistically treated. The degree of W(VI) and Mo(VI) recovery was calculated from results of three parallel determinations. These results were characterized by the variance of reproducibility, S^2, accuracy of reproducibility S, and confidence interval at 0.95 confidence level X_m.

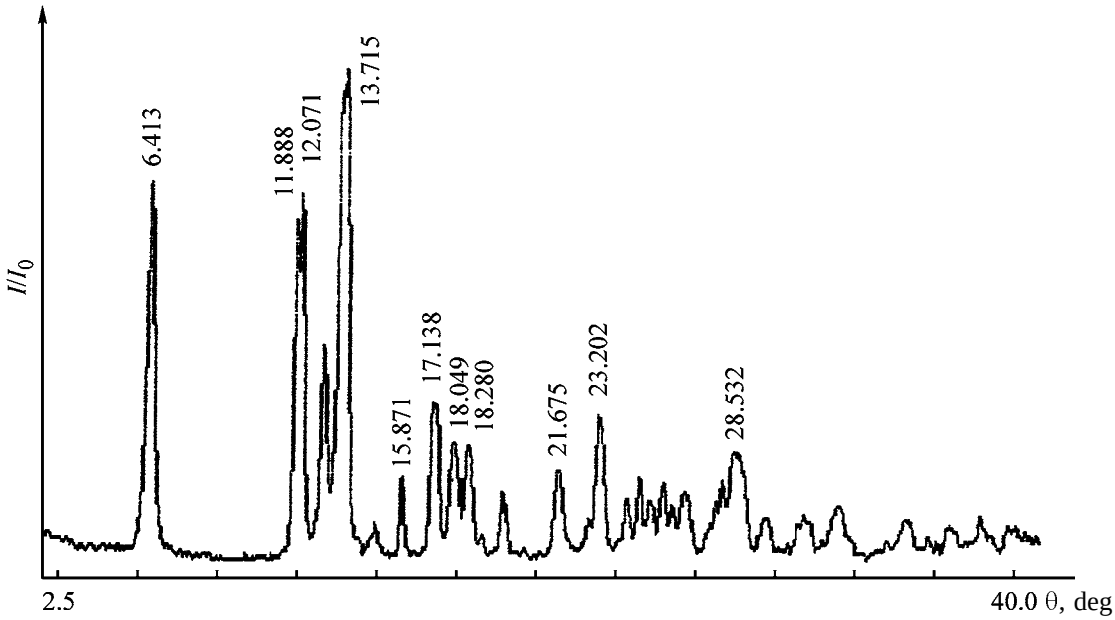
Parameter	Mo	W
S^2	0.737	0.985
S	0.858	0.992
X_m	±0.572	±0.662

In our experiments, the molybdenum(VI) impurity was extracted from aqueous solutions containing 120, 60, 30, 15, 10 and 5 g dm^{-3} W(IV) at the molar ratio W : Mo = 100 : 1. The extraction conditions and results are listed in Table 1.

With decreasing W(VI) concentration in the initial solution, the consumption of both H_2O_2 and HCl decreases. At the same time, the distribution factors of W(VI) and Mo(VI) increase and, as a result, the degree of the metal recovery grows. However, with increasing degree of tungsten recovery ε_W, the W(VI)/Mo(VI) separation factor β decreases. Thus, in extraction from highly concentrated solutions (C_W 120 and 60 g dm^{-3}), the separation of W(VI) from Mo(VI) is the most efficient, whereas the extraction from less concentrated tungsten(VI) solutions (C_W 30 g dm^{-3}) allows the maximal recovery of molybdenum(VI), with somewhat lower but still high separation factor β of molybdenum from tungsten. With further decreasing the W(VI) concentration, the separation factor sharply decreases.

For all the extraction systems, ε_W and ε_{Mo} increase with increasing extractant volume. With decreasing H_2O_2 concentration below its optimal value, the degree of the metal recovery decreases. In extraction of the metals in the absence of H_2O_2, colloids are formed, deteriorating the phase separation. This phenomenon is the most pronounced in extraction from concentrated metal solutions. Under these conditions, $\varepsilon_W > \varepsilon_{Mo}$ and $\beta < 1$. With increasing H_2O_2 content to 2 mol mol^{-1} W(VI) + Mo(VI), the extraction characteristics do not change noticeably.

With increasing HCl consumption, the H_2O_2 decomposition sharply accelerates, and the W(VI) and Mo(VI) peroxide complexes decompose. Under these conditions, tungstic and molybdic acids coprecipitate. With decreasing acidity of solutions, the Mo recovery ε_{Mo} virtually does not change, whereas the tungsten recovery ε_W strongly increases. We believe that such a behavior of W(VI) and Mo(VI) is due to the fact that, in strongly acidic solutions (pH < 0.5), nondissociated peroxy acids of Mo(VI) and W(VI) prevail, whereas at high pH partly protonated peroxyanions $HMoO_6^-$ and HWO_5^- are predominantly formed [8]. The conditions for extraction of the metals are the most favorable at pH corresponding to conversion of nondissociated species to their anionic forms. This transformation depends on the metal concentration: the lower the metal concentration, the faster is conversion and the higher the required pH. The large HCl consumption in the course of extraction of the metals is caused both by association of Cl^- with the peroxyanions HA^- and by recovery of HCl with TAA.



X-ray diffraction pattern of tungstic acid precipitated from a raffinate after extractive recovery of Mo(VI) from the initial solution containing W(VI) (30 g dm^{-3}) and Mo(VI) (0.3 g dm^{-3}). (I/I_0) Relative intensity and (θ) Bragg's angle.

We found that, on saturation of the extractant with Mo(VI), the ratio TAA : (W + Mo) = 1 : 0.35 remains constant irrespective of the metal content in the liquid phase. This fact shows that W and Mo are extracted in the form of an extractable complex of definite composition.

Table 1 shows that the recovery of Mo(VI) as a function of the tungsten concentration in the aqueous phase has a maximum at c_W = 30 g dm^{-3}. (ε_{Mo} = 78.87%). At this maximum, the extraction is characterized by fairly high separation factor $\beta_{Mo/W}$ = 29.19. Furthermore, at c_W = 30 g dm^{-3} the consumption of H_2O_2 and HCl can be decreased to 0.75 mol mol^{-1} (Mo + W) and 34.5 g dm^{-3}, respectively, and the ratio of organic and aqueous phases, to 1 : 4. These data show that the conditions for extraction separation of Mo(VI) from W(VI) are optimal at c_W 30 g dm^{-3} [9].

The extraction of Mo(VI) and W(VI) from aqueous–peroxide solutions with TAA–isooctanol in kerosene is described by following equations of the heterogeneous chemical reactions:

$$HA^- + (R_3NH)^+ \rightleftarrows (R_3NH)HA, \quad (1)$$

$$HA^- + H^+ + 2(R_3NH)HA \rightleftarrows [(R_3NH)HA]_2 \cdot H_2A, \quad (2)$$

where HA^- is HWO_5^- and HWO_6^-.

The extraction of the metals by the mechanism of the addition reaction (Eq. 2) is more characteristic of peroxomolybdic acid which is weaker than peroxotungstic acid. This difference allows the selective recovery of molybdenum impurities from concentrated Na_2WO_4 solutions. With increasing acidity, the dissociation of the peroxy acids is suppressed, which hinders the extraction of the metals by the mechanism of the addition reaction. At a very low Mo(VI) content, its extraction by this mechanism becomes insignificant. Therefore, on the phase contact for 30–45 min, when approximately one third of Mo(VI) remains in the aqueous phase (about 0.26% of c_W), the extraction of Mo(VI) stops, whereas the extraction of tungsten (ε_W) continues.

As noted above, the extraction of W(VI) from highly concentrated solutions is complicated by formation of poorly soluble WO_3 precipitate. This phenomenon can be used for additional purification of tungsten to remove molybdenum [10]. Once the main part of Mo(VI) is removed by extraction, tungstic acid precipitates, and, after a lapse of 2 days, about 92% of W(VI) and slightly more than 40% of Mo(VI) accumulate in the precipitate.

The figure shows the X-ray diffraction pattern (DRON-1 X-ray diffractometer, CuK_α radiation) of tungstic acid precipitated from a raffinate containing 120 g dm^{-3} W(IV) and 1.2 g dm^{-3} Mo(VI).

The relative reflection intensities I/I_0 and the interplanar spacings d calculated from the X-ray diffraction pattern are listed in Table 2 and are compared with those of both synthetic tungstic acid H_2WO_4 and tungsten trioxide WO_3.

This comparison shows (Table 2) that the structural parameters calculated from the most intense reflections

				1.709	8

in the X-ray diffraction patterns of both tungstic acid precipitated from a raffinate and synthetic tungstic acid are identical. At the same time, several weak reflections can be assigned to tungsten trioxide. According to X-ray phase analysis, tungsten precipitated from the raffinate consists to 89.82% of $H_2WO_4 \cdot H_2O$, with the remainder being WO_3.

After precpitation of tungstic acid, the raffinate contains H_2O_2 and HCl (pH ~0) and, therefore, it can be used as a leaching solution for processing of tailing piles and wastes, especially of those containing reduced tungsten and molybdenum species. Ammonium paratungstate (APT) can also be precipitated from this solution.

Spectrum analysis of tungstic acid and APT precipitated from the raffinate showed that these compounds contain no more than 0.016% Mo(VI). However, these compounds are contaminated with relatively large amount of sodium and chlorine impurities, which can be removed by repeated precipitation.

It should be noted that, in the course of extraction treatment of aqueous–peroxide solutions of sodium tungstate, TAA is converted to trialkylamine oxide due to reaction with hydrogen peroxide [11]. This oxidized extractant strongly binds molybdenum and especially tungsten. As a result, these metals gradually accumulate in the organic phase. It was found that Mo(VI) and a considerable part of W(VI) can be backwashed from these organic concentrates with aqueous NaOH, aqueous ammonia, and distilled water. Furthermore, the organic extract saturated with W(VI) and Mo(VI) can be used as a binder in solid-phase reduction of tungsten oxides [12]. To overcome the above-noted problems caused by accumulation of W(VI) and Mo(VI) in the organic phase, quarternary ammonium salts and neutral reagents like TBP can be used as extractants instead of TAA.

CONCLUSIONS

(1) With increasing W(VI) concentration in aqueous hydrogen peroxide solutions contaminated with Mo(VI), the extractive recovery of Mo(VI) impurities with trialkylamine decreases, whereas the separation factor of molybdenum(VI) from tungsten(VI) increases.

(2) After extractive removal of the main part of molybdenum(VI), W(VI) can be precipitated from the raffinate as tungstic acid, which allows the additional purification of tungsten(VI) to decrease the molybdenum(VI) impurity content in the target metal.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of How Copper Oxide Is Obtained on the Behavior of Copper Oxide Electrodes in Lithium-Ion Power Cells

S. P. Kuksenko

Vernadsky Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received December 2, 2003

Abstract—The electrochemical parameters of copper oxide electrodes in hermetically sealed lithium power cells were studied in relation to routes of copper oxide preparation, with the aim to diminish the share of side reactions.

Owing to high specific energy parameters, working voltage, and very low level of self-discharge, copper oxide–lithium (COL) power cells have long attracted the attention of development engineers and consumers as an alternative to silver–zinc (SZ) and mercury–zinc (MZ) power cells of cylindrical and button designs of various sizes [1, 2]. Recently, interest has been aroused in improvement of the fabrication technology of COL power cells in view of the increasing requirements to their electrical characteristics [3–5].

As the discharge capacity, the manner in which the voltage varies in the course of discharge, and the output power of COL power cells largely depend on how and under what conditions copper oxide is obtained, it is necessary to continue the search for industrially acceptable methods for preparing copper oxide and also for compositions of cathode pastes on its base that would ensure the required electrical parameters of the cells in various operation modes.

Presently, a wide variety of methods for obtaining copper oxide are known. These methods differ in the compositions of the starting substances and in conditions of their chemical and thermal treatment. However, there is no unambiguous published evidence that would make it possible to estimate the electrochemical parameters of copper oxide prepared by one or another technique as the active component of the positive electrode of COL power cells. Moreover, there are quite opposite assessments of the discharge characteristics of electrodes based on copper oxide obtained using the same starting substance under identical treatment conditions [3–12].

Studying the electrochemical behavior of electrodes based on copper oxide (or on other active materials suitable for fabrication of lithium power cells with a voltage of 1.5 V) involves a number of experimental difficulties because of the necessity for taking into account side reductive processes, which may occur at these electrodes under load (in contrast to oxidative processes at the cathodes of power cells with a voltage of 3 V, which occur at a higher rate under open-circuit conditions [13, 14]). Differing degrees of suppression of side processes can account for the discrepancies in the results of previous experiments.

In the present study, an attempt was made to examine the electrochemical characteristics of electrodes based on copper oxide obtained by different methods, with a minimized contribution from side reactions and electrodes operating in a mode as close as possible to that in lithium power cells working under real conditions.

EXPERIMENTAL

For fabricating copper oxide electrodes we chose copper oxide samples obtained by the following methods.

(1) Thermal decomposition of $Cu(NO_3)_2$. After preliminary drying at 105°C in a vacuum for 8 h in order to remove water of crystallization, copper nitrate was subjected to thermal treatment in air at 400°C for 8 h.

(2) Oxidation of Cu_2O. Copper(I) oxide was heated in an oxygen atmosphere to 400°C and kept at this temperature for 1 h.

(3) Thermal decomposition of $CuCO_3 \cdot Cu(OH)_2$. Copper hydroxycarbonate was dried in a vacuum at

1070-4272/04/7705-0763 © 2004 MAIK "Nauka/Interperiodica"

105°C for 8 h in order to remove water of crystallization and then heated in air to 400°C and kept at this temperature for 4 h.

(3a) The resulting copper oxide was additionally thermally treated in air at 800°C for 1 h.

(3b) Copper oxide was thermally treated at 800°C for 4 h.

(4) Oxidation of spherical copper particles in pure oxygen at 1000°C.

(4a) The resulting copper oxide was additionally thermally treated in air at 800°C for 1 h.

The completeness of conversion of the starting substances into copper oxide was verified by X-ray diffraction analysis, with monitoring the strongest lines.

Commonly, an electrically conducting additive, acetylene black [6–8] or graphite [3, 10, 11], is introduced in the electrode paste with copper oxide characterized by high electrical resistance [11]. In a number of studies [3, 6–8], a binder, Teflon, was also introduced into the paste (in [7], a carbon black hydrophobized with Teflon served as a filler); in [10, 11], no binder was used. It should be kept in mind, when choosing materials for an electrically conducting additive and a binder and deciding upon the amount of these, that these materials may be electrochemically active in the range of copper oxide reduction potentials. Indeed, studies of the cathodic behavior of various carbon materials point to their inherent electrochemical activity [15]. The discharge capacity of such electrodes is the higher, the greater the specific surface area of carbon, and it mainly depends on the structure of the amorphous region, rather than on the crystal structure. Use of a Teflon-containing binder in experiments concerned with the behavior of copper oxide electrodes cannot be considered justified because of the ability of this binder to be electrochemically reduced at potentials of 2.1–1.8 V relative to the lithium reference electrode Li/Li^+ under loads of 1–10 $\mu A\ cm^{-2}$ to give amorphous carbon [16–18]. An electrode made of a mixture of carbon black with 15 wt % Teflon discharged in a 1 M solution of $LiClO_4$ in propylene carbonate (PC) to a potential of 1.0 V with an output capacity of 120 $mA\ h\ g^{-1}$, whereas an electrode without Teflon produced only 8 $mA\ h\ g^{-1}$ under the same conditions [15]. A wave at a potential of 2.1 V was observed in the potentiodynamic curve of an electrode composed of a mixture of graphite with Teflon, measured in a 1 M solution of $LiClO_4$ in a mixture of PC and 1.2-dimethoxyethane (DME) in the first cathodic cycle. In [20], with a graphite electrode without binder in the same electrolyte, the cathodic wave appeared in the first cycle only at 0.8 V relative to Li/Li^+ [21].

In this study, the necessary electrical conductivity was ensured by mixing the copper oxide samples under study with powdered graphite of C1 brand in a weight ratio of 97 : 3 (which constituted approximately 92 : 8 v/v). Copper oxide electrodes without binder were compacted into pellets under a pressure of 2300 $kg\ cm^{-2}$. The absence of a binder did not impair the strength of the pellets and made it possible to raise the capacity of the copper oxide electrodes because of the increased content of the active substance. The pellets were placed in an evacuated cell and kept there at 300°C for 1 h in the atmosphere of dry argon.

The electrochemical behavior of copper oxide electrodes was studied in hermetically sealed cells with a lithium anode. In doing so, it is necessary to take into account the fact that, in the course of discharge, the copper oxide electrode grows in size (swells) because the volume of discharge products somewhat exceeds the initial volume of the electrode (theoretically, by 78%). The thickness of the electrode pellets was chosen so that the cells did not overcome their overall dimensions in discharge. In a hermetically sealed cell, the copper oxide electrode experiences a deficiency of electrolyte, in contrast to the case of tests in an electrochemical cell with an excess of electrolyte [6–8]. The procedure used in this study makes it possible to assess the electrochemical characteristics of copper oxide electrodes under the conditions close to those in practical use of COL power cells.

The anodes were fabricated as disks of rolled lithium. To diminish the contribution of the anode to the voltage drop across the cells in the pulsed mode of its discharge, an alloy of lithium with aluminum was formed on the anode surface, using the procedure described in [22]. The cells were fabricated with an excess of the anode capacity.

Previously, most of studies concerned with the electrochemical behavior of copper oxide electrodes have been performed with electrolytes containing PC (1 M $LiClO_4$/PC [6, 7] and 1 M $LiClO_4$/PC + DME [11]), which are the most readily available. According to [23], PC in 1 M $LiClO_4$/PC is reduced at potentials more negative than 1.3 V; at the same time, there have been numerous reports that a PC + DME mixed electrolyte is stable on a graphite electrode down to 0.8 V relative to Li/Li^+ (see, e.g., [21]). It should be taken into account that oxygen adsorbed by the electrically conducting carbon additive (more by acetylene black, than by graphite) and copper oxide, and also

dissolved in the electrolyte, is reduced at potentials of 2.0–1.8 V relative to Li/Li^+ unless special measures to remove it are taken. At potentials more negative than 1.3 V relative to Li/Li^+, water that was not removed in preparing the electrolyte undergoes reduction [23]. When the discharge behavior of copper oxide electrodes was studied in electrochemical cells with an excess of electrolyte [6–8], this had to lead to increased share of side reactions associated with reduction of oxygen and water dissolved in the electrolyte, in contrast to studies in which electrodes were tested in hermetically sealed lithium cells under the conditions of electrolyte deficiency [10, 11]. Thorough drying of the electrolyte and reliable sealing of a cell are also necessary because dehydrated copper oxide readily adsorbs water. In this study, a 1.4 M solution of $LiClO_4$ in a mixture of PC and DME (42 : 58 w/w) and water content of less than 30 ppm was used as an electrolyte. The electrolyte was subjected to an additional drying by a previously described procedure [24] and bubbled-through with dry argon to remove dissolved oxygen.

The cells were assembled in a glove box filled with dry argon. The results reported here were obtained with cells 9.5 mm in diameter and 2.10 mm high. Discharge curves of the cells were measured after 1 month of aging. The discharge was done through a continuous load of 30 kΩ with a pulsed load of 1 kΩ connected in parallel for 1 s once in 24 h. This procedure rules out any influence of side processes that occur in tests on a continuous high load (when the active cathode substance is reduced at lower potentials). To determine how the components of the total voltage drop across the cell in a pulse, ΔU_Σ, vary during discharge across a continuous load, the voltage drops across the cell were recorded as follows: at the instant of switch-on of the load, as a sum of ohmic components of the polarization resistances of both the electrodes and voltage drop in the interelectrode space, ΔU_r; 1 ms after the switch-on of the load, as a sum of activation polarizations of the electrodes, ΔU_a. The difference between ΔU_Σ and ΔU_r was regarded as a sum of the diffusion polarizations of both the electrodes, ΔU_d, at the end of the 1-s period of time. As the cells were fabricated with an excess of lithium and the type of the anode polarization had to be invariable in the course of the discharge, the relative changes in the electrochemical parameters of the cell were determined during the continuous discharge with the copper oxide electrodes.

The copper oxide electrodes used contain graphite as an electrically conducting additive. For this reason, to evaluate the contribution of side processes that occur at the copper oxide electrodes, cells with a graphite positive electrode containing no copper oxide were fabricated under the same conditions and discharged through a load of 30 kΩ. The capacity of such cells in discharge to a voltage of 1.0 V was less than 1.2 mA h (the corresponding discharge curve is represented by a dotted line in Fig. 1).

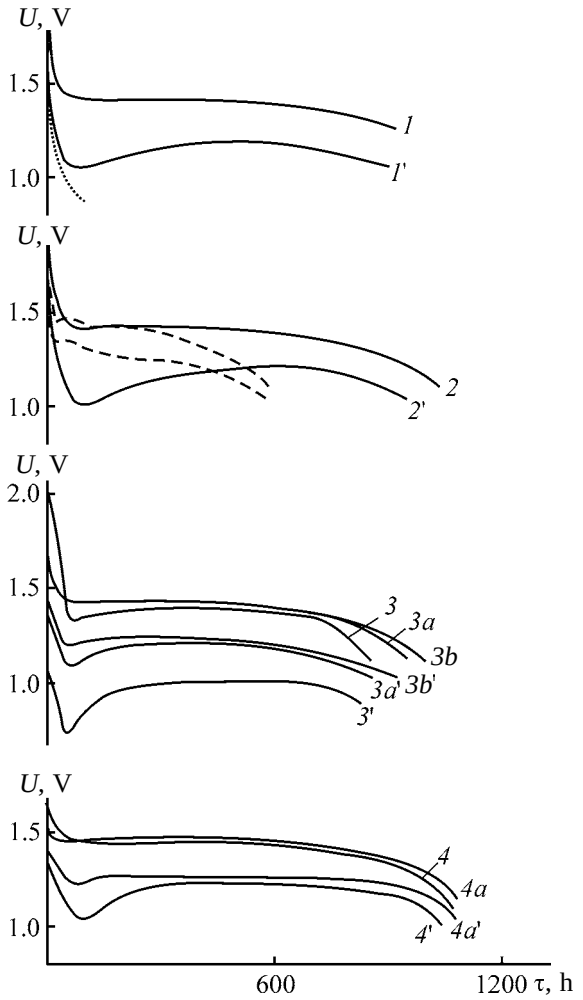

Fig. 1. (*1–4*, *3a*, *3b*, *4a*) Discharge curves of lithium power cells with a copper oxide cathode and (*1'–4'*, *3a'*, *3b'*, *4a'*) dependences of the cell voltage at the end of a load pulse on the duration of a continuous discharge. Cell size type 921, constant load 30 kΩ, pulsed load 1 kΩ s. (*U*) Voltage and (τ) duration of continuous discharge. Digits at curves: methods used to produce copper oxide. Dotted line: discharge curve of a cell with a graphite cathode; dashed lines: discharge curve of a cell with a Cu_2O cathode (upper) and dependence of the cell voltage by the end of a load pulse on the duration of a continuous discharge (lower).

Figure 1 shows the discharge curves and dependences of the cell voltage at the end of a load pulse on the duration of discharge for power cells with cop-

per oxide electrodes for which copper oxide was prepared using procedures 1–4a. The discharge capacity of a cell with copper oxide produced by method 1 was 42 mA h in discharge to a final voltage of 1.2 V, and 46 mA h, to 1.0 V. The utilization factor (UF) for copper oxide was 77 and 83%, respectively. This result is in agreement with the UF of 80% [11] obtained for copper oxide under similar conditions (in hermetically sealed cells of size type 1142 with a copper oxide electrode composed of a mixture of copper oxide obtained by decomposition of copper nitrate and 5 wt % graphite without a binder), but contradicts the data of [6]. According to [6], a copper oxide electrode composed of a mixture of copper oxide (also produced by decomposition of copper nitrate) and 33 wt % acetylene black and 17 wt % fluoroplastic binder is characterized by a UF of 40% for copper oxide in the case of its electrochemical reduction in an excess of electrolyte. Discharge curve 1 is characterized by a relatively prolonged transition portion before that of a stable working voltage, despite the low open-circuit voltage (OCV) of 1.98 V. The dependence of the cell voltage at the end of the pulse on the duration of a continuous discharge (curve *1*) shows a decrease in the pulsed voltage during the first several tens of hours, with the subsequent slow rise till approximately half of the total duration of discharge. The further run of the curve of the pulsed voltage corresponds to that of the discharge curve.

Of the 12 methods for obtaining copper oxide, studied in [6], the best was a short-time (1 to 3 h) oxidation of Cu_2O in an atmosphere of oxygen at 300–500°C. The thus obtained copper oxide had a UF as high as 92%, but the discharge characteristic of the electrode made of this material exhibited a prolonged transition region before a stable discharge plateau (with low average level of potentials of about 1.35 V). In the present study, copper oxide obtained using the same technique as that in [6] (method 2) differed only slightly in its electrochemical characteristics from copper oxide prepared by method 1. Its UF was found to be 79% in the case of cell discharge to 1.2 V (cell capacity was 43.5 mA h) and 89% in discharge to 1.0 V (49 mA h). In discharge curve *2*, as also in curve *1*, the voltage reaches a stable level in a relatively long time; curve *2*' shows, similarly to curve *1*', a decrease in the pulsed voltage in the first half of the discharge. Under the same testing conditions, Cu_2O was reduced in the case of a continuous load at the same potentials as copper(II) oxide synthesized from this material, but the cell with a Cu_2O cathode exhibited no dip in the curve for pulsed voltage (upper and lower dashed lines in Fig. 1, respectively) and was characterized by a lower OCV: 1.90 V, compared to 2.12 for the cell with a cathode made of copper oxide produced by method 2.

As follows from curves *3* and *3*', the cell with copper oxide prepared by method 3 is distinguished by an extremely high initial discharge voltage in discharge on a continuous load (the OCV of the cell was 2.56 V), a dip in curve *2* before the plateau, and the corresponding deep dip in curve *2*' for pulsed discharge. The cell capacity was relatively low: 38 and 41 mA h in discharge to 1.2 and 1.0 V, respectively. An X-ray phase analysis of the copper oxide produced by method 3 did not reveal presence of any other phases.

It is noteworthy that, under the experimental conditions of [6], the electrode based on copper oxide produced by thermal decomposition of copper hydroxycarbonate at 300°C in the course of 76 h also discharged at high initial potentials, but exhibited no stable discharge plateau and had high capacity, more than 90% of the theoretical value (calculated for the reaction of copper oxide reduction).

An even higher discharge capacity (99% of the theoretical value in discharge of the electrode to 1.0 V relative to Li/Li^+ with a current of 0.5 mA) was observed [7] for copper oxide produced by thermal decomposition of $Cu(OH)_2$ at 300°C for 2 h. The discharge curve of the electrode with copper oxide of this kind was also distinguished by a sloping run during the entire course of discharge. Prolonged heating of copper oxide samples decreased the discharge capacity and the reduction potentials of copper oxide electrodes. This was attributed to changes in nonstoichiometry upon removal of residual OH groups from the active form of copper oxide.

Curves *3a* and *3b* indicate that, under the experimental conditions, a prolonged thermal treatment of copper oxide at high temperature (1 and 4 h at 800°C, respectively) improved the electrochemical parameters of copper oxide electrodes. The continuous discharge of cells with thermally treated electrodes proceeded at higher stable voltage (with relatively low initial voltage). The cell capacity increased to, respectively, 43 and 45 mA h (in discharge to 1.2 V), and the OCV decreased to 2.16 and 2.06 V. However, the strongest positive influence was exerted by thermal treatment of copper oxide produced by method 3 on the dependences of the cell voltage by the end of a load pulse on the duration of a continuous discharge (curves *3a*', *3b*'). The average level at which these curves ran increased substantially and the dip in the pulsed voltage

in their initial portions decreased dramatically (more so for curve *3b*'). As the temperature and duration of thermal treatment increased, the peaks in the X-ray diffraction patterns of copper oxide samples became narrower and higher, which indicated that the grain size increased and the crystal lattice perfection was improved.

The positive influence of a prolonged thermal treatment of copper oxide on the specific capacity of copper oxide was observed in [9]: the specific capacity of electrodes based on industrial copper oxide increased from 150–300 to 550 mA h g^{-1} after its thermal treatment in air for 16 h. A correlation was revealed between the ratio of CuO and Cu_2O peak intensities for copper oxide samples and the specific capacity of the electrodes. The specific volume capacity of the electrodes based on industrial copper oxide increased by 50–70% on heating copper oxide samples to 600–800°C followed by fast cooling (quenching) [4]. This was attributed to the appearance of an oxygen nonstoichiometry.

The relatively high electrochemical parameters in a continuous discharge were observed for a cell with copper oxide produced by high-temperature oxidation of spherical copper particles (method 4). The cell had a relatively stable discharge voltage with an average value of 1.40 V (Fig. 1, curve *4*) and high capacity of 48 and 51 mA h in discharge to 1.2 and 1.0 V, respectively. The OCV of the cell was 2.05 V. It is noteworthy that the discharge of a cell with copper oxide produced by controlled oxidation of copper particles (of a certain size and shape) at 400°C [10] proceeded at an average voltage of 1.4 V (at the same current density) and high output capacity, but the discharge curve differed from that obtained in this study in the longer time in which the stable voltage plateau was reached and higher value of OCV of 2.3 V. Under other experimental conditions, a copper oxide electrode made of a copper powder oxidized in air at 400°C for 1 h discharged at an average potential of 1.35 V and a UF of about 78%, and upon oxidation for 10 h, at 1.2 V and UF of 50% [6]. As can be seen from curve *4*' in Fig. 1, short-time oxidation of spherical copper particles by method 4 also leads (as also do methods 1–3) to a dip in the curve for the pulsed voltage in the initial stage of discharge of a COL cell through a continuous load.

Figure 2 shows how the overall voltage drop under pulsed load and its components vary in discharge of the given cell through a continuous load. It can be seen that, in the initial stage, the major contribution to the overall voltage drop comes from the diffusion component, which grows until the cell discharges by approximately 10% relative to the total duration of discharge. Also grows during this period of time the ohmic component, and the activation component does not change its sign. Further, the diffusion and activation components decrease and, after 1/4 discharge of the cell, remain virtually unchanged till 4/5 of the total discharge duration is reached. In the process, the ohmic component makes the most pronounced contribution to the overall voltage drop. In the final stage of discharge, the diffusion component again grows and, at the end of the discharge process, much exceeds the activation and ohmic components.

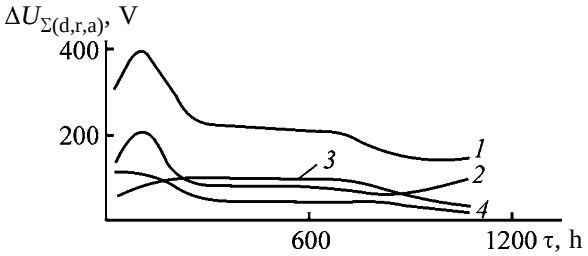

Fig. 2. Variation of the overall voltage drop and its components (diffusion-related, ohmic, activated) $\Delta U_{\Sigma(d,r,a)}$ under pulsed load in discharge through a continuous load of a cell with copper oxide produced by method 4. (τ) Duration of continuous discharge. (*1*) ΔU_{Σ}, (*2*) ΔU_{d}, (*3*) ΔU_{r}, and (*4*) ΔU_{a}.

Curve *4a*' in Fig. 1 shows that additional thermal treatment of copper oxide results in that both the depth and the duration of the dip in the curve for the pulsed voltage decrease substantially. Further discharge of the cell was more stable and proceeded with a higher pulsed voltage. The cell with such a copper oxide was distinguished by a lower OCV of 1.90 V and higher discharge capacity of 50 and 52 mA h in discharge to 1.2 and 1.0 V, respectively. In discharge to 1.2 V, the specific discharge capacity of the copper oxide electrode was 625 mA h g^{-1}, and the UF of copper oxide, 95%. The cell voltage in continuous discharge rapidly reached a stable level (Fig. 1, curve *4a*) at a relatively high average discharge voltage of 1.43 V. In addition, curve *4a* is characterized by a rather strong bend at the end of discharge (the capacity in discharge to a final voltage of 1.35 V was 44 mA h, i.e., 88% of the capacity in discharge to 1.2 V). It was found that a minor dip in the curve for pulsed voltage in the initial stage of a continuous discharge is also associated with the corresponding change in the diffusion component of the overall voltage drop. In the plateau in the dependence of the pulsed voltage on the duration of a continuous discharge, the diffusion and ohmic components were

virtually the same. The X-ray diffraction pattern of a copper oxide sample subjected to an additional thermal treatment showed no peaks of copper(I) oxide, which were observed in the X-ray diffraction pattern of the initial copper oxide sample.

Discharge curves of COL cells are distinguished by a common feature: the longer the delay of the initial voltage in a continuous discharge, the deeper the dip in the curve describing the dependence of the pulsed voltage on the duration of the continuous discharge. This phenomenon is associated with the state of the surface of copper oxide, which depends on the method by which it is produced and on the mode of its further thermal treatment. In a discharge of a copper oxide electrode, lithium cations are introduced into the monoclinic lattice of copper oxide to give $Cu^{II}_{1-x}Cu^{I}_{x}Li_{x}O$ [8]. The reaction occurs at places of contact between copper oxide particles and particles of the distributed current lead (graphite in the given case). This process is preceded by reduction of surface groups, which are inevitably formed when copper oxide is obtained and processed using the methods described here. Possibly, residual OH groups can catalyze reduction of Teflon from a Teflon-containing carbon black and reduction of PC. This probably accounts for the high capacity and discharge potentials of continuously loaded electrodes with copper oxide produced at a relatively low temperature and short time of thermal treatment [6, 7].

In electrochemical reduction of surface groups, a layer of a lithium-conducting solid electrolyte grows on copper oxide particles and the diffusion of lithium cations across this layer is slow. Also slow is the diffusion of lithium cations into the particles via formation of an intermediate compound $Cu^{II}_{1-x}Cu^{I}_{x}Li_{x}O$, whose subsequent reduction gives Cu and Li_2O or Cu_2O and Li_2O [8] and results in disintegration of the primary film of the solid electrolyte under the action of mechanical stresses. In the same range of potentials, Cu_2O enters into an electrochemical reaction (being reduced to Cu and Li_2O). The rise in the diffusion polarization of the electrode in the final stage of the discharge is due to exhaustion of the electrolyte within the micropores of the swollen cathode. According to [7], the removal of chemically bound water and oxygen from copper oxide samples obtained from $Cu(OH)_2$ continues at above 500°C. Controlled oxidation of spherical copper particles at a high temperature in pure oxygen rules out any involvement of water molecules in the synthesis process.

Hydrogen-containing groups on the surface of copper oxide particles presumably appear in the contact of these particles with the ambient atmosphere. Prolonged high-temperature treatment of copper oxide samples in air largely removes the surface groups, improves the crystal perfection, and gives rise to a mosaic structure of grains, which facilitates diffusion of lithium cations into the particles in the course of electrochemical reduction. This leads to a high and stable voltage in discharge through a continuous load and to a pronounced stabilization of the pulsed voltage. Additional ways to completely eliminate the dip in the curve for the pulsed voltage in the initial stage of discharge are to be sought for. Preliminary experiments demonstrated that one of the possible ways is incorporation of lithium into copper oxide in high-temperature treatment with lithium carbonate.

CONCLUSIONS

(1) In studying the electrochemical parameters of copper oxide electrodes, it is necessary to take into account the influence of side reactions that involve the electrically conducting carbon additive, Teflon binder, oxygen, and water.

(2) Under testing conditions that are close to real working conditions of copper oxide–lithium power cells, the highest electrochemical parameters are ensured by copper oxide produced by high-temperature oxidation of spherical copper particles in pure oxygen.

(3) Prolonged high-temperature treatment of copper oxide in air improves the electrical parameters of power cells, but fails to completely eliminate the dip in the curve for the pulsed voltage in the initial stage of discharge through a continuous load.

CATALYSIS

Origin of the Activity of Hydrogenation Catalysts Based on Palladium Complexes and Primary Phosphines

L. B. Belykh, T. V. Goremyka, and F. K. Shmidt

Irkutsk State University, Irkutsk, Russia

Received December 3, 2003

Abstract—The activity of the catalytic system based on palladium bisacetylacetonate and phenylphosphine in hydrogenation catalysis was studied.

The unique capability of transition metals to catalyze hydrogenation of unsaturated organic molecules with gaseous hydrogen is known for a long time and is used in numerous industrial processes [1–3]. Among Group VIII transition metals, much attention is given to palladium-based catalysts. Modification of palladium with nitrogen-containing compounds (quinoline, ethylenediamine, alkaloids) allows preparation of highly selective catalysts for hydrogenation of alkynes, chemoselective hydrogenation of unsaturated aldehydes and ketones, enantioselective hydrogenation of derivatives of α,β-unsaturated acids, etc. [1, 2]. Along with studies of heterogeneous supported palladium catalysts, active efforts have been made in the past three decades to elucidate factors responsible for the activity of palladium complexes with phosphine ligands as hydrogenation catalysts. Whereas the modifying effect of tertiary [4–7] and secondary [8] phosphines on the properties of palladium complexes as hydrogenation catalysts has been studied in detail, primary phosphines have not yet been used in hydrogenation catalysis. Interest in these systems is due to the fact that primary phosphines exhibit simultaneously the properties of Lewis bases and Brønsted acids. Furthermore, primary phosphines, like other three-coordinate phosphorus compounds, are reductants.

The goal of this work was to gain insight into the promoting effect of PH_2Ph in a microheterogeneous hydrogenation catalyst based on $Pd(acac)_2$.

EXPERIMENTAL

The solvents were purified by standard procedures used in organometallic chemistry [9].

Palladium bisacetylacetonate was prepared according to [10].

Phenylphosphine was prepared by reaction of phenylchlorophosphine with lithium aluminum hydride [11] and isolated by vacuum distillation (38°C/5 mm Hg). ^{31}P NMR: δ –122 ppm ($^1J_{PH}$ 200 Hz). The compound was stored in a sealed ampule under argon.

The catalyst based on $Pd(acac)_2$ and PH_2Ph was prepared as follows. To a solution of 0.00304 g (1×10^{-5} mol) of $Pd(acac)_2$ in DMF, prepared in a duck-shaped vessel that had been evacuated and filled with hydrogen, 1 ml of a phenylphosphine solution was added; the P/Pd ratio was 0.1–2.0. The lemon-yellow reaction mixture was stirred in a hydrogen atmosphere at 80°C for 5–15 min. The resulting black-brown "solution" was cooled to 30°C, and a substrate to be hydrogenated was introduced with a syringe. Hydrogenation was performed with vigorous stirring at the initial hydrogen pressure of 1 atm. The reaction progress was monitored volumetrically and by GLC.

Acetylacetone and benzene in the catalyzate were determined by GLC, after evaporation–condensation of the solution in a vacuum unit (20°C/1×10^{-3} mm Hg), on a Chrom-5 chromatograph equipped with a 3.6-m packed column (stationary phase SE-30) and flame ionization detector. The column temperature was 100°C, and the carrier gas was nitrogen. The error in determination of acetylacetone and benzene did not exceed 10%.

The UV spectra were recorded on a Specord UV VIS spectrometer in an all-sealed cell. The concentration of $Pd(acac)_2$ was calculated from the absorption band at 330 nm (ε_{330} = 10 630 l mol^{-1} cm^{-1}), and that of acetylacetone, from the band at 290 nm [for Hacac, ε_{290} = 5000, and for $Pd(acac)_2$, 3090 l mol^{-1} cm^{-1}].

X-ray phase analysis of the catalyst samples was performed on a DRON-3M diffractometer, CuK_α

1070-4272/04/7705-0770 © 2004 MAIK "Nauka/Interperiodica"

radiation. The procedure for determination of Pd(0) was described in [12].

We showed previously that palladium bisacetylacetonate, like palladium(II) acetate [13], is not reduced with hydrogen in aprotic solvents (benzene, toluene) below 80°C in the absence of water. We found that water breaks down the oligomeric species $[Pd(acac)_2]_n$ preserved upon dissolution in benzene and facilitates heterolytic cleavage of the hydrogen molecule. The hydrogenolysis of $Pd(acac)_2$ in DMF occurs under milder conditions. At 30°C, it takes no less than 2 h, whereas at 80°C it is complete in 5–15 min depending on the Pd(II) concentration.

The initial rate of styrene hydrogenation in the presence of the thus generated Pd black is relatively low, and the maximal specific activity W does not exceed 19 mol of styrene per mole of Pd per minute. At low initial concentrations of $Pd(acac)_2$, the catalyst undergoes rapid deactivation in the course of hydrogenation (Table 1). Introduction of water enhances the performance of Pd black.

To obtain a more effective catalytic system, we used PH_2Ph as modifier. Catalytic hydrogenation of styrene in the presence of the system based on $Pd(acac)_2$ + $n PH_2Ph$ (P/Pd = 0.3, 1.0, 2.0) at 30°C in DMF is characterized by a long induction period (40 min) and low reaction rate. The catalyst that is the most active in hydrogenation is formed after preliminary reaction of the system components, $Pd(acac)_2$ + $n PH_2Ph$, with H_2 in DMF at 80°C for 5–15 min. The catalytic system exhibits the highest performance at the $PH_2Ph : Pd(acac)_2$ ratio of 0.3 (Fig. 1).

The specific activity of the system $Pd(acac)_2$ + $0.3PH_2Ph$ does not change upon hydrogenation of no less than 3000 mol of styrene per mole of Pd, after which the activity gradually decreases with formation of a precipitate. The reaction rate as a function of the catalyst concentration nonlinearly grows in the range 0.5–2 mM and starts to decrease at $c_{Pd} > 1.4$ mM (Fig. 2).

In hydrogenation of other unsaturated hydrocarbons and of carbonyl and nitro compounds, the system under consideration also shows high activity and selectivity (Table 2).

In reduction of benzaldehyde on palladium catalysts (Pd/C), the C–O bond in the forming benzyl alcohol usually undergoes further hydrogenolysis, with the rates of both steps being comparable [2]. At the same time, the selectivity of the system $Pd(acac)_2$ + $0.3PH_2Ph$ in benzaldehyde hydrogenation reaches 92%. Nitrobenzene is usually selectively reduced to aniline on palladium catalysts. The advantage of our catalyst is the high reaction rate. The specific activity of our catalyst in reduction of the nitro group exceeds by a factor of 3.5 that of Pd nanoparticles immobilized on the styrene–divinylbenzene copolymer [14] but is lower than that of the Pd catalyst with diphenylphosphine [8].

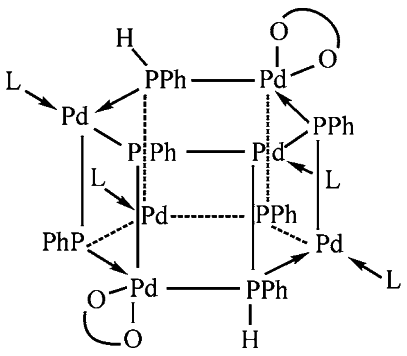
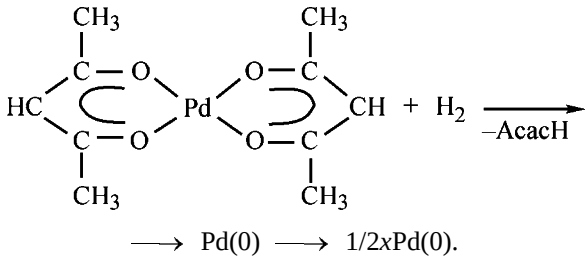
Phenylphosphine, in contrast to tertiary phosphines, exhibits both base and acid properties. The previous study of the reaction of $Pd(acac)_2$ with PH_2Ph in benzene and DMF in an inert atmosphere [15] showed that the reaction went beyond simple complexation and was accompanied by fast exchange of acetylacetonate ligands for organophoshorus groups, yielding acetylacetone and polynuclear palladium complexes containing μ_3-PPh, μ_2-PHPh, and coordinated PH_2Ph ligands, and also *O*,*O*-chelate acetylacetonate ligands, like



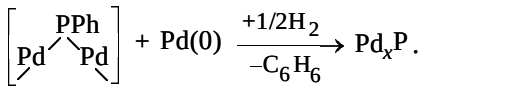
where L = PH_2Ph.

The reaction is complete in 2–3 min. At the P/Pd ratio of 0.3, upon ligand exchange, about 15% of Pd appears in the form of polynuclear complexes, and 85%, in the form of $Pd(acac)_2$. The degree of conversion of $Pd(acac)_2$ to the reaction products grew with an increase in the P/Pd ratio. Quantitative formation of acetylacetone was observed at P/Pd > 2.

Additional treatment of the system $Pd(acac)_2$ + $n PH_2Ph$ with hydrogen results in quantitative formation of acetylacetone (Table 3), i.e., not only $Pd(acac)_2$ but also acetylacetonate ligands incorporated in polynuclear Pd complexes are subject to hydrogenolysis. The catalyzate from the reaction with H_2 contained not only acetylacetone but also benzene originating from decomposition of the organophosphorus ligands. The amount of benzene formed per mole of PH_2Ph grows as the P/Pd ratio is decreased. The content of $Pd(acac)_2$ grows in the same direction. Similar trends were observed with triphenylphosphine [5]. The observed dephenylation is consistent with the previously proposed mechanism according to which degradation of organophosphorus ligands occurs in the coordination sphere of Pd(0) [8]; therefore, the mechanism of benzene formation in the system can be tentatively presented as follows.



$Pd(acac)_2$ is readily reduced with hydrogen in DMF at 80°C to Pd(0). The Pd(0) atoms arising from hydrogenolysis of $Pd(acac)_2$ can both aggregate to form palladium clusters and react with phenylphosphinylidene ligands in polynuclear palladium complexes. Oxidative addition of Pd(0) to these complexes with hydrogenolysis of the P–C bond yield benzene and, probably, palladium phosphides:



Elemental analysis of the black precipitate (sample 1) isolated from the reaction system $Pd(acac)_2$ + $0.3PH_2Ph$ + H_2 corresponds to the empirical formula $Pd_8P_1C_1H_1$, and the content of Pd(0) determined chemically does not exceed 28%. According to X-ray phase analysis, sample 1 is elemental palladium in the dispersed state; the size of its coherent scattering domain, as estimated from the shape of the Pd line *hkl* 111, is 2 nm. We believe that the results of X-ray phase and elemental analyses do not contradict each other. Sample 1 may contain higher palladium phosphides in the X-ray amorphous state for which the main reflections are observed in the same region as for elemental palladium and overlap with the broadened Pd(111) line. It should be noted that the products formed by the components of the catalytic system in an inert atmosphere, associates of polynuclear palladium complexes, were X-ray amorphous, giving a diffuse maximum (halo) at d/n = 13.556 Å; the size of coherent scattering domains was 2.7 nm. The absence of an amorphous halo at small diffraction angles ($2\theta = 5°–40°$) in the diffraction pattern of sample 1 indicates that the structure of polynuclear palladium complexes is broken down upon treatment of the catalytic system with hydrogen.

It was shown previously that the catalytic activity of the system $Pd(acac)_2$ + $n PPh_3$ in hydrogenation of phenylacetylene was maximal at the P/Pd ratio of 0.3 also [16], and the solid reaction products identified were palladium phosphide Pd_3P and crystalline Pd. However, whereas formation of the system with triphenylphosphine took no less than 24 h, with phenylphosphine the formation time was as short as 5 min.

Our results suggest that, in the course of formation of the catalytic system based on $Pd(acac)_2$ at P/Pd = 0.3, phenylphosphine acts as a structural promoter. Its effect can be described as follows. The reaction of PH_2Ph with $Pd(acac)_2$ yields nanosized associates of polynuclear palladium complexes with organophosphorus ligands. The associates of the polynuclear palladium complexes and palladium phosphides formed in an H_2 atmosphere by decomposition of organophosphorus ligands act as crystallization centers for immobilization and growth of Pd(0) clusters. At higher P/Pd ratios, the content of Pd(I) and Pd(II) complexes with phosphorus-containing ligands increases relative to Pd(0), and the catalytic activity of the system decreases.

CONCLUSIONS

(1) A new high-performance catalyst based on $Pd(acac)_2$ and PH_2Ph was suggested for hydrogenation of unsaturated bonds and of carbonyl and nitro groups.

(2) Transformations of the catalytic system $Pd(acac)_2$ + $n PH_2Ph$ in hydrogen yield nanosized particles (2 nm) containing elemental palladium and, probably, palladium phosphides. Associates of polynuclear palladium complexes and palladium phosphides are crystallization centers for immobilization and growth of Pd(0) clusters. Phenylphosphine acts as a structural promoter.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Activated Carbons from Waste Wood in Wastewater Treatment To Remove Surfactants

A. O. Eremina, V. V. Golovina, M. Yu. Ugai, and A. V. Rudkovskii

Institute of Chemistry and Chemical Technology, Siberian Division, Russian Academy of Sciences, Krasnoyarsk, Russia

Received December 25, 2003

Abstract—Activated carbons synthesized by steam–gas treatment of charcoal produced from wastes formed in cutting of mixed wood were tested in adsorption of surfactants from aqueous solutions: anionic (Volgonat, Uglepen, neutralized black catalyst) and cationic (Katamin AB). Isotherms of adsorption of these impurities are presented, and a flowsheet of step-by-step wastewater treatment to remove surfactants by adsorption is suggested.

A search for effective methods for wastewater treatment to remove various organic and inorganic impurities is one of the most important problems of environment protection. Among the known contaminants are surfactants, which are widely used in the industry and in households. The problem of wastewater treatment is complicated by the wide variation of the concentration of surfactants: from 20–30 mg l^{-1} in household wastes to 50–1000 mg l^{-1} in industrial wastewater. Particularly severe difficulties are encountered at the very plants that manufacture surfactants because the concentration of surfactants in wastewater is subject to wide fluctuations, which requires that systems for local purification of process wastewater should be created.

Various techniques have found application in the practice of wastewater treatment to remove surfactants: foam separation, pressure flotation, ion exchange, biological treatment, and also membrane, adsorption, destructive (thermal detoxication, ozonation, radiation treatment) and other methods [1, 2]. The efficiency of these techniques depends on a multitude of factors. For example, the key part in adsorption purification is played by the choice of an adsorbent. Surfactants are commonly adsorbed, depending on their nature and concentration in wastewater, with peat, slag, undersized low-temperature coke, limestone, clayey minerals, zeolites, etc. [3]. In the process, the adsorbents are rather rapidly deactivated, which is caused, among other factors, by adsorption of other organic impurities. Activated carbons of various brands, which can be used for adsorption of surfactants, are manufactured in limited amounts by outdated technologies and their cost is high. Rather economical should be use of low-cost adsorbents manufactured from wastes of wood and woodworking industries. This would simultaneously allow utilization of waste wood, which is an important environmental problem.

This study is concerned with purification of aqueous solutions to remove surfactants by adsorption on activated carbons manufactured by steam–gas activation of charcoal that is produced from wastes formed in cutting of mixed wood.

EXPERIMENTAL

As raw materials for manufacture of activated carbons served charcoal produced from waste birch and aspen wood: branches, offcut, and crown posts.[1] The charcoal was produced on a UVP-5B installation. Further, the charcoal was subjected to a steam–gas activation in a fluidized-bed reactor at 850°C for 0.5 h; the content of oxygen and steam in the steam– gas mixture was 5 and 35%, respectively. The commercial fraction of the activated carbon with a particle size of more than 1 mm was isolated from the overall activated product. The yield of the commercial fraction was more than 80%. The main characteristics of the charcoal and of the activated carbon manufactured from it are listed in Table 1. The basic physicochemical and adsorption properties were determined using the known methods [4, 5].

Prior to tests, the activated carbons were dried at

[1] The basin of the Biryusa River in Krasnoyarsk krai.

Bulk density, kg m^{-3}	223	186
Total pore volume, cm^3 g^{-1}	0.06	1.80
Adsorption capacity:		
for iodine, %	6.5	63
for Methylene Blue, mg g^{-1}	12.9	77

105–110°C for 2 h and cooled in a desiccator over a drying agent, and their samples (0.1 to 10 g) were weighed with an accuracy of 0.2 mg. Then the activated carbons were saturated with water vapor. For this purpose, the samples were placed in a vessel with the air humidity of 98–99% (over a saturated solution of sodium carbonate) at 40°C and kept under these conditions for 3 h.

The samples of activated carbons were placed in flasks with ground-glass stoppers, each with 150 ml of an aqueous solution of a surfactant, and the flasks were gently shaken for 48 h. The aqueous solution was separated by centrifugation and the residual content of a surfactant was determined by photometry [6].

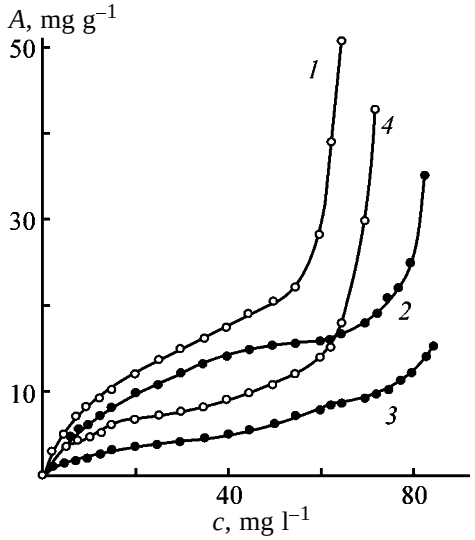

Fig. 1. Isotherms of adsorption *A* of surfactants on activated carbon. (*c*) Equilibrium concentration of surfactants. Surfactant: (*1*) Volgonat, (*2*) Uglepen, (*3*) neutralized black catalyst, and (*4*) Katamin AB; the same for Fig. 2.

Aqueous solutions of anionic (Volgonat, Uglepen, neutralized black catalyst) and cationic (Katamin AB) surfactants with an initial concentration of the main substance of 100 mg l^{-1} were used in the tests.

Figure 1 shows isotherms of adsorption of the surfactants on activated carbons. The isotherms of adsorption have the same shape for all the surfactants and belong to type II by the BET classification [7]. This indicates that the mechanisms of adsorption of the surfactants of varied nature are the same and that the activated carbons contain, together with micropores, also a considerable amount of meso- and macropores. This conclusion is confirmed by the following data: the total volume of pores is 1.80 cm^3 g^{-1} (Table 1), and the volume of micropores, 0.28 cm^3 g^{-1}.

Several regions can be distinguished in the isotherms of adsorption. The first, initial, portion has a convex shape and is due to electrostatic adsorption of separate anions (cations) of a surfactant by positively (negatively) charged centers on the surface of the activated carbons. Raising the concentration of a surfactant leads to enhancement of the mutual attraction of the hydrocarbon radicals in the anions (cations) of the surfactants and to the onset of association in the adsorption layer. In the third region of the isotherms, the rise in adsorption with increasing concentration of a surfactant gradually becomes less pronounced. This is presumably due to increased density of surface filling with adsorbed anions (cations) of the surfactants, to enhanced association of the hydrocarbon radicals and stronger forces of electrostatic repulsion between likely charged anion (cation) groups of the surfactants, and to a change in the sign of the charge at the phase boundary as a result of adsorption (through the van der Waals forces) of the nonpolar part of anions (cations). The fourth region of the isotherms, in which they form nearly a plateau, is due to complete coverage of the surface of the activated carbon with ionic associates or to the fact that the activity of unassociated anions (cations) of the surfactants remains constant despite the increase in the total analytical concentration of these substances. The steep rise exhibited by the isotherms is probably due to formation of a polymolecular adsorption layer, 3D association in the system, and dramatic increase in the enthalpy (build up of the entropy) because of the disintegration of the structure of water around the molecules being associated [3].

The efficiency of purification of contaminated water to remove anionic surfactants decreases in the order Volgonat > Uglepen > neutralized black catalyst. The cationic surfactant, Katamin AB, occupies an

Table 2. Expenditure of the activated carbon in multistage adsorption of surfactants ensuring 99% degree of purification

Surfactant	Expenditure of activated carbon, kg m^{-3}, at indicated number of stages (adsorbers)		
	1	2	3
Volgonat	33.00	11.25 + 3.00 = 14.25	6.76 + 4.25 + 0.67 = 11.68
Uglepen	45.00	15.00 + 4.09 = 19.09	8.25 + 4.48 + 0.91 = 13.64
Neutralized black catalyst	82.50	45.00 + 7.50 = 52.50	22.86 + 12.14 + 1.67 = 36.67
Katamin AB	49.5	20.00 + 4.50 = 24.50	11.76 + 5.31 + 1.00 = 18.07

intermediate position between the last two anionic surfactants: Uglepen and neutralized black catalyst.

The expenditure of activated carbon does not exceed 8–10 kg m^{-3} in purification to remove Volgonat and Uglepen, 15–20 kg m^{-3} in removing Katamin AB, and 25–30 kg m^{-3} for neutralized black catalyst, at a degree of purification of 85–90% (Fig. 2). If 99% purification is required, the expenditure of the activated carbon increases dramatically (Table 2).

The expenditure of the activated carbon can be decreased by performing a step-by-step purification by adsorption in a system of in-series connected adsorbers. In performing the adsorption process in two stages, the concentration of a surfactant in the aqueous solution was to be decreased tenfold, i.e., from 100 to 10 mg l^{-1}, in the first stage and completed, with the concentration of the surfactant diminished from 10 to 1 mg l^{-1} (permissible concentration of a surfactant for industrially used water), in the second. In performing the adsorption in three stages, the surfactant concentration in the aqueous solution was to be decreased from 100 to 20 mg l^{-1} in the first stage, from 20 to 3 mg l^{-1} in the second, and from 3 to 1 mg l^{-1} in the third.

With the two-stage scheme of purification applied, the expenditure of the activated carbon decreases by 36–57% as compared to the single-stage scheme, and with the three-stage scheme, by 16–29% as compared to the two-stage scheme and by 56–70% as compared to the single-stage scheme. As the adsorption capacity of the activated carbon in the first adsorber is exhausted, the adsorber is discharged, filled with a fresh portion of the activated carbon, and connected as the last stage in the system of adsorbers. Naturally, the increasing number of stages (i.e., assembling of additional adsorbers) leads to a directly proportional rise in the cost of the installation. Thus, the introduction of each new stage (if more than two) requires a thorough feasibility study.

It is inexpedient to regenerate spent activated carbon because of its low cost and a dramatic decrease in its mechanical strength upon regeneration. Therefore, it is recommended to burn spent activated carbons in power installations as an improved solid fuel.

Wastewater from a mechanized laundry and a plant for dry-cleaning and dyeing of clothes was purified under laboratory conditions. This was done on an activated carbon from waste wood in a flow-through installation at a specific load of 8–10 h^{-1} (adsorber 40 mm in diameter and 450 mm long). The input wastewater had the following composition (mg l^{-1}): anionic surfactants 52–130, phenols 0–5, chemical oxygen demand 1020–1200 mg O/l. After filtration across a bed of activated carbon, the concentrations of these impurities decreased dramatically to become as follows (mg l^{-1}): anionic surfactants 0.5–2.0, phenols 0–0.01, chemical oxygen demand 510–560 mg O/l. The concentrations of the contaminants in the purified wastewater exceed those permissible for water to be discharged into open water basins, but well conform

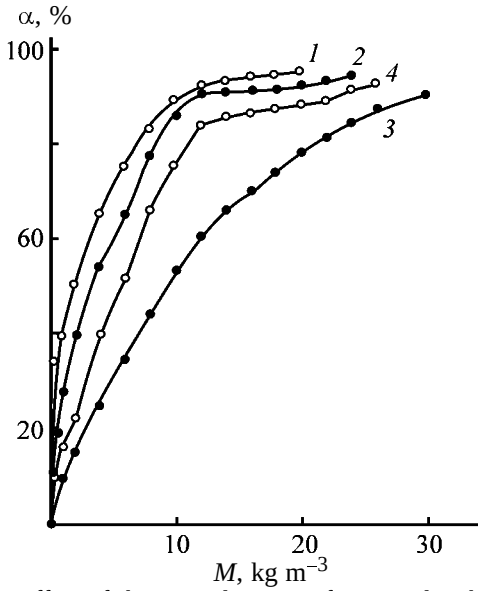

Fig. 2. Effect of the expenditure M of activated carbon on the degree α of purification of aqueous solutions to remove surfactants.

to the regulations concerning discharge of wastewater into municipal sewers for subsequent additional purification.

CONCLUSION

A rather high efficiency of purification of wastewater from some service plants was demonstrated in a study of the fundamental aspects of adsorption of surfactants (anionic: Volgonat, Uglepen, neutralized black catalyst; cationic: Katamin AB) on active carbons from wastes formed in cutting of mixed wood.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Di-*tert*-butylhydroxylamine in Synthesis of Poly(Methyl Methacrylate) and Polystyrene

D. F. Grishin, L. L. Semenycheva, and M. V. Pavlovskaya

Research Institute of Chemistry, Lobachevsky Nizhni Novgorod State University, Nizhni Novgorod, Russia

Received January 9, 2004

Abstract—The effect of di-*tert*-butylhydroxylamine on polymerization of methyl methacrylate and styrene under conditions of radical initiation, similar to the commercial synthesis conditions, was studied.

Radical polymerization remains the main pathway of commercial synthesis of polymeric materials, since the procedure and the required equipment are relatively simple, the synthesis is well reproducible, a wide range of monomers can be involved in the reaction, etc. However, applications of radical polymerization are limited by such a significant drawback as nonuniform reaction progress with the occurrence of the gel effect (spontaneous growth of the molecular weight) impairing the polymer properties. In particular, the products become less heat-resistant, their molecular-weight distribution (MWD) becomes broader, etc. [1, 2]. A possible way to solve this problem is development of efficient methods for controlling the polymer chain propagation under conditions of radical initiation and, primarily, elaboration of theoretical principles and practical applications of so-called controlled radical polymerization [3, 4].

Controlled synthesis of polymers in the living chain mode has recently received much attention of macromolecular chemists. Among processes of this type, polymerization by the reversible inhibition mechanism in the presence of nitroxyl radicals, such as 2,2,6,6-tetramethylpiperidyl-1-oxyl and its analogs, is the most studied [5–7]. When this mechanism is realized in polymerization of vinyl monomers in the presence of nitroxyl radicals, a number of characteristic features are observed: weaker gel effect, linear growth of the molecular weight with conversion, and lower polydispersity coefficients (1.2–1.4).

Previous studies [8, 9] revealed side rections that occur in the course of polymerization in the presence of nitroxyl radicals along with reversible inhibition and temporarily remove nitroxyl from the polymerization sphere. One of the products of such reactions is hydroxylamine, which can generate the nitroxyl radical under the action of peroxy initiators:

$$>\!N\!-\!OH \xrightarrow{(O)} >\!N\!-\!O^{\bullet}. \qquad (1)$$

Also, chain transfer to hydroxylamine with formation of the nitroxyl radical is also possible:

$$>\!N\!-\!OH + R^{\bullet} \longrightarrow >\!N\!-\!O^{\bullet} + RH. \qquad (2)$$

This can be followed by realization of the reversible inhibition mechanism according to the scheme

$$\sim P^{\bullet}_m + A^{\bullet} \underset{k_d}{\overset{k_t}{\rightleftharpoons}} \sim P_m\!-\!A, \qquad (3)$$

where $\sim P^{\bullet}_m$ is the propagating radical; $A^{\bullet}$, nitroxyl spin adduct; k_d, rate constant of adduct reinitiation; k_p, propagation rate constant; and k_t, rate constant of adduct formation.

To develop new effective chain-terminating agents and gain deeper insight into the mechanism of polymerization in the presence of nitroxyl radicals, we studied the synthesis of poly(methyl methacrylate) (PMMA) and polystyrene in the presence of di-*tert*-butylhydroxylamine (DBHA) under conditions of radical initiation.

EXPERIMENTAL

Di-*tert*-butylhydroxylamine was prepared as described in [10, 11]. Dicetyl peroxydicarbonate (DPC), benzoyl peroxide (BP), and azobis(isobutyronitrile) (AIBN) used as initiators, and also the monomers and solvents were purified by standard procedures. The polymerization kinetics was monitored gravimetrically

[12] and thermographically [13]. The molecular weight M of the polymer was determined viscometrically [14]. Gel permeation chromatography (GPC) was performed on a device equipped with a set of five Styrogel columns with the pore size of 10^5, 3×10^4, 10^4, 10^3, and 250 Å (Waters, the United States). An R-403 differential refractometer (Waters) was used as detector. Tetrahydrofuran (THF) was the eluent. Calibration was performed using close-cut polystyrene references [15]. The ESR spectra were recorded on an AE4700 radiospectrometer. Crystalline MgO doped with Mn^{2+} ions was used as a reference for the magnetic field calibration.

Polymerization of methyl methacrylate (MMA) in the presence of DBHA was performed at 50°C in the presence of DPC, which simultaneously acts as oxidant for DBHA and as initiator of radical polymerization. On introducing 0.005–0.01 mol % DBHA into the system, the gel effect noticeably decreases, which, as noted above, is one of the evidences of polymerization in the living chain mode. The molecular weight of the polymer formed in the presence of DBHA linearly grows with the conversion (Fig. 1, curve *2*), and the unimodal MWD curves shift toward higher molecular weights with increasing conversion. However, the initially low polydispersity coefficient noticeably increases at conversions exceeding 30% (see table).

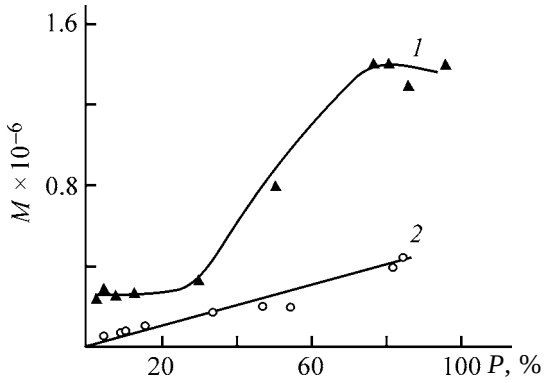

Fig. 1. Variation of the viscosity-averaage molecular weight M of PMMA with conversion P. Initiatior DPC (0.1 mol %), synthesis temperature 50°C. DBHA concentration, mol %: (*1*) 0 and (*2*) 0.015.

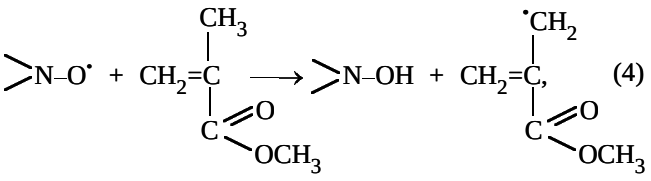
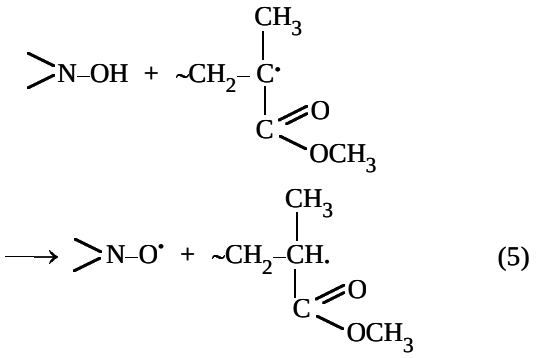
Similar results were obtained in polymerization of styrene in the presence of DBHA (0.2–0.4 mol %) and another peroxy initiator, BP (1.0 mol %). Polymerization of styrene at 100°C occurs without gel effect, and the molecular weight of polystyrene (PS) formed in the presence of DBHA also linearly grows with conversion (Fig. 2). The MWD curves are unimodal, and the maximum (mode) somewhat shifts toward higher M with conversion (Fig. 3). It is particularly important that the polydispersity coefficient of the samples prepared in the presence of DBHA is lower compared to the samples prepared without it (see table, run nos. 5–9). Furthermore, the polydispersity of polystyrene decreases with increasing conversion (see table, run nos. 6–9).

Our results give good grounds to suggest that, in polymerization of MMA in the presence of DBHA and DPC, some polymeric chains propagate by the reversible inhibition mechanism [Eq. (3)], but the secondary catalytic inhibition [Eqs. (4), (5)] also

makes a significant contribution:



(4)



(5)

According to published data [16, 17], reactions (4) and (5) are more typical of methacrylic monomers and virtually do not occur with styrene. Also, in the presence of DBHA formation of the nitroxyl radical (*in situ*) occurs concurrently with chain propagation and termination by the common radical mechanism. The polymer chain propagation by several mechanisms, occurring in the presence of DBHA, results in increased polydispersity of PMMA.

The results of the kinetic studies of styrene polymerization in the presence of DBHA and BP, and also the molecular-weight characteristics of the synthesized polymers suggest predominant realization of the reversible inhibition mechanism in this case [Eq. (3)]. Of particular importance in this case are linear dependence of M on conversion, issuing virtually from the origin, pronounced shift of the MWD curves toward higher M with conversion, and low polydispersity coefficients of the polystyrene samples at high conversions.

To evaluate the contribution of reaction (5) to control of the chain propagation, we studied polymerization of styrene in the presence of a nonperoxy initiator, AIBN, which is incapable of oxidizing hydroxylamine to the nitroxyl spin adduct.

With AIBN used as initiator of styrene polymerization in the presence of DBHA at 70°C, the decreased gel effect, linear growth of the polystyrene molecular weight with conversion (Fig. 4), and shift of MWD curves toward higher M with conversion are observed also. Although the polydispersity coefficient of the samples prepared in the presence of DBHA is somewhat lower compared to the samples prepared without

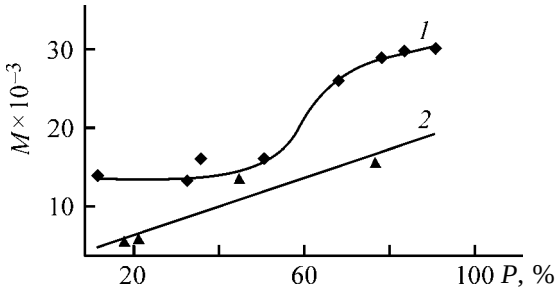


Fig. 2. Variation with conversion P of the (*1*) viscosity-average and (*2*) number-average molecular weight M of polystyrene prepared in the presence of BP (1.0 mol %). Synthesis temperature 100°C. DBHA concentration, mol %: (*1*) 0 and (*2*) 0.4.

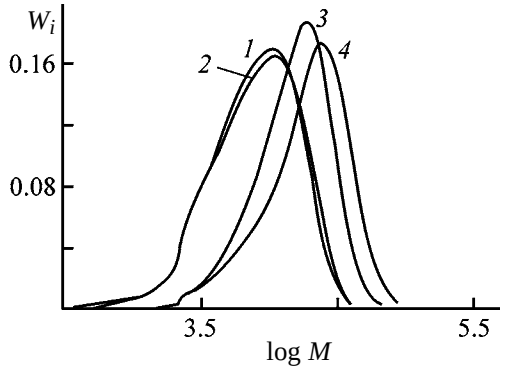

Fig. 3. MWD curves of polystyrene prepared in the presence of BP (1.0 mol %). DBHA concentration 0.4 mol %, synthesis temperature 100°C. (W_i) Fraction of the polymer and (M) molecular weight. Conversion, %: (*1*) 18, (*2*) 22, (*3*) 45, and (*4*) 77.

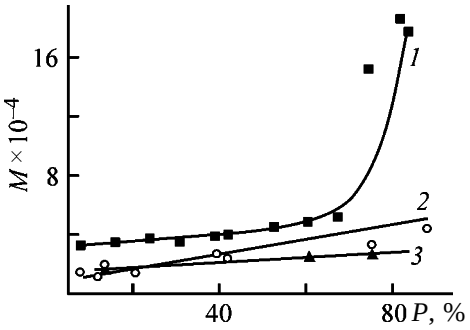

Fig. 4. Variation with conversion P of the (*1*, *2*) viscosity-average and (*3*) number-average molecular weight M of polystyrene. Initiator AIBN (0.8 mol %), synthesis temperature 70°C. DBHA concentration, mol %: (*1*) 0 and (*2*, *3*) 0.5.

it (also with AIBN as initiator; see table, run no. 10), it considerably grows with conversion, exceeding the polydispersity coefficients of the samples prepared in the presence of DBHA with BP as initiator.

Azobis(isobutyronitrile), in contrast to peroxides, does not oxidize DBHA to nitroxyl radical. Nitroxyl

radcal can form in the course of polymerization exclusively by hydrogen abstraction from hydroxylamine with the propagating macroradical [Eq. (5)]. Hence, in this case the concentration of the nitroxy spin adduct as chain-terminating agent [Eq. (3)] is considerably lower than with the peroxy initiator. Furthermore, the half-lives of AIBN and BP differ considerably. For example, AIBN can initiate radical polymerization of styrene throughout the process: The half-life of AIBN at 70°C is longer (300 min) than that of BP at 100°C (25 min). Formation of the "dead" polymer due to decomposition of residual AIBN and the lower concentration of di-*tert*-butylnitroxyl cause the polydispersity coefficient to increase.

In contrast to AIBN, benzoyl peroxide in polymerization in the presence of DBHA not only acts as initiator, but also oxidizes hydroxylamine to nitroxyl spin adduct reinitiating the chain propagation by Eq. (3). Formation of di-*tert*-butylnitroxyl by oxidation of DBHA with benzoyl peroxide was confirmed by ESR. The ESR spectrum contains a triplet with the hyperfine coupling constant a_N = 15.5 Oe, belonging to the di-*tert*-butylnitroxyl radical. Participation of the di-*tert*-butylnitroxyl radical in chain propagation appreciably reduces the contribution of the so-called "dead" process as compared to styrene polymerization in the presence of AIBN.

CONCLUSIONS

(1) Additions of di-*tert*-butylhydroxylamine control the kinetic parameters of polymerization of styrene and methyl methacrylate and the molecular-weight characteristics of the polymers under the conditions similar to those of the commercial synthesis.

(2) The polymerization control with di-*tert*-butylhydroxylamine is the most efficient in polymerization of styrene with peroxy initiators.

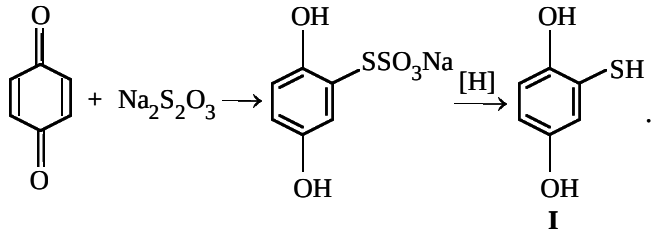
Abstract—S-Substituted 2-mercapto-1,4-dihydroxybenzenes were prepared, and their antioxidative activity in autooxidation of cumene and in the reactions with cumylperoxy radicals and cumyl hydroperoxide was studied.

Sulfur-substituted phenols as effective oxidation inhibitors are widely used for stabilization of petroleum products [1]. Their high inhibiting performance is due to the presence in one molecule of two functional groups: phenolic hydroxyl and sulfide sulfur, making these compounds capable to inhibit oxidation by scavenging of peroxy radicals and decomposition of peroxides [2, 3].

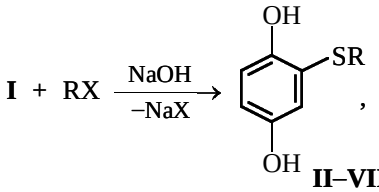
Proceeding with studies on synthesis of phenolic sulfides [2–7], we prepared S-substituted 2-mercapto-1,4-dihydroxybenzenes and studied their antioxidative activity in cumene oxidation.

2-Mercapto-1,4-dihydroxybenzene **I** was prepared as follows:



I

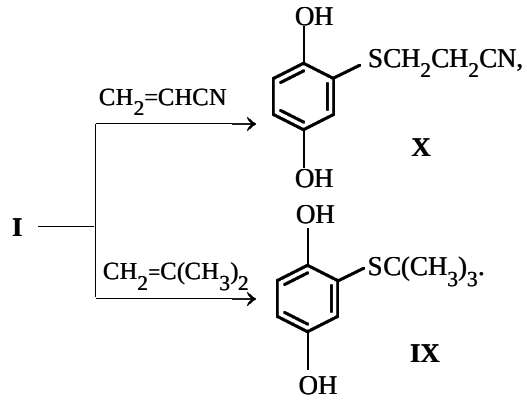
S-Methyl (**II**), *S*-ethyl (**III**), *S*-isopropyl (**IV**), *S*-carboxymethyl (**V**), *S*-acetyl (**VI**), *S*-allyl (**VII**), and *S*-benzyl (**VIII**) derivatives of **I** were prepared by the reactions of **I** with the corresponding halides in the presence of NaOH:



II–VIII

where R = CH_3, X = I (**II**); R = C_2H_5, X = Br (**III**); R = $(CH_3)_2CH$, X = Br (**IV**); R = CH_2COOH, X = Cl (**V**); R = CH_3CO, X = Br (**VI**); R = CH_2=$CHCH_2$, X = Br (**VII**); R = $C_6H_5CH_2$, X = Cl (**VIII**).

S-tert-Butyl (**IX**) and *S*-(2-cyanoethyl) (**X**) derivatives of **I** were prepared, respectively, by addition of **I** to acrylonitrile in the presence of triethylamine and to 2-methylpropene in the presence of catalytic amounts of sulfuric acid:



The purity of the compounds was checked by TLC and elemental analysis (Table 1), and their structures were proved by IR and ^{1}H NMR spectroscopy.

The IR spectra of **I**–**X** contain absorption bands at about 1450 (C···C stretching vibrations in the aromatic ring), 3450 (stretching vibrations of the O–H bond involved in hydrogen bonding with the adjacent S atom [8]), and 810–860 cm^{-1} (1,2,4-substituted benzene ring). The ^{1}H NMR spectra of mercaptophenols **I**–**X** contain a proton signal from two hydroxy groups (7.4 ppm). The multiplets of three benzene ring protons are observed at about 5.9 ppm. Compound **I** exhibits a band at 2530 cm^{-1} in the IR spec-

trum (S–H stretching vibrations), and its NMR spectrum contains an SH proton singlet at 3.3 ppm. The IR and ^{1}H NMR spectra of **II**–**X** exhibit features characteristic of the substituents at the S atom.

To evaluate the inhibiting activity of **I**–**X**, we used as model substrate cumene, as the mechanism of its oxidation is well understood. Experiments on cumene autooxidation in the presence of **I**–**X** revealed their fairly high inhibiting performance. Experiments on oxidation of cumene initiated with azobis(isobutyronitrile) (AIBN; 60°C, [AIBN] = 2×10^{-2} M) showed that these compounds actively terminate oxidation chains, reacting with cumylperoxy radicals. Data for **I** as example are shown in Fig. 1. From the induction period τ_{ind}, we calculated the stoichiometric inhibition coefficient f equal to the number of oxidation chains

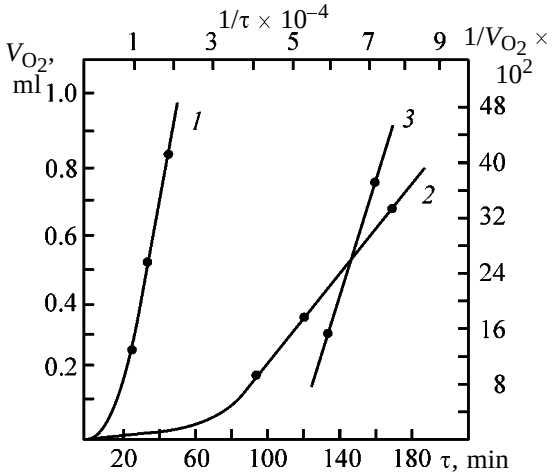

Fig. 1. Kinetic curves of O_2 uptake in initiated oxidation of cumene (*1*) without additives and (*2*) in the presence of **I**. (*3*) Linearization of curve *2* in the coordinates $1/\tau$–$1/V_{O_2}$. (V_{O_2}) Volume of oxygen taken up and (τ) time.

terminated on one molecule of an inhibitor and its transformation products:

$$f = \tau_{ind} v_{ind}/[In]_0,$$

where τ_{ind} is the induction period; v_{ind}, initiation rate; and $[In]_0$, initial concentration of inhibitor In.

From the kinetics of the oxygen uptake, we calculated the rate constants of the reactions of the inhibitors with peroxy radicals k_7 [8, 9]. To do this, we transformed the kinetic curves of the oxygen uptake from the coordinates $[O_2]$–τ to the coordinates $[O_2]^{-1}$–τ^{-1} and from the slope $\tan\alpha$, equal [9, 10] to

$$\tan\alpha = fk_7[In]_0/(k_2[RH]v_{ind}),$$

found the constant k_7:

$$k_7 = \tan\alpha k_2[RH]v_{ind}/f[In]_0,$$

where k_2 is the rate constant of chain initiation [9, 10], equal to 1.51 l mol^{-1} s^{-1}; [RH] = 6.9 M.

Table 2 shows that the constants k_7 for the compounds with electron-donor substituents are higher compared to the compounds with electron-acceptor substituents. As for f, it varies in the range 1.05–2.20.

Reactions of **I**–**X** with cumyl hydroperoxide (CHP) were performed in chlorobenzene under nitrogen at 110°C. All the compounds **I**–**X** decompose CHP. Figure 2 shows (by the example of **I**) that the kinetic curve of CHP decomposition in the presence of mercaptophenols is S-shaped, which is typical of autocatalytic processes. The reaction starts with a certain induction period in which the consumption of CHP is insignificant; this is followed by fast catalytic decom-

position of CHP and then by reaction deceleration due to a decrease in the CHP concentration. Apparently, the inhibitor first reacts with CHP to give a product that catalytically decomposes CHP.

To determine the reaction order, we studied how the initial rate of the catalytic decomposition of CHP depends on the concentrations of the reactants. We found that the initial rate v_0 of catalytic decomposition of CHP under the action of **I**–**X** obeys the kinetic equation

$$v_0 = k[\mathrm{In}][\mathrm{ROOH}]^2.$$

To determine the reaction stoichiometry, we took CHP in excess. The catalytic factor ν characterizes the number of CHP molecules decomposed with one inhibitor molecule; it was calculated by the formula

$$\nu = [\mathrm{ROOH}]_0 - [\mathrm{ROOH}]_\infty/[\mathrm{In}]_0,$$

where $[\mathrm{ROOH}]_0$ and $[\mathrm{ROOH}]_\infty$ are, respectively, the initial and final concentrations of [CHP], and $[\mathrm{In}]_0$ is the initial inhibitor concentration.

Experiments showed that one molecule of **I**–**X** can decompose up to several thousands of CHP molecules (Table 2). The kinetic parameters of the reaction show certain correlation with the properties of substituents at the S atom. In particular, in going to branched alkyl substituents (compounds **II**–**V**) k decreases, probably owing to steric factors; ν is higher for the compounds with electron-donor substituents at the S atom.

EXPERIMENTAL

The IR spectra were recorded on a Specord 75-IR spectrophotometer, and the ^{1}H NMR spectra, on a Varian T-60 spectrometer, with tetramethylsilane as internal reference.

2-Mercapto-1,4-dihydroxybenzene I. A solution of 43.2 g of benzoquinone in 150 ml of glacial acetic acid was heated to 40–50°C, and then a solution of 150 g of $Na_2S_2O_3$ in 200 g of water was gradually added, avoiding warming-up of the reaction mixture by more than 10°C. After short stirring, the transparent and almost colorless solution was saturated with KCl to precipitate sodium *S*-(2,5-dihydroxyphenyl) thiosulfate. A solution of 2.6 g of this salt in 10 ml of water was mixed with 20 ml of concentrated HCl, and 5 g of zinc dust was gradually added; the reaction temperature was maintained at 40–50°C until the gas evolution ceased.

Table 2. Kinetic parameters of the reactions of mercaptophenols **I**–**X** with cumylperoxy radicals k_7 and f (60°C, [AIBN] = 2×10^{-2} M) and of decomposition of cumyl hydroperoxide k and ν (110°C)

Compound	$k_7 \times 10^{-4}$, l mol^{-1} s^{-1}	f	k, l mol^{-1} s^{-1}	ν

2,5-Dihydroxyphenyl methyl sulfide II. A 2-g portion of NaOH was added at 10–15°C to a solution of 7.1 g (0.05 mol) of **I** in 30 ml of isopropyl alcohol, after which 7.1 g of methyl iodide was added at the same temperature. The reaction was performed under nitrogen. The temperature was raised to 60°C, after which the mixture was stirred for an additional 3 h and washed first with 2 M HCl and then with water to neutral reaction. The organic layer was treated with petroleum ether (30–60°C) and dried over sodium sulfate.

Compounds **III**, **IV**, **VII**, **VIII**, and **X** were prepared similarly.

2,5-Dihydroxyphenyl *tert*-butyl sulfide IX. A 3-ml portion of isobutylene was added to a mixture of 7.1 g of **I** and five drops of concentrated H_2SO_4 saturated with $(NH_4)_2SO_4$, heated to 110–120°C. Then the mixture was neutralized with 13 ml of 2 M NaOH, treated with petroleum ether, and washed three

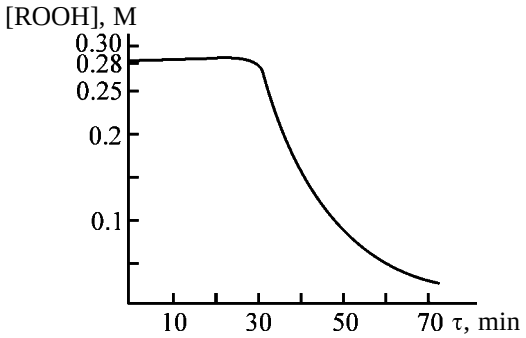

Fig. 2. Kinetic parameters of decomposition of cumyl hydroperoxide (ROOH) under the action of **I**. [In] = 3×10^{-4}, $[\mathrm{ROOH}]_0$ = 0.285 M. (τ) Time.

times with water. After drying over Na_2SO_4, the solvent was distilled off.

2,5-Dihydroxyphenyl 2-carboxymethyl sulfide V. A 7.1-g portion of **I** was added to a solution of 2 g of NaOH in 10 ml of water, and a concentrated solution of 4.7 g of chloroacetic acid, neutralized with sodium hydrogen carbonate, was added with stirring and cooling. After 5 h, the solution was heated, impurities were steam-distilled, and the solution was acidified with dilute H_2SO_4.

2,5-Dihydroxyphenyl 2-cyanoethyl sulfide X. A mixture of 7.1 g of **I**, 20 ml of anhydrous benzene, and a drop of triethylamine was stirred at 60–70°C for 3 h. Then the mixture was washed with water and dried over Na_2SO_4. The solvent was distilled off, and the product was recrystallized from diethyl ether.

CONCLUSIONS

(1) 2-Mercapto-1,4-dihydroxybenzene was prepared and converted into various S-substituted derivatives.

(2) The compounds synthesized exhibit synergism as inhibitors of cumene oxidation and, being polyfunctional antioxidants, terminate cumene oxidation chains by reactions with peroxy radicals and catalytically decompose cumene hydroperoxide.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Some Transformations of 2-Amino-4-phenyl-1,3-thiazole

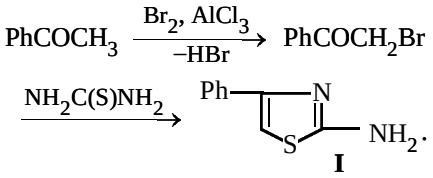
Abstract—Reactions of 2-amino-4-phenyl-1,3-thiazole with aromatic aldehydes, phenyl isocyanate, and carboxylic acid chlorides were studied.

Various thiazoles exhibit antimicrobial, antihelmintic, antiparasitic, and antipyretic properties [1–3]. Thiazole derivatives are widely used as antioxidants [4], vulcanization accelerators [5], and photochromic compounds [6]. Thiazoles and azomethines derived from them are important analytical reagents [7]. Thiazoles are also used for preparing various heterocycles [8], cyclizing terpenes [9], and concentrating some transition metals. In many cases, the triazoles used contain aryl and basic (amino) groups.

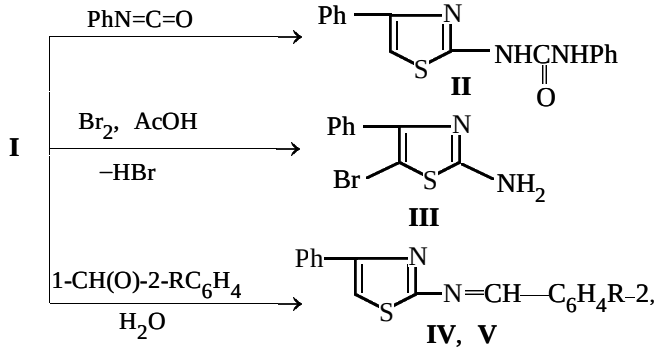
In this context, it seemed appropriate to prepare a thiazole containing simultaneously aryl and amino groups, 2-amino-4-phenyl-1,3-thiazole **I**, and its derivatives.

Compound **I** was prepared according to [10] in two steps: bromination of acetophenone followed by the reaction of the resulting α-bromoacetophenone with thiourea; the yield of the target product was 90%:



I

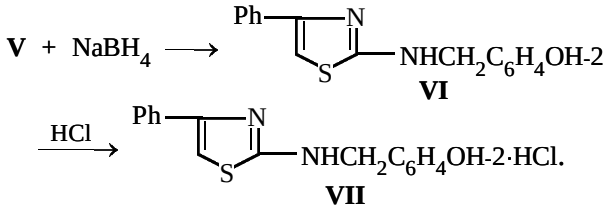
Reaction of thiazole **I** with phenyl isocyanate gave urea derivative **II**; hydrogen substitution with bromine in **I** yielded 2-amino-5-bromo-4-phenylthiazole **III**:



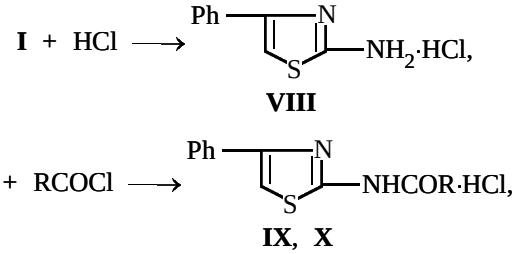
where R = H (**IV**), OH (**V**).

It is known thart condensation of various amines with aldehydes yields Schiff bases. We have studied for the first time the reactions of **I** with benzaldehyde and salicylaldehyde and obtained the corresponding Schiff bases **IV** and **V**.

2-(2-Hydroxybenzylidenimino)-4-phenyl-1,3-thiazole **V** is hydrogenated under mild conditions with sodium borohydride to give 2-(2-hydroxybenzylamino)-4-phenyl-1,3-thiazole **VI**. Treatment of **VI** with HCl gives the corresponding hydrochloride:



With the aim to synthesize potentially physiologically active derivatives of thiazole **I**, we prepared its hydrochloride **VIII**, which, in contrast to the free base, is readily soluble in water; acylation of **I** gave amide hydrochlorides **IX** and **X**:



where R = Me (**IX**), Ph (**X**).

The IR spectra of Schiff bases **IV** and **V** are similar to that of thiazole **I**. However, there is a new absorption band at about 3450 cm^{-1} in the spectra of **IV** and **V**, characterizing an intramolecular hydrogen bond between the phenolic hydroxyl and N=CH fragment.

X	87	195	60.48	4.03	8.72	10.95	$C_{16}H_{13}N_2OSCl$	60.66	4.14	8.84	10.12

No bands characteristic of NH_2 stretching vibrations were revealed. The bands at about 3300 cm^{-1} in the IR spectrum of **VI** characterize the intramolecular hydrogen bond HN···HO.

The UV spectrum of **V** dramatically differs from that of its hydrogenated analog **VI**. The absorption bands at 208 and 278 nm in **V** belong to conjugated aromatic rings, and the long-wave band at 385 nm is due to the $\pi \rightarrow \pi^*$ transition in the conjugated azomethine fragment C=N. In the spectrum of **VI**, this band is absent. The lack of conjugation between the benzene rings results in this case in the presence of two bands at 260 and 282 nm, assignable to the monosubstituted benzene and phenolic rings, respectively, instead of a single band at 278 nm.

In the ^{1}H NMR spectrum of **V**, the phenolic hydroxyl proton gives a signal at about 3.25 ppm, and the N=CH proton, at 7.85–7.90 ppm. In the hydroxyphenyl moiety, the four nonequivalent protons give a multiplet at 7.2–7.5 ppm.

The yields and melting points of **I**–**X** are listed in the table. The purity of **I**–**X** was confirmed by TLC, and the compositions and structures were proved by elemental analysis and by IR, UV, and ^{1}H NMR spectroscopy.

EXPERIMENTAL

The IR spectra of **I**–**X** were taken on a Specord IR-75 spectrophotometer. Samples were prepared as thin films or mulls in mineral oil. The spectra were recorded in the range 700–3700 cm^{-1} using KBr, NaCl, and LiF prisms. The ^{1}H NMR spectra were taken on a Varian VXR-400S spectrometer (400 MHz, solutions in DMSO-d_6, internal reference TMS). The TLC analysis was performed on Silufol UV-254 plates. A 1 : 1 (by volume) mixture of isopropyl alcohol and heptane was used as eluent. The plates were developed with iodine vapor.

2-(Phenylaminocarbonylamino)-4-phenyl-1,3-thiazole II. A 2.4-g (0.02-mol) portion of phenyl isocyanate was added dropwise with stirring to a solution of 3.4 g (0.02 mol) of **I** in 20 ml of anhydrous toluene. The stirring was continued for 24 h at 60°C. Then the mixture was cooled to room temperature, and the colorless crystalline precipitate was filtered off and recrystallized from acetone.

2-Amino-4-phenyl-5-bromo-1,3-thiazole III. A solution of 3.2 g (0.02 mol) of bromine in 10 ml of acetic acid was added at 20°C to a solution of 3.4 g (0.02 mol) of **I** in 20 ml of glacial acetic acid, and the mixture was stirred at 20°C for 30 min. Then 100 ml of water was added. The yellowish precipitate that formed in 2 h was filtered off and recrystallized from ethanol.

2-Benzylidenamino-2-phenyl-1,3-thiazole IV. A 8.8-g (0.05-mol) portion of **I** was added to 5.3 g (0.05 mol) of benzaldehyde, and the mixture was vigorously stirred for 3 min. Then the mixture was transferred into a beaker, 15 ml of ethanol was added, and the mixture was cooled. The colorless crystalline precipitate that formed in several minutes was filtered off.

2-(2-Hydroxybenzylidenamino)-4-phenyl-1,3-thiazole V. A 8.8-g (0.05-mol) portion of **I** was added to 6.1 g (0.05 mol) of salicylaldehyde, and the mixture was vigorously stirred for 30 min. In so doing, the mixture spontaneously warmed up to 40°C. Then the mixture was transferred into a beaker, 15 ml of ethanol was added, and the mixture was cooled with ice. The crystalline precipitate that formed was filtered off.

2-(2-Hydroxybenzylamino)-4-phenyl-1,3-thiazole VI. A 30-ml portion of ethanol was added to 5.6 g (0.02 mol) of **V**, and the mixture was stirred to obtain a suspension. Then sodium borohydride was added, and the mixture was stirred for an additional 30 min. After that, 100 ml of water was added, and the mixture was acidified to pH 7.5. The colorless crystalline precipitate that formed was filtered off and recrystallized from benzene.

2-Amino-4-phenyl-1,3-thiazole hydrochloride VIII. Dry HCl was passed through a solution of 8.2 g (0.05 mol) of **I** in 30 ml of isopropyl alcohol, cooled to 0°C. The colorless crystalline precipitate that formed was filtered off and washed three times with anhydrous diethyl ether. The resulting hydrochloride was recrystallized from ethanol.

Compound **VII** was prepared similarly.

2-Acetylamino-4-phenyl-1,3-thiazole hydrochloride IX. Freshly distilled acetyl chloride (1.5 g, 0.02 mol) was added dropwise to a solution of 3.4 g (0.02 mol) of **I** in 10 ml of anhydrous toluene, cooled to 0–5°C. The colorless crystalline precipitate that formed was filtered off and recrystallized from acetone.

Compound **X** was prepared similarly.

CONCLUSION

2-Amino-4-phenyl-1,3-thiazole was synthesized in a high yield and converted into various derivatives (azomethines, halides, amides), which may be promising as bioactive substances, antioxidants, and analytical reagents.

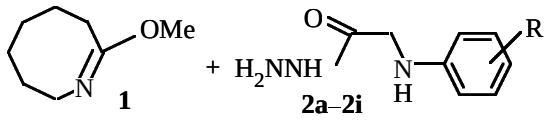
Abstract—Inhibiting effect on acid corrosion of steel 45 and biocidal activity with respect to sulfate-reducing bacteria are studied for a series of *N*-aryl-*N*-(6,7,8,9-tetrahydro-5*H*-[1,2,4]triazolo[4,3-*a*]azepin-3-ylmethyl)-amines.

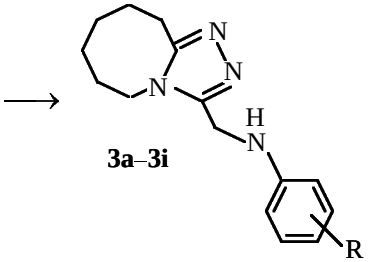
Both acid corrosion inhibitors [1] and biocides [2] are known among nitrogen-containing heterocyclic organic compounds. We made an attempt to synthesize compounds demonstrating these properties in combination. Such compounds can find application in developing inhibitor formulations, paint and varnish materials, and protective compositions for metals exploited under the impact of several corrosion factors.

The goal of this work is to study the inhibiting activity of *N*-aryl-*N*-(6,7,8,9-tetrahydro-5*H*-[1,2,4]triazolo[4,3-*a*]azepin-3-ylmethyl)amines in hydrochloric acid solutions and also to characterize the biocidal activity of these compounds with respect to sulfate-reducing bacteria as the major factor of biocorrosion.

EXPERIMENTAL

N-Aryl-*N*-(6,7,8,9-tetrahydro-5*H*-[1,2,4]triazolo-[4,3-*a*]azepin-3-ylmethyl)amines **3a**–**3i** were synthesized by reactions of 7-methoxy-3,4,5,6-tetrahydro-2*H*-azepine with hydrazides of substituted *N*-arylaminoacetic acids [4, 5]. To 0.01 mol of hydrazide **2a**–**2i** in 30 ml of 2-propanol, 0.011 mol of compound **1** was added and the mixture was refluxed for 2 h. The reaction progress was monitored chromatographically. After the reaction completion, the mixture was cooled, and the precipitate was filtered off, washed with 2-propanol, dried, and recrystallized from 2-propanol. The characteristics of the products are summarized in Table 1.





where R = H (**a**), 4-F (**b**), 4-Cl (**c**), 4-I (**d**), 4-CH_3O (**e**), 2,4-$(CH_3)_2$ (**f**), 4-CH_3 (**g**), 2-CH_3 (**h**), and 3-CH_3 (**i**).

The composition and structure of the products were confirmed by ^{1}H NMR. The spectra in DMSO-d_6 were recorded on a Bruker-300 instrument with TMS as internal reference. The reaction was monitored by TLC on Silufol UV-254 in the system chloroform/methanol = 9/1.

The inhibiting activity of the compounds was studied in 1 M HCl at 293 K by the electrochemical method using a P-5845 potentiostat [6]. Polarization curves (80 mV min^{-1}) were recorded at the stationary potential of free corrosion φ_s in a three-electrode glass cell with separated cathode and anode spaces (working steel 45 end face electrode, Ag/AgCl reference electrode, and Pt auxiliary electrode). The potentials were recalculated to the standard hydrogen scale. The concentration of **3a**–**3i** was 2 mM. From the polarization curves, we determined the potential and current of free corrosion φ_f and I_f, and also potentials and currents of cathodic (φ_c, I_c) and anodic (φ_a, I_a) corrosion. Then we estimated the Tafel coefficients a_c, a_a, b_c, and b_a; electrochemical corrosion inhibition coefficients γ_s, γ_c, and γ_a; protective efficiency Z_f, Z_c, and Z_a; and, finally, the shift of the adsorption potential $\Delta\Psi'$ [1].

The kinetics of adsorption was monitored by a decrease in the cathode current (by 0.6 V relative to the stationary current) after adding an inhibitor to the electrolyte solution. To elucidate the most probable mechanism of inhibiting action, we estimated the correlation coefficients r in processing data in the coordinates $\log I$–τ, ΔI–$\log\tau$, $\log\Delta I$–$\log\tau$, $\log\log I/I_\infty$–τ, $\log\gamma$–$\log\tau$, and $\log\log\gamma$–$\log\tau$ [1].

The antibacterial activity was studied by the method of diffusion of the compounds studied to agar using paper disks impregnated with 0.1, 0.2, and 2% alcoholic solutions of **3a**–**3i**. The biocidal effect was characterized by the diameter of the growth suppression area [7]. As a test culture we used a culture of sulfate-reducing bacteria (SRB) separated from ferrosphere of corroding steel and grown in Postgate medium B.

Experimental data were statistically treated at a 0.95 confidence level (three replicates) [8].

The anticorrosive properties of compounds **3a**–**3i** are given in Tables 2–4 and in the figure. Addition of the inhibitor increases the free corrosion potential of steel 45 by 5–40 mV (Table 2), suggesting preferen-

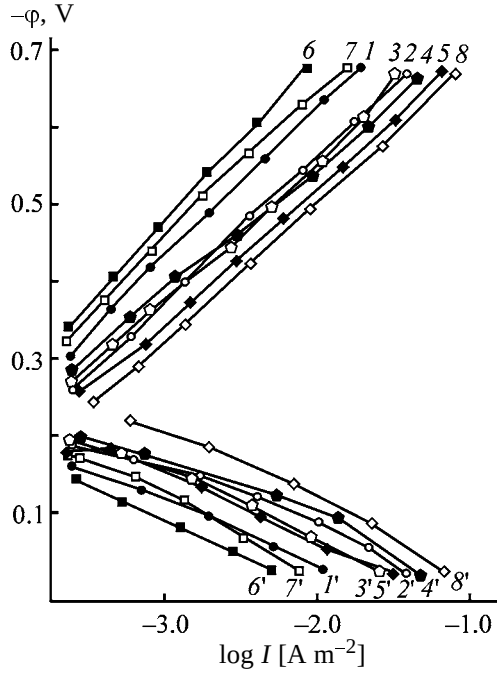
tial inhibition of anodic dissolution of the metal at φ_f in the presence of the inhibitor. Addition of compounds **3a**–**3i** decreased the free corrosion current by a factor of 1.8–9.6, and the anode and cathode currents, by factors of 3.6–38.0 and 1.1–5.5, respectively. Relatively high protective effect was shown by compound **3c** with a chlorine atom in the *para* position of the benzene ring ($\sigma_p = +0.227$). The inhibition coefficients γ_f, γ_c, and γ_a of **3c** are higher that those of the unsubstituted compound **3a** by factors of 4.3, 2.9, and 10.6, respectively (Table 3). The lowest protective characteristics were shown by **3e** (substituent OCH_3; $\sigma_p = -0.268$).



(*1*–*8*) Cathode and (*1*'–*8*') anode polarization curves of steel 45 in 1 M HCl. Inhibitor concentration 2 mM. (φ) Potential and (*I*) current density. Inhibitor: (*1*, *1*') **3d**, (*2*, *2*') **3b**, (*3*, *3*') **3f**, (*4*, *4*') **3a**, (*5*, *5*') **3e**, (*6*, *6*') **3c**, (*7*, *7*') **3g**, and (*8*, *8*') no inhibitor.

Addition of the inhibitors into 1 M HCl changes the electrochemical parameters of electrode processes as follows: the Tafel constant a_c increases by 15–131 mV, and a_a, by 30–100 mV, which is consistent with the inhibition coefficients (Table 3). The overvoltage of electrode reactions increases as a result of increase in the adsorption potential Ψ' by 21–169 mV.

Adsorption of protonated molecules of **3a**–**3i** from the acid solution on the negatively charged metal surface proceeds through electrostatic interaction. In this case, the charge on the adsorption sites of the sorbate, i.e., on the amine nitrogen and nitrogen atom of the triazole ring, is of considerable importance.

The nature of a substituent in the *para* position of the benzene ring affects most significantly the electron density on the amine nitrogen in **3a**–**3i**. A decrease in the electron density on this atom caused by introduction of electron-acceptor substituents into the benzene ring favors adsorption of the inhibitors on the metal surface. As a result, the highest protective efficiency was shown by compound **3c** with a chlorine atom as a substituent.

The adsorption equilibrium of compounds **3a**–**3i** on the negatively polarized metal surface is established in 20–25 s. According to [1], if physical adsorption dominates, purely energetic inhibiting effect may be expected. However, no significant difference was found in the correlation coefficients *r* obtained in treating data on decrease in the cathode current (Table 4) in the coordinates $\log I$–τ and $\log\log I/I_\infty$–τ, suggesting realization of a complex energetic–adsorption-blocking mechanism of inhibition on a uniform metal surface. This suggestion is supported by the lack of a distinct correlation between the anticorrosion characteristics of the compounds studied and the shift of the adsorption potential.

Another practically important characteristic of corrosion inhibitors is their biocidal activity with respect

to sulfate-reducing bacteria as the major factor of biocorrosion. The mechanism of biocidal action involves adsorption of a compound on the negatively charged surface of the bacterial cell and penetration into it to destroy its metabolism. All the compounds studied in this work exhibit a weakly pronounced biocidal effect with respect to iron-reducing bacteria [9].

The biocidal effect with respect to SRB was found only for the compounds with the methyl substituent. In the case of *ortho* substitution in the benzene ring (compound **3h**), the diameter of the growth suppression area is 21.0, 28.0, and 42.7 mm; and in the case of *meta* substitution (**3i**), it is 25.7, 37.3, and 49.3 mm at the inhibitor concentration of 0.1, 0.2, and 2 wt %, respectively. The *para*-substituted compound **3g** practically totally suppresses the growth of SRB. Thus, the position of the methyl substituent in the benzene ring strongly affects the biocidal effect, which increases in the order *ortho* < *meta* < *para*. Introduction of two methyl groups in positions 2 and 4 of the benzene ring (compound **3f**) decreases the biocidal effect on SRB. In this case, the diameter of the growth suppression area was found to be 10.0, 10.0, and 20.0 mm at the inhibitor concentration of 0.1, 0.2, and 2 wt %, respectively.

CONCLUSION

A series of *N*-aryl-*N*-(6,7,8,9-tetrahydro-5*H*-[1,2,4]-triazolo[4,3-*a*]azepin-3-ylmethyl)amines are synthesized. These compounds are acid corrosion inhibitors and demonstrate biocidal activity with respect to sulfate-reducing bacteria, which increases in compounds with a methyl substituent in the benzene ring in the order *ortho* < *meta* < *para*.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Cobalt(III) Ammine Complexes as Explosives for Safe Priming Charges

A. V. Smirnov, M. A. Ilyushin, and I. V. Tselinskii

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received October 16, 2003; in final form, March 2004

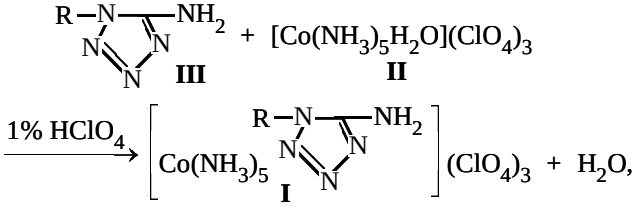
Abstract—Physicochemical and explosive properties of Co(III) pentammine complexes containing in the inner coordination sphere monodentate polynitrogen heterocyclic ligands, 1-methyl-5-aminotetrazole and 1,5-diaminotetrazole, were studied, and it was shown that these compounds can be used in priming charges.

Domestically produced standard priming explosives (PEs) allow production of reliable priming charges (PCs) meeting the requirements of modern engineering, industry, and building. However, requirements to PCs continuously rise; PCs with elevated safety with respect to mechanical impact and static electricity are required. In addition, environmental safety requires elimination of toxic metal ions from PC formulation. It is impossible to accomplish the above task with standard PCs.

Cobalt(III) tetrazolate pentamminates show promise for development of a new generation of high-performance PEs of increased safety. The use of 5R-tetrazols in PE synthesis is expedient because of their positive enthalpies of formation, while coordination chemistry allows variation of physicochemical and explosive properties within a wide range by varying outer- and inner-sphere ligands.

The synthesis of the compounds of this group and their physicochemical characteristics were reported in [1]. In all the complexes described, a heterocyclic ligand is located in the inner sphere of the complex as an anion, while coordination of the neutral ligand should increase the content of the outer-sphere ion by 1 mol, which will affect the properties of the complex. In this work, we prepared and studied high-energy-capacity cobalt(III) complexes with neutral ligands, (1-methyl-5-aminotetrazole)pentamminecobalt(III) perchlorate (C1M5AT) and (1,5-diaminotetrazole)pentamminecobalt(III) perchlorate (CDAT).

Their synthesis was performed by the scheme



where **I** is C1M5AT (R = CH_3), **I** or CDAT (R = NH_2).

The isolated complexes are yellow-orange crystalline powders soluble in water, DMSO, and DMF and weakly soluble in ethanol, isopropanol, and isobutanol. The physicochemical and explosive properties of C1M5AT and CDAT in comparison to (5-aminotetrazolato-N_2)pentamminecobalt(III) perchlorate (CAT, [2]) are listed in the table.

The densities of the compounds synthesized were calculated using an additive scheme through specific volumes of the molecular fragments with the error of 0.02 g cm^{-3} [2].

The detonation rate of compounds was estimated by fragmentation of the molecule into active (perchlorate ions and ligands) and inert (metal ion) parts followed by calculation using increments of structure fragments, with the average error of ±140 m s^{-1} [2].

A study of the thermal decomposition of the substances obtained under nonisothermal conditions at a heating rate of 5 deg min^{-1} showed that they are fairly heat-resistant, having T_d higher than 210°C (onset of active decomposition). In the initial stage of decomposition of Co(III) ammine complexes, ammonia molecules are eliminated from the inner coordination sphere. This is followed by stepwise decomposition of tetrazole ligands accompanied by their oxidation with outer-sphere perchlorate ion located in the outer sphere [2]. In all cases, the initial endothermic process overlaps with the subsequent exothermic process. C1M5AT has two exothermic peaks at 216 and 238°C in the DTA curve, and CDAT, three peaks at 218, 271, and 300°C.

The IR spectra of complexes contain bands of all their fragments: coordinated ammonia molecules,

Physicochemical and explosive properties of the compounds synthesized

Characteristic	C1M5AT	CDAT	CAT
Density, ρ (calc.), g cm^{-3}	1.95	2.03	1.95
Oxygen coefficient, α	0.96	1.17	0.86
Detonation rate, D^{ρ} (calc.), km s^{-1}	7.32	7.68	7.14
Temperature of the onset of active decomposition, T_d, °C	218	216	240
Minimal charge (MC) for cyclonite, g (BC no. 8)	0.4	0.2	>0.5
Shock sensitivity, $H_{25\ cm}$, % (weight 2 kg, substance sample 20 mg)	40	12	0

methyl and amino groups, tetrazole ring, and perchlorate ions.

The electronic spectra of C1M5AT and CDAT in aqueous solution are typical for this group of compounds [3] and reflect *d*–*d* transition ($^1T_{1g} \rightarrow {}^1A_{1g}$) at 463 nm, ε = 77 l cm^{-1} mol^{-1} for CDAT and 464 nm, ε = 62 l cm^{-1} mol^{-1} for C1M5AT. The second strong absorption band ($^1T_{2g} \rightarrow {}^1A_{1g}$) in both cases overlaps with the band of the tetrazole ligand. Apparently, the complexes studied, like CAT, contain octahedral chromophore CoN_6.

The ^{1}H NMR spectra of the compounds contain signals at 3.3–3.8 ppm belonging to equatorial (in lower field) and axial (in higher field) ammonia molecules. The difference between the positions of equatorial (3.66 and 3.68 ppm) and axial (3.52 and 3.50 ppm) ammonia molecules for C1M5AT and CDAT, respectively, is the evidence of the *trans* effect of heterocyclic ligands and agrees with their coordination through nitrogen atoms [4]. The heterocycle is the most probably coordinated via N^4 atom [5].

The salts obtained surpass CAT in the shock sensitivity. The shock sensitivity of CDAT is close to that of pentaerythritol tetranitrate (TEN) and somewhat lower than that of C1M5AT [5]. In contrast to CAT, C1M5AT and CDAT are priming explosives. In accordance with the minimal charge with respect to cyclonite within blasting cap no. 8 (BC no. 8) dimension, the priming performance of C1M5AT is approximately close to that of mercury fulminate, and that of CDAT is higher by a factor of approximately 2. CDAT is of most practical interest as PE for safe PCs.

We can suggest that the presence of an additional 1 mol of perchlorate ion as oxidant increases the priming performance and shock sensitivity and decreases the thermal stability of the complexes obtained as compared to CAT.

EXPERIMENTAL

The IR spectra of C1M5AT and CDAT were recorded on a Perkin–Elmer M-457 spectrometer using films or mulls in Nujol or perfluorinated oil on KBr pellets.

The UV spectra were recorded on a Perkin–Elmer LAMBDA 40 spectrometer in quartz cells (l = 1 cm) at analytical concentrations of 10^{-1}–10^{-2} M.

The ^{1}H NMR spectra were recorded on a Bruker AC spectrometer (300 MHz) in DMSO-d_6, internal reference hexamethyldisiloxane (HMDS).

The synthesis progress was monitored by thin-layer chromatography on Silufol UV-254 plates, eluent 3% NaCl.

Thermographic studies were performed on an OD-102 device (20–500°C, heating rate 5 deg min^{-1}). T_d was measured on a thermographic device at a heating rate of 5.3 deg min^{-1}. The shock sensitivity measurements were performed with an impact machine according to GOST (State Standard) 4545–88. The minimal charge of complexes was determined relative to cyclonite within BC no. 8 dimensions (P_{pr} of the compound 300, and P_{pr} of cyclonite, 800 kg cm^{-2}).

Aquapentamminecobalt(III) perchlorate (**II**) was synthesized by the method described in [6]. After drying, the yield of **II** was 77%. IR, ν, cm^{-1}: 3330 s, 3270 s, 1630 m, 1350 m, 830 m (H_2O, NH_3), 1100 s (ClO_4^-). ^{1}H NMR (DMSO-d_6), δ, ppm: 3.75 (3H, NH_3 ax); 4.90 (12H, NH_3 eq).

Found (%): H 3.6; N 15.4; Cl 23.3.
$H_{17}Cl_3CoN_5O_{13}$.
Calculated (%): H 3.7; N 15.2; Cl 23.1.

The properties of this compound agree with data of [6].

(1-Methyl-5-aminotetrazolo)pentamminecobalt(III) perchlorate (C1M5AT). Aquapentammine-

cobalt(III) perchlorate (0.5 g) was dissolved in 5 ml of 1% perchloric acid, and 0.5 g of 1-methyl-5-aminotetrazole synthesized according to [7] was added. The reaction mixture was kept on a boiling water bath for 4 h and cooled to 15°C; the precipitate was filtered off, washed with ethanol (2 × 5 ml), and recrystallized from 1% $HClO_4$. Yield 58%. IR, ν, cm^{-1}: 3328 m, 1354 m (NH_3, Tz), 1100 m (ClO_4^-), 1648 m (C=N), 3112 w, 1660 w (NH_2), 2880 w (CH_3). ^1H NMR (DMSO-d_6), δ, ppm: 3.52 (3H, NH_3 ax); 3.66 (9H, NH_3 eq); 3.90 (3H, CH_3–Tz), 7.58 (2H, NH_2–Tz).

Found (%): C 4.6; H 3.8; N 25.7.
$C_2H_{20}Cl_3CoN_{10}O_{12}$.
Calculated (%): C 4.4; H 3.7; N 25.8.

(1,5-Diaminotetrazolo)pentamminecobalt(III) perchlorate (CDAT) was synthesized similarly to C1M5AT. Yield 62%. IR, ν, cm^{-1}: 3304 m, 1376 m (NH_3, Tz), 1072 m (ClO_4^-), 1628 m (C=N), 3104 w, 1664 w (NH_2). ^1H NMR (DMSO-d_6), δ, ppm: 3.68 (9H, NH_3 eq); 3.52 (3H, NH_3 ax); 6.90 (2H, NH_2–C); 7.45 (2H, NH_2–N).

Found (%): C 2.3; H 3.7; N 28.2.
$C_1H_{19}Cl_3CoN_{11}O_{12}$.
Calculated (%): C 2.2; H 3.5; N 28.4.

CONCLUSION

Two high-energy-capacity coordination compounds, (1-methyl-5-aminotetrazolo)pentamminecobalt(III) perchlorate and (1,5-diaminotetrazolo)pentamminecobalt(III) perchlorate, were synthesized. The second compound in accordance with its properties is a promising priming explosive for safe priming charges.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Acylation of Amino Acids with Dextran Derivatives

A. V. Krasnikova and A. A. Iozep

St. Petersburg State Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

Received January 15, 2004

Abstract—The conditions of N-acylation of amino acids with carboxymethyl dextran ethyl ester and with carboxymethyl and carboxyethyl dextran azides were studied.

Derivatives of amino acids containing primary amino and carboxy groups receive steady researchers' attention due to a wide spectrum of the biological activity. They are active components of many antibacterial, antitumor, antiphlogistic, antiulcer, and other drugs. Typical examples are ampicillin, oxacillin, cephalexin, cephalotin, etc. [1]. In this context, binding of amino acids with polysaccharides through a peptide bond is also of interest, since it allows, on the one hand, preparation of potentially bioactive substances and, on the other hand, improvement of existing drugs [2].

Polysaccharide–amino acid conjugates are prepared by such methods as azide method, method of activated esters, cyanogen bromide method, and also via dextran dialdehyde [3–5]. The goal of this study was to look for new routes and improve existing routes to polysaccharide–amino acid conjugates (see scheme).

As agents for acylation of amino acids we used carboxymethyl dextran ethyl ester (CMDEE, **I**) and carboxymethyl dextran (CMD) and carboxylethyl dextran (CED) azides. Compound **I** was prepared as suggested in [6] by heating the H form of CMD at 80°C with excess ethanol under the conditions of autocatalysis. CMD hydrazides (**III**) were prepared by acylation of hydrazine with CMDEE in water at 5–15°C for 24 h [7]. CED amides (**II**) and hydrazides (**III**) were prepared by alkylation of dextran with

acrylamide, followed by acylation of hydrazine hydrate with the resulting CED amide as described in [8]. CMD and CED azides (**IV**) were prepared as described previously [8, 9], by dissolving hydrazides **III** in 2.5 M aqueous $NaNO_2$ at 0°C, with subsequent acidification with HCl to pH 2. Dextran azides **IV** were used for acylation of amino acids without isolation from solution.

Acylation of amino acids with CMDEE was performed in aqueous alkaline solution at 0–20°C for 1–24 h or in ethanol in the presence of triethanolamine (TEA) at 78°C for 5–20 h; the amino acid was taken in the amount of 3–5 mol per mole of monosaccharide units. The reactions of amino acids with CMD and CED azides were performed in water; the pH, reactant ratio, and reaction time were varied. To a solution of carboxyalkyl dextran azide, after decomposition of excess HNO_2 with urea, we added a solution of an amino acid sodium salt (1–3 mol per mole of monosaccharide units); then we adjusted pH by adding alkali or acid solution and diluted the mixture with water to the required volume (4–7 ml). The mixture was kept at 0–25°C for 1–24 h. The resulting products were precipitated and reprecipitated with ethanol from aqueous alkali to remove low-molecular-weight impurities. Their absence in the reaction products was checked by TLC.

Substituted carboxyalkyl dextran amides **VI** are white or yellowish white amorphous powders readily soluble in water and insoluble in alcohol, acetone, ether, and the majority of other organic solvents.

The IR spectra of the reaction products in the H^+ form contain bands at 1535–1590 and 1640–1685 cm^{-1} (CMD amides), or at 1540–1550 and 1650–1670 cm^{-1} (CED amides), absent in the spectra of the starting substances and characteristic of δ_{N-H} (amide II) and $\nu_{C=O}$ (amide I) vibrations. In the IR spectra of the sodium salts of the products, the band at 1730 cm^{-1} disappears, and a new band at 1580 (CED amides) or 1600 cm^{-1} (CMD amides) appears. This band, characteristic of the carboxylate ion, obscures the bands of amide groups. The spectra also contain bands characteristic of aromatic rings of the starting amino acids.

UV spectroscopy is a convenient tool in our case, since the spectra of aqueous solutions of N-substituted carboxyalkyl dextran amides and of the starting amino acids are similar, whereas the polysaccharide shows no absorption in this range.

CMD and CED amides were quantitatively characterized by the degree of aminocarbonylalkylation C_{aca} (numbere of amide groups per monosaccharide unit of the polymer), and the acylation reaction, by the degree of amidation C_{am} (percentage of the polysaccharide acyl groups involved in the reaction). The C_{aca} values were calculated from the elemental analysis data and UV spectra.

Since CMDEE readily acylates aliphatic and aromatic amines [10, 11], we studied its reaction with amino acids. As expected, this reagent allows binding of amino acids with dextran, but with α-amino carboxylic acids in water and ethanol CMDEE reacts worse than with other amino acids (Table 1).

This may be due, firstly, to a stronger, compared to other amino acids, effect of the carboxy group in α-amino acids on the nucleophilicity and steric accessibility of the amino group and, secondly, to physicochemical properties of the amino acids, which are poorly soluble or insoluble in water and the majority of organic solvents. Addition of bases to the reaction mixture for solubilization of the substrate in water causes hydrolysis of CMD ester, which occurs faster than acylation. Therefore, in aqueous solutions CMDEE virtually does not acylate tryptophan, which is sparingly soluble even in alkali solutions, and poorly reacts with more soluble β-phenyl-α-alanine. Similar pattern is observed in ethanol in which CMDEE poorly acylates α-amino acids irrespective of their solubility in alcohol.

Lysine and ε-aminocaproic acid are soluble in water and at pH 7–8 react with CMDEE almost as readily as do aliphatic amines. The degree of amidation of CMDEE ester groups in reactions with these

Table 2. Results of acylation of α-amino acids with CMD and CED azides at optimal pH of the medium (4 and 24 h, respectively; 18–20°C; 3 mol of amino acid per mole of monosaccharide units)

Amino acid	Isoelectric point	CMD azide		CED azide	
		pH_{opt}	C_{am}, %	pH_{opt}	C_{am}, %
Glutamic	3.22	11	86	11	88
D,L-β-Phenyl-α-alanine	5.07	8	86	10	80

D,L-Diiodotyrisone	–	9	77	12	75
D,L-Tryptophan	5.89	8	34	9	36
D,L-Histidine	7.64	8	54	12	56

amino acids is approximately similar, being somewhat higher with lysine. This fact suggests that the ε-amino group of lysine reacts predominantly, but acylation at the α-amino group cannot be ruled out either.

Experiments on acylation of α-, β-, γ-, and ε-amino acids with CMDEE in water and ethanol showed that, the more remote is the amino group in the substrate molecule from the carboxy group, the higher the degree of conversion of CMD esters into amides. The reaction in water is faster than in ethanol, but the dependences of C_{am} on the position of the amino group are similar in water and ethanol (Fig. 1). Despite lower reaction rate in ethanol, it is, however, preferable to perform the reactions of dextran with amino acids in ethanol. In this case, the reaction is not complicated by hydrolysis of the ester groups and can be performed for longer time, leading to higher C_{am} than in water. For example, with α-amino acids, an increase in the acylation time from 5 to 20 h resulted in a 1.8-fold growth in the conversion of ester groups, and with ε-aminocaproic acid, 100% conversion of CMD ester groups into amide groups was attained in 8 h.

Since modification of polysaccharides with α-amino acids via CMDEE involves serious problems, we examined the suitability for this purpose of CMD and CED azides. The conditions for acylation of amino acids with carboxyalkyl dextran azides were optimized by examining the dependence of C_{am} on the solution acidity, as it was shown previously that the results of similar reactions with amines strongly depend on pH [9, 12]. Indeed, as in the case of amines, in acylation of α-amino acids there is a certain optimal pH at which the degree of conversion of the azide groups in the polysaccharides into the amide groups passes through a maximum. For example, the reactions of CMD and CED azides with phenylalanine are the most efficient at pH 8 and 10, respectively (Fig. 2); under these conditions, the amino acid fully dissolves in water, and the reaction mixture is homogeneous. The optimal pH values for acylation of the other amino acids are listed in Table 2.

We found that the reactions of CMD azide with α-amino acids were the most efficient at approximately the same pH values, pH 8–9, and only with glutamic acid pH 11 was optimal. As in acylation of aromat-

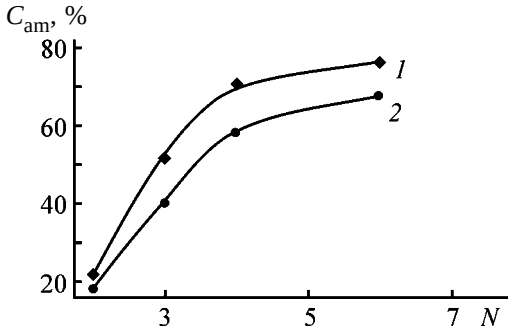

Fig. 1. Degree of amidation C_{am} of CMDEE ester groups in reactions with α- and β-alanine, γ-aminobutyric acid, and ε-aminocaproic acid in (*1*) water and (*2*) ethanol, plotted vs. position of the amino group in the molecule (number of the carbon atom *N*).

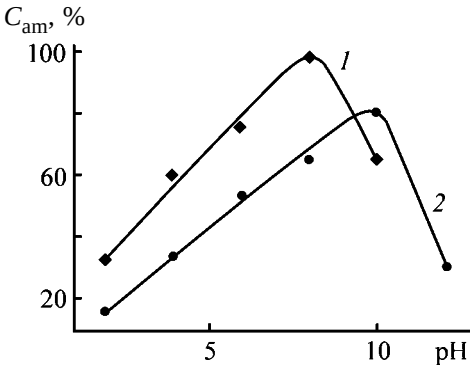

Fig. 2. Degree of amidation C_{am} of azide groups in reactions of β-phenyl-α-alanine with (*1*) CMD and (*2*) CED azides as a function of solution pH (4 and 24 h, respectively; 18–20°C; 3 mol of amino acid per mole of monosaccharide fragment).

ic and aliphatic amines [12], CED azide reacts with amino acids in more alkaline media than does CMD azide, and the optimal pH values in this case are pH 9–12. To compare, replacement of CMD azide by CED azide in reactions with benzylamine and aniline shifts the optimal pH of the reaction mixtures from 8 to 10 and from 2 to 5, respectively. This may be due to lower reactivity of CED azides and higher activity of the nucleophile at higher pH. However, higher stability of CED azides allows the reaction time to be extended to 18–24 h, and the results similar to those of acylation with CMD azides can be obtained. Indeed, in all the cases, under similar other conditions, C_{am} of azide groups in CMD and CED derivatives in reactions with the same α-amino acids is similar (Table 2).

It should also be noted that carboxyalkyl dextran azides acylate α-amino acids better than does CMDEE. Under proper conditions, C_{am} of CMD azide in reactions with the majority of the amino acids studied exceeds 70% and in some cases even 90%. The results of acylation of amino acids with CED azides are somewhat worse but also high. And only with tryptophan, whose acylation occurs in a heterogeneous medium in contrast to the other acids, C_{am} does not exceed 40% in both cases.

We also examined the influence of time on the reaction of carboxyalkyl dextran azides with amino acids. We found that the reaction was complete in 2–4 h with CMD azides and in 16–24 h with CED azides. For example, in acylation of β-phenyl-α-alanine with CMD azide, C_{am} was 57% in 1 h and 98% in 2 h. The molar ratio of amino acids to CMD monosaccharide units should be no less than 2 : 1, at the concentrations of 0.154 and 0.077 M, respectively.

CONCLUSIONS

(1) Carboxymethyl dextran ethyl esters acylate amino acids in water and ethanol and can be used for preparing dextran–amino acid conjugates.

(2) Carboxymethyl and carboxyethyl dextran azides react with α-amino acids more readily than does carboxymethyl dextran ethyl ester. For any particular amino acid, there is a certain optimal pH at which C_{am} is maximal; this pH is in the range 8–11 with carboxymethyl dextran azide and 9–12 with carboxyethyl dextran azide.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Electronic Spectra and Protonation of 1,4-Di(arylamino)anthraquinones and Their Monodimethylformamidinium Salts in Acid Solutions

V. P. Shapkin, S. I. Popov, and V. V. Marshalova

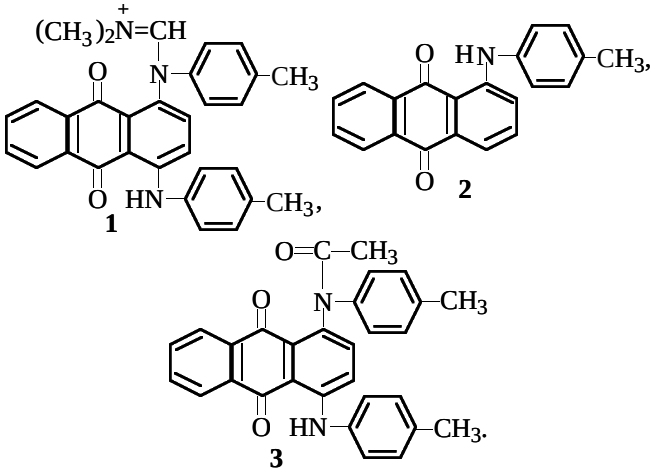
Received August 18, 2003; in final form, January 2004

Abstract—Electronic spectra of arylaminoanthraquinones and their amidinium salts in acids were studied, and experimental data on electrophilic substitution of diarylaminoanthraquinone amidinium salts in acetic and sulfuric acids of various concentrations were considered.

To explain different inhibiting effect of dimethylformamidinium group in acetic and sulfuric acids on the reactivity of 1,4-di(arylamino)anthraquinone aryl core [1–4], we have studied the electronic spectra of these derivatives in the corresponding media.

Monodimethylformamidinium salts of 1,4-di(arylamino)anthraquinone [e.g., monodimethylformamidinium salt of 1,4-di(4-methylanilino)anthraquinone (**1**)] in acetic acid solutions have spectra characteristic for compounds in which one arylamino group is absent or is not involved in conjugation with the anthraquinone core as, e.g., in the case of 1-(4-methylanilino)anthraquinone (**2**) or its acetylamino derivative (**3**) (Fig. 1). This shows that the arylaminodimethylformamidinium group is removed from the conjugation, and its inactivity in electrophilic substitution in acetic acid solutions suggests partial localization of the positive charge on the nitrogen atom bonded to the anthraquinone core:



The spectral characteristics of 1,4-di(arylamino)anthraquinones and their monodimethylformamidinium salts in solutions containing sulfuric acid are more complex. Additon of sulfuric acid to a solution of 1,4-di(4-methylanilino)anthraquinone with $c \geq 1 \times 10^{-3}$ M in acetic acid causes appearance of a band at 507 nm and finally leads to a spectrum characteristic of 1-(4-methylanilino)anthraquinone (Fig. 2a, curve *9*). This suggests protonation to the nitrogen atom of one of arylamino groups (**4**). In the region of lower substrate concentrations ($\leq 0.25 \times 10^{-4}$ M), similar increase in the sulfuric acid concentration leads to appearance of a band at 714 nm (Fig. 2b, curve *8*), which can be explained by protonation of the oxygen

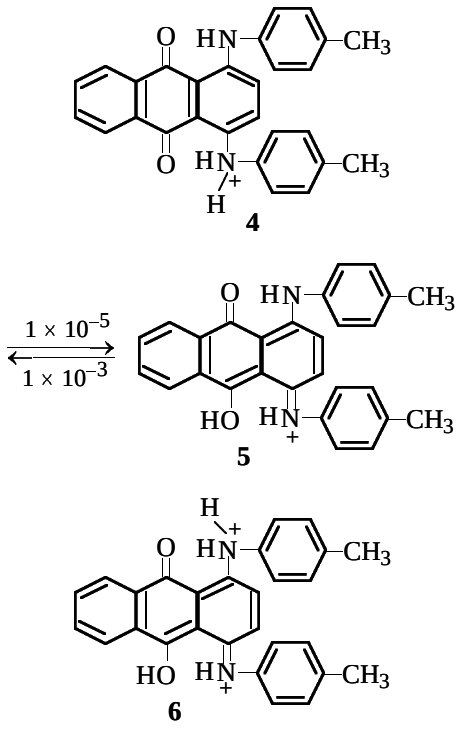
H_2SO_4 concentration (wt %): (a) (*1*) 0, (*2*) 0.33, (*3*) 0.69, (*4*) 1.1, (*5*) 1.5, (*6*) 2.06, (*7*) 2.5, (*8*) 5.0, and (*9*) 7–9; (b) (*1*) 0, (*2*) 0.17, (*3*) 0.36, (*4*) 0.74 (*5*) 1.3, (*6*) 1.26, (*7*) 5.08, and (*8*) 9–16.

atom of the keto group accompanied by redistribution of bonds in the nitrogen(C^4)–oxygen(C^{10}) chain and formation of more deeply colored 1,10-quinonimine structure (**5**):



Since data on distribution of the bonds in the protonated species of 1,4-di(arylamino)anthraquinones and their dimethylformamidinium salts are lacking, in the schemes and in the text we show for each case one of possible boundary structures explaining to a certain extent the color transitions observed.

At intermediate concentrations of the substance, 1×10^{-3}–1×10^{-5} M, with correspondingly chosen thicknesses of the absorbing layers, and constant concentration of sulfuric acid, both species are observed. In such solution, the initial 1,4-di(4-methylanilino)-anthraquinone is absent, and the presence of isobestic points indicates equilibrium between two protonated species **4** and **5**. Near the boundary concentrations and outside these boundaries, when only one species exists, the solution obeys Lambert–Beer's law. At higher concentrations of sulfuric acid, species **4** and **5** convert into one diprotonated species **6**.

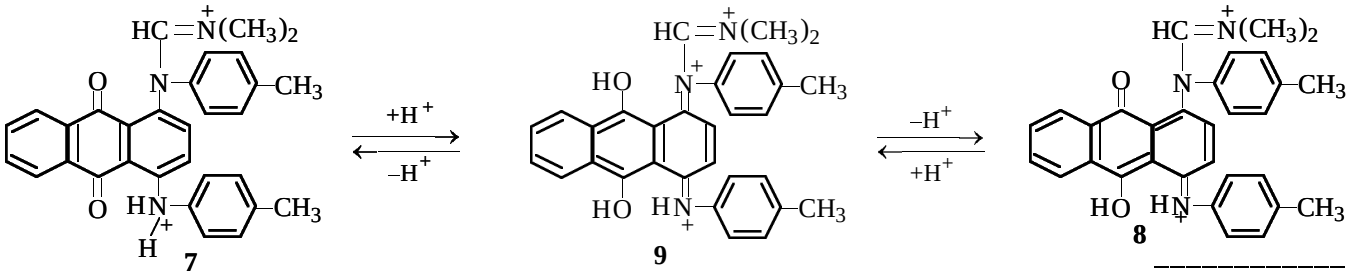
The calculated values of pK_a for red (**4**) and green (**5**) forms are –1.64 and –1.67, respectively. This demonstrates close properties of protonation centers and possibility of formation of different protonated species when the protonation conditions are changed. At present, this phenomenon has no strict explanation. Presumably, in the more concentrated solutions associates (dimers) exist. Different surrounding of the protonated molecule in this case can cause proton localization on different atoms.

Similar protonation pattern is observed at various concentrations of 1,4-dianilinoanthraquinone (p$K_{a(C=O)}$ = 1.82, p$K_{a(N–H)}$ = 1.81), 1-(2-bromo-4-methylanilino)-4-(4-methylanilino)anthraquinone, and

1-(2-nitro-4-methylanilino)-4-(4-methylanilino)anthraquinone.

In the case of 1,4-di(2-bromo-4-methylanilino)-anthraquinone, addition of sulfuric acid to solution within a wide range of substrate concentrations leads to appearance of the band at 714 nm, suggesting protonation of the carbonyl oxygen atom. In turn, more basic 1-methylamino-4-(4-methylanilino)anthraquinone converts into the red form owing to protonation of the methylamine group at any concentrations.

Different protonated species were also detected for monodimethylformamidinium salt (**1**). At salt concentrations $c \geq 1.6 \times 10^{-3}$ M and addition of sulfuric acid, the red salt solution becomes colorless, and species **7** is formed, while at $c \leq 4.0 \times 10^{-5}$ M, deeply colored blue species **8** appears. Formation of different species is confirmed by the electronic spectra. The calculated values of basicity ($pK_{a(C=O)} = -3.9$, $pK_{a(N-H)} = -3.8$) are also close, but two orders of magnitude lower as compared to pK_a for 1,4-di(4-methylanilino)anthraquinone due to the effect of the positively charged dimethylformamidinium group. Both species **7** and **8** convert into deeply colored form **9** as the sulfuric acid concentration is increased further:



This transition is, most likely, caused by protonation of the oxygen atom at the second (at C^9) keto group. The deep color of diprotonated monodimethylformamidinium salt of 1,4-di(4-methylanilino)anthraquinone (bathochromic shift by 72 nm as compared to species **6**) suggests existence of the 1,4-quinonediimine structure **9**. In this structure, free rotation of the fragment unsubstituted with the dimethylformamidinium group around the N–C bond is, probably, hindered by conjugation through the C=N bond. In this case, only one *o*-position of the 4-methylphenylimino group is free for substitution, while the second position is blocked with the C^3–H fragment of the anthraquinone ring.

The spectral changes observed with monodimethylformamidinium salt of 1,4-di(4-methylanilino)anthraquinone as the sulfuric acid concentration is increased correspond to the color differences of solutions used for bromination. For instance, dibromination of monodimethylformamidinium salt of 1,4-di(4-methylanilino)anthraquinone in 85–87% sulfuric acid yields 1-(4-methylanilino)-4-(2,6-dibromo-4-methylanilino)-anthraquinone, whereas the same reaction in 97% sulfuric acid yields the 2,5-dibromo isomer. In the latter case, only 1-(4-methylanilino)-4-(2-bromo-4-methylanilino)anthraquinone is formed as intermediate.

The spectra were recorded on a Specord spectrophotometer with standard optical cells from 0.1 to 10 cm thick. Analytically and chromatographically pure grade substances were used for preparing solutions.

CONCLUSIONS

(1) In the series of 1,4-di(arylamino)anthraquinones and their monodimethylformamidinium salts, various protonated species are formed in the acid solutions depending on the substance concentration at the same acid concentration.

(2) According to the electronic spectra recorded at different substrate concentrations, in dilute solutions proton is added to the carbonyl oxygen atom, and in more concentrated solutions, to the nitrogen atom of the arylamino group.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Phase Separation in Aqueous Solutions of Binary Copolymers of Acrylamide with Sodium 2-Acrylamido-2-Methylpropanesulfonate and Sodium Acrylate

V. F. Kurenkov, I. N. Nadezhdin, O. A. Antonovich, and F. I. Lobanov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received October 22, 2003

Abstract—Phase separation in aqueous solutions of binary copolymers of acrylamide with sodium 2-acrylamido-2-methylpropanesulfonate and sodium acrylate is studied over the temperature range from 20 to 100°C, as influenced by addition of calcium, magnesium, and sodium chlorides, inorganic salt concentration, and molecular characteristics of the copolymers.

Water-soluble copolymers of acrylamide (AA) with sodium salt of 2-acrylamido-2-methylpropanesulfonic acid (HAMS) demonstrate a wide spectrum of useful properties such as thickening and flocculating activities [1–3], adhesion and antistatic properties [4], and also stabilizing and structuring activities. They are used in oil production, borehole drilling, and water treatment [1, 2, 5]. Water-soluble polymers are often prepared and used in media containing salt additives capable of influencing the conformation and stability of macromolecules in solutions and also the properties of polymers. For example, the viscosity of polyacrylamide (PAA) hydrogels, used in oil production, decreases under the effect of calcium, magnesium, and sodium chlorides from stratal water. Therefore, it is important to study the effect of salt aggression on the stability of polymers, as influenced by various factors.

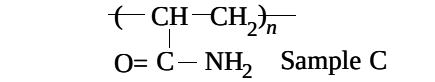
Previously Ikegami reported on the effect of mixtures of Na and Ca chlorides [6] and Na chloride and Mg, Ca, and Ba nitrates [7, 8] on the phase separation in aqueous solutions of PAA and its hydrolyzed derivatives. Also the effect of calcium chloride on the phase separation in solutions of copolymers of AA with sodium acrylate (NaA) and NaAMS [9], of AA with HAMS and 4-acrylamido-4-methylsulfolane-3-sulfonic acid, and of acrylonitrile with HAMS [10] was studied.

In this work we reported new data on the phase separation in aqueous solutions of copolymers of AA with NaAMS and NaA over the temperature range from 20 to 100°C, as influenced by addition of calcium, magnesium, and sodium chlorides, inorganic salt concentration, and concentration and molecular characteristics of the copolymers. For comparison, the features of phase separation were also studied in solutions of homopolymers: PAA and poly-NaAMS (NaPAMS).

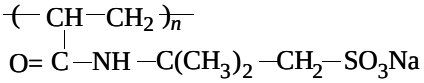
EXPERIMENTAL

In this work we studied copolymers of AA with NaAMS and NaPAMS, obtained by radical polymerization and copolymerization in aqueous solutions [11]. After synthesis, the products were separated by adding acetone, and then they were washed with acetone and vacuum-dried at 50°C to constant weight. The characteristics of the resulting products are given in Table 1.

The structural formulas of the macromolecules of the samples studied are given below.



Sample C



Sample B

AA/NaAMS copolymers with various molecular weights (MW) and given chemical composition of macromolecules were obtained by degradation of the high-molecular-weight sample R (SNF Flodger, France) (Table 1). Degradation was carried out in 0.2% solutions at 60°C in the presence of a radical-type degrading agent, potassium peroxodisulfate $K_2S_2O_8$, according to the procedure described in [12]. Using the calibration curve $[\eta] = f(t)$ (η is the intrinsic viscosity of the copolymer and t, degradation time) (Fig. 1), we obtained AA/NaA copolymers with various $[\eta]$. The MW of the resulting products was estimated from $[\eta]$ by the Mark–Houwink–Kuhn equation.

In the work we used polyacrylamide and AA/NaA copolymers from Moscow–Stockhausen–Perm Closed Corporation, Russian–German Enterprise. Their characteristics are given in Table 1. The salts NaCl, $MgCl_2$, and $CaCl_2$ were of chemically pure grade.

The content of ionic groups in macromolecules of the AA/NaAMS copolymers was estimated from the sulfur content determined according to the procedure described in [13]. The content of NaA units in the AA/NaA copolymer was determined by potentiometric titration [14]. The intrinsic viscosity of copolymers was measured at 30°C in 0.5 M NaCl using VPZh-3 viscometer (capillary diameter 0.43 mm).

The phase separation was studied in 0.2% solutions of copolymers in distilled water. An inorganic salt was added into the copolymer solution (30 ml), and the mixture was stirred on a magnetic stirrer with slow heating (<1 deg min^{-1}). After the solution became clear, it was cooled, and the cloud point was accepted as the phase separation temperature ($T_{p.s}$), which was determined to within 1°C.

Initially we studied phase separation in AA/NaA copolymers of various chemical compositions (Table 1, samples D, E, F, G), as influenced by the temperature and inorganic salt concentration. The $CaCl_2$ and $MgCl_2$ concentrations varied from 0.25 to 3%, and the NaCl concentration, from 3 to 10%. Figure 2 shows a typical dependence of $T_{p.s}$ in AA/NaA copolymer solutions on the $MgCl_2$ concentration. As seen, in the range of low salt concentrations, $T_{p.s}$ decreases, and in the range of high salt concentrations, increases with increasing $MgCl_2$ concentration. Such a dependence with a lower critical point $T_{p.s}$ was observed for all the salts and AA/NaA copolymer samples, which is well consistent with the published data [5, 8].

For AA/NaA copolymers of various compositions, the effect of the $CaCl_2$, $MgCl_2$, and NaCl concentration on $T_{p.s}$ is shown in Table 2. Phase separation occurs at low $CaCl_2$ and $MgCl_2$ concentrations (0.25–3%), but with NaCl the required concentration is higher (3–10%). The observed effects can be attributed to a decrease in the solubility of the copolymers [15, 16] as a result of specific interaction (chelation) of divalent cations Ca^{2+} and Mg^{2+} with polyanions of the AA/NaA copolymer with formation of strong intra- and intermolecular bonds resulting in decomposition of the hydration shell around the macromolecules. In this case, the electrostatic repulsion between likely charged ions along the chain weakens, decreasing the linear size of coils of the polyions. When the number of salt bonds between the polyanions and cations approached the critical value, the

* (n) No phase separation.

copolymer became insoluble and precipitated. Compared to the divalent metal salts, NaCl demonstrates lower dehydrating capacity, and phase separation of the copolymers occurs at higher salt concentration than in the case of Ca and Mg chlorides (Table 2).

Analysis of data obtained at a fixed concentration of inorganic salts (Table 2) shows that, for all the salt additives studied, $T_{p.s}$ decreases with increasing content of ionic groups in macromolecules of the AA/NaA copolymer, which is consistent with the published data [7, 8]. Increase in the ionic group content in the copolymer increases the concentration of salt bonds between polyanions and cations, decreasing the stability of the macromolecules in solution. This is also favored by the reduced possibility of H-bond blocking of ionic groups of the copolymers in interaction with the amide groups as the content of the NaA units in the AA/NaA copolymers increases.

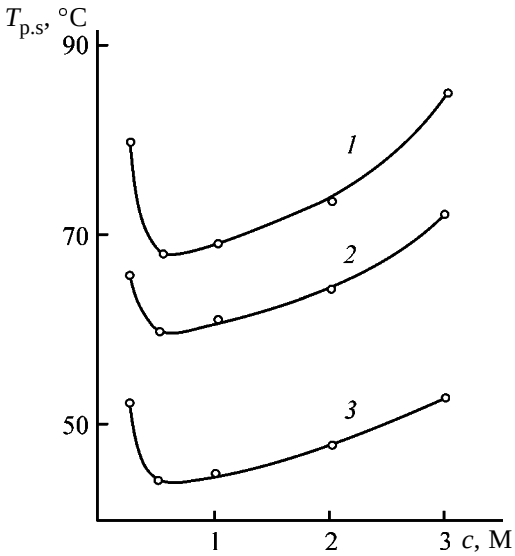

Fig. 2. Phase separation temperature $T_{p.s}$ of AA/NaA copolymers in aqueous solutions as a function of the $MgCl_2$ concentration *c*. c_p = 0.2%; the same for Fig. 3. Samples: (*1*) E, (*2*) F, and (*3*) G.

Let us consider the effect of divalent metal salts, $CaCl_2$ and $MgCl_2$, on the phase separation in solutions of AA/NaA copolymers. The dependence of $T_{p.s}$ on the solution ionic strength μ controlled by salt additions is presented in Fig. 3a (sample E) and Fig. 3b (sample F). Analysis of data obtained at μ = const (Fig. 3) shows that $T_{p.s}$ decreases on passing from Mg^{2+} to Ca^{2+} (curves *1*, *2*). This is probably due to the fact that Ca^{2+} is more strongly bound to polyacrylate anion than Mg^{2+} [17].

The phase behavior in solutions of AA/NaAMS copolymers of different compositions and of the homopolymers, PAA and NaPAMS, was studied in the presence of $CaCl_2$, $MgCl_2$, and NaCl at 25–100°C. Table 2 shows that, over the experimental salt concentration range, the indicated polymers and copolymers remain to be soluble up to 100°C.

The effect of the concentration of AA/NaAMS copolymer on the phase separation was studied at 20 and 100°C over the copolymer concentration range from 0.1 to 0.5% in the presence of 0.25 and 3% $CaCl_2$ (Table 3). At low copolymer concentration (0.1

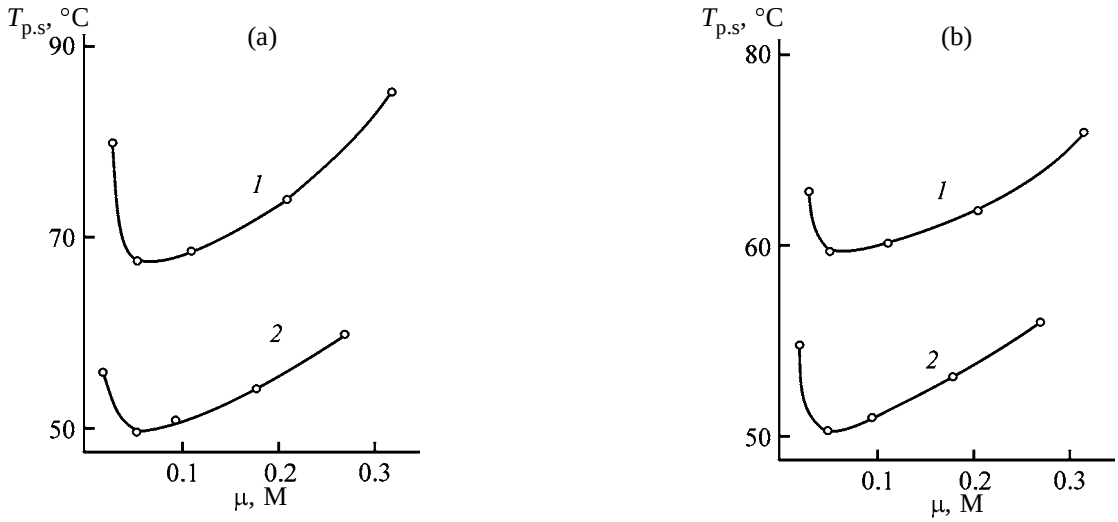

Fig. 3. Phase separation temperature $T_{p.s}$ of AA/NaA copolymers as a function of the solution ionic strength μ: (*1*) $MgCl_2$ and (*2*) $CaCl_2$. Sample: (a) E and (b) F.

and 0.2%), no phase separation was observed. With increasing c_p to 0.3%, we did not observe phase separation only at the lower $CaCl_2$ concentration, and at c_p = 0.5%, phase separation was observed at both $CaCl_2$ concentrations.

We also studied the effect of MW of AA/NaAMS copolymer on the phase separation. Experiments were carried out at c_p = 0.2% and the $CaCl_2$ concentration of 0.25 and 3% over the temperature range 20–100°C. The results obtained for AA/NaAMS copolymers of the same chemical composition showed that, over the [η] range from 50 to 570 $cm^3\ g^{-1}$, no phase separation occurred.

The observed higher phase stability of AA/NaAMS copolymers in the presence of divalent metal salts, compared to AA/NaA copolymers, can be attributed to different geometry of anions in these copolymers. AA/NaAMS copolymer contains longer substituents [–C(O)–NH–C$(CH_3)_2$–CH_2–SO_3Na] as compared to AA/NaA [–C(O)–ONa]. As known, longer substituents provide higher flexibility and lower charge density along the chain. Evidently, this should favor lower degree of bonding of divalent cations with the polysulfonate anions as well as higher phase stability of AA/NaAMS as compared to AA/NaA.

Another reason is different strength of bonding between divalent cations and strong and weak polyelectrolytes. It was demonstrated [17] that specific bonding between the counterions and polyions is untypical of strong polyelectrolytes such as AA/NaAMS copolymer, being significant in the case of weak polyelectrolytes such as AA/NaA copolymer. Therefore, divalent cations, Ca^{2+} and Mg^{2+}, are more readily bound to AA/NaA as compared to AA/NaAMS, providing higher phase stability for the latter.

CONCLUSIONS

(1) Copolymers of acrylamide and sodium 2-acrylamido-2-methylpropanesulfonate demonstrate higher phase stability in the presence of inorganic salts ($CaCl_2$, $MgCl_2$, and NaCl) as compared to copolymers of acrylamide and sodium acrylate.

(2) No phase separation was observed for copolymers of acrylamide and sodium 2-acrylamido-2-methylpropanesulfonate with different ionic group contents and 50 < [η] < 570 $cm^3\ g^{-1}$ over the copolymer concentration range 0.1–0.2%, irrespective of the $CaCl_2$ and $MgCl_2$ concentrations and temperature (20–100°C).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Specific Features of Interaction of Polyacrylic and Polymethacrylic Acids with Nanoparticles of Amorphous Selenium

Abstract—A study was made of formation of selenium nanoparticles in water from reduction of sodium selenite with ascorbic acid in the presence of polyacrylic and polymethacrylic acids.

It is well known that nanoparticles of zero-valence metals and nonmetals, with their specific structural features and high surface energy, exhibit abnormal physicochemical properties because of the scale effect of matter [1]. Of special interest are nanoparticles of selenium, a chemical element with unique photoelectric, semiconducting, catalytic, and biological properties and X-ray sensitivity.

Ligand-free nanoparticles are metastable and tend to rapidly aggregate in aqueous solutions. Therefore, they are usually stabilized by water-soluble polymers whose interaction with nanoparticles yields nanostructures of various morphologies [2]. However, the nature of this interaction in formation of nanoparticles in aqueous solutions of polymers still remains to be elucidated.

This work was aimed at elucidating the nature of the above-mentioned interactions and their role in polymer stabilization of selenium nanoparticles (nano-Se^0). To this end, we studied for the first time formation of nano-Se^0 particles in the presence of synthetic polymers differing in the hydrophylic–lipophilic balance. Also, we carried out optical studies of the morphological characteristics of the nanostructures being formed.

EXPERIMENTAL

We studied nano-Se^0 nanoparticles prepared by reducing selenious acid (SA) with ascorbic acid, with and without polymer additions.

As polymeric stabilizers of nano-Se^0 served synthetic polymers, polyacrylic acid (PAA) and polymethacrylic acid (PMAA), with molecular weights M_w of 27×10^6 and 25×10^3, respectively. This choice was dictated by close structures and Kuhn segment sizes of these polymers, of which only PMAA has side hydrophobic methyl groups [3].

The ionic selenium species SeO_3^{2-} was reduced at the selenium concentration in solution of 0.01 wt % and the polymer-to-selenium mass ratio of 9 : 1 (i.e., under exhaustive saturation of the adsorption capacity of nanoparticles, as revealed for other selenium–polymer nanostructures [4]).

Using the method of flow birefringence [5], we estimated the molecular dispersity of the solutions of the adsorbates being formed, based on analysis of the gradient dependence of the birefringence Δn. Specifically, we studied the birefringence versus the gradient of the rotor rotation rate g and the polymer concentration c at a fixed selenium concentration of 0.01 wt %. We used titanium dynamooptometer with a 4-cm-high internal rotor and the rotor–stator slit width of 0.03 cm. The solutions for birefringence measurements were kept at a constant temperature of 21°C to prevent variations of their viscosities and optical distortions due to the temperature gradient. The measuring facility was calibrated against 2-phenylethanol having a significant birefringence ($\Delta n/g = 17 \times 10^{-12}$), as well as against the polystyrene–bromoform system. The intrinsic birefringence $[n] = \lim_{g \to 0, c \to 0}(\Delta n/gc\eta_0)$ (η_0 is the viscosity of the solvent) was measured accurately to within 10%. The measurements were carried out at $g < g_k$, where g_k is the rate gradient corresponding to the onset of flow turbulence.

1070-4272/04/7705-0809 © 2004 MAIK "Nauka/Interperiodica"

The experimentally determined intrinsic birefringence $[n]$ in a general case ($dn/dc \neq 0$, where dn/dc is the increment of the refractive index of the solution, estimated for PAA–Se^0–H_2O and PMAA–Se^0–H_2O systems at 0.245 and 0.165, respectively) has three components: $[n] = [n]_e + [n]_{fs} + [n]_f$, where $[n]_e$ is the intrinsic anisotropy; $[n]_{fs}$, microform effect; and $[n]_f$, macroform effect [5]. The full segment anisotropy $[n]_{fs} + [n]_e$ is determined by the equilibrium rigidity A of the polymer chain and by the structure of the polymer unit, and $[n]_f$ is related to the shape asymmetry parameter p of the macromolecule (particle) as

$$[n]_f = [(n_s^2 + 2)/3]^2[M_w(dn/dc)^2 f(p)]/(30\pi RTn_s)$$

$$= \text{const}\, M_w(dn/dc)^2 f(p), \quad (1)$$

where M_w is the molecular weight of the adsorbate macromolecule; n_s, refractive index of the solvent; T, absolute temperature; R, universal gas constant; and $f(p)$, tabulated function of the ratio of the axes of a rigid (impermeable by the solvent) ellipsoid approximating the particle [5].

Relationship (1) is valid both for isolated macromolecule and nanostructure; all what is needed of a particle is to be impermeable by the solvent. Thus, for high-molecular-weight flexible-chain and moderately rigid-chain polymers ($A < 5$ nm), having minor optical anisotropy and low-molecular-weight units, the intrinsic birefringence can be fitted by the approximation $[n] \approx [n]_f$, which allows the parameter p to be estimated directly from the experimentally measured birefringence [5].

Using the elastic (static) light scattering method [6], we estimated M_w and the root-mean-square inertia radii R_g of the polymers and nanostructures, as well as their affinity for solvent, water (from the second virial coefficient A_2). Based on the ratio of the parameters M_w for poly acids and nanostructures they form, we determined the number of the macromolecules adsorbed on the nano-Se^0 surface. The reduced intensity of light scattering by solutions R_0 was measured on a Fica photogoniodiffusometer. The wavelength of the incident, vertically polarized, light was 546.1 nm. The measurements were carried out at light scattering angles θ within 30°–150°.The solutions and solvents were purified by centrifugation at 15×10^3 rpm for 1–1.5 h. The refractive index increment dn/dc was determined from the refractive indices measured on an IRF-23 instrument.

The experimental light scattering data were processed by the Zimm method, by double extrapolation ($c \to 0$, $\theta \to 0$) of the plots of Kc/R_θ vs. $\sin^2(\theta/2) + kc$ (K is the calibration constant, and k, numerical constant).

We determined the average hydrodynamic particle sizes R_H by quasielastic (dynamic) light scattering method [7]. Based on the experimental R_g-to-R_H ratio for the nanostructures, we estimated the parameter ρ^* characterizing the conformation of the nanostructure [8–11].

The optical component of the facility for measuring the dynamic light scattering comprised an ALV-SP (Germany) goniometer (a Spectra-Physics He–Ne laser with a wavelength $\lambda = 632.8$ nm, power ca. 20 mV, as light source). The correlation function of the scattered light intensity was obtained on a 288-channel Photo Cor-FC correlator (Anteks Closed Joint-Stock Company, Russia). Data processing was carried out by standard methods of cumulants and Tikhonov regularization, using appropriate software.

According to the static light scattering data, the parameter M_w remains unchanged ($M_w = 27 \times 10^7$) in going from the PAA–H_2O to PAA–Se^0–H_2O system, i.e., in the presence of PAA, no nanostructure is formed. For the PMAA–Se^0–H_2O system, M_w was estimated at 1.5×10^8, i.e., it increased by a factor of 4300 relative to free PMAA macromolecules. This unambiguously suggests the deciding importance of hydrophobic interactions between macromolecules and nano-Se^0 in formation of nanostructures.

The second virial coefficient A_2 for the PMAA–Se^0–H_2O system is equal to zero, which suggests an ideal thermodynamic quality of the solution. For the PAA–Se^0–H_2O system, A_2 is negative, namely, -0.8×10^{-4} $cm^3\,mol\,g^{-2}$, which suggests a bad thermodynamic quality of the solution. Thus, adsorption of macroions on nano-Se^0 improves the thermodynamic quality of the solution.

The parameter R_H for nano-Se^0 particles obtained without polymeric stabilizer was estimated at 170 nm. The particle size of the PMAA–Se^0 adsorbate, estimated by dynamic and static light scattering methods, is much smaller (root-mean-square inertia radius R_g = 90 nm and mean hydrodynamic radius R_H = 90 nm). The parameter $\rho^* = R_g/R_H$ is equal to unity, which suggests virtually ideal spherical shape of the particles of the adsorbate being formed [8–11].

To determine the radius of the selenium particles occurring in the core of the nanostructure, we lyophilically dried an aqueous solution of PMAA–Se^0,

and the resulting dry pelletized product was examined by small-angle X-ray scattering. We estimated the radius of the spherical Se^0 particles at 15 nm, which is by an order of magnitude smaller than that of selenium particles obtained without polymeric stabilizer. Thus, the nano-Se^0 particles in aqueous solutions have a ca. 75-nm-thick polymer shell.

Optical studies of the PAA and PMAA macromolecules showed that, in the nonionized state, these are Gaussian globules with the asymmetry parameter $p \sim 2$ [12].

Calculation of the parameter p in the $[n] \sim [n]_f$ approximation for the PAA–Se^0–H_2O and PMAA–Se^0–H_2O systems yielded, respectively, $p \sim 1$ (spherical conformation) and $p \sim 2$ (which is inconsistent with the value of the parameter p^*, corresponding to the spherical conformation of the nanostructure) [5]. Also, the fact that the reduced optical anisotropy for the PMAA–Se^0–H_2O system is independent of the concentration (Fig. 1) suggests that the parameter p tends to unity, i.e., that the nanostructure is spherical [5]. The fact that hybrid nanostructures formed by macromolecules and nanoparticles have a spherical shape, even in the case of such a rigid macromolecule as DNA [13], suggests that the $[n] \sim [n]_f$ approximation is invalid for the PMAA–Se^0–H_2O system. Evidently, in this case a significant contribution to the optical anisotropy comes from an effect similar to the microshape effect for an isolated macromolecule (Lyubina [12] showed that the intrinsic optical anisotropy even for PMAA with its high degree of ionization is negligible). This is supported by the fact that the $\Delta n = f(g)$ curves (Fig. 2) for the PMAA–Se^0–H_2O system reach saturation. This suggests an increase in the rigidity of the PMAA macromolecules owing to hydrophobic interactions. Thus, hydrophobic interactions of nonpolar fragments of the macromolecules with one another and with nano-Se^0 constitute the major driving force of adsorption.

In the case of PAA, no nanostructure is formed, and the conformation of the macroions changes, in contrast to nonionic hydrophilic polymers such as polyacrylamide [4]. This is presumably due to dipole–dipole interactions of PAA with selenium nanoparticles.

We showed that selenium nanoparticles are adsorption matrices suitable for accommodating in high local concentrations anionic polyelectrolytes containing hydrophobic methyl groups in the side chains. Our results can be applied to molecular designing of new materials with desired properties.

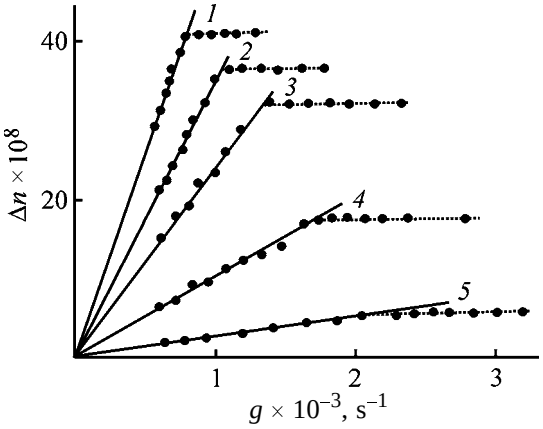

Fig. 2. Variation of the birefringence Δn with the flow rate gradient g for the PMAA–Se^0–H_2O system. c_{PMAA}, wt %: (*1*) 0.1, (*2*) 0.071, (*3*) 0.049, (*4*) 0.0195, and (*5*) 0.0048.

CONCLUSIONS

(1) Reduction of sodium selenite with ascorbic acid in an aqueous solution of polymethacrylic acid yielded spherical nano-Se^0 particles with a size of ca. 15 nm.

(2) Molecular-optical studies showed that the polymethacrylic acid macromolecules adsorbed on nano-Se^0 form an ultra-high-molecular-weight (MW = 150×10^6) spherical nanostructure with a size of ca. 90 nm, comprising over 4000 densely packed macromolecules.

(3) The PMAA–Se^0–H_2O system exhibits an induced conformational transition of polyacrylic acid from a Gaussian globule to a sphere.

(4) The hydrophobic interactions of the macromolecules with nano-Se^0 play the deciding role in their adsorption on nanoparticles.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

NMR Study of the Structure of Polymers Based on 2,3-Epoxypropyl Methacrylate

E. E. Ergozhin, N. A. Bektenov, and N. N. Chopabaeva

Bekturov Institute of Chemical Sciences, Ministry of Education and Science of Kazakhstan Republic, Almaty, Kazakhstan

Received January 20, 2004

Abstract—The structure of homo- and copolymers of 2,3-epoxypropyl methacrylate and methyl methacrylate was studied by high-resolution NMR. The stereochemical sequences in the polymer chains were established.

High-resolution NMR is an efficient method in study and identification of vinyl monomers and polymers based on these, since it allows determination of molecular distribution in polymer chains and furnishes data on the composition of polymers, microstructure, and stoichiometry of macromolecular chain [1–11].

Here we report on the structure of homo- and copolymers of 2,3-epoxypropyl methacrylate (2,3-EPMA) and methyl methacrylate (MMA) studied by ^{1}H and ^{13}C NMR.

EXPERIMENTAL

Poly-2,3-epoxypropyl methacrylate (poly-2,3-EPMA), polymethyl methacrylate (PMMA), and copolymers based on 2,3-EPMA and MMA (2,3-EPMA–MMA) were synthesized by radical polymerization in 1,4-dioxane in the presence of an initiator, azobis(isobutyronitrile) (AIBM) in a concentration of 5×10^{-3} M at 60°C under argon. The polymers were purified from unchanged monomers by threefold reprecipitation from acetone to ethyl ether and dried in a vacuum oven. The content of epoxy groups in 2,3-EPMA, poly-2,3-EPMA, and 2,3-EPMA–MMA was determined by the chemical method based on their reaction with hydrochloric acid in acetone [12].

The ^{1}H and ^{13}C NMR spectra of 10% solutions of monomers and polymers in dimethyl sulfoxide (DMSO–d_6) with hexamethyldisiloxane (HMDS) as an internal reference were recorded at room temperature on a Varian Mercury-300 spectrometer operating at 300.06 MHz for protons.

The signals in the ^{1}H and ^{13}C NMR spectra of the polymers were assigned using the spectral data for the initial monomer 2,3-EPMA and the structural analogs of 2,3-EPMA–MMA: poly-2,3-EPMA and PMMA (Table 1).

The olefin protons of 2,3-EPMA give multiplets in the range 5.6–6.2 ppm with the geminal constant of 1.5 Hz and constants of remote spin–spin coupling with methyl protons equal to 1.0 and 1.5 Hz in *trans* and *cis* positions with respect to this group, respectively. The signal of the methyl group is observed at 1.89 ppm. The protons of the methylene group adjacent to the ester group are nonequivalent and give two doublets of doublets with the geminal constant of 12.3 Hz and vicinal constants of 2.8 and 6.3 Hz. The signals at 2.65, 2.79, and 3.23 ppm are assigned to the protons of the epoxy ring. The first two of them, a doublet of doublets and a triplet with a broadened central component, belong to protons of the methylene group. They have the same splitting of 5.4 Hz arising from geminal coupling, and the splittings of 2.4 and 4.8 Hz corresponding to *cis* and *trans* coupling with protons of the oxirane ring. A complicated structure of the third signal assigned to the methine proton is caused by its coupling with the protons of the neighboring methylene groups.

In the ^{1}H and ^{13}C NMR spectra of homo- and copolymers of 2,3-EPMA and MMA (Table 1), the signals of methyl groups at the double bond, olefin protons, and corresponding carbon atoms disappear. At the same time, new signals characteristic of α-CH_3 groups at a single bond, methylene groups, and quaternary carbon atoms in the polymer chain appear in the spectrum. The positions of the signals of methoxy groups, epoxy ring, and neighboring methylene group do not change noticeably.

The signals in the ^{1}H and ^{13}C NMR spectra of the

O–CH_3	–	–	–	–	3.55	52.69	3.55	52.71

polymers have no fine structure and are broadened in comparison with the signals of the initial monomer.

The quantitative content of epoxy groups in the polymer can be estimated from the epoxy number (EN). For the 2,3-EPMA homopolymer synthesized, EN determined by the chemical method [12] coincides with the EN found for the initial 2,3-EPMA and is equal to 30.28%. This suggests complete preservation of oxirane rings in poly-2,3-EPMA. The NMR data suggest that radical homo- and copolymerization of 2,3-EPMA initiated by AIBN involves scission of double bonds without participation of epoxy groups. This is in good agreement with the results of chemical analysis.

The composition of the copolymer 2,3-EPMA : MMA = 66 : 34 mol % found from the relative integral intensities of signals of epoxy and methoxy groups in the ^{1}H NMR spectrum (66 : 34 mol %) practically coincides with the values obtained by elemental and chemical analysis: 68.18 : 31.82 and 65.30 : 34.70 mol %, respectively. In the initial mixture of monomers, [2,3-EPMA] : [MMA] = 60 : 40 mol %.

Found, %: C 59.37, H 7.28, O 33.36; EN 22.04.
Calculated, %: C 59.43, H 7.35, O 33.23: EN 20.61.

It is seen that the copolymer is somewhat enriched with fragments of 2,3-EPMA, which is more active than MMA in accordance with the copolymerization constants ($r_{2,3\text{-EPMA}} = 0.94$, $r_{MMA} = 0.75$) [13].

It is well known [14] that, in polymers synthesized from a vinyl monomer with different α-substituents, the monomer molecules add to the end of the growing chain, as a rule, in the "head-to-tail" manner. In this case, every second carbon atom, being the center of the stereoisomerism, can occur in one of two configurations differing in location of α-substituents with respect to the carbon chain. The knowledge of the fractions of these configurations allows determination of the polymer structure.

It is seen from Table 1 that almost each group in the monomeric unit of the polymer gives several signals whose chemical shifts essentially depend not only on the nature of this group but also on the relative configuration of the neighboring monomeric units. The exceptions are methoxy and epoxy groups and also adjacent methylene group, which are insensitive to the isomerism of the main polymer chain because of relatively remote location.

In the range of proton resonance of α-methyl groups, there are three signals of different intensities. This suggests that the polymers are not highly stereoregular, i.e., there are various configuration sequences

Table 2. Distribution of triad sequences in poly-2,3-EPMA, PMMA, and 2,3-EPMA–MMA

Compound	Triad	^{1}H NMR of α-CH_3 at 0.7–1.2 ppm	^{13}C NMR			P_m	Calculation of triads according to Bernoulli
			C_{quat}, 44–46 ppm	$-CH_3$, 17–20 ppm	C=O, 176–179 ppm		
Poly-2,3-EPMA	*mm*	0.03	0.03	0.03	0.03	0.23	0.05
	mr	0.36	0.37	0.37	0.35		0.36
	rr	0.61	0.60	0.60	0.62		0.59
PMMA	*mm*	0.05	0.05	0.05	0.05	0.24	0.06
	mr	0.37	0.35	0.36	0.39		0.36
	rr	0.58	0.60	0.59	0.56		0.58
2,3-EPMA–MMA	*mm*	0.04	0.04	0.04	–	0.24	0.06
	mr	0.38	0.38	0.37	–		0.36
	rr	0.58	0.58	0.59	–		0.58

in these polymers. The presence of three signals means that the configuration of only short fragments of the chain, containing three monomer units, can be determined from the ^{1}H NMR spectrum. These signals belong to α-methyl groups in the central units of iso- (*mm*), syndio- (*rr*), and heterotactic (*mr*) triads. The signals were assigned considering the influence of magnetic susceptibility anisotropy of carbonyl groups in the terminal units of the triads on the chemical shift. In the syndiotactic triad, whose units occur in opposite configurations, α-methyl group is in the region of shielding effect of two carbonyl groups similarly arranged with respect to this group. As a result of shielding, its signal is shifted upfield relative to the signal of the isotactic triad. The signal of the heterotactic triad is positioned between these signals, with intermediate chemical shift. Thus, three α-methyl signals at 0.74–0.79, 0.93–0.96, and 1.13–1.18 ppm correspond to *rr*, *mr*, and *mm* triads, respectively. It should be noted that a large difference in the chemical shifts of the triads is mainly caused by the characteristics of carbonyl group with α-glycidyl and methoxyl substituents and by orientation. For poly-2,3-EPMA, PMMA, and 2,3-EPMA–MMA, this difference is equal to 0.39 and 0.35 ppm, while for polypropylene [15] having no electronegative and magnetoanisotropic α-substitutents which can noticeably affect the chemical shift, this difference is as small as 0.05 ppm.

The measurements of the integral intensities of the signals of α-methyl groups allow estimation of the relative fractions of stereochemical sequences in the polymers (Table 2). These values suggest predominant formation of syndiotactic polymers and show that the distribution of monomeric units in the macromolecular chain of poly-2,3-EPMA, PMMA, and 2,3-EPMA–MMA, synthesized in the presence of AIBN radical initiator in 1,4-dioxane at 60°C, is described by the Bernoulli statistics and is characterized, within the limits of the experimental error, by the probability of formation of mesodiad $P_m = 0.23 \pm 0.02$.

Along with the signals corresponding to triads, carbonyl carbon gives an additional signal at 177.95 ppm, which belongs to *mrrr* pentads with the probability equal to 0.15.

We failed to distinguish the sequences of comonomer units in 2,3-EPMA–MMA from the evidence of NMR data owing to the fact that the shielding effect of the carbonyl group linked to glycidyl and methyl substituents is practically the same. However, the configuration sequences in the form of *mm*, *mr*, and *rr* triads differ clearly in the signals of α-methyl groups and quaternary carbon atom in the polymer chain. The found distribution of triad sequences in copolymer is the same as in the homopolymers (Table 2).

CONCLUSION

Homo- and copolymers of epoxypropyl methacrylate and methyl methacrylate, produced by radical polymerization in a solution in the presence of azobis(isobutyronitrile) at 60°C, are predominantly syndiotactic and obey the Bernoulli statistics with the probability of isotactic addition $P_m = 0.24 \pm 0.02$.

Abstract—Rheological and adhesion characteristics of water-soluble adhesive composites based on copolymer of acrylamide with sodium acrylate and corn dextrin were studied. The optimum composition of these composites in their use as label adhesives was determined.

High-quality label adhesives should have the following characteristics: high reliability of the adhesive joint in the initial stage of drying, short time of setting, and, desirably, pseudo-plastic character of flow [1].

It is well known that aqueous saline solutions of copolymers of acrylamide with sodium acrylate (CASA) are used as label adhesives [1–3]. However, these adhesives have poorly pronounced pseudo-plasticity and fairly prolonged time of setting; they ensure low reliability of the adhesive joint in the first minutes. These characteristics can be improved by increasing concentration of polymer in the solution. However, increase in the concentration of CASA results in significant increase in the solution viscosity, which hampers its use as adhesive [3].

Another approach to improvement of characteristics of adhesives based on CASA is, apparently, development of composites with other polymers.

Here we studied the possibility of using corn dextrin (CD) for improvement of adhesion and rheological characteristics of glues based on CASA.

EXPERIMENTAL

As the initial materials we used aqueous–saline solution of CASA with the concentration of 27.5% and shear viscosity of 35 Pa s, and also acidic corn dextrin (high grade, pale yellow), GOST (State Standard) 6034–74. Copolymers of acrylamide with sodium acrylate were produced by base hydrolysis of Nitron D polyacrylonitrile fiber according to TU RB (Technical Specification of Belarus Republic) 00 280 198.026–96. The resulting hydrolyzate was neutralized with acetic acid.

The viscosity of the resulting solutions was determined on a Rheotest 2 rotary viscometer with a cylinder–cylinder working unit at $20 \pm 0.1°C$ [4].

To determine adhesion characteristics of the hydrolyzate solutions in the system glass–adhesive–paper, we used an RMU-0.05-1 tearing machine with the limits of load measurements of $(0–10) \pm 0.02$ kgf and velocity of the guide rod of the machine of up to 100 mm min^{-1} [2, 3].

The content of the dry substance was determined gravimetrically by drying in a thermostat at 80°C to constant weight. The polymer concentration was determined by subtraction of the salt concentration from the content of dry substance. The salt content was evaluated by the formula

$$c_{salt} = 82 n_{acid} / m_h,$$

where c_{salt} is the concentration of salt in the neutralized hydrolyzate (%), n_{acid} is the amount of acetic acid consumed for neutralization (mole), and m_h is the weight of the neutralized hydrolyzate (g).

The ^{13}C NMR spectra were recorded on a Tesla BS-587A spectrometer operating at 20 MHz. We used 10% solutions of copolymers in D_2O placed into standard ampules (10 ml). The spectra were recorded without Overhauser effect with pulse delay exceeding $7T_1$, where T_1 is the spin–lattice relaxation time of the most slowly relaxing nuclei. The signals were assigned by the DEPT procedure with the use of model compounds [5]. The chemical shifts were measured using the signal of methyl group of acetone-d_6 added to the reaction mixture as a reference (δ 30.2 ppm).

The composites of aqueous saline solution of CASA with CD were prepared at room temperature and at $65 \pm 5°C$.

Concentration of CD, %: (*1*) 0, (*2*) 10, (*3*) 15, (*4*) 20, and (*5*) 25; the same for Figs. 2 and 4.

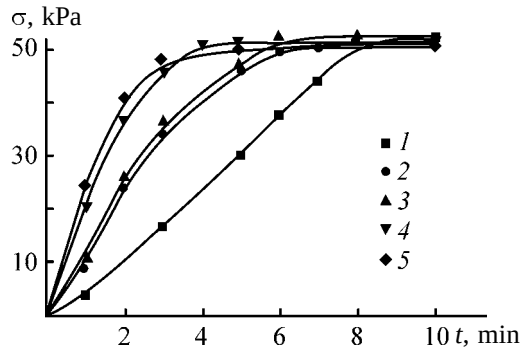

Fig. 2. Shear strength of the glue joint σ as a function of keeping time *t* for hydrolyzate of polyacrylonitrile fiber and mixtures of the hydrolyzate with CD.

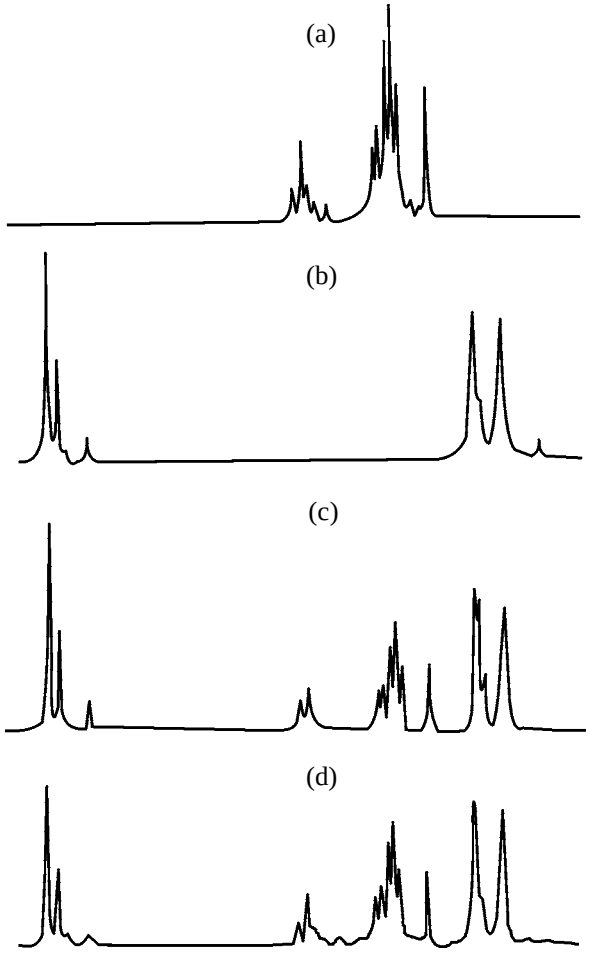

Fig. 3. The ^{13}C NMR spectra of the samples of (a) CD, (b) CASA, and (c, d) composites of CASA with CD prepared at (c) 20°C and (d) 65±5°C.

The flow curves for the mixtures CASA–CD with CD content from 10 to 25%, prepared at room temperature, are shown in Fig. 1. It is seen that, on adding CD to the CASA solution, its viscosity significantly increases (to 146 Pa s at a shear rate of 0.33 s^{-1} and CD content in the composite of 20%). In this case, the viscosity of 20% aqueous solution of CD is as low as 13 mPa s at the same shear rate. Hence, mixing of CD with the hydrolyzate results in superadditive increase in the viscosity.

It can be noted that the resulting solutions of composites have significantly more pronounced pseudoplastic character of flow than the initial solution of CASA.

It should also be noted that mixing of the CASA solution with CD in the concentration exceeding 25% is of no practical interest, since in this case the solutions are highly viscous. In addition, thread formation is observed in using these blends as label adhesives in high-speed label lines.

The results of determination of adhesion characteristics of the mixtures of CASA solution with CD, prepared at room temperature, are shown in Fig. 2. It is seen that addition of CD to aqueous saline solution of CASA results in improvement of the adhesion characteristics. This is primarily manifested in accelerated growth of the glue joint strength. On adding 20% CD, the setting time reaches a minimum equal to 2 min, which corresponds to adhesion characteristics of the best imported glues.

Variation of rheological characteristics of the composites in comparison with CASA solutions can be caused by formation of covalent and noncovalent bonds between CASA molecules and CD. To confirm this assumption, we studied these compositions by ^{13}C NMR.

The ^{13}C NMR spectra of CASA, CD, and composites of CASA with 15% CD, prepared at room temperature and 65±5°C, are shown in Fig. 3. It is seen that the spectrum of CASA–CD composite (Fig. 3c)

Rheological characteristics of CASA–CD composites prepared at various blending temperatures

Content of CD, wt %	T_{bl}, °C	Viscosity,* Pa s
10	20	67.2/60
10	65±5	65.5/61.6
15	20	106.5/80
15	65±5	114.7/91.2
20	20	146/104
20	65±5	143.3/102.3
25	20	197/127
25	65±5	220/147

* Viscosity at the shear rate of 0.33/16.2 s^{-1}.

contains the same signals as in the spectra of the individual components (Figs. 3a, 3b). There are no changes in the positions of signals and their intensities. This suggests no covalent bonding between functional groups of CASA and CD macromolecules. It could be assumed that these bonds would arise in composites produced at elevated temperatures. However, as seen from Fig. 3, the ^{13}C NMR spectra of composites produced at room temperature and at 65± 5°C are the same (Figs. 3c, 3d), i.e., even after heating no covalent bonds between CASA and CD macromolecules are formed.

Hence, the only explanation of variation of the rheological characteristics of the composites in comparison with the initial CASA solution is strengthening of intermolecular interactions in the system with participation of CASA and CD functional groups.

It could be expected that the interchain interactions would change under heating. The shear viscosities of the composites prepared at room temperature and at 65°C are listed in the table. These data show that the blending temperature does not noticeably affect the rheological characteristics of the composites.

The dependences of the strength of glue joints on the duration of keeping for the CASA–CD composites prepared at 65±5°C are shown in Fig. 4. Comparison of Figs. 2 and 4 shows that the curves of strength growth for the composites containing different amounts of CD and prepared at different temperatures practically coincide. Hence, the blending temperature does not affect the adhesion characteristics of the composites.

Comparison of the rheological and adhesion characteristics of the composites prepared at various temperatures shows that an increase in the temperature of composite preparation to 65±5°C does not result in variation of the interchain interaction.

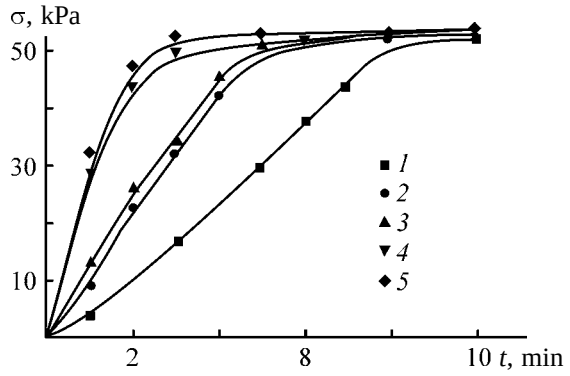

Fig. 4. Shear strength of glue joint σ as a function of keeping time *t* for hydrolyzate of polyacrylonitrile fiber and mixtures of the hydrolyzate with CD. Blending temperature 65±5°C.

CONCLUSION

Mixing of corn dextrin with aqueous saline solution of copolymer of acrylamide with sodium acrylate prepared by base hydrolysis of polyacrylonitrile fibers results in transformation of the hydrolyzate from a Newtonian liquid to a pseudo-plastic liquid, increase in viscosity at any shear rate, and improvement of adhesion characteristics of the composites in the system glass-paper in comparison with the individual components. The composition containing 20% corn dextrin has the optimal adhesion and rheological characteristics for use as a label adhesive. This composition can be produced by mixing at room temperature.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Dilatometric Characteristics of Polyacrylonitrile in a Mixture with Fullerene C_{60}

A. V. Sidorovich, O. E. Praslova, A. V. Novoselova, and V. N. Zgonnik

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received January 9, 2004

Abstract—Thermal cyclization of polyacrylonitrile, synthesized by anionic and radical polymerization, in films containing 0.5 wt % fullerene C_{60} and without it was studied dilatometrically in the range 20–400°C.

Fullerenes are a family of polyhedral molecules with a closed large-diameter spherical structure built from three-coordinate carbon atoms with an extended π-electron system capable of diverse interactions with molecules of inorganic and organic substances [1–3]. This made fullerenes a subject of active studies aimed to elucidate their promise for modification of the properties of polymers.

Fullerene C_{60} acts as inhibitor in thermal and thermooxidative degradation of polymethyl methacrylate [4–6]. Calorimetric studies revealed enhanced thermal stability of complex and covalent compounds of polymers of *N*-vinylpyrrolidone and ethylene glycol with C_{60} [7, 8]. Much attention has been given to studying the properties of polymers containing fullerene C_{60} in solutions [9, 10].

There are virtually no published data concerning the influence of C_{60} on dilatometric characteristics of polymers under physicochemical transformations, despite scientific and practical importance of this issue.

In this work we studied dilatometrically the thermal cyclization of polyacrylonitrile (PAN) films, with and without fullerene C_{60}, as influenced by the method of synthesis (anionic and radical polymerization) and by the chemical and supramolecular structure of PAN. This is urgent in view of the fact that heat treatment of PAN is essential for preparation of high-modulus heat-resistant fibers, as well as of semiconductor and carbon materials [11].

EXPERIMENTAL

We studied films prepared from PAN with $M_\eta = 8 \times 10^5$ Da, synthesized by anionic (A-PAN) and radical (R-PAN) polymerization. Anionic polymerization was carried out in DMF at –60°C using lithium alkoxide [12], and radical polymerization, by conventional procedure in water at 25°C in the presence of potassium peroxosulfate and $NaHSO_3$. Films of A-PAN exhibited a narrow MWD (M_w/M_η = 1.3), microtacticity with a block structure coefficient $K \sim 1.57$ [13], and virtually perfect chemical structure of the chain due to the lack of side reactions in the case of anionic polymerization [14]. Films of R-PAN exhibited a wide MWD ($M_w/M_\eta \approx 10$) and no microtacticity ($K \sim 1.02$) [13].

To elucidate the influence of C_{60} on the properties of PAN, we took a small amount of C_{60}, since it is known [15] that the properties of polymers are most strongly affected by the monomeric form of C_{60}, which is the most abundant at low concentrations.

The films were cast from solutions of polymers (5 wt %) and their mixtures with fullerene (0.5 wt % with respect to PAN) in DMF containing the desired amount of *N*-methylpyrrolidone (MP) as solvent for C_{60}. The solutions were heated for 1 h at 100°C. After filtration and cooling to room temperature, these solutions, without preliminary keeping, were used for casting R-PAN and A-PAN films onto glasses.

The R-PAN·C_{60} and A-PAN·C_{60} films were cast after keeping the solutions at room temperature for 3 days. Prolonged maturing of the solution favored structuring and improved the mechanical properties. The films cast without preliminary keeping were brittle, virtually unsuitable for cutting out samples for measurements. The films were dried at room temperature for 5 days.

Dilatometric measurements were carried out on an installation capable of recording the changes in the longitudinal linear dimensions of films accurately to

1070-4272/04/7705-0820 © 2004 MAIK "Nauka/Interperiodica"

within 0.01 μm, when the samples are heated at a rate of 10 deg min^{-1} at 20–400°C [16]. The samples were film stripes 30 mm long, 4 mm wide, and 20–35 μm thick, aligned under a small load of 1 kg cm^{-2}.

Calorimetric measurements within 20–400°C were carried out with a DSM-2M microcalorimeter at a scanning rate of 16 deg min^{-1} and the threshold sensitivity of 0.04 mW [17].

The dilatometric curves of the films (Fig. 1) of R-PAN (curve *1*) and A-PAN (curve *2*) exhibit nonmonotonic, complex patterns, which suggests structural transformations during heat treatment. Three sections are distinct in these curves, namely, those corresponding to temperatures below 120, within 120–260, and above 260°C, respectively, for which the size variation patterns strongly differ. Below 260° the dilatometric curves for R-PAN and A-PAN are similar. Below 120°C these samples exhibit contraction (shrinkage), followed by elongation up to 260°C, almost linear for A-PAN and more complex for R-PAN. The R-PAN and A-PAN films differ only in the shrinkage ratio and in the shrinkage onset temperature. In the case of the R-PAN film, contraction began above 60°C; below 60°C, the film elongated. At the same time, the A-PAN film exhibited no initial elongation region, and its contraction began at 50°C. The third sections of the dilatometric curves (heating above 260°) differ significantly: The R-PAN film contracts (this section is restricted by the subsequent failure of the sample), whereas the A-PAN film sharply elongates.

The shapes of the curves in Fig. 1 suggest that there are structural transformations within two temperature regions, namely, in low-temperature (below 120°C) and high-temperature (above 260°C) regions. Low-temperature transformations are virtually complete at 120°C both for R-PAN and A-PAN, as suggested by a shrinkage minimum in the dilatometric curves.

As mentioned above, in the high-temperature region, the R-PAN and A-PAN films substantially differ in the size variation pattern, namely, the A-PAN film elongates (onset of flow) and R-PAN film contracts. In the intermediate region (120–260°C), virtually no physicochemical processes are observed; the polymer structure is fairly stable, since we recorded a linear elongation with rising temperature due to thermal expansion.

Figure 2 shows the dilatometric curves recorded for mixed films, R-PAN·C_{60} (curve *1*) and A-PAN·C_{60} (curve *2*). They differ significantly from the curves

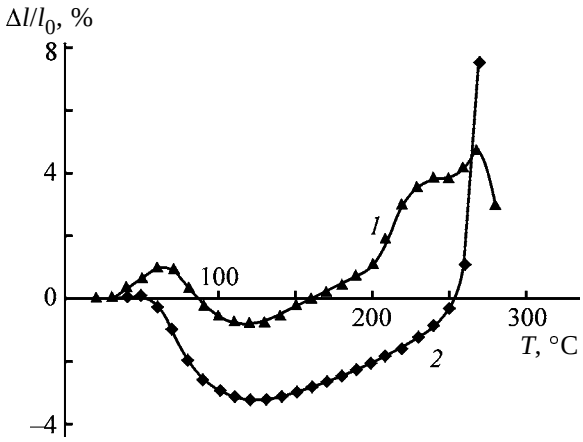

Fig. 1. Dilatometric curves for (*1*) R-PAN and (*2*) A-PAN films. Continuous heating (first run). ($\Delta l/l_0$) Relative change in size, %, and (*T*) temperature, °C; the same for Figs. 2 and 4.

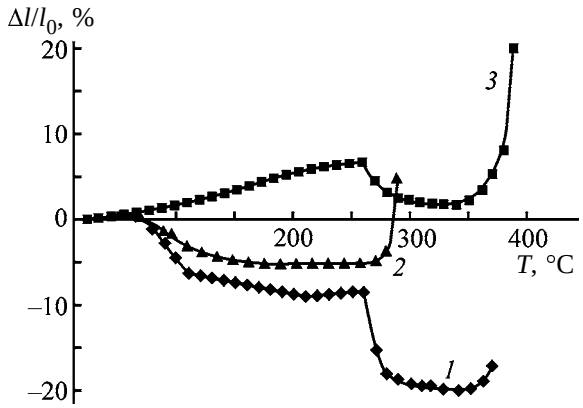

Fig. 2. Dilatometric curves for (*1*) R-PAN·C_{60}, (*2*) A-PAN·C_{60} films (continuous heating, first run), and (*3*) R-PAN·C_{60} [repeated stepwise heating to 160, 260, and 390°C after heating of the initial samples to 160 and 260°C (for explanation, see text)].

recorded for films containing no C_{60} (R-PAN and A-PAN). In the case of the R-PAN·C_{60} film, contraction persists up to 200°C (shrinkage up to 9%), while in the case of the R-PAN film, contraction (no greater than 1%) ceased at 120°C (Fig. 1, curve *1*). Upon heating above 250–260°C, the curves for R-PAN·C_{60} film exhibited a second contraction section, with a total shrinkage of over 20%, and upon rising temperature to 340–250°C, the film, on the contrary, elongated. According to the differential scanning calorimetric (DSC) data, specifically the 260–350°C region corresponds to thermal cyclization (Fig. 3b, curve *1*). Upon introduction of C_{60}, the A-PAN·C_{60} film contracts, similar to R-PAN·C_{60}, though with a smaller total shrinkage of 5%, ceasing at 200°C. This slightly exceeds the shrinkage of the initial A-PAN film, 3% at a maximum, ceasing at 120°C (Fig. 1,

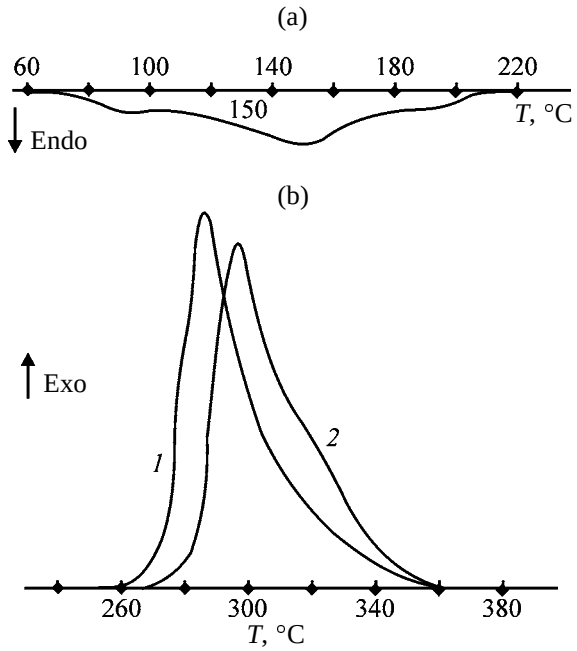

Fig. 3. DSC curves. (*T*) Temperature. Film: (a) R-PAN·C_{60} and (b) (*1*) R-PAN·C_{60} and (*2*) A-PAN·C_{60}.

curve *2*). Further heating from 200 to 270°C corresponds to stabilization, and above 270°C there is an abrupt change to elongation (flow), corresponding to the onset of exothermic effect of thermal cyclization in the DSC curve (Fig. 3b, curve *2*).

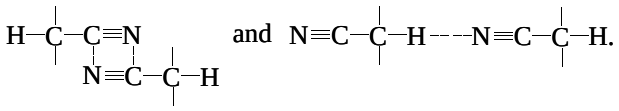
The dilatometric curves demonstrate variations of the film size due to thermal expansion and structural transformations yielding new intermolecular bonds, which can be accompanied by a mass loss owing to removal of residual solvents and thermal degradation products.

Therefore, interpretation of the nonmonotonic complex curves describing the primary continuous heating of the initial samples (Figs. 1, 2; curves *1* and *2*) requires understanding of the physicochemical processes occurring during heating.

To this end, we carried out repeated stepwise heating of the films heated to different temperatures in the first run, as illustrated by curve *3* in Fig. 2 for the R-PAN·C_{60} film. Curve *1* was recorded in the first run of continuous heating, and curve *3*, under repeated heating of the two initial samples heated in the first run to 160 and 260°C. Comparison of curves *1* and *3* suggests irreversible changes due to structural transformations, since there is a different monotonic plot of $\Delta l/l_0$ vs. *T*. The above-mentioned data suggest that even primary heating of the initial sample to 160°C is accompanied by structural transformations. When the temperature of primary heating is further risen to 260°C, the monotonic linear dependence observed in the repeated heating run is the same as after heating to 160°C. This suggests that the structural changes that occurred upon heating to 160°C were not followed by further changes on heating to 260°C. However, upon repeated heating above 260°C of the initial sample heated in the first run to 260°C, there appears a section corresponding to sharp contraction followed by elongation. This suggests a second type of structural transformations. Thus, the dilatometric curve *1* provides information about two types of structural transformations, namely, low-temperature transformations up to 260°C and high-temperature transformations above 260°C.

Our calorimetric studies revealed within 80–200°C endothermic low-temperature heat effects with $\Delta H \sim$ 15–20 kJ kg^{-1} and exothermic high-temperature effects with much stronger heat effects $\Delta H \sim$ 650–800 kJ kg^{-1} (Fig. 3). These include an endothermic effect for the R-PAN·C_{60} film (ΔH = 20 kJ kg^{-1}) and exothermic effects for R-PAN·C_{60} (ΔH = 827 kJ kg^{-1}) and A-PAN·C_{60} (ΔH = 623 kJ kg^{-1}).

The calorimetric data concerning the temperature regions of structural transformations correlate with dilatometric data. Opposite signs of the heat effects suggest different types of structural transformations. In the low-temperature region, the endothermic nature of the structural transformations (which is manifested in the dilatometric characteristics as well) is due to a special role played by the cyano groups. On the supramolecular level, they form donor–acceptor bonds with α-hydrogen atom of the polymer and with one another, as well as complexes with the solvent (DMF). This favors numerous interactions of the macromolecules with one another and with the solvent, yielding strong complex bonds, the so-called "physical cross-links" [18]



The strength of such interactions reaches 33–35 kJ mol^{-1}, and they can be responsible for insolubility in DMF of the R-PAN and A-PAN films heat-treated to 110°C. The mixed films preserved their solubility in DMF upon heating to higher temperatures: to 150°C in the case of R-PAN·C_{60} and to 160°C in the case of A-PAN·C_{60}. This can be explained by the fact that C_{60} molecules can act in this case as "traps" hindering formation of interchain cross-links [4, 5]. Heating within 80–200°C involves superposition of the heat effects from scission of the

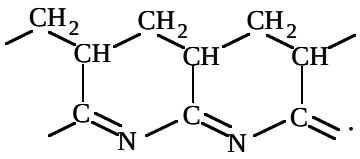
bonds formed by CN groups with one another and with DMF and from the onset of formation of the interchain chromophore moieties. This is evidenced by the fact that the films acquire light brown colors. The heat effects corresponding to the structural changes in the low-temperature regions have opposite signs. While scission of intermolecular bonds with cyano group and removal of the solvent consumes energy, formation of an insoluble colored polycyclic polymer with chromophore groups is accompanied by heat liberation.

Since the energy of nonvalent bonds is 33–35 kJ mol^{-1} and they act as fairly strong cross-links [18], the energy consumption prevails, which is responsible for an endothermic effect. In fact, changes in the supramolecular structure and the initial reaction of cyano groups, yielding moieties comprising chromophore bonds, are the initial steps, preparing the high-temperature cyclization.

Analysis of our results allows the temperature dependence of the dilatometric characteristics to be interpreted as follows. The initial rearrangements of the macrochains, initiating and preparing interactions of the cyano groups, are recorded dilatometrically even upon heating to above 70–80°C. This is evident from the change in the thermal expansion sign, followed by appearance of characteristic sections corresponding to contraction (shrinkage) during the first heating run.

The shrinkage ratios reflect, for the most part, the processes occurring in the first stage of structural transformations which are complete at 200°C in the case of fullerene-containing films and at 120°C in the case of fullerene-free films. Within the same temperature range, the complexes degrade and the solvent is removed. All this exerts the deciding influence on the shrinkage ratio, which reflects the depth of transformation in the first stage. This interpretation is supported by two facts, namely, by irreversible nature of transformation, as directly evidenced by the difference in the dilatometric dependences measured in the repeated heating runs, and by the occurrence of an endothermic effect within 80–200°C, as evidenced by DSC data.

The high-temperature region corresponds to the second stage of transformations, thermal cyclization, which is accompanied by a significant exothermic effect and a sharp change in the film size. This is due to cleavage of the triple bond in the cyano groups of the polymer and formation of ladder structures with conjugated imine sequences [11]:



Like C_{60}, such polymer structures are polyunsaturated compounds; they actively react with one another, forming strong intermolecular complex bonds. This is responsible for compaction of the polymer macromolecules, which can result in a sharp contraction, and even in failure, of the PAN films. However, thermal cyclization of PAN, evidently, involves interchain reactions also giving rise to chemical cross-links between rigid ladder structures of cyclic PAN. Possibly, the number of such cross-links and the rate of their formation govern the heat resistance of films in this stage of heat treatment. Our studies showed that the presence of C_{60}, and especially preheating, favor more active formation of chemical "cross-links," which enhances the heat resistance of R-PAN·C_{60} during thermal cyclization (the yield point increases to 390°C). This is the main factor affecting the shape of the dilatometric curve of R-PAN·C_{60} in the high-temperature region.

Our study showed that the dilatometric properties are extremely strongly influenced by the synthesis conditions, since the relationships for the anionic and radical films are completely different. The PAN films prepared by anionic polymerization tend to sharply elongate in the high-temperature region, rather than contract like the films prepared by radical polymerization. Such behavior of A-PAN films can be explained by the structural features of this polymer. Specifically, homogeneity of the molecular weight and chemical structure, as well as the stereoblock character of its macromolecules, can favor their predominant existence in solutions and in films as double helices. In such films, without C_{60}, even at 260°C weaker bonds between the double helices of the macromolecules can be disturbed, making possible the "flow" effect for the PAN film even before thermal cyclization, as we observed in this work.

In the presence of C_{60}, which, most likely, is inserted between the double helices, the bonds linking the helices are strengthened. In the case of the A-PAN·C_{60} film, the onset of flow coincides with the onset of thermal cyclization. In this case, interaction of cyano groups, most preferably, involves one or two A-PAN·C_{60} macromolecules integrated into a double helix. Interaction of the "ladder" moieties of cyclized A-PAN·C_{60} with one another is more efficient than their interaction with C_{60}, and the structures formed

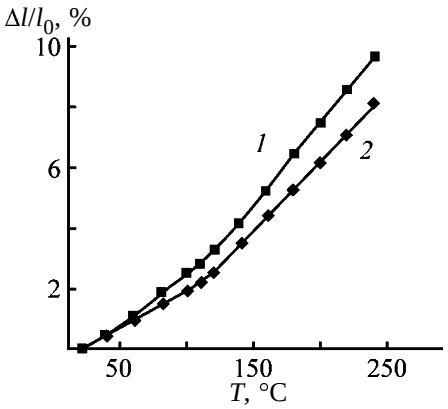


Fig. 4. Dilatometric curves for repeated heating runs with (*1*) A-PAN·C_{60} and (*2*) R-PAN·C_{60} films.

from the double helices flow even in the presence of C_{60}.

Repeated heating of the A-PAN·C_{60} films favors denser contacts between the macromolecules, yielding cross-links between the macromolecules not only inside the double helix. This can be specifically responsible for the fact that the dilatometric curves in this case do not show contraction characteristic of R-PAN·C_{60} (Fig. 2, curve *1*).

Figure 4 presents the data for mixed films, obtained after repeated heating (after primary heating). The dilatometric curves exhibit a prominent inflection at 120°C, which suggests a transition. This can reflect a change in the supramolecular structure due to arising of interchain bonds in the course of formation of chromophore groups. However, elucidation of the real nature of this effect requires special structural studies.

CONCLUSIONS

(1) Thermal cyclization of films of polyacrylonitrile, synthesized by anionic and radical polymerization, with and without fullerene C_{60} (0.5 wt %), were studied by dilatometric method and by differential scanning calorimetry within 20–400°C. Two temperature regions were revealed, which correspond to structural transformations in two stages of transition of PAN from the linear to polycyclic state. Based on analysis of the physicochemical processes in stepwise transformations, the temperature dependence of the dilatometric characteristics was interpreted as due to scission of intermolecular bonds and formation of chromophore groups, followed by transition to the final polycyclic state.

(2) The shape of the dilatometric curves depends on the method of PAN synthesis. The shrinking film samples prepared by radical polymerization contract by up to 20% in the thermal cyclization region, and the film samples prepared by anionic polymerization, on the contrary, elongate, exhibiting flow. This results from the difference in the molecular and supramolecular structures of the polymers.

(3) A procedure was proposed for identifying the temperature regions corresponding to physicochemical transformations, based on comparison of the dilatometric curves recorded after the primary heating and repeated heating runs.

Abstract—Eight fractions of polystyrene with linear structure and different molecular weights were prepared by fractional precipitation with methanol from a solution of polystyrene in chloroform. The polystyrene fractions were dissolved in toluene to prepare solutions with different concentrations for dynamic property studies. The dynamic shear modulus and the tangent of the mechanical loss angle for these solutions were measured by the acoustic-resonance method.

The molecular weight of polymers can be determined by numerous methods [1]. They imply studies of both polymers proper and their solutions (flow temperature, relaxation properties, viscosity, etc.). Molecular weight is a major characteristic of macromolecular compounds, since the chemical and physical characteristics of polymers are directly related to the size of their molecules [2].

Dynamic deformations of highly elastic materials typically entail only reversible deformations due to displacements of individual fragments of macromolecules, which make them independent of the molecular weight of the macromolecules as a whole. However, at temperatures below the flow point, irreversible displacements of macromolecules become also prominent. In this case, the dynamic deformation parameters become sensitive to the molecular weight of the polymer and thus can be used for determining the molecular weight.

The aim of this work was to study the dynamic viscoelastic properties of polymer solutions as influenced by the molecular weight and concentration.

For fractional precipitation and estimation of the molecular weight we chose polystyrene (PS) whose samples serve as international standards in checking the accuracy of determining the molecular weights of polymers. Polystyrene is a linear polymer, and its molecular characteristics are most often estimated by studying the properties of its solutions.

EXPERIMENTAL

Fractional precipitation of linear PS yielded eight fractions with a 3.95% weight loss. Based on the intrinsic viscosities of the PS fractions and initial PS, we calculated the molecular weights by the equation $[\eta] = KM^{\alpha}$. For the PS prepared by fractional precipitation we took the empirical coefficients $K = 0.007 \times 10^{-3}$ and $\alpha = 0.93$ [3]; $T = 20°C$; toluene served as solvent because of its relatively low volatility making it especially suitable for determining the dynamic properties of solutions. Table 1 presents the results of fractional precipitation, the intrinsic viscosities of the

fractions and the initial polymer, and the molecular weights.

Figures 1a and 1b present the integral and differential curves of the molecular weight distribution (MWD), respectively [4]. The solvents were purified by the known techniques. Polystyrene was subjected to fractional precipitation with methanol from a 2.5% chloroform solution. The resulting PS fractions were dried to constant weight in a vacuum oven at 60°C under residual pressure of 2–5 mm Hg. The intrinsic viscosities of the fractions and the initial PS in a toluene solution were measured on an Ubbelohde capillary viscometer with a suspended level at 20 ± 0.05°C.

In our experiments we used a piezoelectric-crystal resonator filled with the liquid under study, whose working surfaces were preliminarily cleaned in a glow discharge. The dynamic shear modulus G and tangent of the mechanical loss angle $\tan\theta$ were estimated by measuring the acoustic parameters of the resonator; also, the effective viscosity η_{eff} of the PS solutions in toluene was calculated. The acoustic-resonance experiments [5, 6] were carried out at the shear impact frequency of 74 kHz at 19 ± 0.1°C. The resonance method of determining the shear characteristics of liquids consists in the following. The horizontal surface of a piezoelectric crystal (an X-18.5° cut) with a Poisson coefficient of zero, oscillating at the fundamental resonance frequency, contacts the liquid interlayer covered with a solid application. The application with a liquid interlayer occurs at one end of the piezoelectric crystal; the liquid interlayer is subjected to shear strain, and the parameters of the resonance curve of the piezoelectric crystal vary with the liquid interlayer thickness.

Theoretically, when the liquid interlayer thickness is assumed to be much smaller than the shear wavelength and the application is assumed to be virtually at rest, the tangent of the mechanical loss angle and the dynamic shear modulus (estimated by the acoustic-resonance method) can be described by the expressions [5]:

$$G = \frac{4\pi^2 M_p f_0 \Delta f' H}{S}, \qquad (1)$$

$$\tan\theta = \frac{\Delta f''}{\Delta f'},$$

where $\Delta f'$ and $\Delta f''$ are the real and imaginary shifts of the resonance frequency of the piezoelectric crystal, respectively; M_p, piezoelectric crystal mass; S, contact area; H, liquid interlayer thickness; and f_0, resonance frequency of the piezoelectric crystal.

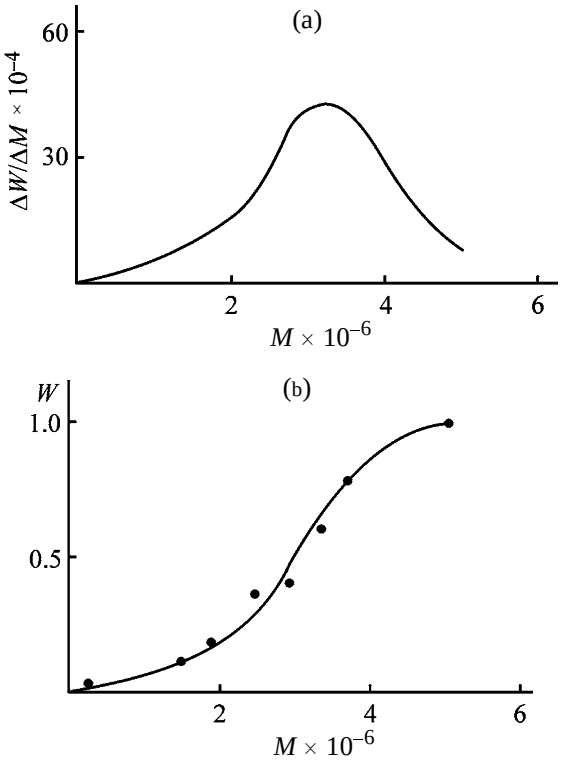

Fig. 1. (a) Differential and (b) integral MWD curves of PS solutions.

The imaginary shift is equal to the change in the resonance curve half-width. Equation (1) shows that, when the liquid under study exhibits shear elasticity, the real frequency shift should be proportional to inverse interlayer thickness.

The resonance experiment was carried out with a piezoelectric crystal with a mass of 6.24 g; the contact surface area was 0.2 cm^2. An important advantage of the resonance method is no limit on the viscosity of the liquids under study (from several hundredth to 10^5 P). A drawback of the method is that it can be realized at a strictly fixed invariable frequency. A positive shift of the resonance frequency of the oscillating system is indicative of a shear elasticity.

Having determined the dynamic shear modulus and tangent of the mechanical loss angle, we can estimate the effective viscosity by the formula

$$\eta_{eff} = \frac{G(1 + \tan^2\theta)}{2\pi f_0 \tan\theta}. \qquad (2)$$

Assuming that the effective viscosity correlates with

the intrinsic viscosity, we can determine the relation between the parameters G and M:

$$\rho M^{\alpha} \sim \frac{G(1 + \tan^2\theta)}{2\pi\eta_w f_0 \tan\theta}, \qquad (3)$$

where ρ is the density of the polymer solution; η_w, viscosity of water; and M, molecular weight of the polymer.

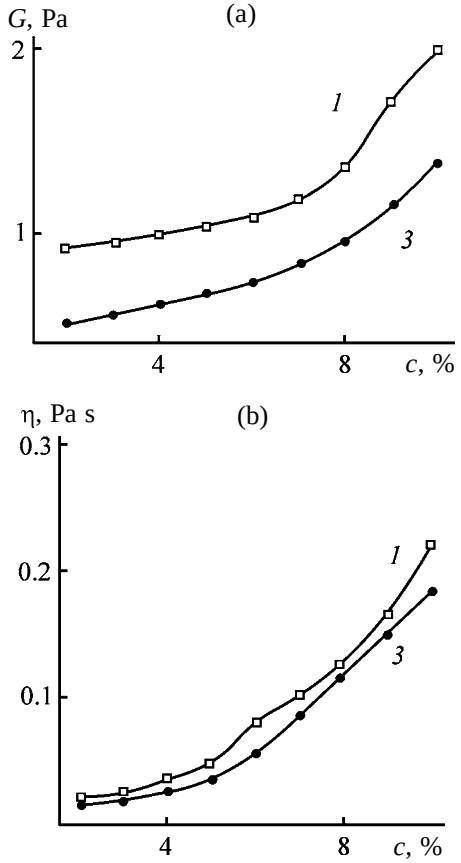

Fig. 2. (a) Shear modulus G and (b) effective viscosity η, as functions of the content c of PS in toluene for fraction nos. 1 and 3, respectively.

Equation (3) suggests that the shear modulus varies with the molecular weight.

Table 2 presents the viscoelastic properties of 10% solutions of PS in toluene for different fractions. It is seen that, with decreasing molecular weight of the polymer, the dynamic shear modulus and effective viscosity tend to decrease. Tangent of the mechanical loss angle tends to increase with decreasing molecular weight. Also, the effective and intrinsic viscosities vary similarly.

Knowing how the viscoelastic properties vary with the molecular weight, we can estimate the molecular weights of various polymers after measurement of the parameters G. The influence of polydispersity on the shear modulus requires special investigation.

Bazaron [5] found earlier that, for high-molecular-weight polymethylsiloxanes, the dynamic shear modulus G linearly varies with the molecular weight. Probably, this will hold for a polymer with a more uniform molecular weight. To elucidate how the dynamic characteristics vary with the concentration of the solution, we studied the properties of various PS fractions. Figures 2a and 2b show the experimental data for fraction nos. 1 and 3 (Table 1). It is seen that, with decreasing PS concentration, the shear modulus and the effective viscosity tend to decrease. The pattern of variation of the dynamic characteristics for PS solutions in toluene is qualitatively similar to that revealed by Moore *et al*. [8] for PS solutions of various concentrations in dibutyl phthalate (at 40 MHz). The dynamic shear moduli of solutions of PS in toluene, estimated by the acoustic-resonance method, are consistent with those measured by the impedance method by Matheson [7]. Moore *et al*. [8] analyzed

the experimental results from the viewpoint of the molecular structure of the polymer solutions. In this article, we restricted ourselves to estimation of the molecular weight of PS by the acoustic method.

CONCLUSIONS

(1) Dynamic viscoelastic properties of solutions of polystyrene in toluene were measured by the acoustic method at 74 kHz. The dynamic shear modulus G and effective viscosity η_{eff} of the solutions decrease with decreasing molecular weight.

(2) The plots of G and η_{eff} vs. molecular weight are nearly linear. The molecular weight of an unknown polymer can be estimated from the dynamic shear modulus of its solution, measured by the acoustic method.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Flocculation of Butadiene–Styrene Latex with Polymeric Ammonium Salts of *N*,*N*-Dimethylaminoethyl Methacrylate and Mineral Acids

V. N. Verezhnikov, T. V. Min'kova, and T. N. Poyarkova

Voronezh State University, Voronezh, Russia

Received January 14, 2004

Abstract—The flocculation performance of cationic polyelectrolytes (polymeric ammonium salts of *N*,*N*-dimethylaminoethyl methacrylate) and mineral acids (HCl, HNO_3, H_2SO_4, H_3PO_4) in recovery of rubber from SKS-30 ARK butadiene–styrene latex was studied.

Flocculation of latexes using cationic polyelectrolytes is a promising salt-free procedure to recover rubbers after emulsion copolymerization [1]. These flocculants eliminate discharge with wastewater of sodium chloride consumed in significant amounts in coagulation of latexes by the existing procedures (up to 1000 kg per ton of rubber). Therefore, study of latex flocculation with polymers and search for new effective polymeric flocculants are of particular importance; and among them, polymers based on aminoalkyl methacrylates show much promise [2–4] due to their high reactivity in (co)polymerization, simple preparation of monomers and polymers, and their high solubility in water.

As the monomers are bases, it seems the most feasible to prepare flocculants in the form of polymeric ammonium salts of aminoalkyl methacrylates and mineral acids. Synthesis and polymerization of ammonium salts of *N*,*N*-dimethylaminoethyl methacrylate (DM) and mineral acids (HCl, HNO_3, H_2SO_4, H_3PO_4) were studied in [5], and the electrical conductivity of solutions and acid–base properties of poly-DM ammonium salts (PDMASs) were analyzed in [6, 7]. It was found that PDMASs in aqueous solutions are polyelectrolytes with basic properties and, depending on the salt structure, the pH of their half-neutralization, $pH_{0.5}$, is within 6.2–7.2 range [7].

The flocculation power of these polyelectrolytes in recovery of rubber from latexes is of particular importance. In this work we studied the flocculation performance of PDMAS and above mineral acids in their interaction with industrial latex of butadiene–styrene rubber as influenced by the salt structure, concentration of the latex dispersed phase, and solution pH.

We used *N*,*N*-dimethylaminoethyl methacrylate purchased from Metakor company (Yaroslavl, Russia). According to the potentiometric titration data, the content of amino ester in the initial sample was 99.8%. Chemically pure grade mineral acids (HCl, HNO_3, H_2SO_4, H_3PO_4) were used in the experiments.

The poly-DM ammonium salts were prepared by two procedures.

(A) The initial monomeric salts were synthesized in isopropanol according to [5]. The corresponding hydrochlorides were obtained by passing gaseous hydrogen chloride and polymerized in aqueous solution (50% weight fraction) without initiating agent at the following temperatures, °C: 100 $DM \cdot HCl$, 95 $DM_2 \cdot H_2SO_4$, and 80 $DM \cdot H_3PO_4$. Polymerization was performed for 3–4 h until a viscous difficult-to-stir mass was obtained.

(B) The monomeric salts were prepared and polymerized in aqueous solution without isolation of salts from the reaction mixture. Equivalent amounts of DM were added to the aqueous acid solutions at two temperature modes: 0–5 (procedure B_5) and 20–25°C (procedure B_{25}). After neutralization, the concentration of the resulting salt was determined by potentiometric titration, which was performed in aqueous alcohol with a 0.5 M alcoholic solution of potassium hydroxide. For polymerization, the solutions were heated to the same temperatures (as in method A) for 3–4 h.

The intrinsic viscosity (see table) of the resulting polymeric salts $PDMAS \cdot HCl$ (**I**), $PDMAS \cdot HNO_3$ (**II**), $PDMAS \cdot H_2SO_4$ (**III**), and $PDMAS \cdot H_3PO_4$ (**IV**)

1070-4272/04/7705-0830 © 2004 MAIK "Nauka/Interperiodica"

was measured on a VPZh-1 viscometer (capillary diameter 0.86 mm, formamide, 30°C).

For flocculation studies, we chose SKS-30 ARK commercial butadiene–styrene latex prepared using emulsifiers based on salts of disproportionated rosin and fatty and resin acids of tall oil. The latex properties were as follows: dry substance weight fraction 239 g l^{-1}, pH 9.7, surface tension 58.0 mJ m^{-2}, and average particle radius 25.9 nm (light scattering data [8]).

The PDMAS flocculation performance was determined by the fraction of the precipitated rubber φ (wt %) relative to the initial polymer weight in the latex. In these tests, the required amounts of distilled water, acidifying agent (0.1 N H_2SO_4), and flocculant (1.5–3.0 g dl^{-1} aqueous solutions) were added to the latex (5 ml) with stirring up to the total volume of the reaction mixture of 10 ml. The recovered rubber was filtered off, washed, and dried to the constant weight at 80–90°C.

The turbidity of the diluted latex solutions was measured using an NFM visual turbidimeter and solution pH, with an EV-74 pH-meter.

The dependences (flocculation curves) of the degree of rubber recovery φ on the concentration of polyelectrolytes **I**–**IV** are shown in Fig. 1. As seen, in all the cases the polymer yield sharply increases with increasing flocculant concentration c_{PE}, reaching the highest constant value (≥95%). The quantity c_{PE} corresponding to the beginning of the plateau in the flocculation curves [optimal flocculation concentration (OFC)] is almost independent of the anions in polymeric salts **I**–**III**, preparation procedure, and intrinsic viscosity. The OFC values for these salts correspond to the relative flocculant consumption Q of ~10 kg per ton of rubber. In the case of phosphoric acid DM derivative, the consumption is greater and reaches 18–25 kg per ton of rubber.

The flocculation tests reflected in Fig. 1 were performed at constant concentration of the dispersed phase (120 g l^{-1}). However, it was shown [9, 10] that the shape of the flocculation curves can change with changing rubber concentration in the latex c_d. The same phenomenon was observed with PDMAS flocculants. The curves of the latex flocculation in the presence of PDMAS · HNO_3 are shown in Fig. 2. As seen, the shape of the φ–c_{PE} curves significantly changes with decreasing c_d; the dependence with a plateau, obtained for relatively concentrated latex solution (120 g l^{-1}), transforms into the dependences with a maximum, which becomes more pronounced with decreasing polymer concentration in the latex. Similar phenomenon was observed with polystyrene [9], butadiene–styrene, and butadiene–acrylonitrile latexes [10] at their flocculation in the presence of poly-*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride.

the features of the flocculation effect of cationic polymeric reagents on negatively charged sols [11, 12]. The interaction involves neutralization of the particle surface charge in the course of interaction of the emulsifier anions (in the case of negatively charged latex particles) with the cationic centers of polyelectrolyte macromolecules to form insoluble ionic complexes. Along with neutralization, the bridging mechanism with simultaneous sorption of macromolecules on several particles also contributes to the flocculation. The flocculation optimum is often attained at complete neutralization of the particle surface charge. Further sorption of the charged polyelectrolyte macromolecules on the particle surface causes recharging and "restabilization" of the system. The recharging effect was confirmed by measurements of the electrophoretic mobility of the latex particles as influenced by c_{PE} [9, 10, 13]. The stabilizing effect of excess flocculant is also due to the formation of a fairly thick layer of the hydrophilic polymer on the particle surface [11, 12].

Disappearance of the restabilization section of the flocculation curves at high concentration of the dispersed latex phase can be due to the relaxation of macromolecules in sorption interaction with the particle surface [14, 15]. The probability of formation of the bridging bonds between the neighboring particles decreases with increasing time of sorption contacts between macromolecules and particle surface. At sufficiently high concentration of the dispersed phase, the "free-path" time of the particles between collisions becomes smaller than the relaxation time of sorbed macrochains and they preserve the capability for bridge formation [14, 16]. In this case, despite recharging, polyelectrolytes exhibit high flocculation activity at their concentrations higher than OFC.

It was shown in [7] that PDMASs exhibit base properties, i.e., the ionization equilibrium is shifted toward charged polymer structures capable to bind emulsifier anions. This equilibrium can be shifted with changing concentration of hydrogen ions, and thus the solution pH can affect the flocculation power of PDMAS. To analyze this effect, we studied the dependence of the initial flocculation rate on the flocculant concentration at various solution pH. The "minute turbidity" τ_1, i.e., the increase in a turbidity of the diluted latex solution (1 : 5000) in 1 min after addition of the flocculant into the latex solution, was used as a measure of the initial flocculation rate [8]. The pH of the flocculating solutions was adjusted by adding 0.1 N solutions of H_2SO_4 and KOH. The dependences of the initial flocculation rates of the latexes on the $PDMAS \cdot H_2SO_4$ concentration at various pH are shown in Fig. 3. In all the cases, the τ_1–c_{PE} curves pass through a maximum at c_m, which shits toward higher concentrations with decreasing solution acidity. Thus, the increase in the solution pH decreases the flocculation performance of the DM polyelectrolytes, which is probably due to the decreasing fraction of charged units (amino ester fragments) in the polymeric chains.

The contribution of the neutralization factor to the latex destabilization decreases with decreasing charge density on the macromolecules.

To verify the above assumptions, we studied the effect of pH on the interaction of PDMAS with anionic latex stabilizer Leukanol (L, a mixture of oligomeric sodium salts of the products of condensation of β-naphthalenesulfonic acid and formaldehyde) by the nephelometric method. Butadiene–styrene latexes often contain Leukanol (about 0.4 wt % relative to the polymer) along with alkaline salts of fatty and resin acids [1]. At coagulation in the presence of mineral acids, the carboxyl-containing emulsifiers lose the stabilizing power because of the hydrolysis, whereas Leukanol remains active even in acidic solutions.

As in the case of the other cationic polyelectrolytes [17], addition of PDMAS into the Leukanol solution makes it turbid owing to the formation of an insoluble nondissociating oligomer–polymer ionic complex. The effect of the solution pH on formation of this complex was studied as follows. The Leukanol solution was added to aqueous solutions of $PDMAS \cdot H_2SO_4$ containing various amounts of H_2SO_4 or KOH, so that the concentrations of Leukanol and polyelectrolyte in the mixture were constant and equal to 8×10^{-4} and 4×10^{-4} M, respectively. The components were quickly mixed, and the minute turbidity of the resulting dispersion was measured. The τ_1–pH dependence is shown in Fig. 4. We also performed potentiometric titration of the polyelectrolyte solution with an alkali solution (Fig. 5). As seen from the τ_1–pH dependence, the amount of the resulting insoluble complex decreases with increasing pH; there are two sections in which the complex formation sharply depends on pH. In the acidic section (pH < 3), the increase in the complex formation with decreasing pH can be due to the suppression of hydrolysis of the polymeric salt of the weak organic base, which increases the number of cationic groups in the polymeric chains and promotes linking with Leukanol. In passing to the alkaline section (pH >~ 6.5), deprotonation of the nitrogen atoms in the amino groups probably begins, and it increases with increasing pH. In the process, the fraction of the neutral units in the polymeric chains increases, decreasing the complexation efficiency up to its complete termination at pH 8.5. As seen from the potentiometric titration curve (Fig. 5), this pH value corresponds to the half-neutralization point of the polymer.

The middle section (plateau) in the τ_1–pH curve, within which the intensity of complexation is constant, corresponds to the pH region from 3 to ~6.5, in which the charge density of macromolecules remains approximately constant.

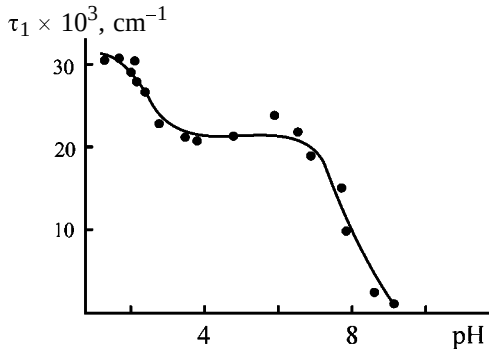

Fig. 4. Minute turbidity τ_1 of the $PDMAS \cdot H_2SO_4$ + L system as a function of pH. Concentrations of Leukanol and polyelectrolyte 8×10^{-4} and 4×10^{-4} M, respectively.

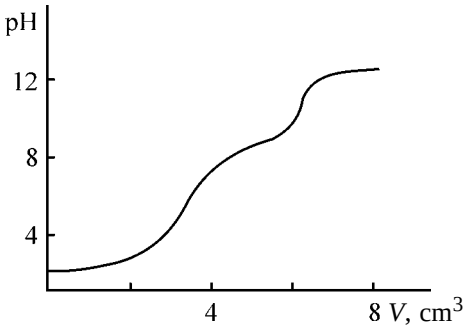

Fig. 5. Potentiometric titration curve of $PDMAS \cdot H_2SO_4$. (V) Volume of 0.5 M KOH solution.

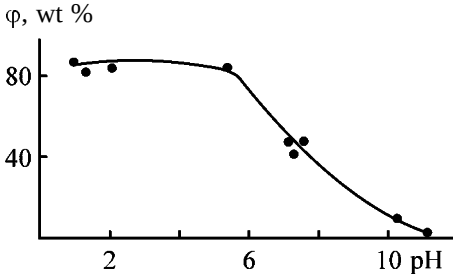

Fig. 6. Rubber fraction φ recovered with $PDMAS \cdot H_2SO_4$ flocculant as a function of pH. Concentration of the dispersed phase 50 g l^{-1}, specific consumption of flocculant 15 kg per ton of rubber.

It was of particular interest to compare the nephelometric data characterizing interaction between the anionic stabilizer and cationic flocculant with the data on the effect of pH on the rubber recovery in the course of the latex flocculation (Fig. 6). The flocculation was carried out at various contents of acid or alkali. After the rubber recovery, the serum pH was determined. As seen from the φ–pH curve, in the acidic section (pH < 6), the degree of rubber recovery is independent of pH, and it decreases in alkaline

solutions virtually to zero at pH ~ 12. Constancy of φ in the initial section (pH < 6) is probably due to the fact that, despite possible changes in the density of the positive charge of macromolecules, Leukanol is completely linked by excess polyelectrolyte under the experimental conditions ([PE] : [L] = 3 : 1). At pH > 6, deprotonation of the polyelectrolyte units increases with simultaneous conversion of the carboxy-containing emulsifiers to the salt form. As a result, the deficiency of the cationic groups required for binding of the stabilizer anions (soap and Leukanol) grows, making the coagulum yield lower.

It should be noted that the flocculation power disappears at higher solution bacisity (pH 12) than that at which the Leukanol binding is terminated (pH ~ 8.5). This fact indicates that the latex flocculation cannot be explained solely by chemical interaction between the flocculant and anionic stabilizer and neutralization of the particle surface charge. In strongly alkaline solutions, the rubber recovery (though not very efficient) is possible by the bridging mechanism of flocculation.

CONCLUSIONS

(1) In rubber recovery from SKS-30 ARK latex with polymeric ammonium salts of *N,N*-dimethylaminoethyl methacrylate and mineral acids, the optimal flocculant concentration is independent of particular mineral acid, procedure of the salt preparation, and intrinsic viscosity of the polyelectrolyte; it corresponds to the specific consumption of the chloride, nitrate, and sulfate of 10 (up to 25 for phosphate) kg per ton of rubber.

(2) The data on the initial flocculation rate and interaction of polymeric ammonium salts of *N,N*-dimethylaminoethyl methacrylate with the latex stabilizer (Leukanol) as influenced by pH of the medium showed that the flocculant performance decreases with decreasing solution acidity. This fact may be due to the decreasing positive charge of macromolecule and contribution of the neutralization factor to the latex destabilization.

Abstract—Polycondensation of bifunctional hydroxyl-containing oligodienes with diisocyanates was studied by gel permeation chromatography, IR spectroscopy, and rheokinetic method. The kinetics of oligodiene urethane formation and the properties of the resulting oligomers, including the molecular-weight distribution and viscosity, were studied in relation to the ratio of the isocyanate and hydroxy groups.

Reactions of diisocyanates with hydroxyl-containing dienes attract particular interest due to their wide use in production of elastomers, urethane foams, adhesives, coatings, and other items. Despite seeming simplicity of such reactions, preparation of oligomers containing terminal isocyanate groups and exhibiting the required set of physicochemical properties is impossible without comprehensive study of the synthesis process, including the kinetic, molecular-weight, and rheological aspects.

In this work, we studied by gel permeation chromatography (GPC), IR spesctorscopy, and rheokinetic method the molecular-weight distribution (MWD) and dynamic viscosity of oligodiene urethanes in relation to the synthesis conditions. Also we examined the kinetic features of polycondensation of diisocyanates with bifunctional oligodienes containing terminal hydroxy groups.

EXPERIMENTAL

As investigation objects we used linear bifunctional oligodienes with terminal hydroxy groups (M_w 3600–3800), prepared by radical polymerization of 1,3-butadiene in the presence of an azo dinitrile initiator, 4,4'-azobis(4-cyanopentanol), and toluene 2,4-diisocyanate (TDI).

The IR spectra were recorded on a Specord IR-75 spectrophotometer. Samples were prepared as films between CaF_2 plates. The kinetics of the reactions of oligodienes with the diisocyanate were studied by monitoring the IR absorption of the NCO groups at ν = 2275 cm^{-1}. One of the oligomer bands [ν(C–H) of the methylene fragment] was used as internal reference.

Chromatography of oligomers was performed on a Waters-244 module-type chromatograph using three Styrogel columns with the pore size of 100, 500, and 1000 Å. The eluent was tetrahydrofuran (elution rate 1 ml min^{-1}). A differential refractometer was used as detector.

The rheological behavior of the reaction mixture in the course of the synthesis and that of the final products were studied with a Hoeppler rheoviscometer.

Synthesis of oligodiene urethanes with terminal isocyanate groups was performed in the bulk in the temperature range 3–70°C to constant content of NCO groups, which differed from the calculated content by no more than 0.05% [1].

The rate of the reaction of functional isocyanate and hydroxy groups depends on their concentrations and reaction temperature, following the common kinetic relationships. At [NCO]/[OH] = 2.05–2.15, the synthesis of oligodiene urethanes is complete in 3–4 h (T = 60°C), whereas at the equimolar ratio of the reacting groups, under similar conditions, the time required to prepare the product containing less than 0.1 wt % NCO groups was as long as 10–12 h.

It should be noted that the rate constants of the reaction of NCO and OH groups are apparent quantities. Actually the kinetics of formation of diene urethane prepolymers from oligodiene diols and TDI can be described by four rate constants because of different reactivities of the NCO groups of TDI at the *o*- and *p*-positions to the methyl substituent [2, 3].

The temperature dependence of the rate constants of the reaction between the isocyanate and hydroxy groups ([NCO]/[OH] = 2.15), plotted in the Arrhenius

* Calculated for the "polymeric" fraction of the product.

coordinates (Fig. 1), shows that the activation barrier of the reaction is relatively low (activation energy E_a = 3.19 ± 2.6 kJ mol^{-1}), allowing preparation of oligodiene urethanes in a wide temperature range (20–60°C).

Synthesis of the prepolymers is accompanied by an increase in the dynamic viscosity of the reaction mixture due to the growth of M_w of the polymer and to formation of urethane groups capable of strong intermolecular interactions. The rheokinetic data suggest rapid growth of the dynamic viscosity in the initial step of polycondensation (Fig. 2).

Then, as the reactive groups are consumed, the growth of the viscosity decelerates. The plateaus in the η–τ curves correspond to the virtually ready product, indicating that modification of the oligodiene with the diisocyanate has been completed. Comparison of the η–τ dependences for systems with different [NCO]/[OH] ratios shows that the constant viscosity is attained most rapidly at the highest [NCO]/[OH] ratios.

Figure 2 shows that, at [NCO]/[OH] = 1.5, the rheokinetic curve is S-shaped, which may be due to formation of intermediates $(oligomer–TDI)_n$ (n = 1, 2) in the initial step of the process, with an increase in the weight-average molecular weight by a factor of 2–3. Condensation of these intermediates with each other causes active growth of the viscosity without pronounced plateau, in contrast to the pattern observed at [NCO]/[OH] = 2.1.

Quantitative data illustrating the relationship of MWD and viscosity of oligodiene urethanes with the [NCO]/[OH] ratio are given in the table.

The viscosity of the oligomer prepared at [NCO]/[OH] = 3.0 is minimal because of the narrow MWD of the polymeric fraction of the sample and the highest content of the low-molecular-weight component, TDI, in the final product. As the [NCO]/[OH] ratio is decreased, the dynamic viscosity of oligodiene urethanes grows, which is due both to a decrease in the TDI content in the system and to an increase in M_w of the polymeric component.

The average molecular weights and polydispersity coefficient of oligodiene urethanes are minimal in the range of [NCO]/[OH] ratios from 2.0 to 3.0. As the [NCO]/[OH] ratio is decreased to 1.1–1.2, the molecular weights grow substantially, and MWD becomes broader owing to intense chain propagation with no exchange reactions (Fig. 3).

The fact that at [NCO]/[OH] = 1.1–1.2 the experimental polydispersity coefficient appreciably exceeds

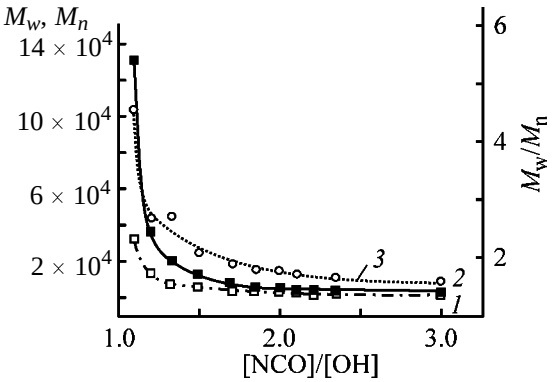

Fig. 3. Influence of the [NCO]/[OH] ratio on the MWD parameters of oligodiene urethanes: (*1*) M_n, (*2*) M_w, and (*3*) M_w/M_n.

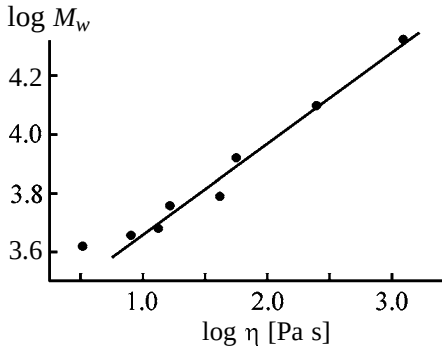

Fig. 4. Logarithmic plot of M_w of oligodiene urethanes vs. their dynamic viscosity η.

the theoretical value for polycondensation processes (M_w/M_n = 2) is also due to development of side reactions yielding branched macromolecules. At substoichiometric [NCO]/[OH] ratios, the average molecular weights and the polydispersity coefficient of the oligodiene urethanes obtained regularly decrease.

The log–log plot of the dynamic viscosity of the oligomers synthesized vs. their weight-average molecular weight is linear (Fig. 4), which is typical of structurallly related liquid polymers in the entire range of molecular weights.

CONCLUSIONS

(1) Hydroxy groups of an oligodiene react with isocyanate groups of toluene 2,4-diisocyanate in the bulk at a fairly high rate with relatively low activation energy, which allows the synthesis of oligodiene urethanes in a wide temperature range.

(2) Oligourethanes prepared at the ratio of the isocyanate and hydroxy groups [NCO]/[OH] = 2.1–2.2 exhibit the best structural and viscosity characteristics required of prepolymers to be used in preparation of urethane elastomers by reaction with cross-linking agents.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Structure and Properties of Polyurethane–Ureas Prepared from Blends of Thermodynamically Incompatible Oligomer Diisocyanates

Abstract—The structure and properties of materials based on oligo(divinyl–isoprene) and oligoether diisocyanates cured with an aromatic diamine were studied.

Preparation of segmented polyurethanes (SPUs) from individual oligomers does not always yield materials with optimal properties. For example, the frost resistance of SPUs with flexible oligodiene segments is high (down to –60°C), but, as compared to SPUs derived from oligoethers, their strength is lower, and the reaction mixture is more viscous and has shorter working life (time in which the system remains in the state of a low-viscosity liquid [1]).

An efficient way to control the properties of such materials is the use in polyurethane formulations of not one but several (usually two) oligomers [2–5]. Oligomers both compatible in any ratios at temperatures of SPU preparation and virtually incompatible [5] can be used. In the latter case, an SPU may have a heterogeneous structure with a disperse phase with flexible blocks incorporated in a polymeric matrix of a different structure, also with flexible blocks. Formation of such a disperse phase in SPUs may both improve and impair the properties of materials, depending on the component ratio.

In this work we studied the structure and properties of SPUs with thermodynamically incompatible polar polyether and nonpolar poly(divinyl–isoprene) flexible blocks.

Our main goal was to examine the possibility of reinforcing the elastomer with nonpolar flexible blocks by introducing polar flexible blocks into the composition of the flexible phase and of controlling the rheological properties of the SPU reaction mixture.

EXPERIMENTAL

We used segmented polyurethane–ureas (SPUUs) with similar rigid blocks and different flexible blocks. SPUUs were prepared from commercial prepolymers: P-10.000 (M ~4500) based on oligo(divinyl–isoprene)-diol (molar ratio of butadiene and isoprene units 70/30, M ~400) and SKU-PFL-100 (M ~1400) based on oligo(tetramethylene oxide)diol (M ~1000). The prepolymers were prepared by reactions of the oligomeric diols with toluene 2,4-diisocyanate taken in a twofold excess. The molecular weight of the oligomers was estimated from the content of isocyanate groups. Blends of the prepolymers were prepared by mixing in a vacuum for 30 min at 60 ± 1°C. Then we added into the mixer the melt of an aromatic diamine, 3,3'-dichloro-4,4'-diaminodiphenylmethane (Diamet Kh) and stirred the components for 3 min under the above-indicated conditions.

The rheological properties of the reaction mixture were determined with a Rheotest-2 device (cone–plate working unit) at a shear rate of 180 s^{-1}.

The samples cured for 4 days at 80 ± 1°C were stored at room temperature for no less than 15 days before tests.

The physicomechanical characteristics of SPUUs [tensile strength σ_t (ultimate stress per initial cross section of the sample) and relative elongation at break ε_b] were determined at 25°C and extension rate of 0.28 s^{-1}.

Because of the lack of an approach to evaluating the parameters of the three-dimensional network of heterogeneous polymer blends, we determined the density of the chemical (N_c) and physical (N_p) networks (the points of the latter are domains of rigid urethane–urea blocks) only for SPUUs with individual flexible blocks. The effective network parameters were estimated following the procedure from [6].

SPUU-8	0.75	50	1040	26	–	–
SPUU-9	0.80	57	1048	28	–	–
SPUU-10	0.85	65	1068	30	–	–
SPUU-11	0.90	75	1090	32	–	–
SPUU-12	1.00	100	1129	37	1.51	0.08

The glass transition points T_g^s of flexible SPUU blocks were determined with a DSM-2 differential scanning calorimeter under conditions of slow sample heating (0.02 deg s^{-1}).

The properties of SPUUs were studied in a wide range of the prepolymer ratios. The mole fractions (x_2) and weight percentages (c_{PFL}) of SKU-PFL in prepolymer blends, sample densities ρ, contents of the rigid phase in them (c_r), and effective network parameters N_c and N_p are given in the table.

As expected, because of thermodynamic incompatibility of P-10.000 and SKU-PFL-100, an emulsion of one of the prepolymers in the other is formed already on mixing the components. After adding a curing agent, two phases are formed: phase 1 consisting of P-10.000 and Diamet Kh and phase 2 consisting of SKU-PFL-100 and Diamet Kh. At a stoichiometric ratio of the NH_2 and NCO groups, the calculated weight ratio of the diamine to the prepolymer m is m_1 = 0.059 in phase 1 and m_2 = 0.191 in phase 2.

Our experiments showed that the solubility of the chosen aromatic diamine in the two prepolymers at the mixing temperature (60°C) is essentially different. The experimental values are m_1 = 0.047 and m_2 = 0.350. Comparison of these results with the calculated values shows that the curing agent is in deficiency in phase 1 and in excess in phase 2.

If phase 1 is the dispersion medium in the reaction mixture, then deficiency of the active agent in it should result in preservation of the low viscosity of the polyurethane formulation for a long time, i.e., in longer working life of the formulation, which is the case. For example, the dynamic viscosity η = 20 Pa s of SPUU-1 formulation based on individual P-10.000 at 60°C is attained in 10 min after the compounding. The same viscosity of SPUU-5 and SPUU-6 formulations based on prepolymer blends is attained in 65 and 110 min, respectively (Fig. 1, curves *2*, *4*, *5*). Hence, addition of a small amount of SKU-PFL-100 prepolymer (see table, c_{PFL} = 13–21%) to the reaction mixture containing P-10.000 increases the working life of the formulation by approximately an order of magnitude. If phase 2 is the dispersion medium (c_{PFL} = 65%, x_2 = 0.85), the working life of the reaction mixture, on the contrary, becomes shorter.

Curing of the disperse phase and dispersion medium with an aromatic diamine yields an elastomer with a flexible polymeric matrix incorporating particles of an elastic filler.

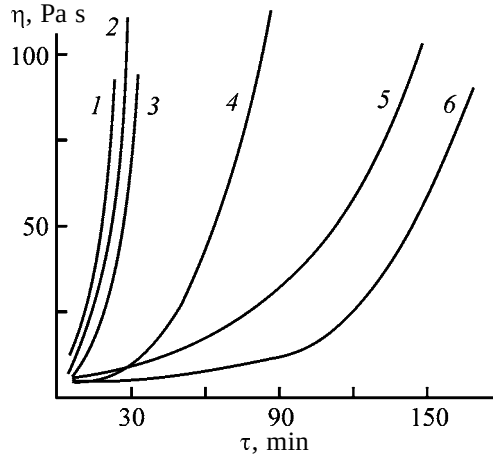

Fig. 1. Variation with time τ of the dynamic viscosity η of polyurethane–urea samples: (*1*) SPUU-10, (*2*) SPUU-1, (*3*) SPUU-12, (*4*) SPUU-4, (*5*) SPUU-5, and (*6*) SPUU-6.

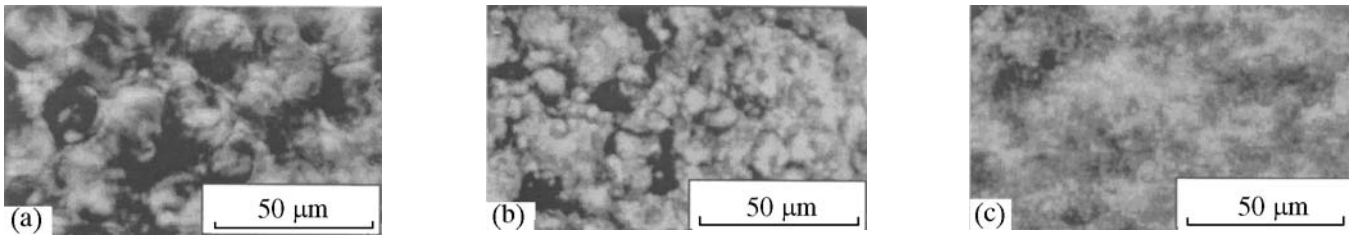

Fig. 2. Photomicrographs of SPUUs based on prepolymer blends with different content of SKU-PFL-100: (a) SPUU-6 (x_2 = 0.3), (b) SPUU-7 (x_2 = 0.6), and (c) SPUU-8 (x_2 = 0.75, c_{PFL} = 50%).

The structure of the cured material depends on the component ratio. At a low content of one of the prepolymers (up to 30%), the filler particles are spherical with a clear phase boundary and size of about 10–25 μm (Fig. 2a). As the filler concentration increases, continuous domains of agglutinated filler particles are formed (Fig. 2b), and at equal content of the prepolymers in the blend (c_{PFL} = 50%, x_2 = 0.75) the phases overlap (Fig. 2c).

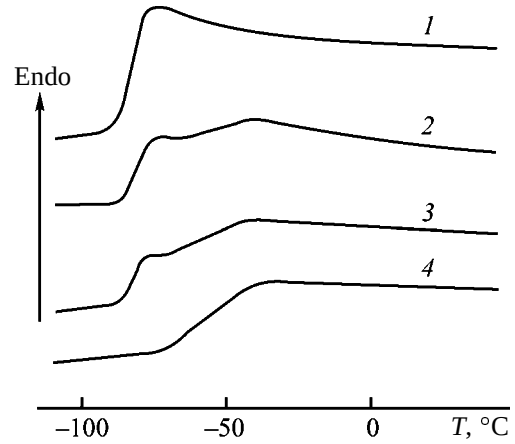

Fig. 3. DSC curves of SPUU samples: (*1*) SPUU-1 (P-10.000), (*2*) SPUU-7 (c_{PFL} = 33%), (*3*) SPUU-10 (c_{PFL} = 65%), and (*4*) SPUU-12 (SKU-PFL-100). (*T*) Temperature.

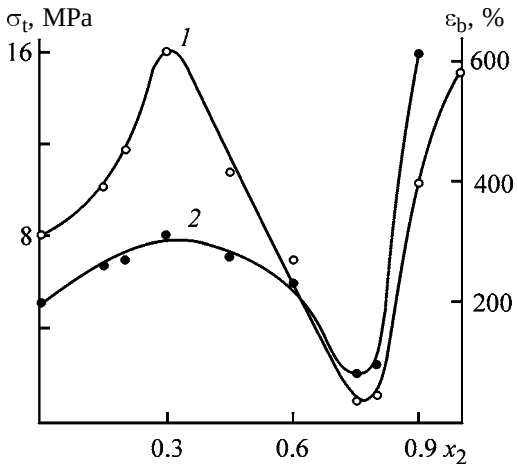

Fig. 4. (*1*) Relative elongation at break ε_b and (*2*) strength σ_t of SPUU as a function of the mole fraction of SKU-PFL-100 x_2 in the prepolymer blend.

The DSC curves (Fig. 3) show that the compounds based on prepolymer blends are characterized by two glass transition points of flexible blocks T_g^s, differing insignificantly from T_g^s of the materials based on the individual prepolymers: –54 (SPUU-12) and –82°C (SPUU-1). This fact indicates that the materials based on the two prepolymers are heterogeneous blends of two polyurethane–ureas in which the flexible blocks do not mix with each other. It should be emphasized that such structures are not necessarily formed in materials with polar and nonpolar flexible blocks. For example, at MW ~200, as shown in [4], polybutadiene and polyether flexible segments are miscible in any ratios.

The mechanical characteristics of polydiene–urethane–ureas based on a single prepolymer, P-10.000, and those of polyether–urethane–ureas based on another single prepolymer, SKU-PFL-100, differ dramatically. The high density of the physical network (N_p = 1.51 kmol m^{-3}) in SPUU-12 with polyether flexible segments and the high concentration of rigid blocks (37%), in combination with dipole–dipole and specific interchain interactions, provide high strength (42 MPa) and high nominal modulus (11.5 MPa at 100% relative strain) of the material. The relative elongation at break, ε_b, reaches 560%. In SPUU-1 with nonpolar flexible segments, low N_p and low concentration of rigid blocks (see table) are responsible for the poor strength (5.4 MPa), low nominal modulus (2.7 MPa), and lower ε_b (320%). The influence of various factors on the mechanical properties of polyurethane materials in considered in detail in [7, 8].

Combination in one material of polyurethane–ureas strongly differing in the mechanical properties results in nonmonotonic dependence of the mechanical characteristics of the heterogeneous polymeric composite on the prepolymer ratio (Fig. 4). On adding SKU-PFL-100 to the reaction mixture containing P-10.000,

the strength and breaking strain grow, reaching a maximum at x_2 = 0.3. The tensile strength σ_t increases from 5.4 to 8.2 MPa, and the relative elongation at break, from 320 to 630%.

The material of the composition corresponding to the inversion point of the filler and polymeric matrix (x_2 = 0.75, c_{PFL} = 50%) has the lowest strength. As the fraction of SKU-PFL-100 is increased further, polyuether–urethane–urea becomes the dispersion medium, and polydiene–urethane–urea, the filler. With decreasing concentration of the low-strength filler in the polyether matrix, the strength of the material regularly grows. Such a pattern is typical of thermodynamically incompatible polymer blends.

Significant enhancement of the mechanical characteristics is observed at such material composition at which, as noted above, the working life of the reaction mixture considerably grows; this is important from the viewpoint of preparation of big polyurethane items of high quality.

CONCLUSIONS

(1) Segmented polyurethane–ureas with polydiene and polyether flexible blocks are heterogeneous blends of two polyurethane–ureas differing in the chemical structure of the flexible chains.

(2) The dependences of the mechanical characteristics of the polyurethane elastomer on the prepolymer ratio pass through extrema, which is due to the heterogeneous structure of the material and to strong difference in the mechanical characteristics of the filler and polymeric matrix.

(3) Introduction of 13–20% oligoether diisocyanate into the polydiene–urethane–urea formulation ensures the 1.5 times higher strength of the material and 2 times larger elongation at break. Furthermore, the working life of the polyurethane compound increases by an order of magnitude owing to depletion in the curing agent of the liquid phase containing oligodiene diisocyanate.

Abstract—Solid-phase synthesis of certain metal carboxylates and their effect on stabilization of polyvinyl chloride under intense high-pressure shear treatment were studied.

Metal carboxylates are widely used as thermal stabilizers and lubricants in development of new materials and goods based on polyvinyl chloride (PVC) [1]. The main method of industrial production of metal carboxylates is the exchange reaction between aqueous solution of metal chloride or nitrate and sodium carboxylate, e.g., stearate, at elevated temperatures. It is characterized by a large amount of wastewater, the need in additional operations to isolate target products, etc. [2]. In known methods of solid-phase synthesis of metal carboxylates [3, 4], sophisticated and power-consuming devices with abrasive, cutting, and impact action are used. The product yields in such procedures are usually low.

A new method of solid-phase synthesis of chemical materials and processing and modification of polymers under intense high-pressure shear treatment (IHPST) at elevated temperatures in special dispersers is being actively developed today [5, 6]. Under IHPST, various chemical reactions can proceed in polymers: change of supramolecular structure, disintegration, and increase in specific surface area of the material treated with formation of a superfine powder.

The goal of this work is to perform solid-phase synthesis of certain metal carboxylates and to study polyvinyl chloride (PVC) stabilization with these carboxylates under IHPST.

EXPERIMENTAL

The solid-phase synthesis of metal carboxylates and processing of polyvinyl chloride compositions under IHPST were performed in a rotary disperser designed at the Institute of Chemical Physics, Russian Academy of Sciences [6]. The yield of metal carboxylates was determined analytically in accordance with TU (Technical Specifications) 6-09-4104–87 from the residual content of carboxylic acids in the reaction mixture and by IR spectrometry on a Bruker IFS-88 spectrometer from the intensity of the absorption bands within the 1400–1650 cm^{-1} range depending on metal. Pure grade stearic, lauric, and palmitic acids and calcium, barium, cadmium(II), lead(II), and zinc(II) oxides or their binary mixtures, and sodium and potassium carbonates were used. The method of determination of the PVC dehydrochlorination rate was similar to that described in [7]. The thermal stability time of polymeric compositions was determined in accordance with GOST (State Standard) 14041–91.

The IHPST method has no disadvantages characteristic for other methods of metal carboxylate synthesis and provides high yield of the reaction products and short reaction time; no catalysts are required. The specific feature of solid-phase reactions with IHPST is that the combined effect of high pressure and shear strain brings solid substances to the plastic flow state. In the process, a great amount of structural defects is formed in the substance, electronic properties of molecules change, and the activation barrier of reactions decreases [8].

The solid-phase synthesis of metal carboxylates proceeds by the reactions

$$MO + 2RCO_2H \rightarrow M(RCO_2)_2 + H_2O,$$

$$M'_2CO_3 + 2RCO_2H \rightarrow 2M'(RCO_2) + H_2O + CO_2,$$

where M = Ca, Ba, Zn, Cd, Pb; M' = K, Na; R = $C_{11}H_{23}$, $C_{15}H_{31}$, $C_{17}H_{35}$.

1070-4272/04/7705-0842 © 2004 MAIK "Nauka/Interperiodica"

The reaction products are formed during passing of the reaction mixture through the rotary disperser for 3–5 min at a single IHPST effect on the reactants. The yield of the target product, which is obtained as a dry superfine powder, was 96–99% of the calculated amount (Table 1). The method allows preparation in the same device of a wide assortment of individual metal carboxylates and their mixtures (including synergistic mixtures).

Estimation of the stabilizing performance of salts of saturated monocarboxylic acids with respect to vinyl chloride polymers (PVC; copolymer of vinyl chloride with 4 wt % propylene, VCPR-4; copolymer of vinyl chloride with 15 wt % vinyl acetate, VCVA-15) showed that, with respect to the "thermal stability time" index, it is not inferior to the performance of stabilizers prepared by the industrial method (Table 2).

The solid-phase method of obtaining metal carboxylates under IHPST has substantial advantages as compared to the industrial synthesis method: it is continuous and single-stage, synthesis can proceed in one apparatus at a high rate without heating, the process is characterized by elevated environmental safety, and the chemical modification of stabilizers and preparation of synergistic mixtures on their base are possible.

The synthesis of metal carboxylates is also possible directly in a polymer matrix, when a mixture of PVC with a metal oxide (or another base) and an equivalent amount of a carboxylic acid is processed in a rotary disperser. The high stabilizing performance of the components under IHPST is apparently due to solid-phase synthesis of metal carboxylates from the initial reactants. It should be noted, however, that, with the carboxylates prepared *in situ*, the thermal stability time is shorter than when PVC is stabilized with the corresponding metal carboxylates prepared in advance (Table 3).

To improve PVC grinding under IHPST, various components, in particular, metal carboxylates can be used as process additives. Joint grinding of PVC mixtures with metal carboxylates under IHPST substantially improves the process efficiency and increases the degree of dispersion of the powder formed.

Joint grinding of PVC with metal carboxylates under IHPST substantially enhances stabilizing performance of additives with respect to thermal stability time index as compared to usual mechanical mixing (Table 3). The stabilizing performance of additives also increases with respect to the "dehydrochlorination rate" index when coordination-unsaturated metal

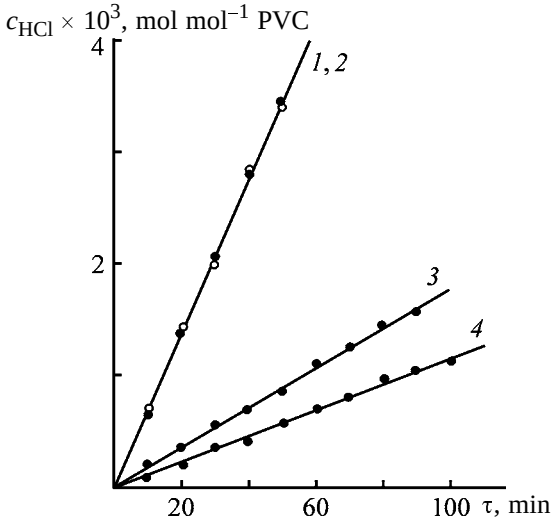
$C_{17}H_{19}CO_2H$	–	–	–	–	–	–	–	–	4.04	4.70	4.64	3.67	4.20
Thermal stability time at 175°C, min:													
before IHPST	97	24	50	153	64	274	105	74	48	18	115	75	50
after IHPST	109	32	58	171	73	282	118	85	84	43	143	181	88
$V_{HCl} \times 10^6$ at 175°C, mol HCl : mol PVC*:													
before IHPST	1.20	1.20	1.20	1.21	0.32	0.30	0.32	1.19	1.33	1.46	1.70	0.85	1.06
after IHPST	1.21	1.19	1.20	1.22	0.21	0.18	0.24	1.18	1.26	1.28	1.31	0.39	0.52

* Temperature in disperser at IHPST: in compression chamber 115°C and in grinding chamber 60°C; speed of screw rotation 35 min^{-1}.

** Dehydrochlorination rates in the initial period of degradation.



Kinetics of dehydrochlorination (175°C, air) of PVC stabilized (5 wt parts per 100 wt parts of PVC) with (*1*, *2*) barium stearate and (*3*, *4*) lead stearate (*1*, *3*) before and (*2*, *4*) after intense high-pressure shear treatment in a rotary disperser; (c_{HCl}) hydrogen chloride concentration and (τ) time.

[Cd(II) and Pb(II)] stearates are used, which, in addition to HCl scavenging, inhibit PVC dehydrochlorination due to chemical deactivation of the labile groups [7] (Table 3).

The physical and chemical processes occuring under IHPST are characterized by high rate of mass transfer (apparent diffusion coefficient becomes several times higher [8]). In this case, increased stabilizing performance of metal carboxylates can be explained by more uniform distribution of the thermal stabilizer in the polymer and by better accessibility of labile groups in reaction with stabilizing additives.

CONCLUSION

The method of intense high-pressure shear treatment shows promise in solid-phase synthesis of metal carboxylates. It also enhances their stabilizing performance in processing of polymeric compositions based on polyvinyl chloride.

Adsorption of Ammonia and Sulfur Dioxide by Sorbents Based on Modified Montmorillonite

A. S. Panasyugin, G. V. Bondareva, and A. I. Rat'ko

Research Laboratory on Waste Gas Treatment, Belarussian National Technical University, Minsk, Belarus
Institute of General and Inorganic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received October 28, 2003

Abstract—The sorption properties of montmorillonite modified with Fe(III) and Al(III) polyhydroxo complexes and with Fe(III)–Zr(IV), Fe(II)–Ni(II), and Fe(III)–Al(III) heteronuclear polyhydroxo complexes with respect to ammonia and sulfur dioxide were examined.

Synthetic sorbents such as activated carbons, zeolites, and ion exchangers used in the majority of adsorption processes can be replaced with inexpensive mineral sorbents based on smectite minerals. Of specific interest are clay minerals with expandable cell, whose layers are intercalated with polyhydroxo complexes (PHCs) of multiply charged metals. After calcination, the above PHCs transform into the oxide clusters, which support certain spacing between clay layers.

In this study, the sorptive properties of montmorillonite (MM) intercalated with PHCs of metals of various origin with respect to acid and base gases were considered by an example of ammonia and sulfur dioxide.

The initial material was montmorillonite clay of Askanskoe deposit (Georgia) containing (wt %) 53.3 SiO_2, 18.1 Al_2O_3, 0.84 Fe_2O_3, 4.9 MgO, 1.65 CaO, 1.1 Na_2O, 0.32 K_2O, and 7.98 H_2O.

The PHCs of metals were prepared and montmorillonite was modified according to the methods proposed in [1–3]. The specific surface area S_{sp} of the modified montmorillonite samples was determined by low-temperature sorption of nitrogen on a Micromeritics 2200 express analyzer. The parameters d_{001} for the first basal reflection from modified clays were determined with a Siemens 5000 diffractometer after drying samples at 120°C. The adsorption-structural characteristics of the obtained samples were calculated using data on the adsorption–desorption isotherms of benzene vapor. The isotherms of ammonia and sulfur dioxide sorption were taken gravimetrically at 20°C.

The table shows that the montmorillonite modification makes the spacing between aluminosilicate layers considerably larger, i.e., the d_{001} parameter for the first basal reflection from the Fe–Ni–MM sample increases to 2.42 nm, compared to the value of 0.95 nm for the initial sample. Noteworthy, S_{sp} of the montmorillonite samples containing heteronuclear PHCs amounts to 250–280 $m^2 g^{-1}$, which is somewhat larger compared to montmorillonite modified with individual iron and aluminum individual complexes (190 and 180 $m^2 g^{-1}$, respectively).

The presence of mesopores of radius larger than 20 nm in the pore structure of the modified samples can be judged from the shape of the isotherms of benzene vapor sorption [4]. Sharp rise of the isotherms in the low-pressure range for the Al–MM and Fe–Al–MM samples is an evidence for the considerable content of micropores.

The NH_3 sorption isotherms in Fig. 1a show that the maximal sorption capacity for NH_3 is exhibited by the Fe–MM sample and the minimal, by the Al–MM

Characteristics of natural and modified montmorillonites

Sample	Amount of modifying metal		d_{001}, nm	S_{sp}, $m^2 g^{-1}$
	Fe	Al, Ni, Zr

Al–MM	–	3.18	1.75	180
Fe–Al–MM	0.48	3.4	1.63	250
Fe–Ni–MM	0.82	0.14	2.42	270
Fe–Zr–MM	1.26	0.11	1.65	280
Fe–MM	1.23	–	1.59	190

1070-4272/04/7705-0846 © 2004 MAIK "Nauka/Interperiodica"

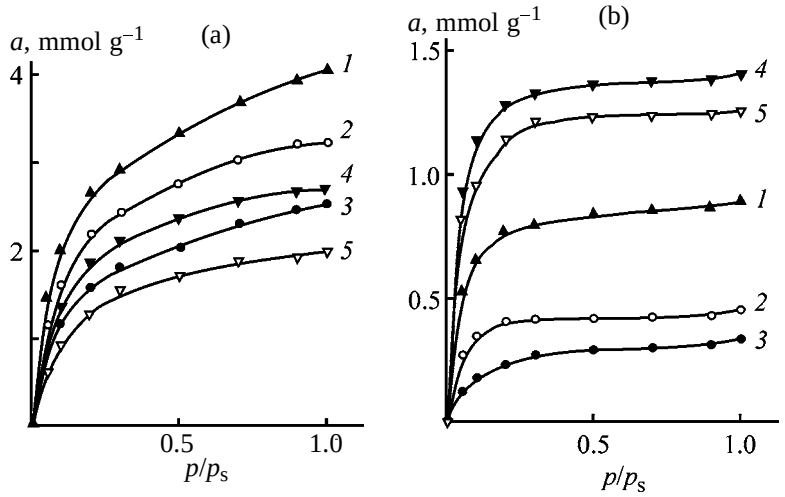

Fig. 1. Isotherms of (a) ammonia and (b) sulfur dioxide sorption a on the montmorillonite samples modified with PHCs of (*1*) Fe(III), (*2*) Fe(III)–Zr(IV), (*3*) Fe(III)–Ni(II), (*4*) Fe(III)–Al(III), and (*5*) Al(III). (p/p_s) Relative pressure.

sample. Adsorption of gaseous NH_3 is commonly used as test method to compare the surface acidity and catalytic activity of catalysts based on natural and synthetic aluminosilicates [5, 6]. Thus, we can suggest that the Fe–MM sample is the most acidic, and the Al–MM sample, the least acidic.

An increase in the acidity of montmorillonite samples modified with metal PHCs, as compared to the initial clay, is usually ascribed to an increase in the interlayer spacing, which, in turn, makes accessible the previously shielded internal acidic centers [7]. Therefore, samples with larger interlayer spacings, i.e., those characterized by higher d_{001} values, should be expected to exhibit higher acidity. However, d_{001} and the adsorption capacity of the samples for NH_3 do not correlate. These facts suggest that the high sorption capacity of the Fe–MM sample is due to the nature of the modifier, rather than to the montmorillonite properties. In such a case, a decrease in the sorption capacity for NH_3 of the Fe–Zr–MM and Fe–Ni–MM samples can be due to a decrease in the amount of intercalating iron agents (see table) and to introduction of Ni(II) and Zr(IV) into the modifier.

The SO_2 adsorption isotherms in Fig. 1b show that all the modified montmorillonite samples as a whole sorb SO_2 worse than NH_3, with the sorbents becoming saturated even at p/p_s ratios close to 0.2–0.3. The best sorption properties with respect to SO_2 are shown by the Al–MM sample. This is quite consistent with the observed trends in the surface acidity of modified montmorillonite samples, i.e., an acid gas is adsorbed to a greater extent by a less acid sample. For SO_2 adsorption, as for NH_3 adsorption, the introduction of additional metal ions into modifying Fe(III) PHC also impairs the sorption properties of modified montmorillonite. This is consistent with the results of [8], according to which catalyst samples containing Ni oxides sorb SO_2 worse than those containing Fe(III) oxides.

To conclude, our study shows that montmorillonite materials modified with iron(III) polyhydroxo complexes are good sorbents for NH_3.

BRIEF COMMUNICATIONS

Surface Tension in Aqueous Dodecylethylaminocarbonyldimethylbenzylammonium Chloride

N. N. Kochurova, O. P. Korotkikh, and M. V. Dmitrovskaya

Chemistry Research Institute, St. Petersburg State University, St. Petersburg, Russia

Received December 17, 2003; in final form, February 2004

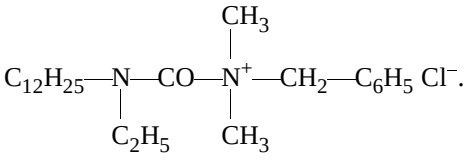
Abstract—The surface tension of aqueous solutions of the cationic surfactant dodecylethylaminocarbonyldimethylbenzylammonium chloride is measured for the first time over a wide concentration range from 7.9×10^{-7} to 3.9×10^{-2} M at 20–35°C. The critical micelle concentration of DAEDMBAC as influenced by temperature is determined.

Surfactants are intensively studied because of their wide use in micellar catalysis, organic synthesis, as detergents and components of lubricants, in dyeing, dry cleaning, photographic processes, as models for various biological and physiological objects, etc. [1]. Addition of surfactants to water and other liquids such as oil and petroleum products decreases the expenses for their pipeline transportation and pipeline steel intensity. All these applications are based on the ability of surfactants to decrease the surface tension of solutions.

In this work we reported on the surface tension of a new, practically unstudied surfactant, dodecylethylaminocarbonyldimethylbenzylammonium chloride (DEADMBAC), as influenced by the solution concentration and temperature, and also on the critical micelle concentration (CMC) of the solutions and adsorption of DEADMBAC.

EXPERIMENTAL

The structural formula of the surfactant studied is



The purity of this compound was confirmed by the shape of the surface tension isotherm (no minimum near CMC). Aqueous DEADMBAC solutions were prepared using double-distilled water.

The surface tension was measured by the ring detachment method with a Markada digital instrument (St. Petersburg) [2]. Initially the instrument was calibrated by measuring the surface tension of hexane, isopropanol, benzene, ethylene glycol, and double-distilled water. The calibration curve (Fig. 1) is linear, allowing determination of the surface tension to within 0.5 mN m^{-1}.

Measurements were conducted at 20, 25, 30, and 35°C and concentrations from 7.9×10^{-7} to 3.9×10^{-2} M. The results are given in Fig. 2. Under the experimental conditions, the surface tension γ decreases by more than 33 mN m^{-1} as the concentration increases, and by 2–3 mN m^{-1} with increasing temperature. Such concentration and temperature dependences are typical of surfactant solutions [1, 3].

From the measured surface tension we estimated the adsorption Γ (mol m^{-2}) by

$$\Gamma = -\frac{1}{2RT}\frac{\partial\gamma}{\partial \ln a}, \qquad (1)$$

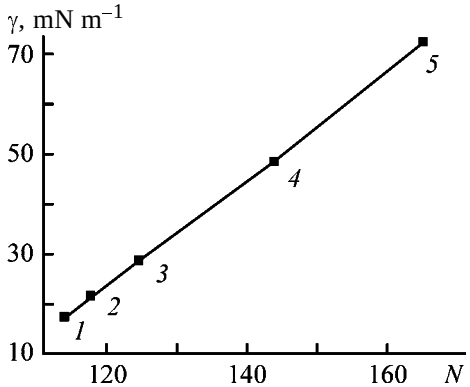


Fig. 1. Calibration curve for determination of the surface tension. (γ) Surface tension and (*N*) scale reading. (*1*) Hexane, (*2*) isopropanol, (*3*) benzene, (*4*) ethylene glycol, and (*5*) water.

where R is the gas constant; T, absolute temperature; a, activity (M) [$a = cf$, here c is the concentration (M) and f, activity coefficient].

The mean activity coefficient can be estimated by the Debye–Hückel approximation [4] using Eq. (2).

$$\log f_{\pm} = -\frac{AI^{1/2}}{1 + BI^{1/2}}, \quad (2)$$

where the coefficients A and B are the functions of the temperature (they were taken from [4]) and I is the solution ionic strength.

The estimated activity coefficients were demonstrated to be close to unity over the entire concentration and temperature ranges studied in this work, ranging from 0.9990 at 7.9×10^{-7} M to 0.9830 at 4×10^{-3} M.

The experimental dependences $\gamma(\ln a)$ obtained at 20, 25, 30, and 35°C were, respectively, approximated by the following relationships:

$$d\gamma/d\ln a = -17.79 - 1.1\ln a,$$

$$d\gamma/d\ln a = -21.21 - 1.46\ln a,$$

$$d\gamma/d\ln a = -22.82 - 1.56\ln a,$$

$$d\gamma/d\ln a = -21.67 - 0.72\ln a.$$

and then the adsorption was estimated by Eq. (1).

The estimated concentration and temperature dependences of the adsorption are presented in Fig. 3. The adsorption obtained for DEADMBAC (about 10^{-6} mol m^{-2}) is well comparable with that of other surfactants [3].

In parallel to the surface tension measurements we determined CMC. It is 4.5×10^{-4}, 3.4×10^{-4}, 2.6×10^{-4}, and 5.5×10^{-4} M at 20, 25, 30, and 35°C, respectively.

These values are plotted in Fig. 4, demonstrating a clearly pronounced minimum near 30°C. It is known that micelles are formed in aqueous surfactant solutions through hydrophobic interactions with water, resulting in displacement of surfactant molecules from water. Study of the kinetic features of the cation DEADMBAC$^+$ in aqueous solutions of the chloride salt showed that, at 30–35°C, the nature of interaction of the cation with water changed. At temperatures below 30°C, the presence of the surfactant decreases the activation energy of translation motion of the nearest water molecules (negative hydration by Samoilov [5]), decreasing the degree of structurization of water. Above 30°C, the surfactant increases the activation energy and the degree of structurization (positive hydration). Therefore, the temperature of about 30°C corresponds to the minimal CMC. At

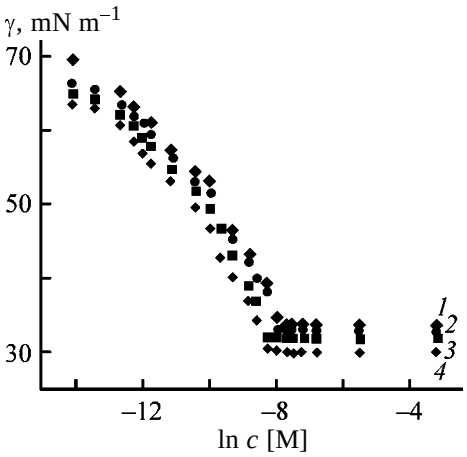

Fig. 2. Isotherms of the surface tension γ in aqueous DEADMBAC solutions. (c) Concentration. Temperature (°C): (*1*) 20, (*2*) 25, (*3*) 30, and (*4*) 35; the same for Fig. 3.

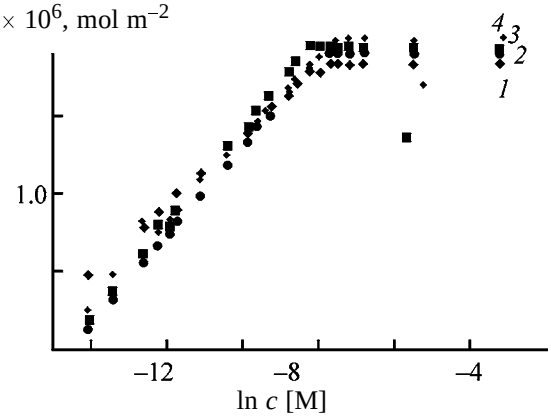

Fig. 3. Adsorption Γ of DEADMBAC as a function of the concentration c.

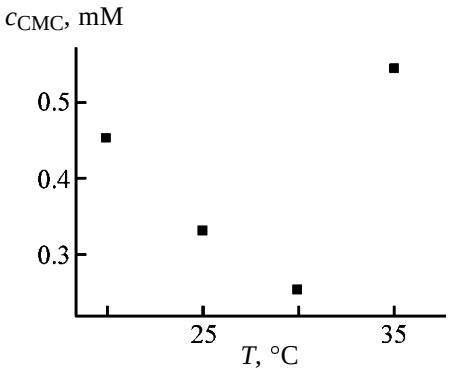

Fig. 4. Critical micelle concentration c_{CMC} as a function of the temperature T.

lower and higher temperatures, higher surfactant concentration is required for micelles to be formed. Similar temperature dependence of CMC was observed for other surfactants (see, e.g., [6]).

CONCLUSIONS

(1) For the first time the surface tension of DEADMBAC is studied at 20, 25, 30, and 35°C over a wide concentration range from 7.9×10^{-7} to 3.9×10^{-2} M.

(2) The critical micelle concentration of DAEDMBAC is determined at various temperatures. The CMC is minimal at about 30°C.

(3) The equilibrium adsorption at 20–35°C is estimated to be approximately 1×10^{-6} mol m^{-2}.

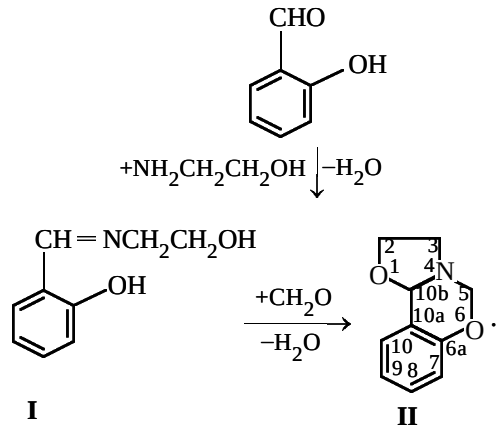
Abstract—A new method was developed for one-pot synthesis of 2,3,5,10*b*-tetrahydrooxazolo[3,2-*c*][1,3]-benzoxazine in 51% yield by successive reactions of monoethanolamine with salicylaldehyde and paraformaldehyde. The corrosion-protective properties of the title compound and intermediate *N*-(2-hydroxybenzylidene)-2-aminoethanol were studied.

It is known that some oxazolidines exhibit corrosion-protective properties [1–4]. In this work, with the aim to reveal corrosion-protective properties of compounds containing oxazolidine and dihydrooxazine rings, we prepared 2,3,5,10*b*-tetrahydrooxazolo[3,2-*c*]-[1,3]benzoxazine **II** and studied its inhibiting performance in carbon dioxide and hydrogen sulfide acid corrosion of steel.

2,3,5,10*b*-Tetrahydrooxazolo[3,2-*c*][1,3]benzoxazine was prepared previously in 43% yield by condensation of *N*-(2-hydroxybenzylidene)-2-aminoethanol **I** with paraformaldehyde in benzene [5]. 2,3,5,10*b*-Tetrahydrooxazolo[3,2-*c*][1,3]benzoxazine derivatives were prepared in 57–67% yields by condensation of oxazolidines unsubstituted at the N atom with salicylaldehyde [6]. Since the conditions for the synthesis of **II** by both methods and for the synthesis of imino alcohol **I** and oxazolidines are very similar [7], we examined the possibility of one-pot synthesis of oxazolobenzoxazine **II** from monoethanolamine, salicylaldehyde, and paraformaldehyde.

In developing the synthesis, we proceeded from the conditions used for each separate step in [5–7]. As solvent we used benzene. Condensation of monoethanolamine with salicylaldehyde was performed by refluxing an equimolar mixture of the reactants, with the azeotropic distillation of water. After the release of water ceased, a stoichiometric amount of paraformaldehyde was added, and the mixture was further refluxed until the release of the new portion of water ceased:



I **II**

The yield of oxazolobenzoxazine **II** under these conditions was 51.2%. When any of the reactants was taken in a small (5–10%) molar excess, the yield of **II** decreased by 5–12%.

Based on the procedure for preparing 2,3,5,10*b*-tetrahydrooxazolo[3,2-*c*][1,3]benzoxazine derivatives [6], we tested another reaction sequence for one-pot synthesis of **II**: initial preparation of oxazolidine from monoethanolamine and paraformaldehyde, followed by condensation of this oxazolidine with salicylaldehyde. However, in this case we obtained only traces of **II**. This may be due to the fact that the simplest oxazolidine formed in the first step readily isomerizes into stable *N*,*N*',*N*"-tris(2-hydroxyethyl)perhydro-1,3,5-triazine [8], which does not react with salicylaldehyde.

Also unsuccessful was our attempt to prepare **II** in one step by mixing all the three components (salicyl-

1070-4272/04/7705-0851 © 2004 MAIK "Nauka/Interperiodica"

aldehyde, monoethanolamine, paraformaldehyde) simultaneously. In this case, monoethanolamine immediately reacts with paraformaldehyde with heat release and formation of *N*,*N*',*N*"-tris(2-hydroxyethyl)perhydro-1,3,5-triazine.

To evaluate the inhibiting power of **II**, we examined its effect on the corrosion of steel under conditions simulating the steel corrosion in oil production [9]. For comparison, we also tested the reaction intermediate, imino alcohol **I**.

The corrosion-protective activity was studied gravimetrically with 2 × 20 × 6-mm samples of St.3 steel according to GOST (State Standard) 9.505–86 in 1% NaCl saturated with CO_2 in the presence of H_2S at 20, 40, and 60°C and contact time of 3 h. When added in a concentration of 10^{-3} M, the compounds showed the following protective effect *Z* (%): 98.1 (20°C), 97.2 (40°C), and 58.5 (60°C) for **II**; 88.2 (20°C), 79.3 (40°C), and 50.1 (60°C) for **I**. Thus, 2,3,5,10*b*-tetrahydrooxazolo[3,2-*c*][1,3]benzoxazine derivatives show promise as corrosion inhibitors.

EXPERIMENTAL

Paraform (99.3% pure), monoethanolamine, and salicylaldehyde were commercial chemicals; the latter two compounds were purified by fractional distillation to no less than 99.8% purity.

2,3,5,10*b*-Tetrahydrooxazolo[3,2-*c*][1,3]benzoxazine II. A mixture of 30.5 g (0.5 mol) of monoethanolamine, 61.1 g (0.5 mol) of salicylaldehyde, and 250 ml of benzene was refluxed with a Dean–Stark trap until the release of water ceased. Then 15.1 g (0.5 mol) of paraform was added, and the mixture was refluxed until the release of water ceased. Then the mixture was cooled and separated by fractional distillation to obtain 90.7 g (51.2%) of **II**; bp 110–112°C at 3 mm Hg; d_4^{20} = 1.2177; n_D^{20} = 1.5624. Published data [5]: bp 111–113°C at 3 mm Hg; d_4^{20} = 1.2180; n_D^{20} = 1.5631. ^{1}H NMR spectrum (400 MHz, $CDCl_3$, HMDS), δ, ppm (*J*, Hz): 3.08 (2H, m, NCH_2), 3.81 (2H, m, OCH_2), 4.67 (1H, d, NCH_2O, ^2J = 9.7), 4.79 (1H, d, NCH_2O, ^2J = 9.7), 5.58 (1H, s, NCHO), 6.84 (1H, d.d, C^7H, $J_{7,8}$ = 8.2, $J_{7,9}$ = 1.2), 6.93 (1H, d.d.d, C^9H, $J_{9,10}$ = 7.6, $J_{8,9}$ = 7.4, $J_{7,9}$ = 1.2), 7.19 (1H, d.d.d, C^8H, $J_{7,8}$ = 8.2, $J_{8,9}$ = 7.4, $J_{8,10}$ = 1.8), 7.24 (1H, d.d, $C^{10}H$, $J_{9,10}$ = 7.6, $J_{8,10}$ = 1.8).

Found, %: C 67.66, H 6.21, N 7.73. $C_{10}H_{10}NO_2$. Calculated, %: C 67.78, H 6.26, N 7.90.

***N*(2-Hydroxybenzylidene)-2-aminoethanol I.** A mixture of 6.1 g (0.1 mol) of monoethanolamine, 12.2 g (0.1 mol) of salicylaldehyde, and 100 ml of benzene was refluxed with a Dean–Stark trap until the release of water ceased. Fractional distillation in a vacuum gave 14.7 g (89%) of **I**, bp 161–163°C at 3 mm Hg; d_4^{30} = 1.1598; n_D^{30} = 1.5957. Published data [7]: bp 137–139°C at 1 mm Hg; d_4^{30} = 1.1547; n_D^{30} = 1.5936.

CONCLUSIONS

(1) Conditions were found for one-pot synthesis of 2,3,5,10*b*-tetrahydrooxazolo[3,2-*c*][1,3]benzoxazine from monoethanolamine, salicylaldehyde, and paraformaldehyde in a higher yield based on the starting reactants than in the two-step synthesis with the intermediate isolation of *N*-(2-hydroxybenzylidene)-2-aminoethanol.

(2) The protective effect of 2,3,5,10*b*-tetrahydrooxazolo[3,2-*c*][1,3]benzoxazine in carbon dioxide and hydrogen sulfide corrosion of steel reaches 98%.

Synthesis of Condensed Nitrofuroxanes Using Hydroxylamine

O. R. Klyuchnikov, V. I. Starovoitov, F. G. Khairutdinov, and V. V. Golovin

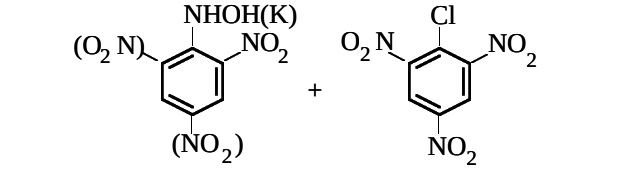
Kazan State Technological University, Kazan, Tatarstan, Russia

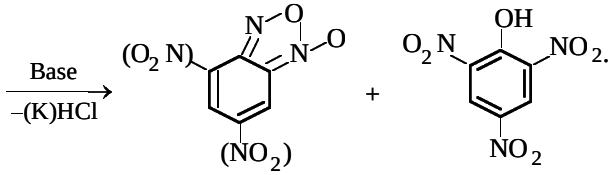
Received January 13, 2004

Abstract—The possibility of preparing condensed nitrofuroxanes using hydroxylamine was examined.

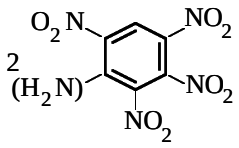
Benzofuroxanes exhibit biological activity and are intermediates in synthesis of a number of effective antimicrobial agents; 4,6-dinitrobenzofuroxane in the form of salts is used in priming charges [1]. In this connection, it is interesting to develop relatively safe methods for preparing nitrofuroxanes without using azides.

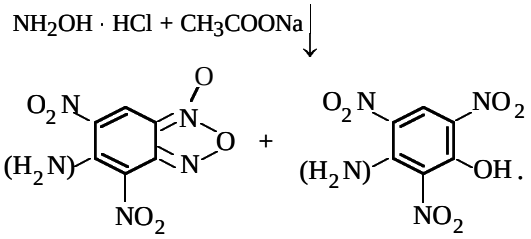
Previous studies concerning formation of the furoxane ring in synthesis of 4,6-dinitrobenzofuroxane by reaction of picryl chloride, hydroxylamine hydrochloride, and sodium acetate showed that the intermediate in this procedure is picrylhydroxylamine [2]. This finding allowed preparation of 3-nitro[4,5-*c*]pyridofuroxane by the reaction of 4-hydroxylamino-3,5-dinitropyridine with picryl chloride [3]. Similarly, the reaction of 2,4- or 2,6-dinitrophenylhydroxylamine or its potassium salt with picryl chloride also yielded, respectively, 4- or 6-nitrobenzofuroxane and picric acid:





From compounds containing a labile nitro group, 4,6-dinitrobenzofuroxane derivatives are formed also:





EXPERIMENTAL

4- and 6-Nitrobenzofuroxanes were prepared by adding 2.48 g (0.01 mol) of picryl chloride to a suspension of 2.37 g (0.01 mol) of potassium salt of, respectively, 2,6- and 2,4-dinitrophenylhydroxylamine in 30 ml of MeOH at room temperature with stirring. The mixture was left for 0.5 h and poured into 60 ml of water. The precipitate of 4- or 6-nitrobenzofuroxane was filtered off, washed with water, and dried. Yield of 4-nitrobenzofuroxane 1.67 g (92%), mp 112°C (from EtOH); yield of 6-nitrobenzofuroxane 1.59 g (88%), mp 74–76°C (from EtOH).

4,6-Dinitrobenzofuroxane was prepared by gradual addition of 5.16 g (0.02 mol) of 1,2,3,5-tetranitrobenzene to a suspension of 1.39 g (0.02 mol) of hydroxylamine hydrochloride and 3.28 g (0.04 mol) of sodium acetate in 50 ml of MeOH at 45–50°C with stirring. The mixture was stirred at this temperature for an additional 1 h, after which it was cooled and diluted with water; the precipitate was filtered off, washed with water, and dried. Yield 2.1 g (93%), mp 172°C (from MeOH).

5-Amino-4,6-dinitrobenzofuroxane was prepared similarly by adding 5.46 g (0.02 mol) of 2,3,4,6-tetranitroaniline to a suspension of 1.39 g (0.02 mol) of hydroxylamine hydrochloride and 3.28 g (0.04 mol) of sodium acetate in 50 ml of MeOH at 45–50°C. The reaction mixture was kept at this temperature for an additional 2 h, after which it was cooled, and the pre-

1070-4272/04/7705-0853 © 2004 MAIK "Nauka/Interperiodica"

cipitate was filtered off, washed with water, and dried. Yield 2.0 g (83%), mp 265–266°C (from AcOH).

The physicochemical constants of the compounds prepared coincide with those of the authentic samples prepared by the azide method [4–6].

CONCLUSION

A procedure for preparing condensed nitrofuroxanes in good yields using hydroxylamine was suggested to replace the less safe azide method.

Orcinol as Inhibitor of Thermal Polymerization in Processing of Pyrolysis Intermediates

A. V. Ivanova, A. F. Gogotov, and V. K. Stankevich

Angarsk Pertochemical Company, Open Joint-Stock Company, Angarsk, Irkutsk oblast, Russia

Received November 20, 2003; in final form, March 2004

Abstract—Fractionation of dihydric phenols from coal-tar chemical productions was studied, and various fractions were tested as inhibitors of thermal polymerization of unsaturated components of pyrocondensates.

Modern pyrolysis production is impossible without using inhibitors [1, 2]. Production of ethylene–propylene and benzene involves the use of such inhibitors as phenols, amines, and various multicomponent formulations in distillation of pyrolysis intermediates. The cheapest and the most readily available inhibitors are phenolic fractions from thermal processing of coal and wood [3, 4]. The most effective phenolic inhibitors are derivatives of dihydric phenols, alkylated hydroquinones and pyrocatechols. Their high inhibiting activity is due to the capability for conformational transition into the corresponding quinones. Among individual phenols, the most widely used polymerization inhibitor is *tert*-butylpyrocatechol (TBPC) [5–7]. The inhibiting activity of FCh-16, an inhibitor widely used in coal-tar chemical industry, and pyrocatechol fraction (PCF) is specifically due to the presence of mono- and dialkyl derivatives of pyrocatechols and hydroquinones [3, 8, 9]. The PCF composition (see table), determined with a Hewlett–Packard gas chromatograph–mass spectrometer using the relevant data bases [8], shows that this fraction contains pyrocatechols, resorcinols, and hydroquinones, with insignificant (~5–6%) content of various monohydric phenols.

We performed fractionation of PCF to closer-cut fractions with the aim to find what groups of dihydric phenols exhibit stronger inhibiting power and to reveal the components (pyrocatechols, resorcinols, or hydroquinones) that inhibit polymerization of pyrocondensates most actively. For this purpose, the fraction of dihydric phenols was subjected to finer fractional distillation. Pyrocatechols and hydroquinones (118–146°C fraction) comprise 84.1 wt % in total, and resorcinols [resorcinol fraction, RF (146–160°C)], 15.9%.

The isolated fractions were tested as inhibitors. The results for RF are shown in Fig. 1. The effect obtained at 0.025–0.030 wt % content of RF was 52–54%, and the maximal effect, 74%, was attained at 0.05 wt % content of RF. The RF (see table) contains in approximately equal amounts unsubstituted resorcinol and methylresorcinol in the form of two isomers with 5- and 2-methyl groups. As for nonphenolic components, RF contains a large set of mono-, di- and trialkylbenzenes. As resorcinol and 3,5-dihydroxytoluene are the major components of RF, they were tested as individual inhibitors. Resorcinol showed poor performance (~20% effect). The performance of 3,5-dihydroxytoluene (orcinol, 5-methylresorcinol) was stud-

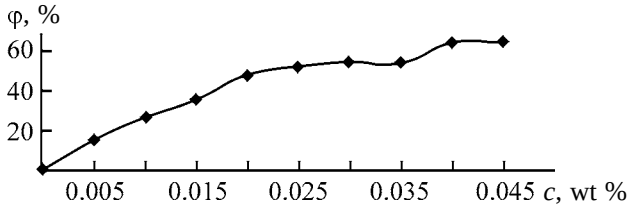

Fig. 1. Efficiency of inhibition of K-27 pyrocondensate φ as a function of the resorcinol fraction content *c*.

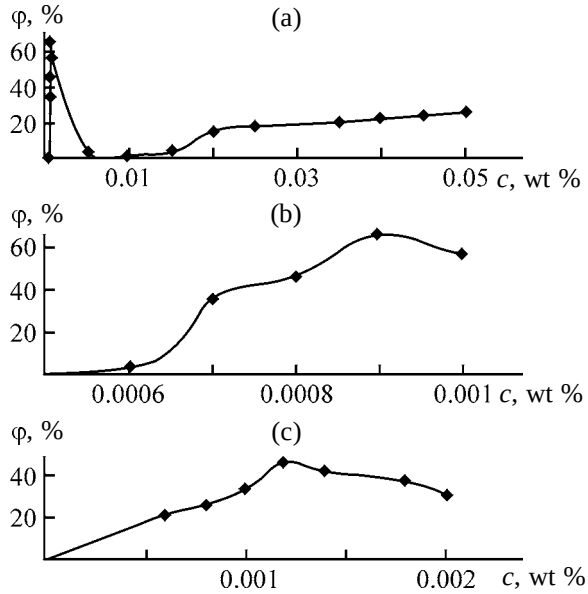

Fig. 2. Inhibiting activity of orcinol φ in polymerization of pyrocondensates as a function of its content *c*: (a) *c* 0–0.05 wt %, K-27 pyrocondensate; (b) *c* 0.0005–0.001 wt %, K-27 pyrocondensate; and (c) *c* 0–0.002 wt %, K-20 pyrocondensate.

ied in the range of its content of 0.0–0.5 wt %; the range 0.0006–0.01 wt % was studied in more detail.

The tests (Figs. 2a, 2b) revealed fairly high performance of orcinol at its extremely low content relative to the weight of the K-27 column pyrocondensate. A specific feature of orcinol is a drastic decrease in the inhibiting activity beyond the range of optimal concentrations; the maximal activity (66% effect) was observed at 0.0009 wt % content or orcinol.

With the K-20 column pyrocondensate, orcinol shows the highest inhibiting activity (45% effect) in the different concentration range (Fig. 2c).

Thus, experiments on inhibition of thermal polymerization revealed extremely high inhibiting activity of some phenolic compounds, comparable only with inhibitors of the last generation, nitroxyl radicals [10]. The high inhibiting activity of resorcinol derivatives in thermal polymerization was also revealed for the first time [11]. As noted above, it was believed until recently that, among dihydric phenols, only pyrocatechols and hydroquinones could show inhibiting activity due to their capability for phenol–quinone redox transformations. Quinones form a well-known class of effective inhibitors of radical processes [12]. The most widely used polymerization inhibitor, TBPC, shows high inhibiting performance at its content of 0.015–0.017 wt %, which is by an order of magnitude higher compared to the optimal content of orcinol. As the TBPC content is decreased to 0.002– 0.004 wt %, its activity drastically decreases, and in concentrations comparable with the optimal concentration of orcinol (0.0008–0.0012 wt %) its activity is as low as 2–3% (against 45–66% for orcinol).

The high inhibiting activity of resorcinol derivatives may be due to possible transformation of these compounds into the diketo tautomer with active methylene group at high temperature. Such transformations are known for 1,3-dihydroxy compounds, and their occurrence depends on the solvent polarity, its acid–base properties, temperature, and mutual location of substituents [13]. The C^2 atom in the 1,3-dioxo form is CH-active, and the activity of such species differs in the nature from the activity associated with the phenol–quinone transformations: responsible for deactivation of radical species are labile hydrogen atoms of the CH_2 groups. It should be noted that orcinol as a methylene-active compound is used in organic analysis for determination of carbonyl groups, e.g., in cellulose (orcinol method) [14].

CONCLUSIONS

(1) Resorcinols exhibit inhibiting activity in thermal polymerization of unsaturated components of pyrocondensates.

(2) Orcinol shows particularly high inhibiting effect (~66%) at its extremely low content, 0.0009–0.0012 wt %, considerably surpassing in the inhibiting performance the widely used inhibitor, *tert*-butylpyrocatechol (added in the same amount).

BRIEF COMMUNICATIONS

Use of Nitric Acid for Determination of Lignosulfonates

Yu. G. Khabarov

Arkhangelsk State Technical University, Arkhangelsk, Russia

Received November 25, 2003; in final form, February 2004

Abstract—The possibility of using the reaction of nitric acid with lignosulfonates for their quantitative determination in aqueous solutions was studied.

For photometric determination of lignins, the Pearl-Benson method based on their nitrosation [1] is used most widely. Nitrosation is carried out for 15 min in acidic medium, and the optical density of the solution is measured after alkalization of the reaction medium.

Nitric acid is used in indirect determination of the degree of delignification of lignocellulose materials [2, 3]. The first procedure is based on release of nitrogen oxides in the reaction of a sample being analyzed with HNO_3. Nitrogen oxides are quantitatively collected, and their amount is determined by titration with $KMnO_4$ [2]. In the second procedure, the lignocellulose material after appropriate pretreatment is heated with 14% HNO_3 at 80°C for 15 min. The solid residue is separated by filtration. The yellow filtrate is analyzed photometrically at 425 nm to determine the lignin content in the sample. It is suggested that, under determination conditions, lignin macromolecules are nitrated and degrade, and lignin passes into solution; the products of this process are intensely colored [3].

The use of nitric acid for determination of lignosulfonates (LS) was not reported.

The aim of this work was to assess the possibility of using HNO_3 for photometric determination of LS formed in sulfite cooking of cellulose.

EXPERIMENTAL

We used 14% HNO_3 and a solution with LS concentration of 10 g l^{-1}. The analysis was carried out as follows: Into a 100-ml volumetric flask a certain volume of LS solution and 10 ml of HNO_3 were added. The flask was placed into a boiling water bath for a certain time, after with the solution volume was brought to the mark and the optical density was measured at 315 and 340 nm on a KFK-2MP photocolorimeter.

The UV spectra were recorded in the range 250–400 nm on a Specord M-40 spectrophotometer (Laboratory of Lignin, Institute of Environmental Problems of North, Russian Academy of Sciences, Ural Division).

Upon heating of LS with HNO_3, the color of the reaction mixture significantly changes. To choose the analytical absorption band, we recorded the electronic spectra of a solution of LS prepared by dilution of the

initial solution by a factor of 500 (λ_{max} = 280 nm), HNO_3 solution diluted with distilled water by a factor of 50, and a solution prepared by mixing of 1 ml of LS solution and 10 ml of the initial HNO_3 solution and heated on a boiling water bath for 60 s and then diluted with distilled water to 500 ml (Fig. 1a). The spectrum of the reaction products differs essentially from the additive spectrum by increased intensity of absorption at 310 nm (Fig. 1a, spectrum *4*).

In further studies we used the wavelengths of 315 and 340 nm. The band at 340 nm has the advantage that nitric acid does not noteceably absorb at this wavelength. During photometric reaction, the optical density of the solution at 315 nm increases by a factor of 2.44, and at 340 nm, by a factor of 3.5 as compared to the initial LS.

To determine the minimum reaction duration, this parameter was varied from 10 to 75 s in various runs (Fig. 1b). It was found that the maximal optical density is attained within 60 s. The color of the reaction products is stable for a long time (Table 1).

The results listed in Table 2 show that the color reaction is well reproducible. As expected, the coefficient of variation decreases with increasing optical density.

From data listed in Tables 2 and 3, using least-squares technique, we evaluated the coefficients of

* (*S*) mean relative deviation.

calibration plots for the analytical bands at 315 and 340 nm:

$$D_{315} = 0.007942c_{LS} + 0.013431 \quad (R^2 = 0.9992),$$

$$D_{340} = 0.007289c_{LS} + 0.005916 \quad (R^2 = 0.9996).$$

The large coefficients of pair correlation R^2 suggest that the system in hand obeys the Bouguer–Lambert–Beer law. The possibility of determining the concentration of lignosulfonates was assessed in the experiments; the results are given in Table 3. In a wide range of LS concentrations, a good accuracy of determination was reached. The measurements performed at 340 nm allow determination of LS content with a better accuracy (mean relative deviation 4.5%) than at 315 nm (mean relative deviation 5.7%).

CONCLUSION

Reaction of lignosulfonates with HNO_3 can be used for proximate quantitative analysis of LS. This procedure consists in short thermal treatment of the solution with a nitric acid solution and subsequent photometry at 315–340 nm.

Sorption Kinetics of Acid and Reactive Dyes on Wool Fiber in the Presence of Redox Systems

O. V. Petrova, A. A. Burinskaya, and V. V. Kotetskii

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received October 28, 2003

Abstract—Low-temperature dyeing with Acid Bordeaux and Reactive Brilliant Red 5CX is studied.

Wool dyeing with acid and reactive dyes is conventionally performed at the boiling temperature of the solution, which may cause unpractical use of expensive raw materials and high energy consumption. Therefore, low-temperature dyeing (at temperature by 15–20°C below the boiling point) is of great practical interest, as allowing minimization of the damage of fiber and decrease in the hydrolysis of reactive dyes, pollution of the environment, and power consumption.

Previously it was demonstrated that addition of redox systems in a dye bath facilitates low-temperature dyeing of wool with acid and reactive dyes [1].

As a substrate we used wool rove with a surface density of 1.32 g cm^{-2}. Dyeing was performed according to the standard procedure [2].

As redox systems we used hydrogen peroxide in a mixture with various reducing agents such as glycerol, glucose, polyoxymethylene, and hexamethylenetetramine.

As demonstrated in [1, 3], the use of redox systems (0.0075–0.015 M) considerably increases the sorption of acid and reactive dyes in the course of low-temperature dyeing. To determine the performance of redox systems in dyeing, we studied the sorption kinetics of acid and reactive dyes on wool fiber. The contact time of the substrate with a dye varied from 15 to 90 min. The sorption was monitored by the residual concentration of dyes in the dye bath. The kinetic curves of Acid Bordeaux and Reactive Brilliant Red 5CX in the presence of various redox systems are given in Figs. 1a and 1b.

In the presence of redox systems, the maximal sorption is observed in the first 60 min. With further increase in the dyeing time, the sorption remains practically unchanged. Thus, the use of any of the redox systems studied facilitates sorption more strongly than does increase in the dyeing temperature from 80°C to the boiling point. To characterize quantitatively the effect of addition of redox systems, we estimated the dyeing rate constants. For this purpose, we plotted the logarithm of the concentration change of a dye against the dyeing time (Figs. 2a, 2b). The observed linearity of the dependence $\log c$–τ suggests the first-order kinetics of dyeing. The rate constants were then estimated by the Stirling's equation [4]. The results are given in the table.

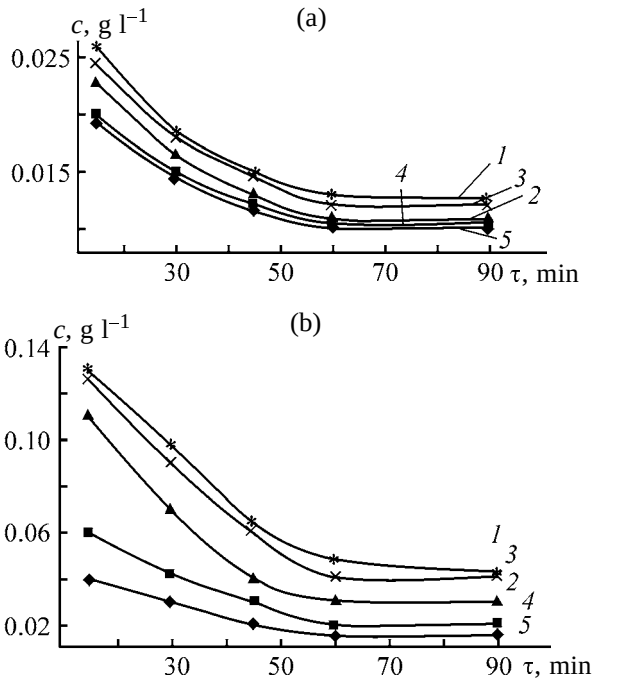

Fig. 1. Kinetic curves of (a) Acid Bordeaux and (b) Reactive Brilliant Red 5CX in the presence of various redox systems: (*1*) no redox system, (*2*) H^2O^{2-}polyoxymethylene, (*3*) H_2O_2–hexamethyleletetramine, (*4*) H_2O_2–glucose, (*5*) H_2O_2–glycerol; the same for Fig. 2. (*c*) Dye concentration and (τ) dyeing time; the same for Fig. 2. Dyeing temperature (°C): (*1*) 100 and (*2*–*5*) 80; the same for Fig. 2.

1070-4272/04/7705-0861 © 2004 MAIK "Nauka/Interperiodica"

Rate constants of dyeing of wool rove with Acid Bordeaux and Reactive Brilliant Red 5CX

Dyeing conditions	Acid Bordeaux		Reactive Brilliant Red 5CX	
	$K \times 10^3$, min^{-1}	E_a, kJ mol^{-1}	$K \times 10^3$, min^{-1}	E_a, kJ mol^{-1}
At bp without redox additive	27.80	133	22.14	119
At 80°C with redox additive:				
H_2O_2–glucose	49.12	116	39.82	106
H_2O_2–glycerol	51.27	113	40.57	86
H_2O_2–hexamethylenetetramine	32.23	123	30.82	113
H_2O_2–polyoxymethylene	46.81	119	32.60	106

$$K = \frac{2.303}{\tau_2 - \tau_1}\log(c_1/c_2),$$

where K is the rate constant (min^{-1}); τ_1 and τ_2 are the times of the start and end of dyeing (min); and c_1 and c_2 are the initial and final dye concentrations in the bath ($g\ l^{-1}$).

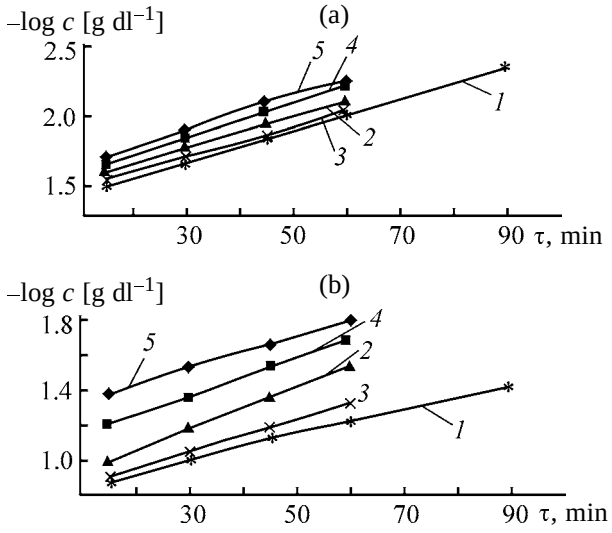

Fig. 2. Concentration change of (a) Acid Bordeaux and (b) Reactive Brilliant Red 5CX in the course of dyeing.

The results show (see table) that introduction of a redox additive increases the sorption rates of the acid and reactive dyes by factors of 1.2–1.9 and 1.5–1.7, respectively, thus creating the necessary prerequisites for reducing the dyeing time. This is also demonstrated by the estimated activation energies.

To conclude, redox additives accelerate sorption of dyes, allowing dyeing with acid and reactive dyes at temperatures below the boiling point of a dyeing liquor and also reduction of the dyeing time.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Vladimir Fedorovich Luginin (to 170th Anniversary of His Birthday)

V.F. Luginin, an outstanding Russian thermochemist, a talented experimenter, and a progressive who created the first Russia's Thermal Laboratory at Moscow University at his own expense was the author of quite a number of manuals of calorimetry and head of a prominent scientific school.

Vladimir Fedorovich Luginin was born in Moscow on May 20, 1834, into a rather wealthy nobleman's family. His father, Fedor Nikolaevich Luginin, a former General Staff officer and a participant of the war with Turkey (1825–1829), owned a large forest estate in Vetluga uezd of Kostroma province, which was inherited by his sons. Luginin received an excellent domiciliary education at home. His teacher was H.A. Trautschold (1817–1902), formerly one of Liebig's assistants, later, a known scientist, professor of geology at Petrovskaya (now Timiryazev) academy. As mentioned in [1–3], Trautschold stimulated his pupil's interest in natural sciences and acquainted him with prominent scientific centers, and primarily those in France and Germany, during their trips to West Europe.

In 1849, at the age of 15, Vladimir Luginin entered, on his father's advice, the Mikhail artillery college in St. Petersburg, which was one of the best Russia's military colleges of that time. At that college, as well as at Mikhail artillery academy, taught the most prominent Russian scientists: mathematician M.V. Ostrogradskii (1801–1862), physicist H.F.E. Lenz (1804–1865), and known chemists A.A. Fadeev (1810–1898) and L.N. Shishkov (1830–1909).

In August 1853, Luginin graduated from the cadet department of Mikhail college and was left there to receive higher artillery education as one of the best graduates. However, the war between Russia and Turkey, which began in October 1853, interrupted Luginin's education, and he was assigned to the front-line forces in February 1854. The young officer took part in military action at the Danube River and in the defense of Sevastopol. Only in May 1856, he returned to St. Petersburg and continued his education at the Artillery academy, wherefrom he successfully graduated in April 1858. In 1861, Luginin retired from military service and could commence studies of natural sciences at the best scientific centers of West Europe. For a long time he attended lectures at Heidelberg University (Germany), worked at the chemical laboratory of R.W. Bunsen (1811–1899), studied organic synthesis at the laboratory of J. Wislizenus (1835–1902) in Zurich, attended lectures delivered by Clausius (1828–1888), perfected himself in organic chemistry at the laboratory of C.A. Wurtz (1817–1884) in Paris. In 1866–1867, Luginin published his first studies in organic chemistry. However, his scientific interests switched by that time to physical chemistry, and primarily to thermochemistry. This was favored by scientist's work at the laboratories of H.V. Regnault (1810–1878) and M. Berthelot (1827–1907) in Paris. At Regnault's laboratory, Luginin studied the applicability of the Henry–Dalton law to the solubility of CO_2 in water at various pressures, determined the density of hydrocarbons of the homologous series of benzene in a wide range of temperatures. Further scientist's attention was focused on studies of thermochemical nature. He preserved friendly relationships with M. Berthelot for many years.

1070-4272/04/7705-0863 © 2004 MAIK "Nauka/Interperiodica"

In 1873, Luginin returned to Russia and organized in St. Petersburg a small private laboratory, where he commenced calorimetric measurements. Later, a special laboratory was organized in St. Petersburg, at Luginin's expense and on his initiative, for determining the calorific value of combustible materials.

Beginning in 1882, Luginin worked in Paris. A laboratory aimed to carry out thermochemical studies was organized at the house where his family lived.

At the end of 1888, Luginin again returned to Russia. V.V. Markownikoff (1837–1904), a professor of Moscow University, allowed him to work at his laboratory. In 1889, a group of professors of Moscow University submitted a petition for conferring on Luginin "the degree of a doctor of chemistry without examinations for master's degree and without submitting a dissertation," in acknowledgment of Luginin's achievements in the field of thermochemistry. In January 1890, this move was satisfied. Having received the degree of a doctor of chemistry, Luginin decided to transfer his thermal laboratory from Paris to Moscow, to Moscow University. As mentioned in his memoirs by I.A. Kablukov (1857–1942, honorary member of the Academy of Sciences of the USSR since 1932), a Luginin's disciple and a professor of Moscow State University, Luginin's thermal laboratory "took the first place among thermal laboratories of not only Russia, but West Europe as well" [4]. At that same time, Luginin started to deliver to students of the physicomathematical faculty of Moscow University lectures on thermochemistry, thermometry, and calorimetry. In 1891, Luginin was elected a privatdocent, and in June 1899, he was appointed a supernumerary extraordinary professor of Moscow University by the initiative of a large group of professors.

In 1897, Luginin donated to Moscow University his personal library, which included journals on chemistry and physics, both domestic and foreign, published during several decades, rare publications by foreign scientists, domestic scientific literature, and books on history, philosophy, and agriculture. Luginin had a perfect command of four European languages and was interested in a wide variety of problems. Up to 8000 of books from the "Luginin library" are kept at the library of Moscow University [4].

In 1903, Luginin decided to hand over to Moscow University the whole equipment of the thermal laboratory, purchased by him. The laboratory was named "Professor Luginin thermal laboratory." In recognition of the scientist's services, he was given the rank of an honorary member of Moscow University.

Because of the deterioration of his health, Luginin had to go abroad more and more frequently. He was at his laboratory for the last time in 1906.

Luginin occupied himself with experimental thermochemistry for about forty years and became a prominent specialist in this field; his experimental data were considered highly reliable for that time and cited in world's reference literature. The main Luginin's studies in this field were considered in a monograph by Yu.I. Solov'ev and P.I. Starosel'skii [5] and in quite a number of other review publications [6–8] and in separate communications [9–11].

The first Luginin's communication, carried out in cooperation with M. Berthelot and reporting the results of a thermochemical study of the decomposition of fatty acid halides, was published in France in 1869. Seven more joint studies of these scientists were carried out and published in French journals during the period from 1870 to 1875. The first study carried out independently by Luginin in Russia was aimed to determine the heat effects of formation of potassium and sodium trichloroacetates (1873). Beginning in 1880, the main attention was paid by the scientist to determining the heats of combustion of various organic acids. Using a combustion chamber modified by him, he studied organic compounds of various classes and types. V.F. Luginin described his experimental methods in a paper "On Measurement of the Heats of Combustion of Organic Compounds," published by him first in France (1882) and then in Russia (1884). A series of studies carried out by him together with I.A. Kablukov were concerned with determining the heat of bromine addition to unsaturated compounds.

Luginin wrote a number of textbooks on calorimetry, of which the most important is *Opisanie razlichnykh metodov opredeleniya teplot goreniya organicheskikh soedinenii* (Description of Various Methods for Determining the Heats of Combustion of Organic Compounds, 1894). In this textbook, the newest experimental techniques for determining the heats of combustion were considered. As a supplement to the book, Luginin presented tabulated heats of combustion for about 1000 substances.

In the 1890s, V.F. Luginin carried out extensive studies of the specific heats and the heats of vaporization of various liquid organic substances: alcohols, ketones, esters of dibasic acids, and saturated hydrocarbons. In the process, the scientist used a rather perfect method for determining the heats of vaporization, developed by him. Based on his own experimental data, Luginin came to a conclusion that the known

"Trouton's rule" is not universal and is observed to some extent only for organic compounds of the same class, or, even better so, within the same homologous series of one or another class. Already at the end of his scientific activities, Luginin carried out, together with A.N. Schchukarev (1864–1926), thermochemical studies of copper and magnesium alloys with aluminum (1906).

Together with his scientific activities, Luginin was actively engaged in Russia's public life. Among his close friends were N.G. Chernyshevskii (1828–1889), A.I. Herzen (1812–1870), and N.P. Ogarev (1813–1877). V.F. Luginin and his younger brother Stanislav Fedorovich Luginin (1837–1866), marshal of the nobility of Vetluga uezd, also paid much attention to solution of zemstvo's problems and published a number of papers concerned with this issue.

An honorary doctor of chemistry of Moscow University, Vladimir Fedorovich Luginin died on October 13 (26) in Paris after a severe prolonged illness. To his memory were devoted spacious obituaries written by Kablukov [4] and K.A. Timiryazev [12], and memoirs by professors of Kharkov University Shchukarev and I.P. Osipov [13]. Owing to the scientist's daughter (married name princess M.V. Volkonskaya), V.F. Luginin's works were published in 1917 under the editorship of Kablukov [14]. She also supported financially the publication of the catalog of the library donated by Luginin to Moscow University [15].

Such known thermochemists as Kablukov, Shchukarev, Osipov, P.V. Zubov, V.V. Swietoslawski, M.M. Popov, and others worked at the Luginin Thermal laboratory at Moscow University at different times [8]. To the history of the Luginin laboratory from the time of its foundation till the middle of the 1980s was devoted a publication by G.L. Gal'chenko [10]. The evidence concerning Luginin's life and scientific and public activities is included in all the main Russian encyclopedias and world's biographic reference books [16, 17].

A. G. Morachevskii

Russian Journal of Applied Chemistry, Vol. 77, No. 5, 2004, p. 866. Translated from Zhurnal Prikladnoi Khimii, Vol. 77, No. 5, 2004, p. 871.

BOOK REVIEWS

Blinov, L.N., *Khimiya i fizika khal'kogenidnykh, galogenkhal'kogenidnykh i fullerenkhal'kogenidnykh stekloobraznykh materialov* (Chemistry and Physics of Chalcogenide, Halochalcogenide, and Fullerene–Chalcogenide Glassy Materials)

St. Petersburg: Sankt-Peterb. Gos. Univ., 2003, 210 pp.

A small original monograph by L.N. Blinov, a known specialist in solid-state chemistry, is concerned with properties of a number of chalcogenide glassy materials. Also, preparation techniques and application fields of some types of chalcogenide glasses are considered.

The book comprises eight chapters and a supplement. Bibliographic lists are given separately for each chapter, which makes a total of 493 references to studies of domestic and foreign authors for the entire monograph. Chapter 1 (pp. 5–33) presents general concepts of glass formation in chalcogenide systems. Emphasizing the importance of disordered systems for modern science and technology, the author of the monograph regards the chemistry of glass as a new independent branch of chemical science, which is concerned with a purposeful search for glassy materials and with their preparation and study. The relationship between the glass-forming ability of substances and the position of their constituent elements in the periodic table is discussed.

Chapter 2 (pp. 34–56) is devoted to magnetic properties of chalcogenide glasses. A major part of chalcogenide glassy formulations exhibit semiconducting properties. The importance of studying the magnetic properties of systems of this kind was mentioned by professor R.L. Myuller more than 40 years ago. The author of the monograph analyzes the results obtained in studying the magnetochemistry of chalcogenide glasses.

Chapter 3 (pp. 57–103) demonstrates the possibilities of ESR spectroscopy in studying various chalcogenide glassy semiconductors. Studies mostly carried out with the author's participation revealed that the ESR spectroscopy is highly informative as applied to objects discussed in the book. Small Chapter 4 (pp. 104–119) describes the results obtained in analysis of how the magnetic susceptibility of glasses depends on temperature.

Chapter 5 (pp. 120–139) includes evidence concerning the preparation methods and properties of chalcogenide dielectric glassy materials and the possibilities of their application. By varying the relative content of the main components and the concentrations of the additives introduced, one can change the properties of chalcogenide glasses in a required direction and, in particular, improve their dielectric properties. Chapter 6 (pp. 140–155) is devoted to synthesis and properties of fluorine-containing chalcogenide glasses. It is shown that the type of a fluoride introduced affects the nature of conduction in glasses based on chalcogenides. Chapter 7 (pp. 156–175) discusses bromo- and iodochalcogenide glasses. The author of the monograph developed methods, devices, and approaches that provide synthesis of materials of these classes and considers promising fields of their application. The final Chapter 8 (pp. 176–202) summarizes evidence concerning chalcogenide fullerene-containing chalcogenide materials. It is noted that the class of chalcogenide glasses that contain fullerenes may be rather wide. The fact that the structure of fullerenes is preserved in the chalcogenide glass matrices opens up opportunities for obtaining disordered materials with high-temperature superconductivity on their base.

The monograph is largely based on studies of its author, Blinov, and a number of his coworkers. The supplement to the monograph (pp. 203–206) presents in concise form the most important conclusions of these investigations: application fields and main technical characteristics of chalcogenide glasses belonging to the classes studied; main-group elements in the periodic table, which form chalcogenide, halochalcogenide, and fullerene–chalcogenide glassy materials; and a list of binary, ternary, quaternary, and quinary chalcogenide systems analyzed in these studies.

Blinov's book is of indubitable interest for a wide audience of specialists working in the field of inorganic materials science.

BOOK REVIEWS

Flottmann, D., Forst, D., and Roßwag, H., *Chemie für Ingenieure, Grundlagen und Praxisbeispiele*

Berlin: Springer, 2004, Zweite völlig überarbeitete und verbesserte Auflage, 434 pp.

The course of chemistry for engineers, written by three German professors from Fachhochschule Aalen, Fachbereich Chemie, Aalen, Germany, may be, as regards its content and structure, of interest for a wide audience of chemistry teachers at higher school institutions and colleges, specialized schools, and lyceums. The book presents in a concise and well understandable manner the main sections of the conventional general chemistry, with considerable attention given to the most important chemical and related production facilities and environment protection.

The book comprises 12 sections (chapters) and contains a well-compiled illustrative material and numerous examples of calculations.

Chapter 1 (pp. 1–17) includes basic evidence concerning the atomic structure and elementary particles and gives notion of the radioactivity and nuclear fission. Chapter 2 (pp. 18–65) discusses various kinds of chemical bonds and the crystal structure. Chapter 3 (pp. 66–113) is devoted to water and aqueous solutions, describes specific features of water as a liquid, dissolution processes, and methods for expressing the concentration, and gives notion of the water hardness and water treatment. The same chapter includes evidence concerning ionic equilibria, the most important acids and bases, buffer solutions, pH measurements, and redox reactions in aqueous solutions.

Chapter 4 (pp. 114–143) briefly reviews the periodic system. It considers the following elements: alkali and alkaline-earth metals; elements that belong to groups of boron, carbon, and nitrogen; chalcogens and halogens; and transition metals. Special attention is paid in this chapter to complexation processes involving transition metals, gives typical examples, and discusses chelate complexes. Chapter 5 (pp. 144–161) presents basic concepts of thermodynamics and kinetics of chemical reactions. In this chapter, the thermodynamic characteristics of reactants and of the process as a whole: the enthalpy and Gibbs energy of compound formation (the authors uses instead of the Gibbs energy the term "free enthalpy") and the enthalpy, entropy, and Gibbs energy of a reaction are considered in sufficient detail, the directions and boundaries of occurrence of the chemical reaction are determined, and examples of necessary calculations are given. The dependence of the reaction rate on the concentrations of the reactants and the influence exerted by temperature and presence of catalysts on the process rate are discussed.

Chapter 6 (pp. 162–198) presents evidence concerning the main classes of organic compounds: saturated and unsaturated hydrocarbons, benzene and its derivatives, alcohols, ethers, esters, organic acids, organochlorine compounds, and also oil, gasoline, inflammable liquids and ignition temperatures of these substances.

Chapter 7 (pp. 199–249) is devoted to fundamentals of electrochemistry. The concepts of electrolysis as a redox process that occurs under external influence, voltaic cells, Nernst equation, and pH measurements with the use of a glass electrode are given. Considerable attention is paid by the authors to various primary and secondary chemical power cells, including lithium batteries.

Chapter 8 (pp. 250–281) discusses problems of corrosion and corrosion protection: theory of the phenomenon, chemical and electrochemical corrosion, types of corrosion, practical examples, and various methods of corrosion protection. Chapter 9 (pp. 282–320) contains evidence concerning the most important products of chemical industry: ammonia (synthesis and use); manufacture of chlorine, alkali, and hydrogen by electrolysis; glasses; and semiconductors. The same chapter describes the manufacture of metals, with the production of iron, steel, and aluminum considered as examples. Chapter 10 (pp. 321–366) is devoted to problems of industrial processing of organic raw materials: oil, natural gas, biomass, and other substances. The authors also review in sufficient detail the chemistry of polymers.

Chapter 11 (pp. 367–393) gives notion of chemical processes that occur in the environment, the ozone

1070-4272/04/7705-0867 © 2004 MAIK "Nauka/Interperiodica"

layer and the hazard of its destruction, and the greenhouse effect. Chapter 12 briefly reviews the biotechnology, its topical tasks, biological foundations, and related industrial processes.

The book luckily combines the diversity of the material presented and the simplicity of presentation. In each chapter, the main body of the material is preceded by a very brief (15–20 lines) introduction containing some interesting evidence of mainly historical nature, which enlivens the presentation. The assimilation of the material is favored by detailed division of each chapter into sections and subsections. The book is very well published and equipped with subject and author indexes. Translation of the book into Russian would be of interest primarily for its use as an additional textbook by college teachers.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Study and Development of a Technology for Manufacture of Special-Purity Calcium Carbonate

A. A. Fakeev

State Research Institute of Chemical Reagents and Special-Purity Chemicals, Moscow, Russia

Received November, 11, 2003

Abstract—The precipitation of $CaCO_3$ from $Ca(NO_3)_2$ solutions with gaseous CO_2 and NH_3 was investigated. Different variants of purification of $Ca(NO_3)_2$ solutions on hydrated aluminum oxide (collector) were considered.

Special-purity calcium carbonate is used in production of optical glass, fiber-optical materials, luminophores, ferromagnetic ferroelectrics, oxide cathodes, etc. In these cases, stringent requirements are imposed on the content of certain admixtures (10^{-4}–10^{-6} wt %).

Commercial $CaCO_3$ of reagent grade [GOST (State Standard 4530–76)] and special-purity grade 16-2 [TU (Technical Specification) 6-09-895–77] [1] fails to meet the requirements of modern industries.

The known procedures for manufacture of $CaCO_3$ yield technical- and reagent-grade products and can be conditionally divided into the following groups: reactions of $Ca(OH)_2$ with gaseous CO_2 or sodium, potassium, and ammonium carbonates; decomposition of calcium formate, acetate, or oxalate upon heating; precipitation of calcium salts from solutions under the action of gaseous CO_2 and NH_3 (or of their aqueous solutions); and exchange reactions of solutions of calcium salts with sodium, potassium, or ammonium carbonates.

The reaction of $Ca(OH)_2$ (solution or aqueous suspension) with gaseous CO_2 [2, 3] or with Na_2CO_3 solution [4] and the decomposition of calcium formate, acetate, or oxalate in a vacuum or in air at 300–600°C [5] are not promising for obtaining a special-purity product, as the technological processes include no purification stages and sufficiently pure compounds involved in the processes are not manufactured industrially [1].

The last two procedures for obtaining $CaCO_3$ from solutions of calcium salts under the action of gaseous CO_2 and NH_3 or solutions of Na_2CO_3, K_2CO_3, and $(NH_4)_2CO_3$ are widely used in industry to produce technical- or reagent-grade products [6–9]. The technological scheme of the processes can be supplemented with a stage of preliminary purification of the starting reagents.

In liquid conversion of calcium salts under the action of solutions of sodium, potassium, or ammonium carbonates into $CaCO_3$, the process is rather fast; however, the volume of dilute mother liquors that contain the corresponding nitrates or chlorides increases [9–11].

In gaseous conversion of calcium salts (with gaseous CO_2 and NH_3), the consumption of the starting compounds increases and complete precipitation of $CaCO_3$ is not achieved. Therefore, it has been suggested to carry out the process in two stages with gaseous CO_2 and NH_3 and with a solution of $(NH_4)_2CO_3$ successively [12].

Despite the considerable number of publications devoted to the precipitation of $CaCO_3$ with gaseous CO_2 and NH_3 from solutions of calcium salts, the process has been investigated insufficiently. Data on selection of technological parameters (relative amounts and feed rates of reagents, concentration of a calcium salt solution, temperature, and pH), on the mechanism and kinetics of the reactions, and on the behavior of admixtures are lacking.

The aim of this study was to develop a technological process for manufacture of special-purity $CaCO_3$.

EXPERIMENTAL

With account of published data, the reaction of a preliminarily purified $Ca(NO_3)_2$ solution with gaseous CO_2 and NH_3, followed by filtration of the result-

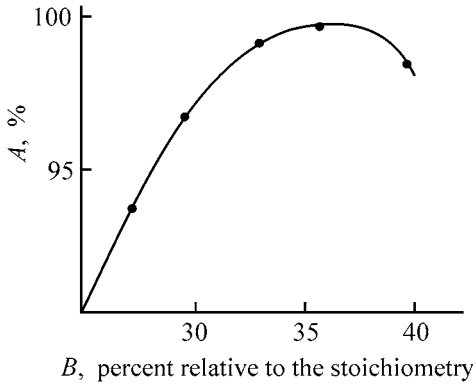

Fig. 1. $CaCO_3$ yield A vs. the excess B of CO_2 and NH_3.

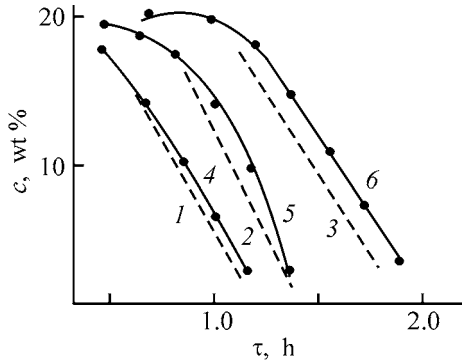

Fig. 2. Kinetics of $CaCO_3$ precipitation from $Ca(NO_3)_2$ solutions. (c) $Ca(NO_3)_2$ concentration and (τ) time. (*1–3*) Calculation, (*4–6*) experiment. CO_2 feed rate ($l\ min^{-1}$): (*1*, *4*) 0.75, (*2*, *5*) 0.55, and (*3*, *6*) 0.35.

ing suspension and washing of the $CaCO_3$ paste with water and its drying, was chosen for experimental verification:

$$Ca(NO_3)_{2(sol)} + 2NH_{3(g)} + CO_{2(g)} + H_2O = \downarrow CaCO_3 + 2NH_4NO_3.$$

The reactions that occur in the precipitation of $CaCO_3$ with gaseous CO_2 and NH_3 point to a complicated character of the process [13, 14]. In addition, the formation of ammonium carbamate NH_4COONH_2 and its hydrolysis proceed in the solution [13, 15–17].

One of the main stages of the technological process, which determines the chemical and granulometric composition of the final product, its quality, and the output capacity of the equipment used, is the stage of $CaCO_3$ precipitation.

In the continuous variant of $CaCO_3$ precipitation, the feed rates of $Ca(NO_3)_2$ solutions and gaseous CO_2 and NH_3 should be selected so that the precipitation is complete at the reactor outlet and the consumption of gaseous precipitants is at a minimum. The output capacity of the stage depends on the concentration of the $Ca(NO_3)_2$ solution. Theoretically, it is preferable to use a concentrated $Ca(NO_3)_2$ solution; however, this would hinder the absorption of gaseous CO_2 and NH_3 by this solution, raise the capture by the $CaCO_3$ solution of the forming NH_4NO_3 at its high concentration in the mother liquor, and, consequently, make more complicated the following stage of washing of the paste. With account of the results of previous studies of purification of $Ca(NO_3)_2$ solutions [18], its concentration was taken to be about 20 wt %.

The effect of the relative amounts and feed rates of the starting reagents and temperature on the yield of the final product was studied experimentally. The installation and the experimental procedure used were described in [19]. The main unit of the installation was a 1.0-l titanium or plexiglass reactor equipped with a stirrer and an external jacket. The feed rates of gaseous CO_2 and NH_3 and the $Ca(NO_3)_2$ solution were measured with rheometers and a rotameter, respectively. The pH values of solutions were determined with a pH-262 instrument, and the $Ca(NO_3)_2$ concentration in the mother liquor, by complexometric titration with trilon B. The feed rates of the gaseous reagents, CO_2 and NH_3, were varied in all the experiments at a constant feed rate of a $Ca(NO_3)_2$ solution.

Introduction of stoichiometric amounts of gaseous reagents (according to the reaction the molar ratio is $NH_3 : CO_2 = 2 : 1$) (Fig. 1) does not lead to complete precipitation of $CaCO_3$, in a satisfactory agreement with published data [12]. A theoretical calculation of the height of a gas-liquid layer in the reactor, which would provide a complete absorption of CO_2 in the reaction, demonstrated that it is necessary to develop rather high bubble-type apparatus (or a cascade) [20], which is not always possible. To achieve a complete precipitation of $CaCO_3$ under real conditions, it is advisable to use a certain excess of CO_2 and NH_3, which is due not only to incomplete dissolution of CO_2 under these conditions, but also to the occurrence of side reactions and the formation of a small constant $(NH_4)_2CO_3$ concentration in solution. Raising the feed rate of CO_2 and NH_3 by more than 35% of the stoichiometry results in an increase in the rates of side reactions and in a certain reduction of the $CaCO_3$ yield (Fig. 1).

Comparison of the calculated and experimental values for three feed rates of CO_2 (Fig. 2) shows that, at a feed rate of 0.35 $l\ min^{-1}$, CO_3^{2-} ions are accumu-

Table 1. Purification of aqueous solutions of $Ca(NO_3)_2$ to remove admixtures of 3*d* elements on a HAO (hydrated aluminum oxides) collector

Purification variant	Coefficient of removal of ions, K_p					
	Fe	Cr	Cu	Mn	Co	Ni
1	800–1000	3000–3100	50–60	20–30	40–50	40–50
2	1000–1200	150–200	120–130	70–80	160–180	80–90
3	800–1000	3000–3100	1000–1100	150–170	150–170	150–170

lated in solution and $CaCO_3$ gradually precipitates (Fig. 2, curve *6*), whereas at a rate of 0.75 l min^{-1} (Fig. 2, curve *2*), a partial breakthrough of the gas is observed. The results obtained show that the best CO_2 feed rate for precipitation of $CaCO_3$ is 0.55 l min^{-1}.

Temperature affects the reactions occurring in solution in the case of $CaCO_3$ precipitation with gaseous CO_2 and NH_3 in different ways: as the temperature increases to 40–45°C, the formation of ammonium carbamate is considerably retarded and the hydrolysis is accelerated [15, 17]; the solubility of CO_2 and NH_3 decreases.

It was established experimentally that the temperature of the reaction medium increases to 40–45°C at a CO_2 feed rate of 0.55 l min^{-1} (Fig. 2) under the conditions of $CaCO_3$ precipitation, which is due to a noticeable exothermic heat effect of the main reaction. This accelerates the hydrolysis of NH_4COONH_2 formed and leads to a more complete precipitation of $CaCO_3$ (Fig. 2).

An analysis of published data on the precipitation of $CaCO_3$ with gaseous CO_2 and NH_3, made with account of the results of this study, demonstrated that the rate-determining reactions are dissolution of CO_2 [13–15, 17, 21], formation of $CaCO_3$ nuclei and their growth [13, 22–24], and hydrolysis of ammonium carbamate [15, 21].

To estimate preliminarily the limiting stages of the technological process, a qualitative theoretical analysis of kinetic equations of the reactions [13–15, 17, 21–24] has been carried out. It has been shown that the rates of all the known reactions considerably exceed the rates of CO_2 dissolution and growth of the $CaCO_3$ crystal [25]. A mathematical model has been developed for describing the $CaCO_3$ precipitation from $Ca(NO_3)_2$ solutions with gaseous CO_2 and NH_3, with the optimization of the total time required for the stages of precipitation, filtration of the resulting suspension, and washing of the $CaCO_3$ paste [20].

To obtain a special-purity product, a preliminary purification of the starting raw materials [$Ca(NO_3)_2$ solution, gaseous CO_2 and NH_3] is necessary.

Earlier studies of the author [18, 26] have shown a high efficiency of inorganic collectors [hydrated aluminum (HAO) or zirconium oxides (HZO) for the purification of $Ca(NO_3)_2$ solutions]. The influence exerted by a number of parameters (weight of the collector, time of contact with the solution, pH of the medium, concentrations of the solution and the admixtures, addition of an oxidizer, and the nature of a collector precipitator) on the efficiency of purification of $Ca(NO_3)_2$ solutions with HAO or HZO has been investigated [18, 26].

On the basis of the investigation performed, three variants of purification of $Ca(NO_3)_2$ solutions on HAO can be considered: (1) precipitation of the collector (HAO) with aqueous ammonia; (2) precipitation of HAO with aqueous ammonia, with preliminary addition of H_2O_2; and (3) precipitation of the collector (HAO) with a NaOH solution (Table 1). The data in Table 1 point to a high efficiency of purification of $Ca(NO_3)_2$ solutions to remove admixtures of 3*d* elements. The precipitation of HAO with aqueous ammonia (variant 1) provides a high efficiency of solution purification to remove admixtures of iron and chromium ions and a considerably lower efficiency for copper, manganese, nickel, and cobalt ions, because of the formation of readily soluble ammino or hydroxoammino complexes with these ions. Addition of H_2O_2 (variant 2) improves the removal of copper, manganese, iron, nickel, and cobalt admixtures, but impairs that of chromium(III) owing to its oxidation to chromium(VI), which coprecipitates with HAO to a much lesser extent in the pH range 7.5–8.0. Precipitation of HAO with an alkali solution (variant 3) results in the highest efficiency of removal of all the admixtures under study. This is due to the formation of hydroxo complexes of 3*d* elements, which rather effectively coprecipitate on the collector, in contrast to

the readily soluble and rather stable ammino or hydroxoammino complexes.

The efficiency of purification of $Ca(NO_3)_2$ solutions on HZO is somewhat lower [26], which seems to be caused by the difficulty of careful separation of the amorphous superfine precipitate of the collector.

For better separation of the collector, such membranes as SPA, PVC, MFF were used, differing in the supporting material and porosity [27]. A study of the microfiltration of a 20% $Ca(NO_3)_2$ solution purified using HZO [collector weight 2.0% in terms of $Ca(NO_3)_2$, time of contact with the solution 2 h, solution pH 8.0, and temperature 50°C] was carried out in a laboratory cell of diameter 47 mm under a pressure of 0.5 kg cm^{-3}, with the size and number of particles monitored (LAM instrument with a flow-through cell). The data obtained with a preliminary separation of the HZO precipitate on a "blue band" filter and with filtration across a PVC-0.25 membrane are listed in Tables 2 and 3.

Thus, the high efficiency of purification of solutions on a collector (HZO), combined with the membrane technology, was experimentally established. Use of membranes in purification ensures a complete separation of microscopic particles of the collector, which contains certain admixtures at a level of 10^{-1}–10^{-3} wt %. Use of membranes in the final stage of purification of solutions in the technological scheme for obtaining special-purity inorganic substances somewhat complicates the process and decreases its output capacity, but makes it possible to improve dramatically the quality of the products.

The experimental data on the fine separation of the collector, obtained in this study, enable a wider use in technological practice of such effective inorganic collectors as hydrated oxides of manganese(IV), titanium(IV), tin(IV), iron(III), chromium(III), cobalt(III), etc.

Special-purity grade CO_2 and NH_3 required for production of special-purity $CaCO_3$ are not manufactured industrially, but the domestic industry produces in large amounts these products of technical grade, with high content of the main substances (liquefied $CO_2 \geq 98.0$ vol %, and liquefied $NH_3 \geq 99.6$ vol %).

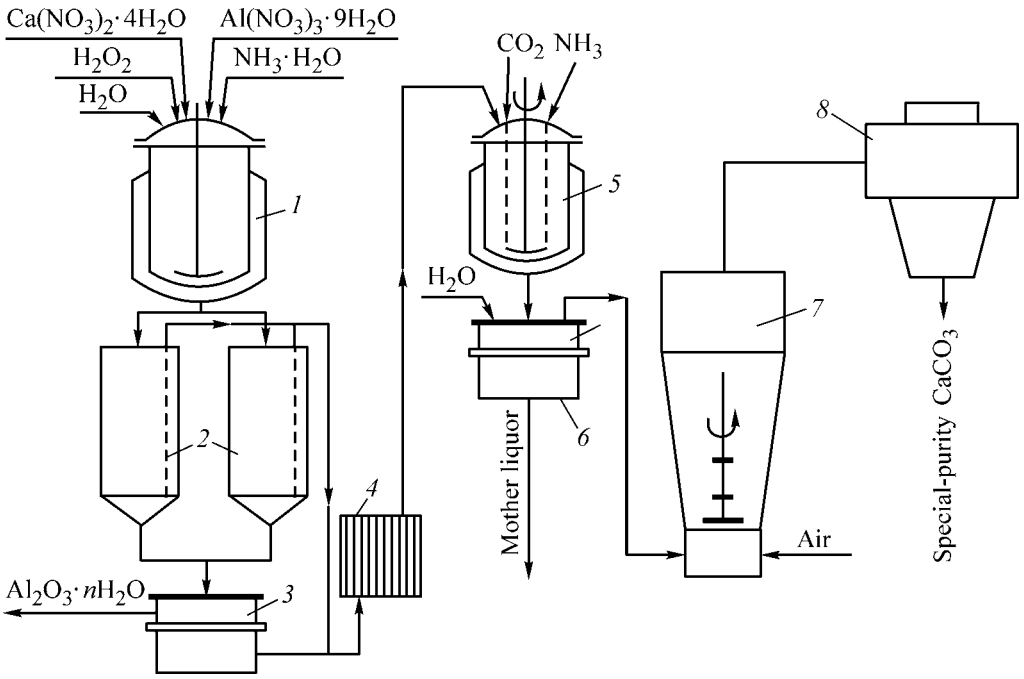

Fig. 3. Technological scheme for manufacture of special-purity $CaCO_3$. (*1*) Reactor for dissolution and purification of the $Ca(NO_3)_2$ solution, (*2*) sedimentation columns, (*3*) filter for collector separation, (*4*) frame fluoroplastic filter, (*5*) reactor for precipitation of $CaCO_3$, (*6*) unit for filtering and washing of the $CaCO_3$ paste, (*7*) fluidized-bed apparatus, and (*8*) cyclone separator.

These products are rather pure as regards the content of admixtures whose content in $CaCO_3$ of special-purity grade is to be limited. For a preliminary purification, gaseous CO_2 and NH_3 are bubbled through a layer of distilled water and an FP filter [28].

The choice of a variant to be used for $Ca(NO_3)_2$ purification is governed by the quality of the starting raw materials and the target product.

Systematic analysis of reagent-grade $Ca(NO_3)_2$ (analytically pure and chemically pure grades, GOST 4142–77) shows a rather low level of 3*d*-element admixtures (10^{-3}–10^{-5} wt %) [26]. If the purification coefficients (Table 1) are taken into account, ingress of impurities into the target product is ruled out, and $Ca(NO_3)_2$ of the above quality and preliminarily purified CO_2 and NH_3 are used, a special-purity $CaCO_3$ containing admixtures at a level of 10^{-5}–10^{-7} wt % can be obtained.

On the basis of the investigation performed, a technological scheme for manufacture of special-purity $CaCO_3$ from preliminarily purified solutions of calcium nitrate (analytically pure and chemically pure grades) and gaseous CO_2 and NH_3 (technical grade) was developed (Fig. 3). The main stages of the technological process are the following: dissolution of $Ca(NO_3)_2$ in distilled water and purification of the solution on a collector (HAO); separation of the collector precipitate; precipitation of $CaCO_3$ with gaseous CO_2 and NH_3; filtering and washing of the precipitate; and drying of the paste. A 20–25% aqueous solution of $Ca(NO_3)_2$ was purified on a collector (HAO), which was precipitated at pH 7.5–8.0 with aqueous ammonia or NaOH. As a collector-forming agent was used analytically pure $Al(NO_3)_3$ (GOST 3757–75) in an amount of 2 g of $Al(NO_3)_3 \cdot 9H_2O$ per 100 g of $Ca(NO_3)_2$. To achieve a deep separation of the resulting HAO gel, which contained 10^{-2}–10^{-3} wt % admixtures of 3*d* elements, and the purified $Ca(NO_3)_2$ solution, the suspension was subjected to aging and settling. The lower condensed layer of the suspension was twice filtered on an ordinary Nutsch filter across two layers of "blue-band" filters, combined with the clarified part of the solution, and filtered on a frame-type microfilter with fluoroplastic filtrating partitions [29]. The rate of filtration of the condensed part of the suspension on a Nutsch filter rapidly decreases, and mechanical removal of the gel-like precipitate of the collector from the filter surface at regular intervals of time is necessary. The precipitation of $CaCO_3$ was carried out in an apparatus, into which purified $Ca(NO_3)_2$ solution and gaseous CO_2 and NH_3 were continuously fed. The suspension of $CaCO_3$ was continuously discharged on-

to a Nutsch filter, where the accumulated and squeezed paste was washed with special-purity water to remove nitrate ions. The washed paste was delivered into a "fluidized-bed" apparatus.

The quality parameters of the resulting special-purity $CaCO_3$ [30] and of the best foreign samples are listed in Table 3.

Comparison of these products shows that the technology developed enables manufacture of special-purity $CaCO_3$, which is comparable in its main characteristics with the best foreign analogues.

CONCLUSIONS

(1) The precipitation of $CaCO_3$ from $Ca(NO_3)_2$ solutions with gaseous CO_2 and NH_3 was studied and the parameters of the process were determined.

(2) A technological scheme was developed for manufacture of special-purity $CaCO_3$ from preliminarily purified $Ca(NO_3)_2$ solutions and gaseous CO_2 and NH_3.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of High-Purity Calcium Hydride

A. D. Bulanov, O. Yu. Troshin, and V. V. Balabanov

Institute of Chemistry of High-Purity Substances, Russian Academy of Sciences, Nizhni Novgorod, Russia

Received December 4, 2003

Abstract—A procedure for synthesizing high-purity calcium hydride in high yield was suggested. The admixture composition of the resulting CaH_2 was determined by laser mass spectrometry.

CaH_2 is used in laboratory practice as a desiccant that can take away water from crystal hydrates [1]. It is highly efficient in drying of hydrocarbons, ethers, and other solvents. Calcium hydride has found wide application as a reducing agent in preparing powders of certain metals (Ti, Zr, Nb, Ta, Mo, and W) from their oxides and halides [2, 3]. A method is known for converting silicon halide compounds (silicon tetrachloride, trichlorosilane, and silicon tetrafluoride) into silane by their reaction with CaH_2 [4]. In this case, admixtures of F_2, H_2O, O_2, N_2, AsH_3, and PH_3 are removed from SiH_4 via their adsorption on a metal hydride [5]. In [6], calcium hydride was used as a reducing agent to obtain high-purity hydrides of monoisotopic silicon ($^{28}SiH_4$, $^{29}SiH_4$, and $^{30}SiH_4$) from monoisotopic SiF_4 by the reaction

$$SiF_4 + 2CaH_2 \rightarrow SiH_4 + 2CaF_2. \quad (1)$$

The choice of CaH_2 was determined by the fact that, unlike NaF in the reaction with NaH, CaF_2 does not react with monoisotopic SiF_4 to give $CaSiF_6$ in synthesis of silane [7, 8]. Moreover, CaF_2 reacts with a BF_3 admixture in silicon fluoride to give a stable $Ca(BF_4)_2$ complex [4], which favors purification of the resulting SiH_4 to remove boron-containing admixtures. At the same time, CaH_2 is the safest in handling, compared with other hydrides and metal aluminum hydrides.

The compound CaH_2 is a light gray crystalline substance that does not react with oxygen up to 400–500°C [9] and reacts with water to give CaO, $Ca(OH)_2$, and hydrogen [10]. In synthesizing SiH_4 from SiF_4, the reactions of SiF_4 with the products of CaH_2 hydrolysis are thermodynamically allowed [11]. It has been established experimentally that presence of several percent CaO in calcium hydride substantially decreases the yield of SiH_4, and, therefore, there is no point in using commercial-grade CaH_2. Moreover, an admixture of metal calcium in CaH_2 may result in thermal reduction of SiF_4 to give monoisotopic elementary silicon [12]. Therefore, development of a procedure for synthesizing active CaH_2 in high yield is a matter of current interest.

The reaction of Ca with H_2 becomes noticeable at 170–250°C [10], $\Delta H_f^{298}(CaH_2) = -45.1$ kcal mol^{-1} [13]. For practical use, temperatures in the range from 250 to 700°C are recommended [14]. The hydrogenation of solid Ca to give a solid product is a topochemical process. Kinetic studies [15] revealed three stages of the reaction: formation of centers of CaH_2 crystallization on the surface of a sample (induction period), formation of a CaH_2 surface layer precluding a direct contact of H_2 with Ca, and diffusion of H_2 with the subsequent reaction at the Ca–CaH_2 interface (dissolution or formation of a chemical bond). The rate of Ca hydrogenation depends on temperature, H_2 pressure, linear dimensions of a sample, internal structure of the metal, and admixtures present in calcium and hydrogen [15–17].

The admixtures of O_2 and H_2O in hydrogen decrease the hydrogenation rate, because CaO formed on the surface of calcium hinders the diffusion of H_2. It was shown in [18] that 0.5% oxygen decelerates the reaction by a factor of 2.5, and 0.5% H_2O, by a factor of 6.

EXPERIMENTAL

To obtain high-purity CaH_2, we used distilled Ca in the form of 1.5-mm-thick shavings [TU (Technical Specifications) 95.768–80, manufactured by Mashinostroitel'nyi zavod Open Joint-Stock Company (Elekt-

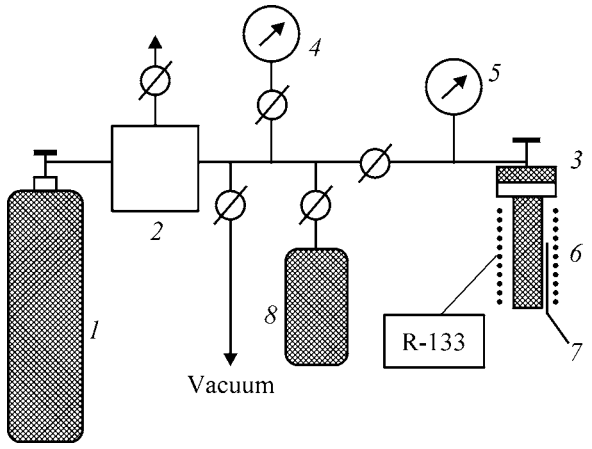
rostal')] and H_2 purified by diffusion across a palladium membrane. The content of admixtures in calcium, as determined by laser mass spectrometry, is listed in the table.

The content of O_2 and H_2O admixtures in purified hydrogen does not exceed 10^{-4} mol %.

We synthesized CaH_2 on an installation shown schematically in the figure. The main units of the installation are a cylinder with H_2 *1*, a H_2 purification unit *2*, and a flange reactor *3*. We controlled the pressure of H_2 during the process with vacuum gages *4* and *5*. The temperature of the resistance furnace *6* was set with an R-133 temperature control unit and monitored with a Chromel–Copel thermocouple *7*.



Schematic of the installation for synthesis of CaH_2. (*1*–*7*) For explanations, see text; (*8*) receiver.

We synthesized CaH_2 by the following procedure. A stainless-steel flange reactor was charged with 350–400 g of Ca, connected it to the installation, evacuated to 10^{-1} mm Hg, and heated to 360°C within 0.5 h. According to [16], melted Ca in the form of shavings starts to react with H_2 at 400°C; hence, we hydrogenated Ca in the temperature range 400–450°C. We filled the reactor with purified H_2 to a pressure of 5 atm and kept it for about 5 min. During this time, the pressure of H_2 in the reactor decreased first gradually and then abruptly to 0.05–0.1 atm. The increase in the rate of H_2 absorption is accounted for by the high rate of the hydrogenation reaction on the surface of Ca. In this stage of hydrogenation, we controlled the flow of H_2 into the reactor in such a manner that the pressure of H_2 in the reactor did not exceed 1 atm, since an elevated pressure of H_2 results in a rise in temperature.

A rise in temperature may lead to caking of CaH_2, which impedes its withdrawal from the reactor. After a layer of CaH_2 is formed on the surface of Ca, diffusion of H_2 to the Ca–CaH_2 interface begins, and the rate of H_2 absorption decreases. To complete the hydrogenation, we raised the H_2 pressure in the reactor to 10 atm, and the temperature to 480°C. We judged the completion of the hydrogenation reaction from the cessation of the H_2 absorption.

The yield of CaH_2 was calculated as the ratio of the weight of CaH_2 obtained in the experiment to its theoretical value. The yield of CaH_2 was $99.6 \pm 0.1\%$, i.e., the synthesis procedure results in an almost complete hydrogenation of Ca. The output capacity of the pilot installation for CaH_2 synthesis is 150 g of CaH_2 per hour.

The resulting CaH_2 was analyzed by laser mass spectrometry for the content of admixtures. The results obtained are listed in the table. It can be seen that the main admixtures in CaH_2 are C and Cl, whereas the content of metal admixtures is at the level of 10^{-3} at.%.

After the process was complete, we placed the cooled reactor in a box purged with dried nitrogen and then ground the CaH_2 obtained to powder with particle size of less than 0.6 mm. The powdered CaH_2 was charged into the reactor in a flow of purified H_2 in order to obtain silane.

An effective procedure for removal of carbon from metals [19] is their "washing" with purified H_2. The admixtures of hydrocarbons can be formed in the reaction of H_2 with admixtures of metal carbides present in calcium:

$$M_nC_m(\text{solid}) + 2mH_2 = nM(\text{solid}) + mCH_4(\text{gas}). \quad (2)$$

In [20], CaH_2 was obtained in the reaction of calcium carbide with H_2 at 100–1000oC under an elevated pressure (up to 100 atm):

$$CaC_2 + 5H_2 \rightarrow CaH_2 + 2CH_4. \quad (3)$$

Therefore, side reactions of hydrogenation of carbon and its compounds to give hydrocarbons can occur under the conditions of CaH_2 synthesis.

In this study, we blew CaH_2 with a flow of purified H_2 at 250°C for 8 h in order to diminish the content of carbon admixtures. It was shown that, after contact with CaH_2, the content of hydrocarbon admixtures in H_2 increases by two orders of magnitude, which allowed us to diminish the content of the most difficultly removable admixture of ethylene in silane by an order of magnitude.

CONCLUSIONS

(1) High-purity calcium hydride was obtained by hydrogenation of distilled metallic calcium with purified hydrogen.

(2) The main admixtures in CaH_2 are C and Cl, whereas the content of metal admixtures is at the level of 10^{-3} at.%. The procedure of "washing" of CaH_2 was used to decrease the content of carbon admixture in it.

Received December 9, 2003

Abstract—Prospects for application of a modular technology in manufacture of high-purity hydrofluoric acid to perform automated control of the production process and further improve the quality of the high-purity product are considered.

At present, the existing industrial production of hydrofluoric acids of special purity 27-5 and special-purity 20-6 grades[1] satisfies the demands of widely diverse fields of technology. The technology for manufacture of special-purity hydrofluoric acid, which employs a block-module installation made of fluoroplastic-4 (of the Proton type) makes it possible to obtain a higher-quality product that satisfies the requirements of leading companies, such as Merk, Canto chemical, etc., to the content of the main impurities and particles in conformity with regulations [1].

The modular installation comprises the following units: unit for chemical treatment of the acid with a potassium permanganate solution (to convert microscopic admixtures of volatile compounds of arsenic, phosphorus, sulfur, etc. into nonvolatile compounds); unit for separation of a concentrated acid into the gas (hydrogen fluoride) and liquid (azeotropic solution of HF) phases with a unit for purification of hydrogen fluoride by filtration on a sprinkled self-cleaning filter made of Ftorlon fiber; unit for reactive purification of the azeotropic solution; unit for absorption of purified hydrogen fluoride with a purified azeotropic solution (to give a product with a prescribed concentration of hydrogen fluoride); unit for microfiltration of the acid to remove suspended microparticles; unit for collection and agitation of the finished product; and unit for feeding the high-purity product into the transport unit (with supply of filtered air into the working zone).

[1] Created in accordance with the design by the Institute of Chemical Reagents and Special-Purity Substances at Galogen Production Association.

However, the advances of modern science and technology impose even more stringent requirements on the quality of high-purity hydrofluoric acid. In view of the aforesaid, the existing technology is being further modified in the following scientific and technological areas.

(1) Development and creation of computer systems for optimization of technological units and the whole computerized automated control system.

(2) Development of a new unit for chemical treatment of hydrofluoric acid to oxidize volatile microimpurities to convert them into nonvolatile compounds in order to ensure continuity and closed nature of the entire process.

(3) Development of a new additional unit for finishing purification of the azeotropic solution to remove dissolved impurities (electrolytes).

(4) Creation of a unit for storage and transportation of the finished product.

Let us consider in more detail the chemical and technological aspects of these areas of research. To purify HF_{aq} to remove volatile impurities that possess reducing properties, it was suggested to generate O_3 in solution from dissolved oxygen. The process occurs in accordance with the equation

$$3H_2O \cdot 2HF + 3O_2 \xrightarrow{h\nu,\ T^\circ C} 2H_2O + 2HF + 2O_3\uparrow.$$

UV photons are produced using ultraviolet quartz mercury sources of light with wavelengths of 180–360 nm.

1070-4272/04/7706-0878 © 2004 MAIK "Nauka/Interperiodica"

In contrast to the existing method, a new technique associated with the above photochemical reaction was suggested for oxidation of an arsenic microimpurity.

The process suggested is based on the mainly homogeneous reaction of oxygen dissolved in hydrofluoric acid with molecules of water in azeotropic clusters at a temperature of about –10°C. The ozone formed in the acid solution oxidizes the arsenic(III) microimpurity by the reaction

$$AsF_3 + O_3 + H_2O \rightarrow AsOF_3 \cdot H_2O + O_2,$$

with As(III) converted into a nonvolatile compound. Simultaneously are oxidized other volatile microimpurities, such as compounds of phosphorus, sulfur, etc.

A most important issue of the technique is its optimization. To achieve this goal, the following problems are to be solved: it is necessary to select a construction material that would be chemically stable and transparent to ultraviolet light. As demonstrated by the studies performed, these requirements are satisfied by fluoropolymers F-4, F-4MB, and F-50, whose transparency to UV light exceeds that of quartz (in the wavelength range 150–380 nm). However, irradiation of the hydrofluoric acid solution is complicated by strong scattering and absorption of UV light by this solution. Therefore, the hydrofluoric acid saturated with oxygen at the optimal temperature should be in the form of a thin layer, which can be accomplished by using a special apparatus. One of the possible variants is shown in Figs. 1, 2. In addition, it was necessary to use an appropriate power of the light source and find the optimal temperature of the process that includes chemical reactions of ozone formation and oxidation of arsenic(III) microimpurities.

Figure 3 shows how the optimal yield of O_3 and oxidation of the arsenic(III) microimpurity depend on the process temperature. The optimal time of irradiation of the liquid reaction medium with UV light depends on the apparatus height and the number of cycles of liquid recycling, and also on the velocity of the liquid flow in the reaction zone.

To determine the time dependence of the concentration of O_3 formed, experiments were carried out and the type of the functional dependence $c_{O_3} = f(\tau)$ was found. It was shown that the adequate expression for the differential equation has the following form:

$$\frac{dc_{O_3}}{d\tau} = b - ac,$$

where c_{O_3} is the concentration of ozone; a, the coefficient describing the rate at which the concentration of O_3 increases; and b, the limiting concentration of O_3, which depends on the solubility of oxygen, c_{O_2}.

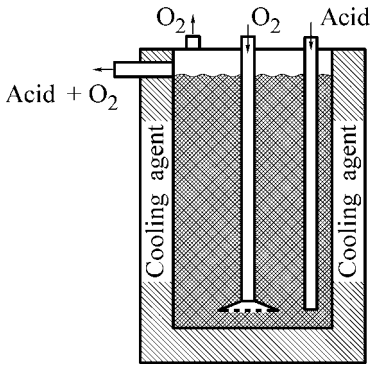

Fig. 1. Apparatus for saturation of hydrofluoric acid with oxygen gas at the optimal temperature.

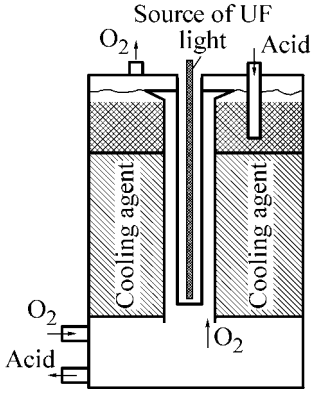

Fig. 2. Apparatus for performing the photochemical reaction of ozone formation with the subsequent oxidation of the arsenic(III) microimpurity.

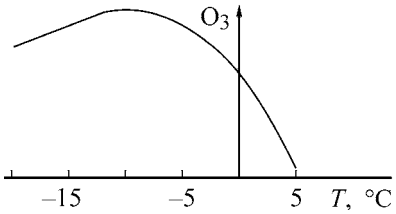

Fig. 3. Concentration of ozone formed in a hydrofluoric acid solution vs. temperature T.

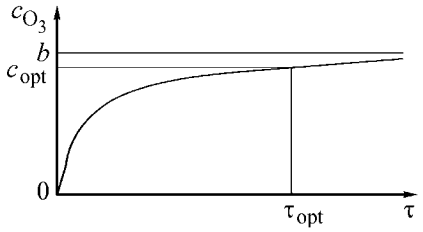

Fig. 4. Graphical optimization of the photochemical process of ozone synthesis.

The integral expression has the form

$$c_{O_3} = b(1 - e^{-a\tau}).$$

Figure 4 illustrates the graphical procedure for kinetic optimization of the photochemical process of ozone synthesis.

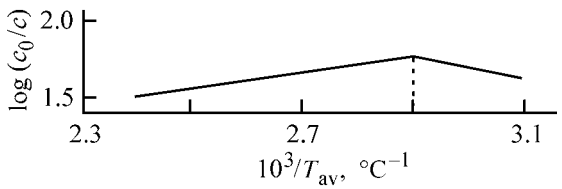

Fig. 5. Optimization of the hydroion convection with respect to temperature.

The necessity for additional purification of the azeotropic solution of hydrofluoric acid to remove admixtures of compounds-electrolytes to a level below 10^{-7}–10^{-8}% is due to the fact that, even in slow boiling or evaporation without boiling, the HF vapor is contaminated with these compounds. This process can be accounted for in its simplest form by ionic carry-over [2, 3]. In solution, ions of microimpurities form hydrates (clusters). These formations are rather stable (binding energy of about 1000 cal mol^{-1}), whereas their binding to other dipoles in the solution is considerably weaker (100 cal mol^{-1}).

In evaporation of the surface layer of the liquid, clusters of impurity ions are the first to evaporate. In this context, another problem arises: how can ionic clusters be supplied to the surface layer of the liquid film flowing down over the inner surface of, e.g., a cylindrical apparatus. For this purpose, two more effects are used in addition to carry-over: ionic repulsion (occurs because of the poor wettability of the fluoropolymeric surface with the liquid) and thermodiffusion transfer. Thus, the total internal work done by the system in the process, ΔE, is constituted by the effects of cluster formation (ΔE_1), ionic repulsion (ΔE_2), and thermodiffusion transfer (ΔE_3): $\Delta E = \Delta E_1 + \Delta E_2 + \Delta E_3$. The driving force of the thermodiffusion transfer is the temperature gradient δ between the inner (adjacent to the apparatus) and outer surface of the downflowing liquid film.

The evaporation of ionic clusters from the surface of the acid solution requires a heat Q, supplied from the outside. The entire process, which is named ionic convection and is associated with a change in the ion concentration in the liquid (azeotropic mixture) being purified can be represented as an exponential

$$c = c_0 \exp(-\Delta E - Q) \quad \text{or} \quad \ln\frac{c_0}{c} = \frac{\Delta E - Q}{RT},$$

where c_0 is the concentration of ions in the initial mixture, and c is the running concentration of ions.

It is known [6] that

$$\Delta E_1 = K_1 \rho \xi,$$

where ρ is the ion charge; ξ, the degree of ion hydration; and K_1, the constant of cluster formation;

$$\Delta E = K_2(1 + \cos\theta_a)/(1 + \cos\theta_w),$$

where θ_a and θ_w are the contact angles between the fluoropolymeric surface and acid or water, and K_2 is the ionic repulsion constant;

$$\Delta E_3 = K_3 \Delta T/\delta,$$

where $\Delta T/\delta$ is the temperature gradient across the thickness of the liquid film, and K_3 is thermodiffusion constant.

Thus,

$$\ln\frac{c_0}{c} = \frac{1}{RT}\left(K_1 \rho \xi K_2 \frac{1 + \cos\theta_a}{1 + \cos\theta_w} K_3 \Delta T/\delta\right).$$

The constants of cluster formation (K_1), hydroionic repulsion (K_2), and diffusion transfer (K_3) are found experimentally.

It was demonstrated that, in the overall process under study, $\ln(c_0/c)$ takes values in the range from 1.5 to 2. This means that the total decrease in the concentration of ion impurities is as high as two orders of magnitude. The total concentration of ion microimpurities in the purified azeotropic mixture is as low as 10^{-8}–10^{-10} wt %.

The optimization of the process performed in the unit in question can be done, as can be seen from the process equation, by choosing the average optimal temperature T and temperature gradient $\Delta T/\delta$ (Fig. 5) and by selecting a construction fluoropolymer with a contact angle θ_a. For hydrofluoric acid, T = 70°C and $\Delta T/\delta \approx$ 30–50°C. The height of a vertical apparatus at a liquid motion velocity of 20–30 cm s^{-1} is about 100 cm. Thus, the residence time of the fluid in the evaporation zone is 3–5 s. At an average thickness of the liquid film of up to 1 mm and diameter of the cylindrical apparatus of 30 mm, the output capacity of a single element of the unit is as high as 2–3 cm^3 s^{-1}, or 30–50 tons year^{-1}. With a multiple-element apparatus used, the output capacity can be raised to the required level.

Using the results of the study performed makes it possible to achieve a sufficiently high (by present standards) quality of high-purity hydrofluoric acid, surpassing the best world's analogues.

Abstract—Binary and ternary parameters of the Pitzer equation and also the thermodynamic potentials of solid phases and the solubility diagrams of ternary aqueous-salt systems $Na^+, K^+ \| Cl^- – H_2O$ and $Na^+, K^+ \| Cl^-, H_2PO_4^- – H_2O$ in the temperature range 0–100°C, which corresponds to the technological conditions of brine formation, were calculated.

The previously developed thermodynamic model [1–3] makes it possible to quantitatively describe the processes of concentration of natural water and brines, precipitation of salts, interaction of salts with water and brines (congruent and incongruent dissolution), and formation of secondary salts. However, the consideration has been restricted to description of the behavior of macrocomponents of natural water (Na^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, SO_4^{2-}, etc.) because it is their content that determines the hydrochemical type of a brine, as well as the composition and mass of the crystallizing salt minerals.

The aim of this study was to determine the parameters of the thermodynamic model that makes it possible to take into account the presence of such a component as the $H_2PO_4^-$ ion in natural brines.

The model is thermodynamically based on the conditions for phase and chemical equilibria [4]. Let us consider these conditions for the example of the ternary system M, $N \| X – H_2O$. The liquid phase in such a system is a solution that contains cations M and N and anion X, and the solid phases may be in the form of anhydrous salts MX and NX, their crystal hydrates, and compounds on their base. The general formula of the solid phase whose crystallization is possible in the given system, can be represented as $l_1MX \cdot l_2NX \cdot l_3H_2O$, where l_i is the stoichiometric coefficient of ith component (salt or water) in the solid phase. According to the conditions for a phase or chemical equilibrium for any solution saturated with respect to a given compound in the system M, $N \| X – H_2O$, the linear combination of the logarithms of activities of the components of the system, multiplied by the respective stoichiometric coefficients ($l_1 \ln a_{MX} + l_2 \ln a_{NX} + l_3 \ln a_w$), must be constant at a given temperature and pressure, because it characterizes the logarithm of the solubility product, ln SP, of this compound with account of the activity coefficients of all the components.

The dependences of the excess thermodynamic functions (activity coefficients of electrolytes and osmotic coefficient of water) on the solution composition were approximated using Pitzer equations [5]. These equations, as well as the algorithm for calculating the solubility diagrams and evaluating the saturation of brines, were reported in [1–3].

A description of a binary system by means of the Pitzer method requires no less than four parameters: $\beta^{(0)}$, $\beta^{(1)}$, $\beta^{(2)}$, and $C^{(\varphi)}$, which are independent of the ionic strength and characterize binary ($\beta^{(0)}$, $\beta^{(1)}$, $\beta^{(2)}$) and ternary ($C^{(\varphi)}$) short-range interactions between ions in an electrolyte. They can be determined from experimental values of the activity of water or the activity coefficients of electrolytes in binary systems. The parameters θ and ψ correspond to binary and ternary short-range interactions between ions of different electrolytes and are calculated on the basis of experimental data for ternary systems. On passing to systems with more than three components, no additional

parameters appear and, in the overwhelming majority of cases, all calculations are performed using data for binary and ternary subsystems. The only exception are the cases when solid phases that were not present in any of the ternary subsystems crystallize in multicomponent systems. This circumstance is an advantage of the Pitzer method over other methods for calculation of the activity coefficients in electrolyte solutions.

Thus, the database for constructing the thermodynamic model of a multicomponent aqueous-salt system with the use of the Pitzer equations includes a set of parameters of the binary and ternary subsystems of the system under study, as well as a set of thermodynamic potentials (ln SP) of solid phases that crystallize in the system.

* $\ln \mathrm{SP} = (\ln \mathrm{SP})_0^{(0)} + (\ln \mathrm{SP})_0^{(1)}T$; T is temperature, °C.

As shown previously [1–3], the solubility diagrams of multicomponent systems that model natural brines are described with a satisfactory precision in the temperature range 0–100°C by a set of parameters of binary systems for 25°C. As for the parameters of ternary systems and the values of ln SP for solid phases, it was sufficient, in most cases, to introduce a linear temperature dependence in accordance with the formula $\mathrm{Par}(T) = \mathrm{Par}(T_0) + (\mathrm{dPar}/\mathrm{d}T)(T - T_0)$, where $T_0 = 25$°C.

This study is devoted to calculation of the set of parameters that is necessary for constructing a thermodynamic model of the aqueous-salt system in the temperature range 0–100°C. Tables 1–3 list values of parameters of the binary and ternary subsystems and of ln SP of the solid phases that crystallize in the system, with part of the binary parameters taken from the literature [5–7]. The calculation was performed on the basis of published data on how the activity coefficients of the salt components and the osmotic coefficient of water depend on the composition of binary solutions and data on solubility in three-component aqueous-salt systems Na^+, $K^+ \| Cl^- – H_2O$ and Na^+, $K^+ \| Cl^-$, $H_2PO_4^- – H_2O$. The calculation included processing of a sufficiently large body of experimental data for different temperatures (in the range from 0 to 100°C). The procedure for finding the parameters of the Pitzer equations from data on solubility was described in [8]. The volume of calculation strongly varied between different systems because of the unequal extents to which these systems were studied. The calculation was based on experimental data on solubilities in three-component systems for two or three markedly different temperatures, so that the temperature range under study was covered sufficiently completely. Preference was given to those temperatures, for which an as complete body of experimental data as possible could be found in the literature.

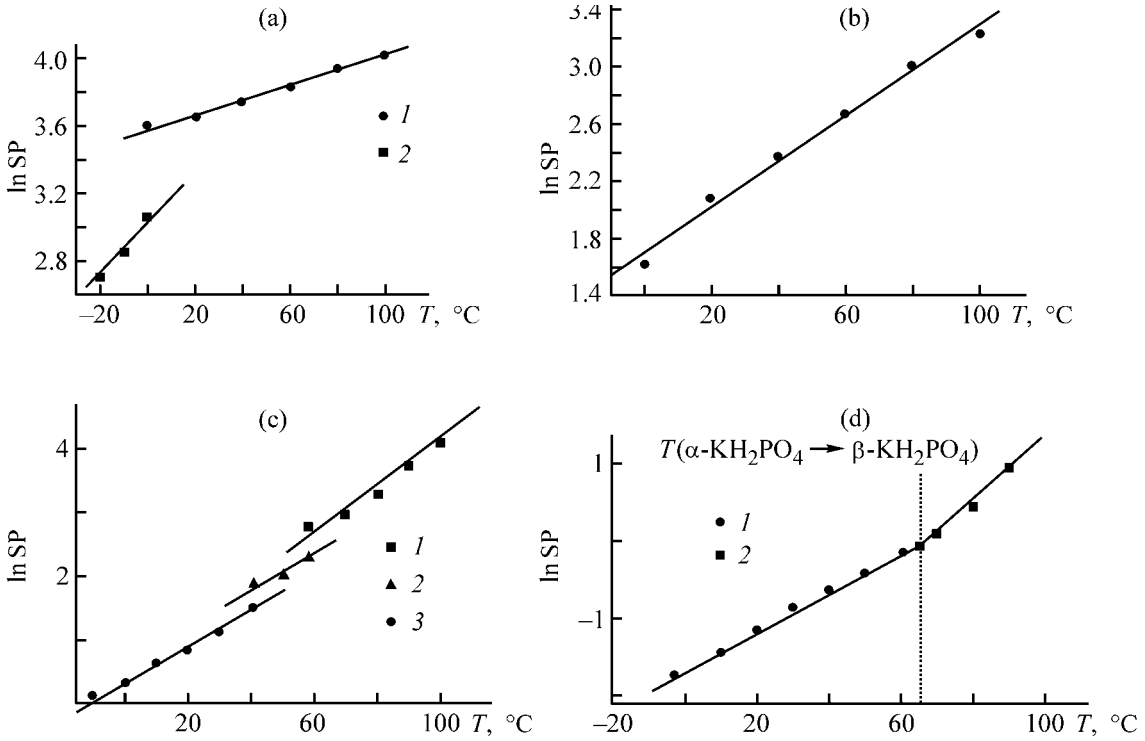

Fig. 1. Thermodynamic potentials of the solid phases, ln SP, vs. temperature *T*. Solid phase: (a) (*1*) NaCl and (*2*) $NaCl \cdot 2H_2O$; (b) KCL; (c) (*1*) NaH_2PO_4, (*2*) $NaH_2PO_4 \cdot H_2O$, and (*3*) $NaH_2PO_4 \cdot 2H_2O$; (d) (*1*) α-KH_2PO_4 and (*2*) β-KH_2PO_4. *Lines*, calculation; *points*, experimental data for binary subsystems.

The binary Pitzer parameters are listed in Table 1. The binary parameters of the system KH_2PO_4–H_2O, which could not be found in the literature, were calculated by the authors of this study on the basis of experimental data on how the osmotic coefficient of water depends on the composition of the binary solution [9]. The root-mean-square deviations σ^{φ} of the calculated φ from the experimental values were 0.005.

Table 2 lists the parameters of the Pitzer equations for three-component systems, and also their temperature dependence. To achieve a better agreement between these parameters in the quaternary mutual system Na^+, $K^+||Cl^-$, $H_2PO_4^-$–H_2O, all parameters of the θ type are set zero.

Table 3 lists values of ln SP for the solid phases that crystallize in the systems under consideration in the temperature range 0–100°C, as well as the quantities that characterize their derivative with respect to temperature. The accuracy of the linear approximation of the function ln SP(*T*) is illustrated in Fig. 1.

The solubility isotherms calculated using the resulting set of Pitzer equation parameters and values of ln SP for three-component systems containing sodium and potassium chlorides and dihydrophosphates are presented in Figs. 2, 3 and Tables 4, 5. The solution compositions are expressed in molalities of salts. Also given are published experimental data on solubility. As can be seen in Figs. 2, 3, an, on the whole, convincing agreement is observed between the results of calculation and experimental values.

In all the figures, nonvariant points are designated in accordance with the terminology introduced in [12, 13]. Letter *E* denotes ternary eutonics, and letter *O*, transfer points corresponding to an equilibrium of a three-component solution with two crystal hydrates of the same salt composition. No ternary peritonics *P* were found in the systems in question in the temperature range under study (0–100°C).

Figures 2a–2e show the solubility diagrams of the system NaCl–KCl–H_2O at 0, 25, 50, 75, and 100°C. In the same figures are plotted the experimental data of [10, 11] for 0, 25, 50, 75, and 100°C. As can be seen from Fig. 2, at all temperatures except 0°C the solubility diagram of the system NaCl–KCl–H_2O is simple eutonic, comprises two branches corresponding to crystallization of NaCl and KCl, and contains one nonvariant eutonic point. At 0°C there appears an additional, very short branch corresponding to crystallization of hydrogalite $NaCl \cdot 2H_2O$, and an additional nonvariant point *O* corresponding to joint crystallization of $NaCl \cdot 2H_2O$ and NaCl.

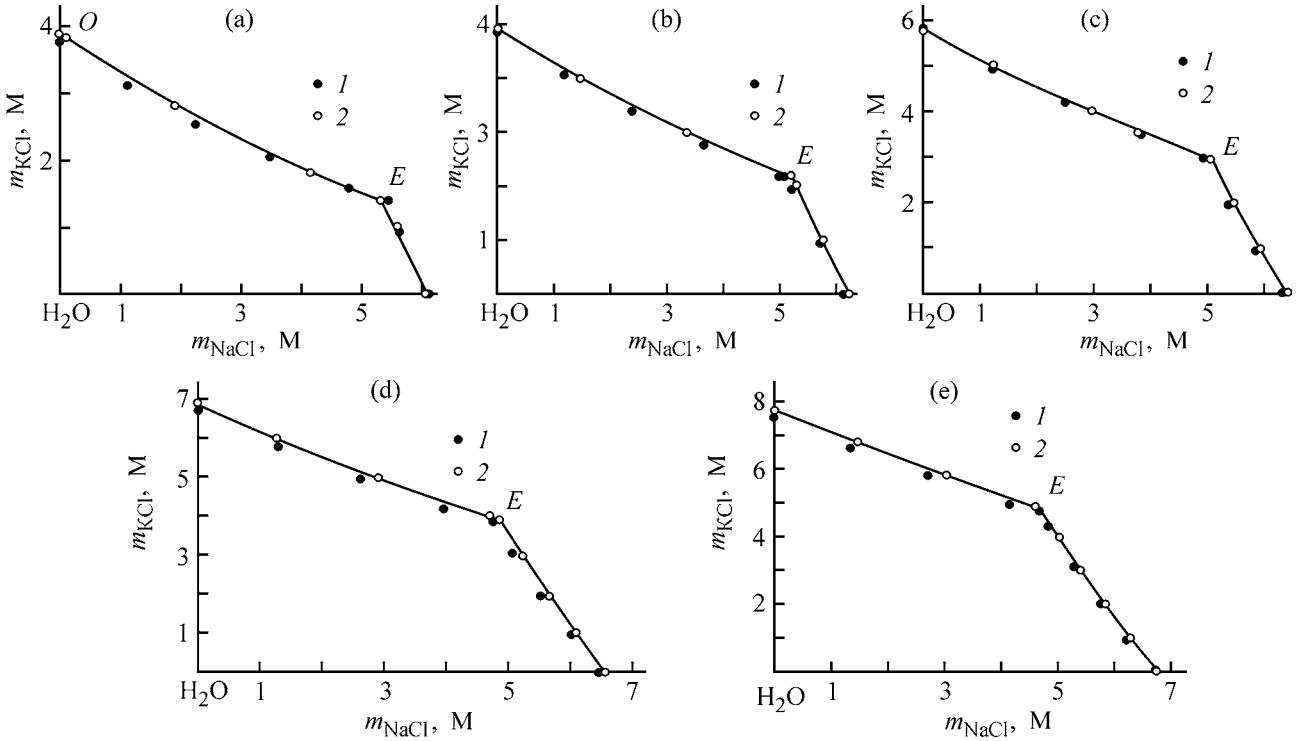

Fig. 2. Solubility diagrams for the system Na^+, $K^+||Cl^-$–H_2O at (a) 0, (b) 25, (c) 50, (d) 75, and (e) 100°C. *Lines*, calculation by the Pitzer method; *points*, experimental data of [10, 11]; the same for Fig. 3. (*m*) Molal concentration of salts; the same for Fig. 3.

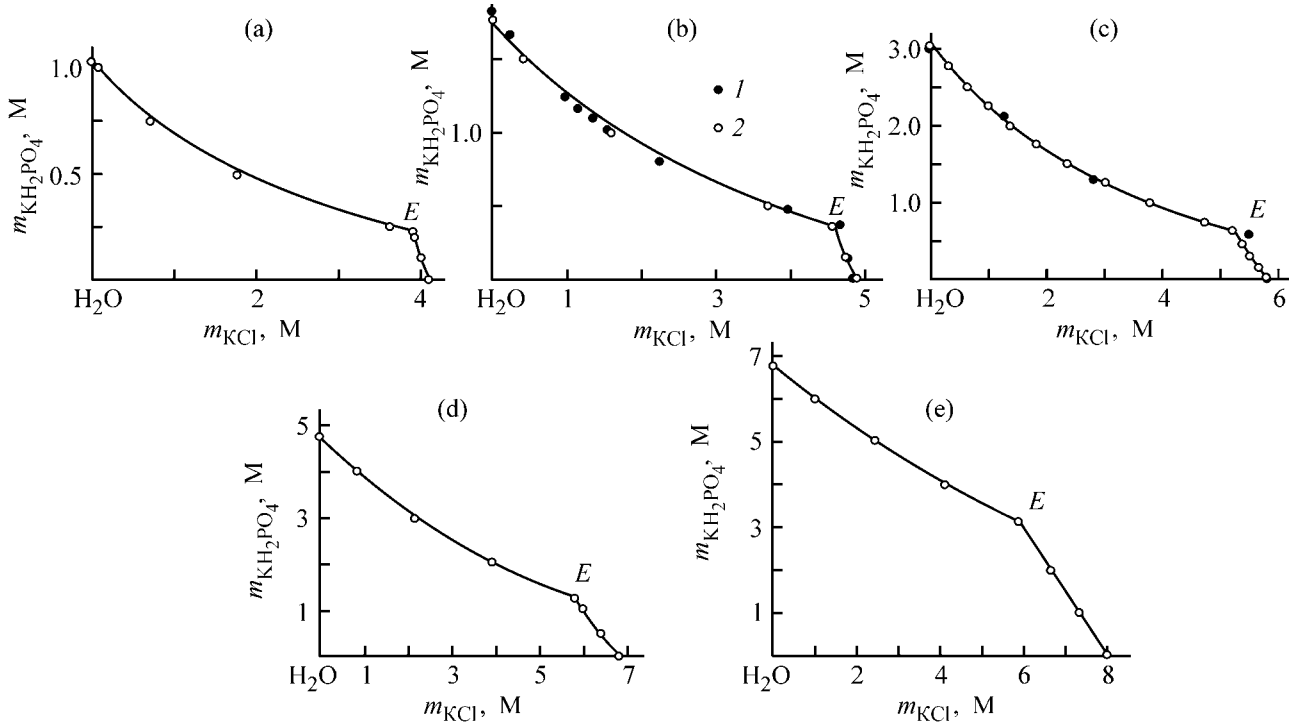

Fig. 3. Solubility diagrams of the system $K^+||Cl^-$, $H_2PO_4^-$–H_2O at (a) 0, (b) 25, (c) 50, (d) 75, and (e) 100°C.

Figures 3a–3e show the solubility diagrams of the system KCl–KH_2PO_4–H_2O at 0, 25, 50, 75, and 100°C. In the same figures are plotted experimental data of [10, 11] for 25 and 50°C. It can be seen in Fig. 3 that, at all the temperatures, the solubility diagram of the system KCl–KH_2PO_4–H_2O is simple

eutonic, with two branches corresponding to crystallization of KCl and KH_2PO_4 and a single nonvariant eutonic point. However, α-KH_2PO_4 crystallizes at temperatures of 0, 25, and 50°C, and the β-modification at 75 and 100°C.

CONCLUSION

The binary and ternary Pitzer parameters and thermodynamic potentials of solid phases of the binary and ternary subsystems of the quaternary mutual system Na^+, $K^+ \| Cl^-$, $H_2PO_4^-$–H_2O in the temperature range 0–100°C were calculated, which made it possible to construct the solubility diagrams of the subsystems. The results of the thermodynamic calculation are in a good agreement with the available published experimental data.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Calculation of Conditional Equilibrium Constants of Reactions of Reduction of Titanium, Zirconium, and Hafnium Chlorides with Alkali Metals in a Melt of Their Chlorides

V. A. Oleinikova, N. A. Loginov, and V. V. Chebykin

Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received November 19, 2003

Abstract—Equilibrium constants of the reactions of reduction of Ti, Zr, and Hf chlorides with metallic Li, Na, K, Rb, and Cs in their molten chlorides were calculated from published data.

Metallic sodium finds use as a reducing agent in manufacture of some metals, and primarily titanium. Both in the domestic and in the foreign literature there exhibit monographs devoted to production, properties, and use of alkali metals [1–8], and also to description of the method based on reduction with sodium for manufacture of titanium. Sodium and titanium are virtually mutually insoluble [1–12]. Rather extensive studies have been performed in order to analyze the behavior of alkali metals, determine the redox potentials, and measure the vapor pressure of alkali metals [13–19].

$TiCl_4$ is reduced by sodium in accordance with the equation

$$TiCl_4 + 4Na = Ti + 4NaCl.$$

Theoretically, obtaining 1 kg of titanium requires 1.92 kg of sodium, and the theoretical consumption of magnesium in production of titanium is 1.01 kg [1]. The reduction occurs in the range 1074–1156 K, which is delimited by the melting point of sodium chloride (1074 K) and the boiling point of sodium (1156.3 K). The melting point of sodium is 370.98 K (97.83°C). The working range of the reduction of titanium chlorides with sodium to the metal is 1123–1193 K. $TiCl_4$ can be reduced in a single- or double-stage mode. In the single-stage scheme, titanium tetrachloride is reduced directly to the metal.

In manufacture of spongy titanium, sodium has a number of advantages as a reducing agent over magnesium. It is more active and the ?extent of its utilization is as high as 98–99.5% at high reaction rates and lower temperatures; below 880°C it does not react with iron. However, the power consumption for manufacture of sodium exceeds by 25% that for magnesium. The amount of reduction products formed exceeds that in the case of reduction with magnesium. During the process, reactions of incomplete reduction also occur, i.e., $TiCl_3$ and $TiCl_2$ are formed and dissolve in molten chlorides of alkali metals to give compounds of the types $MTiCl_4$, $MTiCl_3$, M_2TiCl_4, and M_3TiCl_6. This makes necessary the double-stage method, in which a melt of lower titanium chlorides is obtained in the first stage, and these chlorides are reduced to titanium in the second stage. The initial stage is performed in the first reactor and then the melt with lower chlorides is transferred to the second reactor. The final stage consists in reduction of $TiCl_2$ and $TiCl_3$ to metal.

Large-scale use of sodium requires serious safety precautions and a high production efficiency. Several characteristic features of reduction with sodium should be pointed out. The considerably stronger heat release in reduction reactions complicates heat removal from the reactor. Magnesium chloride formed reduction with magnesium can serve as a raw material for manufacture of metallic magnesium. In a production process combining manufacture of titanium with electrolysis of magnesium, the latter is recycled, whereas obtaining sodium by electrolysis of its chloride is a more complicated task. However, a simple charging and additional charging in the course of reduction and the quality of titanium obtained eliminate these disadvantages [1–12].

In this communication, a procedure for calculating conditional equilibrium constants of reactions in which

CsCl	918	$4.247–6.40 \times 10^{-4} T$	[21]

titanium, zirconium, and hafnium chlorides are reduced by metallic lithium, sodium, potassium, rubidium, and cesium in molten chlorides of these alkali metals. The equations describing how the conditional values of the standard electrode potentials of the metals depend on temperature, taken from [20], are listed in Table 1. Table 2 presents temperature dependences of the decomposition voltages of lithium, sodium, potassium, rubidium, and cesium chlorides. The data in Tables 1, 2 were used to calculate temperature dependences of the conditional equilibrium constants $\log K_n^*$ for the processes represented in Table 3. The calculation procedure was described in detail in [22, 23].

Of particular interest are reactions in which titanium, zirconium, and hafnium chlorides are reduced by sodium and potassium. The conditional equilibrium constants K_n^* of reactions (1)–(7) for different temperatures in NaCl and KCl melts, which are of practical interest, are listed in Table 4. Table 4 also gives for reactions (1)–(7) the values of K_n^* at 1150 K in relation to the nature of a metal and a cation of the solvent-salt. Reduction of $TiCl_2$, $ZrCl_2$, and $HfCl_2$ by alkali metals [reactions (1), (4), (6)] occurs less intensively than that of the tetrachlorides $TiCl_4$, $ZrCl_4$, and $HfCl_4$ [reactions (3), (5), (7)]. The conditional constant K_n^* increases by approximately 44–50 orders of magnitude (Tables 3, 4).

It should be noted that the final stage of titanium reduction in a NaCl melt occurs by reactions (1)–(3) (Table 3). At 1150 K, the conditional equilibrium constant of these reactions (Table 4) has the following values: $K_1^* = 2.13 \times 10^{44}$, $K_2^* = 1.10 \times 10^{66}$, and $K_3^* = 4.49 \times 10^{82}$. The equlibrium of these reactions is deeply sheefteed to the target products. Titanium tetrachloride forms complexes of the types $TiCl_5^{2-}$ and $TiCl_4^{2-}$ [20]. K_2 exceeds K_1 by 22 orders of magnitude.

The values of K_n^* for reactions (1)–(3), (6), and (7) at 1150 K in a potassium chloride melt are listed in Table 4. It is of interest to compare the values of the conditional equilibrium constants for the processes in which titanium and hafnium chlorides are reduced by molten magnesium, which are 1.1×10^6, 9.7×10^{19}, and 5.4×10^{17}, respectively for reactions (1)–(3) at 1150 K in a KCl melt [24], and 1.09×10^7 and 1.6×10^{12} for processes (6) and (7) under the same conditions [25]. The difference in the values of K_n^* is 40 to 80 orders of magnitude.

Use of metallic lithium, rubidium, and cesium as reducing agents is economically unfeasible.

CONCLUSIONS

(1) Conditional equilibrium constants of the reactions of titanium, zirconium, and hafnium chlorides with molten metallic lithium, sodium, potassium, rubidium, and cesium in molten chlorides of these alkali metals were calculated using published data. Their values of these constants are rather high.

(2) Titanium, zirconium, and hafnium tetrachlorides react with alkaline metals more vigorously than dichlorides of the same metals do. The value of K_n^* increases by approximately 44–50 orders of magnitude.

(3) Use of metallic lithium, rubidium, and cesium as reducing agents is economically unfeasible.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

On Assessment of the Thermodynamic Consistency of Data on Liquid–Vapor Equilibrium

A. N. Marinichev

St. Petersburg State University, St. Petersburg, Russia

Received November 6, 2003

Abstract—A new method for assessment of the thermodynamic consistency of binary isothermal data on the liquid–vapor equilibrium by calculating the Redlich–Kiester integral with account of how the pressure of phase coexistence depends on the vapor composition is suggested. The Maple 8 software is used to compare the values of the integral and other characteristics calculated for systems with varied nature of departures from the Raoult law.

The thermodynamic consistency of experimental data on the liquid–vapor equilibrium in binary systems is frequently assessed using the value of the Redlich–Kiester integral I defined by

$$I = \int_0^1 \ln \frac{\gamma_1}{\gamma_2} \, dx, \qquad (1)$$

in which γ_1 and γ_2 are the activity coefficients of components 1 and 2, and x is the mole fraction of a component (let, for definiteness, this be the first component) in solution.

Strictly speaking, the equality $I = 0$, as also the Gibbs–Duheme equation used to establish it, are valid under isothermal–isobaric conditions (see, e.g., [1]). As a rule, the experimental data presented in reference books of the type [2, 3] refer to isothermal or isobaric conditions. In discussing isothermal data (and just this type of data is considered in the present study), it is commonly believed that the effect of pressure on the state of the condensed phase can be disregarded. In other words, the contribution from the "nonisobaricity" of isothermal data, which is due to the small (but still nonzero) excess molar volume of the solution, transforms the equality $I = 0$ into an expression $I \approx 0.0001$. A conclusion has been made on the basis of the results of measurements for a number of binary systems that the accuracy of data is satisfactory if $I < 0.02$ and that the deviations in composition by 3–5 mol % strongly affect the value of the integral [1]. It is recommended by the manual [3] that the dimensional (J mol^{-1}) criterion $RTI \equiv |RTI|$, where R is the universal gas constant and T is temperature (K), should be used to assess the thermodynamic consistency of isothermal data. It is also stated that data show a very good thermodynamic consistency at $RTI \leq 12$, good consistency at $RTI \leq 40$, and lack of consistency at $RTI > 40$.

The value of I can be found from different data sets. This is commonly done by calculating the activity coefficients, determining the concentration dependence of the logarithm of their ratio, $\ln(\gamma_1/\gamma_2)$, and performing "direct" integration over the entire range of solution compositions [1]. The limiting values of this ratio (for $x = 0$ and $x = 1$) cannot be calculated from experimental data. These values are different if different parametric approximating equations (like Redlich–Kiester, Margules, Van Laar, Wilson, *NRTL*, etc. equations) are used for the concentration dependence of the activity coefficients of a component. Moreover, in the case of such a "direct" calculation of integral I, only the compositions of the coexisting liquid and vapor phases are analyzed for thermodynamic consistency, whereas the question as to whether or not experimental data are consistent as regards the concentration dependence of the phase coexistence pressure remains unsolved. The known Van Ness method [1, 5] is aimed to study the thermodynamic consistency of complete data (x–y–T–P) on phase equilibria. An opinion has been expressed that, even if the composition of the vapor phase is known, it is possible to do without these data and it is only necessary that the dependence of the pressure P on the so-

1070-4272/04/7706-0891 © 2004 MAIK "Nauka/Interperiodica"

lution composition x should be known. Then, the composition of the vapor phase can be calculated after the parameters of the concentration dependences of the activity coefficients of the components are found by minimizing the discrepancy between the calculated and experimental data on pressure and using thermodynamically compatible equations for the above dependences [5].

Presently, various kinds of new equipment have become available (various vapor-phase analyzing attachments to gas chromatographs) and the composition of the vapor phase can be determined with a sufficiently high accuracy. Therefore, it is well justified to verify the thermodynamic consistency of incomplete data on phase equilibria and, in particular, of isothermal data on saturated vapor pressure and composition of the vapor phase. It turns out in this case that information about the composition of the liquid phase (which may be even heterogeneous) is not quite necessary. If integral (I) is transformed in such a way that the mole fraction y of the first component in the vapor phase is under the differential sign, then, as shown below, it becomes possible to analyze this issue too. It should be noted that, for thermodynamically consistent data (compositions and coexistence pressure of phases), the values of integral I and *RTI* criterion should be independent of the set of data used to calculate the integral. However, the thermodynamic consistency of the phase compositions does not mean yet in practice that they are consistent with the values of pressure. Hence follows the known statement that the closeness of integral I to zero is a necessary, but not sufficient condition for consistency of data. To establish the sufficiency, it is, apparently, necessary to use some additional equation that is a consequence of the conditions for isothermal interphase equilibrium. As an equation of this kind can serve the previously obtained expression [6], which relates the pressure P and the compositions of the coexisting solution (x) and ideal vapor (y):

$$x = y\left[1 - \beta(1 - y)\frac{\mathrm{d}\ln P}{\mathrm{d}y}\right], \qquad (2)$$

where β is the ratio of the difference between the molar volumes of the vapor and liquid phases to the molar volume of the vapor phase at the temperature of the experiment (at $\beta = 1$, this expression can also be derived from the conventional form of the Duheme–Margules equation [1]).

Let us introduce the following designations

$$\varphi(y) = \frac{\mathrm{d}\ln P}{\mathrm{d}y}, \quad \alpha = \frac{y(1 - x)}{x(1 - y)}$$

and use the apparent identity

$$\frac{x}{y} = x + \frac{1 - x}{\alpha}$$

to bring the relative volatility α to the form

$$\alpha = \frac{1 + y\varphi(y)}{1 - \beta(1 - y)\varphi(y)}. \qquad (3)$$

As $(\gamma_1/\gamma_2) = \alpha(P_2^0/P_1^0)$, the Redlich–Kiester integral I can be expressed as

$$I = \int_0^1 \left(\ln\alpha + \ln\frac{P_2^0}{P_1^0}\right)\frac{\mathrm{d}x}{\mathrm{d}y}\,\mathrm{d}y, \qquad (4)$$

where P_2^0 and P_1^0 are the vapor pressures of the individual components 1 and 2 at the phase coexistence temperature under study.

Using relations (2)–(4) and taking into account that $\beta = 1$, we can write the following calculation formula for integral I:

$$I = \int_0^1 \ln\left\{\frac{[1 + y\varphi(y)]P_2^0}{[1 - (1 - y)\varphi(y)]P_2^0}\right\} \times\left\{1 - (1 - y)\varphi(y) + y\left[\varphi(y) - (1 - y)\left(\frac{\mathrm{d}[\varphi(y)]}{\mathrm{d}y}\right)\right]\right\}\mathrm{d}y. \qquad (5)$$

If the dependence of $\ln P$ on y is, e.g., a third-order polynomial

$$\ln P = a + by + cy^2 + dy^3, \qquad (6)$$

then the functions $\varphi(y)$ and $\mathrm{d}[\varphi(y)]/\mathrm{d}y$ in the right-hand part of relation (5), expressed in terms of the coefficients b, c, and d, will apparently have the form

$$\varphi(y) = b + 2cy + 3dy^3,$$
$$\mathrm{d}[\varphi(y)]/\mathrm{d}y = 2c + 6dy.$$

On substituting the last two expressions with the coefficients b, c, and d found by the least-squares procedure into (5), we can calculate the values of integral I and *RTI* criterion. The basic equations were derived [and, in particular, Eq. (5)], their adequacy was verified, and all the calculations [determining the polynomial coefficients in relation (6), with subsequent integration] were carried out using Maple 8 software, which is applicable both to symbol transformations and to mathematical calculations. The dis-

crepancy between the calculated and experimental data was evaluated by the quantity

$$\Delta_z = \frac{1}{(n - k)} \Sigma |\hat{z}_i - z_i|,$$

in which the pressure P_i and mole fraction x_i of ith experimental point are regarded as a property z_i; n is the total number of (points) sets (x, y, P); k, the number of parameters (k = 4 in this study) in the polynomial regression equation $\ln P(y)$; and $\hat{z}_i$, the value of the property z_i for ith experimental point, calculated using a regression equation of the type (6) for the value of $\hat{P}_i$ or expression (2) for the value of $\hat{x}_i$ at a value y_i.

Let us present as an example the calculation of the Redlich–Kiester integral for the acetone–benzene system with the use of data on the liquid–vapor equilibrium at a temperature of 50°C. Let us consider the main stages of a calculation using Maple 8 software. The lines with sign > are commands, and those without this symbol, comments (ignored in the course of calculation).

(1) Pre-starting procedure, calling of necessary procedures.

```
> restart:
> with(stats):with(student):
```

(2) Input of experimental data {x_1, y_1, P} and their transformation to the necessary form. The figures in square brackets, with a sign := on the left and designated as P, x_1, and y_1 are, respectively, ordered "lists" of values of pressure and mole fractions of the first component in solution and in vapor. They are easily replaced in passing from one system to another.

The above "listing" of the main stages is to be regarded as a finished template for calculating Δ_P, Δ_x, Redlich–Kiester integral I, and *RTI* criterion; the results of calculations, presented below, can serve as "test examples."

Table 1 compares the procedure suggested for assessment of the thermodynamic consistency of data with the previously known method for some systems represented in the monograph [1]. Data on phase equilibria in the systems represented in Table 1, taken from the known reference book [2], were obtained in studies published before 1965. On the whole, the new method for calculating the Redlich–Kiester integral is in an agreement with the results obtained using the conventional technique. However, these systems are characterized by noticeable errors in determining the composition of the vapor phase. There is good reason to believe that these errors are smaller in more recent data because of the use of modernized equipment for experimental studies of phase equilibria. Therefore, it was worthwhile to used data published after 1965. An information of this kind for vapor–liquid equilibria in binary mixtures can be found in the reference book [3].

Table 2 lists the results of data processing for some systems represented in this reference book by the method we suggested. In particular, it was found by comparing different-order polynomials that the depen-

* For all the systems, the dimension of pressure is mm Hg.

dence $\ln P(y)$ is, as a rule, well described by a third-order interpolation polynomial.

The results listed in Table 2 suggest that, at a number of experimental points of no less than 10, the cubic dependence of the logarithm of the pressure on the vapor composition well describes the experimental data, and small deviations (0.01 mole fraction and less) of the calculated solution composition from that found experimentally are in a full agreement with the small value of the Redlich–Kiester integral. This indicates the thermodynamic consistency of the experimental data. It is more difficult to analyze data with a number of points less than 10; in these cases, the deviation Δ_x may be frequently rather pronounced, whereas the value of integral I may indicate a thermodynamic consistency of the data on $P(y)$.

The benzene–cyclohexane system has an azeotrope of an equimolar composition, which corresponds to the highest pressure. If the range of the vapor phase compositions is represented as two concentration

intervals, before and after the azeotrope, and, e.g., second-order interpolation dependences are found, we obtain the following equations:

$$\ln P = 5.200 + 0.50641y - 0.503y^2 \quad (7)$$

for the interval $y \in [0-0.4979]$ and, with the coefficient of determination equal to 0.9997,

$$\ln P = 5.211 + 0.48641y - 0.500y^2 \quad (8)$$

for $y \in [0.5239–1]$, with the coefficient of determination equal to 0.99994. Let us represent expression (5), which is the Redlich–Kiester integral, as a sum of two integrals with changes in the composition of the vapor phases before and after the azeotrope. With account of Eqs. (7) and (8), their values are 0.1289 and –0.1300, and the integral itself, which is a sum of these two values, equals –0.0011, which points to a good thermodynamic consistency of the experimental data on the pressure and composition of the vapor phase. Calculation of the liquid phase composition with the use of equations of the type (2) and expressions (7) and (8) for the equimolar composition (0.5) of the vapor phase gives values of 0.4993 and 0.5035, which indicates the coincidence, within the experimental error, of the compositions of the liquid and vapor phases. The above example shows that the approach of this kind can be also extended to systems with limited mutual solubility of components. Similarly performed calculations for systems of this kind make it possible both to assess the thermodynamic consistency of data and to specify the compositions of the liquid phases into which decomposes in condensation the vapor phase of a heteroazeotropic composition.

CONCLUSION

It was shown that the Redlich–Kiester integral expressed in terms of pressure and vapor phase composition, combined with additional parameters, can characterize the thermodynamic consistency of data on phase equilibria and can be applied to systems with a heteroazeotrope.

SORPTION AND ION-EXCHANGE PROCESSES

Preparation and Properties of Spherically Granulated Titanium Phosphate Modified with Fe(III) Hexacyanoferrate(II)

V. K. Mardanenko, V. V. Strelko, V. A. Kanibolotskii, and N. M. Patrilyak

Institute of Sorption and Endoecological Problems, National Academy of Sciences of the Ukraine, Kiev, Ukraine

Received August 12, 2003; in the final form, April 2004

Abstract—Spherically granulated titanium(IV) phosphate modified with Fe(III) hexacyanoferrate(II) was prepared by the improved sol–gel procedure, and its physicochemical and sorption characteristics were studied in comparison with those of the unmodified Ti(IV) phosphate.

This paper continues the series of publications [1–4] aimed at preparing radionuclide sorbents by depositing ferrocyanides(II) of heavy metals onto various supports.

It is known, owing to their structural features, that several poorly soluble heavy metal hexacyanoferrates(II) exhibit high affinity for toxic metals and especially for ^{137}Cs radionuclide [5–19].

Preparation of granulated hexacyanoferrates(II) suitable for sorption of metals from aqueous solutions under dynamic conditions is power-consuming. The sorbents based on finely dispersed hexacyanoferrate(II) are more available, but, due to their high hydrodinamic resistance, they are unsuitable for purification of contaminated solutions. Depending on the kind of problem, either granulated or gel-like hexacyanoferrate(II) sorbents are used [20]. Numerous attempts have been made to develop effective sorbent convenient for use and suitable for sorption of radionuclides, in particular ^{137}Cs. These attempts involved application of heavy metal hexacyanoferrate(II) to various supports: ion-exchange resins [5], fibrous activated carbon [12], cellulose [14–16], silica gel [18], aluminum oxide [19], natural aluminosilicates [15, 16, 21], sawdust [22], etc. In order to develop a new effective sorbent of this kind, an appropriate inexpensive support must be found.

Our approach to preparation of improved hexacyanoferrate(II) sorbents is based on the use of spherically granulated Fe(III)-containing titanium(IV) phosphate as support. This kind of titanium(IV) phosphate can be prepared by a sol–gel technique from aqueous solution of $TiOSO_4$ used for production of commercial TiO_2. The use of granulated support with required grain size in preparing the sorbent modified with hexacyanoferrate(II) is very advantageous, since in this case the granulometric composition of the modified sorbent is determined by the grain size of the initial titanium(IV) phosphate. Under these conditions, a nearly 100% yield of the desired modified sorbent is achieved.

As a rule, in all studies except [21], a support is sequentially treated in preparing sorbents modified with hexacyanoferrate(II), with aqueous solutions of an appropriate heavy metal salt and potassium hexacyanoferrate(II) $K_4[Fe(CN)_6]$ (K–HCF). In preparing our modified sorbent, a spherically granulated titanium phosphate (TiP) containing 2.0 to 3.2 wt % Fe(III) [23] was used as a support. By modification of these grains with aqueous potassium hexacyanoferrate(II), spherically granulated sorbents [24] containing from 40 to 120 mg g^{-1} Fe(III) hexacyanoferrate(II) $Fe_4[Fe(CN)_6]_3$ (Fe(III)–HCF) were prepared; these sorbents were used in our experiments.

The procedures used for titanium phosphate modification were optimized by varying the Fe(III) content in the initial TiP, pH, the modifier (K–HCF) concentration at constant TiP : K–HCF solution ratio, TiP grain size, and impregnation time. The sorption power of the initial TiP and its modified forms for radionuclide ions ^{137}Cs, ^{90}Sr, and some ions of heavy metals (Cu^{2+}, Cd^{2+}) was studied.

EXPERIMENTAL

A fresh spherically granulated titanium phosphate hydrogel in the H forms prepared by a sol–gel technique, was modified with Fe(III) hexacyanoferrate(II) under static conditions as follows. A granulated

Table 2. Influence of pH of aqueous modifying solution on fixation of Fe(III)–HCF by titanium phosphate

pH of aqueous K–HCF		Fe(III)–HCF content in MTiP, mg g^{-1}	Fe(III) bound to modifier, %	pH of aqueous K–HCF		Fe(III)–HCF content in MTiP, mg g^{-1}	Fe(III) bound to modifier, %
initial	equilibrium			initial	equilibrium		
1.2	1.2	49.6	44.7	3.0	2.4	42.2	40.6
2.2	2.2	57.2	55.0	4.2	2.7	41.8	40.2

TiP hydrogel (5–20 g) was kept in 0.2 M aqueous $K_4[Fe(CN)_6]$ (7–67 cm^3) at pH 1.2–4.2 with stirring for 24 h at 19–20°C. Upon contact, the solid phase was separated and washed with distilled water to remove $K_4[Fe(CN)_6]$. The resulting modified TiP was airdried for 2 days and analyzed for $[Fe(CN)_6]^{4-}$. The initial TiP was analyzed for phosphorus, titanium, and iron. All the analyses were carried out by the conventional techniques [25, 26].

The sorption power of modified titanium phosphate for metal ions was determined upon its contact with a solution of the metal nitrate in 0.1 M $NaNO_3$ (supporting electrolyte) or in water. In the case of sorption of radionuclides, the Ringer solution (mM: NaCl 136.9, KCl 5.6, $CaCl_2$ 2.2 and $NaHCO_3$ 1.2) [27] was used as a supporting electrolyte. This supporting electrolyte was chosen taking into account that the deactivation of biological liquid media is a problem of current interest.

The static sorption experiments were carried out at the ratio of solid and liquid phases, s : l = 1 : (200–1000) with their stirring for 24 h. Under these conditions, the sorption equilibrium was attained upon contact for 10–24 h. The sorption of heavy metals was determined as the difference between their concentrations in the initial and equilibrium solutions. Similarly, the sorption of ^{137}Cs was determined as the difference between its activity in the initial and equilibrium solutions. The sorption kinetics of ^{137}Cs was studied under limited-volume conditions [28]. The specific surface area S_{sp} of sorbents was determined by gas–chromatography from the thermal desorption of argon. The volume of the sorptive pores V_s was determined with a desiccator technique [29] by sorption of benzene and water vapors.

The physicochemical characteristics of the initial granulated titanium phosphate are listed in Table 1.

Table 2 shows that, all other factors being the same, the maximal Fe(III) HCF fixation by titanium phosphate is reached at pH 2.2 of aqueous K–HCF. We found that deviation from this pH deteriorates the modifier accumulation in TiP. Therefore, all further experiments were carried out at pH 2.2.

It should be noted that, in the course of modification of titanium phosphate with Fe(III)–HCF, the pH of aqueous solutions of K–HCF somewhat decreases (from 2.9–3.0 to 1.2–2.7). We found that, in dilution of aqueous modifier, its fixation by titanium phosphate decreases. For example, at pH 2.2 and identical weighed portions and aqueous phase volumes, the content of Fe(III)–HCF in titanium phosphate decreases from 78.8 to 65.6 mg g^{-1} with the initial modifier concentration decreasing from 0.168 to 0.038 M.

It was found (Table 3) that, although the degree of modification somewhat grows with increasing Fe(III)

Table 3. Influence of Fe_{tot} content in TiP on the degree of Fe(III) fixation

content in the initial TiP, the fraction of Fe(III) bound to K–HCF does not exceed 50%. We believe that the low efficiency of Fe(III) binding with the modifier is caused by formation of a dense Fe(III)–HCF surface film on the surface of TiP granules, hindering the penetration of $[Fe(CN)_6]^{4-}$ into the grain bulk. This effect was confirmed by a decrease in the intenity of the Fe(III)–HCF color from the grain surface to the center, observed visually in crushing coarse grains (2 mm).

The effect of grain size on the efficiency of titanium phosphate modification was studied with granulaed titanium phosphate hydrogel containing 2.56 wt % Fe(III). In these experiments, 0.1–0.3, 0.3–0.5, 0.5–1.0, and 1.0–2.0 mm fractions of TiP grains were used. With the grain size increasing in this series, the specific content of $Fe_4[Fe(CN)_6]_3$ in MTiP (mg g^{-1}) decreases: 50.5, 41.2, 30.0 and 15.6, mg g^{-1}, respectively. These data are consistent with our hypothesis about formation of a $Fe_4[Fe(CN)_6]_3$ surface layer hindering the penetration of hexacyanoferrate(II) anions into the grain bulk.

Our kinetic experiments showed that TiP grains became saturated with the modifier after no less than 2 days, i.e. the modification is a slow process. Data on the kinetics of Fe(III)–HCF accumulation in TiP grains (0.3–0.5 mm) are given below.

Fe(III)–HCF, mg g^{-1}	30.1	58.7	79.7	80.5
τ, h	5	10	24	48

The X-ray diffraction pattern in (Fig. 1) shows that modified TiP contains the Fe(III)–HCF phase with the interlayer spacings identical to those of the individual Fe(III)–HCF. This means that Fe(III)–HCF is not chemically bound to the TiP matrix. Figure 2 shows kinetic curves of ^{137}Cs sorption from the Ringer solution on the initial and modified TiP. In going from the initial TiP to its modified form MTiP, all other factors being the same, the degree of ^{137}Cs sorption increases from 28 to 98%. The sorption rate of ^{137}Cs on the modified sor bent also substantially increases. For example, within the first 0.5 h, radiocesium is sorbed by MTiP and TiP to 38% and 4% of the equilibrium amount, respectively. These data show that the sorbents based on granulated titanium phosphate are characterized by slow sorption kinetics; the sorption equilibrium is attained within 22–24 h. Therefore, all the sorption experiments were carried out for 24 h.

The comparison of sorption isotherms of ^{137}Cs on the initial and modified titanium phosphate (Fig. 3) shows that introduction of Fe(III)–HCF into the sorbent raises the cesium sorption by a factor of 5–6. However, there is no proportionality between the modifier content in the sorbent and its sorption power; the increase in the sorption power is substantially

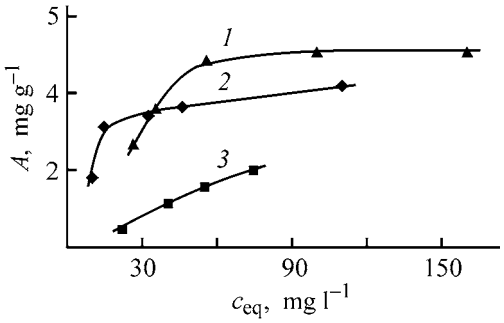

Fig. 4. Sorption isotherms of (*1*) Cu^{2+} and (*2*) Cd^{2+} on MTiP and (*3*) Cu^{2+} on the initial TiP from aqueous chloride solutions. (*A*) Sorption and (c_{eq}) equilibrium metal concentration.

weaker than that in the modifier content. A similar effect was found by us in [4]. The distribution factor K_d of ^{137}Cs between modified titanium phosphates and the Ringer solution, calculated from the sorption isotherms, is $(20-60) \times 10^3$ $cm^3\ g^{-1}$.

We found that the sorption of ^{90}Sr on titanium phosphate modified with Fe(III) hexacyanoferrate(II) is significantly lower than that of ^{137}Cs (K_d = 30–40 $cm^3\ g^{-1}$). These results are consistent with the data reported in [30, 31].

We also studied the sorption power of MTiP for several heavy metals. Figure 4 shows the sorption isotherms of copper and cadmium on the initial and modified titanium phosphate from their aqueous chloride solutions. These data show that, in going from the initial titanium phosphate to its modified form, the sorption of the heavy metals increases, but this effect is smaller than for radiocesium. Our experimental results show that titanium phosphate modified with Fe(III) hexacyanoferrate(II) is an effective sorbent for radiocesium and can be used for decontamination of aqueous solutions to remove this radionuclide under both dynamic and static conditions. These results can also be used for optimization of procedures for preparing titanium phosphate modified with metal hexacyanoferrate(II).

CONCLUSIONS

(1) Granulated titanium phosphate modified with Fe(III) hexacyanoferrate(II) (40–120 $mg\ g^{-1}$) was prepared from an initial granulated titanium phosphate containing 2–3.2 wt % Fe(III).

(2) The distribution factors of ^{137}Cs and ^{90}Sr between titanium phosphate modified with Fe(III) hexacyanoferrate(II) and aqueous solution are $(20-60) \times 10^3$ and 30–40 $cm^3\ g^{-1}$, respectively.

(3) Granulated titanium phosphate modified with Fe(III) hexacyanoferrate(II) can be used for efficient decontamination of aqueous solutions to remove radiocesium.

SORPTION AND ION-EXCHANGE PROCESSES

Properties of Monocarboxy Cellulose Containing Sorbed Fe(III), Al(III), and Cr(III) Cations

Abstract—Sorption of Fe(III), Al(III), and Cr(III) on monocarboxy cellulose at various pH, concentrations of metal chloride or sulfate in solution, and time was studied. The effect of type and amount of the cation sorbed on the physicomechanical properties, swelling, and stability in phosphate buffer of monocarboxy cellulose fibers was considered.

Multicharged Fe(III), Al(III), or Cr(III) cations introduced into carboxyl-containing cation exchangers form intermolecular bonds, which affect the exchanger properties: swelling decreases, mechanical strength and stability with respect to chemical reagents increase, etc. [1, 2].

Among medical polymers that can coordinate with the above cations, monocarboxy cellulose (MCC), which is the product of cellulose oxidation with nitrogen(IV) oxide, is of special interest. Monocarboxy cellulose is biocompatible with a living body, exhibits hemostatic effect, and can resolve in the organism without toxic reaction. These properties of MCC threads and the physicomechanical parameters of the initial cellulose fibers make them applicable as a resolving surgical sutures. However, along with the positive properties, MCC has substantial disadvantages: high swelling, low stability in alkaline media, and high rate of biodegradation.

In this study, we examined effect of Fe(III), Al(III), and Cr(III) sorption conditions on the content of cation sorbed, swelling, mechanical properties, and stability *in vitro* of MCC salt forms.

EXPERIMENTAL

Viscose cord threads (184 tex) oxidized with a 5% solution of nitrogen(IV) oxide in carbon tetrachloride [3] were used. The content of carboxy groups (CC) in MCC samples, determined by the Ca acetate method, [4] was 0.3–1.4 mmol g^{-1}. Sorption of Fe(III), Al(III), and Cr(III) with H form of MCC was performed under static conditions at $20 \pm 1°C$ from chloride and sulfate solutions for various times (from 1 min to 24 h). The cation exchanger sample weight was 1 g, and the solution volume, 40 ml. In the initial solutions, the salt concentration was 0.07–0.11 (Cr^{3+}), 0.02–0.17 (Fe^{3+}), and 0.02–0.14 M (Al^{3+}), pH of Cr(III) and Al(III) sulfate solutions was varied by addition of $Ba(OH)_2$. The relationship between pH and the amount of $Ba(OH)_2$ added is shown in Fig. 1. The pH limits are determined by instability of chromium and aluminum salts in alkaline media. The degree of swelling, Q, of MCC salt in water was determined by centrifugation [5]. The mechanical strength of fibers in dry and wet state and as a knot: P_d, P_w, and P_k, respectively, was determined by the method described in [6].

The Al(III), Cr(III), and Fe(III) content in the MCC phase was determined (after breakdown of an MCC sample in sulfuric acid, with hydrogen peroxide added)

complexometrically with Dithizone as an indicator, chromatometrically, and colorimetrically in the presence of sulfosalicylic acid, respectively [7].

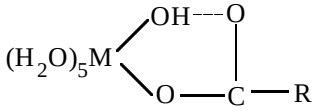
The isotherms of Fe^{3+}, Cr^{3+}, and Al^{3+} sorption from chloride and sulfate solutions on MCC samples with various contents of carboxy groups are shown in Fig. 2. It can be seen that the maximum exchange capacity (EC) of the cation exchanger at the equilibrium cation concentration of 0.03–0.1 M amounts to 0.21 (Fe^{3+}), 0.15 (Al^{3+}), and 0.12 mmol g^{-1} (Cr^{3+}), i.e., with respect to the maximal sorption, the metal ions are ranked in the order $Fe^{3+} > Al^{3+} > Cr^{3+}$.

Probably, the observed differences in the filling of the MCC phase with cations Fe^{3+}, Al^{3+}, and Cr^{3+} depend on the energy of their coordination interaction with fixed carboxy groups and denticity of ligands with respect to various cations. It was shown by potentiometric titration that complexes with the M : COO ratio of 1 : 2 prevail in the Fe(III)–MCC and Cr(III)–MCC systems, and 1 : 1 complexes, in the Al(III)–MCC system [8]. These results show that the fraction of carboxy groups that can be involved in formation of polymeric complexes is 51–57% (Fe^{3+}–MCC system with EC = 0.7 and 1.4 mmol g^{-1}), 20–28% (Cr^{3+}–MCC system with EC = 0.5 and 0.8 mmol g^{-1}), and 19% (Al^{3+}–MCC system with EC = 0.8 mmol g^{-1}). It should be noted that the degree of MCC filling with metal cations somewhat increases with decreasing exchange capacity of the cation exchanger.

It is well known that the degree of MCC filling with cations strongly depends of pH.

Figure 3 shows that Al(III) sorption with MCC fibers increases with pH and reaches a maximum at pH 3.2–3.7. The chromium(III) sorption is substantially lower and becomes the strongest at pH 2.6–2.8; it remains unchanged as the pH grows further.

The rise in metal sorption with MCC with increasing pH can be caused by the following factors: an increase in the content of chromium(III) and aluminum(III) hydroxo complexes, which form with carboxy groups stable six-membered rings [2]



where R is the cellulose radical; an increase in the content of dissociated carboxy groups in the MCC phase; and an increase in the size of chromium(III) and aluminum(III) complexes because of their olation.

A well-defined maximum of Al(III) sorption is characteristic not only of the system studied but also of aluminum fixation on collagen [2]. In accordance with published data, a decrease in aluminum(III) sorption at pH > 3.7 is caused by substitution of carboxy groups in the inner coordination sphere of aluminum-containing complexes by OH groups and formation of aluminum hydroxide, which can precipitate in the sorbent phase. The absence of a similar maximum in the Cr^{3+}–MCC system at pH ≤ 3.5 indicates that the bonds between this cation and carboxy group are more stable in this case [2].

Figure 3 shows that maximum content of Al^{3+} ions fixed on MCC exceeds by more than a factor of two the content of Cr^{3+} ions. However, the degrees of binding of MCC carboxy groups with Al^{3+} and Cr^{3+} ions are similar, amounting to 60% of the total exchange capacity at the maximum sorption.

Influence of the amount of metal cations on mechanical properties and stability with respect to phosphate buffer of oxidized viscose threads with various exchange capacities

It follows from Fig. 4 that the sorption equilibrium is attained within 60 min for Fe^{3+} and Al^{3+} and within 10 min for Cr^{3+}.

Figure 5 and the table illustrate the effect of cation sorption on MCC thread swelling and mechanical properties. As seen, swelling decreases from 0.75 g g^{-1} for oxidized MCC fibers containing no metal to 0.62 g g^{-1} (by approximately 20%) for iron- and chromium-containing MCC, which can be a measure of increased cross-linking. By contrast, the water sorption with

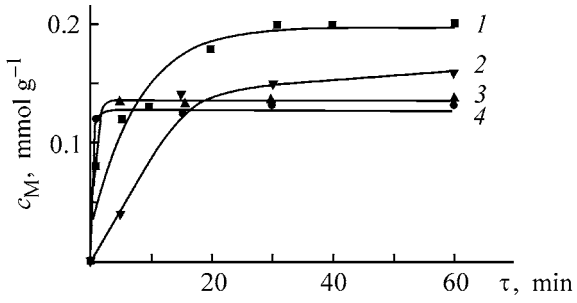

Fig. 4. Amount of cations c_M sorbed with MCC (EC_{COOH} = 0.7 mmol g^{-1}) vs. time τ. Cation: (*1*) Fe^{3+}, (*2*) Al^{3+}, and (*3*, *4*) Cr^{3+}. Solution, c_{in} = 0.1 M: (*1*, *3*) chloride and (*2*, *4*) sulfate.

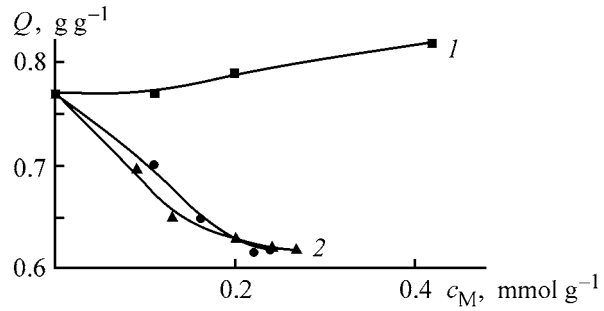

Fig. 5. Dependence of the degree of swelling, Q, of MCC salt species (EC_{COOH} = 0.7 mmol g^{-1}) on the amount of cation sorbed c_M. Cation: (*1*) Al^{3+} and (*2*) Cr^{3+}, Fe^{3+}.

aluminum-containing MCC increases relative to sorption with the initial oxidized cellulose. These results agree with published data that swelling depends on the composition and density of the complexes formed [1].

It follows from Fig. 5 that the minimum swelling of MCC with the 0.7 mmol g^{-1} content of carboxy groups is observed for samples containing 0.15–0.20 mmol g^{-1} metal salt sorbed and then remains unchanged with the further metal sorption. This can be accounted for by the fact that the further increase in the metal sorption is achieved by raising pH. In this case, the hydrolysis products are formed in the cation exchanger bulk. As a result, each cross-link involves several metal cations, which increases the metal consumption for formation of the network of the same density.

The table shows that a decrease in swelling of chromium-containing MCC is accompanied by preservation of the thread strength *in vitro* for a longer time. At the same time, we can see that the lowest stability toward the action of a phosphate buffer is characteristic of iron-containing MCC fibers. This effect can be accounted for by catalysis of the alkaline-oxidative degradation of carboxyl-containing cellulose with iron salts [9]. We can suggest that this property of iron(III) salts in preparing Occelon resolving retention sutures (MCC–Fe–tannin complex) [10] is masked by cation complex formation not only with oxidized cellulose but also with tannin.

It should be noted that there is no correlation between the composition, concentration, and stability of polycomplexes and mechanical properties of the salt forms of low-substituted MCC. The table shows that the value of sorption of multicharged cations does not affect noticeably the thread in both dry and wet states and as a knot. In accordance with published data [11], this can be caused by two reasons. Firstly, bridging bonds formed by metal ions are rigid and do not provide a sufficient segmental mobility of macromolecules. Secondly, the formation of small amounts of cross-links between macromolecules of oxidized cellulose is accompanied by partial rupture of H bonds that existed before metal sorption.

CONCLUSION

Iron(III), aluminum(III), and chromium(III) cations sorbed with monocarboxy cellulose from chloride and sulfate solutions do not affect noticeably the cellulose mechanical properties. The degree of swelling of monocarboxy cellulose salt form, compared to its H form, depends on the type and content of the metal cation and, at the same composition of the polycomplex, is independent of preparation conditions (pH of the initial solution 1.6–4.0; salt concentration 0.02–0.17 M; sorption time no more than 24 h).

SORPTION AND ION-EXCHANGE PROCESSES

Planar Chromatography for Quantitative Analysis of Amino Acids in Fermentation Solutions of Industrial Producer Cultures

V. D. Krasikov and I. I. Malakhova

Lenkhrom Scientific and Technical Center, St. Petersburg, Russia

Received December 25, 2003; in final form, February 2004

Abstract—Proximate procedures for quantitative analysis of amino acids using high-performance thin-layer chromatography were developed.

Amino acids (hereinafter, natural *L*-amino acids) are the main building material in synthesis of specific tissue proteins, enzymes, peptide hormones, and other physiologically active compounds [1–5].

Analysis of amino acids in medicine, biochemistry, molecular genetics, etc. is problem of current unterest. Modern procedures for analysis of amino acid derivatives in albumin hydrolyzates, peptides, and biomedical samples are based on high-performance liquid chromatography. However, data on application of high-performance quantitative thin-layer chromatography (HPTLC) to separation of multicomponent mixtures of free amino acids (including 20 natural acids) are lacking.

In this study we developed chromatographic procedures for separation and quantitative determination of free amino acids in culture broths (CBs) of certain producer cultures. The main analytical method was HPTLC, and high-performance liquid chromatography (HPLC) was used for comparison [6–8]. In some specific cases, an amino acid analyzer (AA) was used.

It should be noted that the requirements to the reliability and adequacy of chromatographic procedures in biochemistry and biotechnology are essentially different. For example, procedures providing experimental error of no more than 15% and reproducibility of 90% are acceptable in biochemistry [9].

Similar requirements are imposed upon analytical chromatographic procedures in biotechnology at the stage of development of the producer cultures of amino acids. However, at the stage of optimization of the fermentation procedure the analysis error should not exceed 5%. The same requirement is imposed upon the chromatographic analysis in recovery and purification of the desired amino acid, because the error of 10–15% may cause either production of the preparation of insufficient purity or a significant loss unacceptable in the large-scale production.

EXPERIMENTAL

In our study we used densitometers (Shimadzu, Japan), a High Speed TLC Scanner CS-920 (Shimadzu, Japan), a TLC-Scanner-II (Camag, Switzerland), a DenSkan-01 video system (Lenkhrom, Russia), a DenSkan-04 video system (Lenkhrom, Russia), and a Delta Prep 3000 liquid chromatograph equipped with a Lambda Max 481 spectrophotometric detector and a 4.6×250-mm stainless steel column packed with μ-Bondapak C18 sorbent (5 μm, Waters, USA). The eluent was 10^{-3} M solution of copper(II) sulfate in 20% aqueous acetonitrile (0.5 ml min^{-1} flow rate, λ 235 nm).

The concentrations of some amino acids in CBs were measured using a Biocal amino acid analyzer (USA).

The tests were carried out using the following chromatographic plates: Sorbfil PTSKh-P-V (Institute of Macromolecular Compounds, Russian Academy of Sciences, Sorbpolymer Company, St. Petersburg, Russia) and Kieselgel 60 (Merck, Germany).

Mixtures of 1-propanol, 2-propanol, ethanol, ethyl acetate, chloroform, acetone, acetic acid, 25% aqueous ammonia, and water were taken as mobile phases.

(b) Exposure of the chromatogram to the NH solution for 20 s, *T* = 50°C. (*1*) Lysine; (*2*) serine, valine, and glutamic acid; and (*3*) phenylalanine. (c) Exposure of the chromatogram to the NH solution for 20 s, τ = 30 min. (*1*) Lysine; (*2*) serine, valine, and glutamic acid; and (*3*) phenylalanine.

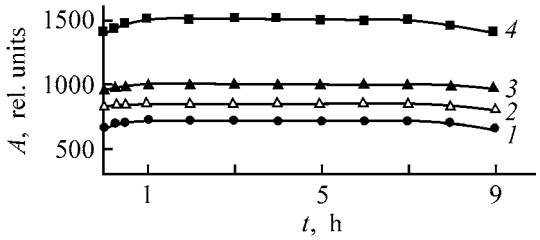

Fig. 2. Densimetric signal *A* of the spots of amino acids vs. time after completion of the color reaction on the chromatographic plate; system B as eluent, *T* = 21°C. (*1*) Lysine, (*2*) serine and valine, (*3*) glutamic acid, and (*4*) phenylalanine.

Organic solvents of ultrapure and chemically pure grades were used without additional treatment; water for analysis was prepared on a Super Q apparatus (Millipore, USA).

Free amino acids were separated on Sorbfil-P-V HPTLC plates based on silica gel with silica sol binder, which is an essential distinction of this chromatographic material from Silufol and Kieselgel 60 plates used previously in separation of free amino acids; this, in most cases hinders direct use of available data concerning mobile phases. Therefore, it was necessary to modify these mobile phases or develop new elution systems.

Amino acids (excluding tryptophan) were visualized in the chromatograms with ninhydrin (NH) solution, which was deposited on a chromatographic plate not by common spraying, but by immersion of the plate in a solution. This is due to the fact that the metrological characteristics of the results of quantitative analysis of some compounds (densitometry) with immersion were better than those obtained using the spraying procedure [12–15]. There are no data on the conditions for applying the ninhydrin reagent (immersion method) and performing the color reaction for amino acids. Therefore, we made special experiments to determine the optimal conditions of the color reaction on the chromatograms after their immersion in the ninhydrin solution (0.3% solution of ninhydrin in acetone containing 3% glacial acetic acid).

Using model mixtures of amino acids belonging to various classes (phenylalanine, lysine, glutamic acid, serine, and valine), we studied the dependences of the densimetric signal[1]/noise ratio (*S*/*N*) on the time of the exposure of a chromatogram to the NG solution (Fig. 1a), time of the color reaction (Fig. 1b), and temperature at which the color reaction was performed (Fig 1c).

These data showed that the optimal conditions for visualization of the spots of amino acid belonging to various classes are as follows: exposure of the chromatogram to the NH solution for 17–20 s; color reaction for 30–40 min at 45–50°C. Above 50°C, a light crimson background appears on the chromatogram surface owing to the thermal oxidation or condensation of the NH molecules.

In accordance with validation regulations of the planar chromatography (PC) [16] and for quantitative densimetric analysis, it was advisable to evaluate the coloration stability of the spots of the ninhydrin complexes on the chromatograms after completion of the color reaction.

We studied changes in the densimetric signals of some amino acids with time (Fig. 2). It can be seen

[1] The "densimetric signal" is the difference between the intensities of light of a certain wavelength reflected from the plate surface without and with a spot of a compound to be determined.

that the coloration of the spots of amino acids is stable in 0.5–7.0-h storage of the chromatograms in the dark at 21°C. These results were used in our experiments on visualization and quantitative analysis of amino acids.

Quantitative determination of serine, homoserine, and threonine. The CB of the serine producer culture often contains proline, glutamic acid, glycine, alanine, threonine, lysine, and, in rare cases, γ-aminobutyric acid. This mixture was separated using mobile phase A (designed with a PRIZMA model [17]): 2-propanol–acetone–ethyl acetate–25% aqueous ammonia–water (20 : 15 : 7 : 9 : 5 volume ratio); binary elution, l_1 = 75 and l_2 = 85 mm); R_f[2] of the serine spot was 0.40 (Fig. 3).

As a rule, the CB of the homoserine producer culture contains alanine, glutamic acid, lysine, glycine, isoleucine, and threonine. These amino acids were separated from homoserine using the same mobile phase A (binary elution, l_1 = 70 and l_2 = 80 mm); R_f of homoserine, alanine, and valine was 0.31, 0.25, and 0.38, respectively. Under these experimental conditions, threonine had R_f = 0.75 (Fig. 3).

As for CB of the threonine producer culture, it was treated using system B (2-propanol–ethyl acetate–25% aqueous ammonia–water, 20 : 20 : 1.5 : 25 volume ratio), which provided separation of threonine (R_f = 0.40) from the concomitant glutamic acid, lysine, glycine, and alanine. The content of the target amino acids in CB was determined on a DenSkan-01 video densitometer (Table 1). It was found that the concentration dependence of the densimetric signals of serine, homoserine, and threonine is linear in the 0.03–0.3 μg range, and the detection limit of these amino acids is 0.015 μg [18–22].

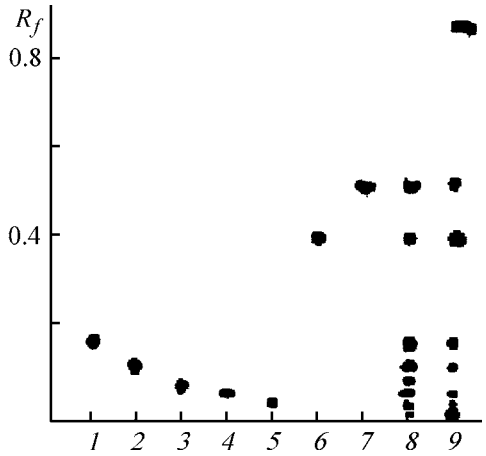

Fig. 3. Separation of amino acids in the CB of the serine producer culture; system A eluent, T = 20°C. (*1*) γ-Aminobutyric acid, (*2*) alanine, (*3*) glycine, (*4*) glutamic acid, (*5*) lysine, (*6*) serine, (*7*) threonine, (*8*) mixture of the above amino acids, and (*9*) CB of the serine producer culture.

[2] The retention factor R_f characterizes the spot location on the plate and is determined as the ratio of the distances from the start to the center of the spot and from the start to the eluent front.

Table 2. Response factor *a* of amino acids present in the CB of the serine producer (λ = 500 nm, Sorbfil HPTLC plates, Shimadzu CS-920 densitometer, $n = 5$, $P = 0.95$)

We determined the densimetric signals of the spots of amino acids accompanying serine (λ = 500 nm, content of each amino acid in the sample was 0.2 μg) and evaluated the correcting normalization coefficients (response factor); the magnitude of the densimetric signal of the serine spot was taken as unity (Table 2) [18–22].

Working with the serine producer culture required data not only on the content of the desired product, but also on the content of amino acids present in CB. This problem was solved with the use of the response factor; this parameter is widely used in liquid chromatography with spectrophotometric detection.

Quantitative determination of aromatic amino acids. Analysis of a tryptophan-containing CB, performed on the amino acid analyzer, showed that it also contained phenylalanine, tyrosine, leucine, isoleucine, threonine, valine, histidine, serine, lysine, glutamic acid, and asparagine. Such an amount of impurities significantly hindered complete separation of four aromatic amino acids: phenylalanine, tryptophan, and leucine-isoleucine mixture. Mobile system C (2-propanol–25% aqueous ammonia, 7 : 3 volume ratio) provided formation of compact tryptophan spots suitable for scanning ($R_f = 0.54$) and their separation from the spots of phenylalanine ($R_f = 0.65$) and valine ($R_f = 0.47$); however, the retention factors of leucine and isoleucine were very close ($R_f = 0.57$).

The selective quantitative determination of tryptophan in CB was provided using the modified Ehrlich reagent (0.5% ethanolic solution of *p*-dimethylaminobenzaldehyde containing 5% concentrated sulfuric acid) [19–21]. The quantitative analysis of chromatograms was performed by two procedures: (1) direct densimetric measurements of the tryptophan spots at λ = 276 nm and (2) immersion of the chromatograms in the detecting solution (I) and their spraying according to the Waldi procedure (II) [23], with subsequent heating at 110°C for 7–10 min (Table 3).

It was found that the spot color on the chromatograms is stable for at least a year of storage in the dark, and the concentration dependence of the densimetric signal magnitude is linear at the tryptophan content of 0.1 to 0.6 μg; the detection limit is 0.05 μg.

The quantitative analysis was performed simultaneously on Shimadzu CS-920 and DenSkan-01 densitometers. A comparison of the metrological characteristics of Shimadzu CS-920 (ε = 8–9%) and DenSkan-01 (ε = 3–5%) showed that the latter is preferable for immersion procedures [24, 25] (Table 3).

The reliability of the tryptophan CB analysis performed by procedure I (DenSkan-01 unit) was additionally checked using the amino acid analyzer (Table 4) [26–28].

An analysis of a series of CBs on the amino acid analyzer showed that phenylalanine is often accompanied by the following by-products: glycine, alanine, glutamic acid, threonine, valine, leucine, tyrosine, tryptophan, tyramine, and tryptamine. Phenylalanine was separated from the mixture of amino acids occurring in CB using mobile phase D (designed with a PRIZMA model [29]): chloroform–ethanol (96%)–glacial acetic acid–water, (19.0–27.0) : (20.0–26.0) : (13.5–16.0) : (1.3–3.5) volume ratio [28]. This system allowed separation of phenylalanine from concomitant amino acids and gave individual chromatograms of valine, leucine, tryptophan, and tyrosine. Thus, the problem of separation of the "critical triad" of phenylalanine, tyrosine, and tryptophan was solved for the first time using domestic Sorbfil plates in the onedimensional mode [28]. The chromatogram development (treatment with ninhydrin reagent and color reaction) was performed similarly to the case of serine; phenylalanine had $R_f = 0.73 \pm 0.03$ (Fig. 4).

It was found that the output signal of the densitometer is a linear function in the 0.1–1.0 μg concentration range of phenylalanine; the detection limit is 0.05 μg.

The results of phenylalanine analysis in various CB series with the DenSkan-01 densitometer well agree with HPLC data ($r = 0.991$; Table 5) [28, 30, 31].

Quantitative determination of the main amino acids (lysine, ornithine, and arginine). In CB, lysine is accompanied by glutamic acid, alanine, valine, leucine (isoleucine), and homoserine. These amino acids were separated with eluent E (2-propanol–25% aqueous ammonia, 55 : 45 volume ratio), which provides separation of lysine ($R_f = 0.40$) from the concomitant amino acids. The content of lysine in the CB samples was measured on a DenSkan-01 densitometer (the concentration dependence of the densimetric signal intensity is linear in the 0.015–0.2 μg range; de-

tection limit 0.009 μg) and using an HPLC device (Table 6, $r = 0.9907$).

The CBs of arginine and ornithine contain lysine, citrulline (arginine precursor), glutamic acid, alanine, valine, and leucine. Arginine ($R_f = 0.40$) and ornithine ($R_f = 0.62$) were separated from the above amino acids, using mobile phase G: 2-propanol–25% aqueous ammonia–water, (3.5–4.1) : (0.9–1.5) : (7.5–9.0) volume ratio [28] (Fig. 5). The quantitative analysis of the chromatograms was carried out on a DenSkan-04 densitometer.

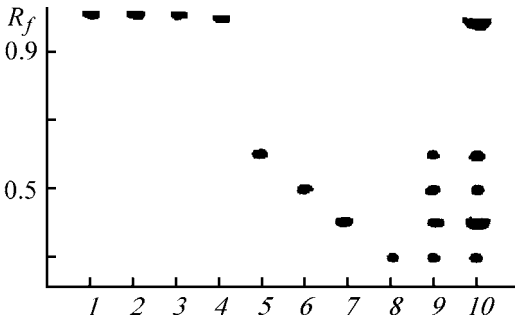

Fig. 5. Separation of amino acids in the CB of the arginine producer culture; system G as eluent, $T = 20°C$. (*1*) Glycine, (*2*) alanine, (*3*) glutamic acid, (*4*) valine, (*5*) ornithine, (*6*) lysine, (*7*) arginine, (*8*) citrulline, (*9*) mixture of the above amino acids, and (*10*) CB of the arginine producer culture.

It was found that the concentration dependences of the magnitudes of the densimetric signals of arginine and ornithine are linear in the 0.05–0.4 and 0.02–0.25 μg ranges for arginine and ornithine, respectively. The data on the content of these amino acids in various CB batches in comparison with HPLC results are listed in Table 7.

Quantitative determination of saturated amino acids (valine and leucine). The CB samples of the industrial valine and leucine producer cultures often contain homoleucine, lysine, glycine, alanine, glutamic acid, and isoleucine. Among these compounds, homoleucine is an especially undesirable impurity, because it significantly complicates purification of valine and leucine, cocrystallizing with them in the course of their recovery [32, 34]. The homoleucine content should not exceed 0.1%. At such a low content of this

impurity, whose properties are similar to those of the desired products, only expensive amino acid analysis is an alternative to the planar chromatography.

Amino acids were separated with eluent D (binary elution, $l_1 = 60$ and $l_2 = 65$ mm). After elution, we observed round compact spots of valine ($R_f = 0.49$), leucine ($R_f = 0.64$), and homoleucine ($R_f = 0.71$) in the chromatograms. The concentration range of the linear dependence of the densimetric signal is 0.04–0.4 μg (detection limit 0.02 μg).

The results of valine + homoleucine and leucine + homoleucine analysis are listed in Tables 8 and 9, respectively.

As can be seen from these data, only in six out of 14 CB samples the content of homoleucine is less than 0.1% with respect to the desired product.

This example confirms once again that planar chromatography allows a fast and reliable analysis of the content of impurities in the final product even when the impurity/product ratio is less than 1/1000. In this case, the time of the analysis is a decisive factor, because the accumulation of homoleucine (to 0.1% with respect to valine and leucine) proceeds, as a rule, in 3–5 h and prompt detection of this impurity indicates that the fermentation process should be terminated, which is especially important in the large-scale industrial production.

To suppress the biosynthesis of homoleucine, new producer cultures with greater degrees of leucine accumulation due to transaminase activation were designed by genetic engineering. However, an analysis of the fermentation solutions of these producer cultures indicated the presence of an unknown compound

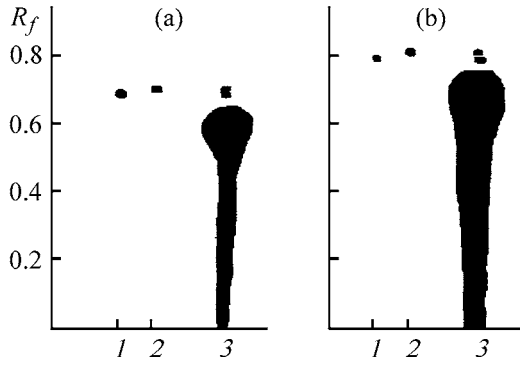

Fig. 6. Chromatogram of the CB of the leucine recombinant producer culture. (a) Keiselgel 60 HPTLC plates, system D as eluent, T = 20°C, single-step elution l = 55 mm; (b) ten-step elution (l_1 = 55, :, l_{10} = 85 mm, Δl = 3.0 mm). (*1*) Phenylalanine, (*2*) homoleucine, and (*3*) CB of the leucine produce culture.

whose R_f was greater than that of leucine, but smaller than that of homoleucine (Fig. 6a), and its mobility was similar to that of phenylalanine. Since accumulation of phenylalanine is untypical of the producer cultures used previously, this compound required additional identification. Homoleucine and unknown compound were separated by multiple elution under the isocratic conditions. They were separated after 10 elution steps (l_1 = 55, …, l_{10} = 85 mm, Δl = 3.0 mm) (Fig. 6b). The separation was performed on the Kieselgel 60 HPTLC plates with *in situ* spectrophotometric detection of the absorption spectra of the unknown compound and phenylalanine reference (Camag TLC Scanner II densitometer). It was found that the UV spectrum of this compound is similar to that of phenylalanine.

For additional identification, we recovered this compound from the CB by column chromatography and recorded its ^{1}H NMR spectrum, which was similar to that of the phenylalanine reference [35].

This example shows that the chromatographic procedures provide not only identification and quantitative analysis of the desired products and impurities, but also allow determination of the ways for improvement of the producer cultures and the conditions of their cultivation.

Quantitative determination of Schiff bases in CBs of industrial amino acid producer cultures. Schiff bases may cause loss in industrial biosynthesis of amino acids. At biosynthesis the pH of the fermentation solutions varies within 6.3–7.2. These conditions are favorable for formation of Schiff bases, i.e., the condensation products of amino groups in amino acidswith carbonyl groups of sugars, which are present in CBs and act as sources of carbon. It is known that Schiff bases are stable in aqueous solutions at pH 5.5–7.5 [36]; therefore, acidification of CB and use of eluents and detecting solutions containing acid or base reagents should cause decomposition of Schiff bases both in CBs and on the chromatographic plates. To verify this assumption, model solutions (equimolar mixtures) containing *D*-glucose and four amino acids (valine, phenylalanine, lysine, and serine) were incubated in a fermenter for 3 days at 35–37°C. Then, aliquot samples were deposited on plates (in the presence of references of *D*-glucose and amino acids, two replicate samples) and eluted using elution systems H (propanol–water, 70 : 30 volume ratio). The resulting chromatograms were treated with 1-butanol saturated with hydrochloric acid, dried, and then treated with a solution of ninhydrin and phosphomolybdic acid.

The ninhydrin reagent revealed the presence of a free amino acid and the same amino acid in the unknown product, and phosphomolybdic acid provided visualization of free glucose and glucose in the unknown product. To confirm the fact that this compound is the condensation product of amino acid and glucose, we determined the glucose:amino acid ratio in the unidentified products occurring after incubation in the four model systems. It was found that the glucose : amino acid ratio was 0.95 : 1.03 (except lysine), which confirmed the occurrence of condensation. Moreover, it was found that certain fractions of valine (6.3 ± 0.4%), phenylalanine (6.4 ± 0.4%), serine (5.8 ± 0.5%), and lysine (10.6 ± 0.4%) (n = 6, P = 0.95) were bound with sugar after incubation.

Based on the data for several drained CBs of the valine producer cultures grown on the media containing glucose, we found that 3.5 to 6.5% of the target product occurred in the form of Schiff bases by the end of the fermentation process (n = 5, P = 0.95) [37, 38].

Sample no.	Content of Schiff Base, %
1	4.3 ± 0.4
2	3.5 ± 0.4
3	6.5 ± 0.3
4	6.3 ± 0.4
5	4.1 ± 0.4

These results indicate that the drained CBs of the amino acid producer cultures should be acidified before recovery. We recommended to include acidification in the flowsheets of the amino acid production.

CONCLUSIONS

(1) The optimal conditions of the color reaction on the chromatograms in the course of the quantitative analysis of amino acids were determined. Chromatograms were immersed in the ninhydrin solution for 17–20 s, the color reaction was performed for 30–40 min at 45–50°C. The color of the spots of the reaction products of ninhydrin and amino acids is stable at 21°C for 0.5–7.0 h in the dark.

(2) Procedures were developed for quantitative analysis of aromatic, basic, saturated, and hydroxy amino acids in culture broths of the producer cultures: serine, threonine, homoserine, tryptophan, phenylalanine, lysine, ornithine, arginine, valine, and leucine. The undesirable admixtures of homoleucine and phenylalanine in the cultural broths of the valine and leucine producer cultures can be determined at their content less than 0.1% with respect to the desired products.

(3) The possibility of formation of the condensation products of amino acids with carbohydrates (Schiff bases) was confirmed experimentally. It was found for the example of the drained cultural broth of the valine producer culture that the content of Schiff base may be as high as 6% with respect to the target product. It is recommended to include in the flowsheet the stage of acidifying of the cultural broth of the amino acid producer cultures before recovery in order to improve the yield of the desired product.

Received March 28, 2003; in final form, September 2003

Abstract—Solid electrolytes were synthesized in the systems Li_2O–Al_2O_3–TiO_2–P_2O_5 and Li_2O–Al_2O_3–TiO_2–P_2O_5–H_2O–H_2O_2. Their ionic conductivities were studied and compared. The possibility of obtaining a film of $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ solid electrolyte on a sapphire substrate from an aqueous peroxide solution of a precursor was analyzed.

To be suitable for practical application in chemical power cells or secondary batteries, a solid electrolyte must primarily have the maximum ionic conductivity, so that potential drop across the internal resistance of a cell be much lower than its working voltage. Presently, only few lithium-based solid electrolytes with a room-temperature ionic conductivity on the order of 10^{-3} Cm cm^{-1} are known [1]. These are, in the first place, lithium analogues of nasicons, compounds based on double lithium and titanium phosphates, in which some Ti^{4+} cations are replaced with In^{3+}, Sc^{3+} or Al^{3+} cations.

An important requirement to the solid electrolytes of lithium power cells is their high chemical stability when in contact with cathode and anode materials. In this case, it is necessary to take into account that metallic lithium or lithium alloys used as anode are rather chemically active. The known solid electrolytes based on double lithium and titanium phosphates are chemically unstable at elevated temperatures because of the interaction of metallic lithium with titanium phosphate [2]. Hence follows that, to enhance the chemical stability of this type of solid electrolytes, it is necessary to decrease the content of titanium and phosphate groups in them.

Previously [3], $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ solid electrolytes have been synthesized by the ceramic method. However, this technique has some drawbacks limiting its application in the cases of increased requirements to the stability and reproducibility of properties of the materials. These drawbacks are due to the mechanism of solid-state reactions, which occur originally at the interface and then continue owing to the diffusion of atoms across a layer of the products formed. In the course of a reaction, the diffusion length increases and the reaction rate decreases. The ceramic process can commonly come to sufficiently full completion only in the case of an intermediate multiple grinding of the reaction mass. But even then, the required chemical and structural homogeneity of the product cannot be always achieved. To overcome the above difficulties, various modifications of the ceramic method, based on a number of procedures for preliminary homogenization down to the molecular level of the solid-phase reaction mixture, have been suggested. These are coprecipitation of components from solutions, drying of solutions by spraying, pulverization of the solutions into liquid nitrogen (cryochemical method), or sol–gel procedure. The sol–gel method shows promise for synthesis of lithium-based solid electrolytes [4].

The goal of this study was to search for ways to raise the ionic conductivity and chemical stability of phosphate lithium-conducting solid electrolytes in the solid-phase and sol–gel syntheses.

EXPERIMENTAL

As starting reagents were used Li_2CO_3 (special purity); $LiNO_3$ (analytically pure); $Al(NO)_3 \cdot 9H_2O$,

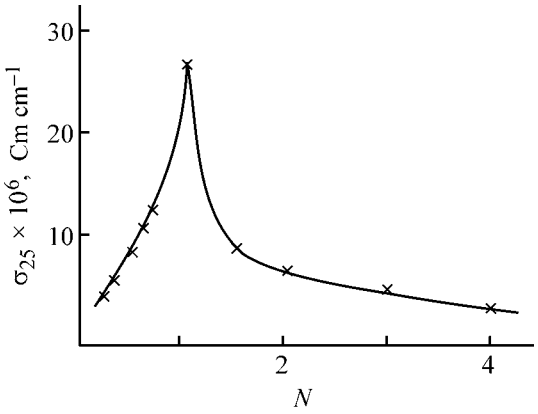

Fig. 1. Ionic conductivity σ_{25} of double lithium and titanium phosphates vs. Li_2O : TiO_2 molar ratio *N*.

Al_2O_3, and $(NH_4)_2HPO_4$ (all chemically pure); TiO_2 (special purity); and $(NH_4)_2TiO(SO_4)_2 \cdot H_2O$ (chemically pure). Freshly precipitated titanium(IV) hydroxide was obtained by dissolving a weighed portion of titanium(IV) oxide of the anatase modification in hydrofluoric acid. The resulting acid fluoride solution was heated to 50–60°C and added in small portions to a 25% solution of ammonium hydroxide under vigorous agitation. The precipitated amorphous titanium(IV) hydroxide was washed with a 5% NH_4OH solution to remove fluoride ions by repulping. The content of the F^{-1} ions was controlled potentiometrically using a Kh-F-001 fluoride-selective electrode. The content of the F^{-1} ions in the washing water from the final repulping was 10 mg l^{-1} and less.

The method for determining the ionic conductivity σ_{25} (at 25°C) of the samples of lithium-conducting solid electrolytes has been described in detail previously [5]. The measurements were done on an E7-12 digital LCR-meter at a frequency of 1 MHz in a cell with graphite electrodes on several pellets of different heights. For samples of the same composition, the σ_{25} values were reproduced to within ±5%.

Table 1. Ionic conductivity of $Li_{2+x}Al_xTi_{1-x}(PO_4)_2$ and $Li_{2-3x}Al_xTi_{1-x}(PO_4)_2$ solid solutions

Solution	Composition	σ_{25}, Cm cm^{-1}
(I)	$Li_2Ti(PO_4)_2$	2.7×10^{-5}
	$Li_{2.1}Al_{0.1}Ti_{0.9}(PO_4)_2$	1.3×10^{-4}
	$Li_{2.2}Al_{0.2}Ti_{0.8}(PO_4)_2$	3×10^{-5}
	$Li_{2.3}Al_{0.3}Ti_{0.7}(PO_4)_2$	2.3×10^{-5}
(II)	$Li_2Ti(PO_4)_2$	2.7×10^{-5}
	$Li_{1.7}Al_{0.1}Ti(PO_4)_2$	2.7×10^{-4}
	$Li_{1.4}Al_{0.2}Ti(PO_4)_2$	5.4×10^{-4}
	$Li_{1.1}Al_{0.3}Ti(PO_4)_2$	5.6×10^{-4}
	$Li_{0.8}Al_{0.4}Ti(PO_4)_2$	2.5×10^{-4}

The electronic conductivity σ_e was determined by the polarization Wagner method in a cell with irreversible graphite electrodes. A voltage lower than the voltage of electrolyte decomposition was applied to the measuring cell and the current in the circuit was measured with a U5-11 charge amplifier [6].

The phase composition of the products synthesized was studied by X-ray phase analysis (DRON-2 diffractometer, Cu_{K_α} radiation, graphite monochromator).

The base component of the known lithium-conducting solid electrolyte $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ is double phosphate $LiTi_2(PO_4)_3$ with the molar ratio Li_2O : TiO_2 = 1 : 4. No data for double lithium and titanium(IV) phosphates with other molar ratios are available.

The synthesis of double lithium and titanium(IV) phosphates and the measurement of their ionic conductivity were performed at the Li_2O : TiO_2 ratio in the range from 1 : 4 to 4 : 1. These compounds were synthesized by the ceramic method [3] at the temperature of the final sintering stage equal to 800–1000°C, depending on composition. The results obtained in a study of σ_{25} of the samples obtained are presented in Fig. 1. It can be seen that the optimal composition is obtained at Li_2O : TiO_2 = 1 : 1 and corresponds to chemical formula $Li_2Ti(PO_4)_2$. The generally accepted composition $LiTi_2(PO_4)_3$ is unremarkable.

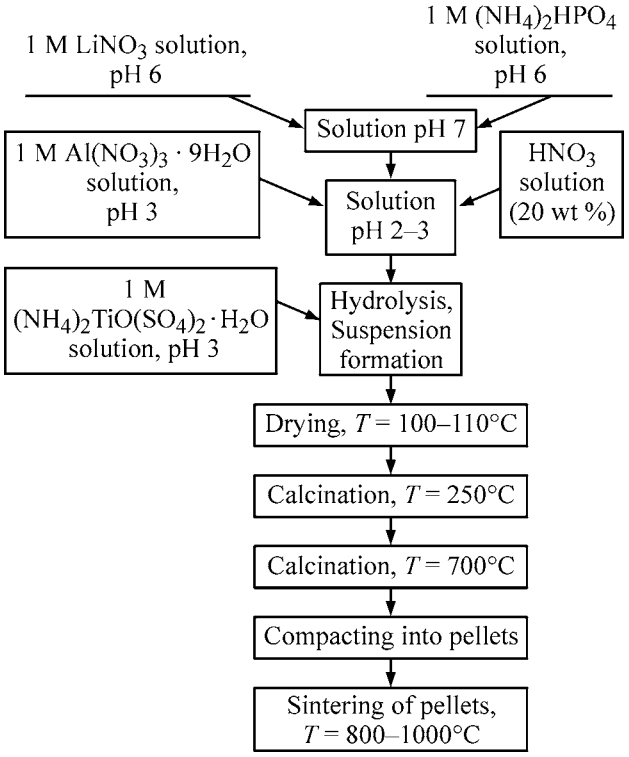
To study the influence exerted on the ionic conductivity by the $Ti^{4+} \rightarrow Al^{3+} + Li^+$ heterocharge substitution, experiments on the synthesis of $Li_{2+x}Al_xTi_{1-x}(PO_4)_2$ solid solutions were performed. The results presented in Table 1 show that such a substitution results in an increase in the ionic conductivity only at $x = 0.1$.

Because the composition $Li_2Ti(PO_4)_2$ is characterized by relatively high concentration of lithium ions, it was appropriate to perform the heterocharge substitution $3Li^+ \rightarrow Al^{3+}$. The data of Table 1 show that this type of heterocharge substitution considerably increases the ionic conductivity in the range $0.1 \le x \le 0.4$, with the ionic conductivity of the composition $Li_{1.1}Al_{0.3}Ti(PO_4)_2$ being the highest.

The results of experiments with mixed heterocharge substitution, i.e, with joint occurrence of $Ti^{4+} \rightarrow Al^{3+} +$

Li^+ and $3Li^+ \rightarrow Al^{3+}$ processes, are listed in Table 2. It can be seen that the composition $Li_{1.4}Al_{0.2}Ti(PO_4)_2$, in which the Ti : Li and PO_4^{-3} ratios are 0.71 and 1.43, respectively, is the most promising from the standpoint of chemical stability. At the same time, for the generally accepted composition $Li_{1.3}Al_{0.3}Ti(PO_4)_2$, these ratios are 1.3 and 2.31.

The room-temperature electronic conductivity of $Li_{1.4}Al_{0.2}Ti(PO_4)_2$ is 3×10^{-8} Cm cm^{-1}. Its ionic conductivity linearly increases in the range 25–100°C from 5.4×10^{-4} to 8.1×10^{-4} Cm cm^{-1}.



Scheme of the sol–gel process.

The sol–gel synthesis of lithium-conducting phosphate solid electrolytes was performed using 1 M aqueous solutions of the starting reagents, $LiNO_3$, $Al(NO_3)_3$, $(NH_4)_2HPO_4$, and $(NH_4)_2TiO(SO_4)_2 \cdot H_2O$, taken in stoichiometric amounts in accordance with the formula $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$. The process by which the solid electrolyte was synthesized is illustrated by the scheme. A neutral solution of $LiNO_3$ (pH 6) and a weakly alkaline solution of $(NH_4)_2HPO_4$ (pH 8) were poured together, and the acidity of the resulting solution was adjusted to pH 2–3 with a 20% solution of HNO_3. Then, $Al(NO_3)_3$ (pH 3) and $(NH_4)_2TiO(SO_4)_2$ (pH 1) solutions were successively poured-in under vigorous agitation. As a result, a white suspension was formed. The necessary condition was that the pH value was preliminarily adjusted to pH 2–3. Otherwise, crystalline quick-settling precipitate appeared in the solution instead of a suspension. The suspension obtained was poured onto a fluoroplastic pan, evaporated, and dried at 100–110°C for 8 h. As a result, a precursor of the solid electrolyte was formed as a loose bulky powder.

Table 2. Ionic conductivity of $Li_2Ti(PO_4)_2$-based solid solutions with a mixed heterocharge substitution

Composition	σ_{25}, Cm cm^{-1}
$Li_{0.9}Al_{0.1}Ti_{1.2}(PO_4)_2$	1.4×10^{-4}
$Li_{1.0}Al_{0.2}Ti_{1.1}(PO_4)_2$	6.2×10^{-4}
$Li_{1.1}Al_{0.3}Ti(PO_4)_2$	5.6×10^{-4}
$Li_{1.2}Al_{0.4}Ti_{0.9}(PO_4)_2$	2.4×10^{-4}
$Li_{1.3}Al_{0.1}Ti_{1.1}(PO_4)_2$	4.2×10^{-4}
$Li_{1.4}Al_{0.2}Ti(PO_4)_2$	5.4×10^{-4}
$Li_{1.5}Al_{0.3}Ti_{0.9}(PO_4)_2$	1.4×10^{-4}
$Li_{1.8}Al_{0.2}Ti_{0.9}(PO_4)_2$	1.1×10^{-4}

To obtain the final product, the precursor was calcined. The temperature mode and calcination time were determined from the results of thermal and X-ray phase analyses. According to the thermal analysis, the weak endothermic effects exhibited by the electrolyte precursor (Fig. 2) at temperatures of up to 158°C are due to removal of water. The exothermic effect at 254–293°C is associated with the interaction of $LiNO_3$ and $(NH_4)_2HPO_4$, with evolution of nitrogen oxides and $NH_3 \cdot (NH_4)_2TiO(SO_4)_2$ decomposes within the range 400–700°C. At higher temperatures, no thermal effects or mass loss was observed. There-

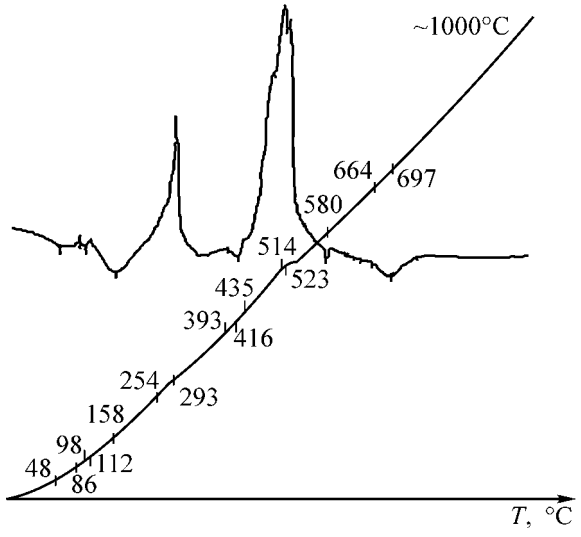


Fig 2. Thermogram for a precursor of lithium-conducting solid electrolyte $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$. ($T$) Temperature.

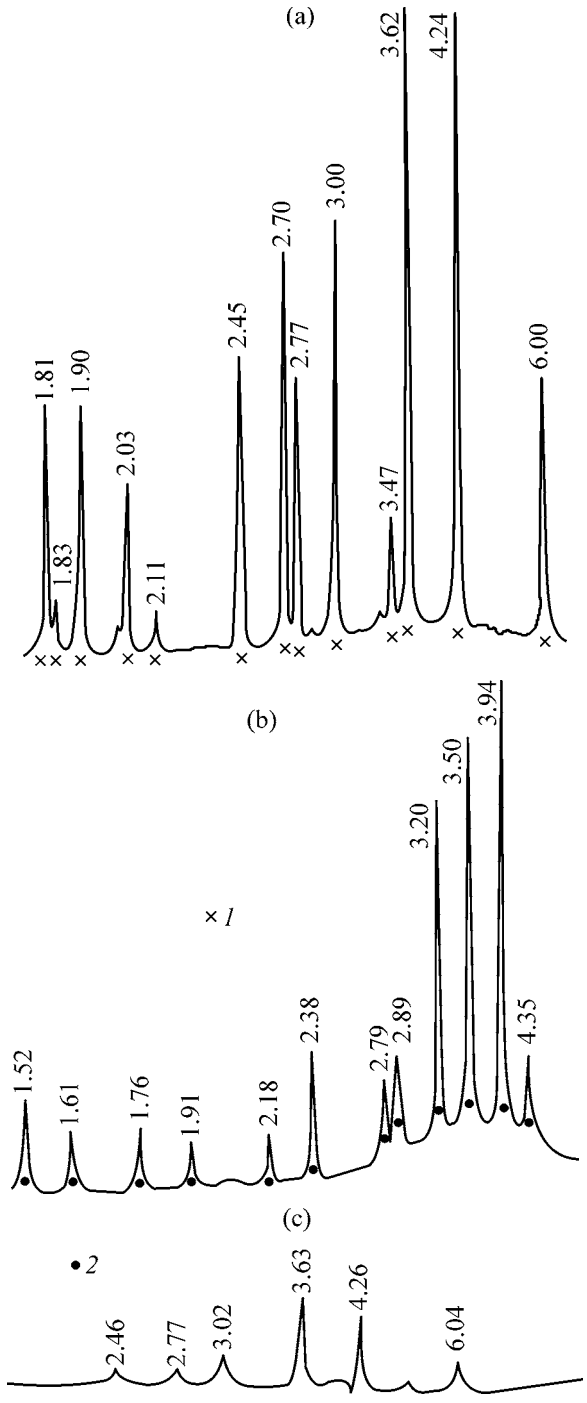

Fig. 3. Diffraction patterns of (a) lithium-conducting solid electrolyte $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$, (b) product of a synthesis of solid electrolyte with a 1.5-fold excess of H_3PO_4, and (c) $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ film on a sapphire substrate. (*1*) $LiTi_2(PO_4)_3$ and (*2*) TiP_2O_7.

fore, the temperature was raised stepwise to 700°C. The precursor powder was kept at 250°C for 1 h (till gas evolution stopped) in the first stage and at 700°C for 2 h in the second. The product obtained (bulky, loose, and easily disintegrating) was compacted into pellets 12 mm in diameter and 2–3 mm thick and sintered at 800–1000°C. The sintered pellets frequently separated into layers, cracked, and deformed. To improve sintering and avoid deformation of the pellets, a C_2H_5OH binder was introduced into the powder before compaction. The diffraction patterns of the electrolyte samples sintered at $T > 800$°C contain only reflections associated with $LiTi_2(PO_4)_3$ (Fig. 3a). As follows from Table 3, the highest ionic conductivity $\sigma_{25} = 5 \times 10^{-4}$ Cm cm^{-1} is observed for the electrolyte sample sintered at 1000°C for a long time (7h).

In preliminary studies, we established that freshly precipitated titanium(IV) hydroxide satisfactorily dissolves in the form of a peroxide complex in an acid medium. To synthesize lithium-conducting solid electrolyte $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$, a freshly precipitated titanium(IV) hydroxide was dissolved in initial experiments in a mixture containing 40 vol % H_3PO_4 (acid concentration 85 wt %) and 60 vol % H_2O_2 (peroxide concentration 30 wt %). After stoichiometric amounts of aqueous solutions of $LiNO_3$ and $Al(NO_3)_3$ were added to the resulting titanium(IV) peroxide solution, a transparent solution (pH 0.7) of intense ruby color was formed. After evaporation of this solution at 150–160°C and subsequent drying of the precipitate at 300°C, a white powder was formed. The powder was compacted into pellets and sintered at 900°C for 1 h, with a mass loss of 35%. The sintered pellets were porous and could be easily broken. To obtain high-density pellets, sintering was performed at 1000°C for 1 h. It was found that the ionic conductivity is about 1×10^{-7} Cm cm^{-1}, i.e., is lower by three orders of magnitude than the predicted value. Additional sintering at 1200°C did not affect σ. According to XPA, the diffraction pattern of the product synthesized contains no reflections corresponding to $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ (Fig. 3b), with the main reflections belonging to titanium diphosphate TiP_2O_7. Apparently, titanium(IV) polyphosphates, which do not decompose even at high temperature, are formed owing to excess content of H_3PO_4 in the initial solution.

In this connection, HNO_3 was used for obtaining an acid medium in dissolution of a freshly precipitated titanium(IV) hydroxide. The freshly precipitated titanium(IV) hydroxide was dissolved in a mixture containing 70 vol % HNO_3 (65 wt % concentration) and 30 vol % H_2O_2 (30 wt % concentration). To the resulting solution, stoichiometric amounts of aqueous solutions of $LiNO_3$, $Al(NO_3)_3$, and H_3PO_4 were added under agitation. The resulting aqueous peroxide solution of ruby color was transparent and contained 160–170 g l^{-1} of the final product. Evaporating the solution

in a desiccator at 150–160°C yielded a white powder, which was sintered at 900°C for 1 h with a mass loss of 31%. The powder was compacted into pellets and sintered at 1000°C for 1 h. The ionic conductivity of the sintered pellets was 6×10^{-4} Cm cm^{-1}, which coincides with the conductivity of $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ samples obtained by the solid-phase synthesis. The electronic conductivity did not exceed 2×10^{-8} Cm cm^{-1}.

The scheme described was used to synthesize $Li_2Ti(PO_4)_2$ solid electrolyte and a number of electrolytes on its basis. The ionic conductivities of the samples synthesized are listed in Table 4.

It can be seen that the ionic conductivities of the samples obtained by two methods are virtually the same.

The main advantage of the method developed for preparing stable aqueous peroxide solutions in the Li_2O–Al_2O_3–TiO_2–P_2O_5–H_2O–H_2O_2 system consists in the possibility of using such solutions for obtaining thin films of solid electrolytes. Aqueous peroxide solution of a precursor of the $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ electrolyte, which contained glycerol as a film-forming agent, was used to deposit films onto substrates by "dipping" method.

A solution containing (per 100 ml) 12 g of a precursor of the $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ solid electrolyte and 5 ml of glycerol was stable (i.e., retained transparency and homogeneity) for seven days. To apply a film, the substrate was dipped into a solution and then withdrawn at a rate of 0.6 cm min^{-1}, dried in air, annealed at 450°C for 15 min, and cooled to room temperature. Then the solution was applied to the substrate again, only with the sample annealed at 850°C for 30 min this time. The existence of the film was confirmed by visual observation under a Neophot-2 microscope (magnification 200). An X-ray phase analysis showed that four relatively weak reflections (6.04, 4.26, 3.63, and 3.02 Å), which are characteristic of a powder-like electrolyte, are present in the diffraction pattern of the film obtained (Fig. 3c). The study performed demonstrated that dipping is a suitable method for obtaining on appropriate substrates films of lithium-conducting titanium phosphate solid electrolytes, which are promising for fabrication of thin-film chemical power cells.

CONCLUSIONS

(1) A study of the ionic conductivity of solid electrolytes obtained by the solid-phase method in the Li_3PO_4–$Ti_3(PO_4)_4$ system established that the maximum conductivity ($\sigma_{25} = 2.7 \times 10^{-5}$ Cm cm^{-1}) is observed for the composition $Li_2Ti(PO_4)_2$. The $Li_{1.4}Al_{0.2}Ti(PO_4)_2$ solid electrolyte with $\sigma_{25} = 5.4 \times 10^{-4}$ Cm cm^{-1} and the Ti : Li and PO_4^{3-} : Li molar ratios of 0.71 and 1.43, respectively, was obtained upon heterocharge substitution of some Li^+ ions for Al^{3+} ions in this compound. The same ratios for the generally accepted composition $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ are 1.3 and 2.31.

Table 3. Ionic conductivity of $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ at different conditions of pellet sintering

T_{sin}, °C	τ_{sin}, h	h_{tab}, cm	σ_{25}, Cm cm^{-1}
800	2	0.227	4×10^{-5}
	4	0.181	1.1×10^{-4}
900	2	0.130	3.9×10^{-4}
	7	0.118	3.8×10^{-4}
1000	2	0.428	3.8×10^{-4}
	7	0.427	5.0×10^{-4}

Table 4. Ionic conductivity of $Li_2Ti(PO_4)_2$-based solid electrolytes

Composition	σ_{25},* Cm cm^{-1}
$Li_{1.1}Al_{0.3}Ti(PO_4)_2$	4.8×10^{-4} (5.6×10^{-4})*
$Li_{1.4}Al_{0.2}Ti(PO_4)_2$	4.5×10^{-4} (5.4×10^{-4})
$Li_{1.6}Al_{0.2}Ti(PO_4)_2$	2×10^{-4}
$Li_2Ti(PO_4)_2$	1×10^{-4} (1×10^{-4})

* The σ_{25} values for samples obtained by solid-phase method are given in parentheses.

(2) A method for obtaining stable aqueous peroxide solutions of precursors of solid electrolytes in the Li_2O–Al_2O_3–TiO_2–P_2O_5–H_2O–H_2O_2 system was developed. It was established that the solid electrolytes obtained from these solutions compare well in the ionic conductivity with electrolytes synthesized by the solid-phase method.

(3) It was shown that aqueous peroxide solutions of precursors are suitable for obtaining films of lithium-conducting titanium phosphate solid electrolytes on appropriate supports, which are promising for fabrication of thin-film chemical power cells.

Abstract—Linear voltammetry, X-ray phase and differential thermal analyses, diffuse reflection IR Fourier spectroscopy, Raman spectroscopy, and scanning electron microscopy (SEM) were used to study the electrochemical oxidation of galenite in carbonate electrolytes.

The current interest in studying the oxidation of sulfides contained in wastes formed in extraction and concentration of ores stems from the fact that this process gives environmentally hazardous water-soluble salts of non-ferrous metals and changes the technological properties of mining wastes, part of which is presently regarded as deposits of technological origin [1–4].

The part played by a particular mechanism of oxidation of sulfides is determined by the climatic, hydrologic, and geochemical conditions of storage of mining wastes [5–7]. Frequently, electrochemical processes govern the kinetics of oxidation of sulfide mixtures both during storage of mining wastes and in flotation [8–13].

In this study, we examined the electrochemical oxidation of PbS in a 0.7 g l^{-1} solution of K_2CO_3 (pH 10.2). As shown previously [7], carbonate solutions are formed in weathering of chemically active nonmetalliferous minerals, such as dolomite, calcite, and others. Therefore, a solution of K_2CO_3 was chosen as a model solution. The results of the study could also be useful for better understanding of flotation processes. This study proceeds with investigation [14–16] of the electrochemical oxidation of the surface of sulfide minerals in carbonate solutions.

The electrochemical properties of PbS have been described in a number of publications, mostly for the case of flotation [8, 9, 17–24]. Anodic polarization of PbS at pH 6.8–11 results in the formation of a layer of PbO and S^0, which inhibits further oxidation [9]. The authors emphasize that, in opinion of a number of researchers, the thiosulfate ion is a major product of PbS oxidation in alkaline solutions. The formation of $S_2O_3^{2-}$ was established in [18, 19]. The IR Fourier spectroscopy of disturbed total internal reflection was used to identify *in situ* the compounds formed on the surface of galenite in the case of anodic polarization at potentials of –0.5…+0.7 V relative to a standard hydrogen electrode in a deoxygenated $Na_2B_4O_7$ solution (pH 9.18) [21]. It was concluded that lead hydroxide is formed on the surface of PbS by the "salt-film" mechanism. In the next stage of oxidation, PbS_2O_3 and $PbSO_3$ are formed [21]. In [22], the surface of PbS was studied electrochemically in solutions of various acids, and it was shown that the passivation is not associated with shielding of the electrode surface with sulfur, and lead salts and oxides, as well as acid anions, are directly involved in the electrochemical reactions. It was of interest to verify this assumption in the case carbonate alkaline solutions.

The following methods were used in the study: linear voltammetry with fast and slow potential sweeping, potentiostatic electrolysis, X-ray phase and differential thermal analyses, diffuse reflection IR Fourier spectroscopy, Raman spectroscopy and SEM. Natural galenite (Rudnyi Altai) was used, from which an edge electrode with area of about 10 mm^2, embedded in epoxy resin, was fabricated. An insulated copper wire served as a current lead. The electrode surface was polished and washed with distilled water and ethanol before each experiment. Silver chloride electrode was used as reference, and a platinum mesh (surface area of about 15 cm^2), as auxiliary electrode.

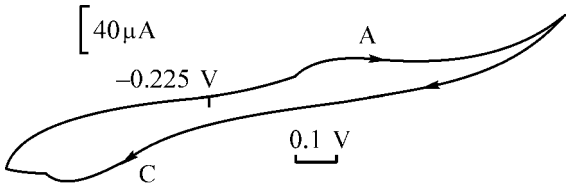

Fig. 1. Cyclic voltammogram of galenite at a potential sweep rate of 0.2 V s^{-1}.

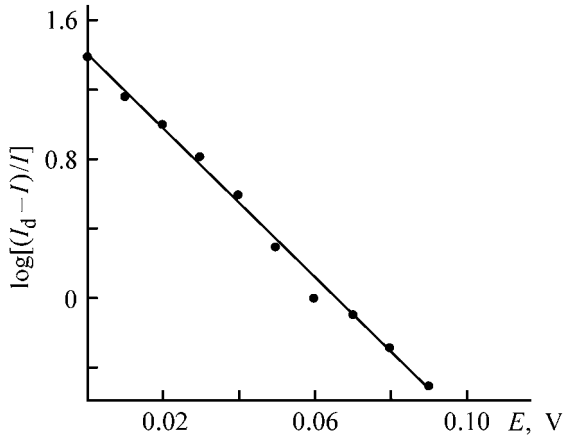

Fig. 2. $\log[(I_d - I)/I]$–E dependence. Potential sweep rate 0.001 V s^{-1}.

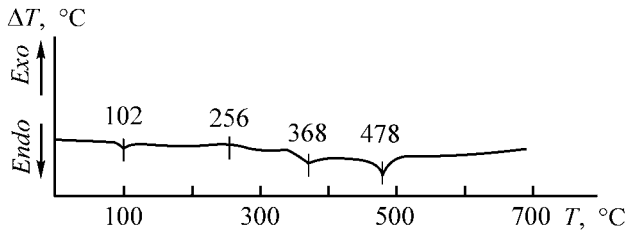

Fig. 3. Thermogram of the anodic products. Sample mass 6 mg, heating rate 15 deg min^{-1}. (T) Temperature.

The study was performed in argon atmosphere. The electrodes were polarized using a PI-50.1 potentiostatand a PR-8 programming unit. Voltammetric curves were recorded with a PDA-1 potentiometer.

An X-ray phase analysis of the products of the electrode reactions was done using an RKU-114 Debye chamber (Cu_{K_α} radiation). An IR spectroscopic analysis of the electrolysis products was performed with a Perkin-Elmer 2000 IR Fourier spectrometer. Raman spectra were recorded on a Renishaw 2000 Raman microscope.

A microscopic study was done on a Hitachi-405 electron microscope, and the differential thermal analysis, on an installation described in [25].

The electrode was polarized starting from the stationary potential of galenite, which is equal to –0.225 V relative to a silver chloride reference electrode. A typical cyclic voltammogram measured at a potential sweep rate of 0.2 V s^{-1} is shown in Fig. 1. It can be seen that the anodic polarization is characterized by a current peak A, to which corresponds a cathodic peak C. At potentials of +0.23…+0.54 V the voltammetric curve shows a plateau. The manner in which the potential of peak A depends on the rate of electrode polarization suggests that the anodic process is controlled by charge-transfer (the potential is shifted into the anodic region as the polarization rate increases).

For a voltammogram with fast potential sweep rate, the product βn_β can be calculated using the Matsuda–Ayabe equation [26]:

$$E_p - E_{p/2} = 1.857RT/\beta n_\beta F, \quad (1)$$

where β is the transfer coefficient; n_β, the number of electrons; and E_p and $E_{p/2}$, the peak and half-peak potentials, respectively.

Estimating the number of electrons involved in the anode reaction at polarization rates in the range 0.2–2 V s^{-1} yields an average value of 2.45 at β = 0.5.

For a steady-state voltammetric curve, the βn_β product can be calculated using the Frumkin–Bagotskii equation [26]:

$$E = E_{1/2} + 2.303RT/(\beta n_\beta F)\log[(I_d - I)/I], \quad (2)$$

where E is potential (V); I, the current density; and I_d, the limiting current density (A m^{-2}).

The $\log[(I_d - I)/I]$–E dependence measured for process A at a potential sweep rate of 0.001 V c^{-1} is shown in Fig. 2. The value obtained using Eq. (2) is n_β = 2.48 at β = 0.5.

Potentiostatic electrolyses at A-wave potentials of +0.14 and +0.5 V were performed. The phases newly formed on the surface of the mineral were carefully detached and studied by X-ray phase analysis, IR and Raman spectroscopies, differential thermal analysis, crystal-optical method, and SEM.

The X-ray phase analysis revealed the formation of basic lead carbonate $Pb_3(OH)_2(CO_3)_2$. The DTA curve for the new formations shows endothermic peaks at 102, 368, and 478°C and an exothermic peak at 256°C (Fig. 3). Probably, the first endothermic effect corresponds to melting of sulfur, and the exothermic effect, to its oxidation [27]. The second and third endothermic effects can be assigned to dissociation of $Pb_3(OH)_2(CO_3)_2$ to give $PbCO_3$ and nPbO · $PbCO_3$

[27, 28]. Figure 4a shows a diffuse reflection IR Fourier spectrum of the anodic products after the electrolysis in the range of the A-wave potentials. It contains bands at 680, 1046, 1104, 1435, 1734, 2413, and 2922 cm^{-1}. These bands are typical of basic lead carbonate $Pb_3(OH)_2(CO_3)_2$ [29–31]. Figure 5 shows the Raman spectrum of these products. The peaks at 146, 216, 427, and 464 cm^{-1} are characteristic of elementary sulfur [32]. The surface morphology of the galenite electrode after the electrolysis is shown in Fig. 6.

With account of the aforesaid, the electrode reaction can be hypothetically represented as

$$3PbS + 2H_2O + 2K_2CO_3 = Pb_2(OH)_2(CO_3)_2 + 3S + 4K^+ + 2H^+ + 6e. \quad (3)$$

Upon further polarization, S^{2-} is oxidized to oxidation numbers higher than S^0. The anodic products formed upon electrolysis at +0.5 V were studied by IR Fourier spectroscopy of diffuse reflection. Their typical spectrum is shown in Fig. 4b. Along with the bands characteristic of basic lead carbonate, the spectrum contains bands at 982 and 1118 cm^{-1}, probably associated with lead thiosulfate [29–31]. Thus, at potentials corresponding to the plateau, the sulfide sulfur is oxidized to thiosulfate ions $S_2O_3^{2-}$. The reaction can be represented as:

$$6PbS + 14H_2O + CO_3^{2-} = 3PbS_2O_3 + Pb_3(OH)_2(CO_3)_2 + 26H^+ + 28e. \quad (4)$$

After grinding of the mineral in an alkaline medium in air, $Pb_3(OH)_2(CO_3)_2$ and PbS_2O_3 are formed on the surface of galenite [31]. In [33], a similar mechanism of PbS oxidation was suggested to describe the surface processes that occur on galenite in flotation.

$$2PbS + 2H_2O + CO_3^{2-} = Pb(OH)_2 + PbCO_3 + 2S + 2H^+ + 4e. \quad (5)$$

CONCLUSION

The study of the electrochemical oxidation of galenite in a carbonate solution showed that the carbonate ion affects the formation of new phases on the surface of the mineral. It was established that $Pb_3(OH)_2(CO_3)_2$, PbS_2O_3, and S^0 are formed.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Corrosion-Electrochemical Behavior of Special-Purity Aluminum and Its AK1 Alloy Alloyed with Scandium

I. N. Ganiev

Nikitin Institute of Chemistry, Academy of Sciences of Tajikistan, Tajikistan

Received October 21, 2003

Abstract—The anodic behavior of aluminum of varied purity and the effect of scandium on the corrosion resistance of AK1 alloy based on special-purity aluminum in NaCl electrolyte solutions was studied.

Aluminum and its alloys are used as construction materials in a wide variety of fields of technology [1]. In a certain state and under severe working conditions, aluminum alloys may suffer dangerous types of corrosive destruction. Of particular interest is the corrosion of aluminum is nearly neutral solutions ($6 < pH < 8$). This is corrosion in natural media, such as seawater and water in lakes and rivers, potable water, and atmospheric precipitation. Under these conditions at ordinary temperatures, the rate of aluminum reaction with H^+ ions or H_2O molecules with evolution of hydrogen is negligible [2].

In this study, experiments were carried out in neutral solutions that contained NaCl in various concentrations, in accordance with the recommendations of GOST (State Standard) 9.017–74, i.e., in solutions imitating seawater, in order to reveal the influence exerted by chloride ions on the corrosion-electrochemical behavior of aluminum of varied purity and of AK1 alloy.

As is known, AK1 alloy is manufactured on the basis of special-purity aluminum and used in microelectronics to obtain epitaxial layers in integrated circuits [1]. Together with having a number of advantages, alloying of special-purity aluminum with single-crystal silicon is characterized by disadvantages, the main of which is a certain decrease in the corrosion resistance of the metal. Hence, an extremely important goal of modern materials science is to improve the corrosion resistance of AK1 alloy.

To solve this problem, AK1 alloy was alloyed in the present study with scandium, a metal of the same group as aluminum. However, scandium differs from aluminum in a lower electronegativity [3], standard potential E^0 [4], and high affinity for oxygen. The choice of scandium as the alloying element was also based on previous studies carried out by the author with pure aluminum [5] and on results of other researchers [6].

EXPERIMENTAL

Alloys were prepared using aluminum of varied purity (Table 1), single-crystal silicon, and (Al + 2.5% Sc) alloying additive with a total content of impurities of 0.13% (0.017% Fe, 0.11% Si, 7×10^{-4}% Cu, and 3.7×10^{-3}% Ti).

Table 1. Content of impurities in aluminum of various brands

Brand	Total content of impurities, wt %	Content of indicated impurity, wt %				
		Fe	Cu	Si	Zn	Ti
A6NO	1×10^{-4}	1×10^{-5}	5×10^{-4}	1×10^{-4}	1×10^{-6}	–
A995	5×10^{-4}	1.5×10^{-3}	1×10^{-3}	1.5×10^{-3}	1×10^{-3}	1×10^{-3}
A6	0.4	0.25	0.03	0.20	0.06	0.03

Table 2. Corrosion-electrochemical parameters of aluminum of varied purity in a NaCl solution

Al brand	c_{NaCl}, %	$-E_{fr.cor}$	$-E_{pt}$	$-E_{rp}$	$-E_{cor}$	ΔE_{pr}	Corrosion rate	
		V					A m^{-2}	g m^{-2} h^{-1}
A6 (99.6% Al)	3	0.730	0.625	0.700	0.760	0.105	0.024	8.04×10^{-3}
A995 (99.9995% Al)	3	0.950	0.680	0.750	0.960	0.270	0.003	1.01×10^{-3}
	0.3	0.850	0.620	0.680	1.120	0.230	0.006	2.01×10^{-3}
	0.03	0.760	0.540	0.600	1.160	0.220	0.009	3.01×10^{-3}
A6NO (99.9999% Al)	3	0.955	0.740	–	1.180	0.215	0.00048	1.65×10^{-4}

The content of scandium in AK1 alloy was 0.005, 0.05, and 0.1 wt %. AK1 and aluminum–scandium alloys were obtained in an SNV vacuum resistance furnace in graphite crucibles. The alloy was alloyed with the alloying additive in SShOL open shaft laboratory furnaces. The resulting alloys and aluminum were cast in graphite molds to obtain cylindrical rods 8–10 mm in diameter and 80–100 mm long. The lateral surfaces of these rods were covered with a lacquer and the working edge was ground and polished with fine emery paper, washed with distilled water and ethanol, and, on being dried in a desiccator, used as the working electrode.

The study was carried out with a PI-50-1.1 potentiostat and LKD-4-002 recorder in a 3% NaCl solution. Some experiments were performed in 0.3 and 0.03% NaCl solutions. A silver chloride electrode served as reference, and platinum, as an auxiliary electrode. The potential sweep rate was 1 mV s^{-1}.

The electrodes were potentiodynamically anodically polarized from the stationary potential till a steep rise in current (to a constant value of 2 A) and then in the opposite direction to a potential of –1.5…–1.6 V, at which the oxide film is reduced. Then the samples were again polarized in the positive direction to the pitting potential. The thus obtained potentiodynamic curves were used to determine the basic electrochemical characteristics of the alloys: corrosion potential E_{cor}, corrosion current i_{cor}, and pitting (E_{pt}) and repassivation (E_{rp}) potentials.

The value of E_{rp} was found graphically as the potential at which a first inflection is observed in the back run of the anodic curve, or as the potential at which the forward and back runs of the anodic polarization curve intersect [7]. The interval of potentials E_{pas} of the passive region was determined as the difference between the potential at which passivation begins (after cathodic polarization) and the pitting potential. The corrosion current, the main electrochemical characteristic of the corrosion process, was calculated from the cathodic curve with account of the Tafel constant b_c = 0.12 V, because the pitting corrosion of aluminum and its alloys in neutral media is governed by the cathodic reaction of oxygen ionization. The rate of corrosion was found from the corrosion current by the formula

$$K = i_{cor} K^1,$$

where K^1 = 0.335 g A^{-1} h^{-1} for aluminum.

The results of a corrosion-electrochemical study of aluminum of varied purity are summarized in Table 2. The influence exerted by chloride ions on the corrosion rate was studied for the example of aluminum of A995 brand. It can be seen that the corrosion rate grows as the dilution of the NaCl solution becomes higher. The pitting and repassivation potentials are shifted to more positive values. The free corrosion potential $E_{fr.cor}$ is also shifted in the positive direction with dilution of the electrolyte. In this case, the corrosion potential of the activated electrode is shifted to more negative values. All the above-mentioned changes in the electrochemical parameters of aluminum in a NaCl solutions of various concentrations point to different dynamics of formation of a protective oxide film.

A study of the behavior of aluminum of varied purity in a 3% NaCl solution demonstrated the following. Such electrochemical parameters as E_{pt}, E_{rp}, and E_{cor} depend on the purity of the metal rather strongly, with their values widely varying (e.g., E_{pt} varies from –0.625 for aluminum of A6 brand to –0.740 for A6NO, and E_{cor}, from –0.760 to –1.180 V, respectively) and can be used to roughly estimate the purity of the metal. The free corrosion potential was the least sensitive to changes in metal purity. Of primary importance in corrosion of aluminum is, irrespective of the purity of the metal, the structure and

state of the initial surface oxide film, and it is this film that determines the further behavior of the metal.

As is known [8], the difference between the pitting potential and the free corrosion potential of the metal (pitting-resistance base ΔE_{pr}) is used as a comparative criterion of its susceptibility to pitting corrosion in a given medium. If the experimental data obtained are analyzed with regard to this parameter, it can be seen that the pitting-resistance base ΔE_{pr} grows to the greatest extent on passing from aluminum of A6 brand to A995, whereas further increase in metal purity to A6NO has virtually no effect on the E_{pr}. The corrosion rate of aluminum in a neutral medium containing chloride ions strongly depends on the purity of the metal. For example, on passing from technical-grade aluminum to special-purity aluminum, the corrosion current decreases by approximately a factor of 200 (from 0.024 to 0.00048 A m^{-2}), and on passing from aluminum of A995 brand to A6, the corrosion rate increases 8-fold. This is in an agreement with the data of [1], where it was shown that the corrosion rate in a 5% HCl solution increases by a factor of 3–15 in the above case. Analysis of the impurity composition of aluminum and the available published data indicates that the corrosion rate is strongly affected by such impurities as iron and copper, and to a lesser extent, by silicon.

According to [2], the passivation oxide formed on aluminum in neutral media has a low electrical conductivity. It hinders virtually completely not only the anodic reaction of metal dissolution, but also the conjugated cathodic reduction of oxygen dissolved in the electrolyte. The conductivity of oxide films formed on technical-grade aluminum and its alloys is higher. This accounts for the pronounced increase in the rate of oxygen reduction and, consequently, that of corrosion of technical-grade aluminum, too, compared with its high- and special-purity brands. In neutral solutions, oxide films formed on special-purity aluminum exhibit strongly protective properties and the corrosion occurs uniformly, at a minimum rate, and mainly at separate defects of the oxide film. In technical-grade aluminum, in which the total impurities (especially iron and silicon) amount to 1.0–1.5%, and the impurities are mainly contained in the form of anodic inclusions of intermetallic compounds, the corrosion occurs by the pitting mechanism and the rate of corrosion in a 3% NaCl solution occasionally reaches catastrophic values.

Thus, one of efficient methods to improve the corrosion resistance of aluminum is to raise its purity (which primarily refers to more electropositive impurities).

50	0.960	0.940	0.830	0.775	0.765
60	0.955	0.935	0.830	0.775	0.765

The results of a study of AK1 alloy alloyed with scandium are presented in Tables 3, 4. The dynamics of variation of the free-corrosion potential with the time of keeping in a 3% NaCl solution characterizes the rate of formation of a protective oxide layer on the alloy surface. For example, for special-purity aluminum and scandium-free AK1 alloy, $E_{fr.cor}$ stabilizes in 1 h, whereas for alloys with scandium, this process is complete in 30–40 min, which indicates that a protective oxide layer is formed on alloys with scandium faster than on the scandium-free alloy. With special-purity aluminum, AK1 alloy, and alloys with scandium, the free-corrosion potential is shifted to more positive values when the time of keeping increases. The most positive potential (–0.765 V) is observed for AK1 alloy with 0.1% Sc. Addition of scandium increases, irrespective of the amount of scandium, the free-corrosion potential. In this case, the shift of the potential to more positive values is 160–190 mV as compared with the scandium-free aluminum and AK1 alloy. According to how the potential varies with time, the protective oxide film is formed on the electrode surface at the highest rate during the first 3–5 min after the electrode is submerged in the solution (Table 3).

Table 4. Corrosion and electrochemical parameters of A6NO aluminum and AK1 alloy with scandium in a 3% NaCl solution

Brand	Sc, wt %	$-E_{fr.cor}$	$-E_{cor}$	$-E_{pt}$	ΔE_{pas}	i_{cor}, A m^{-2}	$K \times 10^{-4}$, g m^{-2} h^{-1}
		V					
A6N0	–	0.955	1.180	0.740	0.440	0.00048	1.61
AK1	–	0.935	1.170	0.750	0.420	0.00060	2.0
AK1	0.005	0.830	1.160	0.680	0.480	0.00036	1.21
AK1	0.05	0.775	1.150	0.660	0.490	0.00033	1.11
AK1	0.10	0.765	1.080	0.650	0.330	0.00029	0.97

The corrosion and electrochemical characteristics of the alloys studied, which are listed in Table 4, indicate that alloying of special-purity aluminum with silicon and of AK1 alloy with scandium shifts the free-corrosion, pitting, and corrosion potentials in the positive direction. The free-corrosion potentials of all the alloys studied lie in the passive region, i.e., between the corrosion and pitting potentials. Alloying of aluminum with silicon somewhat narrows the passivation region ΔE_{pas} (from 440 to 420 mV), whereas introduction of scandium into AK1 alloy, especially that in an amount of 0.005–0.05%, markedly expands it (from 420 to 490 mV) (Table 4). On the whole, ternary alloys surpass the initial AK1 alloy both in electrochemical characteristics and in corrosion resistance. For example, alloys with 0.05 and 0.1% scandium surpass the initial, scandium-free AK1 alloy in corrosion resistance by a factor of 2.

The mechanism of corrosion of pure aluminum in neutral media is described by the equations [2]

$$Al + 3OH^- = Al(OH)_3 + 3e, \quad (1)$$

$$Al(OH)_3 + OH^- = Al(OH)_4^-. \quad (2)$$

The process is limited by the rate of supply of OH^- ions to the electrode surface. The role of a depolarizer in aerated neutral solutions is played by oxygen. Its reduction at the metal–solution interface proceeds in accordance with the equation

$$O_2 + 2H_2O + 4e = 4OH^-. \quad (3)$$

The process is limited by diffusion of oxygen dissolved in the electrolyte to the electrode, which, in the end, determines the corrosion rate of the metal. Hydrated oxide of general formula $Al_2O_3 \cdot nH_2O$ is deposited onto the surface as an intermediate formed in the interaction of the metal with OH^- ions. Various modifications of aluminum oxide and hydroxide are well soluble in alkaline and acid media, being virtually insoluble in neutral solutions. For this reason, the application domain of aluminum and its alloys in liquid media covers only nearly neutral solutions. In solutions of this kind, oxide films on aluminum exhibit good protective properties, and uniform corrosion of aluminum and its alloys is, as rule, weak and proceeds at separate defects of the oxide film [2]. The dissolution mechanism of AK1 alloy alloyed with scandium can be understood as follows [6]. When the alloys are brought in contact with the solution, scandium, being an electrochemically active component [4], is in part selectively dissolved from the solid solution and from finely dispersed particles of the intermetallic compound Al_3Sc, which leads to an increase in the vacancy concentration in the surface layer, and in part reacts with oxygen to give Sc_2O_3 accumulating on the surface. The thermodynamic activity of aluminum increases in the defective surface layer, which favors formation of a dense and less defective layer of aluminum oxyhydroxides with good protective properties [reactions (1), (2)]. The oxide Sc_2O_3 is accumulated in the upper part of this layer, whose density exceeds that of Al_2O_3 [4]. The corrosion potential of an alloy coated with a dense, only slightly defective layer of aluminum oxyhydroxides and with scandium oxide increases, whereas the reduction rate of the depolarizer and, accordingly, the corrosion rate of the scandium-containing alloy decrease. Sc_2O_3, which is insoluble in aqueous solutions and forms no mixed oxides with aluminum because of the lattice mismatch, accumulates on the surface and blocks it mechanically, thereby hindering both the dissolution of the alloy in anodic polarization and the pitting formation.

Thus, the studies performed resulted in that an alloying element was chosen, whose small additives can substantially improve the corrosion resistance

of AK1 alloy. The corrosion resistance of the alloy developed exceeds in corrosion resistance special-purity aluminum presently used as the main material for current leads in integrated circuits by nearly a factor of 2.

CONCLUSIONS

(1) It is shown that passing from technical-grade to special-purity aluminum diminishes the corrosion rate by approximately a factor of 200.

(2) Addition of scandium to AK1 alloy improves its corrosion resistance by nearly a factor of 2.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Improvement of the Corrosion Resistance of Compressor Blades with Ion-Plasma-Deposited Titanium Nitride Coatings

Abstract—The effect of various technological procedures for reconditioning with the use of ion-plasma-deposited titanium nitride coatings on the resistance of steel compressor blades to pitting corrosion was studied.

The main type of surface damage to compressor blades of gas-turbine engines for gas-pumping units and aircraft is the erosion- and corrosion-related wear. The problem of improving the corrosion resistance of the working surface of blades is presently solved by using high-alloy steels and titanium alloys as the substrate material and by depositing various protective coatings. In this case, a coating must possess, together with a high corrosion and erosion resistance, also a high resistance to cyclic thermomechanical loads, sufficient plasticity and crack resistance, and good adhesion to the substrate. Promising in this regard are titanium nitride coatings deposited by the ion-plasma technique.

The present study is concerned with the corrosion properties of these coatings. The aim of the investigations of applied nature was to tackle with a concrete problem, i.e., to make longer the total service life of blades of a Nuovo Pignone GTK25I axial-flow compressor, which had exhausted their original durability (~60 000 h) and were subjected to reconditioning by ion-plasma deposition of titanium nitride coatings.

In the course of their operation, steel compressor blades are subjected to a strong attack by air flow at elevated temperatures (up to 350°C). The presence of noxious impurities in the industrial atmosphere, and primarily that of activating chloride ions, leads to nonuniform corrosion [1]. In the initial stage, pinpoint corrosion is observed, and semispherical pittings of depth 50–150 μm with deposits of iron oxides, from which pits are later formed, appear on the working surface of blades. The action of varying thermal and mechanical stresses leads to the formation of corrosion-fatigue cracks. A physicochemical modeling of the corrosion process, which was carried out on 12Kh13 steel samples (in a 10% solution of $FeCl_3$), using the method described in [2], established that corrosion occurs by the pitting mechanism and made it possible to reproduce the patterns of corrosion damage in different stages of the corrosion process [1].

EXPERIMENTAL

In the reconditioning cycle, the following procedures were employed: mechanical treatment (MT), spark-discharge polishing (SDP), reconditioning thermal treatment (TT) at 700°C for 2 h, deposition of ion-plasma TiN coatings by the method of condensation with ion bombardment on a VU-2MBS installation at a base voltage U = 180 V, arc current I = 160 A and a pressure P of the reaction gas in the chamber varied within the range 0.04–0.1 Pa.

The corrosion resistance of materials was determined electrochemically from their resistance to pitting corrosion in accordance with GOST (State Standard) 9.912–89 [3]. The experiments were performed with a P 5848 potentiostat in a 0.5 M aqueous solution of NaCl by measuring cyclic potentiodynamic curves at a potential sweep rate of 0.4 mV s^{-1}, with the pitting-resistance parameters determined after that: free-corrosion potential E_{cor}, pitting potential E_{pt}, repassivation potential E_{rep}, and additional bases of pitting resistance, ΔE_{pt} and ΔE_{rep}. The tests were performed with samples cut directly from the working

blades of the GTK-25I axial-flow compressor in their initial state (before putting into operation) and after exploitation for 60 000 h.

In the initial state, after a mechanical polishing of the blade surface to a roughness $R_a < 63$ μm, the samples exhibited stable negative values of the potentials of pitting (E_{pt}) and repassivation (E_{rep}) (Table 1).

After treatment of the blade surface by spark-discharge polishing, the pitting and repassivation potentials shifted in the positive direction (Fig. 1, curve *2*) and the pitting-resistance base ΔE_{pt} of the material increased both in the initial and in the post-operation states (Table 1). It is known [3] that, when the microprofile of the surface is smoothed and the surface heterogeneity is diminished by fine polishing, the susceptibility of stainless steel to pitting corrosion becomes lower. Therefore, the improvement of the pitting-resistance parameters after spark-discharge polishing is mainly due to better surface uniformity of the samples because of the decrease in their surface roughness (from 0.55 to 0.44 μm for R_a).

The reconditioning thermal treatment used in the technological cycle to relieve the accumulated microstresses [4, 5] leads to a further improvement of all the pitting-resistance parameters (Table 1). The pitting-resistance base ΔE_{rep} increases and becomes positive. It may be assumed that, after the formation of stable pittings, the repassivation state is reached faster. The improvement of the corrosion resistance is probably due to a more uniform distribution of the carbide phase under the action of TT and to the resulting increase in the structural homogeneity. Photographs of the microstructure of blades before and after exploitation (Figs. 2a, 2b) and after reconditioning thermal treatment (Fig. 2c) confirm this assumption. Moreover, thermal treatment may lead to leveling of the concentrations of the alloying elements and to the resulting decrease in the number of chromium-deficient zones.

It is known that the properties of ion-plasma-deposited coatings are determined by a set of technological parameters (arc current, base voltage, substrate temperature, etc.), the main of which is the partial pres-

Fig. 1. sure of the reaction gas in the chamber. In order to optimize the mode of formation of the anticorrosion coating, the properties of titanium nitride obtained at different gas pressures were studied. The phase composition and substructural parameters (microstrain ε, subgrain block size *D*) of TiN were determined by means of X-ray diffraction analysis ("grazing beam" method, probed depth of about 1 μm, Cu_{K_α} radiation). The mechanical properties of the coatings were studied by measuring the microhardness H_μ at a variable load on the indenter. The experimental values of microhardness of the 12Kh13 steel + TiN compositions were used to find the hardness of titanium nitride by a method taking into account the influence of the substrate [6]. On the basis of the resulting values of hardness, the plasticity coefficient δ_H of the coatings was calculated [7]. Table 2 lists the substructural parameters and mechanical characteristics of titanium nitride coatings obtained at different gas pressures in the chamber.

Table 2. Substructural parameters and mechanical characteristics of titanium nitride coatings obtained at different partial pressures P of the reaction gas in the chamber

P, Pa	ε ± 0.00001	*D* ± 2, nm	H_μ ± 0.3, GPa	δ_H
0.04	0.00034	27	16.6	0.67
0.06	0.00008	27	8.2	0.84
0.08	0.00002	28	9.6	0.81
0.10	0.00002	25	8.4	0.83

It was established that the coatings deposited in the pressure range under study have a phase composition δ-TiN + α-Ti. As the gas pressure decreases, an axial texture of the (001) type tends to appear. In this case, the subgrain block size remains virtually unchanged with pressure and equal to 25–28 nm (Table 2). At a lower pressure of the reaction gas, the coatings formed are characterized by a high level of microstrain in TiN grains and, as a consequence, have a higher microhardness (Table 2). In this case, the coatings show no microbrittleness under indentation and have a high plasticity coefficient δ_H = 0.81–0.84 in the pressure range 0.06–0.1 Pa. This favorably distinguishes these coatings from electroplated protective coatings composed of hard chromium (δ_H = 0.77 at the same hardness), which tend to undergo cracking under alternating-sign load. Tests for abrasive wear (with quartz sand used as eroding substance at a particle velocity of 200 m s^{-1}) demonstrated that depositing a titanium nitride coating improves the erosion resistance of the steel surface of compressor blades by 25%, on the average.

As regards the anticorrosion protection, the optimal pressure for depositing a coating is 0.1 Pa. Ion-plasma-deposition of a TiN coating onto the surface of steel samples in this mode leads to a pronounced increase in the pitting potential E_{pt} and in the pitting-resistance bases ΔE_{pt} and ΔE_{rep} (Table 1). Titanium nitride deposited onto a steel substrate serves as a cathodic coating.

Thus, application of an integrated reconditioning technology with the use of ion-plasma TiN coatings leads to a pronounced increase in the corrosion resistance of the working surface of steel compressor blades. The reconditioning treatment leads to a stable increase in the pitting potential E_{pt} and in the pitting-resistance bases ΔE_{pt} and ΔE_{rep} (Table 1), even with respect to the values in the initial state of the material (before exploitation), and to a more pronounced hysteresis in the forward and reverse runs of the polarization curves (Fig. 1).

Additionally, comparative studies of the behavior of 12Kh18N10T stainless steel without a coating and with Ti and TiN coatings in a 5% HCl solution were carried out (Fig. 3). It can be seen that (i) the corrosion potentials of the systems constituted by steel and a Ti coating and by steel and TiN coating are shifted in the positive direction and (ii) the corrosion currents j_{cor} found by extrapolation of the Tafel portions to their intersection become lower. The most pronounced decrease in j_{cor} was observed on depositing a titanium nitride layer onto the surface of the samples (curve *3*), which reflects the higher corrosion resistance of this coating, compared with that composed of titanium [8].

To determine the corrosion resistance of optimized titanium nitride coatings under conditions close to those in which aircraft compressor blades are working, tests were carried out in a salt-spray chamber (using the ISO 9227 procedure: 35°C, NaCl solution with a concentration of 47 g l^{-1}) with finished articles made of EP 866 alloy (15Kh16K5N2MVFAB). It was found that no pitting corrosion developed during 2060 h under an undamaged TiN coating. At the same time, blades without a coating showed corrosion defects already after 94 h.

Thus, the results of climatic tests also demonstrated the effectiveness of anticorrosion ion-plasma-deposited titanium nitride coatings.

The reconditioning technology with the use of ion-plasma-deposited TiN coatings, developed by the authors, was introduced into practice at the Volgotransgaz Ltd. in order to prolong the service life of compressor blades of a GTK-25I gas-pumping unit. The reconditioned blades have worked for more than 20000 h and are still in service now.

CONCLUSIONS

(1) A technology for reconditioning of steel compressor blades of gas-pumping units was developed. The application of this technology improves the corrosion resistance of the working surface of the blades.

(2) It was established that, of all the procedures for reconditioning treatment, the strongest positive influence, with the most pronounced increase in the resistance to pitting corrosion of 12Kh13 steel, is exerted by titanium nitride coatings obtained by the ion-plasma technique in certain modes.

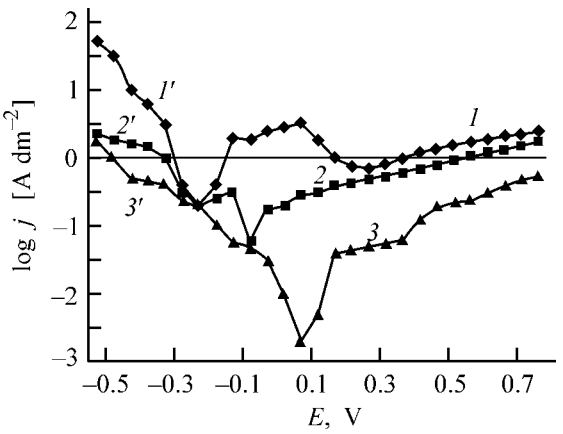

Fig. 3. (*1*–*3*) Anodic and (*1*′–*3*′) cathodic polarization curves obtained on 12Kh18N10T steel (*1*, *1*′) without a coating and with (*2*, *2*′) Ti and (*3*, *3*′) TiN coatings in a 5% HCl solution at 293 K.

(3) Titanium nitride coatings are recommended for anticorrosion protection of compressor blades in aircraft engines and gas-pumping units.

Abstract—The composition and structure of films formed in etching of nickel in a $Ni(NO_3)_2$ solution in the presence of Cl^- and NO_2^- ions was studied.

In fabrication of nickel oxide electrodes (NOE) on a metal-ceramic (MC) support, the impregnation in a solution of a nickel salt, mostly a $Ni(NO_3)_2$ solution, is the longest stage [1]. The impregnation time necessary for obtaining a required amount of the active substance in the pores is mainly determined by the rate of the electrochemical process in which nickel of the MC support is etched in the $Ni(NO_3)_2$ solution [2], and is associated with the hindrance to the cathodic process [3]. In dissolution of nickel, a film of the products is formed on its surface [4, 5], which, shielding the surface, impedes the supply of the oxidant. This makes the etching rate lower, and the impregnation time necessary for producing the active substance, longer.

In [5], the composition of the basic salts formed in $Ni(NO_3)_2$ solution at 60°C under an external cathodic polarization was determined to be $7.2Ni(OH)_2 \cdot Ni(NO_3)_2$. The impregnation of MC supports with a $Ni(NO_3)_2$ solution without external polarization results in the formation of basic salts of the type $Ni(OH)NO_3$ [4], which corresponds to the composition $Ni(OH)_2 \cdot Ni(NO_3)_2$.

In [3, 6], it was recommended to add $NiCl_2$ to a $Ni(NO_3)_2$ solution, and $NaNO_2$ to a $NiCl_2$ solution in order to raise the rate of nickel etching, but the composition of the films formed was not analyzed.

In this study, we determined the structure and composition of films formed by products of nickel etching in a $Ni(NO_3)_2$ solution with $NiCl_2$ and $NaNO_2$ additives.

EXPERIMENTAL

With account of the electrochemical nature of the process of nickel etching, its characteristics were determined in a model galvanic cell with relatively large (S = 14 cm^2) platinum cathode and anode made of nickel foil. The cathode and an anode compartments were separated by a diaphragm. To localize the cathodic process on Pt to a greater extent, a solution containing an oxidant (NO_3^-, NO_2^- ions) was poured into the cathode compartment, and a $NiSO_4$ ($c_{Ni^{2+}}$ = 200 g l^{-1}) or $NiCl_2$ solution ($c_{Ni^{2+}}$ = 320 g l^{-1}), into the anode compartment. The solutions were equal with respect to the ionic strength. It was assumed that the cathodic process is mainly localized on platinum, and the anodic process, on nickel. The results obtained on a model short-circuited galvanic cell Pt|solution|Ni are mainly of qualitative nature. This is because the cathodic process partly occurs on nickel, and, moreover, platinum can have some other electrocatalytic effect on the reduction of the oxidant, compared with nickel. The adequacy of the Pt–Ni model system suggested in impregnating solutions was confirmed by comparing the nickel etching process with that in a model system Ni | solution | Ni. The study was performed at 80°C.

A film of sparingly soluble products intended for X-ray diffraction analysis was formed on platinum. For this purpose, platinum electrode was short-circuited with a nickel electrode and kept in a solution for 1 h and then in air till the crystallization of the products on the electrode surface was complete. The X-ray diffraction patterns were measured on a sample with crystals of salts formed on its surface

1070-4272/04/7706-0934 © 2004 MAIK "Nauka/Interperiodica"

and on the same sample upon dissolution of the products in distilled water to give a monomolecular layer [7].

The X-ray diffraction analysis was performed on a DRON-2 diffractometer (Ag-radiation, λ_α = 0.58 Å, U = 32 kV, I_a = 0.8 mA, entrance and exit slits 1.8 mm). The composition was determined qualitatively by comparng the interplanar spacings of the substance studied and the substances whose presence in the film formed is expected [7]. The amount of the solid phase was judged from the relative intensities I of lines in an X-ray diffraction pattern. The lattice constants were determined by the procedure described in [2].

As reference served the X-ray diffraction pattern of the film formed on platinum in a $Ni(NO_3)_2$ solution without additives.

Only reflections corresponding to the $Ni(NO_3)_2 \cdot 6H_2O \cdot Ni(OH)_2$ complex (Table 1) are present in the diffraction pattern, with the content of $Ni(OH)_2$ in the compound exceeding that of $Ni(NO_3)_2 \cdot 6H_2O$ [7]. The film has a cubic crystal structure. Qualitatively, the composition of the film is similar to that of basic salts formed in a $Ni(NO_3)_2$ solution under the external cathodic polarization [5]. Basic salts are commonly unstable, their chemical composition and structure may change in recovery from solution and in washing, drying, and storage. In addition, the polarization potential, the density and amount of electricity passed in operation of a Pt–Ni macrocouple in a $Ni(NO_3)_2$ solution, differed from the data of [4], and this circumstance could be responsible for a certain discrepancy between the composition of the basic nickel(II) compounds and the data reported in [4].

It should be noted that the interplanar spacings for virtually all the compounds differ from the values for individual substances [7], which indicates that complexation is probable. The presence of the Ni and Pt reflections with a changed interplanar spacing shows that there occurs chemisorption of nickel ions on the platinum surface [8].

It is known [9] that Cl^- ions prevent formation of a passivation film on nickel anodes in nickel plating. The introduction of $NiCl_2$ into the $Ni(NO_3)_2$ solution did not affect the cubic structure of the film formed on platinum.

The X-ray diffraction analysis showed that a film of composition $Ni(NO_3)_2 \cdot NiCl_2 \cdot Ni(OH)_2 \cdot 6H_2O$ is formed on the surface of platinum kept under current in a mixture of $Ni(NO_3)_2$ and $NiCl_2$ solutions (volume ratio 1 : 1) (Table 2). The intensities of reflection

nos. 2, 3, and 5 show that $Ni(OH)_2$ is also present in the film as a major component, but its crystal structure is changed. The intensities of virtually all the reflections in the X-ray diffraction pattern are lower than those for a film formed from a $Ni(NO_3)_2$ solution, which indicates that the amount of the solid phase is lower. The X-ray diffraction pattern of a film obtained from a mixture of $Ni(NO_3)_2$ and $NiCl_2$ solutions contains an additional reflection corresponding to the composition $NiCl_2 \cdot Ni(OH)_2 \cdot 6H_2O$.

The deposit formed in a $Ni(NO_3)_2$ solution containing a $NiCl_2$ additive has a larger lattice constant (Table 3), which indicates that its structure is less densely packed. The theoretically calculated density of a deposit formed in a mixture of solutions is lower by 40% than that of the deposit formed in a $Ni(NO_3)_2$ solution [7].

The results obtained made it possible to explain the fact that, after keeping a Pt–Ni short-circuited pair in a mixture of $Ni(NO_3)_2$ and $NiCl_2$ solutions, the current density in the system remained virtually unchanged and the etching process did not decay in time.

In [6], a method for MC NOE fabrication was suggested, which makes shorter the time necessary for impregnation of MC supports when a $NiCl_2$ solution with a $NaNO_2$ additive is used for impregnation.

Nitrite ions may undergo disproportionation at elevated temperatures in an acid medium [8], which may yield nitrogen(IV) oxide, a stronger oxidant than nitrite and nitrate ions [10]. This must, undoubtedly, change the structure and composition of a solid film also in a $Ni(NO_3)_2$ solution.

The introduction of $NaNO_2$ resulted in the appearance of reflections corresponding to a complex of Pt with $NaNO_2$ and to the $Ni(OH)_2 \cdot NaNO_2$ complex (Table 4). The film formed in a $Ni(NO_3)_2$ solution containing $NaNO_2$ has a composition $Ni(NO_3)_2 \cdot 6H_2O \cdot Ni(OH)_2 \cdot$ β-NiOOH and a cubic structure with a lattice constant of 8Å (Table 3). Nitrogen(IV) oxide can oxidize the components of the film ($E^0_{NiO_2/N_2}$ = 1.35, $E^0_{NO_2/Ni^{2+}}$ = 0.6–1 V, depending on the structure of higher oxides [2]). Therefore, reflections corresponding to β-NiOOH are present in the X-ray diffraction pattern (Table 4). The intensity of virtually all reflections decreases (Tables 1, 4), which points to a lower amount of the solid phase. The theoretically calculated density is four times lower than that of the deposit formed in a $Ni(NO_3)_2$ solution (Table 3), which is due to the less densely packed structure of the deposit formed in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive.

The film formed on platinum in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive is nonuniform across its thickness, which is indicated by the difference in the reflection intensities measured on a sample with salt crystals and that after their dissolution (Tables 4, 5). According to the reflection intensities (Tables 4, 5), the amount of $Ni(OH)_2 \cdot NaNO_2$ on the surface of platinum covered with a monomolecular solid layer is approximately twice that inside the film. This indicates that NO_2^- ions are consumed in the course of time in a $Ni(NO_3)_2$ solution with a $NaNO_2$ additive. The amount of nickel(III) oxide decreases across the thickness of the solid film, since the reflection intensity corresponding to β-NiOOH is higher by 30% on Pt covered with a monomolecular film, compared with Pt with salt crystals (Tables 4, 5). This shows that the oxidizing capacity of the solution de-

7	12.75	1.27	Ni–Pt	15.8	15	23.9	0.69	Ni–Pt	11.5
8	13.7	1.18	Pt–Ni	75.2	16	25.25	0.65	Pt–Ni	12.7

creases with time (E_{NO_2/N_2} = 1.1 and 0.7 V before and after the solution is kept for 1 h, respectively).

The results of an X-ray diffraction analysis of the films formed in a $Ni(NO_3)_2$ solution with and without $NaNO_2$ suggest that the basic salts formed in etching of the metal undergo oxidation.

CONCLUSIONS

(1) The chemical composition and lattice constants of the films formed by etching products depend on the solution composition: Cl^- ions decrease the density of the deposit, the composition of the film is $Ni(NO_3)_2 \cdot NiCl_2 \cdot Ni(OH)_2 \cdot 6H_2O$ (cubic structure, lattice constant 5.6 Å); NO_2^- ions oxidize the components of a solid film to higher nickel oxides (oxidation state Ni^{3+}) and cause a decrease in the deposit density, the composition of the film is $Ni(NO_3)_2 \cdot 6H_2O \cdot Ni(OH)_2 \cdot \beta$-NiOOH (cubic structure, lattice constant 8 Å).

(2) The presence of a $NaNO_2$ additive in a $Ni(NO_3)_2$ solution makes solid films nonuniform across their thickness.

Abstract—The total content of carbon, chlorine, bromine, and oxygen in partly volatile organic impurities in potable water was determined by gas chromatography with atomic emission detection.

Disinfection of potable water with chlorine yields halogenated organic compounds, including those whose concentration in water is subject to hygienic regulations [1, 2]. In particular, chlorination of water containing natural humic compounds yields a large amount of the so-called volatile halohydrocarbons mostly composed of mixtures of chloro- and bromomethanes [3–5]. Halogenated organic compounds with higher molecular weights were studied less extensively. Nevertheless, it is known [6–8] that they can contain haloacetic acids, aldehydes, and aliphatic hydrocarbons. Supposedly, water contaminants of technologicalorigin can also be chlorinated [9, 10] to yield a broader spectrum of compounds. Thus, the mixtures of organic compounds in water from different water sources significantly differ, which makes identification of the chlorination products in each specific case a matter of current interest.

In this regard, much promise is offered by gas chromatography with atomic emission detection (AED) [11–13]. Although unsuitable for identification of all the compounds subjected to chromatographic analysis, this method yields information about the effect of chlorination from variation of the total elemental composition of the impurities.

In this study, we examined how the integrated indices of the elemental composition of partly volatile organic compounds (PVOCs) in water from various water sources are influenced by chlorination.

We studied water samples taken from two large water intakes in the city of Ufa, namely, the Northern open (NO) and Southern infiltration (SI) water intakes. The water source for the former intake is the Ufa river, and for the latter, water from wells situated on bank of the Ufa river.

EXPERIMENTAL

The impurities from the initial and chlorinated water were isolated by extraction with methylene chloride at pH 2, whereupon they were concentrated on a Kuderna-Danish apparatus and analyzed on an HP 6890 (HP G2350A AED) chromatograph (a 30 m × 0.25 mm column coated with 0.32 μm of DV-5; with the column heated at a rate of 20 deg min^{-1} from 35 to 60°C and at a rate of 6 deg min^{-1} from 60 to 280°C). This made it possible to determine the content in water of PVOCs with a molecular weight of up to 500, boiling away within 150–500°C. Using the chromatograms recorded at the carbon emission wavelength of 193 nm, we determined the total carbon content in the components eluted from the chromatographic column under the actual conditions, which is referred to as the organic carbon of technological origin (OCT) [14]. Based on the chromatograms recorded at 181, 178, 174, 479, and 478 nm, we estimated the total content of hydrogen H, phosphorus P, nitrogen N, oxygen O, chlorine Cl, and bromine Br in the PVOC components. Also, for all the samples we determined the total content of dissolved organic carbon (DOC) [15] characterizing the carbon content in organic compounds of primarily natural origin. Although not manifested in chromatograms recorded under the actual conditions, these com-

pounds are responsible for the formation of additional impurities in water being disinfected with chlorine.

Table 1 presents the previously determined annual average elemental composition of PVOCs for water samples from the Ufa river and SI wells.

Notably, the well water contains, on the whole, a smaller amount of organic substances from the group of interest. For example, the total content of impurities in the river water exceeds that in the well water by a factor of nearly 1.3. The PVOC components of the river water exhibit increased content, of OCT and oxygen while chlorine and bromine are virtually lacking in the PVOC components of the initial water.

The fact that the PVOC content in the well water is lower by a factor of ca. 1.3 than that in the river water is, evidently, due to removal of high-molecular-weight humic compounds (which can form side chlorination products) from the river water upon passing the filtration layers. This is indirectly evidenced by the fact that the DOC content in the well water is also smaller (by a factor of nearly 2) than that in the river water (Table 1).

The total PVOC content in the potable water originating from both water intakes tends to increase upon chlorination, namely, by factors of 5.3 and 3.6 for NO and SI, respectively. Along with a major increase in the content of chlorine and bromine in PVOCs, this is also accompanied by an increase in the content of carbon and oxygen by factors of 1.5, 2.4 and 2.2, 6.8, respectively (Table 1). Notably, bromine is the heaviest element in chlorinated water, and its relative content reaches 37% of the total concentration of the elements in the NO water.

Published data suggest that brominated organic compounds can originate both from inorganic bromides activated by water treatment with chlorine and from bromine impurities in the initial chlorine [8, 16, 17]. Also, a certain role is played by the differences in the process parameters of chlorination at NO and SI, namely, the contact time and number of chlorination runs (two runs at NO).

We carried out a comparative study of impurities in the initial water and in water chlorinated at the laboratory (Table 2). As initial water served that supplied from the river (NO) and that from the collecting reservoir of wells (SI). These experiments were carried out during a period of time when the river water was rather heavily contaminated, as evidenced by an enhanced DOC content of 4.8 mg dm^{-3}. We applied different chlorine doses; the chlorine–water contact time was close to that under the process conditions, namely, 4 h for the river water and 2 h for the well water. The fact that the total content of carbon, chlorine, bromine, and oxygen in the components tend to grow with increasing chlorine dose is, evidently, due to

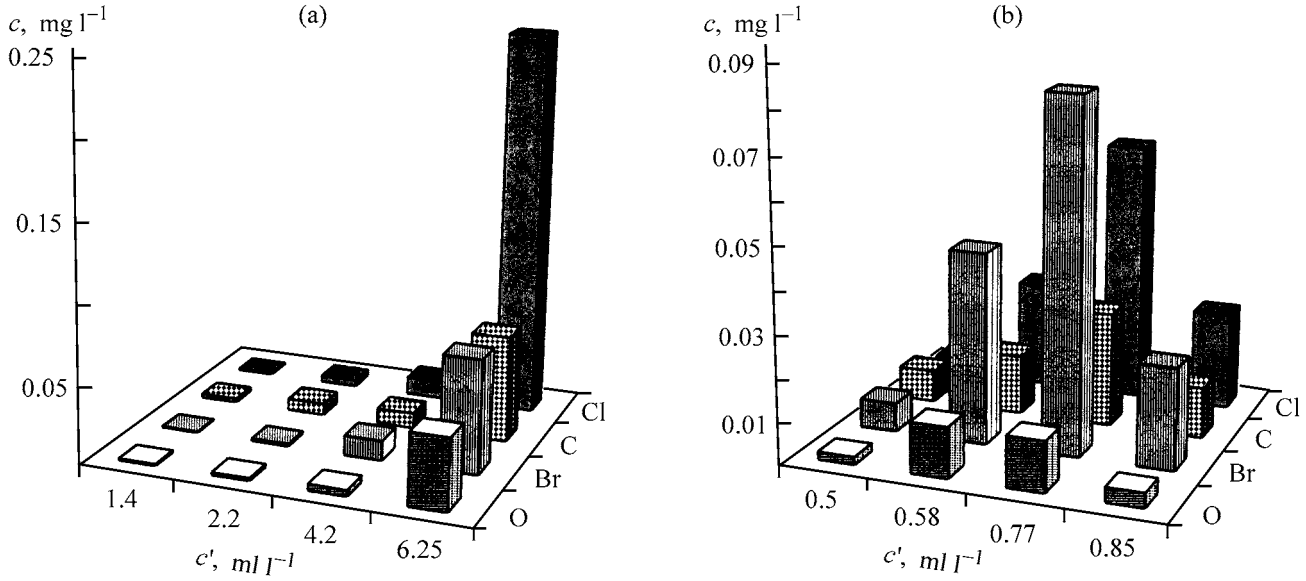
oxidative degradation of high-molecular-weight natural contaminants of water into PVOCs, on the one hand, and by direct halogenation of the available and newly formed impurities, on the other (Figs. 1a and 1b). Interestingly, the content of the major elements in PVOCs passes through a maximum, as clearly demonstrated for the well water. The same pattern is, most probably, characteristic of the river water, but the necessary amount of chlorine is never used in the actual water treatment processes both for the river and well waters.

Table 2 compares the elemental compositions of the organic compounds eluted in chromatographic analysis at the chlorine dose of 2.5 mg dm^{-3}. The residual chlorine concentration was estimated by GOST (State Standard) 18190–72 at 0.8 and 1.9 mg dm^{-3} for the NO and SI water, respectively, which corresponds to 1.7 and 0.6 mg dm^{-3} of spent chlorine. This is a conditional parameter which does not incorporate the amount of the chlorine spent in the formation of volatile compounds, chlorination of humus into compounds heavier than PVOCs, and other possible reactions.



Variation of the content c of elements in partly volatile components under chlorination of the river water at (a) NO and (b) SI water intakes (c') Content of spent chlorine.

A common finding of all our experiments is the sharply increased content of chlorine and bromine in PVOCs contained in the chlorinated water. However, the distributions of these compounds in water from the two water intakes are different. For example, the proportion of chlorine increases from 0.4 to 14% for the river water and from 1 to 22% for the well water. This increase in the proportion of chlorine can be accounted for by degradative chlorination of humic compounds, and primarily of their low-molecular-weight fragments [18]. An increase in the proportion of bromine in PVOCs is even more prominent. For example, the proportion of bromine in the river water and the well water increased from 0.4 to 24 and to 40%, respectively. This is, evidently, due to a higher content of bromides in the well water, compared to the river water. This is accounted for, in turn, by the local hydrochemical features, namely, by the occurrence of halogen-containing rocks (rock salt, anhydrites, gypsums). Bromine contained in these rocks as an impurity can be activated during chlorination and be converted to organic compounds [8].

Water chlorination leads to an increase in the oxygen content in the PVOCs in NO and SI water by factors of 4.4 and 12, respectively. The increase in the concentration of oxygen-containing compounds after chlorination of water from both water intakes suggests that high-molecular-weight compounds degrade into low-molecular-weight compounds, in agreement with published data [19].

The percentage of chlorine spent was estimated at 68 and 24 for the river water and well water, respectively. However, the PVOC content in the well water increases upon chlorination by a factor of 8.8, which almost threefold exceeds the factor of 3 in the case of the river water. This suggests that formation of PVOCs in the case of SI water intake is a more rapid process requiring less chlorine, compared to NO water intake, which is accounted for by the difference in the initial water matrices for these water intakes.

CONCLUSIONS

(1) Water chlorination is a complex multifactor process requiring adjustment of the chlorine dose to the initial water quality.

(2) In the context of the increasingly stringent regulations concerning the content of halogenated organic compounds in water, it is essential to estimate by express analysis such integrated indices as the total carbon, total chlorine, bromine, and oxygen contents in partly volatile organic compounds contained in water.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Study of New Designs of Impact-Centrifugal Mills

A. E. Levdanskii

Belarussian State Technological University, Belarus, Minsk

Received December 3, 2003

Abstract—Main ways to diminish the power consumption in grinding of materials are considered, and their practical implementation in newly developed designs of impact-centrifugal mills with flow-through classification is suggested. Data obtained in experimental studies and industrial tests of the developed designs are presented.

The process of fine grinding of materials is widely used not only in chemical industry, but also in a wide variety of other industries, and, at the same time, is rather power consuming. Therefore, much attention is being paid to a search for ways to diminish the power consumption in grinding. For this purpose, many specialists in grinding suggest [1–3]: (a) to carry out grinding mainly via impact load, (b) to prevent accumulation of a ground material in the working chamber of a grinding apparatus by continuously removing the product from this zone, and (c) to perform classification when removing the ground products from the grinding zone in order to separate the coarse fraction and return it into the mill for additional grinding.

All these requirements can be satisfied with the highest probability in impact-centrifugal mills with a flow-through classification. Three designs of impact-centrifugal mills, which are the most widely used in the industry, are shown in Figs. 1a–1c [4–6].

All the three mills comprise a vertical cylindrical casing *1* with a flat bottom *2* and a removable cover *3*. Within the casing *1* rotates a working disc *4* with blades *5*. In the first two variants of mills (Figs. 1a, 1b) the disc is mounted directly on the shaft of the electric motor *6*, and in the third design, there is a shaft *7* at the center of the vessel *1*, on which two discs *4* with blades *5* are mounted; the shaft is driven by the electric motor *6* by means of a V-belt drive *8*.

In all the three designs, baffle rods *9* are mounted annularly at a small distance from the outer edges of blades *5*. In all the designs, the material is ground by its impact loading. For this purpose, the starting material is fed, through a pipe *10*, into the central part of the mill, wherefrom it is transported by the air flow to blades *5* and further, moving along these blades, is accelerated to high velocities. The particles of the material break loose from the blades *5*, strike the baffle rods *9*, and are ground by this impact. It should be noted that, in all the mills, the continuous medium is set in motion in a similar way, by a centrifugal ventilator, which makes it possible to use the motion of the air flow to transport the material.

The difference in the designs is in the following. In the first design (Fig. 1a), the baffle rods *9* have a rectangular cross-section and are mounted with a certain spacing in between. After the material strikes the rods, ground particles pass through the clearings under the action of a centrifugal force and the air flow and then, moving together with air in the space between the rods and the apparatus casing, arrive via a tangential discharging pipe *11* into a cyclone and filter for separation. Because of the swirling motion of air in the chamber and an oblique impact of the material against the rods, the ground particles approach the slits at a certain angle. Consequently, only particles that are much smaller than the slits between the rods can pass through these slits, which rules out slit clogging. Calculations and experimental studies demonstrated that only particles whose size is 2–3 times smaller than the slit width can pass through the clearings. By selecting a necessary rotation rate of the disc with blades and mounting rods with a certain clearing width, it is possible to achieve the required grinding fineness.

In the second mill design (Fig. 1b), the baffle rods have a circular cross-section and are mounted close to one another. In this case, grinding products are

1070-4272/04/7706-0942 © 2004 MAIK "Nauka/Interperiodica"

carried away from the working zone by the ascending air flow and pass through an annular window of the cover into the spiral channel and further, through the discharging pipe *11*, into the cyclone and filter for separation. Baffle plates *12* mounted obliquely form a flow-through classifier. The flow of a gas and solid particles, which ascends from the grinding zone, passes through the clearing between the classifier blades and executes a zigzag motion. In the process, coarser particles, which have higher inertia, strike the oblique blades, rebound, and fall down on the blades, to be again ground there. Fine particles, which have lower inertia, pass together with air through the clearings and are removed from the mill. In this mill design, the material being ground may suffer multiple impact and, consequently, this mill can be used to ground harder materials.

The third mill design (Fig. 1c) has two stages, with two discs with blades mounted on the common shaft. The material is initially ground in the first stage of the mill, with insufficiently ground coarse particles finally milled in the second stage. The design of the first stage is similar to that of the first variant of the mill (Fig. 1a), and the design of the second stage, to that of the second variant (Fig. 1b). In this mill design, the material does not stay long in the grinding zone, but passes successively both stages and is discharged into the cyclone through an annular window in the bottom part and a tangential pipe. The mill can operate successfully in grinding of medium-strength materials.

The main grinding efficiency criteria for any mill design are the specific power consumption and the quality of the product obtained. The energy consumption is most commonly evaluated by the ratio of the energy expenditure to the amount of ground material (kW h ton^{-1}). The most comprehensive characteristic of the quality of the product obtained is its granulometric (fraction) composition (particle size distribution).

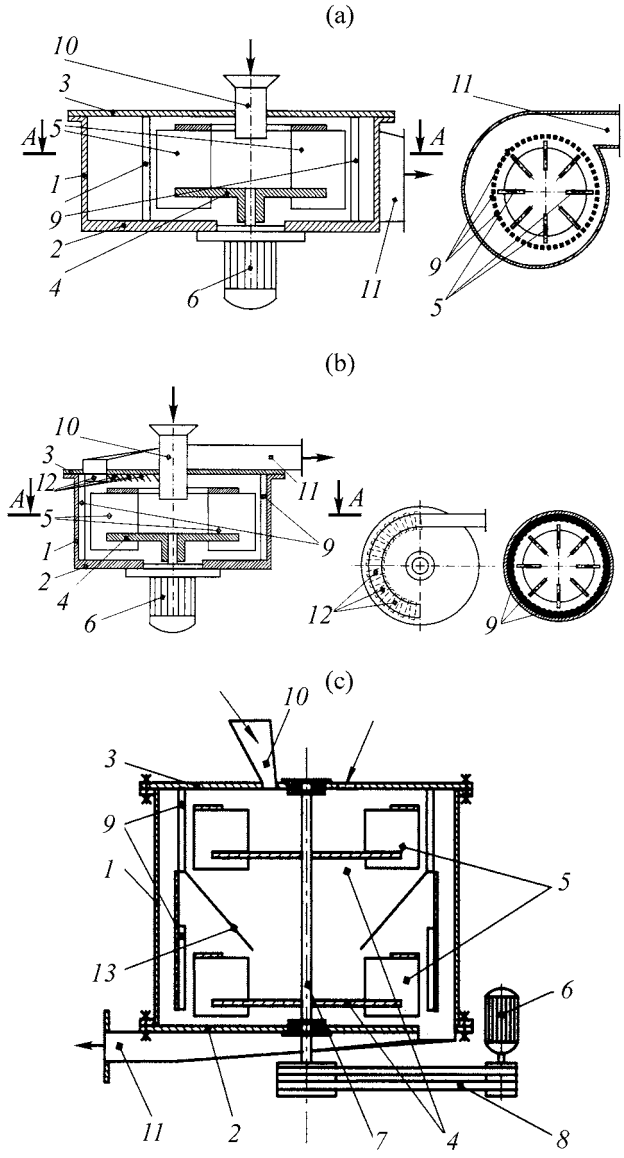

Fig. 1. Schematic of impact-centrifugal mills. Design: (a) with a tangential discharge, (b) with a top discharge, and (c) two-stage with a bottom discharge of a ground material. (*13*) cone, for other explanations, see text.

The power consumption and the grinding quality are affected both by parameters of the grinding process itself and by characteristics of a material being ground. The parameters of impact grinding are the following: impact velocity, number of impacts, impact angle, specific load, geometric dimensions of mill units and elements. To the characteristics of the material being ground should be referred its geometric dimensions, physicochemical parameters (hardness, elasticity modulus, ultimate strength), and moisture content. It is virtually impossible to take into account all the parameters of the grinding process and of the material being ground in constructing the theoretical model of the impact disintegration of the material. Therefore, the efficiency of grinding in mills of the designs developed was determined experimentally. First, the extent of impact grinding of the material upon its single pass through the mill was studied for the mill design (Fig. 1b) in which baffle rods *9* with circular or rectangular cross-section are mounted close to one another (without any clearing). In order to exclude a repeated grinding of the material, the ground material was discharged through an annular window and a tangential pipe in the bottom part, as

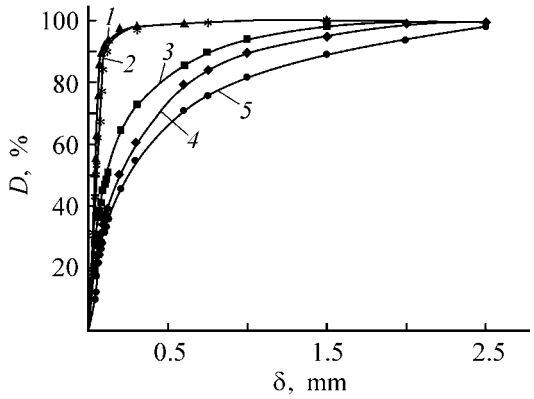

Fig. 2. Fraction composition of the products formed in impact grinding of various materials. (*D*) of the mass of particles (smaller than δ in size) to the total mass of particles and (δ) particle size; the same for Figs. 3–5. Substance being ground: (*1*) lime (grain size 4–8 mm), (*2*) chalk (particle size 4–8 mm), (*3*) gypsum stone, (*4*) sylvinite (particle size 3–10 mm), and (*5*) barley grain.

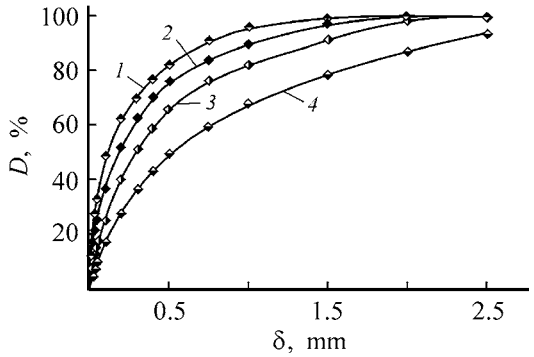

Fig. 3. Fraction composition of the products formed in impact grinding of sylvinite at different output capacities *G*. *G* (kg s^{-1}): (*1*) 0.061 (220 kg h^{-1}), (*2*) 0.133 (480 kg h^{-1}), (*3*) 0.211 (760 kg h^{-1}), and (*4*) 0.333 (1200 kg h^{-1}).

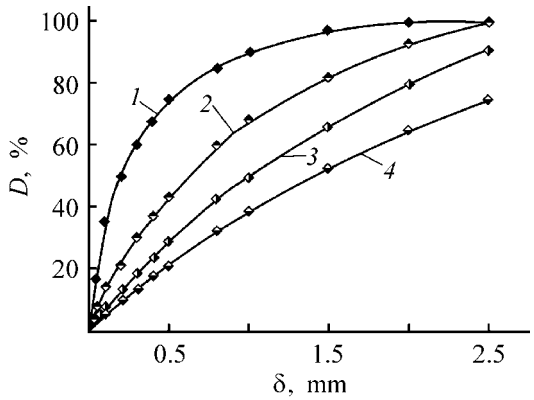

Fig. 4. Fraction composition of the products formed in impact grinding of sylvinite at different rates of rotor rotation (*n*) and linear velocities of the tips of the rotor blades (*w*). *w* (m s^{-1}): (*1*) 62.8, (*2*) 33, (*3*) 21, and (*4*) 16. *n* (rpm): (*1*) 3000, (*2*) 1500, (*3*) 1000, and (*4*) 750.

it is dome in the mill of design shown in Fig. 1c, rather than through the cover. The study was carried out on a mill with a rotor diameter of 400 mm (at blade tips), with the rate of rotation varied from 750 to 2900 rpm.

The results obtained in studying a single-pass impact grinding of materials are shown in Figs. 2–4 in the form of distribution functions in which the particle size δ is plotted along the abscissa axis, and the ratio *D* of the mass of particles with diameter less than δ to the total mass of the grinding product, along the ordinate axis. The curves of the fraction distribution of the products formed in impact grinding (Fig. 2) were obtained at a rotor rotation rate of 2900 rpm for various materials (lime, chalk, gypsum stone, sylvinite, barley grain). In all the experiments, the rate of substance supply was 460–520 kg h^{-1}, and the initial particle size, 4–8 mm. It can be seen that the finest grinding is achieved in the single-pass impact grinding for grains of lime and particles of chalk. As shown by analysis of the grinding products under a microscope, these grains and particles virtually disintegrate into fine crystallites. The worst results are obtained for barley grain, and primarily for its elastic sheath.

Figure 3 shows the fraction composition of products formed in grinding of sylvinite at a load by the starting material varied from 0.061 to 0.333 kg s^{-1} (220–1200 kg h^{-1}), and Fig. 4, the fraction composition of the products of its grinding at different rotor rotation rates.

A mathematical processing of the experimental data with the use of the Rosin–Rammler formula made it possible to obtain an empirical relation for describing the fraction composition of products formed in a single-pass impact grinding of materials in impact-centrifugal mills (Figs. 1a–1c):

$$D = 100\{1 - \exp[-0.68(\delta/\delta_{50})^{0.75}]\}, \qquad (1)$$

where *D* is the ratio of the mass of particles (smaller than δ in size) to the total mass of particles (%); δ, the particle size (*m*); and δ_{50}, the particle size for which the mass of smaller particles is 50%.

For determining the δ_{50} particle size, an empirical relation was obtained that took into account the characteristics of a material being ground, the load on the mill by the material being ground, and the linear velocity of the tips of the rotor blades:

$$\delta_{50} = 2.71cw^{-1.42}G, \qquad (2)$$

where *c* is a coefficient that takes into account the physicomechanical properties of the material and

the size of its initial particles (c = 0.05 for lime and chalk, 0.12 for gypsum stone, 0.2 for sylvinite and 0.25 for barley grain); w, the linear velocity of the tips of the rotor blades (m s^{-1}); and G, the amount of material fed into the mill (kg s^{-1}).

Analysis of the coarsest particles in grinding products shows that, even in grinding of barley grain and gypsum stone, their size is smaller than that in the starting materials by a factor of 2.5–3. When baffle rods with rectangular or circular cross-section were used in experiments, no noticeable influence of the rod shape on the fraction composition of the grinding products was observed. The process of grinding with a simultaneous classification was studied with a mill of the design shown in Fig. 1a. In this case, the baffle rods had a rectangular (14 × 14 mm) cross-section and the distance between the rods was varied from 0.5 to 4 mm. First, sylvinite and then other materials were ground at a rotor rotation rates of 2300 and 1450 rpm and load by material of 0.133 kg s^{-1}. In the course of the experiments, the fraction composition of the grinding products that passed through slits between the rods was constantly monitored. The experiments, whose results are shown in Fig. 5, demonstrated that the main factor that determines the fraction composition of grinding products is the width of the slits between the rods. The maximum size of the particles that passed through the slits was, in all the experiments with various materials, as follows:

$$\delta_{max} = (0.5 - 0.75)b, \quad (3)$$

where b is the width of the slits between the rods.

The fraction composition of the grinding products that passed through the slits between the baffle rods can also be described, with an accuracy sufficient for engineering calculations, using the Rosin–Rammler formula

$$D = 100[1 - \exp(-45.38\, b^{-2.3}\, \delta^{2.5})]. \quad (4)$$

In all the experiments, the power consumption by the mill drive was measured. Figure 6 shows how the power consumed by the mill depends on the load by material. It can be seen from the plot that, even in an idle run, the mills consume 1.8 to 3 kW of electric power. Most part of this energy goes to operation of a mill as a ventilator. Curves *1–3* in Fig. 6 were obtained in studying a mill of design shown in Fig. 1a, in which a continuous flow-through classification is effected by baffle rods mounted at a distance of 1 mm from one another. In grinding of lime (curve *1*), grains are disintegrated by the impact into fine crystals of size less than 0.5 mm (which is well seen in Fig. 2) and these crystals are carried by the air flow and easily pass through the slits between the rods, leaving the grinding zone without delay. Therefore, energy is consumed in this case only for acceleration of particles. Curves *2* and *3* were obtained in grinding gypsum stone and barley grain in the same mill. These materials do not completely ground upon impact into particles of less than 0.5 mm in size and accumulate in the grinding zone. Therefore, additional grinding occurs because of the wear in this zone, and, consequently, the loss of power substantially increases, especially at high loads.

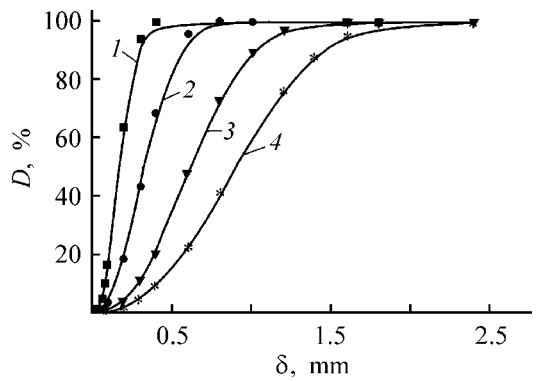

Fig. 5. Fraction composition of the products formed in grinding of sylvinite in the mill of design shown in Fig. 1a at different slit widths b. b (mm): (*1*) 0.5, (*2*) 1, (*3*) 2, and (*4*) 3.

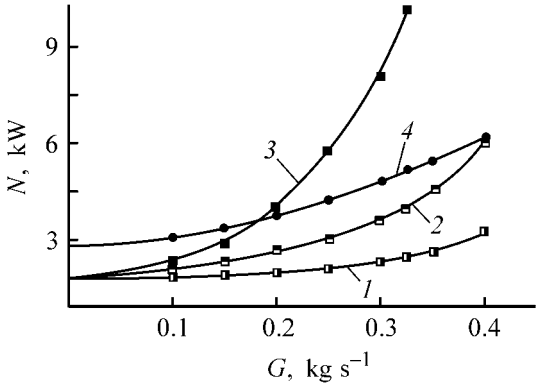

Fig. 6. Consumed power N vs. the load G by material. Ground substance: (*1*) lime, (*2*) gypsum stone, and (*3, 4*) barley grain. Mill design: (*1–3*) first (Fig. 1a) and (*4*) third (Fig. 1c).

Consequently, mills of the first and second designs (Figs. 1a, 1b) can be recommended for grinding of such materials as lime, chalk, lumps of dry clay, grains and crystals of salts. At small loads of up to 200 kg h^{-1} and mill rotor diameter of 400 mm, mills can be used to grind harder materials. For example, several mills

of second design (Fig. 1b) have long been used to grind roots and herbs in production of medicines and food additives.

Curve *4* shows an increase in the power consumption in grinding of barley grain in a mill of the third design (Fig. 1c). There are no dead zones in this mill and the material is ground under two-stage impact load; therefore, the power consumption gradually grows as the load on the mill increases.

CONCLUSION

The quality of grinding of materials with low and medium strength in impact-centrifugal mills substantially exceeds that in hammer mills, which are widely used for this purpose. At the same time, the specific electric power consumption by the impact-centrifugal mills is 20–30% lower. It is advisable to replace hammer mills with impact-centrifugal mills.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Convective Mass Exchange between Flows of Finely Dispersed Media in a Valve-Pulsatory Mass-Exchange Apparatus

R. Z. Aliev, M. R. Aliev, and A. R. Aliev

Daghestan Research Institute of Food Industry, Makhachkala, Daghestan, Russia

Received March 26, 2003; in final form, November 2003

Abstract—A mathematical model of convective mass exchange between flows of finely dispersed media in a valve-pulsatory apparatus is developed with account of the mass exchange between the dispersed and continuous phase at $\mathrm{Sh} \cdot \mathrm{Fo} \geq 1$.

The rate of technological processes carried out in solid–liquid and solid–gas systems increases as the size of dispersed particles of the solid phase becomes smaller, and the relative velocity of counterflowing phases, higher. However, in the known methods of phase interaction, the maximum possible velocity of counterflowing phases is limited and becomes slower as the particle size and the difference of phase densities decrease.

These limitations are overcome in the new method of phase interaction, suggested by the authors. In this method, a dispersed solid phase is mixed with a part of the liquid (or gas) phase to form a suspension (or an aerosol) and a counterflow convective mass exchange between the flows of the resulting suspension and the liquid is carried out in an apparatus with long channels separated by a convectively permeable partition, by creating multiple alternating-sign pressure differences between the channels [1–3].

The new method of phase interaction is used to perform mass and heat exchange between flows of hydro- and gas-dispersed systems in technological processes of extraction and sorption, chemical reactions that yield a solid dispersed phase, phase-selective heating, and cooling of dispersed media [4–7].

In [8], the authors of the present study analyzed the convective mass exchange between flows of finely dispersed media with an inert solid phase in a valve-pulsatory mass-exchange apparatus (VPMEA) [1–3], which is used to carry out effective processes of heat and mass exchange in hydro- and gas-dispersed systems [4–7].

The aim of this study was to construct a mathematical model of the convective mass exchange in VPMEA with account of the interphase mass transfer for the case when the intensity of this mass transfer is so high that the continuous and dispersed phases can be considered to be in equilibrium at any point of the VPMEA at any instant of time. This is the case for a number of the above-mentioned processes, which are carried out effectively in the kinetically advantageous conditions of finely dispersed media, when the characteristic time of the interphase mass exchange is negligible as compared with the residence time t_R of a suspension in the VPME apparatus. Moreover, this situation, being a limiting case, makes it possible to estimate the maximum possible result of a convective mass exchange in a VPMEA and, in this sense, is of a certain practical importance.

First, let us describe in brief the design and operation mode of a VPMEA [8]. The finely dispersed medium is composed of a continuous and a dispersed phases; VPMEA contains two neighboring channels separated by a partition that is permeable to the continuous phases and impermeable to the dispersed phases of the flows (Fig. 1). Each phase contains a component that can pass from one phase into the other as a result of sorption, extraction, etc. The finely dispersed media move within the VPMEA channels in a counterflow. The operation of the VPMEA consists

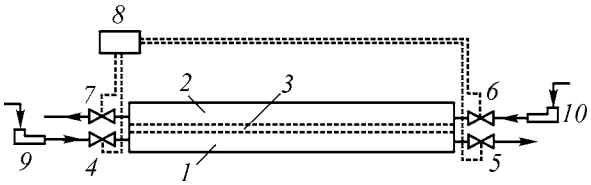

Fig. 1. Schematic of a valve-pulsatory mass-exchange apparatus: (*1*, *2*) VPMEA channels, (*3*) permeable partition, (*4–7*) valves, (*8*) valve control unit, and (*9*, *10*) pumps.

in two alternating time steps of length t_{ts}, determined by the positions of valves at channel inlets and outlets.

In the first time step, the inlet valve of the first channel and the outlet valve of the second are open, whereas the inlet valve of the second channel and the outlet valve of the first are closed. The first finely dispersed medium with an initial concentration of the component $c_1(0, t) = c_{1\,in}$ and porosity $\varepsilon_1(0, t) = \varepsilon_{1\,in}$ is fed into the first channel and filtered through the permeable partition. This creates a flow in the second channel, which exits the second channel with a concentration $c_2(0, t) = c_{2\,out}(t)$ and porosity $\varepsilon_2(0, t) = \varepsilon_{2\,out}(t)$.

In the second time step, the inlet valve of the first channel and the outlet valve of the second are closed, whereas the inlet valve of the second channel and the outlet valve of the first are open. The second finely dispersed medium with an initial concentration $c_2(l_0, t) = c_{2\,in}$ and porosity $\varepsilon_2(l_0, t) = \varepsilon_{2\,in}$ is fed into the second channel and filtered through the partition to create in the first channel a flow with a concentration $c_1(l_0, t) = c_{1\,out}(t)$ and porosity $\varepsilon_1(l_0, t) = \varepsilon_{1\,out}(t)$ leaves the first channel. Here t is time, and l_0, the channel length. Thus, sign-alternating pressure differences are created between the channel spaces. During their residence within a VPMEA in the case of such a pulsatory motion, the first and second finely dispersed phases repeatedly exchange portions of continuous phases, without mixing of their dispersed phases. Owing to this circumstance, there occurs a counter flow convective mass exchange between the flows of the first and second media. As a result, the concentration $c_{2\,out}(t)$ at the outlet of the second channel becomes close to the initial concentration $c_{1\,in}$, and the concentration $c_{1\,out}(t)$ approaches the concentration $c_{2\,in}$ at the inlet of the second channel. As the dispersed phase cannot pass from one channel into the other, $\varepsilon_{1\,out}(t) = \varepsilon_{1\,in}$ and $\varepsilon_{2\,out}(t) = \varepsilon_{2\,in}$ in the stationary case of VPMEA operation.

In [8], it was assumed that the mass exchange between the solid and liquid phases within a VPMEA is low as compared with the convective transfer of the component in the flows. However, in many solid–liquid and solid–gas systems used in industrially important technological processes, there occurs an interphase mass transfer, and, therefore, it is a matter of current interest to determine the influence exerted by this process on the convective mass exchange in VPMEA.

If the interphase transfer of the component is taken into account, then terms responsible the interphase mass transfer appear in the equations that describe the convective mass exchange in VPMEA, derived in [8]. Let us consider the case when the interphase equilibrium in both channels of a VPMEA is described by the equation $c_S = Hc_L^*$, where c_S is the concentration of the component being transferred in the particles of the dispersed phase; c_L^*, the corresponding equilibrium concentration of the component being transferred in the continuous phase; and H, the interphase equilibrium constant, which is common to both the VPMEA channels. Then the system of equations describing the mass exchange in VPMEA can be written as follows {see system (5) in [8]}:

$$\frac{dU_1}{dX} + \frac{s_2}{s_1}\frac{dU_2}{dX} = 0, \tag{1}$$

$$\frac{dU_1}{dX} + \frac{l_0}{d_{e1}}\frac{Re_{01}}{R_{ef1}} = 0, \tag{2}$$

$$\frac{dEu}{dX} + \frac{d}{dX}\left(\rho_1\gamma_1 U_1^2 - \rho_2\gamma_2 U_2^2\right) + \frac{e_{u1}l_0}{2d_{e1}}\rho_1\xi_1 U_1^2 - \frac{e_{u2}l_0}{2d_{e2}}\rho_2\xi_2 U_2^2 = 0, \tag{3}$$

$$\frac{\partial\varepsilon_i}{\partial T} + U_i\frac{\partial\varepsilon_i}{\partial X} - \frac{dU_i}{dX}(1 - \varepsilon_i) = 0, \tag{4}$$

$$\varepsilon_i\frac{\partial C_{Li}}{\partial T} + \varepsilon_i U_i\frac{\partial C_{Li}}{\partial X} - \frac{\partial U_i}{\partial X}(C_{Lj} - C_{Li}) + \frac{l_0}{u_{01}}\beta_i f_i(1 - \varepsilon_i)(C_{Li} - C_{Si}) = 0, \tag{5}$$

$$\frac{\partial C_{Si}}{\partial T} + U_i\frac{\partial C_{Si}}{\partial X} - \frac{l_0}{u_{01}}\frac{\beta_i f_i}{H}(C_{Li} - C_{Si}) = 0, \tag{6}$$

where the index i takes the values 1 or 2 (channel number); $X = x/l_0$; $U_i(X) = u_i(x)/u_{01}$; $T = t/t_0$; $t_0 = l_0/u_{01}$; $C_{Li}(X, T) = [c_{Li}(x, t) - c_{L\min}]/(c_{L\max} - c_{L\min})$ and $C_{Si}(X, T) = [c_{Si}(x, t) - c_{S\min}]/(c_{S\max} - c_{S\min})$ are the dimensionless concentrations of the component in the continuous and dispersed phases; $c_{Li}(x, t)$ and $c_{Si}(x, t)$, the component concentrations in the continuous and dispersed phases; $c_{L\min}$ and $c_{L\max}$, the minimum and maximum concentrations among $c_{L1\,in}$, $c_{S1\,in}/H$, $c_{L2\,in}$, and $c_{S2\,in}/H$; $c_{S\min}$, $c_{S\max}$, the minimum and maximum concentrations among $c_{S1\,in}$, $Hc_{L1\,in}$, $c_{S2\,in}$ and $Hc_{L2\,in}$; $c_{L1\,in}$, $c_{S1\,in}$, $c_{L2\,in}$, $c_{S2\,in}$, the concentrations at the inlet of the first and second channels of VPMEA; l_0, the length of VPMEA; $Eu(X) = [p_1(x) - p_2(x)]/(\rho_L u_{01}^2)$; $\rho_i = \varepsilon_i + (1 - \varepsilon_i)\rho_{Si}/\rho_{Li}$; ρ_{Li}, and ρ_{Si}, the densities of the continuous and dispersed phases; $R_{ef} = s_1 r_{ef}/\pi_{v1}$; $e_{ui} = u_i/|u_i|$; x, the longi-

tudinal coordinate; t, time; $\mathrm{Re}_{01} = u_{01}d_{e1}\rho_{L1}/\mu_1$; π_{vi}, the permeable part of the perimeter of ith channel; $u_i(x)$, the average, over the cross-section of ith channel, longitudinal velocity; $u_{01} = u_1(0)$; $\varepsilon_i(X, T)$, the porosity in ith channel; $p_i(x)$, the pressure in ith channel; s_i, the cross-section of ith channel; r_{ef}, the filtration resistance; d_{ei}, the equivalent diameter of ith channel; ξ_i and γ_i, the coefficients of friction and momentum flux in ith channel; β_i, the interphase mass-transfer coefficient in ith channel; f_i, the ratio between the area of the outer surface of a particle belonging to the dispersed phase and its volume in ith channel; μ_i, the viscosity of the continuous phase; and $\mathrm{Sr} = t_{ts}/t_0$.

The value of j depends on the direction of filtration of the continuous phase in the VPMEA. In the case of filtration from the first channel of the VPMEA into the second (first time step), $j = 1$, and in back filtration (second time step), $j = 2$. The dimensionless concentrations $C_{Li}(X, T)$ and $C_{Si}(X, T)$ are chosen in such a way that $C_{Li}(X, T) = C_{Si}(X, T)$ under the conditions of interphase equilibrium.

Exact calculation of the change in the concentration of the component being transferred in the dispersed phase in a VPMEA is rather difficult. However, this change can be roughly estimated on the basis of the relative values of the characteristic time $t_D \sim d_S^2/D_L$ of molecular diffusion of the component in the continuous phase [9], characteristic time $t_\beta \sim 1/(\beta f) \sim d_S/\beta$ of a change in the concentration of the component being transferred in particles of the dispersed phase through interphase mass transfer, and time step duration t_{ts}. Here, D_L is the diffusion coefficient of the component within particles of the dispersed phase, and d_S is the equivalent diameter of these particles. Let us consider the following ratios: $t_D/t_\beta \sim \beta d_S/D_L = \mathrm{Sh}$, the Sherwood number; $t_{ts}/t_D \sim D_L t_{ts}/d_S^2 = \mathrm{Fo}$, the Fourier number; and $t_{ts}/t\beta \sim \beta t_{ts}/d_S = \mathrm{Sh}\cdot\mathrm{Fo}$. Let $t_{ts} \sim 1$ s. Then we obtain for aqueous suspensions ($D_L \sim 10^{-9}$ m^2 s^{-1}) at $d_S \sim 10^{-5}$ m Fo ~ 10, and, because Sh ≥ 2, then $t_{ts}/t_\beta \sim \mathrm{Sh}\cdot\mathrm{Fo} >> 1$. Similarly, for air aerosols ($D_L \sim 10^{-6}$ m^2 s^{-1}) at $d_S \sim 10^{-4}$ m, we have Fo ~ 100 and $t_{ts}/t_\beta \sim \mathrm{Sh}\cdot\mathrm{Fo} >> 1$.

Thus, for technological mass-exchange processes (sorption, extraction) in finely dispersed media ($d_S \sim 10^{-5}$–10^{-4} m), the time t_β of interphase exchange is negligible as compared with the time step duration t_{ts}, and the more so, compared with the residence time t_R of the suspension in the VPMEA. In this case, the dispersed and continuous phases in the VPMEA can be considered, to a first approximation, to be in equilibrium, and the dimensionless concentrations of the component being transferred in the respective phases, to be equal to each other: $C_{Li}(X, T) = C_{Si}(X, T) = C_i(X, T)$. This equilibrium is itself different at different points of the VPMEA and time-dependent. Then, Eqs. (5) and (6) can be transformed to the form

$$\frac{\partial C_i}{\partial T} + U_i\frac{\partial C_i}{\partial X} - \frac{\Delta_m C_i^L}{\Delta_m C_i^D}\frac{dU_i}{dX}(C_j - C_i) = 0, \qquad (7)$$

where $\Delta_m C_i^L/\Delta_m C_i^D = 1/[\varepsilon_i + (1 - \varepsilon_i)H] = (c_{L\max} - c_{L\min})/[\varepsilon_i(c_{L\max} - c_{L\min}) + (1 - \varepsilon_i)(c_{S\max} - c_{S\min})]$ is the ratio of the maximum possible change in the concentration of the component being transferred in the continuous phase to the maximum possible change in the concentration of the component being transferred in the finely dispersed phase in ith channel of the VPMEA.

Equation (7) is transformed into the corresponding equations of the system (5) from [8] in the case when $(1 - \varepsilon_i)H/\varepsilon_i >> 1$, i.e., the maximum possible change of the component being transferred in the dispersed phase is considerably smaller in both channels of the VPMEA than the maximum possible change in the concentration of the component being transferred in the continuous phase. This circumstance can be regarded as inertness of the dispersed phase.

In what follows, we consider the case when a continuous phase ($\varepsilon_{1in} = 1$) is fed into the first channel of the VPMEA, and a dispersed medium ($\varepsilon_{2in} < 1$), into the second.

If a VPMEA is used for sorption, then, commonly, $c_{L\max} = c_{L1in}$, $c_{L\min} = c_{L2in} = c_{S2in}/H$, $c_{S\max} = Hc_{L1in}$, $c_{S\min} = c_{S2in} = Hc_{L2in}$. Then, the boundary conditions in the dimensionless form are the following:

$$C_1(0, T) = C_{1in} = [c_{L1}(0, t) - c_{L\min}]/(c_{L\max} - c_{L\min}) = [c_{L1in} - c_{L2in}]/(c_{L1in} - c_{L2in}) = 1, \qquad (8)$$

$$C_2(1, T) = C_{2in} = [c_{L2}(l_0, t) - c_{L\min}]/(c_{L\max} - c_{L\min}) = [c_{L2in} - c_{L2in}]/(c_{L1in} - c_{L2in}) = 0 \qquad (9)$$

or

$$C_2(1, T) = C_{2in} = [c_{S2}(l_0, t) - c_{S\min}]/(c_{S\max} - c_{S\min}) = [c_{S2in} - c_{S2in}]/(Hc_{L1in} - c_{S2in}) = 0. \qquad (10)$$

If a VPMEA is used for extraction, then, commonly, $c_{L\max} = c_{L2in} = c_{S2in}/H$, $c_{L\min} = c_{L1in}$, $c_{S\max} = c_{S2in} = Hc_{L2in}$, $c_{S\min} = Hc_{L1in}$. Then, the boundary conditions in the dimensionless form are the following:

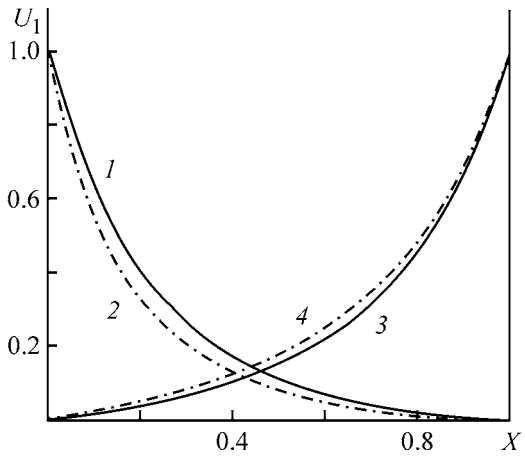

Fig. 2. Calculated dependences $U_1(X)$ of the velocity along the length of the first channel in the (*1*, *2*) first and (*3*, *4*) second time steps. $Re_{01} = 5000$, $l_0/d_e = 500$, $R_{ef1} = 10^6$, $R_{ef2}/R_{ef1} = 1.5$, $\delta_w/d_e = 10^{-2}$, $\varepsilon_{2in} = 0.97$. ρ_S/ρ_L: (*1*, *3*) 0.1 and (*2*, *4*) 10.

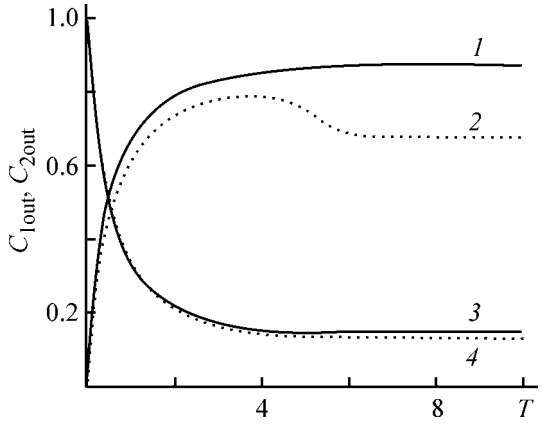

Fig. 3. Calculated dependences of the period-average dimensionless concentrations (*3*, *4*) $C_{1out}(T)$ and (*1*, *2*) $C_{2out}(T)$ on dimensionless time T at the outlets of the first and second VPMEA channels. $Re_{01} = 5000$, $l_0/d_e = 500$, $R_{ef1} = 10^6$, $R_{ef2}/R_{ef1} = 1$, $\delta_w/d_e = 10^{-5}$, $\varepsilon_{2in} = 0.97$, $\rho_S/\rho_L = 1$. H: (*1*, *3*) 0 and (*2*, *4*) 10.

$$C_1(0, T) = C_{1in} = [c_{L1}(0, t) - c_{Lmin}]/(c_{Lmax} - c_{Lmin}) = [c_{L1in} - c_{L1in}]/(c_{L2in} - c_{L1in}) = 0, \quad (11)$$

$$C_2(1, T) = C_{2in} = [c_{L2}(l_0, t) - c_{Lmin}]/(c_{Lmax} - c_{Lmin}) = [c_{L2in} - c_{L1in}]/(c_{L2in} - c_{L1in}) = 1 \quad (12)$$

or

$$C_2(1, T) = C_{2in} = [c_{S2}(l_0, t) - c_{Smin}]/(c_{Smax} - c_{Smin}) = [c_{S2in} - Hc_{L1in}]/(c_{S2in} - Hc_{L1in}) = 1. \quad (13)$$

Thus, the whole spectrum of boundary conditions for the concentrations $c_{L1}(0, t) = c_{L1in}$, $c_{L2}(l_0, t) = c_{L2in}$, $c_{S1}(0, t) = c_{S1in}$, $c_{S2}(l_0, t) = c_{S2in}$ is reduced in the case in question to two variants of dimensionless boundary conditions: $C_{1in} = C_1(0, T) = 1$, $C_{2in} = C_2(1, T) = 0$ or $C_{1in} = 0$, $C_{2in} = 1$. Together with Eqs. (7), these conditions form two possible boundary-value problems. It turns out that, with one of these boundary-value problems solved, the solution to the other can be readily obtained.

Let the functions $C_1(X, T)$ and $C_2(X, T)$ be a solution to the first boundary-value problem with boundary conditions $C_{1in} = 1$, $C_{2in} = 0$. Let us consider the functions $C^1(X, T) = 1 - C_1(X, T)$ and $C^2(X, T) = 1 - C_2(X, T)$. Hence we can express $C_1 = 1 - C^1$ and $C_2 = 1 - C^2$. Substituting the resulting expressions in Eq. (7), we make certain that C^1 and C^2 are solution to Eqs. (7). In addition, $C^1(0, T) = C^{1in} = 1 - C_{1in} = 0$ and $C^2(1, T) = C^{2in} = 1 - C_{2in} = 1$. Thus, we found the functions $C^1(X, T)$ and $C^2(X, T)$, which are the solution to the second boundary-value problem with boundary conditions $C^{1in} = 0$, $C^{2in} = 1$. The solution to the first boundary-value problem can be found similarly if the solution to the second problem is known.

In the calculations, the distributions $U_1(X)$, $U_2(X)$, and $Eu(X)$ are first calculated using Eqs. (1)–(3). Then $\varepsilon_2(X, T)$ is calculated using Eq. (4). Further, $C_1(X, T)$ and $C_2(X, T)$ are calculated by Eqs. (7). The calculations begin from $T = 0$ and continue till the end of the first time step $T = Sr$ with the boundary conditions of the first time step. Then the calculations are continued from $T = Sr$ till the end of the second time step $T = 2Sr$ with the boundary conditions of the second time step. This completes the first period of pulsations. Then, the calculation is performed with the boundary conditions of the first time step in the time interval from $T = 2Sr$ to $T = 3Sr$, with the boundary conditions of the second time step in the range from $T = 3Sr$ to $T = 4Sr$, and so on. After a certain time, the operation of the VPMEA reaches the steady state. The steady operation mode is such a mode at which the period-average concentrations $C_{1out}(T)$ and $C_{2out}(T)$ at VPMEA outlets do not vary between the periods: $C_{1out}(T) = C_{1outst}$ and $C_{2out}(T) = C_{2outst}$. Typical calculated dependences $U_1(X)$, $C_{1out}(T)$, $C_{2out}(T)$ are shown in Figs. 2, 3. The corresponding boundary conditions are described below.

The efficiency of the convective mass exchange between the flows in the VPMEA is the higher, the greater the average amount of the component transferred across the permeable partition during a period (two time steps) of pulsations in the steady mode of

VPMEA operation. The mass of the component transferred from one channel of the VPMEA into the other can be characterized by the difference between the concentrations $c_{\mathrm{L}\,in}$ and $c_{\mathrm{L}outst}$ at the inlet and outlet of one of the VPMEA channels. In the second channel, the concentration of the component in the continuous phase changes not only because of the flow between the VPMEA channels, but also as a result of the interphase transfer of the component. Therefore, the efficiency of the convective mass exchange between the flows in the VPMEA should be determined from the absolute value of the difference between the concentrations $c_{\mathrm{L}1\,in}$ and $c_{\mathrm{L}1outst}$ at the inlet and outlet of the first VPMEA channel. This difference is to be related to the maximum possible difference $c_{\mathrm{L}max} - c_{\mathrm{L}min}$:

$$E = |c_{\mathrm{L}1outst} - c_{\mathrm{L}1in}|/(c_{\mathrm{L}max} - c_{\mathrm{L}min}) = |C_{\mathrm{L}1outst} - C_{\mathrm{L}1in}| = |C_{1outst} - C_{1in}|. \quad (14)$$

The quantity E is named the degree of mass exchange between the VPMEA channels. It is independent of boundary conditions and determines the efficiency of the convective mass exchange between the flows in the VPMEA [8].

The hydrodynamic and mass-exchange characteristics of the VPMEA were calculated using Eqs. (1)–(4), (7) with the following boundary conditions. In the first time step, $U_1(0) = 1$, $U_2(0) = -1$, $U_1(1) = U_2(1) = 0$, $C_1(0, T) = C_{1in}$, $\varepsilon_1(0, T) = \varepsilon_{1in}$. In the second time step, $U_1(1) = 1$, $U_2(1) = -1$, $U_2(0) = U_1(0) = 0$, $C_2(1, T) = C_{2in}$, $\varepsilon_2(1, T) = \varepsilon_{2in}$. Initial conditions: $C_1(X, 0) = C_{01}$, $\varepsilon_1(X, 0) = \varepsilon_{01}$, $C_2(X,0) = C_{02}$, $\varepsilon_2(X, 0) = \varepsilon_{02}$. Here, $C_{j\mathrm{in}}$ is the dimensionless concentration of the component in the finely dispersed medium at the inlet of jth VPMEA channel, and C_{0j} and ε_{0j} are the dimensionless concentration and the porosity at the initial instant of time in the jth VPMEA channel. The parameters of the system being calculated are the following: $\varepsilon_{1in} = 1$; $\varepsilon_{2in} = 0.97$, 0.98, 0.99; $C_{1in} = 1$; $C_{2in} = 0$; $\varepsilon_{01} = \varepsilon_{1in}$; $\varepsilon_{02} = \varepsilon_{2in}$; $C_{01} = C_{1in}$; $C_{02} = C_{2in}$; $\rho_{L1} = \rho_{L2} = \rho_L$; $\rho_{S2} = \rho_S$; $\rho_S/\rho_L = 0.1$, 1, 10; $\mu_1 = \mu_2 = \mu$; $c_{L1} = c_{L2} = c_L$; $c_{S2} = c_S$; $c_S/c_L = 0$, 1, 10, 100, 1000; $t_{ts1} = t_{ts2} = t_{ts}$; $d_{e1} = d_{e2} = d_e$; $s_1 = s_2 = s$; $u_{01} = u_{02} = u_0$; $\pi_{v1} = \pi_{v2} = \pi_v$; $\mathrm{Sr} = t_{ts}/t_0 = 0.05$; $\mathrm{Re}_{01} = 200$, 400, 600, 800, 1000, 2000, 4000, 5000, 6000, 8000, 10 000; $l_0/d_e = 100$, 200, 300, 400, 500, 600, 700; $R_{ef1} = 10^6$, 10^7, 10^8; $R_{ef2}/R_{ef1} = 1.0$, 1.5; $\delta_w/d_e = 10^{-5}$, 10^{-2}; R_{ef1} and R_{ef2} are the effective dimensionless resistances to filtration in the first and second time steps; and δ_w is the thickness of the permeable partition in the VPMEA. Because $\varepsilon_{1in} = 1$, we have $\Delta_m C_1^L/\Delta_m C_1^D = 1$ and $\Delta_m C_2^L/\Delta_m C_2^D(X, T) = \{\varepsilon_2(X, T) + [1 - \varepsilon_2(X, T)]\mathrm{H}\}^{-1}$ for the first and second channels, respectively.

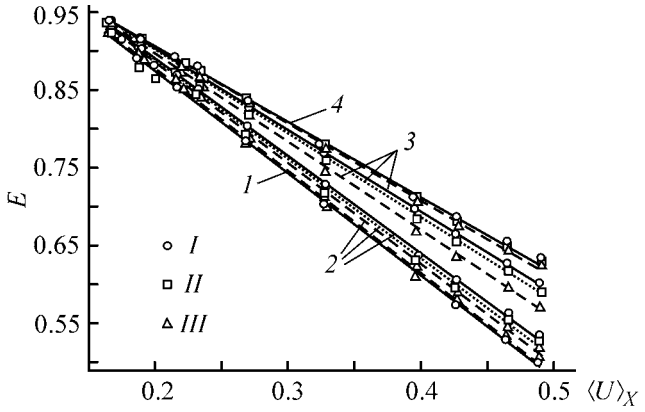

Fig. 4. Calculated dependences of the degree E of mass exchange between the flows in the VPMEA channels on $\langle U\rangle_X$. $R_{ef2}/R_{ef1} = 1$, $\delta_w/d_e = 10^{-5}$, $\rho_S/\rho_L = 1$. H: (*1*) 0, (*2*) 10, (*3*) 100, (*4*) 1000. ε_{2in}: (*I*) 0.97, (*II*) 0.98, (*III*) 0.99; the same for Fig. 5. Different values of $\langle U\rangle_X$ are set by varying Re_{01}, l_0/d_e, and R_{ef1} (Table 1).

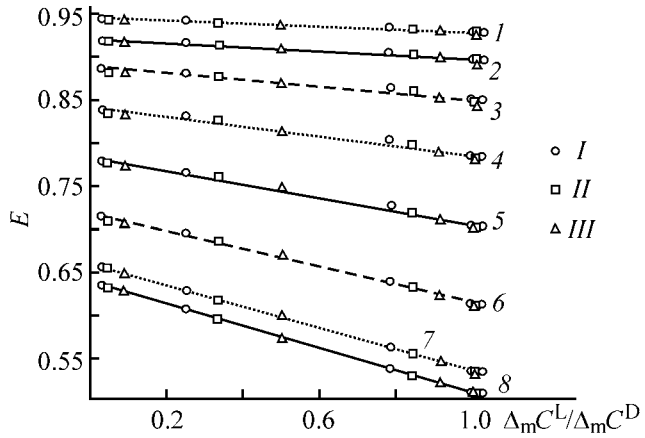

Fig. 5. Calculated dependences of the degree E of mass exchange between the flows in the VPMEA channels on $\Delta_m C^L/\Delta_m C^D = 1/[\varepsilon_{2in} + (1 - \varepsilon_{2in})H]$. $\mathrm{Re}_{01} = 5000$, $R_{ef2}/R_{ef1} = 1$, $\delta_w/d_e = 10^{-5}$, $\rho_S/\rho_L = 1$. R_{ef1}: (*1–7*) 10^6 and (*8*) 10^8. l_0/d_e: (*1*) 700; (*2*) 600; (*3, 8*) 500; (*4*) 400; (*5*) 300, (*6*) 200; and (*7*) 100. Different values of $\Delta_m C^L/\Delta_m C^D$ are set by varying H (Table 2).

The procedure for calculation of the hydrodynamic and mass-exchange characteristics of the VPMEA was described in detail in [8–18]. The results of calculations are presented in Figs. 2–6.

As can be seen from the above-mentioned calculation conditions, a continuous medium (continuous

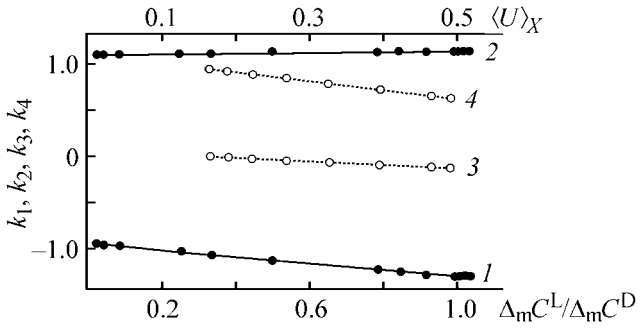

Fig. 6. Calculated dependences (*1*) $k_1(\Delta_m C^L/\Delta_m C^D)$, (*2*) $k_2(\Delta_m C^L/\Delta_m C^D)$ and (*3*) $k_3(\langle U\rangle_X)$, (*4*) $k_4(\langle U\rangle_X)$. $R_{ef2}/R_{ef1} = 1$, $\delta_w/d_e = 10^{-5}$, $\rho_S/\rho_L = 1$. Different values of $\langle U\rangle_X$ are set by varying Re_{01}, l_0/d_e, and R_{ef1} (Table 1); and those of $\Delta_m C^L/\Delta_m C^D$, by varying ε_{2in} and H (Table 2).

phase with a dimensionless concentration equal to unity) is delivered at the inlet of the first channel, and a finely dispersed medium with a dimensionless concentration equal to zero, at the inlet of the second channel.

In operation of a VPMEA, a continuous phase with high concentration flows from the first channel into the second during the first time step, and a continuous phase with low concentration flows from the second channel into the first during the second time step. Because of the flow of portions of the continuous phase between the VPMEA channels, the dimensionless concentration decreases in the first channel, and increases in the second. The changes in concentration in the VPMEA channels, which are caused by the flow, are described by the third term in Eq. (7). This term contains the factors $\Delta_m C_i^L/\Delta_m C_i^D$ and dU_i/dX. From Eqs. (1), (2) follows that $|Eu| \sim |dU_i/dX|$. The quantity $|Eu|$ determines the rate of flow between the channels (filtration rate). The efficient work of the VPMEA can be ensured in the following operation mode of the VPMEA: in the first time step, $|Eu|$ should be large in the input part of the VPMEA and small in its output part; in the second time step, by contrast, $|Eu|$ should be small in the input part of the VPMEA and large in its output part. During the first time step, the flow of the continuous phase with a high concentration between the channels occurs mainly in the input part of the VPMEA near the outlet of the second channel, whereas in the second time step, the flow of the continuous phase with a low concentration between the channels occurs mainly in the output part of the VPMEA near the outlet of the first channel. In this way, a high concentration of the component in the flow at the outlet of the second channel is ensured in the first time step, and a low concentration of the component in the flow at the outlet of the first channel, in the second time step.

Consequently, the efficient operation of a VPMEA requires that $|dU_i/dX|$ should be large at small X and small at large X in the first time step, and large at large X and small at small X in the second time step. This can be achieved at a large curvature of the curve describing the dependence $U_i(X)$ (Fig. 2). The larger the curvature of the $U_i(X)$ curve, the higher the efficiency of VPMEA operation. It has been shown [8, 13–18] that the efficiency of VPMEA operation is the higher, the greater Re_{01} and l_0/d_e and the smaller R_{ef1}. It is these three parameters that mainly determine the hydrodynamic situation in the VPMEA channels. In order to find out which combination of these three parameters is the most advantageous, it is necessary to determine, using Eqs. (1)–(3) the $U_i(X)$ distributions and to compare the curvatures of the $U_i(X)$ curves. The most advantageous is that combination of the parameters Re_{01}, l_0/d_e, R_{ef1} at which the curvature of the $U_i(X)$ is the largest. However, the notions "larger" and "smaller" curvature are insufficiently exact. Instead, it is necessary to use a clearly defined and readily calculable quantity that varies with the curvature of the $U_i(X)$ curve. As a parameter of this kind can serve the dimensionless longitudinal flow velocity averaged over the length of *i*th channel, $\langle U_i\rangle X$.

It is noteworthy that the extreme points of the dependence $U_i(X)$ are always fixed (Fig. 2). This follows from the boundary conditions presented above. It can be seen from Fig. 2 that the larger the curvature of the $U_i(X)$ dependence, the lower the dimensionless longitudinal flow velocity averaged over the length of *i*th channel $\langle U_i\rangle X$:

$$\langle U_i\rangle_X = \frac{1}{2}\left(\langle U_i\rangle_{1X} + \langle U_i\rangle_{2X}\right) = \frac{1}{2}\left(\int_0^1 U_i^{(1)}(X)\,dX + \int_0^1 U_i^{(2)}(X)\,dX\right), \quad (15)$$

where $U_i^{(1)}(X)$, $U_i^{(2)}(X)$, $\langle U_i\rangle_{1X}$, $\langle U_i\rangle_{2X}$ are dimensionless longitudinal velocities and their values averaged over the length of *i*th channel in the first and second time steps.

In the case of a counterflow, the absolute value of $\langle U_i\rangle_X$ coincides for the first and second channels, because $U_1(X) = -U_2(X)$ at any instant of time. Therefore:

$$\langle U\rangle_X = |\langle U_1\rangle_X| = |\langle U_2\rangle_X|. \quad (16)$$

The smaller $\langle U\rangle_X$, the larger the value of $|dEu/dX|$. Therefore, we can analyze, instead of the dependence

Table 1. Dimensionless longitudinal flow velocity averaged over the VPMEA length, $\langle U\rangle_X$, in relation to the characteristics of the VPMEA (R_{ef1}, l_0/d_e, Re_{01}) and to the porosity ε_{2in} of the finely dispersed medium $R_{ef2}/R_{ef1} = 1$, $\rho_S/\rho_L = 1$, $\delta_w/d_e = 10^{-5}$, $Re_{01} = 5000$, $l_0/d_e = 500$, $R_{ef1} = 10^6$

* For each particular calculation, those parameters are given, which differ from the prescribed conditions.

of E on $|dEu/dX|$, that of E on $\langle U\rangle_X$. Thus, the value of $\langle U\rangle_X$ is a parameter that determines the efficiency of the convective mass exchange between the flows in a VPMEA, and, in this regard, it replaces the quantity $|dEu/dX|$. The advantage of the parameter $\langle U\rangle_X$ over $|dEu/dX|$ consists in that it is more rigorously defined and can be more easily calculated. Table 1 lists values of $\langle U\rangle_X$ for different parameters of the VPMEA. The value of $\langle U\rangle_X$ decreases as Re_{01} and l_0/d_e increase and R_{ef1} decreases. The data in Table 1 indicate that, at Re_{01} 200–2000, $\langle U\rangle_X$ remains invariable. This circumstance can be readily understood if Eu is expressed in terms of Eq. (2) and substituted in Eq. (3), and account is taken of the fact that, in the case of a laminar flow, $\xi_i \sim \text{const}_i/[Re_{01}U_i(X)]$ and $\gamma_1 = \gamma_2$. At $\rho_S/\rho_L = 1$, we have $\rho_1 = \rho_2$ because $U_1^2 = U_2^2$ for a counterflow. The remaining three terms in Eq. (3) contain Re_{01} in their denominators. Therefore, Re_{01} can be canceled, with Eq. (3) brought to a form that is independent of Re_{01}. Consequently, the distributions of the x components of the dimensionless flow velocities along the VPMEA channels are independent of the Reynolds numbers at the cannel inlets in the case of a laminar flow.

Another parameter determining the value of E is the ratio $\Delta_m C_2^L/\Delta_m C_2^D$. The convenience of using the parameters $\langle U\rangle_X$ and $\Delta_m C_2^L/\Delta_m C_2^D$ consists, among other things, in that they have limited variation limits. At $H \to \infty$ we have $\Delta_m C_2^L/\Delta_m C_2^D \to 0$, and at $H = 0$, $\Delta_m C_2^L/\Delta_m C_2^D = 1/\varepsilon_2$. The data in Table 1 demonstrate that $\langle U\rangle_X$ varies from 0 to 1/2.

Figure 3 shows the calculated dimensionless concentrations $C_{1out}(T)$ and $C_{2out}(T)$ at the outlet of the first and second channels of the VPMEA at different values of H. It can be seen that, as the value of H increases (in this case, the $\Delta_m C_2^L/\Delta_m C_2^D$ ratio decreases), the stationary values C_{1outst} and C_{2outst} of the dimensioness concentrations C_{1out} and C_{2out} decrease. This fact is accounted for as follows. The concentration of the component being transferred in the second channel of the VPMEA increases because of the inflow of a continuous phase with a high concentration of this component from the first channel. The higher H, the larger the mass of the component that passes into the dispersed phase for an equilibrium to be established and the lower equilibrium concentration is attained in the second channel. This directly

Table 2. $\Delta_m C^L/\Delta_m C^D$ ratio of the maximum possible change in the concentration of the component being transferred in the continuous medium, averaged over the length of the second channel, to the similarly averaged maximum possible change in the concentration of the component being transferred in the finely dispersed medium at different interphase equilibrium constants H and porosities ε_{2in} of the finely dispersed medium at the inlet of the second channel of the VPMEA

H	$\Delta_m C^L/\Delta_m C^D$ at ε_{2in}		
	0.97	0.98	0.99
0	1.03	1.02	1.01
1	1.0	1.0	1.0
10	0.787	0.847	0.917
100	0.252	0.336	0.503
1000	0.032	0.048	0.091

follows from Eq. (7). The increase in the mass of the component being transferred in the second channel of the VPMEA as a result of the inflow of a continuous phase from the first channel is described by the last (third) term in Eq. (7). As H increases, this term becomes less important ($\Delta_m C_2^L/\Delta_m C_2^D$ ratio decreases), and the concentration in the second channel increases to a lesser extent. The concentration in the first channel decreases to a greater extent.

The dependence of the calculated degree $E = 1 - C_{1outst}$ of mass exchange between the VPMEA channel on the parameters $\langle U\rangle_X$ and $\Delta_m C_2^L/\Delta_m C_2^D$ for $R_{ef2}/R_{ef1} = 1$, $\delta_w/d_e = 10^{-5}$, $\rho_S/\rho_L = 1$ is generalized in Figs. 4, 5. The calculations were carried out at porosities $\varepsilon_{2in} = 0.97, 0.98, 0.99$ and interphase equilibrium constants $H = 0, 1, 10, 100, 1000$. For each pair of ε_{2in} and H, 19 calculations (19 values of $\langle U\rangle_X$; Table 1) were performed by varying Re_{01}, l_0/d_e, and R_{ef1}. Thus, a total of 285 calculations were performed to give 285 values of E.

Figure 4 shows the dependence of E on $\langle U\rangle_X$. It was found that the points for $H = 1$ differ only slightly from the corresponding points for $H = 0$, and, therefore, the points for $H = 1$ are not shown in the figure. Thus, Fig. 4 reflects the results of 228 calculations. It can be seen that the 19 points calculated at different VPMEA parameters (different $\langle U\rangle_X$), but at constant ε_{2in} and H fall approximately on the same straight line. Thus, there are 12 straight lines in Fig. 4, each of which is plotted using the least-squares method for 19 calculated points. As also can be seen from Fig. 4, the smaller the parameter $\langle U\rangle_X$ and the greater the constant H, the larger the calculated value of E, i.e., the higher the efficiency of the convective mass transfer between the flows in the VPMEA. In the absence of an interphase transfer ($H = 0$), the efficiency of the convective mass exchange between the flows in the VPMEA is at a minimum.

Figure 5 shows the dependence of E on the ratio $\Delta_m C^L/\Delta_m C^D$ of $\Delta_m C_2^L$ and $\Delta_m C_2^D$, averaged over the length of the second channel: $\Delta_m C^L/\Delta_m C^D = [\langle\varepsilon_2\rangle_X + (1 - \langle\varepsilon_2\rangle_X)H]^{-1}$, where $\langle\varepsilon_2\rangle_X$ is the porosity averaged over the length of the second channel. The use of the $\Delta_m C^L/\Delta_m C^D$ ratio is due to the fact that the variation of the porosity along the channel was insignificant in all the calculations [8]. Therefore, it was approximately taken that $\langle\varepsilon_2\rangle_X = \varepsilon_{2in}$. The values of the parameter $\Delta_m C^L/\Delta_m C^D$ at different ε_{2in} and H are listed in Table 2. In order not to overcharge Fig. 5, it shows the results of calculations only for 8 out of 19 different variants of the characteristics R_{ef1}, l_0/d_e, Re_{01} of the VPMEA. Thus, Fig. 5 reflects the results of 120 calculations. Because the quantity H does not appear in the hydrodynamic equations (1)–(3), 24 different values of $\langle U\rangle_X$ correspond to these 120 calculations (Table 1). The data of Table 1 indicate that changing ε_{2in} from 0.97 to 0.99 results in that the value of $\langle U\rangle_X$ changes by less than 2%. At the same time, changing the characteristics of the VPMEA leads to a significant change in $\langle U\rangle_X$. Therefore, the calculations performed at different ε_{2in} and H, but constant VPMEA characteristics show how E varies with $\Delta_m C^L/\Delta_m C^D$ at a constant $\langle U\rangle_X$. Figure 5 shows that the 15 points calculated at constant VPMEA characteristics for three different values of ε_{2in} and five different values of H fall approximately on the same straight line. Thus, Fig. 5 shows eight straight lines, each of which is plotted by the least-squares method for 15 calculated points. Each of these eight straight lines corresponds to a certain set of VPMEA characteristics and, accordingly, to a certain value of $\langle U\rangle_X$. The $\langle U\rangle_X$ averaged over three values of porosity are listed in Table 1. As can be seen in Fig. 5, the smaller the parameter $\Delta_m C^L/\Delta_m C^D$, the higher the value of E, i.e., the higher the efficiency of the convective mass exchange between the flows in the VPMEA.

According to Eqs. (7), the parameter $\Delta_m C^L/\Delta_m C^D$ directly affects the change in the concentration C_2 in channel *2* of VPMEA when the continuous phase flows from channel *1* into channel *2* (first time step). When the continuous phase flows from channel *2* into channel *1* (second time step), the last term in Eq. (7) for C_2 is zero. In Eq. (7) for C_1, the last term is zero during the first time step, and in the second, the coefficient of this term is unity. Therefore, the smaller

the parameter $\Delta_m C^L/\Delta_m C^D$, the weaker the influence exerted by the flow of the component from channel *1* into channel *2* on the change in the concentration C_2 in channel *2*, i.e., the lower C_2. Then, a continuous phase with a lower dimensionless concentration arrives at channel *1* in the second time step, and we obtain a lower $C_{1\,outst}$ at the outlet of channel *1* of the VPMEA and, accordingly, a higher degree E of mass exchange between the flows in the VPMEA channels.

Let us now discuss the influence exerted by the parameter $\Delta_m C^L/\Delta_m C^D$ on the efficiency of a VPMEA in terms of common dimensional concentrations. The parameter $\Delta_m C^L/\Delta_m C^D$ decreases when the constant H becomes larger (Table 2). A higher value of H means that, in passing from one equilibrium to another, the change in the concentration c_{L2} of the component in the continuous phase is considerably smaller than the change in the concentration c_{S2} of the component in the dispersed phase. The greater H, the smaller the change in c_{L2} and the greater the change in c_{L1}. In the case of adsorption, a considerable change in c_{L1} means that the initial continuous phase with a high concentration of the component is delivered to the inlet of channel *1*, whereas at the outlet of this channel we have a continuous phase with a low concentration of the component. In this case, a suspension with small c_{L2} and c_{S2} is delivered to the inlet of channel *2*. In the case of desorption, a substantial change in c_{L1} means that the initial continuous phase with a low concentration of the component is delivered to the inlet of channel *1*, and a continuous phase with a high concentration of the component is obtained at the outlet of channel *1*. In this case, a suspension with large c_{L2} and c_{S2} is delivered to the inlet of channel *2*. Thus, both in the case of adsorption and in desorption, the greater H, the higher E, i.e., the better the efficiency of the convective mass exchange between the flows in the VPMEA.

Each straight line in Fig. 4 is plotted at a certain value of $\Delta_m C^L/\Delta_m C^D$, and each straight line in Fig. 5, at a certain value of $\langle U\rangle_X$. Therefore, the family of straight lines in Fig. 4 can be described as

$$E\left(\langle U\rangle_X, \frac{\Delta_m C^L}{\Delta_m C^D}\right) = k_1\left(\frac{\Delta_m C^L}{\Delta_m C^D}\right)\langle U\rangle_X + k_2\left(\frac{\Delta_m C^L}{\Delta_m C^D}\right), \quad (17)$$

and the family of straight lines in Fig. 5, as

$$E\left(\langle U\rangle_X, \frac{\Delta_m C^L}{\Delta_m C^D}\right) = k_3(\langle U\rangle_X)\frac{\Delta_m C^L}{\Delta_m C^D} + k_4(\langle U\rangle_X). \quad (18)$$

The coefficients k_1, k_2 and k_3, k_4 were calculated for each straight line in Figs. 4, 5 by the least-squares method.

The dependences $k_1(\Delta_m C^L/\Delta_m C^D)$, $k_2(\Delta_m C^L/\Delta_m C^D)$, $k_3(\langle U\rangle_X)$, and $k_4(\langle U\rangle_X)$ are shown in Fig. 6. It can be seen that these dependences are linear. Each straight line in Fig. 6 is plotted on the basis of the calculated points, using the least-squares method:

$$k_1\left(\frac{\Delta_m C^L}{\Delta_m C^D}\right) = k_{11}\frac{\Delta_m C^L}{\Delta_m C^D} + k_{12}, \quad (19)$$

$$k_2\left(\frac{\Delta_m C^L}{\Delta_m C^D}\right) = k_{21}\frac{\Delta_m C^L}{\Delta_m C^D} + k_{22},$$

$$k_3(\langle U\rangle_X) = k_{31}\langle U\rangle_X + k_{32}, \quad (20)$$

$$k_4(\langle U\rangle_X) = k_{41}\langle U\rangle_X + k_{42},$$

where $k_{11} = -0.3521$, $k_{12} = -0.9529$, $k_{21} = 4.0394 \times 10^{-2}$, $k_{22} = 1.0998$, $k_{31} = -0.3539$, $k_{32} = 4.140 \times 10^{-2}$, $k_{41} = -0.9592$, $k_{42} = 1.1027$.

Substituting Eq. (19) into (17) and Eq. (20) into (18), we obtain

$$E\left(\langle U\rangle_X, \frac{\Delta_m C^L}{\Delta_m C^D}\right) = k_{11}\frac{\Delta_m C^L}{\Delta_m C^D}\langle U\rangle_X + k_{12}\langle U\rangle_X + k_{21}\frac{\Delta_m C^L}{\Delta_m C^D} + k_{22}, \quad (21)$$

$$E\left(\langle U\rangle_X, \frac{\Delta_m C^L}{\Delta_m C^D}\right) = k_{31}\langle U\rangle_X\frac{\Delta_m C^L}{\Delta_m C^D} + k_{32}\frac{\Delta_m C^L}{\Delta_m C^D} + k_{41}\langle U\rangle_X + k_{42}. \quad (22)$$

Thus, the dependence $E(\langle U\rangle_X, \Delta_m C^L/\Delta_m C^D)$ can be represented as

$$E\left(\langle U\rangle_X, \frac{\Delta_m C^L}{\Delta_m C^D}\right) = a_1\langle U\rangle_X\frac{\Delta_m C^L}{\Delta_m C^D} + a_2\frac{\Delta_m C^L}{\Delta_m C^D} + a_3\langle U\rangle_X + a_4, \quad (23)$$

where the coefficients $a_1 = (k_{11} + k_{31})/2 = -0.3530$, $a_2 = (k_{21} + k_{32})/2 = 4.090 \times 10^{-2}$, $a_3 = (k_{12} + k_{41})/2 = -0.9560$, $a_4 = (k_{22} + k_{42})/2 = 1.1012$.

An important temporal characteristic of the convective mass exchange between the flows in the VPMEA is the residence time $t_R \sim V/G \sim l_0/u_{01}$ of the finely dispersed phase in the VPMEA. Here, $V = l_0(s_1 + s_2)$ is the volume of the VPMEA; $G = (u_{01}s_1t_{ts1} + u_{02}s_2t_{ts2})/(t_{ts1} + t_{ts2})$, the average (in two time steps) flow rate of dispersed flows; and t_{ts1} and t_{ts2}, the durations of the first and second time steps. The residence

time is directly related to the time in which a steady-state operation of the VPMEA is attained. An exact calculation of the residence time is only possible for the dispersed phase. As particles of the dispersed phase do not pass from one channel into the other, the residence time of these particles in the VPMEA is the time of their motion within a certain channel, from inlet to outlet. A displacement dx along the channel takes a time d$x/u(x)$. Then, the residence time is found by integration along the channel length

$$t_R = \int_0^{l_0} \frac{dx}{u(x)} \quad \text{or} \quad T_R = \frac{t_R}{l_0} = \int_0^1 \frac{dX}{U(X)}. \qquad (24)$$

Exact calculation of the residence time for the continuous phase is impossible, because its different portions may move within a channel from inlet to outlet or may flow from one channel into the other, and such an interchanell flow may occur at any point of the permeable partition. At the same time, there is no doubt that the characteristic time of flow motion within the VPMEA is the l_0/u_{01} ratio, and the residence time will be of the same order of magnitude as this parameter. Therefore, if we are only interested in the order of magnitude of the residence time, we can use the l_0/u_{01} ratio. A more reliable estimate of the residence time is given by the V/G ratio. For the system being calculated, $V/G = 2l_0/u_{01}$. The corresponding value of the dimensionless time $T = 2$. It should also be noted that the parameter $1/\langle U\rangle_X$ can be regarded as the dimensionless residence time. This assumption is confirmed by the results of calculations. In Fig. 3, curves *1* and *2* level off (reach the stationary concentrations) at $T \approx 4$, with $1/\langle U\rangle_X = 4.221$. The discrepancy between these values does not exceed 5–6%.

CONCLUSIONS

(1) Integral parameters determining the efficiency of the convective mass exchange (degree of mass exchange) between flows of finely dispersed media in a valve-pulsatory mass-exchange apparatus were found for the case when the intensity of interphase mass transfer is so high that the continuous and dispersed phases can be considered to be in equilibrium ($\mathrm{Sh}\cdot\mathrm{Fo} = \beta t_{ts}/d_S >> 1$) at any point of the apparatus at any instant of time. These parameters are the following: (1) ratio $\langle U\rangle_X$ of the longitudinal flow velocity averaged over the channel length to the flow velocity at the channel inlet and (2) ratio $\Delta_m C^L/\Delta_m C^D = 1/[\varepsilon + (1 - \varepsilon)H]$ of the maximum possible change in the concentration of the component being transferred in the continuous phase to the maximum possible change in the concentration of the component being transferred in the dispersed phase. Here ε is the porosity of the finely dispersed phase and H is the constant characterizing the interphase equilibrium in the finely dispersed phase.

(2) It was established that the efficiency of the convective mass exchange (degree of mass exchange) between the flows of the finely dispersed and continuous media is the higher, the smaller the values of $\langle U\rangle_X$ and $\Delta_m C^L/\Delta_m C^D = 1/[\varepsilon + (1 - \varepsilon)H]$.

(3) It was shown that the parameters $\langle U\rangle_X$ and $\Delta_m C^L/\Delta_m C^D = 1/[\varepsilon + (1 - \varepsilon)H]$ can be used in optimization of the design and operation modes of a valve-pulsatory mass-exchange apparatus in the case of a very strong interphase mass transfer ($\mathrm{Sh}\cdot\mathrm{Fo} = \beta t_{ts}/d_S >> 1$).

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Flow Hydrodynamics of non-Newtonian Fluid in a Cylindrical-Conical Hydrocyclone

V. O. Yablonskii

Volgograd State University, Volgograd, Russia

Received October 1, 2003

Abstract—A system of equations of rheodynamics that describes the flow of a non-Newtonian fluid with a free surface in a cylindrical-conical hydrocyclone was solved numerically. The fields of velocities and pressure, as well as the dependence of the thickness of the fluid film on the axial coordinate, were calculated. The influence exerted by the rheological properties of the fluid and by the defining similarity criteria on the flow hydrodynamics was studied.

Cylindrical-conical hydrocyclones are the most widely used industrial apparatus for separating inhomogeneous dispersed systems. The simplicity of their design, small size, and high separation efficiency ensure their preferential use as compared with centrifuges and separators.

Suspensions separated in chemical industry are in many cases non-Newtonian fluids whose effective vscosity depends on the deformation rates. Suspensions of this kind are separated in manufacture of protein–vitamin concentrates (paprin, haprin, meprin), in production of suspensions of biomass, glaze, and SiC_3, and in purification of wastewater to remove oil, fats, and other substances. The lack of any adequate model of the hydrodynamics of non-Newtonian fluids in a cylindrical-conical hydrocyclone is still the main obstacle on the way to development of a general procedure for calculating these apparatus.

The known studies devoted to a theoretical analysis of the hydrodynamics of cylindrical-conical hydrocyclones [1–4] cannot be used in developing a procedure for an engineering calculation of a hydrocyclone because of the fact that the mathematical models of the flow in a hydrocyclone most frequently do not reflect the real process and lead to deviation of calculated separation parameters from their true values. In particular, the studies mentioned did not consider the fluid flow in a hydrocyclone with a free surface, which impairs the accuracy and applicability of calculation formulas derived in these studies.

It was mentioned in [1] that, to construct an adequate model of the flow in a cylindrical-conical hydrocyclone, it is necessary to use complete Navier–Stokes equations, which are transformed into equations of rheodynamics in the case of separation of non-Newtonian media. In [5, 6], a conclusion was made that the rheological equation of state of a non-Newtonian fluid, which is commonly written in the form of a power-law Ostwald de Veille equation, is applicable to suspensions.

In [7, 8], the author modeled the hydrodynamics of a non-Newtonian fluid in a cylindrical straight-flow hydrocyclone used to classify particles of the solid phase of the suspension into fractions and to separate and purify suspensions in a centrifugal field. However, no solution of the complete equations of rheodynamics of a non-Newtonian fluid for a swirling flow in a cylindrical-conical hydrocyclone has been reported in the literature.

The mathematical model of the process of development of a rotatory flow of a film of a non-New tonian fluid in a cylindrical-conical hydrocyclone is a set of equations of rheodynamics, a continuity equation, boundary conditions, and an equation that expresses the constancy of the fluid flow rate along the axis of the hydrocyclone. The flow pattern is shown schematically in Fig. 1.

The hydrocyclone comprises a cylindrical chamber, into which a fluid is tangentially fed, and a conical part. The fluid fed into the casing of the hydrocyclone

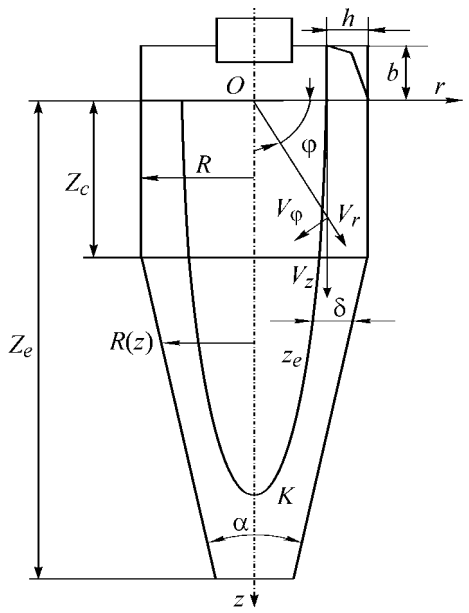

Fig. 1. Scheme of the flow in a cylindrical-conical hydrocyclone.

flows down, swirling, along the walls under the action of the gravity force and the pressure, being characterized by radial (V_r), circumferential (V_φ), and axial (V_z) velocity components. It is assumed that the velocity distribution is independent of the angular coordinate and the flow has a rotation symmetry. This assumption is well justified in practice [9], when the centrifugal acceleration exceeds the gravitational acceleration, which is characteristic of hydrocyclones of any design. It is also assumed that the flow is laminar, the surface tension force and that of friction of the film against the gas medium are negligible, the fluid is incompressible, and the flow is wave-free. The air pressure within the hydrocyclone casing is constant and equal to the atmospheric pressure P_0.

It is assumed that the rheological properties of the suspension are described by the generalized Ostwald de Veille law

$$\tau_{ij} = kA^{n-1}\gamma_{ij}, \qquad (1)$$

$$A = \sqrt{2\left(\frac{\partial V_r}{\partial r}\right)^2 + 2\left(\frac{V_r}{r}\right)^2 + 2\left(\frac{\partial V_z}{\partial z}\right)^2 + \left(\frac{\partial V_\varphi}{\partial r} + \frac{V_\varphi}{r}\right)^2 + \left(\frac{\partial V_\varphi}{\partial z}\right)^2 + \left(\frac{\partial V_z}{\partial r} + \frac{\partial V_r}{\partial z}\right)^2},$$

where τ_{ij} are components of the stress tensor (Pa); γ_{ij}, components of the deformation rate tensor (s^{-1}); A, the intensity of the deformation rates (s^{-1}); n the nonlinearity indicator for the flow curve; k, the consistency index (Pa s^n); and r, φ, z, the radial, circumferential, and axial coordinates, respectively.

The Navier–Stokes equations in terms of the components of the stress tensor and the continuity equation, written in a cylindrical system of coordinates [11], will have for the flow under consideration the following form

$$V_r\frac{\partial V_r}{\partial r} + V_z\frac{\partial V_z}{\partial z} - \frac{V_\varphi^2}{r} = -\frac{1}{\rho}\frac{\partial P}{\partial r} + \frac{1}{\rho}\left(\frac{\partial \tau_{rr}}{\partial r} + \frac{\partial \tau_{rz}}{\partial z} + \frac{\tau_{rr} - \tau_{\varphi\varphi}}{r}\right), \qquad (2)$$

$$V_r\frac{\partial V_z}{\partial r} + V_z\frac{\partial V_z}{\partial z} - \frac{V_\varphi^2}{r} = -\frac{1}{\rho}\frac{\partial P}{\partial z} + \frac{1}{\rho}\left(\frac{\partial \tau_{rz}}{\partial r} + \frac{\tau_{rz}}{r} + \frac{\partial \tau_{zz}}{\partial z}\right) + g, \qquad (3)$$

$$V_r\frac{\partial V_\varphi}{\partial r} + \frac{V_r V_\varphi}{r} + V_z\frac{\partial V_\varphi}{\partial z} = \frac{1}{\rho}\left(\frac{\partial \tau_{r\varphi}}{\partial r} + 2\frac{\tau_{r\varphi}}{r} + \frac{\partial \tau_{\varphi z}}{\partial z}\right), \qquad (4)$$

$$\frac{\partial V_r}{\partial r} + \frac{\partial V_r}{\partial z} + \frac{V_r}{r} = 0, \qquad (5)$$

where P is the pressure in the fluid (Pa); ρ, the average fluid density (kg m^{-3}); and g, the free fall acceleration (m s^{-2}).

The system of equations (2)–(5) should be solved with the following boundary conditions

$$z \le z_c,$$

$$r = R,\ V_r = 0,\ V_\varphi = 0,\ V_z = 0,$$

$$r = R - w,\ \tau_{r\varphi} = 0,\ \tau_{rz} = 0,\ V_r = V_z(\partial w/\partial z),\ P + \tau_{rr} = P_0;$$

$$z > z_c,$$

$$r = R - (z - z_c)\tan(\alpha/2),\ V_r = 0,\ V_\varphi = 0,\ V_z = 0,$$

$$r = R - (z - z_c)\tan(\alpha/2) - w,\ \tau_{r\varphi} = 0,\ \tau_{rz} = 0,$$

$$V_r = V_z(\partial w/\partial z),\ P + \tau_{rr} = P_0;$$

$$z = 0,$$

$$V_\varphi = (2/h)U_0(R - r),$$

$$V_z = [2U_0(R - r)b]/[\pi h(2R - h)],\ V_r = 0,\ P = P_b(r);$$

$$z = z_c,$$

$$\frac{\partial V_z}{\partial z} = \frac{\partial V_\varphi}{\partial z} = \frac{\partial V_r}{\partial z} = 0, \qquad (6)$$

where z_c and R are the axial size and the radius of the cylindrical chamber of the hydrocyclone casing (m); α, the cone angle of the conical part of the hydrocyclone casing (deg); $P_b(r)$ the pressure distribution function over the radial cross-section at $z = 0$ (Pa); z_e, the coordinate of the discharge opening in the conical part of the hydrocyclone casing (m); w, the thickness of the fluid film (m); and h and b, the width and height of the inlet pipe (m).

At the exit from the conical part of the hydrocyclone casing, a "soft" boundary condition is set [12]: the derivatives of the velocity components along the axial coordinates should be zero.

Substitution of the values of the stress tensor components found using the rheological relation (1) into the system of the Navier–Stokes and continuity equations (2)–(5) yields a system of rheodynamic equations for the non-Newtonian fluid in the dimensionless form:

$$f\frac{\partial f}{\partial \bar r} + H\frac{\partial f}{\partial \bar z} - \frac{\theta^2}{\bar r} = -\frac{\partial F}{\partial \bar r} + \frac{1}{\mathrm{Re}_n}\left[2\frac{\partial A_0^{n-1}}{\partial \bar r}\frac{\partial F}{\partial \bar r} + 2A_0^{n-1}\frac{\partial^2 F}{\partial \bar r^2} + \frac{\partial A_0^{n-1}}{\partial \bar z}\left(\frac{\partial H}{\partial \bar r} + \frac{\partial f}{\partial \bar z}\right) + A_0^{n-1}\frac{\partial^2 H}{\partial \bar z \partial \bar r} + A_0^{n-1}\frac{\partial^2 F}{\partial \bar z^2} + 2A_0^{n-1}\frac{1}{\bar r}\frac{\partial F}{\partial \bar r} - 2A_0^{n-1}\frac{f}{\bar r^2}\right], \quad (7)$$

$$f\frac{\partial H}{\partial \bar\tau} + H\frac{\partial H}{\partial \bar z} = -\frac{\partial F}{\partial \bar r} + \frac{1}{\mathrm{Re}_n}\left[\frac{\partial A_0^{n-1}}{\partial \bar r}\left(\frac{\partial H}{\partial \bar r} + \frac{\partial f}{\partial \bar z}\right) + A_0^{n-1}\left(\frac{\partial^2 H}{\partial \bar r^2} + \frac{\partial^2 f}{\partial \bar r \partial \bar z}\right) + 2A_0^{n-1}\frac{\partial^2 H}{\partial \bar z^2} + 2A_0^{n-1}\frac{\partial A_0^{n-1}}{\partial \bar z}\frac{\partial H}{\partial \bar z}\right] + \frac{1}{\mathrm{Fr}}, \quad (8)$$

$$f\frac{\partial \theta}{\partial \bar r} + \frac{\theta f}{\bar r} + H\frac{\partial \theta}{\partial \bar z} = \frac{1}{\mathrm{Re}_n}\left[\frac{\partial A_0^{n-1}}{\partial \bar r}\left(\frac{\partial \theta}{\partial \bar r} - \frac{\theta}{\bar r}\right) + A_0^{n-1}\left(\frac{1}{\bar r}\frac{\partial \theta}{\partial \bar r} - \frac{\theta}{\bar r^2} + \frac{\partial^2 \theta}{\partial \bar r^2}\right) + \frac{\partial A_0^{n-1}}{\partial \bar z}\frac{\partial \theta}{\partial \bar z} + A_0^{n-1}\frac{\partial^2 \theta}{\partial \bar z^2}\right], \quad (9)$$

$$\frac{\partial f}{\partial \bar r} + \frac{\partial H}{\partial \bar z} + \frac{f}{\bar r} = 0. \quad (10)$$

After a transformation to the dimensionless form, the boundary conditions (6) will look like

$$\bar z \le \bar z_c,$$

$$\bar r = 1,\ f = 0,\ \theta = 0,\ H = 0,$$

$$r = 1 - \bar w,\ \partial\theta/\partial\bar r - \theta/\bar r = 0,\ \partial H/\partial\bar r + \partial f/\partial\bar z = 0,$$

$$f = H\partial\bar w/\partial\bar z,\ F = -(2kU_0^{n-2}/\rho R^n)(A_0^{n-1}\partial f/\partial\bar r);$$

$$\bar z > \bar z_c,$$

$$\bar r = 1 - (\bar z - \bar z_c)\tan(\alpha/2),\ f = 0,\ \theta = 0,\ H = 0,$$

$$\bar r = 1 - (\bar z - \bar z_c)\tan(\alpha/2) - \bar w,$$

$$\partial\theta/\partial\bar r - \theta/\bar r = 0,\ \partial H/\partial\bar r + \partial f/\partial\bar z = 0;$$

$$z = 0,$$

$$\theta = (2/\bar h)(1 - \bar r),$$

$$H = [2\bar b(1 - \bar r)/(\pi\bar h(2 - \bar h),\ f = 0,\ F = F_b(\bar r);$$

$$z = z_e,$$

$$\frac{\partial H}{\partial \bar z} = \frac{\partial \theta}{\partial \bar z} = \frac{\partial f}{\partial \bar z} = 0, \quad (11)$$

where

$$\mathrm{Fr} = \frac{U_0^2}{gR},\ \mathrm{Re}_n = \frac{\rho R^n U_0^{2-n}}{k},\ \bar Q = \frac{Q}{\pi R^2 U_0} = \frac{bh}{\pi R^2}.$$

Fr is the centrifugal Froude number (separation factor); Re_n, an analogue of the Reynolds number for power-law fluids; $\bar Q$, the dimensionless flow rate; and

$$A_0 = \sqrt{2\left(\frac{\partial f}{\partial \bar r}\right)^2 + 2\left(\frac{f}{\bar r}\right)^2 + 2\left(\frac{\partial H}{\partial \bar z}\right)^2 + \left(\frac{\partial \theta}{\partial \bar r} - \frac{\theta}{\bar r}\right)^2 + \left(\frac{\partial \theta}{\partial \bar z}\right)^2 + \left(\frac{\partial H}{\partial \bar z} + \frac{\partial f}{\partial \bar r}\right)^2}.$$

A_0 is the dimensionless intensity of the deformation rate.

The dimensionless and dimensional variables are related by

$$\bar z = \bar z/R,\ \bar r = r/R,\ H(\bar r, \bar z) = V_r/U_0,\ f(\bar r, \bar z) = V_z/U_0,$$
$$\theta(\bar r, \bar z) = V_\varphi/U_0,\ F(\bar r, \bar z) = (P - P_0)/(\rho U_0^2),\ \bar w = w/R,$$
$$\bar h = h/R,\ \bar b = b/R,\ U_0 = Q/bh,$$

where $\bar z$, $\bar r$ are the dimensionless axial and radial coordinates, respectively; $H(\bar r, \bar z)$, $f(\bar r, \bar z)$, and $\theta(\bar r, \bar z)$, the dimensionless axial, radial, and circumferential components of the flow velocity; $F(\bar r, \bar z)$, the dimen-

sionless pressure; $F_b(\bar{r})$, the distribution function of dimensionless pressure over the radial cross-section at $\bar{z} = 0$ $\bar{w}$, the dimensionless thickness of the fluid film; $\bar{h}$, $\bar{b}$, the dimensionless width and height of the inlet pipe; $\bar{z}_c$, the dimensionless axial size of the cylindrical chamber of the hydrocyclone; $\bar{z}_e$, the dimensionless coordinate of the discharge opening in the conical part of the hydrocyclone casing; U_0, the average flow velocity in the inlet pipe of the hydrocyclone (m s^{-1}); and Q, the flow rate of the fluid (m^3 s^{-1}).

To determine the hydrodynamic parameters of the flow, it is necessary to numerically integrate the system of differential equations (7)–(10) in partial derivatives at appropriate boundary conditions (11) with account of the geometry of the working space of a hydrocyclone. The integration of the system of differential equations in partial derivatives was performed by the finite-difference method. The finite-difference analogue of the rheodynamic and continuity equations served as a basis for developing a calculation program written in the Compaq Visual Fortran language. The software developed performed calculations by formulas constructed on the basis of a finite-difference analogue of the mathematical model (7)–(11), which is an implicit finite-difference scheme. The solution was obtained on a computer by means of a sequential (over grid nodes) cyclic procedure based on the Zeidel method. At a grid node, the pressure P was found from the finite-difference analogue of Eq. (7); the axial component H of the flow velocity, from an analogue of Eq. (8); the circumferential component θ of the flow velocity, from an analogue of (9); and the radial component f of the flow velocity, from an analogue of the continuity equation (10). The calculated flow region was divided using a nonuniform grid with 50×50 cells along the radial and axial coordinates. The shape of the grid cells was determined by the profile of the free surface of the film and by the cone angle of the conical part of the hydrocyclone casing.

The thickness of the fluid film was found from the integral continuity equation

$$\bar{Q} = 2\int_{\bar{R}(\bar{z})-\bar{w}}^{\bar{R}(\bar{z})} \bar{r}H(\bar{r}, \bar{z})\mathrm{d}\bar{r} = \text{const}, \qquad (12)$$

where $\bar{R}(\bar{z}) = R(z)/R$ is the nondimensional radius of the hydrocyclone casing.

Equation (12) expresses the condition of a constant flow rate in a hydrocyclone in the axial direction. In expression (12), the profile of the axial component of the velocity was integrated across the fluid film thickness at a running value of the dimensionless radius $\bar{R}(\bar{z})$ of the apparatus casing, which is a piecewise-linear function of $\bar{z}$ and can be found from the relation $\bar{R}(\bar{z}) = 1$ for the cylindrical chamber of the hydrocyclone at $\bar{z} \le \bar{z}_c$ and from the formula

$$\bar{R}(\bar{z}) = 1 - (\bar{z} - \bar{z}_c)\tan(\alpha/2).$$

for the conical part of the casing at $z > z_c$.

The film thickness was calculated using the expression derived from Eq. (12):

$$\bar{w} = \bar{R}(\bar{z}) - \sqrt{\bar{R}(\bar{z}) - \bar{Q}/H_{\mathrm{av}}(\bar{z})}, \qquad (13)$$

where $H_{\mathrm{av}}(\bar{z})$ is the average value of the axial component of the velocity in the radial cross-section at $z = \text{const}$.

The value of $H_{\mathrm{av}}(\bar{z})$ was found by numerical integration of the resulting profile of the axial component of the velocity, $H(\bar{r}, \bar{z})$, in each radial cross-section at $\bar{z} = \text{const}$.

The film thickness was found using Eq. (13) in the direction of the $\bar{z}$ axis as far as the point of confluence of the fluid film into a continuous flow in the bottom zone of the conical part of the hydrocyclone casing (Fig. 1, point K). This point was named the critical point, on reaching which the calculation was terminated and the control was transferred to the loop operator for calculating the next approximation. In the case when no flow confluence occurred, the calculation was performed as far as the discharge opening in the conical part of the hydrocyclone casing.

The flow of a non-Newtonian fluid in a hydrocyclone is characterized by the nonlinearity indicator n for the flow curve, centrifugal Froude number Fr (separation factor), analogue of the Reynolds number for non-Newtonian fluids Re_n, and dimensionless flow rate $\bar{Q}$.

The numerical modeling was carried out at the nonlinearity indicator for the flow curve varying in the range $n = 0.6$–1.3, which corresponds to pseudoplastic ($n < 1.0$) and dilatant ($n > 1.0$) fluids, and also to a Newtonian fluid at $n = 1.0$, for a cylindrical-conical hydrocyclone in which the height of the cylindrical chamber is equal to the apparatus diameter ($z_c = 2$) and the cone angle of the conical part of the apparatus $\alpha = 10°$.

Figure 2 shows calculated dependences of the dimensionless thickness $\bar{w}$ of the film on the axial coordinate $\bar{z}$ at different nonlinearity indicators n for the flow curve. Analysis of the dependences shows that the dimensionless thickness of a film of a non-Newtonian fluid in a cylindrical-conical hydrocyclone first decreases and then starts to increase in the direction of the $\bar{z}$ axis of the apparatus. This is due to an steep rise in the axial component of the flow velocity in the initial region because of the influence exerted on the flow by the gravity force and pressure and to a decrease in the perimeter of the flow section of the conical part of the apparatus casing in the direction of the $\bar{z}$ axis. As the nonlinearity factor n for the flow curve increases, the dimensionless thickness $\bar{w}$ of the film grows, and this rise is the most pronounced near the discharge opening in the conical part of the hydrocyclone casing, which is caused by an increase in the effective viscosity of the non-Newtonian fluid.

The calculated dependences of the dimensionless thickness $\bar{w}$ of a film of a pseudoplastic liquid (n = 0.6) on the axial coordinate $\bar{z}$ for different values of the Froude number (separation factor) Fr are shown in Fig. 3a, and the same dependences for a Newtonian fluid (n = 1.0), in Fig. 3b. Analysis of the dependences in Figs. 3a and 3b shows that, as the Fr number increases, the thickness of the film of a pseudoplastic fluid grows, which is accounted for by the increasing influence of centrifugal forces on the flow and by the decreasing influence of gravity, especially in the bottom zone of the conical part of the cylindrical-conical hydrocyclone casing, where the circumferential component of the flow velocity increases dramatically. For the Newtonian fluid, the film thickness grows with increasing Froude number Fr more steeply, because at high shear rates the effective viscosity of a pseudoplastic fluid decreases, and that of Newtonian fluid remains constant.

The obtained dependences of the axial and circumferential components of the flow velocity on the radial coordinate can be approximated by the expressions

$$H(\bar{r},\bar{z}) = H_{\max}(\bar{z})\left[1 - \left(1 - \frac{1-\bar{r}}{\bar{w}}\right)^{M}\right],$$
$$\theta(\bar{r},\bar{z}) = \theta_{\max}(\bar{z})\left[1 - \left(1 - \frac{1-\bar{r}}{\bar{w}}\right)^{L}\right], \quad (14)$$

where $H_{\max}(\bar{z})$ is the maximum value of the axial component of the flow velocity at the surface of the fluid film; M, the filling factor of the profile of the axial component of the flow velocity; $\theta_{\max}(\bar{z})$, the maximum value of the circumferential component of the flow velocity on the surface of the fluid film; and L, the filling factor of the profile of the circumferential component of the flow velocity.

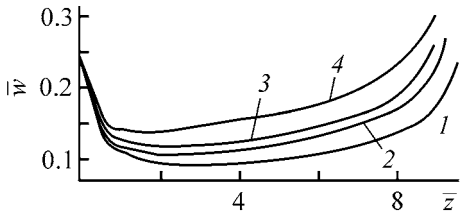

Fig. 2. Dimensionless thickness $\bar{w}$ of the fluid film vs. the axial coordinate $\bar{z}$ at different nonlinearity indicators n for the flow curve. Fr = 73.4, Re_n = 4000.0, $\bar{Q}$ = 0.04, α = 10°; the same for Figs. 4, 6. n: (*1*) 0.6, (*2*) 0.8, (*3*) 1.0, and (*4*) 1.2.

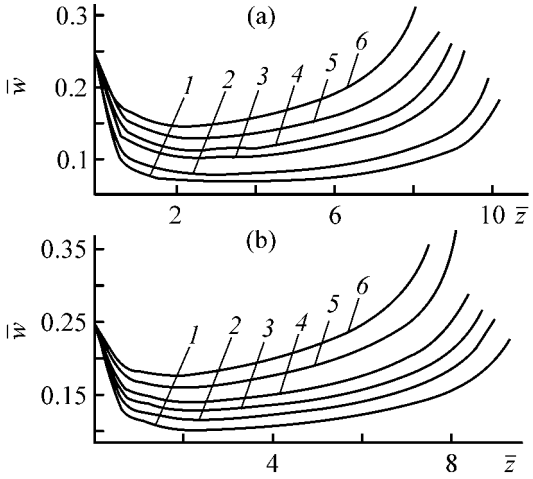

Fig. 3. Dimensionless thickness $\bar{w}$ of the fluid film vs. the axial coordinate $\bar{z}$ at different Froude numbers Fr. Re_n = 4000.0, $\bar{Q}$ = 0.04, α = 10°; the same for Fig. 5. n: (a) 0.6 and (b) 1.0. Fr: (*1*) 32.6, (*2*) 50.0, (*3*) 100.0, (*4*) 130.5, (*5*) 203.9, and (*6*) 293.6.

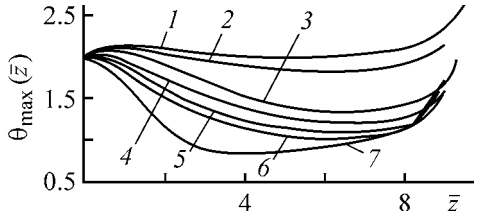

Fig. 4. Maximum circumferential component of velocity at the film surface, $\theta_{\max}(\bar{z})$, vs. the axial component $\bar{z}$ at different nonlinearity indicators n for the flow curve. n: (*1*) 0.6, (*2*) 0.7, (*3*) 0.8–0.9, (*4*) 1.0, (*5*) 1.1, (*6*) 1.2, and (*7*) 1.3.

Figure 4 shows how the maximum circumferential component of the flow velocity on the surface of a film of a non-Newtonian fluid, $\theta_{\max}(\bar{z})$, depends on the axial coordinate $\bar{z}$ at different nonlinearity indicators n for the flow curve. It was established that the cir-

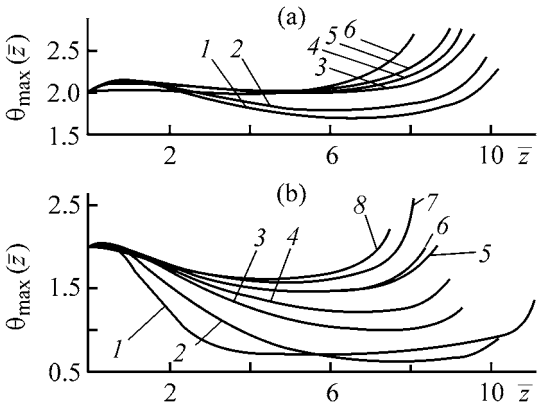

Fig. 5. Maximum circumferential component of velocity at the film surface, $\theta_{max}(\bar{z})$, vs. the axial component $\bar{z}$ at different Froude numbers Fr. *n*: (a) 0.6 and (b) 1.0. Fr: (a) (*1*) 32.6, (*2*) 50.0, (*3*) 73.4, (*4*) 100.0, (*5*) 130.5, and (*6*) 293.6; (b) (*1*) 8.2, (*2*) 18.4, (*3*) 50.0, (*4*) 73.4, (*5*) 100.0, (*6*) 130.5, (*7*) 203.9, and (*8*) 293.6.

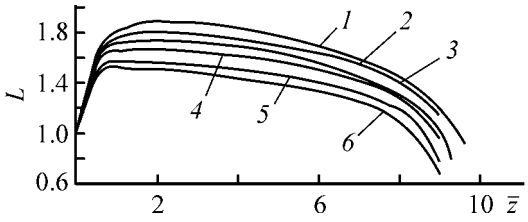

Fig. 6. Filing factor *L* of the profile of the circumferential component of the flow velocity vs. the axial component $\bar{z}$ at different nonlinearity indicators *n* for the flow curve. *n*: (*1*) 0.6, (*2*) 0.7, (*3*) 0.8–0.9, (*4*) 1.0, (*5*) 1.1, and (*6*) 1.2.

cumferential component of the flow velocity at the film surface first decays in the direction of the hydrocyclone axis and then, as the conical part of the casing becomes narrower, again increases, with this increase being the most pronounced in regions close to the film surface. The increase in the circumferential component of the velocity at the film surface is due to the conservation of the initial angular momentum of the swirling fluid. Analysis of the calculated dependences presented shows that the rate at which the maximum circumferential component of the flow velocity decays for pseudoplastic fluids ($n < 1.0$) decreases as the anomaly of non-Newtonian properties becomes more pronounced (as *n* decreases) because of a decrease in the effective viscosity in zones with high shear rates. For dilatant fluids, the rate at which the maximum circumferential component of the flow velocity grows as the anomaly of non-Newtonian properties becomes more pronounced (as *n* increases) because the effective viscosity of dilatant fluids increases with *n*.

Figure 5a shows how the maximum circumferential component of the flow velocity, $\theta_{max}(\bar{z})$, depends on the axial coordinate $\bar{z}$ for different values of the Froude number Fr for a pseudoplastic liquid ($n = 0.6$); similar dependences for a Newtonian fluid ($n = 1.0$) are presented in Fig. 5b. Analysis of the dependences in Fig. 5a shows that, as the Fr number increases, the maximum circumferential component of the flow velocity grows, especially near the discharge opening in the conical part of the hydrocyclone casing, which is accounted for by the increasing thickness of the fluid film. Analysis of the dependences in Fig. 5b shows that the decay of the circumferential component of the flow velocity in the direction of the hydrocyclone's axis decreases as the Froude number Fr grows, and does so to a greater extent than in the case of a pseudoplastic fluid, because the effective viscosity of the Newtonian fluid is independent of the shear rate.

Figure 6 shows how the filling factor of the profile of the circumferential component of the flow velocity of a non-Newtonian fluid, *L*, depends on the axial coordinate $\bar{z}$ for different nonlinearity indicators for the flow curve. Analysis of the dependences shows that the filling factor of the profile of the circumferential component of the flow velocity increases in the initial part of the flow and then decreases in the conical part of the hydrocyclone casing, especially near the discharge opening, which is due to the conservation of angular momentum of the swirling flow. As *n* becomes higher, the filling factor of the profile decreases, which corresponds to a decrease in the anomaly of the non-Newtonian properties of a pseudoplastic fluid or to an increase in the anomaly of the non-Newtonian properties of a dilatant medium.

According to the results of calculations, the thickness of the fluid film becomes lower as Re_n increases, which is due to a decrease in the effective viscosity of the fluid. As a result, as Re_n becomes higher, the maximum value of the circumferential component of the flow velocity at the film surface, $\theta_{max}(\bar{z})$, increases, and the rate at which $\theta_{max}(\bar{z})$ decays along the axial coordinate becomes lower, which is due to a decrease in the effective viscosity of the fluid and an increase in the axial component of the flow velocity because of the diminishing thickness of the film. As Re_n becomes higher, the filling factor of the profile of the circumferential component of the flow velocity grows, which is also accounted for by a decrease in the effective viscosity of the fluid.

CONCLUSIONS

(1) The influence exerted by the anomaly of the non-Newtonian properties of a fluid and by the defin-

ing similarity criteria on the hydrodynamics of flow in a cylindrical-conical hydrocyclone was analyzed by means of a numerical modeling. It was established that the circumferential component of the flow velocity at the film surface first decays in the direction of the hydrocyclone's axis, but then, as the conical part of the casing becomes narrower, again increases, with this increase being the steepest near the film surface.

(2) For pseudoplastic fluids, the rate at which the circumferential component of the flow velocity decays in the direction of the hydrocyclone's axis decreases as the anomaly of the non-Newtonian properties becomes more pronounced. The circumferential component of the flow velocity increases with Fr and Re_n numbers, and this increase is the most pronounced near the discharge opening in the conical part of the hydrocyclone casing and for Newtonian fluids.

(3) The dependences obtained can be used in modeling the concentration field in a cylindrical-conical hydrocyclone.

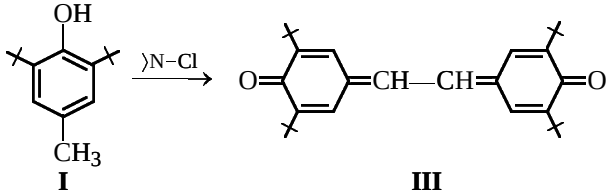
Abstract—1-Halo derivatives of the 2,2,6,6-tetramethylpiperidine series oxidize sterically hindered phenols to form dimers and *p*-quinones.

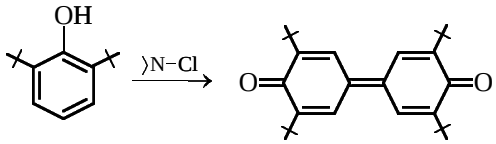
The capability of sterically shielded phenols to undergo oxidation is well known [1] and is one of the main characteristic properties of this class of compounds, allowing their use as effective antioxidants [2]. Diverse oxidation products are formed (phenoxyl radicals, quinoid compounds, quinones), depending on the structure of the phenols being oxidized and on the oxidant chosen. For example, oxidation of 2,4,6-tri-*tert*-butylphenol with PbO_2 or MnO_2 yields a stable phenoxyl radical, whereas oxidation with $NaNO_2$ yields quinones [1].

In this context, it seemed of interest to study the oxidation of shielded phenols with 1-halo derivatives of the 2,2,6,6-tetramethylpiperidine (TMP) series. These agents have apparent advantages over other *N*-haloalkylamines in that they show relatively high stability and low nucleophilicity; these compounds can be prepared in high yield from the available 2,2,6,6-TMP derivatives [3–5].

The oxidation of sterically hindered phenols with halo derivatives of the 2,2,6,6-TMP series is usually performed in an organic solvent, e.g., benzene or methylene chloride. 2,6-di-*tert*-butyl-4-methylphenol **I** and 2,6-di-*tert*-butylphenol **II** are oxidized with 1-halo derivatives of the 2,2,6,6-TMP series to form dimers: 3,3',5,5'-tetra-*tert*-butylstilbenoquinone **III** and 3,3',5,5'-tetra-*tert*-butyldiphenoquinone **IV**, respectively:

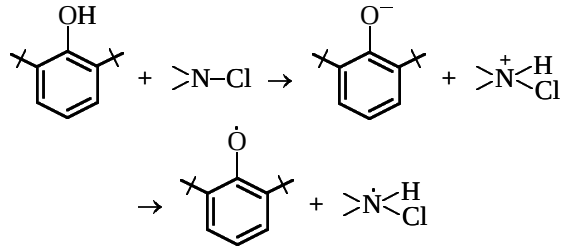


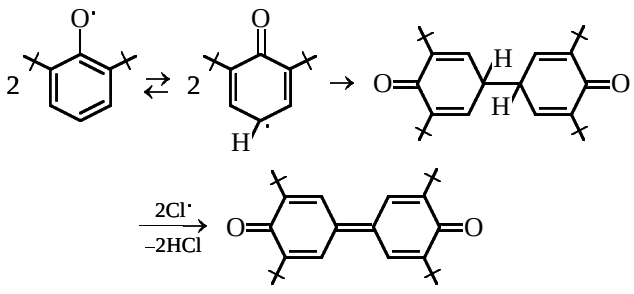
I **III**



II **IV**

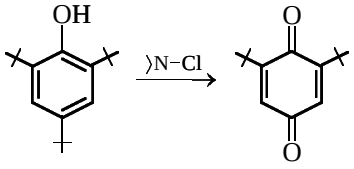
In an organic solvent, the dimerization apparently occurs by the radical mechanism [1]. The reaction rate depends on the rate of protonation of the 1-halo derivative. The possible pathway of dimer formation in the oxidation of phenols with chloramines of the 2,2,6,6-TMP series is shown in the scheme:





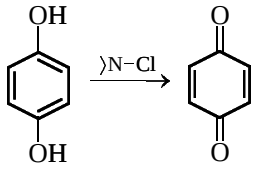
1070-4272/04/7706-0964 © 2004 MAIK "Nauka/Interperiodica"

The stability of the forming phenoxyl radical is determined by the structural features of the initial phenol molecule. For example, in oxidation of 2,4,6-tri-*tert*-butylphenol **V**, we obtained 2,6-di-*tert*-butylbenzoquinone **VI**. 2,4,6-Tri-*tert*-butylphenol does not undergo noticeable dimerization because of the high stability of the forming 2,4,6-tri-*tert*-butylphenoxyl radical [6]:



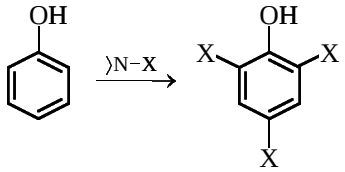
V **VI**

1-Chloro-2,2,6,6-TMP oxidizes hydroquinone **VII** in an organic solvent to *p*-benzoquinone **VIII** in quantitative yield:



VII **VIII**

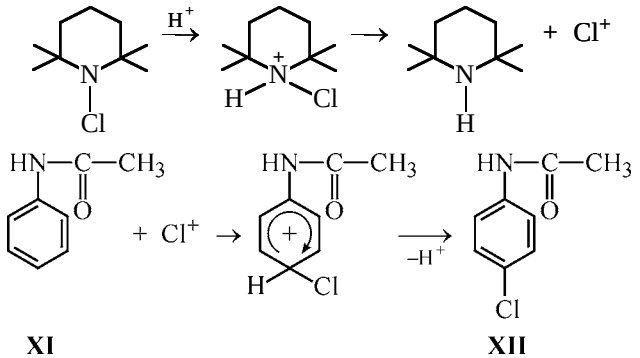
Phenol **IX** in organic solvent reacts with 1-chloro derivatives of the 2,2,6,6-TMP series to form 2,4,6-trichlorophenol **Xa** and with 1-bromo derivatives to form 2,4,6-tribromophenol **Xb**:



IX **Xa**, **Xb**

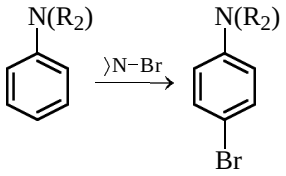
where X = Cl (**Xa**), Br (**Xb**).

In acidic solutions, the reactions apparently occur by the electrophilic mechanism, which is confirmed by the formation of *p*-chloroacetanilide **XII** as the only product in the reaction of acetanilide **XI** with 1-chloro-2,2,6,6-TMP:



XI **XII**

1-Bromo-4-hydroxy-2,2,6,6-TMP reacts with dimethylphenylamine and diethylphenylamine in a weakly acidic solution (pH 4–5) also to form the corresponding *p*-bromo derivatives **XIIIa** and **XIIIb**:



XIIIa, **XIIIb**

where R = CH_3 (**XIIIa**), C_2H_5 (**XIIIb**).

EXPERIMENTAL

3,3',5,5'-Tetra-*tert*-butylstilbenoquinone III. 2,6-Di-*tert*-butyl-4-methylphenol (Ionol), 4.4 g (0.02 mol), and 1-bromo-4-hydroxy-2,2,6,6-tetramethylpiperidine, 9.2 g (0.04 mol), were dissolved in 50 ml of benzene, and the mixture was allowed to stand at 25°C for 4–5 days. After the disappearance of the starting Ionol (TLC monitoring), the precipitate of 4-hydroxy-2,2,6,6-tetramethylpiperidinium bromide was separated. The solvent was distilled off under reduced pressure; 3.9 g (90%) of 3,3',5,5'-tetra-*tert*-butylstilbenoquinone was obtained; mp 304–305°C (from benzene).

The reaction with 1-chloro-4-hydroxy-2,2,6,6-tetramethylpiperidine was performed similarly. The reaction was slower, being complete in 6–7 days. Yield of **III** 3.6 g (85%).

3, 3', 5, 5'-Tetra-*tert*-butyldiphenoquinone IV. A mixture of 1 g (0.005 mol) of 2,6-di-*tert*-butylphenol and 1.7 g (0.01 mol) of 1-chloro-4-hydroxy-2,2,6,6-tetramethylpiperidine in 50 ml of benzene was allowed to stand for 2 days. After the disappearance of the starting phenol (TLC monitoring), the precipitate of 4-hydroxy-2,2,6,6-tetramethylpiperidinium chloride was separated. The solvent was distilled off under reduced pressure; 0.9 g (90%) of 3',3,5',5-tetra-*tert*-butyldiphenoquinone was obtained; mp 240–242°C. The isolated product was identified by comparison with an authentic sample [5].

2,6-Di-*tert*-butyl-*p*-benzoquinone VI. A mixture of 2.6 g (0.01 mol) of 2,4,6-tri-*tert*-butylphenol and 3.4 g (0.02 mol) of 1-chloro-2,2,6,6-tetramethylpiperidine in 50 ml of benzene was placed in a flask equipped with a reflux condenser and heated for 20 h on a water bath kept at 60°C. The mixture was cooled, the precipitated crystals of 2,2,6,6-tetramethylpiperi-

dinium chloride were filtered off, the solvent was evaporated, and the residue was chromatographed on a column (Al_2O_3, Brockmann grade II l = 20 cm, d = 3 cm, eluent hexane). The yellow fraction was collected. The solvent was removed under reduced pressure; 1.15 g (55%) of 2,6-di-*tert*-butyl-*p*-benzoquinone **VI** was obtained; mp 78–79°C (from hexane); published data [6]: mp 78–80°C.

***p*-Benzoquinone VIII.** A mixture of 2.2 g (0.02 mol) of hydroquinone and 3.6 g (0.02 mol) of 1-chloro-2,2,6,6-tetramethylpiperidine in 20 ml of methylene chloride was allowed to stand for 12 h. The precipitate of 2,2,6,6-tetramethylpiperidinium ch loride (3.5 g) was filtered off, and the solvent was distilled off on a rotary evaporator; 1.72 g (80%) of *p*-benzoquinone **VIII** was obtained, mp 116°C (from water). The product was identified by comparison with an authentic sample [7].

2,4,6-Trichlorophenol Xa. A mixture of 0.94 g (0.01 mol) of phenol and 5.66 g (0.03 mol) of 1-chloro-4-hydroxy-2,2,6,6-tetramethylpiperidine in 50 ml of benzene was allowed to stand for 24 h at room temperature. The benzene solution was extracted with 10% NaOH, the organic layer was separated, and the aqueous layer was acidified with HCl to pH 1. 2,4,6-Trichlorophenol precipitated from the aqueous phase; it was separated, washed with water, and dried in air. Yield 1.78 g (91%); mp 63–65°C (from ethanol–water, 1 : 1); published data [8]: mp 64–65°C. 4-Hydroxy-2,2,6,6-tetramethylpiperidine was isolated from the benzene layer; yield 4.2 g (90%), mp 130–132—C (from ethyl acetate) [9].

2,4,6-Tribromophenol Xb was prepared similarly, by the reaction of phenol with 1-bromo-4-hydroxy-2,2,6,6-tetramethylpiperidine. Yield 82%, mp 96–98°C (from ethanol–water, 1 : 1). Mixing with an authentic sample gave no depression of the melting point [8].

***p*-Chloroacetanilide XII.** Acetanilide, 2.7 g (0.02 mol), and 1-chloro-2,2,6,6-tetramethylpiperidine, 3.7 g (0.021 mol), were dissolved in 30 ml of benzene, and 25 ml of 1 M HCl was added. The mixture was stirred and heated on a water bath at 50–60°C for 15–20 min. The reaction progress was monitored by TLC. After the reaction was complete, the mixture was cooled, the organic layer was separated, and the solvent was evaporated under reduced pressure. The crystals of 4-chloroacetanilide were filtered off. Yield of **XII** 3.2 g (92%); rhombic needles, mp 175–177°C; published data [10]: mp 177–178°C.

***p*-Bromoacetanilide** was prepared similarly by the reaction with 1-bromo-2,2,6,6-tetramethylpiperidine; mp 167–168°C (from ethanol–water, 1 : 1). The product was identified by comparison with an authentic sample [10].

***p*-Bromo-*N*,*N*-diethylaniline XIIIb**. *N*,*N*-Diethylaniline, 1.49 g (0.01 mol), was dissolved in 20 ml of benzene, and a solution of 2.5 g (0.01 mol) of 1-bromo-4-hydroxy-2,2,6,6-tetramethylpiperidine in 20 ml of benzene was gradually added. The mixture was heated on a water bath at 60°C for 40–45 min. Then the mixture was cooled, and white crystals of 4-hydroxy-2,2,6,6-tetramethylpiperidine were filtered off. The solvent was evaporated, and 2.1 g (90%) of *p*-bromo-*N*,*N*-diethylaniline (white oily crystals) was obtained; mp 31–33°C (from ethanol–water, 1 : 1). Mixing with an authentic sample gave no depression of the melting point [10].

***p*-Bromo-*N*,*N*-dimethylaniline XIIIa** was prepared similarly. Yield 85%; mp 54–56°C (from ethanol–water, 1 : 1); published data [10]: mp 55–56°C.

CONCLUSIONS

(1) 2,6-Di-*tert*-butyl-4-methylphenol and 2,6-di-*tert*-butylphenol in an organic solvent are oxidized by 1-halo derivatives of 2,2,6,6-tetramethylpiperidine to form dimers.

(2) 1-Chloro-2,2,6,6-tetramethylpiperidine oxidizes in an organic solvent 2,4,6-tri-*tert*-butylphenol and hydroquinone to 2,6-di-*tert*-butylbenzoquinone and *p*-benzoquinone, respectively.

(2) Phenol in an organic solvent and aromatic amines in an acidic solution in the presence of 1-halo derivatives of the 2,2,6,6-tetramethylpiperidine series undergo halogenation.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Influence of Ionic Surfactants on Tetrabromophenylfluorone Ionic Associates

S. A. Shapovalov, E. S. Gladkov, and T. A. Chernaya

Research Institute of Chemistry, Karazin Kharkov National University, Kharkov, Ukraine

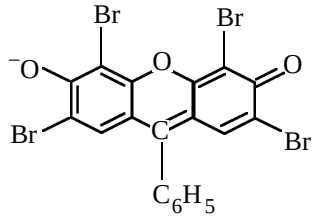
Received December 9, 2003; in final form, March 2004

Abstract—Stability constants of ionic associates of a hydroxyxanthene dye, tetrabromophenylfluorone, with a series of organic cations were determined spectrophotometrically. The possibility of quantitative determination of anionic surfactants (alkyl sulfates) in an aqueous solution in the form of a dye anion associate with tetrabutylammonium cation was considered.

Ionic association of organic dyes substantially changes the optical properties of the medium and is studied in connection with a search for novel photosensitive materials [1, 2] and optically transparent polymers [3], and with biochemical research [4].

Dye ionic associates have been used for quantitative estimation of the content of surfactants in aqueous solutions [5]. Along with the dye ion, the associate contains an oppositely charged organic ion. Ionic associates can be more "sensitive" with respect to the content of ionic surfactants as compared to dye ions, because the spectral changes in the associate + surfactant system [6] occur at substantially lower concentrations of surfactant than in the dye + surfactant system [7].

Hydroxyxantene dye anions are of special interest as components of the associate. They have intense color and exhibit bright luminescence in aqueous solutions. Tetrabromophenylfluorone (TBPF), which is a structural analogue of eosin devoid of carboxy group, is one of such dyes. It has been found that the $TBPF^-$ anion



forms ionic associates with an organometallic complex of copper(I). This fact was used as a basis of an extractive procedure for the spectrophotometric determination of the metal in aqueous solutions [8]. Intensely colored hydroxyxantene anion in the associate provides a high sensitivity of the quantitative determination of copper.

It has been found previously [9] that associates decompose under the action of ionic surfactants. The color intensity of the solution directly depends on the surfactant concentration. This phenomenon is of interest as a basis of a sensitive method for determination of anionic surfactants. In this study, association of the $TBPF^-$ anion with tetrabutylammonium cation (TBA^+) and reaction of the TBA^+–$TBPF^-$ associate with anionic surfactants, alkyl sulfates, were examined to develop a procedure for quantitative determination of these surfactants in aqueous solutions.

EXPERIMENTAL

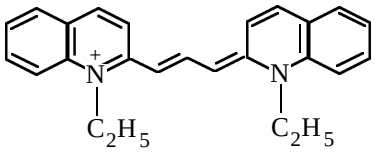
A sodium salt of TBPF was used [8]. The dye purity was monitored spectrophotometrically using the known extinction coefficients ε_{max} of protolytic species (aqueous solution) at absorption band peaks λ_{max}. Analytically pure tetrabutylammonium iodide [TU (Technical Specifications) 6-09-05-410–75] was used without additional purification. An anionic surfactant, sodium dodecyl sulfate (SDS), and a cationic surfactant, cetylpyridinium bromide (CPB), contained $98 \pm 1\%$ main substance. The other chemicals were of analytically pure grade. The pH of the solution was adjusted with acetate, phosphate, and borate buffers [10] and was monitored potentiometrically with a glass electrode. Absorption spectra were recorded on Hitachi-U3210 and SF-46 spectrophotometers at room temperature.

1070-4272/04/7706-0968 © 2004 MAIK "Nauka/Interperiodica"

TBPF is a monobasic acid with pK_a 3.0 [8]. At pH 5–9, it actually exists as a single-charged anion $TBPF^-$; its hydrolysis becomes noticeable at pH > 9.5. It was found experimentally that TBPF association occurs at fairly low (approximately 1×10^{-6} M and more) concentrations. The characteristic feature of TBPF association with organic counterions in aqueous solution is a decrease in the intensity of hydroxyxanthene absorption band. This is clearly observed in the case of colorless cations, e.g., TBA^+ (Fig. 1, spectra *1*, *4*). The extinction coefficient of the associate is almost half that of TBFF (see table). Similar spectral changes were observed when anions of the other hydroxyxanthenes (fluorescein, eosin, Rose Bengal B, erythrosine [6, 11]) associate with certain organic cations and when TBA^+ associates with other organic anions (anionic cyanines [12, 13]).

We found that, at dye concentrations of 1×10^{-6}–5×10^{-5} M, association follows the scheme $TBA^+ + TBPF^- \rightleftarrows TBA^+ \cdot TBPF^-$.

The stoichiometric ratio of the components in the associate, found by Adamovich's method [14], is 1 : 1. A similar scheme of association was determined for reaction of $TBPF^-$ with a cyanine dye, pinacyanol (PNC^+):



The logarithm of the association thermodynamical constant $\log K_{as}^T$ (calculated by analogy with data of [12]) for the $TBA^+ \cdot TBPF$ associate (see table) is lower than that for the $PNC^+ \cdot TBPF^-$ associate (6.38 ± 0.11) [11].

The $TBPF^-$ anion is more planar as compared to other hydroxyxanthenes containing carboxy group. The dihedral angle between the phenyl ring plane and the xanthene fragment, equal to 57°, is smaller than that in eosin (65°) and other xanthenes (results of RM3 geometric optimization [15]). As known [12, 16–18], the planar structure of the molecule favors ionic association between organic ions. Therefore, the $TBPF^-$ anion forms more stable associate with the more planar PNC^+ cation (the ethylquinolinium fragments are turned about the polymethine chain by only 15°) as compared to nonplanar TBA^+ cation.

Addition of an ionic surfactant to the $TBA^+ \cdot TBPF^-$ associate causes changes in the solution spectra. The experimental data show that, in the submicellar range of surfactant concentrations, the associate reacts with dodecyl sulfate anion (DS^-) or with cetylpyridinium cation (CP^+) in the substitution fasion:

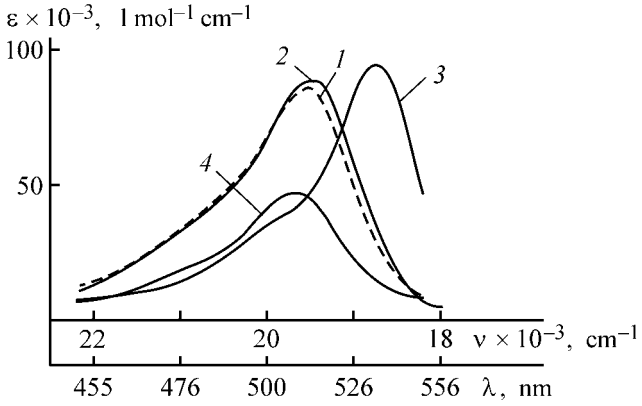


Fig. 1. Absorption spectra of $TBPF^-$ anion in (*1*) water, (*2*) SDS micelles, (*3*) CPB micelles, and (*4*) $TBA^+ \cdot TBPF^-$ associate. (ε) Extinction coefficient, (ν) wave number, and (λ) wavelength.

$$TBA^+ \cdot TBPF^- + DS^- \rightleftarrows TBA^+ \cdot DS^- + TBPF^-, \quad (1)$$

$$TBA^+ \cdot TBPF^- + CP^+ \rightleftarrows TBA^+ + CP^+ \cdot TBPF^-, \quad (2)$$

In the range of micellar concentrations (8.1×10^{-3} M SDS and 6.6×10^{-4} M CPB [19]), the associate reacts with the surfactant by another pathway. This interaction leads to solubilization of each counterion in the Stern layer of the corresponding micelles [7]:

$$TBA^+ \cdot TBPF^- + (x + y)DS^- \rightleftarrows (TBA^+)_{xDS^-} + (TBPF^-)_{yDS^-}, \quad (3)$$

$$TBA^+ \cdot TBPF^- + (x + y)CP^+ \rightleftarrows (TBA^+)_{xCP^+} + (TBPF^-)_{yCP^+}, \quad (4)$$

where x and y take integer values.

The spectral changes in the $TBA^+ \cdot TBPF^-$ + surfactant systems confirm the above schemes. For instance, in the case of SDS, the $TBPF^-$ anion is

Characteristics of $TBPF^-$ anion and $TBA^+ \cdot TBPF^-$ associate

Characteristics	$TBPF^-$	$TBA^+ \cdot TBPF^-$
λ_{max}, nm	515–516 [8]	508
$\varepsilon_{max} \times 10^{-3}$, l mol^{-1} cm^{-1}	86.0 [8]	43.0
$\log K_{as}^T$	–	4.87 ± 0.15

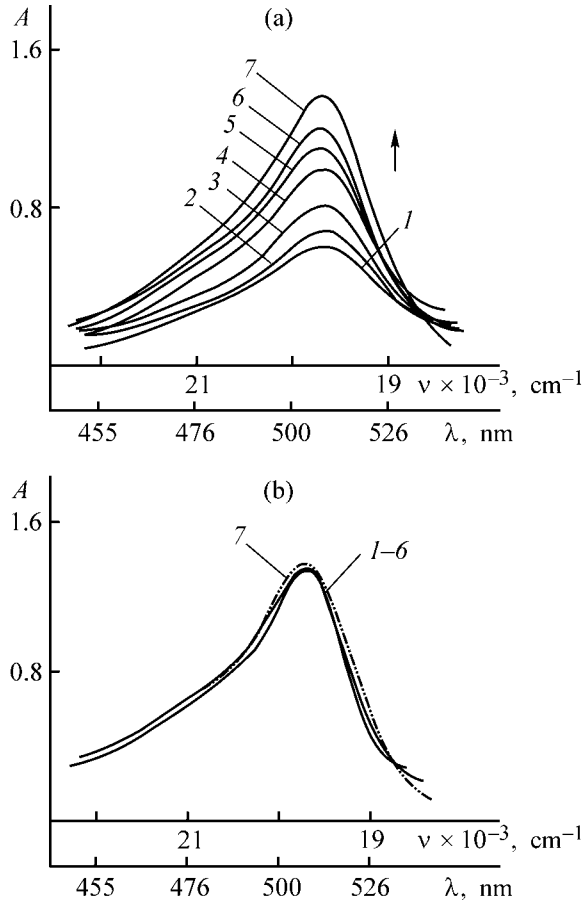

Fig. 2. Absorption spectra of aqueous solutions containing (a) $TBA^+ \cdot TBPF^-$ associate, (b) $TBPF^-$ anion, and SDS additives. Reference solution is water; absorbing layer thickness 1.00 cm; pH 6.9; $c_{TBPF} = 1.5 \times 10^{-5}$, $c_{TBA} = 6 \times 10^{-5}$ (M). (*A*) Optical density, (ν) wave number, and (λ) wavelength. c_{SDDS} (M): (*1*) 0; (*2*) 5×10^{-6}, (*3*) 1×10^{-5}, (*4*) 5×10^{-5}, (*5*) 1×10^{-4}, (*6*) 3×10^{-4}, and (*7*) 1.5×10^{-3}.

a product of associate decomposition in the submicellar range [scheme (1)]. At the constant initial $TBPF^-$ and TBA^+ concentrations and increase in SDS content (Fig. 2a, spectra *2*–*7*), the optical density of the solution increases due to increase in the resulting $TBPF^-$ concentration. The associate $TBA^+ \cdot DS^-$ formed does not absorb in the visible region, because it contains no colored ions.

At the same time, due to electrostatic repulsion, $TBPF^-$ does not form any associate with DS^-. This follows from invariability of the $TBPF^-$ spectrum in the presence of various concentrations of DS^- (Fig. 2b, spectra *2*–*7*). This fact indicates that the behavior of the anionic surfactant with respect to the dye anion and associate differs substantially: only in the second case the system is sensitive to the presence of the anionic surfactant in aqueous solution.

In the case of CPB, the associate decomposition is noticeable only in the micellar medium [scheme (4)], while at the submicellar concentrations the associate $CP^+ \cdot TBPF^-$ [scheme (2)] is formed. Its spectrum is similar to the spectrum of $TBA^+ \cdot TBPF^-$ associate (Fig. 1, spectrum *4*). It is important that the competitive character of the $TBA^+ \cdot TBPF^-$ reaction with CP^+ [scheme (2)] is confirmed by the fact that the stability of the $CP^+ \cdot TBPF^-$ associate is approximately the same ($\log K_{as}^T = 5.3 \pm 0.11$) as that of the $TBA^+ \cdot TBPF^-$ associate.

In the micellar region, the surfactants studied behave with respect to the associate components as a micromedium: the counterions are separated by surfactant micelles [schemes (3) and (4)]. Thus, $TBPF^-$ anions are released from the associate. This is confirmed by the spectra, which are similar in the shape and intensity to the spectra of $TBPF^-$ in micelles of anionic (Fig. 1, spectrum *2*) and cationic (Fig. 1, spectrum *3*) surfactants. This fact agrees with the reference data [7] on the influence of ionic surfactant micelles on the protolytic species of hydroxyxanthene dyes.

The sensitivity of the associate to the surfactant content in the solution is connected with the associate stability, since, at constant $TBPF^-$ and TBA^+ concentrations, changes in the associate + surfactant system appear at the lower surfactant content [schemes (1) and (2)]. It is found that the optical density of solutions with fixed $TBFF^-$ and TBA^+ concentrations increases in proportion to the concentration of alkyl sulfates (AS), anionic surfactants of the general formula $C_nH_{2n+1}OSO_3H$ (n = 8 and more). The optical density of the solution at λ 515 nm, A_{515}, and concentrations of $TBPF^-$ of 1.5×10^{-5} M and TBA^+ of 6×10^{-5}, within the AS concentration range 5×10^{-6}–8×10^{-5} M, is described by the equation

$$A_{515} = (0.07 \pm 0.01) + (2.09 \pm 0.12) \times 10^4 c_{AS},$$

where c_{AS} is AS molar concentration in the solution.

Similar dependences underlie spectrophotometric determination of AS, characterized by insignificant influence of pH. As mentioned above, both $TBPF^-$ and TBA^+ undergo no protolytic transformations within the pH 4.5–9.5 range. Therefore, AS determination can be performed within this pH range. The main characteristics of the proposed method of AS deter-

mination (DS^- standard) in aqueous solutions using $TBA^+ \cdot TBPF^-$ associate are presented below:

AS detection limit, M:	
by 3σ criterion [20]	2.5×10^{-6}
practical [21]	6.5×10^{-6}
Interval of AC concentrations determined, M	6.5×10^{-6}–2.0×10^{-3}
pH range	4.5–9.5

The properties of $TBA^+ \cdot TBPF^-$ associate can also be used for development of a method for semiquantitative estimation (test control) of the AS concentration. The procedure is as follows. A series of solutions containing the constant concentrations of TBPF and TBA (e.g., TBFF concentration is 1.5×10^{-6} M and TBA concentration is by a factor of 4–6 higher) and various AS concentrations (from 6.5×10^{-6} to 2×10^{-3} M with respect to SDS reference) are prepared. Each solution will have a specific color in accordance with the degree of the associate decomposition. To estimate the AS content, an aliquot of the solution to be analyzed is added to the TBPF and TBA mixture, and the resulting color is compared to that of reference solutions containing known AS concentration. The AS concentration is determined by interpolation using the reference solutions having the closest color.

CONCLUSIONS

(1) In aqueous solutions, tetrabromophenylfluorone anion forms 1 : 1 ionic associates with single-charged organic cations.

(2) Specific features of associate decomposition at various concentrations of anionic and cationic surfactants were determined. The associate decomposition in submicellar solutions is due to a competitive action of surfactant ions on ions forming the associates, while in micellar solutions, ionic surfactants impede association.

(3) The properties of tethabromophenylfluorone associates were used to develop a new method for determination of alkyl sulfate content in aqueous solutions. The proportional relationship between optical density of the associate solution and the content of anionic surfactant introduced is the basis of the quantitative determination. The method is characterized by a low detection limit (6.5×10^{-6} M for sodium dodecyl sulfate) and wide ranges of pH and surfactant concentrations.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Epoxy–Oxazolidone Oligomers

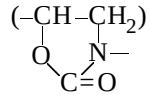
V. V. Mikheev and R. R. Ivanova

Kazan State Technological University, Kazan, Tatarstan, Russia

Received December 22, 2003

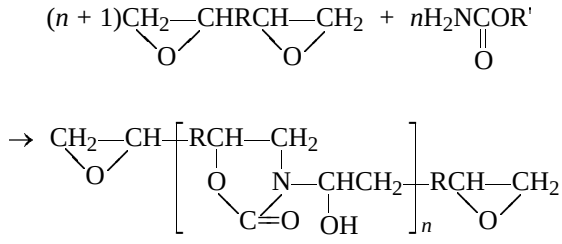
Abstract—A procedure was developed for preparing oligomers containing terminal epoxy groups and 2-oxazolidone rings in the backbone.

One of the ways to improve the performance of epoxy polymeric materials is their modification with urethanes. The best developed modification procedure is preparation of epoxy–urethane oligomers containing urethane bonds in the backbone and terminal epoxy groups [1, 2]. The urethane fragments in such oligomers have a linear structure. It is known, however, that urethane groups in the 2-oxazolidone ring



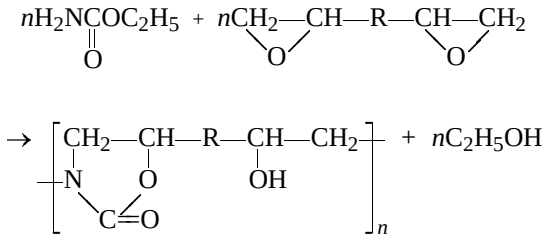
surpass linear urethane fragments in the resistance to base hydrolysis [3] and heat [4, 5].

In this study, we examined the possibility of preparing epoxy–oxazolidone oligomers (EOOs) containing 2-oxazolidone rings in the backbone and terminal epoxy groups by reactions of low-molecular-weight epoxy–4,4'-isopropylidenediphenol oligomers (EOs) with urethanes containing no substituents at the N atom:

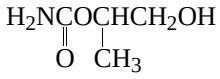


+ nR'OH

It is known [6] that reactions of equimolar amounts of diepoxides and ethyl urethane in the presence of triethylamine catalyst yield polyoxazolidones:



We expected that reactions of urethanes containing no substituents at the N atom with excess EO would yield EOOs. To examine this possibility, we used commercially available low-molecular-weight EOs of the ED-20 and E-40 brands, and also diphenylolpropane diglycidyl ether (DGE). As urethanes we chose *n*-butyl urethane (BU) and 1-hydroxy-2-propyl urethane (HU)



We found that EOs reacted with BU or HU (molar ratio 2 : 1) in the presence of catalytic amounts of tertiary amines (triethylamine, tributylamine) at 120–160°C. The reaction is accompanied by the release of by-products (butanol with BU and 1,2-propylene glycol with HU) but yields a gel. The gelation may be due to the fact that tertiary amines apparently catalyze not only the formation of the 2-oxazolidone ring but also the polymerization of excess epoxy groups. It is well known [7] that epoxides tend to polymerize in the presence of tertiary amines.

We found that EOOs could be prepared with dibutyltin dilaurate (DBTDL) used as a catalyst. This substance does not cause any decrease in the content of epoxy groups in EOs on heating to 200°C. The EOOs were prepared as follows. A mixture of urethane with

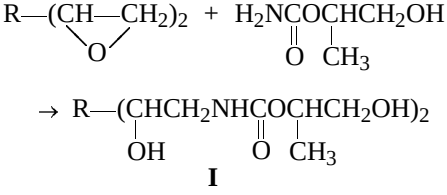
EOO-9	E-40	HU	4 : 3	75–80	3.5	2520	2.40
EOO-10	ED-20	HU	5 : 4	70–75	4.2	2160	2.12

excess EO was heated in the presence of DBTDL first at 130–140°C under atmospheric pressure and then at 170–180°C in a vacuum until the release of the by-product was complete.

Epoxy–oxazolidone oligomers are solids soluble in polar organic solvents (ketones, acetates, Cellosolves). The products were characterized by the melting points T_m, epoxy group content E, molecular weight M_n, and relative viscosity η_{rel}. The structure of EOOs was confirmed by IR spectroscopy. The spectra contain absorption bands of epoxy groups (860, 920 cm^{-1}) and a band at 1740 cm^{-1}, characteristic of the urethane C=O group in the 2-oxazolidone ring [8]. The characteristics of EOOs are listed in the table.

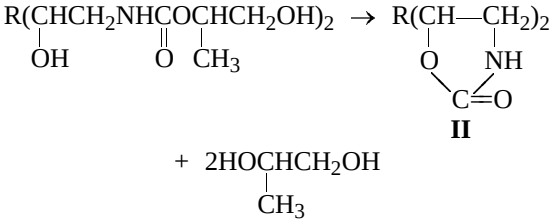
We found that the mechanism of EOO formation involves three consecutive reactions. First, the epoxy groups in the starting EO are opened under the action of urethane to form an addition product. This was confirmed by the reaction of ED-20 with HU (1 : 2 molar ratio) at 130°C. Figure 1 shows that, in the absence of DBTDL, the epoxy groups remain virtually unchanged. The reaction noticeably accelerates in the presence of 1 wt % DBTDL, being complete in 4 h, with full conversion of the epoxy groups. No low-molecular-weight impurities were detected. According to IR data, the product contains no primary urethane groups present in the starting HU. The reaction follows the scheme



I

The reaction product is a highly viscous substance. Analysis for the content of OH groups (found 10.5, calculated 10.9%) confirms the suggested structure.

The next step of EOO synthesis is the elimination of the low-molecular-weight product (butanol or 1,2-propylene glycol) and the formation of oxazolidone structures. This was confirmed by conversion of addition product **I** at 170–180°C in a vacuum:



II

The structure of the resulting dioxazolidone **II** was confirmed by IR spectroscopy and analysis for the nitrogen content (found 5.53, calculated 5.70%), and 1,2-propylene glycol was identified by comparison of

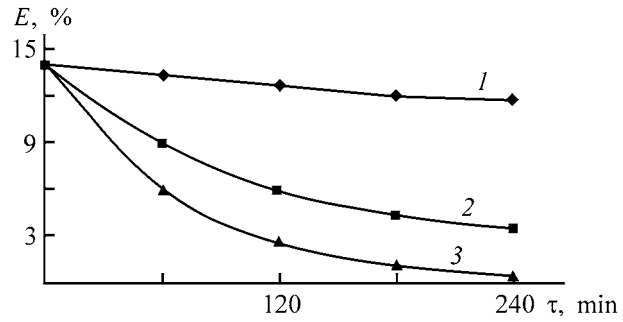


Fig. 1. Kinetic curves of the reaction of ED-20 with HU (molar ratio 1 : 2) at 130°C: (*E*) epoxy group content and (τ) time. DBTDL content, %: (*1*) 0, (*2*) 0.5, and (*3*) 1.0.

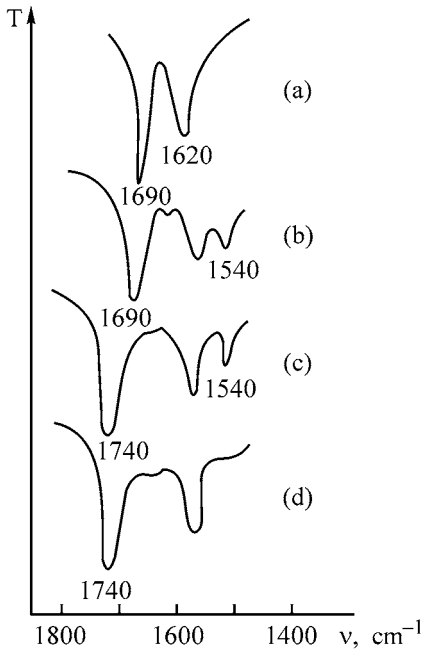

Fig. 2. Fragments of the IR spectra of (a) HU, (b) product of its addition to ED-20, (c) dioxazolidone, and (d) EOO derived from ED-20 and HU. (T) Transmission and (ν) wave number.

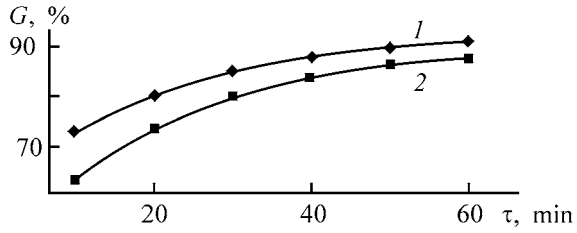

Fig. 4. Gel fraction content G in curing of mixtures of EOO-3 with (*1*) maleic and (*2*) phthalic anhydrides at 170°C.

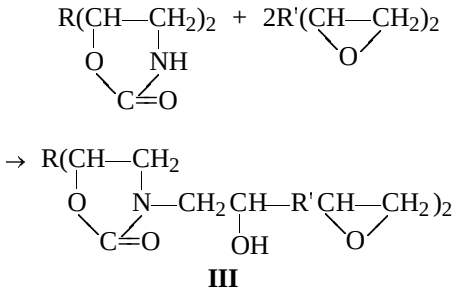
its physical constants with reference data. Dioxazolidone **II** is a solid, T_m 92–96°C.

The final step of EOO formation is the reaction of excess epoxy groups of EO with the N–H bond in oxazolidone rings:



III

The possibility of this reaction was confirmed by the example of the reaction of **II** with ED-20 (molar ratio 1 : 2) at 170–180°C, which yielded EOO-2.

The above transformations are confirmed by the IR spectra. Figure 2 shows the fragments of the IR spectra (1500–1800cm^{-1}) of HU, product of its addition to ED-20 (molar ratio 2 : 1), dioxazolidone, and EOO derived from ED-20 and HU. Comparison of the spectra confirms the transformation of the NH_2 group in the starting HU (band at 1620 cm^{-1}) into the NH group in **I** and **II** (band at 1540 cm^{-1}).

EOO (compound **III**) exhibits no absorption in these regions. The band of the urethane C=O group shifts from 1690 (HU, compound **I**) to 1740 cm^{-1} (**II**, **III**); the latter frequency is typical of the oxazolidone ring. The spectrum of EOO also contains the absorption bands of the epoxy group (860, 915 cm^{-1}).

The EOOs are readily cured via epoxy groups with hardeners traditionally used for EOs. This is illustrated by Figs. 3 and 4. It is seen that network polymers are formed at high rates from mixtures of EOOs with the calculated amounts of aliphatic polyamines (Fig. 3) or anhydrides of dibasic acids (Fig. 4).

EXPERIMENTAL

n-Butyl urethanes were prepared by refluxing a mixture of butanol and urea in the presence of catalytic amounts of zinc acetate [9, 10]. 1-Hydroxy-2-propyl urethane was prepared by the reaction of 1,2-propylene carbonate with ammonia [11]. Diphenylolpropane diglycidyl ether (DGE) was isolated by vacuum distillation of ED-20 [12].

EOOs were prepared as follows (described for EOO-1 as example). A three-necked flask equipped with a stirrer, a thermometer, and a descending condenser with a condensate receiver was charged with 34 g (0.1 mol) of DGE, 6 g (0.05 mol) of HU, and 0.4 g of DBTDL. The mixture was heated with stirring to 130–140°C and kept at this temperature for 2 h at atmospheric pressure. Then the temperature was raised to 170–180°C, and the flask was evacuated to 0.7–0.8 kPa. Under these conditions, 1,2-propylene

glycol was distilled off into the receiver. The reaction was completed at a residual pressure of 0.2–0.25 kPa. The melt of the resulting EOO-1 was cooled to 120–130°C and cast onto a fluoroplastic plate on which it solidified.

The nitrogen content was determined by the Kjeldahl method [13]; the content of hydroxy groups, by acetylation [13]; and the content of epoxy groups, using a solution of HCl in acetone [14]. The molecular weight was determined from the content of epoxy groups, and the relative viscosity, viscometrically using 10% EOO solutions in butyl Cellosolve. The content of the gel fraction in curing of mixtures of EOOs with hardeners was determined by extraction of mixture samples with acetone in a Soxhlet apparatus for 6 h [15].

CONCLUSION

Urethanes react with excess low-molecular-weight epoxy oligomers in the presence of catalytic amounts of dibutyltin dilaurate to form epoxy–oxazolidone oligomers.

Received March 1, 2004

Abstract—Peroxy-containing rosin–maleic and rosin–terpene–maleic resins were prepared and grafted to low-density polyethylene macromolecules by reactive extrusion. The morphology and mechanical properties of blends of functionalized polyethylene with polyamide 6 were determined.

One of the most versatile and economically feasible ways to improve the performance of plastics for machine-building and general technical purposes is the use of polymer blends. However, the applicability of polymer blends is restricted by the fact that many polymers are incompatible with each other, which results in phase segregation on blending [1, 2]. One of the main procedures eliminating or reducing the negative effect of the incompatibility of polymeric components is reactive mixing in which the mixing proper is accompanied by physicochemical transformations of reactive functional groups, which are present in macromolecules of the components or are introduced specially [1–3]. Functionalized (reactive) polymers based on polyolefins (POs) are prepared by grafting functional monomers to their macromolecules in polymer melts [3].

A convenient and efficient procedure for functionalization of POs is grafting of unsaturated monomers in a polymer melt using special extrusion reactors [4–7]. To initiate grafting in a reactive extrusion (RE) process, radical initiators are added to the reaction mixture along with the unsaturated monomers. The most widely used radical initiators are dialkyl peroxides [7].

In preping functionalized POs (FPOs), the functional groups and initiating peroxy groups can be combined in one substance, i.e., functional peroxy initiators (FPIs) can be used [7, 8]. It is suggested that decomposition of FPIs in the course of RE will yield fragments that contain functional groups and can be grafted to the polymer chain.

Apparently, the course of grafting and properties of the resulting FPOs will largely depend on the chemical structure of functional peroxides. For example, experiments on grafting of carboxyl-containing peroxides to polypropylene have shown that the degree of grafting of functional groups and degradation of polypropylene macromolecules could be controlled by varying the molecular structure of the peroxide [8].

The range of the available FPIs studied is limited, which makes it urgent to develop FPIs, optimize conditions of their grafting to PO macromolecules, and study properties of FPOs and blends based on them.

In this study, we prepared peroxy-containing formulations (PFs) based on rosin–maleic (RMR) and rosin–terpene–maleic (RTMR) resins and examined the fundamental aspects of grafting of these resins to polyethylene by RE and the properties of the resulting grafted products and their blends with polyamide 6 (PA6).

EXPERIMENTAL

In our study we used low-density polyethylene [LDPE, 15803-020 grade, GOST (State Standard)

1070-4272/04/7706-0976 © 2004 MAIK "Nauka/Interperiodica"

16337–77, density 0.92 g cm^{-3}, melting point 105°C), functional peroxides derived from RMR and RTMR, and dicumyl peroxide (DCP). Blends were prepared with PA6 of 210/310 grade.

The functionalization of LDPE was performed by grafting of a PF to its macromolecules in a single-screw extrusion reactor (screw diameter 25 mm, L/D = 25) equipped with a static mixer [9], under the following conditions: screw rotation rate 27 rpm (shear rate about 30 s^{-1}), temperature in the reaction zone 185°C, PF concentration in the reaction system 1.5 wt %.

Blends of PA-6 with functionalized LDPE (LDPE-*graft*-FPI) were prepared by extrusion mixing of a blend of the corresponding granulates in a single-screw plasticator (screw diameter 45 mm, L/D = 20); the melt temperature in the extrusion zone was 180–240°C. The LDPE-*graft*-FPI content in the blends was 15 wt %.

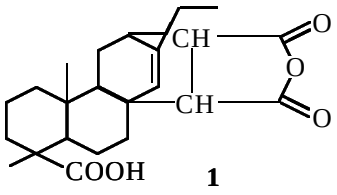
The grafting was characterized by the grafting efficiency α: the ratio of the weight of the grafted resin to the total weight of the resin introduced into the polymer. This quantity was determined by IR absorption spectroscopy, namely, from the content of PF in LDPE-*graft*-FPI before and after extraction with ethanol at 70°C [9].

The viscosity of polymer melts was evaluated by the melt flow index, which was determined at 190°C and 10-kg load with an IIRT-AM device.

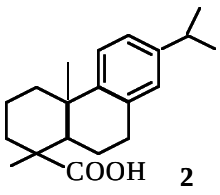
The morphology of polymer blends was studied by scanning electron microscopy (JSM 50 Å electron microscope, Jeol, Japan) on chips of samples cooled with liquid nitrogen (notched bars for determining the impact resilience) and decorated with gold.

The mechanical properties of blends were determined by extension and impact failure methods using the standard procedures; samples were prepared by pressure casting.

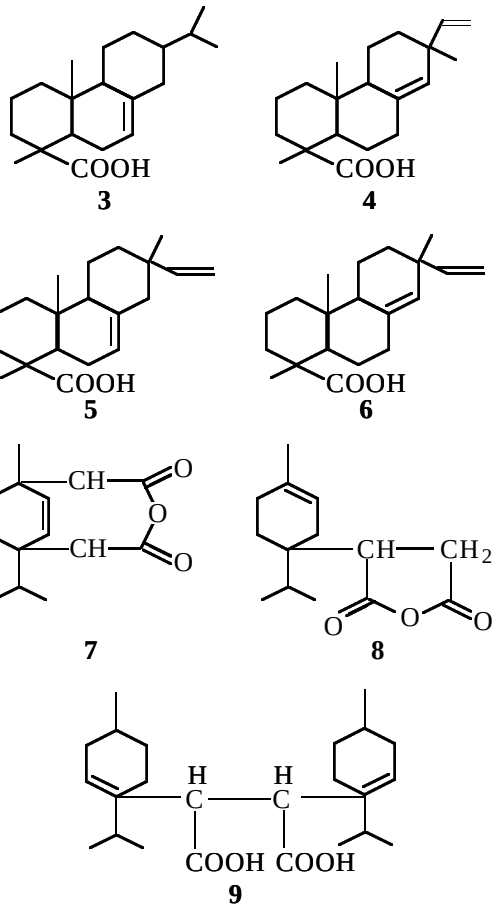
FPIs were prepared from RMR and RTMR. Rosin–maleic resin was prepared from rosin and maleic anhydride at 180–190°C. It consisted of 75% maleopimaric acid **1** and 25% resin acids **2**–**6** [10]. Rosin–terpene–maleic resin was prepared by treatment of turpentine with maleic anhydride at 180–190°C. It contained 40% maleopimaric acid **1**, 40% mixture of adducts **7** and **8** and diadduct **9**, and 20% resin acids **2**–**6** [11, 12].



1

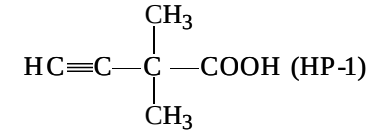


2



3 **4** **5** **6** **7** **8** **9**

FPIs were prepared by treatment of RMR and RTMR with hydroperoxides: *tert*-butyl hydroperoxide (TBHP) and acetylenic hydroperoxide, 3-methyl-3-hydroperoxy-1-butyne (HP-1), in chloroform in the presence of pyridine:



For this purpose, a solution of calculated amounts of resin, peroxide, and pyridine in chloroform was allowed to stand at room temperature for 7 days, after which the reaction mixture was diluted with ether and washed with 18% HCl and water to neutral reaction, and the organic layer was dried over $CaCl_2$. The solvent was distilled off, and the residue was dried in a vacuum at 40°C. The compositions of the reaction systems for preparing PFs are listed in Table 1. As seen from Table 1, the content of available oxygen in the PFs obtained was from 1.53 to 2.48%.

One of FPI samples based on RTMR (Table 1, sample C.40) was prepared by the process involving lithium orthophosphate instead of pyridine. According to

Table 1. Conditions of synthesis of various FPIs and physicochemical properties of the products (synthesis time 7 days, 25°C)

PF	Starting components					mp, °C	Yield based on starting resin, %	Concentration of available oxygen, %	
	RMR, RTMR, g	TBHP, mol	pyridine, mol	lithium orthophosphate, g	chloroform, ml			found	calculated
RMR–TBHP	10	0.0375	0.0625	–	50	55–85	76	2.27	2.54
RTMR–TBHP	10	0.075	0.125	–	50	50–75	70	2.48	2.34
RTMR–TBHP (C.40)	100		–	6	200	70–115	75	1.91	2.34
RMR–HP-1	8	0.02	0.05	–	40	50–105	84	1.58	2.50
RTMR–HP-1	8	0.025	0.075	–	40	40–70	80	1.53	2.24

this process, 6 g of lithium orthophosphate was added to a solution of 100 g of RTMR and 37.5 ml of TBHP in 200 ml of chloroform. The mixture was stirred for 7 days, 5 g of activated carbon was added to coagulate lithium orthophosphate, the catalyst was removed, the solvent was distilled off, and the residue was dried at 40°C/1 mm Hg. We obtained 84 g of a product with mp 70–115°C and available oxygen content of 2.34%. We found that replacement of pyridine with lithium orthophosphate makes FPI preparation considerably simpler and cheaper, since volatile dangerously inflammable solvents are eliminated from the process, as well as the steps of washing with HCl solution and water and drying over $CaCl_2$. With lithium orthophosphate, the target products are isolated immediately after the removal of the catalyst and solvent.

The reaction of RMR and RTMR with hydroperoxides apparently involves opening of the anhydride groups of the adducts to form the corresponding peroxy esters **10**–**12**:

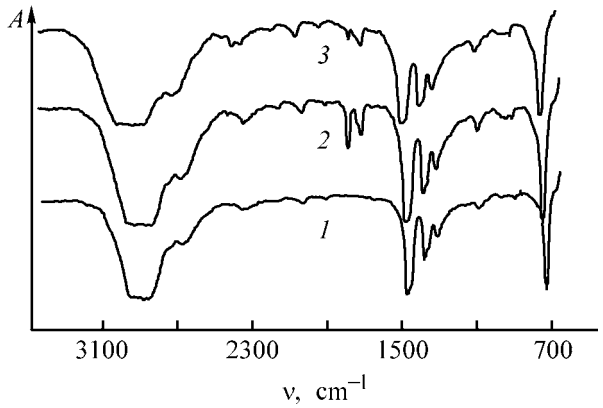


Fig. 1. IR spectra of (*1*) starting LDPE and (*2, 3*) LDPE functionalized with RMR–TBHP, before and after extraction with ethanol, respectively. (*A*) Transmission and (ν) wave number.

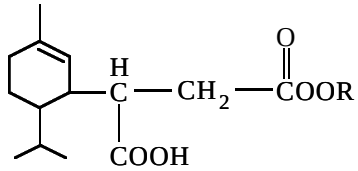
11a, 11b



12a, 12b

where R = $C(CH_3)_3$ (**a**), $C(CH_3)_2C{\equiv}CH$ (**b**).

The PF based on RMR contains peroxy ester **10a**, a part of unchanged maleopimaric acid **1**, and resin acids **2**–**6** from the starting RMR.

With RTMR, TBHP and HP-1 react at the anhydride groups of both maleopimaric acid **1** and adducts **7** and **8**. Functional peroxy initiators derived from RTMR contain peroxy esters **10b**–**12b**, resin acids **2**–**6**, and diadduct **9**. Some properties of the PFs obtained are listed in Table 1.

The chemical structure of the FPIs prepared suggests that these compounds can be used in LDPE functionalization both as components of an initiating system (owing to the presence of peroxy ester groups) and as functional monomers (owing to the presence of fragments of resin acids: pimaric **4**, isopimaric **5**, and sandaracopimaric **6**, containing vinyl groups).

Comparison of the IR spectra of the starting LDPE and LDPE-*graft*-FPI shows that coextrusion of the reaction mixture of LDPE with FPI is accompanied by grafting of fragments of peroxide molecules to the LDPE macromolecules (Fig. 1). The IR spectra of modified LDPE contain a complex absorption band at 1700–1790 cm^{-1}, characteristic of stretching vibrations of

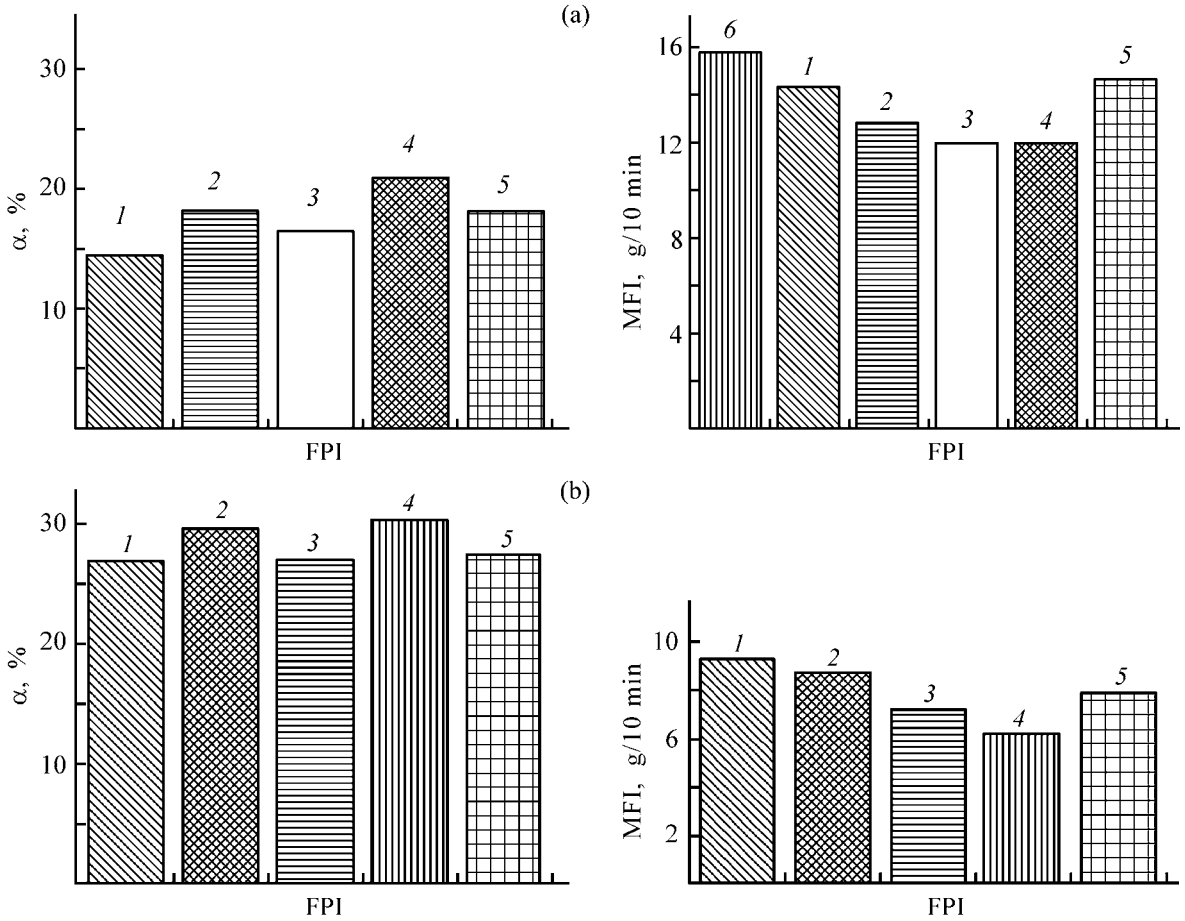


Fig. 2. Influence of (a) the kind of FPI and (b) DCP addition to FPI (0.2 wt %) on the efficiency α of grafting of peroxy fragments to LDPE and on the melt flow index MFI of LDPE-*graft*-FPI. Modifier concentration 1.5 wt %. (*1*) RMR–TBHP, (*2*) RTMR–TBHP, (*3*) RMR–HP-1, (*4*) RTMR–HP-1, (*5*) C.40, and (*6*) no modifier.

the C=O bond in ester, carboxy, aldehyde, and other carbonyl-containing groups. The fact that the C=O absorption is preserved upon extraction of modified LDPE samples with ethanol confirms the chemical binding ot PF molecules with LDPE. However, the intensity of absorption at 1700–1790 cm^{-1} noticeably decreases after the extraction. This fact was used to determine the grafting efficiency. Since the spectra of LDPE modified by PF grafting are characterized by a set of several overlapping bands in the range 1700–1790 cm^{-1}, the grafting efficiency was determined as the ratio between the total peak areas (per unit thickness of the film) in this range after and before extraction of LDPE-*graft*-FPI film samples with ethanol at 70°C.

The values of α for LDPE-*graft*-FPI obtained with vairous kinds of FPI and of the melt flow index (MFI) of LDPE–*graft*-FPI samples are given in Fig. 2a. The efficiency of grafting of FPI fragments to macromolecules varies within 15–21%, depending on the modifier composition. As shown by MFI, the viscosity of LDPE-*graft*-FPI increases only slightly relative to the starting polymer. The MFI values for the starting and modified LDPE differ by no more than 16%. Several factors may be responsible for the relatively low grafting efficiency; the main of these is, apparently, the low concentration of available oxygen. Therefore, the concentration of radicals generated in thermolysis is too low to give rise to a sufficient amount of polyethylene macroradicals to which the FPI fragments are grafted [8].

In this context, we performed a series of experiments on functionalization of LDPE with peroxy-containing formulations in the presence of DCP, which effectively initiates grafting of functional monomers to PO macromolecules [9]. We found that introduction of dicumyl peroxide (0.2 wt %) into the initiating system along with FPI appreciably increases the grafting efficiency (to 31% with FPI based on RTMR and HP-1, Fig. 2b). The rais in the grafting efficiency is accompanied by a decrease in MFI by a factor of 1.8–2.5.

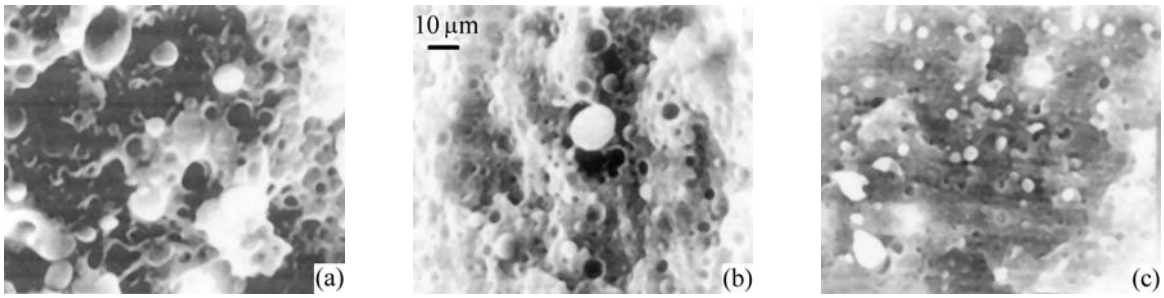

Fig. 3. Electron micrographs of (a) PA6/LDPE blend and (b, c) PA6/LDPE-*graft*-FPI (RMR–TBHP) blends prepared without and with addition of DCP, respectively. LDPE and LDPE-*graft*-FPI concentration in blends 15 wt %.

This is apparently due to an increase in the available oxygen concentration in the initiating system on adding DCP (the available oxygen content in DCP is 5.92%).

The most effective modifiers, from the viewpoint of the grafting efficiency attained under the experimental conditions, are those based on RTMR and HP-1, both in the presence and in the absence of DCP (Figs. 2a, 2b). As for the C.40 sample, which was prepared by a procedure differing from that used with the other FPIs, α and MFI of LDPE-*graft*-FPI obtained with this sample were similar to those of the product obtained with RTMR–TBHP (Figs. 2a, 2b).

Numerous papers [13–15] show that the presence in POs of functional oxygen-containing groups (aldehyde, carboxy, etc.) improves the compatibility of POs with many other polymers and, in particular, with aliphatic polyamides. In this context, it was interesting to assess the prospects for blending LDPE-*graft*-FPI with PA-6 with the aim to prepare composite materials of enhanced performance. In our study, we gave the major attention to the morphological features and physicomechanical properties of the blends.

Figure 3 shows the electron micrographs of chips obtained in liquid nitrogen from 80 × 10 × 4-mm bars of blends of PA6 with the starting LDPE and with LDPE-*graft*-FPI. It is seen that all the blends are two-phase. The polyethylene disperse phase is aggregated and forms droplets varying in size from ≤1 to 10 μm.

Table 2. Mechanical properties of blends*

* (α_f) Upper yield point in extension of samples prepared by one-side injection from the end; (ε_t) relative elongation of samples prepared by one-side injection from the end; (*K*) seam strength coefficient in pressure casting, equal to the ratio of the yield point of the sample prepared by two-side injection of the melt from the blade ends to that of the sample prepared by one-side injection from the end; and (*a*) Charpy impact resilience.

A specific feature of the morphology of blends of PA6 with LDPE-*graft*-FPI prepared without adding DCP is the decreased size of spherical aggregates of the PO disperse phase in the blend and the decreased concentration of coarse aggregates as compared to the PA6/LDPE blend (Figs. 3a, 3b). At the same time, the smooth surface of the agglomerates suggests a relatively low interphase adhesion between the polyamide matrix and the disperse phase formed by LDPE-*graft*-FPI. Introduction of DCP into the reaction mixture in preparation of LDPE-*graft*-FPI increases the efficiency of grafting of FPI polar fragments, which, in turn, is reflected in the morphology of blends with PA6: The agglomerates become still smaller (≤1–2 μm), and the interphase zones in some cases become less sharp (Fig. 3c). Apparently, the decrease in the size of spherical agglomerates is due to intensification of interphase interactions and an increase in adhesion between the blend components owing to the growth of the concentration of polar FPI fragments grafted to LDPE macromolecules [16].

The yield point and relative elongation of the blends prepared show that the mechanical properties of systems of this kind are determined by the intensity of interaction between the components and, hence, depend on the content of polar fragments grafted to LDPE macromolecules (Table 2). In particular, blends with LDPE modified in the presence of DCP show a higher yield point and a larger relative elongation than the blends with LDPE functionalized in the absence of DCP. Blends of PA6 with LDPE-*graft*-FPI prepared both in the absence and in the presence of DCP exhibit considerably higher (by a factor of 2–3) impact resilience compared to the starting PA6 and to the PA6/LDPE blend (Table 2). The blends with LDPE-*graft*-FPI prepared in the presence of DCP show, on the whole, appreciably higher strength coefficient of the seams of melt flows in pressure casting of various items (blades) (Table 2). This fact indirectly confirms the stronger interphase adhesion in blends of PA6 with LDPE-*graft*-FPI characterized by higher grafting efficiency.

The increased impact resilience and the simplicity and environmental safety of production of PA6/LDPE-*graft*-FPI blends make them promising for practice.

CONCLUSIONS

(1) Reactive extrusion of low-density polyethylene with resins modified with maleic anhydride and peroxy compounds results in grafting to polyethylene macromolecules of polar fragments formed by thermolysis of functional peroxy initiators. The efficiency of grafting of functional peroxy initiators is 15–21%. The viscosity of the polymer melt, evaluated by the melt flow index, slightly grows upon grafting, suggesting loose cross-linking in the graft product.

(2) Additional introduction of cumyl peroxide (0.2 wt %) into the reaction mixture increases the efficiency of grafting of polar fragments of functional peroxy initiators by a factor of 2. The cross-linking of macromolecules is also intensified, causing an increase in the viscosity of the polymer melt by a factor of 2.5.

(3) The most effective modifiers from the viewpoint of ensuring the maximum grafting efficiency, both in the presence and in the absence of dicumyl peroxide, are functional peroxy initiators derived from rosin–terpene–maleic resin.

(4) Blends of polyamide 6 with both functionalized and initial polyethylene are heterogeneous. The disperse polyethylene phase occurs as droplets. A specific feature of the morphology of blends of polyamide 6 with functionalized polyethylene, compared to blends with the initial low-density polyethylene, is the smaller size of the disperse phase particles (the maximum particle size decreases from 10 to 2 μm), and also decreased concentration of coarse aggregates. Therefore, the blends exhibit higher impact resistance.

Abstract—The flocculating performance of a cationic polyelectrolyte, poly-*N*,*N*-dimethyl-2-hydroxypropylenammonium chloride, in recovery of butadiene–styrene rubber in the presence of sulfuric acid at various temperatures was studied. The kinetic curves of flocculation of SKS-30 ARK latex at various amounts of the flocculant added were obtained.

Emulsion rubbers occupy one of the leading positions in production of synthetic rubbers. The absence of harmful substances and of dangerously explosive and inflammable organic solvents creates favorable prerequisites for further development of emulsion rubber production and improvement of the production process. An important step in production of emulsion rubbers is their recovery from latexes by coagulation. On the one hand, sodium chloride widely used for this purpose today is cheap and readily available, but, on the other, it gives rise to environmental problems because of large consumption (180–250 kg t^{-1} rubber [1]). Thus, an enterprise producing about 100 000 t $year^{-1}$ of butadiene–styrene rubbers discharges up to 25 000 t $year^{-1}$ of NaCl to water treatment facilities. Since sodium chloride is not subject to biodegradation at the water treatment facilities, this amount is further discharged into natural water reservoirs, causing environmental pollution with mineral salts and irretrievable harm to the nature. Therefore, active efforts are being made in Russia and other countries to develop new coagulating agents that would be adsorbed on the rubber during coagulation and would be recovered together with the rubber crumb. This would reduce the water consumption by rubber recovery shops, the amount of discharged aqueous phase, and the content of harmful and toxic products in it, with an increase in the productive capacity of the process as a whole.

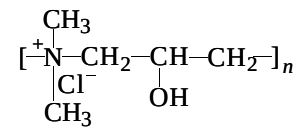
Much attention has been given recently to the use of cationic organic coagulants with both low and high molecular weight [2–4]. With cationic agents, the consumption of coagulants used in recovery of synthetic rubbers from latexes can be considerably reduced.

In this study, we examined the flocculating performance of poly-*N*,*N*-dimethyl-2-hydroxypropylenammonium chloride (PDMHPAC) in recovery of synthetic butadiene–styrene rubber from SKS-30 ARK latex at various temperatures and additions of the acidifying agent.

EXPERIMENTAL

Experiments were performed with SKS-30 ARK commercial latex of butadiene–styrene rubber (content of bound styrene in the copolymer 21.9%). The polymer content in the latex was 190 g l^{-1}; surface tension, 56.4 mN m^{-1}; and mean size of latex globules, 29 nm.

The PDMHPAC sample used as flocculant had the following characteristics: main substance concentration 50%, viscosity 23.85 cP, pH 8.3, concentration of chloride ions 11.2%. The structural formula of PDMHPAC is as follows:



Rubber was recovered from the latex in a coagulation unit, namely, in a vessel equipped with a stirrer

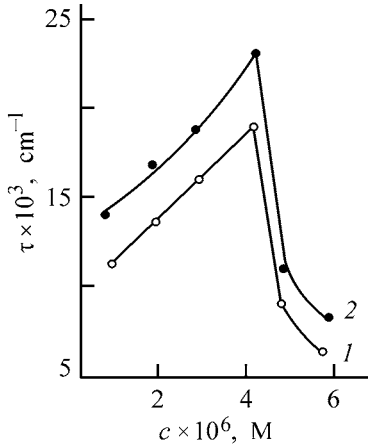

Fig. 2. (*1*) 1-min turbidity τ_1 and (*2*) limiting turbidity τ_∞ vs. PDMHPAC concentration c (in terms of monomeric units).

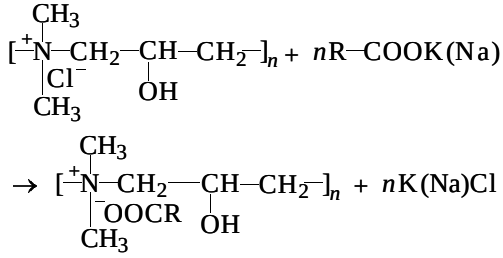
and placed in a thermostat. The completeness of coagulation was evaluated by the weight of the coagulum formed and visually, by the serum transparency (the serum transparency is an evidence of complete coagulation).

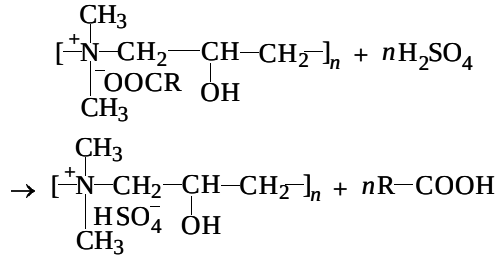
The kinetic curves of flocculation of SKS-30 ARK latex at various of the flocculant added were taken at room temperature with an NFM nephelometer. The procedures for nephelometric monitoring of the kinetics and for determination of the initial flocculation rate are described elsewhere [5].

Variation with time of the turbidity τ of a dilute ($1 : 10^4$) SKS-30 ARK latex in the presence of various amounts of PDMHPAC is shown in Fig. 1. As with other cationic agents (poly-*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride, PDMDAAC [6]; 2-methylimidazole [7]; 2,2,4-trimethyl-1,2-dihydroquinoline [8]), the turbidity initially grows, after which a constant limiting value, τ_∞, is attained, corresponding to the formation of coarse floccules stable in time [9]. The curve of the 1-min turbidity, characterizing the initial flocculation rate, vs. PDMHPAC concentration passes through a pronounced maximum (flocculation optimum) typical of polyelectrolytes (Fig. 2). The polyelectrolyte concentration corresponding to the maximum flocculation rate can be a measure of the flocculating performance [10]. The optimum is due to neutralization of the surface electric charge of particles as a result of binding of emulsifier anions into an insoluble nondissociating complex, which can be followed by recharging and restabilization of the sol through adsorption of excess polymer and build-up of the positive charge of the particles, and also to formation of relatively thick layers of the hydrophilic polymer (Fig. 2). Similar trends have been observed previously in flocculation of polystyrene latex [11, 12] and of butadiene–styrene and butadiene–acrylonitrile latexes [5] with PDMHPAC; in all cases, the occurrence of recharging was confirmed by measuring the electrokinetic potential of the latex particles.

The interaction of PDMHPAC with emulsifiers (potassium soap derived from tall oil, sodium paraffinate, Leukanol) can be schematically described by exchange reactions occurring in latex coagulation:



On acidification, the product can react with sulfuric acid, with the release of free organic acids:



We examined the influence exerted on the coagulation of SKS-30 ARK butadiene–styrene latex by such an important parameter as the concentration of the disperse phase. In real industrial processes, the polymer

content in the latex can vary from 10 to 22%. Such significant fluctuations of the concentration can affect the amount of PDMHPAC required for complete recovery of the rubber from the latex. To examine the influence exerted by the concentration of the disperse phase on the completenes of coagulation with PDMHPAC, we prepared latexes with 50, 100, and 150 g l^{-1} of the disperse phase.

The dependences of the degree of the rubber coagulation φ on the PDMHPAC concentration at 20°C and various concentrations c_{dp} of the disperse phase are shown in Fig. 3. As the concentration of the disperse phase is increased, the curves of coagulum recovery steadily shift to higher flocculant concentrations. In the curves of the degree of rubber recovery vs. flocculant concentration, the initial ascent is followed by a plateau corresponding to complete recovery of the rubber from the latex. In [13], we described the specific features of the flocculating effect of polymeric agents at various concentrations of the disperse phase. Flocculation of sols by oppositely charged polymers was attributed to two destabilization factors: neutralization of the surface charge of the sol particles and bridging mechanism of particle agglomeration. This is followed by restabilization through surface recharging and formation of a dense polymolecular adsorption layer of a hydrophilic polymer on the particle surface. When the concentration of the disperse phase in SKS-30 ARK latex is as high as 50–150 g l^{-1}, the restabilization effect is lost, which may be due to relaxation processes occurring in adsorption layers of macromolecules on the particle surface [14]. It should be noted that the PDMHPAC consumption is virtually independent of the concentration of the disperse phase (in the examined range), amounting to 4–5 kg t^{-1} rubber.

Another important process parameter of rubber recovery from a latex is the consumption of an acidifying agent, an aqueous solution of sulfuric acid. As the H_2SO_4 consumption is increased, the coagulating power of PDMHPAC grows significantly (Fig. 4). This may be due to contraction of the diffuse electrical double layer and decrease in the electrostatic repulsion forces preventing agglutination of latex globules upon collisions. However, the effect of this factor is restricted to relatively low consumptions of H_2SO_4. Apparently, the major effect should be exerted by a nonelectrostatic stability factor, associated with the presence of a hydrated adsorption layer of the emulsifier on the surface of latex globules [15]. The overlapping of these layers determines the structural component of the wedging pressure [16, 17]. It is well known [18, 19] that the thickness of protective hydration

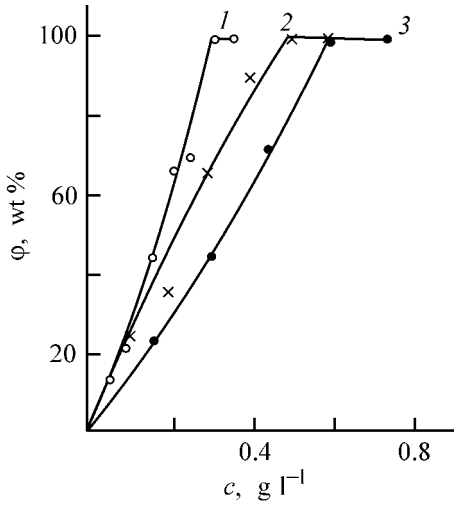


Fig. 3. Degree of coagulation φ of SKS-30 ARK latex vs. PDMHPAC concentration c at various concentrations c_{dp} of the disperse phase. H_2SO_4 amount 15 kg t^{-1} rubber. c_{dp}, g l^{-1}: (*1*) 50, (*2*) 100, and (*3*) 150.

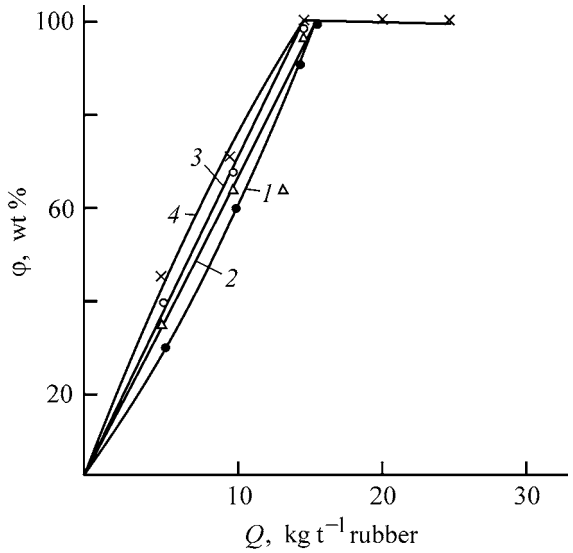

Fig. 4. Degree of coagulation φ of SKS-30 ARK latex vs. sulfuric acid consumption Q at various temperatures. Concentration of the disperse phase c_{dp} = 100 g l^{-1}; PDMHPAC consumption 4 kg t^{-1} rubber. T, °C: (*1*) 20, (*2*) 40, (*3*) 60, and (*4*) 80; the same for Fig. 5.

shells of latex particles decreases as the electrolyte concentration is increased. Hence, the observed increase in the flocculation efficiency in the presence of sulfuric acid, which is a strong dehydrating agent, is also attributable to breakdown and thinning of hydration shells of latex globules. The particles can come in this case closer to each other, making the bridging flocculation mechanism more probable.

Our experiments show that the consumption of the acidifying agent affects the coagulation more strongly

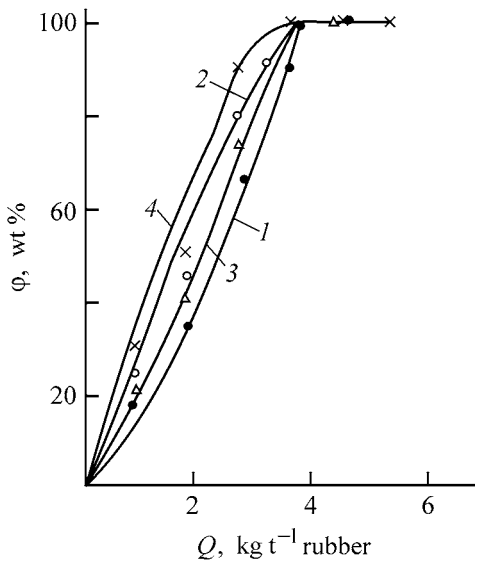

Fig. 5. Degree of coagulum recovery φ from SKS-30 ARK latex vs. PDMHPAC consumption Q at various temperatures. Disperse phase concentration c_{dp} = 100 g l^{-1}, H_2SO_4 consumption 15 kg t^{-1} rubber.

than does the concentration of the disperse phase (in the ranges examined). For example, at a PDMHPAC consumption of about 4 kg t^{-1} rubber (Fig. 4), the coagulum weight regularly grows with increasing amount of added sulfuric acid, reaching 100% at the H_2SO_4 consumption of 15 kg t^{-1} rubber. Further increase in the consumption of the acidifying agent (above 15 kg t^{-1} rubber) at this PDMHPAC consumption is not appropriate, as resulting in an excessive consumption of sulfuric acid and pollution of wastewater.

Our experiments show that, at large consumptions of the flocculant (4 kg t^{-1} rubber) and sulfuric acid (15 kg t^{-1} rubber), the influence of temperature on the degree of rubber recovery from the latex is insignificant. A similar result has been obtained previously [20] in studying the influence of temperature on the degree of rubber recovery from butadiene–acrylonitrile latex with a cationic polyelectrolyte at high latex concentrations, when the restabilization effect is lost.

At the same time, when the amount of PDMHPAC added was below the optimum, the degree of rubber recovery in a wide range of H_2SO_4 consumptions showed an appreciable temperature dependence. In the initial steps of recovery (at low PDMHPAC consumptions), the coagulum weight grew as the temperature increased from 20 to 80°C (Fig. 5). At the PDMHPAC consumption decreased from 4 to 3 kg t^{-1} rubber, the complete coagulation of SKS-30 ARK latex could be attained only at elevated temperatures (80–95°C) and the consumption of sulfuric acid increased to 30 kg t^{-1} rubber, and, at the PDMHPAC consumption decreased to 2 kg t^{-1}, even these conditions were insufficient to recover the rubber completely.

Thus, our studies show that the following reagent consumptions are optimal for coagulation of SKS-30 ARK rubber at the concentration of the disperse phase of 100 g l^{-1} and 60 ± 10°C: PDMHPAC 4 and H_2SO_4 15 kg t^{-1} rubber.

Properties of rubber stocks and vulcanizates based on SKS-30 ARK rubber

Parameter	Sample	
	control	experimental
Mooney viscosity	53	42.5
Karrer plasticity, arb. units	0.30	0.28
Recovery, mm	1.86	1.84
Vulcanization optimum at 143°C, min	80	60
Nominal stress at 300% elongation, MPa	8.4	14.0
Nominal tensile strength, MPa	27.0	27.6
Relative elongation at break, %	600	540
Deformation set, %	16	15
Rebound elasticity, %		
at 20°C	37	32
at 100°C	50	46
Shore hardness, arb. units	59	65
Schopper–Schlobach abrasion, $A \times 10^{-3}$, $cm^3\ m^{-1}$	1.80	1.31
Resistance to cutting propagation to 12 mm with puncture, thousands of cycles	39200	115200
Nominal tensile strength after aging (100°C, 72 h)	18.0	20.0
Relative elongation after aging (100°C, 72 h)	242	257

Under the optimal conditions, we obtained an experimental batch of the coagulum of SKS-30 ARK rubber for subsequent preparation of the standard rubber stock and vulcanizates. We assessed the effect of the coagulant on their properties as compared to the control sample recovered from the latex with NaCl (see table).

It is seen that the rubber stocks and vulcanizates based on the experimental batch of SKS-30 ARK rubber are not inferior in all the main parameters to the control samples obtained using sodium chloride and surpass the control samples in resistance to cutting propagation, aging, and tear.

CONCLUSIONS

(1) The 1-min (τ_1) and limiting (τ_∞) turbidities of SKS-30 ARK latex as functions of the poly-*N*,*N*-dimethyl-2-hydroxypropylenammonium chloride concentration pass through a pronounced maximum (flocculation optimum) typical of the flocculating effect of polyelectrolytes.

(2) The consumption of the acidifying agent exerts a stronger effect on coagulation than the temperature and the concentration of the disperse phase.

(3) Rubber stocks and vulcanizates based on the experimental SKS-30 ARK rubber are not inferior in the main parameters to the control sample obtained using sodium chloride for the rubber recovery and even surpass the control sample in some parameters.

Abstract—Thermal polymerization of *o*-, *m*-, and *p*-pyridinecarbonitriles and their derivatives under the action of Friedel–Crafts catalysts and binary catalysts was studied. The characteristics of the resulting polymers were determined.

In production of polymeric materials, not only the characteristics of functional groups, but also the structural features of macromolecule skeleton are very important. From this standpoint, macromolecular compounds with a system of conjugated bonds, with the backbone containing functional groups capable of ion exchange, complexation, and reversible redox reactions are of interest. These compounds combine high thermal and chemical stability, and radiation resistance, increased electrical conductivity, and capability for electron exchange, characteristic of conjugated polymers. The presence of functional ionogenic and/or redox groups opens up prospects for using these polymers as new redox ion exchangers.

In this context, pyridinecarbonitriles produced by oxidative ammonolysis of alkylpyridines [1–6] and used previously for preparing various ion exchangers [7–15] show considerable promise. Redox ion exchangers based on pyridinecarbonitriles have not been adequately studied [16–18]. The aim of this study was to prepare these polymers and to examine their characteristics.

Contrary to readily polymerizing vinyl monomers and dienes, nitriles of aromatic and heterocyclic acids polymerize only under rigorous conditions with a low yield of target polymers [19, 20].

EXPERIMENTAL

Pyridinecarbonitriles [2-, 3-, and 4-cyanopyridines (2-, 3-, and 4-CP); 2,5-, 3,5-, 2,3-, and 2,6-dicyanopyridines (2,5-, 3,5-, 2,3, and 2,6-diCP); 5-cyano-2-pyridinecarboxamide (A-5-C-2-PC) and 4-hydroxybenzonitrile (4-HBN)] were prepared at the Bekturov Institute of Chemical Sciences [1–6]. 3-Pyridinecarbonyl chloride hydrochloride (3-PCC-HC) was synthesized by the procedure described in [21]. The distillable substances were purified by distillation, and undistillable substances, by recrystallization (Table 1). The majority of the monomers are soluble in benzene, acetone, and ethanol.

The polymers were prepared by thermal polymerization of monomers (Table 1) in the bulk in the presence of stoichiometric amounts of the catalyst in am-

pules in a vacuum, under argon, or in air at the melting point of the nitrile–catalyst complex. The process catalysts were chlorides of coordination-unsaturated metals (Zn, Ti, Sn, Cr, Co, and Fe) of chemically pure or pure grade, produced by Aldrich. After reaction completion, the polymer was ground, purified by repeated precipitation from sulfuric acid to acetone, and washed with distilled water to neutral reaction for the corresponding cations and anions, after which it was dried in a vacuum at 150–200°C to constant weight.

The concentration of metal cations (Cu^{2+}, Co^{2+}, Zn^{2+}, Fe^{3+}, Mg^{2+}, and Hg^{2+}) for estimation of the sorption power of the ion exchangers was determined by titration with Na_2EDTA [22]; Ag^+, by the procedure described in [23]; and Os^{8+}, by the atomic absorption analysis.

Acid–base titration of the samples was carried out by the method of individual weighed portions [24] on a Mettler Toledo MP-220 pH meter. Redox potentiometric titration was carried out in a temperature-controlled cell in an argon flow in the presence of a calomel electrode coupled with a polished platinum electrode in 100 ml of a $K_2SO_4 + H_2SO_4$ buffer solution (pH 0.3–0.7) at 25°C. As an oxidizing agent was used a solution of $Ce(SO_4)_2$ in sulfuric acid, standardized with 0.1 N $Na_2S_2O_3$. To improve the titration efficiency, we used 0.03 N solution of Fe^{3+} as a mediator.[1] Using the titration data, we plotted the dependences of the potential E (mV) on the concentration of the added oxidizing agent. The standard oxidation potential of the polymer E_0 was evaluated by the Nernst equation [18].

Viscometric studies of the polymers synthesized were carried out by the procedure described in [25]. The swellability and moisture content of the ion exchangers, and also their chemical and thermal stability in water, mechanical strength, and bulk weight were determined according to GOSTs (State Standards).[2] The thermal stability of polymers in air was studied on an MOM derivatograph (Hungary). The heating rate was 4.50 deg min^{-1}. The IR spectra of the initial, intermediate, and final products were recorded on a Specord M-80 spectrophotometer.

The lower limiting temperatures of polymerization were found to be 230 (3-CP), 240–250 (2,3-diCP), approximately ~180 (2,5-diCP), approximately ~180 (A-5-C-2-CP), 150–160 (3,5-diCP), 200 (3-PCC-HC), and approximately ~240°C (4-HBN). We established

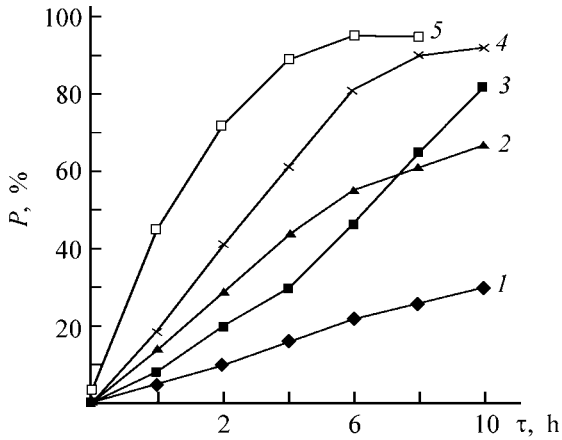

Fig. 2. Kinetic curves of 3-CP polymerization in the presence of binary catalysts: (*1*) Fe^{2+}, Cr^{6+}; (*2*) Co^{3+}, Zn^{2+}; (*3*) Cu^{2+}, Fe^{3+}; (*4*) Fe^{2+}, Co^{3+}; and (*5*) Co^{3+}, Sn^{2+}. Polymerization temperature 240°C.

that only *meta* derivatives of the nitriles studied polymerized under the chosen conditions; with respect to their activity, the nitriles are ranked in the order 3,5-diCP > 2,5-diCP ~ A-5-C-2-CP > 3-CP >> 2,3-diCP. In all cases, the optimal concentration of the catalyst is approximately 0.25 mol %. Its increase decelerates the reaction and causes formation of the products of low molecular weight with low concentration of paramagnetic centers (PMCs). A decrease in the catalyst concentration to 0.1 mol % does not affect the reaction rate and polymer characteristics, but significantly reduces the polymer yield. This is in good agreement with data that pyridine and its derivatives form predominantly complexes with the ratio metal ion : ligand = 1 : 4 [26].

With 3-CP as an example (Figs. 1–3), it is seen that the minimum possible synthesis temperature is

[1] A compound accelerating electron exchange between an insoluble polymer and electrodes [18].

governed by the catalyst nature; the binary catalysts (Fig. 2) capable to form with the initial monomer compounds with various reactivities have the highest catalytic activity.

Table 2. Influence of the nature and amount of the catalyst and duration of polymerization of 3-PCC-HC and 4-HBN on the yield of the polymers (270°C)

Catalyst	Molar ratio 3-PCC-HC : 4-HBN : catalyst	τ, h	Yield, %

	1 : 1 : 0.25	2	39.0

A comparative study showed that, for polymerization of 4-HBN, the most effective is a combination of two Lewis acids, and the activity series of the polymerization catalysts is as follows: Lewis acid < Lewis acid + organic additive < Lewis acid + metal < Lewis acid + Lewis acid. In the presence of $ZnCl_2$, $ZnCl_2$ + epichlorohydrin, $ZnCl_2$ + Zn, and $ZnCl_2$ + $FeCl_3$, the polymer yield is 24.0, 56.8, 62.3, and 86.9%, respectively. In the presence of only Lewis acids, polymerization proceeds with extremely low conversion. The activity of metal chlorides decreases in the order Mg = Zn > Ni (Co) > Ti > Sn > Al > Fe.

In this case, the monomer : catalyst ratio equal to 1 : 4 is not observed. The maximum yield of the polymer is reached on addition of the catalyst in an amount of 10%. The presence of promoter strongly increases the yield of the polynitrile.

In the case of thermal polymerization of pyridine derivative 3-PCC-HC with 4-HBN, the polymer yield is the highest at the catalyst concentration of 0.25 mol % with respect to the monomer (as in the case of heterocyclic nitriles). This confirms once again the probability of formation of 1 : 4 complexes of the catalyst with pyridinecarbonitrile monomers. An increase in the amount of the catalyst to above 0.25 mol % decreases the yield of the polymer (Table 2). For example, in the presence of 0.1, 0.25, and 0.50 mol % Co^{2+}, the yield of the polymers is 58.3, 70.4, and 13.0%, respectively. Similar trends are observed in the other catalytic systems. When using the catalyst, in an amount exceeding 0.25 mol %, the reaction products contain excess metal irrespective of the process duration τ and polymerization temperature T_{pol}. The series of the activity of the Friedel-Crafts catalyst for 4-HBN is Co > Sn > Ti > Zn > Fe.

The medium affects the process kinetics and characteristics of the reaction products: in passing from vacuum or argon to relatively dry air, as in the case of presence of water traces (compare Figs. 1 and 2 with Fig. 3), the reaction rate and conversion of the monomer in some systems increase, but oxygen-containing structures –C(O)N= appear in the macromolecules.

For all the nitriles, the intrinsic viscosity of the resulting polymers [η] slightly increases with the synthesis duration and more significantly, with T_{pol}. In this case, the reaction temperature affects significantly not only the molecular weight of polymers but also the content of PMCs in the polymers. This is illustrated by polymerization of 3-CP, 2,5-diCP, and 3,5-

Table 3. Influence of temperature and reaction duration on the yield and intrinsic viscosity of the polymers based on CPs and on the content of PMCs

** The reaction is accompanied by vigorous release of HCl.

*** Release of HCl is insignificant.

diCP as examples (Table 3): in polymerization of 2,5-diCP (170°C) and 3-CP (260°C) for 14 and 20 h, polynitriles with the intrinsic viscosity [η] of 0.95 and 0.62 and PMC content of 0.60×10^{17} and 0.24×10^{17} spin g^{-1}, respectively, are formed. Raising the polymerization temperature to 200°C and 280°C allows the process duration to be reduced to 4 and 6 h, respectively. In this case, [η] of the samples (1.86 and 1.25), the PMC content (4.00×10^{18} and 3.87×10^{18} spin g^{-1}), and the yield of the polymers increase.

Thus, we can conclude that polymerization of *meta*-substituted nitriles proceeds by scission of triple bonds of the cyano groups of the initial monomers. The process is provided by a combination of chemical transformations of monomers coordinated through the heterocyclic nitrogen atom in the initial complex, which results in significant weakening of the C≡N bond. The process is not complicated by side reactions. The yield of the polymers increases with time and approaches the quantitative yield with heating.

A significant difference in the lower limits of polymerization temperatures for various monomer–catalyst pairs suggests that one of the factors shifting the equilibrium to the formation of the polymer in the absence of a promoter is, apparently, chemical transformation of the monomer (pyridine–hydropyridine) [18], preceding polymerization and caused by a redox reaction of the coordinated monomer with the central metal atom. This corresponds to an increase in the activity of the catalysts with a rise in their standard redox potentials and is also confirmed by degradation of the catalyst in the course of the reaction with release of gaseous HCl and changes in the oxidation state of the metal cation (Table 4).

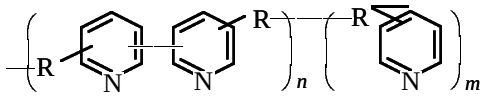
Elemental analysis shows that the composition of the polymeric products formed in an inert medium on

anhydrous catalysts is in good agreement with the elemental composition of the initial monomers. In the IR spectra of all the samples, there are no absorption bands in the range 2240–2260 cm^{-1}, corresponding to vibrations of the C≡N bond, whereas the absorption in the range 1590–1650 cm^{-1}, characteristic of double bonds, is more pronounced. The bands of stretching modes of the pyridine ring ($\nu_{C=C, C=N}$ approximately 1590, 1560–1570, 1470, and 1400 cm^{-1}) are presented, undergoing some changes. The spectra are characterized by noticeable background which becomes more pronounced with increasing color depth, i.e., with increasing molecular weight and PMC content.

Dynamic thermal gravimetric analysis shows that the temperature of the onset of thermal oxidative degradation of the polymers is 340–360°C. The polymers give a strong ESR signal, symmetrical singlet with a width of 1–3 Oe, whose *g*-factor corresponds to that of a free electron. The integral intensity of the signal is 10^{15}–10^{19} paramagnetic species per gram.

The final products are bifunctional weak bases with $pK_{\alpha 1}$ = 0.95–0.48 and $pK_{\alpha 2}$ = 0.67–0.54. These values significantly differ from those of the initial monomers, which is apparently caused by a strong influence of delocalization and electron-acceptor power of the polynitrile skeleton.

Based on the data of elemental analysis, IR and ESR spectroscopy, and data obtained in studying the characteristics of the resulting polymers (without considering the substitution type and possible migration of bonds), the following structure can be assigned to these polymers:



R = >C=N–C(=O)–N=.

The results of a study of the thermal, chemical, and radiation resistance of the resins synthesized suggest the possibility of their use in sorption and ion exchange from highly acidic radioactive solutions at elevated temperatures. The thermal stability of the samples is 98–99% at 100°C in corrosive media, the resistance to the action of oxidizing agents is 98–99% in the systems with redox potential of up to 2 V, and the resistance to alkalis, 98–99%. These samples withstand irradiation up to 10^9 rad.

The polymers with a system of conjugated bonds and functional redox groups in the conjugation chain have in some cases more pronounced redox characteristics in comparison with the analogues having localized bonds. In passing from oxidized to reduced form, the redox resins based on nitriles of heterocyclic acids change the color from bright red-brown to black. The standard redox potentials E_0 are fairly high (722–724, 730, 730, and 670 mV for 3-CP, 2,5-, 3,5-diCP, and A-5-C-2-CP, respectively) and suggest that electron-exchange characteristics of the macromolecules are provided by fragments significantly larger than isolated pyridine rings. The electron-exchange capacity of the polymers based on 3-CP, 2,5-, 3,5-diCP, and A-5-C-2-CP is 8.1, 8.8, 8.9, and 6.2 mg-equiv g^{-1}, respectively. The polymers have abnormally high capacity with respect to silver ions: 8.3–27.9 (pH 6.4–7.2) and 17.1–32.7 mg-equiv g^{-1} (pH 1.2–2.2), which is characteristic of polynitriles with the C=N bond. The static exchange capacity with respect to copper, cobalt, zinc, iron, osmium, palladium, and uranyl ions is 13.8, 2.9, 7.2, 4.7, 0.9–2.2, 1.6–2.4, and 4.4–6.7 mg-equiv g^{-1}, respectively.

CONCLUSIONS

(1) The possibility of a single-stage production of new polymers based on pyridinecarbonitriles, exhibiting along with high redox and sorption characteristics also a high thermal stability and chemical and radiation resistance was demonstrated.

(2) The resulting pyridinecarbonitriles are suitable for synthesis of ion-exchange, complexing, and redox polymers.

Abstract—The performance of allylbenzene and allyl phenyl ether as chain-transfer agents in radical polymerization of styrene, methyl acrylate, butyl methacrylate, vinylpyrrolidone, and vinylcaprolactam was evaluated.

Chain-transfer agents are used in radical polymerization to control the molecular weight (MW) of the product. Allyl compounds are effective chain-transfer agents owing to the presence of a labile C–H bond in the methylene group at the α-position relative to the double bond (α-CH bond). Previously, we have reported on the possibility of preparing polyvinylcaprolactam (PVCL) of relatively low MW in the presence of a series of allyl compounds, among which allylbenzene (AB) appeared to be the most effective chain-transfer agent [1]. Allyl compounds can be used to control radical polymerization of a wide range of monomers.

In this study, we examined the performance of AB and allyl phenyl ether (APE) as chain-transfer agents in polymerization of a series of monomers differing in the reactivity.

EXPERIMENTAL

We studied polymerization of styrene (S), butyl methacrylate (BMA), methyl acrylate (MA), vinylpyrrolidone (VP), and vinylcaprolactam (VCL) in the presence of AB and APE. Methyl acrylate was double-distilled at atmospheric pressure, and the other monomers were double-distilled in a vacuum. The densities and refractive indices of the compounds coincided with reference data. The polymers were prepared under similar conditions by the radical mechanism at an AIBN (initiator) concentration of 1×10^{-2} M in dioxane at 50°C. The experiments were performed in ampules. The mixtures were degassed by freeze–pump–thaw cycles to a residual pressure of 0.13 Pa. The synthesis time was chosen so as to ensure the polymer yield of no less than 10%. Polyvinylpyrrolidone (PVP) and PVCL were reprecipitated into diethyl ether; poly(methyl acrylate) (PMA) and poly(butyl methacrylate) (PBMA), into ethanol; and polystyrene (PS), into hexane.

The polymerization rate was measured dilatometrically. The initiation rate was determined from the dependence of the induction period on the concentration of a stable radical, 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO). In all the systems, the induction period showed a linear dependence on the TEMPO concentration. The intrinsic viscosities of PS, PVP, PBMA, and PMA were determined under the conditions given in Table 1. To determine [η], the experimental data were processed in the coordinates of the Huggins and Kraemer equations. For all the samples, the sum of the Huggins and Kraemer constants was close to 0.5. To calculate the MW of these polymers, we used the Mark–Kuhn–Houwink equations relating [η] to the number-average MW [2, 3]. Since these equations were deduced for fractionated polymer samples, we recalculated the constants K in the Mark–Kuhn–Houwink equations:

$$K^* = K\Gamma(2 + \alpha).$$

The correction $\Gamma(2 + \alpha)$ is characteristic of polymers whose MW is controlled by chain transfer or disproportionation [4]. To calculate the Γ-function, we used the asymptotic Stirling expansion. The MWs were calculated by the formula

$$[\eta] = K^* M_n^{\alpha}.$$

1070-4272/04/7706-0994 © 2004 MAIK "Nauka/Interperiodica"

The constants K^* are listed in Table 1. For PVCL, [η] was determined in DMF at 25°C. The MW was calculated by the equation

$$[\eta] = 7.43 \times 10^{-4} M^{0.53}.$$

The parameters of this equation were determined from the logarithmic dependence of [η] on the number-average MW increment, which was calculated from the integral MWD curves obtained by fast sedimentation method for PVCL samples prepared in the presence of AB [5].

The kinetic characteristics of polymerization are listed in Table 2. In all the systems studied, the polymerization rate and the MW of the polymers decrease as the concentration of AB and APE in the reaction mixture is increased. In all the cases, AB diminishes the rate and degree of polymerization more efficiently than APE does. The chain-transfer constants C_x were determined with the equation

$$P^{-1} = V_p[M]^{-2}K_t K_p^{-2} + C_x[X][M]^{-1}, \qquad (1)$$

where P is the degree of polymerization; [M], monomer concentration; [X], concentration of AB or APE; V_p, polymerization rate; $K_t K_p^{-2}$, ratio of the chain termination and chain propagation rate constants [4].

The dependences in the coordinates of Eq. (1) are plotted in Figs. 1a and 1b. The chain-transfer constants C_x calculated by the least-squares method are listed in Table 2.

The reactivity of monomers in the radical-chain process can be characterized by the Alfrey–Price parameters Q (characterizing the resonance stabilization factor) and e (characterizing the polarity of the double bond in the monomer). The monomers studied exhibit different reactivities. The parameters Q and e listed in Table 2 were taken from [6]. Notably, the chain-transfer constant with AB is higher than that with APE, irrespective of a particular monomer.

The chain transfer to allyl compounds involves reaction of the propagating radical with the labile hydrogen atom of the α-CH bond:

$$R^{\bullet} + B = RH + B^{\sim},$$

where $R^{\bullet}$ is the propagating radical; B, AB or APE; and $B^{\sim}$, the allyl radical stabilized by conjugation.

The activity of $B^{\sim}$ radical generated in this reaction is relatively low because of the electron delocalization over the allyl group. In this context, its reaction with the propagating macroradical seems the most probable:

$$R^{\bullet} + B^{\sim} = RB.$$

In accordance with the above reaction schemes, one molecule of allyl compounds terminates two macroradicals. Obviously, copolymerization of allyl compounds cannot be ruled out, but, owing to the presence of the labile α-CH bond, chain transfer competes with addition of the allyl compound to the macroradical, with opening of the double bond. The reinitiation of the double bond with the $B^{\sim}$ radical and recombination of allyl radicals are also possible theoretically, but the probability of these reactions is low because of the low activity of $B^{\sim}$ radical. It should be noted

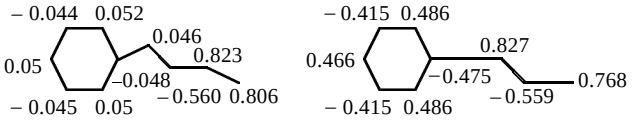
that the substituent at the allyl bond exerts a decisive effect on the stability of the allyl radical.

To estimate the dissociation energy (DE) of the α-CH bond, we optimized the geometry and calculated the electronic structures of allyl compounds and their radicals. The calculation was performed by the PM3 semiempirical method, using the restricted Hartree–Fock method for molecules with closed electronic shells and the unrestricted Hartree–Fock method for radicals. The DE of the bond was calculated as the difference between the energy of the dissociation products and that of the starting allyl compound. The geometry was fully optimized for both the allyl compound and its radical. All calculations were performed with the HyperChem program [7]. The DE of the α-CH bond (kcal mol^{-1}) was 65.23 for AB and 67.12 for APE.

Below are the molecular diagrams of APE and AB radicals, showing the spin density on atoms:



APE radical

AB radical

The molecular diagrams show that, in the AB radical, the unpaired electron is delocalized over all the carbon atoms, including the benzene ring. In the APE radical, only the carbon atoms of the allyl group participate in the delocalization to a significant extent. Thus, the AB radical has a longer conjugation chain and is hence more stable than the APE radical. It is known that the bond dissociation energy is the difference between the energy of the forming radical and hydrogen atom and that of the starting compound [8]. Therefore, any factor stabilizing the forming allyl radical should decrease the dissociation energy of the α-CH bond. Hence, a compound that forms a more stable radical upon hydrogen abstraction should be a more effective chain-transfer agent; the less active radical cannot initiate chain propagation but can recombine with the active propagating macroradical. In this case, such a compound is AB.

It seems appropriate to use for controlling MW such compounds in which the allyl group is directly bonded to the molecular fragment with a conjugation system (e.g., AB). The use of allyl ethers or allyl alcohols for controlling the radical polymerization is appropriate in cases when it is necessary not only to control MW, but also to prepare copolymers in which single allyl units are separated by blocks of the major monomer. Such copolymers may be of interest from the viewpoint of their subsequent modification aimed to prepare materials with special properties, e.g., chemodegradable polymers [9].

CONCLUSIONS

(1) The kinetics of radical polymerization of certain monomers in the presence of allylbenzene and allyl phenyl ether were studied, and the parameters of the reactivity of these allyl compounds in chain transfer from various macroradicals were evaluated.

(2) Allylbenzene is a more effective chain-transfer agent, which is due to the higher stability of its radical, compared to the allyl phenyl ether radical.

(3) It is appropriate to use allylbenzene to control the molecular weight of polymers prepared by the radical mechanism.

Abstract—Oxidation of crotonaldehyde with molecular oxygen and the role of percrotonic acid accumulating in the process were studied.

Crotonic acid (CAc) and its derivatives are used as comonomers in production of rubbers, latexes, adhesives, and plastics. Some crotonic acid esters exhibit insecticidal or herbicidal properties.

The main synthetic route to CAc is oxidation of crotonaldehyde (CAl). In oxidation of CAl with molecular oxygen at atmospheric [1, 2] or elevated [3] pressure, peroxy compounds accumulate in concentrations comparable with that of the forming CAc.

Our goal was to examine the possibility of using peroxides accumulating in the oxidate to raise the yield of CAc.

EXPERIMENTAL

Pure-grade CAl was distilled before use on a laboratory column (10 TP, reflux ratio 2); the fraction with bp 375–376 K was collected. Crotonaldehyde was kept under argon at 253 K. An additional purification was performed by steam distillation, with the collection of the azeotrope (75.7 wt % CAl, 24.3 wt % H_2O), from which water was frozen out at 223 K, and CAl was dried over $MgSO_4$ and distilled on a column. A chromatographically pure CAl was thus obtained (bp 375 K, d_4^{20} 0.853 g cm^{-3}). The optimal medium for CAl oxidation, from the viewpoint of CAc yield, is ethyl acetate [1]. We used ethyl acetate of analytically pure grade ; it was dried over $CaCl_2$ and distilled before use.

Qualitative and quantitative analyses were performed by chemical methods [4], gas chromatography, and IR spectroscopy. Chromatographic analyses were carried out on a Tsvet-100 chromatograph (2000 × 3-mm column; sorbent Polysorb-1, 0.1–0.25 mm; column and vaporizer temperatures 423 and 463 K, respectively; thermal conductivity detector). In the oxidate, we determined the content of CAl and CAc. The total content of carbonyl compounds was determined by the hydroxylamine method [4], and the total content of acids, by titration with 0.1 N NaOH in the presence of phenolphthalein. The content of peroxides was determined by iodometric titration in glacial acetic acid.

The gas–chromatographic analysis gives the total content of crotonic and percrotonic (PCAc) acids, because PCAc transforms into CAc in the vaporizer. To confirm this conclusion, we performed absolute calibration with respect to CAc in the system CAc–ethyl acetate. Percrotonic acid was prepared by oxidation of CAc in ethyl acetate at a low temperature. For example, in oxidation of CAl at 12°C to 15% conversion, the content of PCAc in the sum of acids reaches 93%. Such an oxidate gives a chromatographic peak of CAc, whose area corresponds to the total calculated amount of PCAc and CAc and is consistent with the total acid content determined by chemical analysis.

In oxidation of CAl under various conditions, the oxidate always contains PCAc and CAc (Table 1). The PCAc : CAc ratio decreases with increasing temperature, oxidation time, and partial oxygen pressure. Peroxy compounds disappear from the oxidate upon prolonged storage (100–150 h). The approximate composition of the oxidate stored for 150 h at 20°C is as follows (wt %): ethyl acetate 75.04, CAl 8.97, CAc 12.46, propionaldehyde 0.40, propionic acid 0.50, formic acid 1.20, propenyl formate 0.60, and 1,2-epoxypropenyl formate 0.60.

* (p_{O_2}) O_2 pressure, (τ) time from the start of the reaction, (c) concentration, (X) conversion, and (S) selectivity.

According to [5], CAc is formed by a parallel-consecutive mechanism directly from CAl and via PCAc. Table 1 shows that the selectivity of CAc formation grows with conversion, and the selectivity of PCAc formation decreases. Apparently, the consecutive formation CAc via PCAc is the major pathway.

According to the classical autooxidation scheme, peroxy compounds accumulating in oxidation of unsaturated aldehydes are mainly the corresponding per acids. As shown by Boboleva *et al.* [6], the poor selectivity of CAc formation in autooxidation of CAl at elevated temperature is due to consumption of PCAc in side processes, rather than to cleavage of the C=C bond in the course of oxidation. They believe that PCAc not only transforms into CAc, but also undergoes a radical decomposition:

$$RC(O)OOH \rightarrow RC(O)O^{\cdot} + {}^{\cdot}OH,$$
$$RC(O)O^{\cdot} \rightarrow CO_2 + R^{\cdot}.$$

With decreasing temperature, the decomposition decelerates [6], and the selectivity with respect to the sum of CAc and PCAc increases. Thus, by-products formed in CA oxidation mainly arise from radical decomposition of PCAc. There are also indications [7] that H_2O_2, diacyl peroxides, and polyperoxides are also formed in oxidation of unsaturated aldehydes along with per acids. Quantitative data on the composition of peroxy compounds in oxidation of CAl are lacking. This stimulated us to evaluate the content of undesirable stable peroxides in oxidation of CAl. For this purpose, after completion of the experiments and determination in oxidates of CAc and sum of peroxy compounds, the oxidates were stored for a long time at room temperature, after which the content of peroxides, CAc, and CAl was determined. The results are listed in Table 2.

It is seen that 95–98% of peroxides accumulated by the end of experiments are unstable and undergo consecutive transformations at room temperature. This means that thermally stable peroxides incapable of reacting with CAl are formed in oxidation of CAl in very low amounts (≤0.04 M). Presumably, the peroxides in the oxidate are mainly PCAc and certain amount of H_2O_2. The content of H_2O_2 in the oxidate must not be significant, since, as seen from Table 2, in some experiments (nos. 8, 10, 12, 13, 15), when the content of CAl exceeds that of peroxides, CAl transforms into CAc within the storage time in the amount equivalent to the content of peroxy compounds in the oxidate. This means that all the peroxides in the oxidate oxidize CAl to CAc. At the same time, hydrogen peroxide oxidizes CAl to CAc only in the presence of catalysts, Se^{4+} compounds [7]. Hence, hydroperoxides accumulating in oxidation of CAl with molecular

* (c^0) Content after oxidation, (c^τ) content after storage, (ΣCAc + PCAc) sum of acids, and (HP) hydroperoxides.

oxygen under the experimental conditions consist mainly of PCAc, which oxidizes CAl to CAc in the course of storage of the oxidate at room temperature, transforming itself into CAc. In the absence of a sufficient amount of CAl in the oxidate, PCAc also transforms into CAc (Table 2, run nos. 1, 2, 4, 9, 11, 14), but less selectively.

The fact that PCAc, one of the major products of CAl oxidation, virtually quantitatively transforms into CAc on keeping the oxidate at room temperature and oxidizes in the process an equimolar amount of CAl can be used to achieve the maximum yield of CAc. Oxidation of CAl with molecular oxygen should be performed up to accumulation of the maximum concentration of PCAc in the oxidate. In so doing, the concentration of unchanged CAl should only slightly exceed the PCAc concentration (Table 2, run nos. 6, 7). In the course of storage, CAl virtually quantitatively transforms into CAc in the reaction with PCAc.

For practical synthesis of CAc, it is necessary to find the optimal temperature for decomposition of PCAc in the oxidate, because at room temperature the reaction is too slow. The kinetics of PCAc and CAl consumption and CAc accumulation in the oxidate was studied at 318 and 333 K. After oxidation for 100 min at 309 K, the oxygen supply was stopped, the system was purged with argon and then heated to the required temperature, and the oxidate composition was monitored. The results of some experiments are shown as example in Fig. 1. As seen from Fig. 1a,

* (T) Oxidation temperature.

the concentrations of CAl and PCAc decrease to a similar extent, with the total concentration of CAc and PCAc growing simultaneously. For example, in 7 h, the PCAc concentration decreased by 0.61 M; that of CAl, by 0.59 M; and that of the sum of CAc and PCAc increased by 0.6 M. Within the same time, 9.6 ml of CO_2 and 2.4 ml of CO evolved from the oxidate (30 ml). Hence, at 318 K only 1–2% of PCAc is spent for side reactions (initiated radical decomposition), whereas 98–99% of PCAc reacts with CAl to form CAc.

At 333 K (Fig. 1b), PCAc is consumed considerably faster, and the process is complete within approximately 4 h. However, the relative contribution of PCAc decomposition grows. For example, 15 ml of CO_2 and 5.4 ml of CO evolved from the reactor in 4 h. Percrotonic acid is consumed noticeably faster than CAl: in 4 h, the PCAc concentration decreased by 0.62 M, and that of CAl, by 0.56 M. The total concentration of CAc and PCAc grew by only 0.54 M (87% of the consumed PCAc).

Apparently, to ensure the most efficient utilization of PCAc and maximum yield of CAc, the oxidate should be kept at relatively low temperatures. Table 3 illustrates the variation of the oxidate composition at 318 K in the course of 7 h. It is seen that oxidation of CAl to CAc with PCAc occurs more selectively than oxidation with molecular oxygen to CAc and PCAc. Table 3 shows that the maximum efficiency is reached when the concentrations of the accumulated PCAc and unchanged CAl in the oxidate by the end of autooxidation are approximately equal. This situation is attained at ~60% conversion of CAl. In the course of storage, unchanged CAl is oxidized with PCAc, and the total selectivity with respect to CAc reaches 94%.

The results of these studies allowed development of an efficient procedure for preparing CAc [8].

CONCLUSION

To achieve the maximum yield of crotonic acid, it is appropriate to perform oxidation of crotonaldehyde with molecular oxygen at 300–310 K to 55–65% conversion of crotonaldehyde, when the concentrations of perctoronic acid and unchanged crotonaldehyde in the oxidate become approximately equal. The unchanged crotonaldehyde is subsequently oxidized with percrotonic acid at 315–320 K within 7.0–7.5 h.

CHEMISTRY OF FOSSIL FUEL

Effect of Various High-Octane Additives on Antiknock Quality of Gasolines

A. M. Syroezhko, O. Yu. Begak, and G. S. Makurina

St. Petersburg State Technological Institute, St. Petersburg, Russia

Mendeleev Russian Research Institute of Metrology, Federal State Unitary Enterprise, St. Petersburg, Russia

Received April 7, 2004

Abstract—The possibility of manufacturing AI-92 and AI-95 high-octane blended gasolines using reformer naphthas[1], methyl *tert*-butyl ether, and an additive based on *N*-methylaniline and (methylcyclopentadienyl)-manganese tricarbonyl is studied.

The most important problem in oil refining is to improve the performance and environmental characteristics of gasolines. The increased aromaticity of domestic (Russian) high-octane gasolines is caused by the fact that their base component is reformer naphtha containing up to 5–6% benzene and up to 68% other arenes [1]. The use of oxygenates (methyl *tert*-butyl and methyl *tert*-pentyl ethers) and other environment-friendly high-octane antiknock compounds at Russian refineries is rather limited [2].

The goal of this study is to examine the effect of high-octane additives on the quality of gasolines manufactured by the Ukhta Refinery, and also to optimize formulations of AI-92 and AI-95 blended gasolines based on mixtures of straight-run naphthas and stable reformer naphthas taken in various proportions.

EXPERIMENTAL

Straight-run naphtha (ρ_4^{20} = 0.6689 g cm^{-3}) was taken from an AT-1 preliminary distillation plant; it had an octane number (ON) of 66.4 as determined by the engine method (EM). Its fractional composition was as follows [bp, °C (content, wt %)]: initial boiling (IB) 39; 52 (10); 63 (50); 85 (90); dry point (DP) 94.

Stable reformer naphtha [ρ_4^{20} = 0.7700 g cm^{-3}; ON 83.2 (EM); ON 92.1 (theoretical method, TM)] was taken from an L-35/11-300 plant. Fractional composition: IB 41; 78 (10); 117 (50); 153 (90); DP 178.

Base components were prepared by mixing straight-run naphtha with reformer naphtha (Table 1). As high-octane additives was used BVD containing 65 wt %

Table 1. Physicochemical characteristics of base components and blends

Reforming naphtha	83.2	92.1	86.7	85.1	3.5	3.0	86.8	95.4	3.6	3.3
Reforming naphtha/straight-run naphtha, wt %:										
10/90	68.0	76.2	74.9	83.8	6.9	7.6	74.0	84.6	6.0	8.4
50/50	76.0	85.0	81.8	90.2	5.8	5.2	81.7	91.4	5.7	6.4
70/30	78.5	88.1	83.5	92.0	5.0	3.9	83.6	92.8	5.1	4.7
90/10	81.2	91.0	85.4	95.2	4.2	4.2	85.5	93.8	4.3	2.8

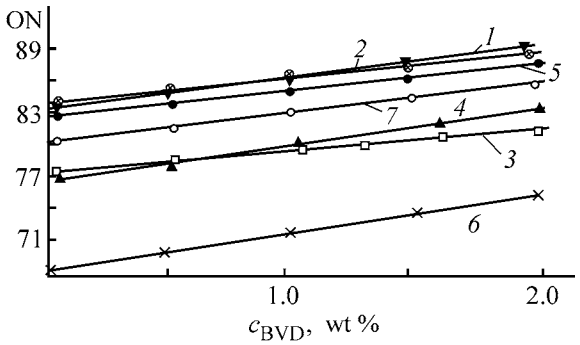
N-methylaniline [TU (Technical Specifications) 38.401-58-228–99] from Flagman Closed Corporation (Moscow); B-grade methyl *tert*-butyl ether (MTBE) (TU 38.103.704–90) from Ekros Closed Corporation (St. Petersburg); *N*-methylaniline (NMA) (TU 2471-269-00 204 168–96) from Volzhskii Orgsintez Joint-Stock Company (Volgograd oblast); and Hitec-3000 containing 24.4 wt % Mn (Ethyl Corporation, the United States). The active component of the latter additive is (methylcyclopentadienyl)manganese tricarbonyl (MMT).

The density of the base blends was determined according to GOST (State Standard) 3900–85 [3]; the fractional composition, to GOST 2177–99 [4]; NO, to GOST 511–82 (EM) [5] and GOST 8226–82 (TM) [6]. Benzene and total arenes in naphthas were determined according to GOST 29 040–91 on an LKhM-80 gas chromatograph.

In their fractional composition, the base components and blends used met the regulatory requirements to AI-92 and AI-95 gasolines (Table 1), but not in the octane number. A mixture containing 90 wt % reformer naphtha and 10 wt % straight-run naphtha has ON 91 (EM). Therefore, manufacture of AI-92 and AI-95 gasolines from this base blend requires a lower amount of high-octane additives.

It is seen from the figure that, even on adding the maximum amount (1.9 wt %) of the additive to the 10/90 and 50/50 base blends, the octane number required for AI-92 gasoline [ON 83 (EM) and 92 (TM)] is not obtained. At the same time, for the 90/10 and 70/30 blends, the required ON is attained at a BVD additive concentration of 1.5 and 1 wt %, respectively. With the BVD concentration increasing to 1.9 wt %, AI-92 and AI-95 gasolines can be obtained from both the reformer naphtha and mixtures of 10–30 wt % straight-run naphtha with reforming naphtha.

The ON benefit (ΔON) at a BVD concentration of 1.9 wt % is 3.6–6 points (EM) (Table 2). Addition of 15 wt % MTBE to the same base components provides ΔON of 3.5–6.9 points (EM) or 3–7.6 points (TM) (Table 2). The largest benefit [5.8–6.9 points (EM)] was obtained with blends containing 10 and 50 wt % reforming naphtha. However, even addition of the maximum amount (15 wt %) of MTBE to the base blends indicated does not provide ON required for AI-92 gasoline. At the same time, addition of the indicated amount of MTBE to AI-92 gasoline and to blends of 70–90 wt % reforming naphtha with straight-run naphtha (10–30 wt %) makes it possible to obtain AI-92 and AI-95 gasolines (Table 2).



Effect of BVD addition on the ON of the base fuel components: (*1*) AI-92, (*2*) stable reforming naphtha, and (*3*) A-76. Reforming naptha/straight-run naphtha (wt %): (*4*) 50/50, (*5*) 90/10, (*6*) 10/90, and (*7*) 70/30. (c_{BVD}) Additive concentration.

Table 3. Performance of BVD/MTBE blend additives

Base component	ON (EM) at indicated MTBE/BVD mass ratio

A-76	76.2	78.2	79.9	81.0	81.5 (90.4)
Reforming naptha	83.2	85.0	86.8	87.0	89.7 (96.4)
Reforming naphtha/straight-run naphtha, wt %:					
10/90	68.0	71.8	75.0	76.1	78.6 (85.0)
50/50	76.0	77.6	80.1	81.6	83.4 (91.4)
70/30	78.5	80.4	82.2	83.5	84.4 (92.6)
90/10	81.2	82.8	84.3	85.7	86.4 (95.0)

* ON (TM) is given in parentheses.

Table 4. ON benefit of base blends on adding 0.5 and 1.3 wt % NMA additive

Base component	Initial ON		ON of a blend with 0.5 wt % NMA		ON of a blend with 1.3 wt % NMA		ΔON (0.5 wt % NMA)		ΔON (1.3 wt % NMA)	
	EM	TM	EM	TM	EM	TM	EM	TM	EM	TM
A-76	76.2	85.1	77.5	86.4	80.6	88.6	1.3	1.3	4.4	3.5
AI-92	83.0	92.0	83.5	92.8	84.6	93.4	0.5	0.8	1.6	1.4
Reforming naphtha	83.2	92.1	83.6	92.6	86.1	94.0	0.4	0.5	2.9	1.9
Reforming naphtha/straight-run naphtha, wt %:										
70/30	78.5	88.1	79.5	89.0	81.8	91.2	1.0	0.9	3.3	3.1
90/10	81.2	91.0	82.6	92.6	84.9	93.8	1.4	1.6	3.7	2.8

The combined action of MTBE and BVD is demonstrated in Table 3. Addition of 10 wt % MTBE + 1.9 wt % BVD to a base blend consisting of 70 wt % reforming naphtha and 30 wt % straight-run naphtha allows preparation of AI-92 gasoline. In the case of a 90/10 base blend, it is sufficient to add 10 wt % MTBE + 0.5 wt % BVD, while addition of 10 wt % MTBE + 1.9 wt % BVD gives AI-95 gasoline. Depending on the composition of the base blend, addition of 10 wt % MTBE + 1.9 wt % BVD provides an ON (EM) benefit from 4.9 to 10.6 points or ON (TM) benefit from 3.1 to 8.8 points.

The largest ON benefit was observed when the additives were taken in combination (Table 3). However, simultaneous addition of BVD and MTBE is inadvisable, because of the lack of a synergistic effect, and the expenses per a benefit ON point are larger compared to the use of individual additives.

The effect of NMA is demonstrated in Table 4 (*N*-methylaniline is a component of BVD additive).

According to the regulatory requirements, the NMA concentration in gasoline must be below 1.3 wt %. As seen, the effect of NMA is weaker than that of BVD [ON (EM) benefit is only 2.9–3.7 and ON (TM) benefit, 1.9–3.1 points].

Table 5 shows the effect of Hitec-3000 additive taken in concentration of 0.005–0.028 wt % (9–50 mg l^{-1} recalculated to Mn).

According to GOST R 51105–97, the maximum Mn concentration in Normal-80, Regulyator-91, Premium-95, and Super-98 grade gasolines is 50, 18, 0, and 0 mg l^{-1}, respectively. Table 5 shows that Hitec-3000 is an inefficient additive even if added to the maximum permissible concentration.

Table 5. Effect of Hitec-3000 additive on octane numbers (MM) of base components

Base component	ON at indicated additive concentration, wt %				
	0 (0)*	0.005(9)	0.01(18)	0.017(30)	0.028(50)

* OM (TM) is given in parentheses.

Our results allow optimization of base blends and additives for manufacture of high-octane gasolines meeting the requirements of the operative Technical Specifications and State Standards (Table 6).

There are no catalytic cracking and hydrocracking, alkylation, isomerization, and isoselectoforming plants at the Ukhta Refinery, which limits the possibility of manufacture of high-octane base components. Therefore, blank AI-95 reformer gasoline manufactured at this refinery contains 4.17 wt % benzene and 57.07 wt % total arenes, which deteriorates its environmental characteristics. AI-95 gasoline with MTBE additive manufactured at the Lukoil–UNP contains 3.93 wt % benzene and 60.71 wt % total arenes.

As a conclusion, to manufacture AI-92 gasoline at the Lukoil-UNP, we suggest to add 15 wt % MTBE + 1.9 wt % BVD to A-76 unleaded gasoline. Now the Ukhta Refinery manufactures Premium-95 gasoline from AI-92 unleaded gasoline (Table 6).

Production of high-octane gasolines using MTBE and BVD additives and, in particular, of Lukoil AI-92 gasoline from A-76 and of Premium-95 from AI-92 unleaded gasoline is cost efficient, because the reformer naphtha is less expensive than AI-92 gasoline, and straight-run naphtha is cheaper than A-76.

CONCLUSIONS

(1) BVD and methyl *tert*-butyl ether additives demonstrate high antiknock efficiency, providing an octane number benefit from 3.6 to 6 points (engine method) and from 2.8 to 4 points (theoretical method) with BVD; and from 3.5 to 6.9 points (EM) and

from 3.0 to 7.6 points (TM) with methyl *tert*-butyl ether.

(2) With BVD additive (1.9 wt %), the formula of AI-92 gasoline is as follows: reformer naphtha 60–65% and straight-run naphtha the rest. For AI-95: reformer naphtha >90%, straight-run naphtha the rest.

(3) Simultaneous use of different additives is less efficient as compared to their individual introduction. Processes of fabrication of AI-92 and AI-95 gasolines can be multivariant. The formula of AI-92 gasoline may include from 60 to 99 wt % reforming naphtha, from 0 to 35 wt % straight-run naphtha, up to 15 wt % MTBE, and up to 1.9 wt % BVD; and that of AI-95, from 90 to 75 wt % reforming naphtha, up to 10 wt % straight-run naphtha, up to 15 wt % MTBE, and up to 1.9 wt % BVD.

(4) *N*-Methylaniline and Hitec-3000 additives are less efficient than methyl *tert*-butyl ether and BVD with regard to the base blends of the Ukhta Refinery.

CHEMISTRY OF FOSSIL FUEL

Volatile Products of Temperature-Programmed Pyrolysis of Oil Shales

Kh. M. Kerimov

Azerbaijan State Petroleum Akademy, Baku, Azerbaijan

Received February 26, 2004

Abstract—Temperature-programmed pyrolysis of oil shales was studied. The composition of pyrolysis products was analyzed by the chromatographic technique.

The rise in thepower consumption in the world, with exhaustion of the traditional fuel resources, requires a search for alternative sources for power production and alternative raw materials for petrochemical synthesis. Among such raw materials are oil shales [1], i.e., organomineral sedimentary rocks containing concentrated sapropelic or humus-sapropelic organic substances of various origins. The main organic substance of oil shales is kerogen, which is inert to chemical reagents and practically insoluble in organic solvents. The main industrial procedure for kerogen recovery is pyrolysis. Other procedures, such as extraction with solvents and biochemical methods, are not yet widely used [2].

Oil shales are distinguished by the type of kerogen: (1) oil shales of sea origin, (2) oil shales formed in semi-closed sea reservoirs and in lakes and bogs, and (3) oil shales of continental genesis. A certain relationship between the type of kerogen and the distribution of alkanes in volatile products of pyrolysis of oil shales was noted in [2, 3].

In this study, we examined temperature-programmed pyrolysis of oil shales of the Dzhangichai deposit and determined the optimum temperature at which the yield of the products is the highest. The distribution of alkanes in the volatile products at various pyrolysis temperatures was also analyzed.

EXPERIMENTAL

The samples of oil shales subjected to pyrolysis were ground in a laboratory mill. A <0.1-mm fraction was selected for the study. This fraction was dried to constant weight at 105°C under nitrogen. The pyrolysis reactor consisted of a steel jacket (400 mm × 15 mm) and a quartz reaction tube with an inner diameter of 10 mm. A weighed portion of the oil shale was mixed with 5 ml of quartz sand (particle size 0.1–0.25 mm) and placed in the reaction tube. A thermocouple for measuring the temperature in the pyrolysis area was placed in the center of the sample bed.

The reaction tube with a sample was placed in a steel jacket of the temperature programmed furnace (electric heating). The temperature in the pyrolysis area was monitored by three thermocouples in the reaction tube. The temperatures measured during the process were recorded with a multichannel unit. The temperature variation along the reaction area did not exceed 1°C. The process was carried out in an argon flow (80 ml min^{-1}) at a heating rate of 2 deg min^{-1}. The reference substance, 0.507% neopentane in N_2, was introduced into the flow of the products released from the pyrolysis area at a rate of 20 ml min^{-1}. Samples were withdrawn from the flow of the products leaving the reactor into evacuated glass ampules. The procedures of sampling and chromatographic analysis of a multicomponent vapor–gas mixture have been described previously [5]. The pyrolysis products were analyzed in a Hewlett Packard HP-6890 capillary gas chromatograph. A 100 m × 0.25 mm column was coated with methylsilicone OV-1. Hydrogen was used as a carrier gas. The detector temperature (FID) was 350°C, and the injector temperature, 290°C. The qualitative identification of the components of the mixtures was carried out by comparison of the retention time with reference data stored in the computer (CHEMSTATION software for recording and processing of chromatographic data).

The quantitative interpretation of the chromatograms was carried out using an internal reference.

Elemental composition and the results of Fischer analysis of oil shales

Products	Content, %*	Products	Content, %*	Products	Content, %*	Products	Content, %*
		Fischer analysis		Elemental analysis of tar		Elemental analysis of residue	
Total carbon	21.93	Tar	14.75				
		Decomposition water	2.62	C	77.46	C	17.76
Organic carbon	20.7	Solid residue	71.54	H	11.31	H	1.07
		Gas + loss including:	11.09	N	1.24	N	0.86
Hydrogen	2.56	CO	3.43	S	1.53	S	4.48
Nitrogen	0.92	CO_2	14.51				
Total sulfur	3.24	CH_4	45.46				
		C_2–C_4	36.6				

* The composition determined from the results of elemental analysis and Fischer analysis is given in weight percent, and the gas composition, in volume percent.

The content of *i*th component c_i (%) in the mixture being analyzed (yield, wt %) was evaluated by the formula

$$c_i = \frac{k_i Q_i}{k_{\text{ref}} Q_{\text{ref}}} \times 100r, \quad (1)$$

where k_i and k_{ref} are the correction coefficients for peak areas of the component and reference, Q_i and Q_{ref} are the peak areas of the component being analyzed and the reference (mm^2), and r is the ratio of the weight of the reference to the weight of the mixture being analyzed.

The rate of formation of the products v ($mg\ min^{-1}$) was evaluated by the formula

$$v = \frac{\Sigma Q - Q_{\text{ref}}}{Q_{\text{ref}}} m_{\text{C}}, \quad (2)$$

where m_{C} is the gravimetric flow rate of carbon in the flow of internal reference ($mg\ min^{-1}$), evaluated from the relationship

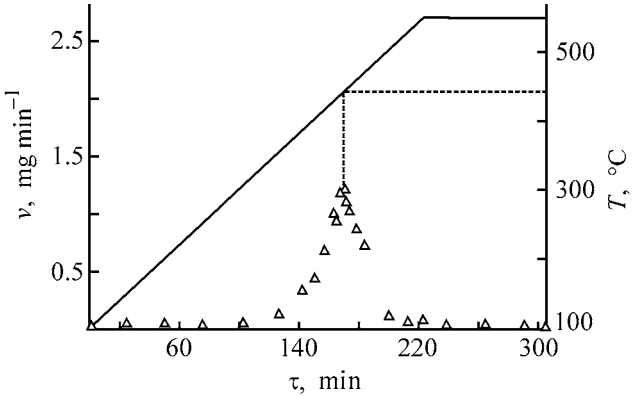

Fig. 1. Rate of formation of aliphatic hydrocarbons v vs. time τ and temperature T.

$$m_{\text{C}} = nN_{\text{C}}M_{\text{C}}/1000. \quad (3)$$

Here n is the molar flow rate of neopentane ($mol\ min^{-1}$); M_{C}, atomic weight of carbon ($12\ g\ mol^{-1}$); N_{C}, the number of carbon atoms in neopentane (5); and ΣQ, the sum of the peak areas in the chromatogram (mm^2).

Average characteristics of oil shales: moisture content 2.84 wt %, ash content 79.45 wt %, and heat of combustion 3880 $kJ\ kg^{-1}$. The following components were found in the ash (wt %): SiO_2 36.94, Fe_2O_3 17.34, CaO 22.95, MgO 0.68, K_2O 1.08, TiO_2 0.88, MnO 0.45, CuO 0.31, ZnO 0.14, SO_3 18.08, and P_2O_5 1.12. The results of elemental analysis and Fischer analysis are listed in the table.

As can be seen from Fig. 1, the rate of formation of pyrolysis products passes through a maximum at 440°C. With increasing pyrolysis temperature, along with increase in the concentration of hydrocarbons C_1–C_4 and C_5–C_{15}, hydrocarbons that are solids under standard conditions ($C_{>15}$) appeared in the pyrolysis products. This is caused by decomposition of kerogen in two consecutive steps.

At fairly low temperatures, the primary decomposition reactions yield gaseous and liquid hydrocarbons, and, beginning from 400°C, macromolecular fragments of kerogen, containing more than 15 carbon atoms, are formed. With further heating, the secondary decomposition begins, and the primary products decompose to form compounds of lower molecular weight. The temperature dependence of the yield of *n*-paraffins in the pyrolysis products is shown in

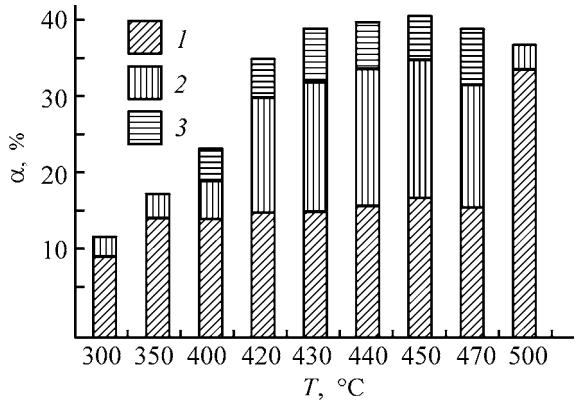

Fig. 2. Yield α and composition of *n*-paraffins vs. pyrolysis temperature *T* (°C): (*1*) C_1–C_4, (*2*) C_5–C_{15}, and (*3*) $C_{>15}$.

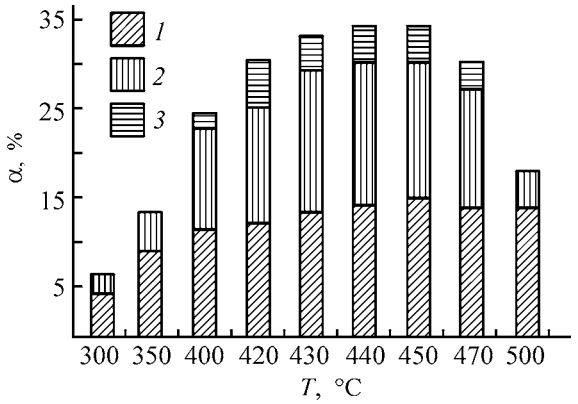

Fig. 3. Yield α and composition of α-olefins vs. pyrolysis temperature *T* (°C): (*1*) C_2–C_4, (*2*) C_5–C_{15}, and (*3*) $C_{>15}$.

Fig. 2. At relatively low temperatures, the composition of *n*-paraffins is characterized by a high content of gaseous products. For example, 12% *n*-paraffins (C_1–C_4 83%) was found in the pyrolysis products at 350°C. With heating, the products get enriched with liquid hydrocarbons. At the optimal temperature of pyrolysis (440°C), 41% *n*-paraffins (C_1–C_4 41%, C_5–C_{15} 44%, and $C_{>15}$ 15%) were found.

The content and distribution of α-olefins in the products at various pyrolysis temperatures are shown in Fig. 3. At 350°C, mainly low-molecular-weight α-olefins were found in the pyrolysis products. For example, in the 14% α-olefins found in the products at 350°C, the content of C_2–C_4 hydrocarbons was 71%. At 440°C 35% of the pyrolysis products were α-olefins (C_2–C_4 42%, C_5–C_{15} 45%, and $C_{>15}$ 13%).

CONCLUSIONS

(1) In temperature-controlled pyrolysis of Dzhangichai oil shales, the maximum yield of the products is reached at 440°C. At lower temperatures, the pyrolysis products are characterized by a high content of *n*-paraffins C_1–C_4 and at 440°C (the optimal pyrolysis temperature) the yield of C_5–C_{15} hydrocarbons is at a maximum, being considerably higher than the yield of $C_{>15}$. In addition, at the optimal temperature of pyrolysis the concentration of C_5–C_{15} alkenes in α-olefins is higher than that of $C_{>15}$.

(2) The distribution of *n*-alkenes and α-olefins in the pyrolysis products is in good agreement with the distribution characteristic of kerogen II.

CHEMISTRY OF FOSSIL FUEL

A Versatile Formulation Inhibiting Thermal Polymerization of Pyrocondensates and Styrene

A. F. Gogotov and A. V. Ivanova

Angarsk Petrochemical Company, Open Joint-Stock Company, Angarsk, Irkutsk oblast, Russia

Received November 20, 2003; in final form, April 2004

Abstract—A formulation composed of *tert*-butylpyrocatechol with copper diethyldithiocarbamate was developed for inhibiting thermal polymerization of styrene and liquid pyrolysis products of 30–180°C benzine fractions, and its performance was studied.

Reduction of loss associated with thermal polymerization of monomers in the course of their distillation is one of the most challenging and currently pressing problems of petrochemical industry [1]. It is known that unsaturated compounds (styrene, divinylbenzene, vinylpyridines, acrylic compounds, vinyl chloride, cyclopentadiene and/or dicyclopentadiene) are thermally unstable and intensely polymerize when heated to above 100°C. Therefore, in the course of their processing aimed to concentrate or purify the target product, it is necessary to add thermal polymerization inhibitors, since polymerization adversely affects the yield of the target product and the state of the equipment. Numerous inhibitors and inhibiting formulations have been suggested, but the actual choice is governed by the availability of compounds and feasibility of their use. Fairly widely used are phenolic inhibitors: Ionol, *tert*-butylpyrocatechol (TBPC), etc. [2, 3].

However, the assortment of antioxidants is not restricted to phenols. Dialkyldithiocarbamates of various metals (sodium, zinc, nickel, etc.) and thiurams also show high inhibiting performance in oxidation processes [4–9]. In petrochemical industry, the most widely used inhibitor of thermal polymerization of pyrocondensates and individual monomers is TBPC [10, 11]. The practice shows that the highest inhibiting performance in processing of pyrocondensates is exhibited by individual compounds, such as, e.g., TBPC, whereas in production of individual monomers (styrene, butadiene, etc.), formulations consisting of two or three components are more effective in inhibiting the undesirable polymerization.

The mechanism and efficiency of the action of metal dialkyldithiocarbamates as oxidation inhibitors have been described in detail [4–9]. In their use as inhibitors of radical processes and, in particular, of radical polymerization, the presence of oxygen as initiator of radical processes is necessary. For example, a high performance of inhibiting formulations consisting of TBPC, copper diethyldithiocarbamate, and oxygen was shown in [12, 13]. However, in processing of pyrocondensates, styrene, and other vinyl monomers, even small amounts of oxygen should be excluded because of the extremely high fire and explosion hazard. It should also be noted that dialkyldithiocarbamates of various metals essentially differ in the solubility. Ammonium, sodium, and potassium salts are soluble in water and insoluble in organic solvents, whereas zinc, nickel(II), and copper(II) salts, by contrast, are readily soluble in organic solvents and show different solubilities in water [14].

In this study, we continued a search for effective inhibiting formulations for processing of liquid pyrolysis products (pyrocondensates) and for production of styrene.

EXPERIMENTAL

We have developed a new inhibiting formulation based on TBPC, effective in production of both ethylene–propylene (EP) and styrene [15]. The results of testing of the inhibiting formulation we suggested in thermal processing of pyrocondensates (liquid pyrolysis products of benzine fractions, EP-300 unit) and styrene at the Angarsk Polymer Plant are listed in Tables 1 and 2.

16	CuDTC (0.0025) + TBPC (0.025)	4.21	19.3	21.5	–	–	–
17	CuDTC (0.005) + TBPC (0.025)	0.19	0.42	0.54	0.55	0.57	0.61
18	CuDTC (0.005) + TBPC (0.02)	0.32	0.61	0.67	0.70	0.72	0.78
19	CuDTC (0.0045) + TBPC (0.0255)	0.33	0.35	0.42	0.50	0.52	0.68
20	CuDTC (0.006) + TBPC (0.024)	0.23	0.32	0.44	0.52	0.57	0.73
21	CuDTC (0.007) + TBPC (0.023)	0.19	0.30	0.35	0.44	0.60	0.65
22	CuDTC (0.0075) + TBPC (0.0225)	0.25	0.35	0.42	0.48	0.68	0.87

The inhibiting formulation suggested: copper(II) diethyldithiocarbamate (CuDTC) + TBPC, was tested under laboratory conditions with pyrocondensates sampled from the bottoms of the K-27 column of the EP-300 unit at the Angarsk Polymer Plant.

The pyrocondensates were heat-treated at 130 ± 1°C for 1 h, with subsequent analysis for the total resin content in pyrocondensates with a POS-77 device [steam distillation at 160°C according to standard procedure, GOST (State Standard) 25336–82]. The results are listed in Table 1.

Table 1 shows that heat treatment at 130°C for 1 h of the pyrocondensate containing various unsaturated compounds (styrene, α-methylstyrene, vinyltoluene, cyclopentadiene, dicyclopentadiene, butadiene, isoprene, 1-butene), with the initial resin content of 10.5 mg/100 cm^3, raises the resin content to 420 mg/100 cm^3. The polymerization is inhibited by CuDTC and TBPC, taken both separately and in combination. With CuDTC, the strongest inhibiting effect is observed at its content of 0.025 wt %: polymer formation decreases by 92.1% (run no. 2). However, the copper salt loses in this case its solubility and precipitates in the course of heat treatment of the pyrocondensate, which is extremely undesirable for the technology. Precipitation was also observed at CuDTC content of 0.020 (run no. 5) and 0.015 wt % (run no. 7). No precipitate was formed only at the CuDTC content decreased to 0.010 wt % (run no. 4), but the inhibiting effect in this case also decreased significantly (to 65%).

tert-Butylpyrocatechol taken alone is also a fairly effective inhibitor of polymerization in pyrocondensates (run nos. 3, 6), though less effective than CuDTC taken in the same amount.

The above-noted shortcoming of CuDTC, precipitation after the heat treatment, can be eliminated by using CuDTC in combination with TBPC. The high

inhibition efficiency (>90%) is preserved at the total content of the inhibitors of 0.020–0.025 wt %, with the CuDTC content being as low as 0.005–0.010 wt % (run nos. 8–11).

The ratio of the coinhibitors in the formulation suggested is determined by physicochemical properties of TBPC and CuDTC.

The formulation suggested (with somewhat other component ratios) was also tested as inhibitor of styrene polymerization in the course of its heat treatment at 120°C for 2–7 h. The results (Table 2) show that this formulation is also effective with respect to styrene.

The results of run nos. 12 and 13 show that the components taken alone do not inhibit polymerization of styrene. Furthermore, the inhibiting performance is low at the maximum content of TBPC (0.025 wt % relative to styrene) and minimum (0.0025 wt % relative to styrene, run no. 16) and maximum (0.025 wt % relative to styrene, run no. 14) contents of CuDTC. The optimal CuDTC : TBPC ratio for inhibition of styrene polymerization is 1 : (3.3–5.7) at a total content of the components of 0.03% relative to styrene (run nos. 15, 17–22).

It should be noted that such a coincidence of the optimal compositions of inhibiting formulations for different substrates is extremely seldom in chemical technology.

CONCLUSION

A formulation composed of *tert*-butylpyrocatechol with copper(II) diethyldithiocarbamate shows high performance in inhibition of thermal polymerization of styrene and of a mixture of various unsaturated compounds from liquid pyrolysis products of benzine fractions in production of ethylene and propylene.

CHEMISTRY OF FOSSIL FUEL

Solubility and Binding of Water in Toluene Solutions of Asphaltenes

D. S. Khvostichenko, S. I. Andersen, and A. I. Viktorov

St. Petersburg State University, St. Petersburg, Russia

Technical University of Denmark, Lyngby, Denmark

Received January 21, 2004

Abstract—The solubility of water in toluene solutions of asphaltenes is determined, and the state of water molecules in these solutions is studied spectroscopically. A number of water molecules bound to an asphaltene molecule is estimated from the experimental data. Aggregation in the system asphaltene–water–toluene is simulated using the pseudophase approximation, and the Flory–Huggins parameters are estimated for the pair asphaltene–water. The potentiality of this model for simulation of mixed aggregates in the asphaltene–water–toluene systems is discussed.

Asphaltenes are heavy polyaromatic compounds contained in high-boiling oil fractions. They are prepared by precipitation from crude oil by adding a nonpolar solvent, mostly *n*-pentane or *n*-heptane. The increased interest in properties of asphaltenes is due to the fact that, under certain conditions, they can precipitate to form solid deposits, giving rise to serious problems in oil production and refining. Precipitation of asphaltenes can be also initiated by the impact of CO_2, mixing of different crude oils, and pressure variation.

Asphaltene-containing petroleum fluids are an example of complex fluid systems with aggregation, whose structure and thermodynamics are regarded as important fundamental problems. Like surfactants, asphaltenes demonstrate critical micelle concentration (CMC), as shown by various methods, such as determination of the surface tension [1, 2], calorimetric titration [3], and small-angle X-ray scattering [4].

Recently Andersen *et al*. have shown that water takes an important part in the colloidal behavior of asphaltenes [5]. In particular, micellization was not observed in toluene solutions of asphaltenes in the absence of trace amounts of water (~0.11 wt %), and that the concentration of water in a solvent (0.001–0.047 wt %) influences CMC of asphaltenes, as determined by the calorimetric method. It has also been shown that the solubility of water in toluene solutions of asphaltenes is higher than that in straight toluene [5]. Such an increase in the solubility can be attributed to the salting-in effect [6] and solubilization of water by asphaltene aggregates.

The state of water in inverse micelles and in organic solvents is commonly studied by IR spectroscopy as a method sensitive to hydrogen bonding [7–16]. The IR spectra of such systems show a set of absorption bands at 3800–3100 cm^{-1} due to stretching vibrations of the OH groups, which are strongly influenced by hydrogen bonding.

In this study, we examined the solubility of water and subjected to infrared analysis its state in toluene solutions of asphaltenes.

EXPERIMENTAL

The working asphaltene solutions were prepared by dilution of a concentrated stock solution (20 g l^{-1} toluene). The working solution was poured over distilled water, avoiding mixing with it, and allowed to stand for at least 72 h in the dark (according to Andersen *et al*. [5], this is the time required for saturation of the organic phase with water). Then a small sample of the organic phase was taken for analysis. The concentration of water s_w^{sat} was determined by Karl Fischer titration using RH 34836 reagent with a 30% toluene content (Hyrdanal coulamat AG). The instrument (652-KF Coulometer) was calibrated against reference solutions with the water concentrations covering the

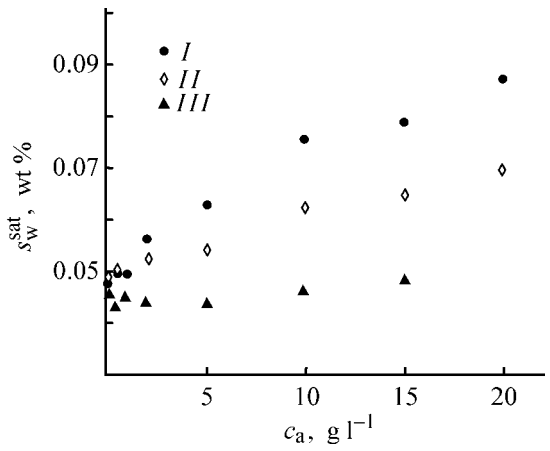

Fig. 1. Solubility of water in toluene s_w^{sat} vs. the asphaltene concentration c_a: (*I*) OMV, (*II*) NM1, and (*III*) A95.

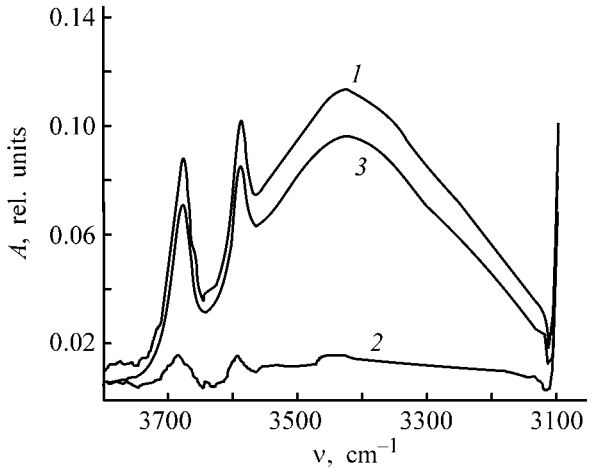

Fig. 2. IR spectra: (*1*) asphaltene–water–toluene, (*2*) asphaltene–toluene, and (*3*) differential spectrum. (*A*) Absorbance and (ν) wave number.

concentration range investigated. The relative error of determination was within 5%.

The IR spectra of the samples were recorded on a Perkin-Elmer PARAGON 1000 FTIR spectrometer using a Specac cell (NaCl windows, path length 0.5 mm). For each sample, 256 scans were made over the range 3800–3100 cm^{-1} with a 4-cm^{-1} resolution. The spectra were recorded against dry toluene as a reference. The absorption bands due to OH stretching vibrations was analytically divided into three Gaussian peaks using Microcal Origin program pack.

Asphaltene OMV was a purified precipitate from crude oil (Austria).

Asphaltenes A95 (Alaska) and NM1 (Venezuela) were prepared by precipitation with *n*-heptane from crude oil at room temperature, according to the modified IP-143 procedure [17]. *n*-Heptane was added to crude oil (30 ml g^{-1} crude oil), and the resulting mixture was allowed to stand in the dark for about 18 h. The precipitate was filtered off and dissolved in toluene, to separate toluene insolubles. Then toluene was removed by evaporation, and dry asphaltenes were washed several times with *n*-heptane as follows. Asphaltene was agitated with *n*-heptane on an ultrasonic bath and then centrifuged. The supernatant was poured out, and the washing was repeated with a fresh portion of heptane. Asphaltene was accepted pure when *n*-heptane after washing remained colorless or became only slightly yellow. Finally, the precipitate was vacuum-dried at 60°C, to remove residual heptane.

Toluene was dried over molecular sieves prior to use. Water-saturated toluene was prepared by mixing with excess water for at least three days. Unsaturated toluene samples were prepared by mixing water-saturated samples with dry toluene taken in desired volume ratios. The water concentration in unsaturated samples was determined by Karl Fischer titration.

The solubility of water in the organic phase was studied with asphaltene samples OMV, A95, and NM1. The solubility grows with increasing asphaltene concentration (Fig. 1), which is consistent with the data obtained by Andersen *et al*. [5]. The water content in the saturated sample was found to be 0.046 ± 0.002 wt % at 295 K, which is well consistent with published data (0.042 and 0.046 wt % at 293 K and 298 K, respectively [18]).

The state of water molecules in the system asphaltene–water–toluene was studied by IR spectroscopy. We studied three series of OMV asphaltene solutions in toluene with a constant total water content s_w (0.013, 0.019, and 0.027 wt %) and variable asphaltene concentration.

Figure 2 shows examples of the IR spectra of asphaltene solutions in dry toluene and in the presence of water and also the difference between these spectra over the range 3800–3100 cm^{-1}. According to published data [9, 14, 16], two sharp absorption bands at 3680 and 3592 cm^{-1} are due to vibrations of the OH groups in monomeric water molecules, not involved in hydrogen bonding. The appearance of a third, broad band is assigned to the presence in the system of hydrogen-bonded water. Since we observed a weak absorption in the systems with dry toluene also, we analyzed the difference spectra obtained by subtraction of the spectra of the corresponding asphaltenes in dry toluene from those of asphaltenes in the presence of water. This weak absorption in the systems with

dry toluene can be attributed to the presence of hydroxy and amino groups in asphaltenes and also to the fact that even dried toluene contains trace amounts of water (<0.001 wt %).

It was demonstrated that, at relatively low concentrations of water in toluene (0.013–0.027 wt %), the area of peak *1* is a linear function of the water concentration. Assuming that water in toluene totally occurs in the unbound monomeric state, we used this linear dependence as a calibration curve for determining the weight concentration of free water in asphaltene solutions in toluene. The results obtained with water-unsaturated toluene are given in Fig. 3.

From the concentration of free water, we estimated the amount of bound water molecules per asphaltene molecule in organic phase R_{wa}^{bound} (Fig. 4). In this case, the molar weight of the monomeric asphaltene was accepted to be 1000 g mol^{-1} [19, 20]. The R_{wa}^{bound} value is high in dilute asphaltene solutions, becoming below unity at higher concentrations. Since, above CMC, the systems contains both asphaltene aggregates and monomers, the amount of water molecules per asphaltene molecule in an aggregate should be somewhat different from the estimated values.

An interesting feature of all the curves shown in Fig. 3 is the local minimum in the concentration of free water at an asphaltene concentration near 0.1 g l^{-1}. The indicated concentration is remarkably lower than the critical concentration of formation of asphaltene aggregates [5], suggesting that water is bound to monomeric asphaltene molecules. With increasing asphaltene concentration to 0.5–2.0 g l^{-1}, micellization is observed, which is accompanied by an increase in the free water concentration. With further increase in the asphaltene concentration, s_w^{free} monotonically decreases.

In extremely dilute solutions, the dependence of the content of bound water on the asphaltene concentration should be linear, i.e., the amount of water molecules per asphaltene molecule should be constant. Assuming that, at an asphaltene concentration of 0.1 g l^{-1}, this dependence is still linear and accepting the mean experimental R_{wa}^{bound} for the three systems at c_a = 0.1 g l^{-1} as the limiting number of water molecules bound to an asphaltene molecule, one can estimate the amount of water bound to an asphaltene molecule at higher c_a (strictly speaking, the limiting R_{wa}^{bound} should be the same in solutions with different total water content; the mean R_{wa}^{bound} for the three systems at c_a = 0.1 g l^{-1} is about 20). However, this calculation gives a concentration of bound water that is

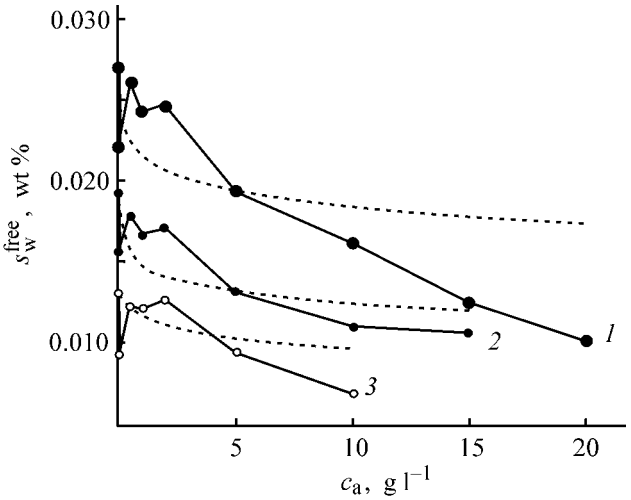

Fig. 3. Free water content s_w^{free} (wt %) vs. the asphaltene concentration c_a in the systems asphaltene–water–toluene at various initial water concentrations s_w (wt %): (*1*) 0.027, (*2*) 0.019, and (*3*) 0.013; the same for Fig. (4). Calculated data are presented by the *dotted lines*.

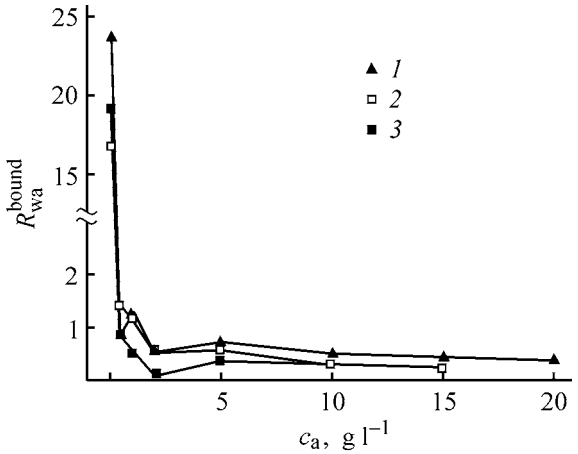

Fig. 4. Amount of bound water molecules per asphaltene molecule R_{wa}^{bound} in the system asphaltene–water–toluene. (c_a) Asphaltene concentration.

considerably higher than the total water concentration s_w in all the three systems even at an asphaltene concentration of 0.5–1.0 g l^{-1}, i.e., at higher c_a, water should be totally bound, which contradicts the experimental data. In this case, it may be suggested that, thanks to the onset of aggregation, only a part of asphaltene molecules is involved in interaction with water.

With further increase in s_a above CMC (at c_a = 10–15 g l^{-1}), the water to asphaltene molar ratio X_w/X_a becomes below unity, and, despite the fact that not all of the asphaltene molecules can participate in bonding with water, s_w^{free} decreases. The observed decrease

in R_{wa}^{bound} is probably due to increase in the asphaltene concentration also, since this parameter is defined as the ratio between the bound water concentration to the total asphaltene concentration, so that, at higher total asphaltene concentrations, this ratio is small. The available experimental data do not allow more detailed conclusions on the structure of the system, i.e., on what part of asphaltenes occurs in aggregated forms, and what is the ratio of the bound water molecules to the amount of aggregated asphaltene molecules.

The pseudophase approach widely used for characterization of surfactant solutions [21] is based on regarding the micelle formation as formation of a new phase. Therefore, the totality of the micelles is considered to be separate phase (pseudophase), and the equilibrium condition in the system is written as

$$\mu_i^M = \mu_i^\beta, \quad (1)$$

where μ_i^M and μ_i^β are the chemical potentials of a component in the micellar pseudophase and solution pseudophase, respectively.

For the dilute solution pseudophase (water and asphaltene mole fractions do not exceed 3×10^{-3}), the chemical potentials of the solutes (asphaltene and water) can be written, using the asymmetrical method of normalization of the activity coefficients, as

$$\mu_i^\beta = \mu_i^{*\beta} + kT \ln x_i^\beta, \quad i = a, w. \quad (2)$$

Assuming that the micellar pseudophase is composed by only the asphaltene and water, and using the symmetrical method of normalization for this pseudophase, we obtain

$$\mu_i^M = \mu_i^{0M} + kT \ln x_i^M \gamma_i^M, \quad i = a, w, \quad (3)$$

where μ is the chemical potential of a component in the pseudophase; μ^* and μ^0 are its standard terms for an infinitely dilute solution and the straight liquid as standard states, respectively; x is the mole fraction of a component in the pseudophase; and γ, the activity coefficient of the component in the pseudophase. Here the indices β and M refer to the solution and micellar pseudophases, and a and w, to asphaltenes and water, respectively.

The μ^* and μ^0 values for the solution pseudophase are related to each other through the limiting activity coefficients $\gamma_i^{\infty\beta}$:

$$\mu_i^* = \mu_i^0 + RT \ln \gamma_i^{\infty\beta}.$$

To determine the compositions of the pseudophase, it is necessary to add the material balance equations (4) to the set of Eqs. (1)–(3).

$$X_i = X_i^\beta + X_i^{aggr}, \quad i = a, w, \quad (4)$$

where X_a^{aggr} and X_w^{aggr} are the total mole fractions of asphaltenes and water occurring in the aggregates; X_{a1}^β and X_{w1}^β, total mole fractions of asphaltenes and water in the solution pseudophase; and X_a and X_w, total mole fractions of asphaltenes and water in the system.

The compositions of the pseudophase can be expressed via the total mole fractions of the components:

$$x_i^M = \frac{X_i^{aggr}}{\sum_i X_i^{aggr}}, \quad i = a, w; \quad (5a)$$

$$x_i^\beta = \frac{X_i^\beta}{X_{tol} + \sum_i X_i^\beta}, \quad i = a, w; \quad (5b)$$

where X_{tol} is the total toluene concentration.

The weight concentration of free water can be expressed in terms of X_w^β, X_w, and the total water concentration in the system s_w (wt %):

$$s_w^{free} = s_w \frac{X_w^\beta}{X_w}. \quad (6)$$

Expanding the equilibrium condition (1) for asphaltenes and water using Eqs. (2) and (3) and fixing the interrelation between μ^* and μ^0, the material balance conditions (4), and Eq. (5) at given total concentrations of the components X_a^{aggr}, X_w^{aggr}, and X_{tol}, s_w^{free} can be determined if the activity coefficients of asphaltenes and water in the micellar and solution pseudophases are known.

The activity coefficients of the components in the micellar pseudophase were estimated on the basis of the Flory–Huggins theory [22]:

$$\ln \gamma_{a1}^M = \ln \frac{\varphi_{a1}^M}{x_{a1}^M} + (1 - m^{a/w})\varphi_{w1}^M + m^{a/w}\chi^{a/w}(\varphi_{w1}^M)^2, \quad (7a)$$

$$\ln \gamma_{w1}^M = \ln \frac{\varphi_{w1}^M}{x_{w1}^M} + \left(1 - \frac{1}{m^{a/w}}\right)\varphi_{a1}^M + \chi^{a/w}(\varphi_{a1}^M)^2, \quad (7b)$$

where φ_{a1}^M and φ_{w1}^M are the volume fractions of asphaltenes and water in the aggregate; $m^{a/w} = \nu_{a1}/\nu_{w1}$

is the ratio of the molar volumes of asphaltene and water; and $\chi^{a/w}$, asphaltene–water interaction parameter.

In addition to the parameters of Eq. (7), for calculation it is also needed to determine the limiting activity coefficients of asphaltene and water in toluene, which relate μ^* and μ^0 to each other. There is no available experimental data for estimating the limiting activity coefficient of asphaltene in toluene $\gamma_{a1}^{\infty\beta}$, and we used the Flory–Huggins model for this purpose:

$$\ln\gamma_{a1}^{\infty\beta} = \ln\frac{v_{a1}}{v_{tol}} + (1 - m^{a/tol}) + m^{a/tol}\chi^{a/tol}, \quad (8)$$

where $m^{a/tol} = v_{a1}/v_{tol}$ is the ratio of the molar volumes of asphaltene and toluene; and $\chi^{a/tol}$, asphaltene–toluene interaction parameter.

The latter parameter (Table 1) was estimated as [22]

$$\chi^{a/tol} = \frac{v_{tol}}{RT}(\delta_a - \delta_{tol})^2, \quad (9)$$

where δ_a and δ_{tol} are the solubility parameters of asphaltenes and toluene, respectively (Table 2).

We estimated δ_a using the empirical relationship between the solubility parameter of asphaltene and its molecular weight [23]. The limiting activity coefficient of water in toluene (Table 2) was estimated using UNIQUAC model [24], since it is the model that has been recommended for representation of experimental data for the system in hand in DECHEMA database (Table 3) [18].

The asphaltene–water interaction parameters $\chi^{a/w}$ (Table 1) were estimated from the experimental free water concentration in asphaltene solutions. It was demonstrated that the effect of the composition (total water concentration in the system) on the Flory–Huggins parameter for the pair asphaltene–water should be taken into account ($\chi^{a/w}$ becomes less negative as the water content increases). Such a necessity has been reported previously for a series of systems [24]. The estimated results are given in Fig. 3 along with the experimental data on the free water concentration. At asphaltene concentrations below CMC, when water is bound to essentially asphaltene monomers, the theory fails to reproduce the distribution of water among free and bound states. At higher asphaltene concentrations (>2.0 g l^{-1}), the theory provides rather adequate qualitative fit to the experimental curves. Above CMC, asphaltenes occur essentially in the aggregated state, and water is bound, most likely, just to the asphaltene aggregates. Our result that the Flory–Huggins theory only qualitatively reproduces the experimental data obtained in this study is probably due to the fact that this theory was developed for flexible chain polymers and, therefore, it is not applicable to the full measure to asphaltenes (even though it was used for simulating phase separation in the systems asphaltene–organic solvent [26]).

Table 1. Flory–Huggins parameters

System	χ	m^*
Asphaltene–toluene (a/tol)	0.141	8.5
Asphaltene–water (a/w)	–0.915(0.013)**	
	–0.612(0.019)**	50.4
	–0.127(0.027)**	

* Estimated from data of Table 2.

** Total water content in the system (wt %) for which the parameter was estimated is given in parentheses.

Table 2. Parameters of Eqs. (7)–(9)

Component	Molar weight, g mol^{-1}	Density, g ml^{-1}	v, l mol^{-1}	δ, $MPa^{1/2}$	$\gamma^{\infty\beta}$
Asphaltene	1000	1.1 [5]	0.9091	20.06 [23]	0.015
Water	18	0.997	0.0181		455
Toluene	92	0.865	0.1064	18.25 [25]	

Table 3. Parameters of UNIQUAC model for the pair water–toluene [18]*

Component	r	q	a_{nm}	
			Water (1)	Toluene (2)
Water (1)	0.9200	1.400	0	1030.4
Toluene (2)	3.9228	2.968	289.19	0

* (r) Reduced van der Waals volume, (q) surface of the molecule, and (a_{nm}) interaction parameters.

CONCLUSIONS

(1) Both free and bound water occur in the asphaltene–toluene–water systems. With increasing asphaltene concentration, the free water concentration changes nonmonotonically, and a local minimum s_w^{free} is found at low asphaltene concentrations. Presumably, such an irregular shape of the experimental curves is caused by aggregation of asphaltenes.

(2) The use of the Flory–Huggins theory (preudophase approximation) for predicting the activity coefficients in the asphaltene–water–toluene systems provided the best fit to the experimental curves s_w^{free} vs. c_a at the asphaltene concentrations above the critical micelle concentration.

BRIEF COMMUNICATIONS

On the Possibility of Using Lithium-doped Copper Oxide in Lithium Cells

S. P. Kuksenko

Vernadskii Institute of General and Inorganic Chemistry, Ukrainian National Academy of Sciences, Kiev, Ukraine

Received January 28, 2004

Abstract—Lithium cells with cathodes based on lithium-doped copper oxide were studied.

Lithium cells with solid cathodes based on MnO_2, $(CF)_n$, FeS_2, and CuO are manufactured industrially [1]. Copper oxide–lithium cells (COL) are of special interest because of their being interchangeable with silver- and mercury-zinc cells as regards the working voltage and its stability. Copper oxide has the highest specific capacity of 4.26 A h cm^{-3}, which considerably exceeds that of MnO_2 (1.55 A h cm^{-3}). As the electrical conductivity of copper oxide is low (1×10^{-6} Ω^{-1} cm^{-1} [2]), we can assume that, after it is made higher, the capacity of COL cells can be increased, with the required pulsed power preserved, by lowering the content of electrically conducting additives and binder in the positive electrode. It has been reported previously that the electrical conductivity of copper oxide increases on introducing various metal ions (lithium, potassium, aluminum [2], and iron [3]) in its structure. The electrical conductivity of copper oxide increases to the greatest extent, to $(1–2) \times 10^{-1}$ Ω^{-1} cm^{-1}, upon doping with lithium [2]. In fabricating electrodes based on iron-doped copper oxide, it is necessary to introduce 3 wt % graphite and 2 wt % polytetrafluoroethylene as a binder [3].

It is known that, in the discharge of COL cells, lithium cations penetrate into appropriate interatomic spaces in the monoclinic lattice of copper oxide to give $Cu^{II}_{1-x}Cu^{I}_{x}Li_xO$ [4]. Moreover, it was demonstrated in [5] that copper oxide electrodes can be subjected to repeated reduction-oxidation without loss of capacity. Hence, a question arises as to what is the nature of lithium-doped copper oxide.

In the present study, we examined ^{7}Li NMR spectra of lithium-doped copper oxide and the discharge characteristics of lithium cells with cathodes based on this material. The study was carried out at varied content of the electrically conducting additive under continuous and pulsed loads in comparison with undoped copper oxide.

EXPERIMENTAL

Lithium-doped copper oxide was obtained as follows: (1) spherical copper particles were oxidized in pure oxygen at 1000°C, the resulting CuO was mixed with Li_2CO_3 in the ratio 100 : 1 [mol %] and annealed in air at 800°C for 8 h; (2) Cu_2O was mixed with Li_2CO_3 in the ratio 100 : 2 [mol %] and annealed under the same conditions. Copper oxide obtained by oxidation of spherical copper particles in pure oxygen at 1000°C with an additional thermal treatment in air at 800°C for 8 h was used as reference.

The completeness of conversion of the starting substances was verified by X-ray diffraction analysis on a DRON-2 X-ray installation with monochromatic Cu_{K_α} radiation. The ^{7}Li NMR spectra were recorded on a CXP-200 Brucker spectrometer in the single-pulse accumulation mode at a frequency of 77.78 MHz. To measure the electrical conductivity of lithium-doped copper oxide, the samples were compacted into pellets and a silver layer was deposited on both sides of a pellet in a vacuum. The conductivity was measured using an R5021 ac bridge.

In fabricating copper oxide electrodes, the copper oxide samples under study were mixed with graphite powder of C1 brand in various ratios and compacted into pellets under a pressure of 2300 kg cm^{-2}.

The thickness of the electrode pellets was selected so that the lithium cells produced remained within the allowed overall dimensions in the course of discharge. The pellets were placed in an evacuated cell, which was kept at 300°C for 1 h and then filled with

dry argon. Disc-shaped anodes were fabricated from rolled lithium, and a Li–Zn–Al alloy was formed on their surface facing the cathode. A $LiClO_4$ 1.4 M solution in a PC (propylene carbonate) : DME = 42 : 58 mixture (by weight) containing less than 30 ppm of water was used as the electrolyte. The electrolyte was additionally dried with a lithium-enriched Li–Al alloy and blown through with dry argon. The cells were assembled in a glove box filled with dry argon. The cells with diameter of 9.5 mm and height of 2.10 mm were used in the measurements. Discharge curves were measured after 1 month of technological storage of the cells. A continuous load of 30 kΩ and a parallel pulsed load of 1 kΩ (1 s once in 24 h) were used to discharge the cells.

The electrical conductivities of the samples of lithium-doped copper oxide obtained by both techniques were the same and equal to $(5–6) \times 10^{-1}$ Ω^{-1} cm^{-1}. The X-ray diffraction patterns of doped and undoped copper oxide were almost identical. However, on raising the $CuO : Li_2CO_3$ ratio to 100 : 5 (wt %) in the first mixture, Li_2O peaks were observed in the X-ray diffraction pattern, which indicates that lithium is introduced into the structure of copper oxide by this technique in a very limited amount. The ^7Li NMR spectra appeared to be more informative in studying the nature of lithium-doped copper oxide. Since the ^7Li nucleus has a quadrupole moment *eQ* in addition to the magnetic moment, the ^7Li NMR line is split into a triplet if ^7Li nuclei experience an electric field with a symmetry lower than cubic. The triplet consists of a central line and two satellites with the intensity ratio of 3 : 4 : 3. The value of the quadrupole splitting is proportional to the electric field gradient (EFG) created by the nearest environment, i.e., the greater the distortion of the environment, the stronger the splitting. We determined the quadrupole coupling constant e^2qQ/h (*eq* is EFG; *eQ*, the quadrupole moment; and *h*, the Plank constant) from the splitting of the ^7Li NMR line of lithium-doped copper oxide samples. This constant was found to be 0.36 MHz, which is rather high for the ^7Li nuclei and points to a significant electric field gradient at the lithium site. A ^7Li atom at the copper site in the CuO lattice can have such a constant, and this may be responsible for the stability of lithium-doped copper oxide samples under common atmospheric conditions.

The discharge curves measured under continuos load and the dependences of the pulse voltage on the duration of continuos discharge of COL cells with cathodes based on lithium-doped copper oxide produced by technique 1 and with cathodes based on undoped copper oxide containing 3 wt % graphite are shown in the figure. Discharge curve *1* shows a dip in the cell voltage after connecting a continuos load and the following stabilization of this voltage. Curve *1*' exhibits a pronounced dip in the pulsed voltage at the beginning of discharge and a slow stabilization of the voltage after approximately 3/4 of the total discharge duration. It is likely that, in the absence of an electrically conducting additive, the reduction of the electrode at places of contact with the current lead begins directly in the stage of formation of metallic copper. The capacity of this cell in discharge to a final voltage of 1.2 V was 45 mA h. As can be seen in the figure (curves *2* and *2*'), introduction of 3 wt % graphite into the cathode results in a stabilization of both the discharge curve measured under a constant load and the curve describing how pulsed voltage varies in the course of the continuos discharge. However, the cell capacity decreased to 43 mA h. Curves *2* and *2*' also reflect the behavior of the cell with doped copper oxide produced by technique 2, mixed with 3 wt % graphite. Consequently, the nature of the starting copper oxide doped with lithium does not affect the discharge parameters of COL cells. Raising the content of graphite in the cathode from 3 to 5 wt % did not affect the run of the curves and the stability of the cell voltage under the continuos and pulsed loads (figure, curves *3* and *3*'), and only resulted in a decrease in the cell capacity to 39 mA h.

Under the same testing conditions, a cell with a mixture of undoped copper oxide and 3 wt % graphite had a higher average values of the voltage under a constant load and of the pulsed voltage, and also

a higher capacity of 50 mA h in discharge to 1.2 V. A small dip in the pulsed voltage in the initial stage of the continuous discharge, which is characteristic of the cell with undoped copper oxide, was absent in the case of the cell with doped copper oxide. This may be due to changes in the state of the surface of copper oxide particles upon doping.

CONCLUSIONS

(1) High-temperature doping of copper oxide with lithium increases its electrical conductivity to (5–6) × 10^{-1} Ω^{-1} cm^{-1}. In this case, lithium occupies copper sites in the CuO structure.

(2) In fabricating electrodes based on lithium-doped copper oxide, 3 wt % graphite without a binder is required to ensure stable voltages under continuous and pulsed loads.

(3) Discharge parameters of cells with lithium-doped copper oxide are independent of the prehistory of copper oxide. The doping makes lower the cell capacity, but eliminates the dip in the pulsed voltage in the initial stage of discharge under a continuous load.

Behavior of Antimony in Desulfation of the Active Paste from Lead Battery Scrap with the Use of Potassium Carbonate or Hydroxide

A. G. Morachevskii, O. A. Kal'ko, and Yu. S. Kuznetsova

St. Petersburg State Polytechnical University, St. Petersburg, Russia

Cherepovets State University, Cherepovets, Russia

Received May 11, 2004

Abstract—The results obtained in a study of the behavior of antimony in desulfation of the active paste from lead battery scrap with the use of potassium carbonate or hydroxide are discussed.

At present, the lead battery scrap is the main type of secondary lead raw materials. Thus far, there have been no serious alternative to application of lead batteries in vehicles, whose number, and in particular that in our country, steadily grows. Now, the world's annual production of lead exceeds six million tons, with secondary lead constituting 55 to 60% of the total amount of the metal smelted.

The most efficient way to utilize worked-out batteries (battery scrap) is to crop them, with the metal (plate grids and connectors), sulfate-oxide (active paste of positive and negative plates), and organic (cases and separators) fractions recovered. The sulfate-oxide fraction is the most difficult for further processing. According to an X-ray diffraction analysis, its main components are $PbSO_4$ (anglesite) and lead oxide PbO_2 (plattnerite, tetragonal modification), which are present in comparable amounts [1]. Antimony and its compounds are the main impurities in the active paste. Antimony is introduced into plate grids of lead batteries to increase their mechanical strength. During operation of batteries, antimony tends to dissolve preferentially from positive plates via corrosion electrochemical processes [2–5]. The following reaction can occur on the positive electrodes

$$5PbO_2 + 2Sb + 5H_2SO_4 + 2H^+ \rightarrow 2SbO_2^+ + 5PbSO_4 + 6H_2O.$$

The most probable process on the negative electrodes is

$$2Sb + 2H^+ + H_2O \rightarrow 2SbO_2^+ + 5H_2.$$

Dissolved antimony is strongly adsorbed by lead dioxide, and only to a minor degree, by lead sulfate [5]. The total content of antimony in the sulfate-oxide fraction, which includes the active pastes of positive and negative plates, may be as high as 1.2–1.4 wt %.

The high content of lead sulfate in the components of the sulfate-oxide fraction makes difficult their direct reduction by carbon, requires rather high temperatures (up to 1000°C), and makes it necessary to catch the evolving sulfur dioxide. To utilize sulfur, the reduction stage is to be preceded by desulfation (desulfuration), which is based on the reaction of lead(II) sulfate with sodium or potassium carbonate or hydroxide [6–8]. The physicochemical and technological characteristics of desulfation with sodium carbonate have been studied in most detail [9, 10]. As demonstrated by X-ray diffraction analysis, the main components of the desulfated paste are cerussite $PbCO_3$, plattnerite PbO_2, and a minor amount of hydrocerussite $Pb_3(CO_3)_2(OH)_2$ [7]. Compounds with a more complex composition, such as $NaPb_2(CO_3)_2OH$ [8], may also be formed. Cerussite, plattnerite, and a minor amount of hydrocerussite are also main components in the case of desulfation with potassium carbonate [1].

An important issue is the extent to which the admixture of antimony in the active paste passes into the aqueous phase in the course of desulfation, because the resulting sodium and potassium sulfates are marketable products, and their purity is essential. It has been shown previously that a minor part of antimony contained in the sulfate-oxide fraction passes

1070-4272/04/7706-1022 © 2004 MAIK "Nauka/Interperiodica"

into the aqueous phase in desulfation with sodium carbonate [11, 12]. Under the common conditions of desulfation (50°C, 20% excess of Na_2CO_3 relative to the amount required for the complete conversion of $PbSO_4$ to $PbCO_3$), up to 1.7% of antimony contained in the paste to be desulfated passes into solution. When the content of lead sulfate in the starting solid phase is raised and temperature is elevated, up to 6% of antimony contained in the material being desulfated passes into the aqueous phase. In the case of desulfation with sodium hydroxide solutions, no antimony was found in the aqueous phase within the limits of experimental accuracy [13]. The detection limit of the method was 0.005 mg of Sb in 10 ml of a solution. An atomic-absorption analysis of anhydrous sodium sulfate obtained from the aqueous phase after desulfation with sodium hydroxide demonstrated that the content of antimony is less than 1×10^{-4}%.

The behavior of antimony in desulfation with potassium carbonate or hydroxide was studied at 50°C in the course of 45 min, with the solid-to-liquid ratio (s : l) varied from 1 : 4 to 1 : 5. The excess of the desulfating reagent was 20%. It has been shown previously that the desulfation proceeds rather effectively under these conditions, with the degree of extraction of sulfate ions from the active paste as high as 99.5%, on the average [1].

The photocolorimetric method with Violet Crystalline reagent, which forms an insoluble salt with antimony(V) if antimony is present in solution as $SbCl_6^-$ anions, was used to determine the content of antimony [12]. The compound formed by antimony(V) with Violet Crystalline is easily extracted with toluene; in this case, the organic layer is colored dark blue with a lilac tint, and the intensity of this color is used to determine the amount of antimony. The choice of techniques for monitoring the content of antimony in the products formed in processing of secondary lead raw materials was considered in detail in [12, 14], with a metrological comparison of the existing methods carried out.

According to a weight analysis, the starting sulfate-oxide fraction contained 45.0 wt % $PbSO_4$ (14.3% SO_4^{2-}), and the results of its X-ray analysis were reported earlier in [1]. The content of antimony was 1.17%, the average and maximum grain size of the material was 0.17 and 0.40 mm, respectively. In each experiment, 50 g of the active paste was desulfated.

In the case of desulfation with potassium carbonate at s : l = 1 : 4, the concentration of antimony in the aqueous phase was 0.050–0.065 g dm^{-3} in six parallel experiments; at s : l = 1 : 5, the content of antimony in the filtrate was 0.039–0.045 g dm^{-3}. The amount of antimony passing into solution was 1.6 to 2.1% (relative to its total amount contained in the material being desulfated) in the first case, and 1.6 to 1.8% in the second case.

In the case of desulfation with potassium hydroxide under the same conditions, the content of antimony in the aqueous phase did not exceed 5×10^{-4} g dm^{-3}.

Thus, the amount of antimony passing into the aqueous phase in desulfation of the active paste with sodium or potassium carbonate remains at the same level. In desulfation with sodium and potassium hydroxides, antimony virtually does not pass into the aqueous phase. These circumstances should be taken into account when selecting a desulfating reagent and developing a technology for production of sodium or potassium sulfate of a required purity.

CONCLUSION

When the active paste from lead battery scrap is desulfated with potassium carbonate, up to 2% of antimony contained in the solid phase passes into solution, whereas in the case of desulfation with potassium hydroxide, antimony virtually does not pass into solution.

Fusibility Diagram of Cyclohexane–Tetradecane–Docosane Ternary System

I. P. Kalinina, A. Yu. Kopnina, and I. K. Garkushin

Samara State Technical University, Samara, Russia

Received July 23, 2003; in the final form, April 2004

Abstract—The fusibility diagram of the cyclohexane–tetradecane–docosane ternary system was obtained by low-temperature differential thermal analysis.

The functioning of heat exchangers is based on heat accumulation by working fluids due to their heat capacity [1–3]. The working fluids in these devices should ensure efficient heat accumulation and meet some other requirements, in particular, they should have low crystallization temperature [4].

Among organic substances meeting these requirements are *n*-alkanes, cyclic and aromatic hydrocarbons, and their mixtures [5].

It has also been found that cyclohexane [6], tetradecane [7], and their mixtures [8] are promising heat accumulators and heat-carriers.

In this study we obtained the melting diagram of the cyclohexane–tetradecane–docosane ternary system.

In our experiments, the heating and cooling curves of organic mixtures were obtained on a low-temperature differential thermal analyzer (LDTA) equipped with a Chromel–Copel thermocouple and a TZ 4620 flatbed *XY* recorder. One of the thermocouple junctions was immersed in an organic mixture being tested and the other was placed in a test tube filled with calcined aluminum oxide powder as reference. The cold thermocouple junction was placed in a Dewar flask filled with water–ice mixture at 0°C. The thermal electromotive force was amplified with a F116/1 photoamplifier. The sensitivity of recording of the thermo-emf was controlled with an MCP-33 resistance box. The baseline was controlled with an IRN-64 voltage source. The temperature was determined with an accuracy of ±0.2°C. In studies of phase transitions, the organic mixtures were cooled and heated in a TK-1 thermal chamber within the temperature range from –40 to +60°C at a temperature variation rate of 1–2 deg min^{-1}. The starting components were weighed on a VLR-200 analytical balance with an accuracy of up to 0.3 mg.

Cyclohexane, tetradecane, and docosane used in our experiments were of pure grade. Their characteristics coincided with reference data [9, 10]. The purity of these reagents was checked by gas–liquid chromatography (a Tsvet-00 gas chromatograph; 50 m × 0.25 mm and 25 m × 0.25 mm capillary columns, vaporizer temperature 350°C; tetradecane and dodecane were injected as toluene solutions).

The fusibility diagram of cyclohexane-tetradecane binary system has an eutectic point (cyclohexane

Crystallizing phases: (*1*) cyclohexane + tetradecane, (*2*) α-docosane, (*3*) β-docosane, and (*4*) cyclohexane + tetradecane + docosane.

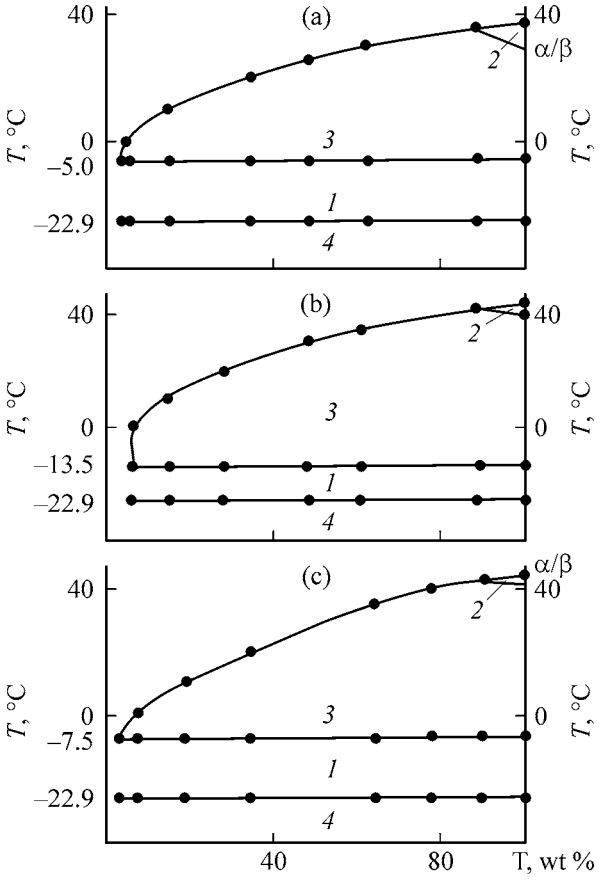

Fig. 4. Fields of joint crystallization of different phases in the cyclohexane–tetradecane–docosane system along sections (a) *I*, (b) *II* and (c) *III* in the plots of the crystallization temperature *T* against the docosane content. Crystallizing phases: (*1*) cyclohexane + tetradecane, (*2*) α-docosane, (*3*) β-docosane, and (*4*) cyclohexane + tetradecane + docosane.

75.03 wt %, tetradecane 24.97 wt %; melting point –22.5°C [7]).

The cyclohexane–docosane and tetradecane–docosane binary systems also form eutctic mixtures. In the cyclohexane–docosane system, the eutectic mixture contains 94.3% cyclohexane and 5.7% docosane (melting point is –4.6°C). The fusibility diagram of this binary system shows polymorphic transition (docosane content 95.2 wt %, mp 43°C) [8].

In the tetradecane–docosane system the eutectic mixture contains 2.3% docosane, mp 4.0°C. In this system, docosane also shows polymorphic transition (docosane content 97.0 wt %, mp 43°C) [11].

Figure 1 shows the phase diagram of the cyclohexane–tetradecane–docosane ternary system constructed as a series of projections on the diagram plane of the crystallization isotherms including the melting points of the corresponding binary systems. The cyclohexane : tetradecane ratio in the ternary eutectic mixture *E* and its melting point (–25.9°C) were determined from the polythermal section e_2–$\bar{E}$–e_3 passing through the field of docosane crystallization (Fig. 2).

The composition of the ternary eutectic was determined from the docosane–$\bar{E}\rightarrow E$ section (Fig. 1). This eutectic mixture contains (wt %) cyclohexane 74.9, tetradecane 24.1, and docosane 1.0 (Fig. 3).

The crystallization temperatures were determined for mixtures belonging to following sections: (*I*) docosane–(cyclohexane 33.7%, tetradecane 66.3%); (*II*) docosane–(cyclohexane 54.1%, tetradecane 45.9%), and (*III*) docosane–(cyclohexane 87.9%, tetradecane 12.1%) (Figs. 4a–4c).

Based on the whole set of the data obtained in our experiments, the series of crystallization isotherms

were constructed in the range 0–40°C and projected on the plane of the fusibility diagram plane. The crystallization isotherm at 43°C divides the triangle into the crystallization field of docosane α-modification, adjacent to the docosane triangle apex, and the field of docosane β-modification. The polythermal section shows that the field of docosane crystallization predominates.

The ternary system under consideration includes the following phase equilibria (see table).

Based on our experimental and calculated data, the specific enthalpy of melting of the ternary eutectic was calculated by the additive equation

$$\Delta H_{me} = x_1 \Delta H_{m1} + x_2 \Delta H_{m2} + x_3 \Delta H_{m3}, \quad (1)$$

where x_1, x_2 and x_3 are the contents of the individual components in the ternary eutectic (wt %).

We found that the specific melting enthalpy of the ternary eutectic is 146 J g^{-1}.

The experimental enthalpy of melting of the ternary eutectic mixture was determined by the equation

$$\Delta H_{me} = \frac{\Delta H_{m1} T_e S m_1}{T_{m1} S_1 m}, \quad (2)$$

where ΔH_{m1} is the specific entalphy of melting of a reference substance (undecane) (J g^{-1}) whose melting point is close to that of the ternary eutectic; T_{m1} is the melting point (K) of the reference substance; S_1 and S are half-areas (mm^2) of the peaks in cooling curve related to a reference substance and the ternary eutectic, respectively; m_1 and m are the weights (g) of the reference substance and the eutectic, respectively; and T_e is the ternary eutectic melting point (K).

The specific enthalpy of melting of the ternary eutectic was found to be 91 J g^{-1}.

CONCLUSION

The cyclohexane–tetradecane–docosane ternary system belongs to an eutectic type (mp –25.9°C, specific melting enthalpy 91 J g^{-1}). The ternary mixtures under consideration can be used as heat-accumulators and thermal-carriers.

BRIEF COMMUNICATIONS

Influence of Filler on Elastic-Relaxation Properties of Vulcanized Rubbers Based on Binary Blends of Diene Rubbers

N. I. Kurbanova

Institute of Polymeric Materials, Azerbaijan National Academy of Sciences, Sumgait, Azerbaijan

Received February 10, 2004

Abstract—The strength and elastic-relaxation properties of vulcanized rubbers based on binary blends of diene rubbers were studied as influenced by a filler, carbon black no. 330.

The progress achieved in the development of polymer-based multicomponent systems offers virtually unlimited scope for this line of modification of polymeric materials to impart to them the desired properties [1–3]. The conditions of preparation and processing of blends, as well as introduction of various additives, also significantly affect the structure and properties of the resulting materials [4–6]. Polymer blends and materials thereof hold much promise and can find other applications than their constituent polymers [7, 8].

Most of commercial rubber stocks are composed of an elastomer, a vulcanizing system, and a filler. Fillers favorably affect the process and physicomechanical characteristics, as well as the cost, of the compositions, which makes their use essential for polymeric materials [2, 5].

In this study, we analyzed how a filler modifies the properties of binary blends of divinyl (SKD) and styrene-butadiene (SKS) rubbers with polyisoprene (SKI).

We used Carifleks IR 309 (Shell) polyisoprene, cis-132 (96% cis) SKD, SKS incorporating 23% SRB-1500 styrene (BSL Olefinverbund GmbH Schkopau), and carbon black no. 330.

The component ratio (mass fraction) in the compositions was as follows: SKD(SKS) : SKI : carbon black = 50 : 50 : 50; vulcanizing system (mass fraction): sulfur 2.0, stearic acid 2.0, ZnO 3.0, thiuram 0.65, Altax 1.0, Captax 1.25 for SKD/SKI blend and sulfur 2.0, stearic acid 2.0, ZnO 5.0, Altax 2.75 for SKS/SKI blend.

The initial components were mixed in a Banbury mixer for 6 min in the case of unfilled systems, and for 7, 10, and 15 min, in the case of filled compositions.

The time, s, of introduction of the components into the mixer was as follows: SKD (SKS) 0, SKI 60, carbon black 90 (in three portions), sulfur + stearic acid + ZnO + accelerators 180.

The mixing mode was as follows: T_{in} = 50, T_{fin} = 60–65°C; n = 60 rpm. The vulcanization conditions and modes were specific to each composition.

We studied the physicomechanical properties of filled and unfilled vulcanizates of the prepared compositions under quasistatic and dynamic loading conditions.

The dynamic mechanical properties of the compositions were studied on a low-frequency (ν = 1 Hz) installation in the sinusoidal oscillation mode at temperatures from –120 to 70°C, and quasistatic properties, at room temperature at a strain rate of 200 mm min^{-1}.

Table lists the formulations and properties of the diene rubber-based binary blends (average of five measurements).

The most important and widely used filler for vulcanized rubbers is carbon black. Active fillers tend to increase the modulus of elasticity, tensile strength, tear resistance, and wear resistance of vulcanized rubbers.

Carbon blacks used for rubber filling contain appreciable amounts of chemically bound hydrogen (0.1–4%), oxygen (0.2–1%), and sometimes sulfur (up to 1%). Carbon black no. 330 or HAF used by us has a relative strengthening power of 100 at the specific surface area of 80 $m^2 g^{-1}$ [5].

* σ_t is tensile strength; ε, relative elongation at break; M_{100}, M_{200}, and M_{300}, stresses at 100, 200, and 300% elongation, respectively; and τ_v^{143}, vulcanization time at 143°C.

The degree of mechanical dispersion of the carbon black particles throughout the elastomer substantially affects the structure of the strengthened system and its physicomechanical properties.

Optical spectroscopic studies showed that, in filled compositions prepared by 7-min mixing, carbon black is poorly dispersed in the system, which is responsible for the relatively poor properties of the resulting vulcanizates. A 10-min mixing affords better properties of the vulcanizates, compared to the blends prepared by 7- and 15-min mixing. Ten minutes can be regarded as the optimal mixing time.

Table shows that, upon introduction of the filler into the SKD/SKI blend, the strength σ_t increases 12-fold, but the relative elongation at break ε decreases 5-fold, and the stress at 300% elongation M_{300} decreases to zero, i.e., the system becomes rigid. Upon introduction of the filler into the SKS/SKI blend, σ_t increases by a factor of 4.5, ε decreases by a factor of 1.9, and M_{300} increases from 1.0 to 11.7 MPa. The vulcanization rate for the filled compositions exceeds by a factor of 1.5 that for unfilled composition. Evidently, carbon black promotes reactions involved in vulcanization of rubbers.

It is known [4] that the properties of filled polymeric materials are governed by the properties of the polymer matrix and filler, as well as by the filler dispersion and the nature of interaction at the polymer–filler interface.

Our study of the physicomechanical properties of vulcanizates of the resulting compositions under quasistatic loading showed that the filler (carbon black) increases the strength of the system. This can be accounted for by enhanced intermolecular interaction in the blends owing to formation of chemical bonds and adsorption bonding.

The results of our dynamic studies of the compositions obtained are presented in Figs. 1a and 1b. Our studies of the vulcanizates of the binary blends of diene rubbers in the range from –120 to 70°C revealed two glass transition points T_g [T_g(SKD) = –94 and T_g(SKI) = –54°C for SKD/SKI system; T_g(SKS) = –44 and T_g(SKI) = –54°C for SKS/SKI system] specific to each polymer; this means that these are two-phase systems. The temperature dependence of the modulus of elasticity E' of the compositions exhibited a two-step pattern, and the curve describing the variation of the mechanical loss indices $\tan\delta$ has two peaks. For the SKS/SKI system, the glass transition points are close for both polymers, which is responsible for the overlapping and broadening of the mechanical loss curve near the peak.

Figures 1a and 1b show that the glass transition points of the polymers remain unchanged upon introduction of active carbon black. This means that the mobility of the chain segments is independent of the presence of the filler particles; otherwise, T_g should shift owing to changes in the mobility of the macromolecules [9]. This suggests that the mechanical properties of vulcanized rubbers containing active filler are improved predominantly by physical forces; chemical bonds seem to be of minor importance.

Figure 1a shows that, in the initial binary blend of diene rubbers SKS/SKI, the modulus of elasticity E' can be estimated at 0 MPa at T = 30°C; upon intro-

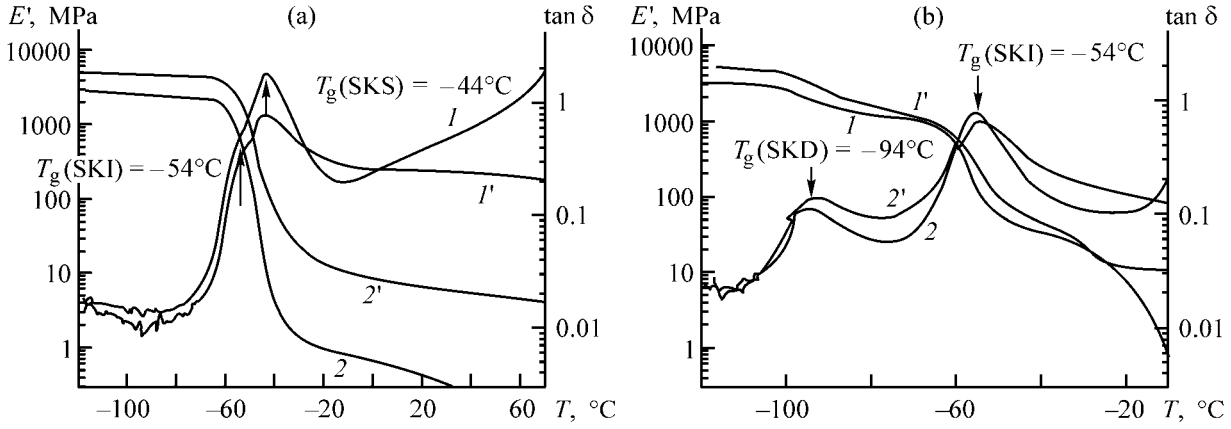

Fig. 1. Temperature dependences of the dynamic modulus of elasticity E', and tangent of mechanical loss tan δ of (a) SKS/SKI and (b) SKD/SKI compositions (ν = 1 Hz). Composition: (*1*, *2*) unfilled and (*1'*, *2'*) filled with carbon black no. 330.

duction of the filler it increases to 4 MPa at T = 30°C and remains unchanged to 70°C, which makes the composition applicable within a broader temperature range.

The tangent of mechanical loss tan δ (Fig. 1a) for the initial blend was estimated at 0.15 for T = 30°C and at 1.1 for T = 70°C, i.e., the mechanical loss increases with rising temperature. Upon introduction of the filler, the mechanical loss tangent decreases by an order of magnitude, namely, from 1.1 to 0.2, remaining virtually unchanged with temperature increasing from –20 to 70°C.

Figure 1b shows that, for the initial SKD/SKI blend at T = –10°C, the modulus of elasticity can be estimated at 1 MPa, and the mechanical loss tangent, at 0.2. Upon introduction of the filler, E' increases to 11 MPa, and tan δ decreases by an order of magnitude, from 0.2 to 0.03 (T = –10°C).

Thus, we showed that, upon introduction of the filler into compositions based on a binary blend of diene rubbers, the modulus of elasticity significantly increases and the mechanical loss tangent decreases by an order of magnitude. This is, evidently, due to enhanced degree of crystallinity or a higher degree of cross-linking of the resulting vulcanizates.

Carbon black no. 330 improves the properties of vulcanized rubbers based on a blend of rubbers, which is essential for preparation of various vulcanized rubbers.

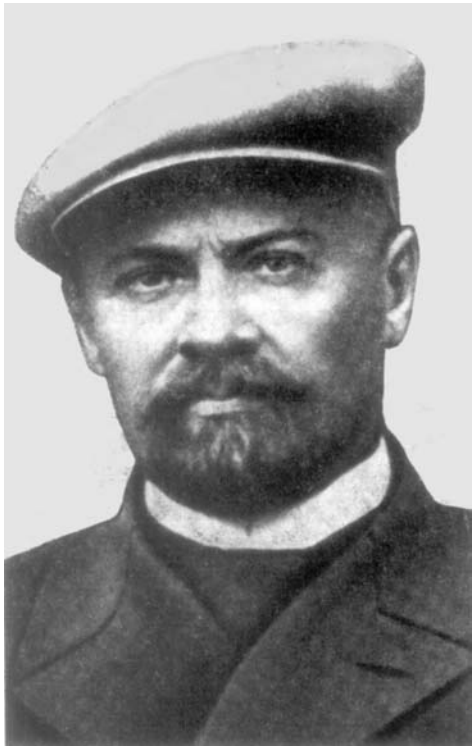
Professor Pavel Pavlovich Fedot'ev (1864–1934)

P.P. Fedot'ev, a professor of the Emperor Peter the Great Polytechnic Institute in St. Petersburg, is the founder of Russia's scientific school of applied electrochemistry and electrometallurgy of nonferrous metals. Together with numerous pupils, he made an outstanding contribution to the organization of the manufacture of aluminum and magnesium in our country and to the creation and development of quite a number of other electrochemical industries.

Pavel Pavlovich Fedot'ev was born on June 21, 1864, in Blagoveshchensk in Amur province into the family of a senior medical attendant. He spent his childhood at this town, and received his secondary education at Siberian Military Gymnasium in Omsk. On leaving the gymnasium, he entered Nikolai Engineering College in St. Petersburg. However, already in a year, he went to St. Petersburg Technological Institute, from whose chemical department he graduated in 1888.

P.P. Fedot'ev commenced his engineering activities at Bondyuzha chemical plant situated near the Kama River, not far from Yelabuga, Vyatka province. By 1890, the plant founded in 1868 occupied the leading position among chemical plants of Russia as regards the diversity and quality of the products it manufactured. The plant even possessed laboratories with newest, by that time, equipment. In 1891, P.P. Fedot'ev moved to Minsk and headed there the laboratory for materials testing at the railroad department. Beginning in December 1893, the young engineer worked at plants in St. Petersburg: he headed ammonia departments at gas plants and, beginning in 1894, supervised the production of nitric and sulfuric acids at Okhta state gunpowder plants. During these same years, P.P. Fedot'ev wrote quite a number of monographs devoted to most important chemical industries. These include: *Proizvodstvo sernoi kisloty* (Manufacture of Sulfuric Acid, 1896), *Dobyvanie potasha iz zoly* (Manufacture of Potash from Ash, 1896), *Sovremennoe sostoyanie khimicheskoi promyshlennosti v Rossii* (Modern State of Chemical Industry in Russia, 1897), *Sodovoe delo i svyzannye s nim proizvodstva* (Manufacture of Soda and the Related Industries, 1898), *Azotnaya kislota i ee soli* (Nitric Acid and Its Salts, 1900), and *Fiziko-khimicheskie tablitsy* (Physicochemical Tables, 1901).



In the autumn of 1902, P.P. Fedot'ev, who had already become known to the scientific community and was experienced in practical work, was invited to the newly organized St. Petersburg Polytechnic Institute to organize the laboratory of mineral technology and technical electrochemistry and deliver the corresponding courses of lectures. To be prepared for occupying the position of a professor, P.P. Fedot'ev was sent to a business trip abroad. He chose Leipzig (Germany), where an international school of electrochemists had formed at the University and at the Institute of Physical Chemistry headed by W. Ostwald (1853–1932, 1909 Nobel Prize in Chemistry). Having returned to St. Petersburg on June 1, 1903, P.P. Fedot'ev presented a dissertation "Ammonia Soda Process from the Standpoint of the Theory of Phases." During his stay in Leipzig, he studied in detail works by J.W. Gibbs (1839–1903) and J.H. Van't Hoff (1852–1911, 1901 Nobel Prize in Chemistry), carried

1070-4272/04/7706-1031 © 2004 MAIK "Nauka/Interperiodica"

out numerous experimental studies, and analyzed above-mentioned complex technological process in terms of the phase rule. Among Russian scientists, only A.A. Yakovkin (1860–1936) applied, earlier than P.P. Fedot'ev, the phase rule to analysis of equilibria in his master's dissertation (1896). Having become an associate professor, P.P. Fedot'ev was elected an extraordinary professor at the chair of mineral technology and technical electrochemistry and his appointment was confirmed. On September 1, 1904, P.P. Fedot'ev started to organize at his chair a laboratory for studies of students and his own research work. At that time, the course of lectures on mineral technology covered basic chemical industries (manufacture of sulfuric and other acids, alkalis, salts, and silicates, such as ceramics, cement, and glass), and the course of lectures on technical electrochemistry, the electrochemical industries and electrometallurgy [1]. For that time, the laboratories were very well equipped; in 1912, undergraduate students started to carry out their graduation works at the chair. P.P. Fedot'ev himself delivered lectures on technology of mineral substances, technical electrochemistry, and electrometallurgy.

In 1906, P.P. Fedot'ev again went to a business trip abroad and visited a number of plants. His trip resulted in his publication of 1907: *"Modern State of Chemical and Electrochemical Industry in Continental Europe."* P.P. Fedot'ev paid much attention to textbooks. In 1906, were published *Tekhnicheskii analiz mineral'nykh veshchestv* (Technical Analysis of Mineral Substances) and *Uchebnik tovarovedeniya* (Manual of Commodity Research). In 1910, P.P. Fedot'ev was elected an ordinary professor of the Polytechnic Institute, and in 1911, he was sent to business trip abroad for familiarization with industrial electric furnaces. Based on the material collected during this business trip, he published a book *Elektricheskie pechi v metallurgii stali* (Electric Furnaces in Metallurgy of Steel, 1912).

The scientific investigations by P.P. Fedot'ev cover a wide range of problems. He paid much attention to the electrolytic method for manufacture of alkali and chlorine and maintained close relationships with plants for manufacture of these compounds. Simultaneously, he studied problems associated with electrochemical production of metals with the use of both aqueous and molten electrolytes. In 1911, P.P. Fedot'ev and his pupil, V.P. Il'inskii (1885–1964), performed an *"Experimental Study of the Electrometallurgy of Aluminum."* They analyzed the binary system AlF_3–NaF, solubility of Al_2O_3 in cryolite, the interaction of aluminum with cryolite-alumina melts, and the decomposition potential of the electrolyte. The authors gave recommendations concerning the choice of the optimal electrolyte composition and studied all the main phenomena accompanying the process of electrolysis [2, 3]. The importance of this publication for the understanding of the physicochemical fundamentals of the electrolyte based on cryolite-alumina melts was analyzed in detail in a monograph by A.I. Belyaev and O.I. Pavlova [4].

In 1915, another P.P. Fedot'ev's pupil, N.N. Voronin (1892–1956), developed methods for dehydration of carnallite and magnesium chloride and studied the electrolysis of molten carnallite. In 1916–1917, production of magnesium was organized under P.P. Fedot'ev's supervision on a large-laboratory scale at workshops of the Military Chemical Committee in Petrograd.

During World War I (1914–1918), P.P. Fedot'ev was actively engaged in works aimed to build-up Russia's military potential and raised the manufacture of chlorine and soda at plants of Southern Russia. The importance of this problems and ways to solve it were considered by V.N. Ipat'ev, head of the Chemical Committee at Chief Artillery Directorate [5, 6].

During the difficult period of 1918–1921, P.P. Fedot'ev was in Petrograd. In 1919, a chemical department was opened at the Polytechnic Institute on his initiative. This department incorporated all the chemical chairs, including the chair of mineral substances and technical electrochemistry. In 1921–1923, P.P. Fedot'ev was dean of the chemical department. In 1920, he also became a professor of the Technological Institute, where he delivered a course of lectures on technical electrochemistry till 1930, when the system of higher education in the country was reorganized.

On July 1, 1930, the Polytechnic Institute was reorganized into a number of separate specialized higher school institutions. The chemical department was included in the Technological Institute, and the metallurgical department was transformed into the Metallurgical Institute. P.P. Fedot'ev headed the chair of the electrometallurgy of nonferrous metals at the latter institute, and stopped lecturing at other places.

The intensive scientific activities at the Polytechnic Institute were resumed in the post-revolution time only in 1924, when the first post-graduate students appeared. Studies by P.P. Fedot'ev and his pupils were closely associated with the demands of industry. In Leningrad, electrolytic refining of silver was organized and problems associated with production of nickel and zinc were studied under P.P. Fedot'ev's

supervision. Much attention was given to preparation for industrial manufacture of aluminum and magnesium in Russia.

In 1929, pilot production of aluminum from entirely domestic raw materials was organized at Krasnyi Vyborzhets plant in Leningrad under P.P. Fedot'ev's supervision with the participation of P.P. Fedot'ev's son N.P. Fedot'ev (1897–1969) and the chief metallurgist of the plant Yu.V. Baimakov (1894–1980). Alumina was obtained at the Pilot Plant of the State Institute of Applied Chemistry (GIPKh) from low-grade Tikhvin bauxites, using the technology developed by Yakovkin. Cryolite and carbon materials were of domestic manufacture too. The first 8-kg batch of aluminum was produced on March 27, 1929. The participants of this work, N.P. Fedot'ev and Baimakov, were graduates from the Polytechnic Institute and P.P. Fedot'ev's pupils. Later, N.P. Fedot'ev headed the chair of technology of electrochemical industries at Leningrad Technological Institute, and Baimakov superceded his teacher at the chair of electrometallurgy of nonferrous metals at the Polytechnic Institute. The works by P.P. Fedot'ev and his pupils were exceedingly important for the creation of the domestic industry of aluminum and magnesium.

In 1933, P.P. Fedot'ev was elected a corresponding member of the Academy of Sciences of the USSR. On March 20, 1934, Pavel Pavlovich Fedot'ev died of a short severe illness. His life and scientific and pedagogical activities are reflected in recollections of those who were intimate with him [7–10] and other authors [4, 11, 12]. The contribution made by P.P. Fedot'ev and his pupils to the creation of the domestic aluminum industry was considered in [13, 14]. Not long before his death, P.P. Fedot'ev prepared for publication the textbook *Elektroliz v metallurgii* (Electrolysis in Metallurgy), whose first part is devoted to electrolysis of aqueous solutions, and the second, to electrolysis of molten salts. The book was published in 1935 [3].During many years, this book was the best manual of the electrometallurgy. A full list of P.P. Fedot'ev's scientific works can be found in [4, 9].

ANNIVERSARIES

Vladimir Aleksandrovich Proskuryakov (To 85th Anniversary of His Birthday)

On June 21, 2004, Vladimir Aleksandrovich Proskuryakov, an excellent person, pedagogue, and a real scientist is 85. The youth of Vladimir Aleksandrovich was scorched by the Great Patriotic War of 1941–1945. A fourth-year student of the Lensovet Technological Institute in Leningrad, V.A. Proskuryakov volunteered to go to the frontline, was badly wounded at Nevskii pyatyachok (foothold), then continued his field-duty, and finished his military service in the Far East in Kharbin. After demobilization, he continued his education at the Technological Institute. Having graduated as an engineer from the chair of pyrogenetic processes, he became a candidate of technical science for solving the problem of shale dressing and was appointed a lecturer at the chair of organic chemistry at the Lensovet Technological Institute in Leningrad.

The persistence, benevolence to people, and the skill to unite like-minded persons around him allowed Proskuryakov to create in 1964 a chair of petroleum- and coal-chemical industries on the basis of the chair of pyrogenetic processes. The chair successfully trains specialists in chemical technology of natural fuels and carbon materials and in basic organic synthesis.

While improving the scientific potentialities of the chair, Proskuryakov created an efficient system of training of highly skilled specialists. More than 200 candidate dissertations have been defended under Proskuryakov's supervision, and 20 doctors of science were trained with his participation.

Proskuryakov is the author of more than 600 scientific publications, including 100 inventor's certificates, patents, and monographs.

In 1967, the degree of a doctor of technical science was conferred on Proskuryakov and he acquired the rank of professor.

In 1965, Proskuryakov was appointed pro-rector of the Institute for educational work. In 1974, he was elected a corresponding member of the Academy of Pedagogical Sciences of the USSR for his important services in the organization of higher education. From 1975 till 1985, Proskuryakov was rector of the Lensovet Technological Institute in Leningrad. In this position, he continued in every possible way to develop new areas of science and technology and did his best to lay the material foundation for the development and implementation of new designs.

In addition to his administrative, educational, and scientific activities, Proskuryakov devoted considerable efforts and energy to popularization of science and to public activities. He headed for 15 years a division of the All-Russia Society Znanie (Knowledge), was deputy chairman and chairman of Leningrad Council of rectors, worked for a long time as an expert and a member of presidium of the Higher Attestation Commission, was chairman of specialized council for doctoral dissertations, and headed the Scientific Council of the Institute.

Proskuryakov has been awarded six Orders and numerous medals for his scientific, pedagogical, and administrative services, and also for feat of arms during the Great Patriotic War.

Proskuryakov is an honorary doctor of Merzburg and Vesprem Technical Universities, he has been awarded orders and medals of the Democratic People's Republic of Korea, Czechia, and Bulgaria.

Vladimir Aleksandrovich is a very well-wishing and kindly man, a good friend, and a patriot.

Many generations of students, post-graduate students, lecturers, and research workers have been and still are aware of his support and help.

1070-4272/04/7706-1034 © 2004 MAIK "Nauka/Interperiodica"

In his 85, Vladimir Aleksandrovich is vigorous and energetic, delivers lectures to students, and is actively engaged in problems of processing of shale and coal. He directs considerable effort to publishing activities as a member of the Editorial boards of the journals *Zhurnal Prikladnoi Khimii* (this journal), *Khimiya tverdogo topliva* (Chemistry of Solid Fuels, Russian Academy of Sciences), and *Goryuchie slantsy* (Oil Shale, Academy of Sciences of Estonia). During the last 10 years he has written and published more than 100 scientific papers.

We congratulate Vladimir Aleksandrovich Proskuryakov on his jubilee and wish him sound health and every success for the benefit of the homeland.

Chair of technology of petroleum- and coal-chemical industries, St. Petersburg State Technical University

Editorial board and editorial staff of Zhurnal Prikladnoi Khimii

Russian Journal of Applied Chemistry, Vol. 77, No. 6, 2004, pp. 1036–1037. Translated from Zhurnal Prikladnoi Khimii, Vol. 77, No. 6, 2004, pp. 1049–1050.

INFORMATION

XII Enikolopov Readings

The XII Enikolopov Readings were held on March 12, 2004, at the Enikolopov Institute of Synthetic Polymeric Materials (ISPM). On March 13, 2004, Academician N.E. Enikolopov could be 80.

The Readings were organized by the Department of Chemistry and Materials Sciences, Russian Academy of Sciences (RAS); ISPM; Scientific Council for Macromolecular Compounds, RAS; Semenov Institute of Chemical Physics (ICP); Institute of Chemical Physics Problems (ICPP); and Moscow Physicotechnical Institute.

The agenda of the Readings included six presentations. A presentation by A.A. Berlin and A.Yu. Shaulov from ICP was concerned with inorganic-organic materials, including various structural materials and their advantages and disadvantages from the viewpoint of the ease of processing, heat resistance, combustibility, strength, brittleness, etc. Particular interest of the audience was aroused by the information about inorganic polyoxides exhibiting a wide range of softening points, incombustibility, and high heat and radiation resistance. These are virtually not oxidizable and often readily available natural polymers. Unfortunately, these materials are brittle and often prone to hydrolysis. A.A. Berlin and A.Yu. Shaulov suggested a number of procedures to modify polyoxides, including that of boron, with various organic and inorganic compounds, in particular, linear polymers, and also discussed some important properties of materials and composites thereof.

The report by A.N. Ozerinskii from ISPM was devoted to nanostructured objects. In particular, he presented the general views on formation, structure, and selected properties of nanosized structural elements in polymers and polymeric materials. Also, A.N. Ozerinskii discussed examples of fabrication of elements of nanotechnologies underlain by development of nanostructures in amorphous and crystalline polymers, copolymers, block copolymers, and molecular composites. The presentation considered various procedures for preparation of polymeric nanostructures via synthesis of polymers with desired spatial architecture, as well as procedures based on molecular recognition, self-assembly, and self-organization of nanostructures in polymeric materials.

A presentation prepared by a group of researchers from ICP and ISPM (E.F. Oleinik, A.D. Kalashnikov, I.A. Karmilov, and N.K. Balabaev) concerned the structure and molecular dynamics of a polymer crystal containing $-CH_3$ branches in chains. It was N.S. Enikolopov who, late in his life, expressed active interest in the chemical and physical processes occurring in the solid phase and attempted establishing a correlation of the structural and defect features of various solids with their chemical reactivity. The presentation by E.F. Oleinik and coworkers showed that, at low concentrations of branchings, the crystal preserves its three-dimensional structure, but, with increasing branching concentration, loses its stability and is amorphisized anisotropically, losing initially the order along the *b* axis and later, along the *a* axis. Also, the presentation covered the variation of the chain dynamics near branchings of various structures and possible changes in the properties of polymers due to branching.

A presentation by A.D. Pomogailo and G.I. Dzhardimalieva (both from ICPP, RAS) was focused on the frontal polymerization of metal-containing monomers, which was recommended for designing of nanocomposites. Based on a study of the thermolysis kinetics of the complexes of interest and evolutionary transformations of the released gaseous products, A.D. Pomogailo and G.I. Dzhardimalieva identified the nature of the initiating particles in such systems. They showed that the structural and the chemical, as well as the thermophysical, characteristics of polymerizing systems are of key importance in frontal polymerization of metal-containing monomers studied by them.

The controlled polymerization of olefins was discussed in a presentation by P.E. Matkovskii (ICPP) who participated in developing the scientific principles and designing the process implementation for preparation of 1-butene, 1,4-hexadiene, C_4–C_{30} higher linear α-olefins, 5-decene, 6-dodecene, 7-tetradecene, waxy polyethylene, higher mono- and polyakylaromatic hydrocarbons, oligomeric bases of unsaturated, hydrogenated, and aromatized synthetic oils of various designation, as well as of synthetic polyethylene composites.

1070-4272/04/7706-1036 © 2004 MAIK "Nauka/Interperiodica"

Lastly, S.L. Bazhenov from ISPM made a report devoted to mechanical failure of filled composites containing a polymer matrix, namely, upon stretching of composites based on a thermoplastic matrix and vulcanized rubber particles. In the case of plastic matrix-based composites, introduction of rubbers typically decreases the elongation at break. S.L. Bazhenov found that the failure of large vulcanized rubber particles yields so-called rhomboid fractures whose propagation is responsible for early failure of composites.

The Enikolopov Readings showed that the ideas advanced by Academician N.S. Enikolopov are being further developed and successfully implemented by his disciples and his disciples' disciples. The scientific school created by Nikolai Sergeevich has been working successfully in the field of preparation of new polymeric materials and composites, study of their properties, and application.

G.E. Zaikov and M.I. Artsis

Russian Journal of Applied Chemistry, Vol. 77, No. 6, 2004, p. 1038. Translated from Zhurnal Prikladnoi Khimii, Vol. 77, No. 6, 2004, p. 1051.

BOOK REVIEWS

V.M. Mukhin, V.V. Chebykin, E.A. Galkin, N.P. Vasil'ev, V.S. Medyanik, and A.N. Tamam'yan, *Aktivnye ugli. Elastichnye sorbenty. Katalizatory, osushiteli i khimicheskie poglotiteli na ikh osnove: katalog* (Active Carbons. Elastic Sorbents, Catalysts, Desiccants, and Chemical Adsorbents Thereof: Catalog), Mukhin, V.M., Ed., Moscow: Ruda i Metally, 2003, 280 pp.

Sorption technologies permit high degrees of purification and high quality of products under minimum energy and capital expenditures. By the present time, sorption materials have significantly grown in importance in industrial pollution abatement. Recent developments in the production of sorption-active materials are successfully applied in industrial and hygienic purification of gases; potable water purification and production of filters for exhaustive treatment of potable water; wastewater treatment; soil protection against residual pesticides and crop yield enhancement; and recovery of precious and rare metals from dilute solutions.

We brought to readers' notice a catalog summarizing the information about the major sorption-active materials commercially produced in Russia. The catalog has five sections, of which Section 1 (pp. 17–152) holds the central position. It is focused on active carbons and has the following subsections: active carbons for gas and vapor adsorption; active carbons for adsorption from liquid media; active carbons for soil treatment; and medical active carbons. Each brand of these active carbons is characterized by its specific preparation procedure, application field, physicochemical properties (as specified by the acting technical specifications), and manufacturer. On the whole, Section 1 covers 79 brands of active carbons.

Section 2 (pp. 153–168) concerns commercial elastic adsorbents and catalysts thereof. Elastic adsorbents rank among the today's most promising technically important materials. Fibrous structure of elastic adsorbents makes them suitable for manufacturing of tapes, fabrics, threads, and fibers. This offers a wide scope for diversified implementation of the corresponding processes. Fibrous materials can be additionally endowed with chemisorptive and catalytic powers.

Section 3 (pp. 169–248) is focused on active carbons suitable as supports for catalysts, desiccants, and chemical adsorbents; these are active carbons with developed macro- and mesopores. Catalysts, most often metal oxides, are fixed on the carbon surface by impregnation with appropriate salts, followed by heat treatment at 110–150°C. Desiccants are active carbons impregnated with hydrophilic salts such as calcium chloride, lithium chloride, or lithium bromide. Presently, three brands of desiccants are manufactured; they are most widely used in facilities for respiratory tract protection against carbon monoxide. Active carbon-based chemical adsorbents (23 brands) are used for removal of aggressive or toxic substances from air; the adsorption is accompanied by a chemical reaction. Adsorbents are used in apparatus for treatment of air and gases without regeneration of the substances sorbed.

Small Section 4 (pp. 249–253) is devoted to reactivation of spent active carbons. Active carbons are produced in the largest volume among sorption-active materials, and their reactivation is of great interest. Presently, two brands of reactivated carbons are manufactured commercially.

Lastly, Section 5 (pp. 254–269) contains information about carbon materials used in production of active carbons or those prepared from raw materials for production of active carbons.

This well-designed catalog comprises both Russian and English versions. This handbook will certainly be of use for those specializing in various applications of sorption-active materials.

A.G. Morachevskii and I.N. Beloglazov

Russian Journal of Applied Chemistry, Vol. 77, No. 6, 2004, p. 1039. Translated from Zhurnal Prikladnoi Khimii, Vol. 77, No. 6, 2004, p. 1052.

BOOK REVIEWS

V. D. Risovannyi, A. V. Zakharov, E. P. Klochkov, and T. M. Guseva, *Bor v yadernoi tekhnike* (Boron in Nuclear Engineering) Dimitrovgrad: Nauchno-Issled. Inst. Atomnykh Reaktorov, 2003.

The monograph *Bor v yadernoi tekhnike* (Boron in Nuclear Engineering) prepared by a group of scientists from the Research Institute of Atomic Reactors, State Scientific Center, Federal State Unitary Enterprise, is the first attempt in the Russian-language literature to analyze in detail the physicomechanical, nuclear, and radiation properties of boron carbide, metal borides, boron-based dispersion materials, and boron steels and alloys, i.e., all boron-containing materials used in manufacturing of atomic reactors. Among these materials, the most widely used in the world practice of reactor engineering is boron carbide with different degrees of enrichment in ^{10}B. Also, some other ^{10}B-containing materials are used as neutron absorbers, namely, boron steels and alloys and boric acid introduced into heat carriers.

Boron steels (with 2–3 wt % boron) are used in nuclear shields for storage and transportation of spent fuel assemblies from atomic reactors and in biological protecting shields. The monograph emphasizes the promise of refractory boron compounds like europium haxaboride EuB_6 and hafnium diboride HfB_2, which contain several absorbing isotopes.

The monograph consists of an introduction, eight chapters, and bibliography with 235 items from Russian and foreign literature.

The Introduction (pp. 6–10) briefly summarizes the problems associated with the use of boron and its compounds in nuclear engineering. A small Chapter 1 (pp. 11–29) presents evidence concerning various absorbing materials, as well as the selection criteria and the extent of their use. Chapter 2 (pp. 30–176), which holds the central position in the monograph, is focused on boron carbide and, in particular, on preparation of boron carbide and articles thereof, as well as on the physical, chemical, and mechanical properties of boron carbide, its structure and compatibility with other structural materials. Special attention is given to radiation resistance of boron carbide. Chapters 3 (pp. 177–192), 4 (pp. 193–211), and 5 (pp. 212–219) concern other boron-containing compositions, namely, boron steels, metal borides, and boron-containing dispersion absorbers. Chapter 6 (pp. 220–281) describes the major designs of control facilities manufactured from the above-mentioned materials and applied in Russian and foreign atomic reactor engineering. It should be emphasized that this monograph is the first attempt to summarise this kind of information. Chapter 7 (pp. 282–297) discusses an important problem of regeneration and reuse of boron carbide. Lastly, Chapter 8 (pp. 298–320) briefly summarizes a wide range of problems concerned with boron applications in other fields of nuclear engineering.

This monograph is intended, above all, for scientists and technical engineers engaged in designing and exploitation of atomic reactors. However, it will be also of interest for those specializing in inorganic materials science and chemistry of boron and its compounds. The monograph is written in a good language, without excessive use of special terminology, which increases the number of its potential readers.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation of Titanium-Containing Sulfuric Acid Solutions

Abstract—The influence exerted by fluorine-containing agents introduced into nitric acid in leaching of calcium oxide from the sphene concentrate on the possibility of performing the process under atmospheric pressure to obtain titanium dioxide of anatase structure in the solid residue was examined. The sulfatization of the titanium–silica product obtained in nitric acid breakdown of the sphene concentrate and aqueous leaching of titanium sulfates from the forming cakes were studied.

The sphene concentrate manufactured on a semicommercial scale [TU (Technical Specification) 1715-069-00 203 938–2000] in dressing of complex ores from the Khibiny deposit[1] contains no less than 37 wt % TiO_2. Its industrial manufacture is hindered by the lack of an efficient technology for manufacturing titanium products of commercial value.

Sulfuric acid methods considered in detail in [1] gave no way of developing an efficient technology that could be used to produce pigment-grade TiO_2 from the sphene concentrate because of a number of inherent disadvantages. The most important of these are the high acid number (mass ratio of H_2SO_4 to TiO_2) of the resulting sulfate solutions of titanium(IV), which makes impossible direct hydrolytic precipitation of metatitanic acid, and the complexity of the necessary equipment. The increased content of TiO_2 (3–5 wt %) in the calcium silicate cake obtained in sulfuric acid treatment of the sphene concentrate predetermines the low recovery of titanium(IV) into a sulfate solution [1]. Despite many years' efforts, the titanium–calcium and titanium–silicate pigments produced by this technology failed to find use, and their semicommercial manufacture was terminated.

As the production of the sphene concentrate can be raised manyfold, it is of interest to develop an efficient technology for manufacture of high-quality titanium products from the concentrate.

One of the reasons for such a low recovery of titanium(IV) into a sulfate solution is the formation of $CaSO_4$, which forms with SiO_2 a composite that blocks the access of H_2SO_4 to sphene particles. Attempts have been made to tackle with this difficulty by preliminary leaching of CaO with nitric acid solutions.

It has been assumed [2] that sphene can be decomposed only with concentrated HNO_3 taken in a considerable excess with respect to the stoichiometrically necessary amount at a temperature of no less than 130°C, which made necessary, as seen from Table 1, use of an autoclave equipment [3]. In this case, the titanium–silica product obtained, as shown by the studies, consisted of a mixture of TiO_2 of mainly rutile modification with SiO_2 and, in fact, was artificial leucoxene, whose TiO_2 very difficultly reacts with H_2SO_4 [4].

As is known [5], HNO_3 salts-out $Ca(NO_3)_2$, which has been disregarded in previous studies of the nitric acid decomposition of the sphene concentrate [2]. Using an excess amount of concentrated HNO_3 created a situation when the concentration of the forming $Ca(NO_3)_2$ exceeded its solubility in a nitric acid solution. This made impossible complete decomposition of the sphene concentrate. Raising the temperature leads to an increase in the solubility of $Ca(NO_3)_2$ in HNO_3 solutions [5]. Therefore, when an excess amount of concentrated HNO_3 was used, it was necessary to carry out the process at an elevated temperature and, as a result, at a higher pressure.

It was of interest to study how the sphene concentrate reacts with nitric acid solutions of medium concentrations.

The sulfating of the titanium–silica product obtained in nitric acid breakdown of the sphene concentrate has not been studied yet. The titanium–silica

product has a composition close to that of the natural leucoxene concentrate. However, TiO_2 of rutile modification, which is contained in the leucoxene concentrate, reacts sufficiently completely only with a large excess of concentrated H_2SO_4 at high temperatures of 250–300°C [6] close to the boiling point of the acid. Therefore, sulfuric acid technologies for its processing proved to be inefficient and it was of interest to study the possibility of obtaining TiO_2 in more readily broken down modifications, rather than in the rutile modification, and to analyze conditions for conversion of TiO_2 into a sulfate solution that can be used to manufacture pigment-grade TiO_2. As is known, solutions of this kind must have an acid number *K* not exceeding 2.0–2.2, contain no less than 220–240 g l^{-1} TiO_2, and be stable against hydrolytic decomposition (characterized by the stability factor K_s, which should be no less than 500) [7].

EXPERIMENTAL

The following chemicals were used in the study: purified sphene concentrate containing (wt %): 38.5 TiO_2, 27.3 CaO, 25.0 SiO_2, 1.18 Ln_2O_3, 1.21 Fe_2O_3, and 0.27 Al_2O_3; concentrated acids of pure grade: HNO_3 (68.1 wt %), HF (44 wt %), or H_2SiF_6 (45 wt %). The consumption of HNO_3 was determined from the equation

$$CaTiSiO_5 + 2HNO_3 \rightarrow Ca(NO_3)_2 + TiO_2(H_2O)SiO_2. \quad (1)$$

In addition to calcium ions, ions of lanthanides, iron, and aluminum may also pass into solution:

$$Ln_2O_3 + 6HNO_3 \rightarrow 2Ln(NO_3)_3 + 3H_2O, \quad (2)$$

$$Fe_2O_3 + 6HNO_3 \rightarrow 2Fe(NO_3)_3 + 3H_2O, \quad (3)$$

$$Al_2O_3 + 6HNO_3 \rightarrow 2Al(NO_3)_3 + 3H_2O. \quad (4)$$

The mineral was decomposed using HNO_3 taken in a 20% excess with respect to the amount stoichiometrically necessary for reaction (1), which was also sufficient for transferring into solution the concomitant compounds of lanthanides, iron, and aluminum. The expenditure of fluorine-containing acids in the experiments was varied from 0 to 1.0 mol F^-/mol TiO_2.

The concentrate was decomposed at 105–150°C in hermetically sealed containers placed, during the experiment, in a rotating furnace (autoclave breakdown) or in a temperature-controlled laboratory reactor with a reflux (breakdown under atmospheric pressure). The time of thermal treatment was 6 h. After cooling to 20–30°C, the slurry was filtered on a Büchner funnel, and the precipitate was washed with distilled water at s : l = 1 : (3–5) and dried at 100°C. The efficiency of the process was evaluated by the average rate of leaching of CaO into solution, V_{CaO} (M s^{-1}), and the extent of its recovery into solution, Q_{CaO} (wt %). The kinetics of leaching was monitored by sampling the solution and analyzing the samples taken at regular intervals of time.

The distribution of calcium, titanium, lanthanide, iron, aluminum, and fluorine atoms among the solution and precipitate, as well as the relative amounts of the rutile and anatase forms of titanium oxide in the titanium–silica products, were studied. The content of the elements (in terms of the corresponding oxides) was determined by the known methods of chemical and spectral analyses, and also by flame photometry. Solid precipitates were additionally subjected to X-ray phase analysis on a DRON-2 diffractometer.

Table 2 shows that the rate of CaO leaching from

sphene in the autoclave process grows as temperature is increased and the content of HNO_3 decreased in the range 68–25 wt %.

For example, reaching 89.6% recovery of CaO into solution with 68% HNO_3 requires that the temperature should be 150°C. In this case, the rate of CaO leaching from the concentrate into a nitric acid solution increases from 0.42×10^{-4} to 2.54×10^{-4} mol l^{-1} s^{-1}. At the same time, a deeper recovery of 96.2 wt % at a comparable rate of 2.32×10^{-4} mol l^{-1} s^{-1} can be achieved with 25% HNO_3 at 120°C. In this case, the pressure in the apparatus decreases from 0.243 to 0.167 MPa. The residual content of HNO_3 in the corresponding mother liquor does not exceed 4 wt %, which leads to a high solubility of $Ca(NO_3)_2$ in this solution [5]. The dependence of the CaO recovery on the HNO_3 concentration has an extremum, which is due to a decrease in the activity of the acid at its concentrations lower than 25 wt %.

An X-ray phase analysis of the solid residues demonstrated that both the rutile and anatase phases may exist in the titanium–silica product. Their relative amounts depend on the process temperature. As the content of HNO_3 is lowered from 50 to 25 wt %, which, simultaneously, makes it possible to lower the temperature of sphene decomposition from 150 to 120°C, the fraction of the anatase TiO_2 phase in the titanium–silica product increases from 26 to 60 wt % [8].

The formation of crystalline phases of TiO_2 (in contrast to amorphous SiO_2) in the titanium–silica product strongly suggests that, in the course of nitric acid decomposition of the sphene concentrate, there occurs not only substitution of the calcium cation with the hydroxonium cation, but also dissolution of TiO_2 to form a rather unstable nitrate compound of titanium that is readily hydrolyzed under these conditions. The precipitation of titanium(IV) from solution gives rise to growth of TiO_2 crystals of various modifications. The possibility of obtaining TiO_2 directly in the form of rutile or anatase by hydrolysis of nitrate solutions of titanium(IV) has been reported previously [9].

Introduction of fluoride ions into the nitric acid solutions used in leaching intensifies the decomposition of the sphene concentrate to an even greater extent. When 68% HNO_3 was used at 120°C, the introduction of 0.2 mol F^-/mol TiO_2 leads to a more than threefold increase in the degree of decomposition, but was insufficient. However, raising the amount of fluoride ions added to 0.8 mol F^-/mol TiO_2 had no effect, because further decomposition was made impossible by the saturation of the $Ca(NO_3)_2$ solution. The introduction of fluorine compounds in an amount equal to, or exceeding 0.2 mol F^-/mol TiO_2 into a solution containing 26 wt % HNO_3 ensured >92.5% recovery of CaO at 105°C and an average rate of the process of 2.23×10^{-4} mol l^{-1} s^{-1}. Hence followed that the process can be performed under atmospheric pressure, and this conclusion was confirmed in experiments on decomposition of the sphene concentrate in a reactor with a reflux (Table 3).

It was found that raising the concentration of fluorine compounds leads not only to an increase in the efficiency of the decomposition process (Table 2), but also to preferential formation of the anatase form of TiO_2, which is virtually complete upon introduction of >0.4 mol F^-/mol TiO_2 (this follows from the X-ray diffraction patterns in Fig. 1). Comparison of the intensities of the characteristic peaks corresponding to the interplanar spacings of rutile and anatase (3.24 and 3.52 Å, respectively) shows that formation of the anatase modification of TiO_2 is favored by lower temperatures and higher concentrations of fluoride ions.

The absence of any differences in the course of the process between the cases when HF and H_2SiF_6 with comparable amounts of fluoride ions are used indirectly points to the following. In nitric acid solutions at a high temperature (>105°C), the hydrolysis of SiF_6^{2-}

and TiF_6^{2-} ions by overall reaction (5) is stronger than at lower temperatures:

$$MF_6^{2-} + (2 + n)H_2O \rightarrow MO_2 \cdot nH_2O + 4H^+ + 6F^-. \quad (5)$$

The room-temperature equilibrium constant of this reaction for the SiF_6^{2-} ion, found to be 10^{-27}–10^{-28} [10], indicates that fluoride ions are formed via hydrolysis of SiF_6^{2-} in nitric acid solutions at room temperature in noticeable concentrations [11]. Raising the temperature must shift the equilibrium of reaction (5) to the right to an even greater extent.

Fluoride ions from solutions react with hydrated SiO_2 and, possibly, with titanium(IV) of the titanium–silica product after leaching of calcium(II); the forming complex fluoride anions pass into solution. At elevated temperatures, they are hydrolyzed in a nitric acid solution of medium concentration, with fluoride ions released in the process continuing to disintegrate the titanium–silica framework. When the breakdown process is complete and the solution is cooled, the main part of fluoride ions is captured by the titanium–silica product, with less than 7% of the introduced fluoride ions remaining in solution.

The kinetic curve that describes the rate of transfer of CaO into solution at 105°C is linear in the coordinates of the following first-order reaction (Fig. 2):

$$\ln c_{CaO} = \ln c_{CaO}^0 - k\tau, \quad (6)$$

where c_{CaO} and c_{CaO}^0 are the initial and running concentrations of the starting substance, and k is the effective rate constant of dissolution by reaction (1) (mol l^{-1} s^{-1}).

The slope of this straight line is equal to the rate constant of reaction (1):

$$k = \tan\alpha = 1.63 \times 10^{-4}. \quad (7)$$

Nitrates of lanthanides, iron, and, to a lesser extent, aluminum pass into a nitric acid solution together with calcium(II). The insufficiently good recovery of aluminum into solution is presumably due to the presence in solution of admixtures of accessory feldspars, and primarily albite, which are stable in nitric acid media. In the absence of fluoride ions, lanthanides(III) as well as iron(III) pass into solution to a greater extent, but their recovery falls as the content of fluoride ions in solution increases (Table 3). In the case of lanthanides(III), the possible reason is the formation of their sparingly soluble fluorides in the presence of an excess amount of fluoride ions.

Under the conditions of nitric acid decomposition of the sphene concentrate, compounds of titanium and silicon remain virtually completely in the solid phase: their concentration in the nitric acid solution does not exceed 0.08 and 0.07 g l^{-1} for TiO_2 and SiO_2, respectively. Their recovery into the liquid phase free of fluorine-containing additives does not exceed 0.05–0.07%. Upon introduction of fluoride ions, compounds of titanium and silicon pass into solution in greater amounts (wt %): 0.42 TiO_2 and 1.77 SiO_2 at 0.5 mol F^-/mol TiO_2. The probable reason is that the forming fluorine-containing complex anions of silicon(IV) and titanium(IV) are preserved in solution. The complexes are more soluble in nitric acid solutions than TiO_2 and SiO_2.

The experimental results show that using 25% HNO_3 with the optimal addition of fluorine compounds in an amount of 0.3 mol F^-/mol TiO_2 ensures recovery of ions of calcium, rare-earth elements, and iron into solution. The high recovery of lanthanides gives reason to believe that they can be concentrated by using in breakdown procedures recovered HNO_3, which can be obtained by treating $Ca(NO_3)_2$ solutions with concentrated H_2SO_4. The recovery of the most part of iron ions into solution simplifies the subsequent manufacture of high-quality titanium compounds from the titanium–silica product.

Nitric acid decomposition of the sphene concentrate under the optimal conditions gives nitrate solutions of $Ca(NO_3)_2$ that contain, in terms of oxides, (g l^{-1}): 120 CaO, <0.5 TiO_2, <0.5 SiO_2, <5.30 Ln_2O_3, <1.5 Fe_2O_3, <0.70 Al_2O_3, <1.2 F, and 20–40 HNO_3, and also a titanium–silica product containing (wt %): 48 TiO_2, 37 SiO_2, 0.56–3.00 CaO, <0.018 Ln_2O_3, <0.64 Fe_2O_3, <0.25 Al_2O_3, <2.2 F^-, and 3.60 NO_3^-. The main part of fluoride ions find way into the titanium–silica product. The calcination loss of the titanium–silica product is about 15 wt %, which somewhat exceeds the value calculated on the assumption that

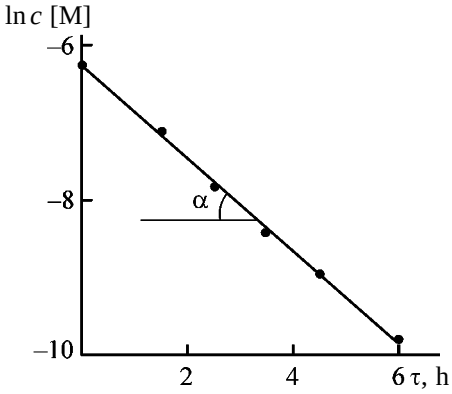

Fig. 2. CaO concentration in the sphene concentrate vs. the time τ of leaching at 105°C.

the amount of chemically bound water in the product is determined by reaction (1). The possible reason is that titanium(IV) is present in the titanium–silica product not only as anatase and(or) rutile, but, in part, also in the amorphous hydrated form.

The sulfatization was studied for the titanium–silica product obtained by leaching of the sphene concentrate with HNO_3 solutions with addition of fluorine-containing compounds (HF, H_2SiF_6) in an amount of 0.25 mol F^-/mol TiO_2. In the product, TiO_2 was present, according to X-ray phase analysis, in the anatase form. Such a product contained (wt %): 46.9–48.8 TiO_2, 34.5–37.4 SiO_2, 0.56–3.30 CaO, 0.003–0.180 TR_2O_3, 0.64 Fe_2O_3, 0.25 Al_2O_3, <2.20 F^-, and <3.69 NO_3^-. The calcination loss was 15–18 wt %. For comparison, some experiments were performed with a product obtained by nitric acid decomposition of the sphene concentrate at 120–130°C without addition of fluorine compounds. The product differed only in that it contained a part of TiO_2 in the rutile modification.

The titanium–silica product was decomposed with concentrated H_2SO_4 of pure grade [GOST (State Standard) 2184–77], from which the working solutions were prepared by dilution with distilled water.

The sulfatization (sintering of a weighed portion of the titanium–silica product with H_2SO_4) was performed by heating the reaction mixture to a prescribed temperature in sealed fluoroplastic containers for 1–5 h. The concentration of H_2SO_4 was varied from 22 to 94%, and the expenditure of the acid was within the range 1.6–2.2 kg kg^{-1} TiO_2. The cake was leached with water under continuous agitation. The sulfatization temperature was varied from 105 to 180°C; the leaching was performed at 50°C. The cooled slurry was filtered, and the precipitate (silica cake) was washed with distilled water.

The content of titanium, silicon, calcium, fluorine,

and iron in the solutions and dry residues was determined. The amount of titanium(IV) that passed into the aqueous phase (filtrate, washing water) and(or) its residual content in the silica cake was used to calculate the recovery of titanium(IV), Q (%), from the titanium–silica product, which served as a measure of the efficiency of the processes under study.

The efficiency of sulfatization was evaluated by the extent to which titanium(IV) passed into an aqueous solution after 3 h of leaching of a sample. As established in preliminary experiments, this time is sufficient for the transfer of the most part of titanium(IV). Figure 3 shows the kinetics of sulfatization at 150°C of a titanium–silica product containing 40% of TiO_2 in the anatase modification, and 60%, in the rutile modification (curve *1*) and of precipitates containing only the anatase phase of TiO_2 (curves *2*, *3*). The sulfatization was carried out with 56 and 77% solutions of H_2SO_4 at its expenditure of 2 kg kg^{-1} TiO_2.

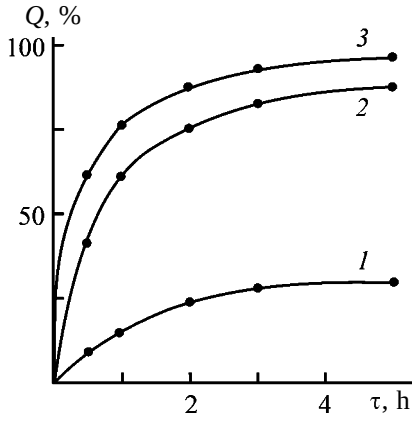

Fig. 3. Recovery Q of titanium(IV) from the titanium–silica product at 150°C vs. the duration τ of sulfatization of the titanium–silica product. Content of rutile in the titanium–silica product (wt %): (*1*) 60 and (*2*, *3*) 0. Content of H_2SO_4 (wt %): (*1*, *3*) 77 and (*2*) 56.

Figure 3 shows that the efficiency of the process depends on the concentration of H_2SO_4 and on the crystal structure of TiO_2. The amount of titanium(IV) that passed into solution from a titanium–silica product containing TiO_2 of anatase structure in 5 h was 87 and 96% depending on H_2SO_4 concentration, whereas the recovery of titanium(IV) from a rutile-containing product did not exceed 30% relative to its initial content. An X-ray phase analysis of the residue obtained after leaching of a sulfatized rutile-containing titanium–silica product revealed only TiO_2 of rutile structure, which, as demonstrated by further investigation, reacted with H_2SO_4 only at temperatures not lower than 180°C.

Thus, a study of the sulfatization kinetics of a titanium–silica product that contained TiO_2 in the anatase phase revealed the following process advantages over

the known methods [4, 6, 12, 13]: relatively low sulfatization temperature, lower expenditure of H_2SO_4, and shorter duration of the process.

The dependence of the recovery of titanium from the titanium–silica product on the concentration and expenditure of H_2SO_4 was studied (Table 4). The range in which the expenditure of the acid was varied was chosen in such a way that an acid factor close to 2 was obtained in leaching of titanium(IV) into an aqueous solution. The reaction mass (liquid suspension at H_2SO_4 concentrations lower than 57% and increasingly thick paste at higher concentration) was heated at required temperature in closed vessels to diminish evaporation of water in the course of sulfatization. The duration of heat treatment was 5 h; the sulfatization temperature was equal to, or lower than the boiling point of H_2SO_4 of a concentration used.

Also noteworthy is a steep rise in the efficiency of the process on raising the concentration of H_2SO_4 within the range 50–60 wt % (Table 4, run nos. 10, 11; 13, 14; 18, 19; Fig. 4). The most efficient is 80–94 wt % H_2SO_4, because it is within this concentration range that water-soluble $TiOSO_4 \cdot H_2O$ is formed [1]. The expenditure of H_2SO_4 within the limits studied does not affect significantly the completeness of the sulfatization process.

The sulfatized cake, which is mainly a mixture of titanium(IV) sulfates and hydrated SiO_2, was studied by thermal analysis and methods of crystal optics.

Figure 5 shows thermograms of cakes obtained at expenditure of 94% H_2SO_4 equal to 1.4, 1.6, and 1.8 kg kg^{-1} TiO_2.

The absence of exothermic effects at 540 and 590°C, which are commonly attributed [14] to thermal decomposition of $TiOSO_4 \cdot 2H_2O$, suggests that it is not contained in noticeable amounts in the cakes obtained. The endothermic effects at 380 and 426°C can be attributed to removal of water from $TiOSO_4 \cdot 2H_2O$, which, according to [9, 14], begins above 300°C. The endothermic effects at 600 and 683–700°C are associated with elimination of SO_3 to give TiO_2. The endothermic effects at 164–202°C are presumably due to removal of water from hydrated SiO_2 present in the cake.

Crystal-optic studies of the cakes demonstrated that they are composed of a finely dispersed amorphous powder (hydrated SiO_2) and crystalline phases. The main part of the crystalline phase consists of birefringent crystals with refractive indices N_g = 1.839 and N_p = 1.702, $TiOSO_4 \cdot 2H_2O$. Also, a minor amount of rhombic $TiOSO_4$ crystals with refractive indices N_g = 1.709 and N_p = 1.628 is observed.

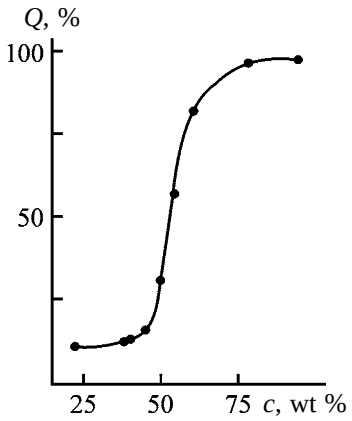

Fig. 4. Recovery Q of titanium(IV) from the titanium–silica product vs. the concentration c of sulfuric acid.

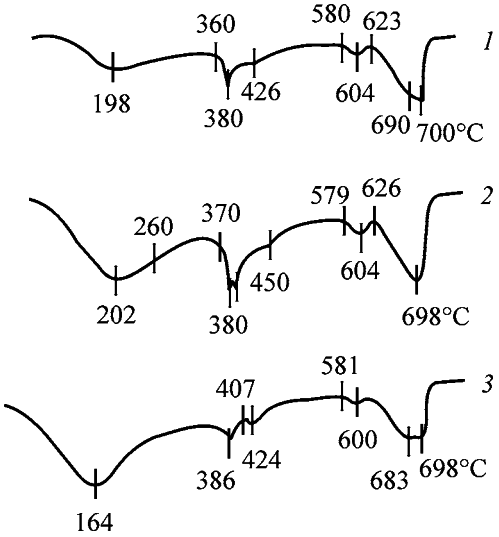

Fig. 5. Thermograms of products formed in sulfatization of the titanium–silica product. Expenditure of H_2SO_4 (kg kg^{-1} TiO_2): (*1*) 1.4, (*2*) 1.6, and (*3*) 1.8.

When the concentration of H_2SO_4 was lowered and its expenditure raised to more than 1.6 kg kg^{-1} TiO_2, the stock was flowing and thermal treatment yielded monolithic, very strong cakes, which virtually could not be removed mechanically from the reaction vessel. The reason for such a morphology of the cakes was presumably that $TiOSO_4 \cdot 2H_2O$ forming in the course of synthesis first dissolved in the excess amount of water contained in the stock and then crystallized to give a very strong composite with hydrated SiO_2. It was established that, when 80–94% H_2SO_4 was used and the acid number was, respectively, 1.6 and 1.8, the starting stock could be prepared in the form of briquettes which retained their shape even in the course of thermal treatment. The cake formed in this case was fragile and could be readily removed from the apparatus. To achieve a high degree of sulfatization of titani-

* Obtained in counterflow leaching.

um(IV), the stock was preliminarily thoroughly mixed. Otherwise, the recovery of TiO_2 into solution decreased to 92.0% when working with heavier weighed portions.

Table 5 lists typical compositions of the products obtained in leaching of titanium(IV) from a sulfatized titanium–silica product, as well as the values of K and K_s for sulfuric acid titanium-containing solutions. The concentration of titanium(IV) in an aqueous solution depends on the relationship between the mass of the cake and the volume of water. After the first stage of leaching, the moist precipitate contained about 20% titanium(IV), which was extracted by subsequent washing by repulpation on a filter. When a larger volume of water was taken in the stage of leaching, the concentration of titanium(IV) decreased, and when, by contrast, this volume was made smaller, the recovery of titanium(IV) declined. For example, when the s : l ratio was changed from 1 : 2 to 1 : 1.5 and 1 : 1.0, the recovery of titanium into the aqueous phase decreased, all other conditions being the same, from 86.7 to 81.2 and 75.8%, respectively. With water and s : l ≈ 1 : 1.5, solutions with 160–206 g l^{-1} of TiO_2 were obtained. A counterflow leaching (three stages) made it even possible to raise the concentration of titanium(IV) to 342 g l^{-1} of TiO_2 without performing the commonly used vacuum evaporation. The values of K in the solutions were in the range 1.6–2.0, and those of K_s, 850–1500, which well satisfies the requirements to thermohydrolysis conditions.

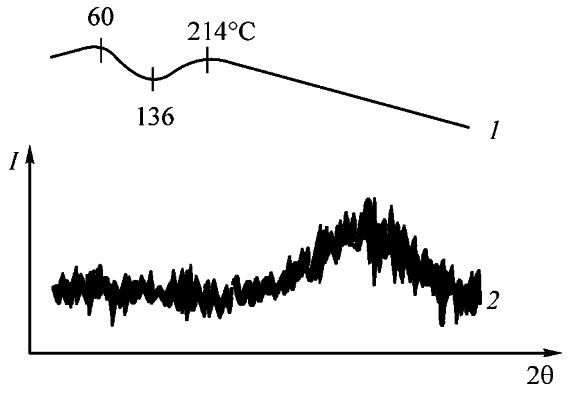

Fig. 6. (*1*) Thermogram and (*2*) X-ray diffraction pattern of a silica cake obtained by leaching of titanium(IV) from a sulfatized titanium–silica product.

Virtually 100% of SiO_2, about 20% of fluoride ions, and less than 5% of iron ions (all relative to the initial amount) remain in the silica cake after sulfatization and leaching. The X-ray diffraction pattern and thermogram shown in Fig. 6 indicate that the product is amorphous and contains SiO_2 as the main phase. 92–98% of titanium(IV) and 90–95% of iron(III) contained in the titanium–silica product are accumulated in the titanium solution.

Compared to the data of [4, 9, 12–15], where the mass ratio Fe_2O_3/TiO_2 in sulfuric acid titanium-containing solutions further subjected to thermohydrolysis was 0.07–0.10, processing of the sphene concentrate yields solution with a smaller ratio, equal to 0.012–0.022.

Thus, the technology being developed can yield sufficiently pure intermediate products, sulfuric acid solutions of $TiOSO_4$ and silica cake.

Under the optimal conditions, the silica cake contains (wt %): 75–80 SiO_2, 3.4 TiO_2, 1.0–1.2 CaO, 1.0–2.0 F, 0.05–0.08 Fe_2O_3, <0.007 TR_2O_3, and water the rest.

The sulfuric acid solutions of $TiOSO_4$, which are distinguished by high stability, contain (g l^{-1}): 160–340 TiO_2, 280–570 H_2SO_4, 1.6–5.6 CaO, 4.4–7.7 F, 1.7–7.4 Fe_2O_3, <0.05 SiO_2, and <0.20 TR_2O_3.

A study of thermohydrolytic precipitation of titanium(IV) from solutions of this kind demonstrated that fluoride ions present in the solutions have no effect on the course of the process and mainly remain in the hydrolytic H_2SO_4. The amount of titanium(IV) that passed into solution was 95.3–95.4%. If reduction of Fe^{3+} to Fe^{2+} was not carried out, the content of Fe_2O_3 in calcined TiO_2 was 0.09–0.11 wt %.

CONCLUSIONS

(1) It was established that HNO_3 solutions with a concentration of 25 wt %, which contain fluorine compounds (HF or H_2SiF_6), effectively leach CaO from the sphene concentrate at 105°C under atmospheric pressure. The titanium–silica product obtained in the process may contain TiO_2 of only anatase structure.

(2) In nitric acid decomposition of the sphene concentrate, up to 98 wt % of CaO, 86 wt % of Ln_2O_3, and 72 wt % of Fe_2O_3 are concentrated in the nitric acid solution, and no less than 99.5 wt % of titanium and silicon oxides find their way into the titanium–silica product, which contains about 48 wt % TiO_2 and 37 wt % SiO_2.

(3) The optimal mode of sulfatization of the titanium–silica product obtained in decomposition of the sphene concentrate with 25% HNO_3 containing fluorine compounds is as follows: process temperature 150°C and expenditure of concentrated (93.5 wt %) H_2SO_4 1.6–1.8 kg kg^{-1} of TiO_2 in the titanium–silica product. In leaching with water of the resulting brittle cake, the recovery of TiO_2 into the leaching solutions is 98%.

(4) To obtain concentrated solutions of $TiOSO_4$, which require no vacuum evaporation before performing the thermohydrolysis, it is necessary to carry out leaching with water in the counterflow mode. The resulting sulfate solutions are characterized by an acid number of 1.6–1.8 and a stability factor of 850–1500 and contain up to 340 g l^{-1} of TiO_2 at a mass ratio Fe_2O_3/TiO_2 = 0.012–0.022. Solutions of this kind can be used to obtain pigment-grade titanium dioxide and for other purposes.

Abstract—The possibility of processing nitric acid leaching solutions to obtain recovered nitric acid and gypsum with good binding properties was studied in order to develop a new technology for processing of the sphene concentrate.

Nitric acid breakdown of the sphene concentrate yields nitric acid solutions of calcium nitrate, in which up to 97% of the spent HNO_3 is concentrated [1].

In order to develop a technology for their processing, it is of interest to study the possibility of recovery of HNO_3 bound to calcium nitrate, for further use of the acid, by sulfuric acid precipitation of sparingly soluble calcium sulfates. Despite that the process of production of $CaSO_4$, including that from sulfuric acid solutions, has been described, it is impossible to predict the degree of hydration of $CaSO_4$ being precipitated in the process under study on the basis of published data. The composition, structure, dimensions, and shape of crystals, number of molecules of the crystallization water, and properties of the compounds depend in a complicated way on numerous factors: temperature conditions, medium, and presence and type of impurities [2–8], whereas the development of a new technology requires that the process parameters and characteristics of the products obtained should be specified.

Therefore, we studied stoichiometric [with respect to Ca(II)] processing of nitrate solutions obtained in breakdown of the sphene concentrate with concentrated H_2SO_4.

In this work we studied the solid phases isolated under comparable conditions from model and process nitric acid solutions of $Ca(NO_3)_2$ and analyzed the composition of solutions of recovered HNO_3. In addition, we examined the conditions under which high-quality binders can be obtained from $CaSO_4$-based precipitates.

No published data are available on the issues mentioned above, although such data would be of practical and theoretical interest.

EXPERIMENTAL

Calcium sulfate was precipitated with concentrated sulfuric acid (94 wt % H_2SO_4) of pure grade. The model solutions contained 300–900 g l^{-1} of $Ca(NO_3)_2$ and 0–250 g l^{-1} of HNO_3 in various relative amounts; the process solutions contained (g l^{-1}): $Ca(NO_3)_2$, 40 HNO_3, 2.9 TR_2O_3, less than 0.15 TiO_2 and SiO_2, 1.5 Fe_2O_3, 0.5 Al_2O_3, and 1.25 F^-.

To the initial model solution was added with stirring, under temperature control (50°C), H_2SO_4 in a stoichiometric [with respect to Ca(II)] amount in accordance with the reaction

$$Ca(NO_3)_2 + H_2SO_4 = CaSO_4 + 2HNO_3.$$

After 15 min (which was sufficient for the precipitation to be complete), the stirring and heating were terminated. The resulting suspension was filtered in a vacuum at 15–20°C, and the humid precipitate obtained was dehydrated in a desiccator. The precipitate of $CaSO_4$, obtained from process solutions by their treatment with 94% H_2SO_4 at acid expenditure close (90–95%) to the stoichiometric amount, was additionally washed on a filter with distilled water at s : l = 1 : (5–10).

The precipitates kept in a desiccator or dried in a vacuum oven at 54°C or in a drying oven at 60–104°C were subjected to thermogravimetric (TGA), chemical, and X-ray phase (XPA) analyses. The content of HNO_3 and calcium and sulfate ions in the filtrates and precipitates was determined. The mass of the dry salt

was used to calculate, on the basis of the established composition of the solid phase, the recovery Q_{Ca} (%) of Ca(II) into the precipitate. Similar calculations were carried out on the basis of a chemical analysis for Ca(II) and sulfate ions in the liquid phase. The discrepancy did not exceed 3%.

$CaSO_4$ samples obtained from process solutions with varied degree of washing (s : l), which were dried in a drying oven in a vacuum or under atmospheric pressure at temperatures of 100–104°C and contained $CaSO_4 \cdot 0.5H_2O$ with admixture of NO_3^-, were tested for conformity to the requirements of GOST (State Standard) 125 (Gypsum Binders. Technical Specifications). The normal thickness of the gypsum paste corresponded in all cases to a water–gypsum ratio (w/g) of 0.9, at which the setting time τ (min) and compression strength P (MPa) were determined.

A study of model systems demonstrated that the degree of hydration of $CaSO_4$ depends on the content of the main components in a solution being processed (Table 1).

The results of TGA and XPA (Table 1, Fig. 1), which are in rather good agreement, indicate that the degree of hydration of $CaSO_4$ being precipitated depends on the concentrations of both free HNO_3 and calcium ions. In all cases, the deposits have the form of a finely crystalline snow-white product. At low or initially zero acid concentrations, mainly anhydrite (anhydrous $CaSO_4$) crystallizes, which is indicated by the presence in the thermograms (Fig. 1, thermograms *1, 2*) of an endothermic effect at 92–95°C and by a set of basic characteristic reflections at 3.50,

2.85, 2.33, and 2.21 Å in the X-ray diffraction pattern. The second endothermic effect at 144–146°C suggests a certain low content of gypsum $CaSO_4 \cdot 2H_2O$ in the precipitate, which is not revealed by XPA because of insufficient sensitivity. As the acidity increases, γ-$CaSO_4$ becomes the main modification of the anhydrite according to XPA. The solid phase becomes also enriched in hemihydrate $CaSO_4 \cdot 0.5H_2O$, bassanite, which is evidenced by the second endothermic effect (Fig. 1, thermograms *4*, *5*) shifted to higher temperatures (185 and 192°C). XPA also reveals this compound (characteristic reflections at 6.00, 3.46, 3.00, 2.80, and 2.19 Å). It should be noted that the hemihydrate is formed in solutions with an initial acid number K [mol HNO_3/mol $Ca(NO_3)_2$] exceeding 0.5 (Table 1). The results obtained are in agreement with published data [6, 8].

In the system under study, gypsum $CaSO_4 \cdot 2H_2O$ precipitates as the predominant phase from concentrated solutions that contain more than 364 g l^{-1} of $Ca(NO_3)_2$. Thermogram *8* in Fig. 1 takes the canonical form [9].

Thus, products with different properties can be obtained by varying the composition of nitric acid solutions of $Ca(NO_3)_2$. When the acidity and(or) concentration of Ca(II) in solution was raised, a transition from formation of anhydrite $CaSO_4$, poorly soluble in aqueous solutions, to a more soluble hemihydrate $CaSO_4 \cdot 0.5H_2O$ and then to gypsum $CaSO_4 \cdot 2H_2O$, which is again poorly soluble, was observed. The presence of insignificant amounts of gypsum in the anhydrite phase, in contradiction with the observed tendency toward a rise in the degree of $CaSO_4$ hydration with the acidity and Ca(II) concentration increasing ($CaSO_4 \rightarrow CaSO_4 \cdot 0.5H_2O \rightarrow CaSO_4 \cdot 2H_2O$), can be attributed to high hygroscopicity of the compounds, which results in that they rapidly absorb atmospheric moisture and are hydrated [6, 8].

The process solutions differ in the content of $Ca(NO_3)_2$, HNO_3, and concomitant elements, depending on the conditions under which the sphene concentrate is leached and the titanium–silica product is washed. $CaSO_4$ was precipitated (Table 2) from these solutions also with concentrated H_2SO_4 (94 wt %) with an expenditure close (90–95%) to that required by the stoichiometry. Calcium sulfates obtained from these solutions also have the form of snow-white finely dispersed clotting precipitates. It should be noted that the main part of $CaSO_4$ crystallizes fast (in the course of approximately 10 min); however, the solutions separated from the precipitate are supersaturated with $CaSO_4$ and become turbid upon subsequent keeping because of the continuing precipitation of $CaSO_4$. In this case, the dilution of the starting solution because of the use of concentrated HNO_3 does not exceed 11%, and the $CaSO_4$ precipitate crystallizes in a nitric acid solution containing 266 to 366 g l^{-1} (23–31 wt %) HNO_3. It is known that it is at this concentration of HNO_3 that the solubility of $CaSO_4$ is the highest (2.0 wt % at room temperature), which may pose difficulties in recycling of the recovered acid.

In order to recover Ca(II) into the precipitate to the maximum possible extent, experiments with freezing out of the suspensions obtained and their filtration at –10°C were carried out. In this case, the residual concentration of Ca(II) in solution decreased from 10 to approximately 6 g l^{-1} of CaO, which affected the recovery of Ca(II) into the precipitate: it increased from 93.2 to 96.7%.

The filtrates obtained contain up to 346 g l^{-1} HNO_3. The concentration of impurity elements (titanium, silicon, iron, aluminum) was less than 1 g l^{-1} from the very beginning, and that of Ca(II) and sulfate ions can be minimized. The recovered HNO_3 contains (g l^{-1}): 266–346 HNO_3, 3.6–6.0 CaO, 6.0–10.0 SO_4^{2-}, 2.5 Ln_2O_3, <1.3 Fe_2O_3, <1.0 F, and <0.4 Al_2O_3. In the acid, ions of rare-earth elements, iron, and fluorine concentrate in amounts, relative to the initial content in the nitric acid solution, of up to (%): 95–98 Ln_2O_3, 96–99 Fe_2O_3, and 99.4 F^-.

Thus, stoichiometric precipitation of calcium sulfates from solutions obtained in breakdown of the sphene concentrate can yield HNO_3 solutions (~25 wt %) whose recycling into the stage of decomposition of the sphene concentrate is rather efficient, but leads to accumulation of ions of rare-earth elements, thorium, and iron in the liquid phase, and Ca(II) in the titanium-silica precipitate. Even though the recovered HNO_3 contains ions of iron, aluminum, lanthanides, and radionuclides in low concentrations, its repeated recycling may lead to their accumulation, which requires an additional purification stage.

It should be noted that the composition of the precipitates obtained from the process solutions differs from that of the precipitates formed in the model solutions under similar conditions. In stoichiometric sulfuric acid precipitation of Ca(II) at temperatures lower than 50°C, mainly $CaSO_4 \cdot 2H_2O$ is formed, which, in contrast to the model systems, contains no anhydrite $CaSO_4$. It may be assumed that impurity elements destabilize the anhydrite and catalyze it fast hydration.

Gypsum preserves its composition $CaSO_4 \cdot 2H_2O$ upon drying in a desiccator or in a vacuum oven at temperatures of up to 60°C. Precipitates kept in a drying oven at temperatures exceeding 100°C have the form of a hemihydrate of the composition $CaSO_4 \cdot 0.67H_2O$ or bassanite $CaSO_4 \cdot 0.5H_2O$ (Figs. 2, 3).

The results obtained in TGA of the resulting $CaSO_4 \cdot 2H_2O$ (20.83% loss of mass virtually coincides with the calculated value) indicate (Fig. 2) that, when temperature is elevated at a rate of 9 deg min^{-1}, loss of water starts to be observed at temperatures

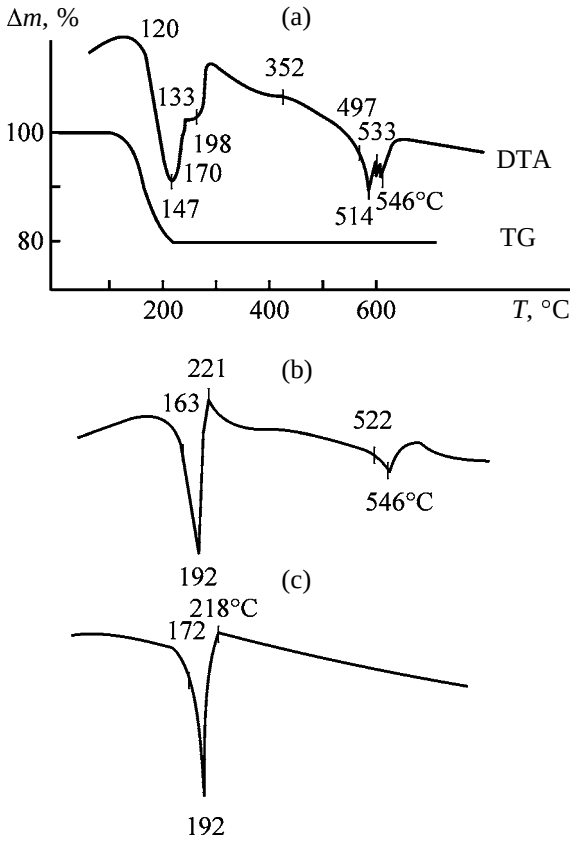

Fig. 2. Thermograms of samples precipitated from nitrate solutions obtained in decomposition of the sphene concentrate. (Δ*m*) Change in mass and (*T*) temperature. Sample: (a) $CaSO_4 \cdot 2H_2O$, (b) $CaSO_4 \cdot 2H_2O$ + $CaSO_4 \cdot 0.5H_2O$, and (c) $CaSO_4 \cdot 0.5H_2O$.

higher than 120°C. However, when subjected to prolonged thermostating, freshly precipitated $CaSO_4 \cdot 2H_2O$ starts to release water even at drying temperatures $T_{dr} \geq 60$°C, to be transformed into the hemihydrate $CaSO_4 \cdot 0.5H_2O$. A modification $CaSO_4 \cdot 0.67H_2O$ close to bassanite was also recorded.

The content of the main and impurity elements in the bassanite $CaSO_4 \cdot 0.5H_2O$ obtained is approximately as follows (wt %): 36.3 CaO, 65.5 SO_4^{2-}, 0.85 NO_3^-, 0.06 F^-, <0.04 Fe_2O_3, <0.20 Al_2O_3, 0.02–0.04 TR_2O_3, <0.01 $Nb(Ta)_2O_5$, <0.1 SiO_2, and 0.041 TiO_2. It should be noted that the recovery of iron and fluorine ions into the precipitate is low (1–3 and <0.55%, respectively), whereas aluminum(III) is distributed among the phases evenly. The low, on the whole, concentration (g l^{-1}) of impurity elements in the starting solution (1.5 Fe_2O_3, 0.5 Al_2O_3, 1.25 F^-) and washing of precipitates with water at s : l = 1 : (5–10) predetermine the high purity of the products obtained.

Table 3. Properties of dried gypsum precipitates based on $CaSO_4 \cdot 0.67H_2O$ and $CaSO_4 \cdot 0.5H_2O$

NO_3^-, wt %	Setting time, min		*P*, MPa			GOST 125	
	onset	end	2 h	1 day	7 days	brand	group

* Drying under atmospheric pressure.

Because $CaSO_4 \cdot 2H_2O$ is unsuitable for production of building articles, it was dried to obtain precipitates of $CaSO_4 \cdot 0.67H_2O$ and $CaSO_4 \cdot 0.5H_2O$, and the possibility of their use to manufacture gypsum binders was studied.

It was established that the precipitates (gypsums) studied can be divided into fast-hardening (A) and normally hardening (B) (Table 3). An increase in the content of NO_3^- in the starting precipitate leads to an improvement of the quality of the building plaster. A similar behavior is observed upon introduction of the above impurity into gypsums obtained from natural raw materials [9, 10]. The optimum content of nitrate ions is 0.9–2.8 wt %, which remains in the sulfates upon washing at s : l = 1 : (5–10). This gives fast-hardening gypsums of white color, which belong to group A. As the content of NO_3^- ions is raised further, the setting time increases and samples become cream-colored. It should be noted that a gypsum sample obtained upon dehydration of the starting $CaSO_4 \cdot 2H_2O$ in a drying oven under atmospheric pressure was found to be substandard because of its exceedingly short setting time and low strength.

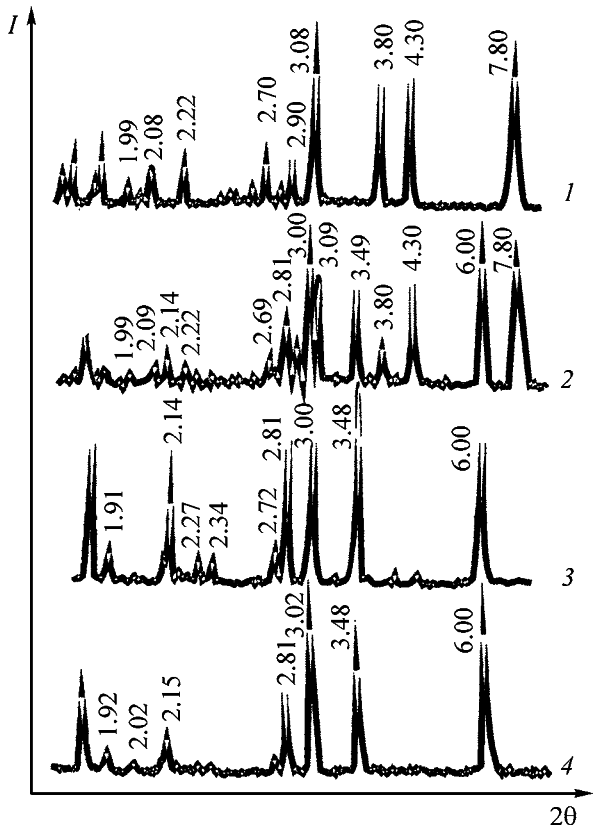

Fig. 3. X-ray diffraction patterns of samples precipitated from nitrate solutions obtained in decomposition of the sphene concentrate. (*I*) Intensity and (2θ) Bragg angle. Sample: (*1*) $CaSO_4 \cdot 2H_2O$, (*2*) $CaSO_4 \cdot 2H_2O$ + $CaSO_4 \cdot 0.5H_2O$, (*3*) $CaSO_4 \cdot 0.67H_2O$, and (*4*) $CaSO_4 \cdot 0.5H_2O$. Interplanar spacing are given in Å.

In their compression strength, setting times, and fineness of grinding, the gypsums correspond to brands G-2AIII, G-4BIII, and G-5BIII. The additionally measured strength of samples dried at 60°C to constant weight after 1 and 7 days of hardening demonstrated that their strength increased upon drying, which is particularly important in fabrication of gypsum articles [10]. As regards the whole set of their properties, gypsums manufactured from precipitates can be used for plastering and manufacture of building articles of any type.

CONCLUSIONS

(1) It was established that mainly $CaSO_4 \cdot 2H_2O$, which, in contrast to the case of model systems, contains no anhydrite $CaSO_4$, is formed in stoichiometric precipitation of calcium(II) from nitric acid solutions formed in nitric acid–fluoride breakdown of the sphene concentrate.

(2) Gypsums obtained on the basis of $CaSO_4 \cdot 0.67H_2O$ and $CaSO_4 \cdot 0.5H_2O$, products formed in vacuum drying of $CaSO_4 \cdot 2H_2O$, correspond to brands G-2AIII, G-2BIII, and G-5BIII and can find wide use in the building industry.

(3) Recovered nitric acid contains 266–346 g l^{-1} of the main substance (HNO_3) and concentrates rare-earth elements to 98% of their initial content, which may lead in repeated recycling to their pronounced accumulation for subsequent recovery into a separate product.

Received January 28, 2004

Abstract—The influence exerted by electrohydraulic treatment of mineral samples of various compositions on the weakening of the ore material and redistribution of gold into finer classes was studied.

In some cases, the conventional processes of crushing and grinding in screw crushers and ball mills fail to improve the breakdown of minerals. By contrast, raising the fineness of grinding (to ~10 μm) leads to overgrinding and sludging of productive solutions and mineral slurries. At the same time, crushing and grinding consumes about 70% of energy expended for the entire process of dressing of mineral raw materials [1].

The failure to break down minerals leads to loss of the valuable component with final tailings. Analysis of the main loss in primary dressing shows [1] that 35–40% of the loss is associated with concretions, and 30–35%, with particles less than 10 μm in size. To diminish this loss in processing of finely disseminated ores and to ensure breakdown of concretions without excessive overgrinding, it is necessary to pass from the conventional nonselective methods of ore treatment to selective disintegration based on energy impact.

The electrohydraulic effect, which arises in electric breakdown of liquid media, may become an effective method of selective disintegration of mineral components. The electrohydraulic impact causes simultaneously a powerful shock pulse and ultrasonic and electromagnetic emission, changes the chemical composition of the medium through erosion of the material of the electrode and destruction of water molecules in the discharge channel. However, the main factors that affect the whole material are shock waves: primary, secondary, and reflected, and also microexplosions of bulk cavitation. Originally, a network of microcracks appears in mineral products under the action of the compression shock wave. The action of a pulse train on minerals enables multiple emission of secondary compression waves, which creates defective zones and strained states in the minerals being processed. Therefore, it is the most appropriate to use electrohydraulic treatment for preliminary disordering of the ore and selective breakdown of minerals [2–4].

EXPERIMENTAL

The efficiency of electrohydraulic treatment was studied on two objects: old tailings of Artemovskaya gold-extracting factory (sample I) and gold-containing ores from Zoloto Joint-Stock Company (sample II).

When choosing the mode of ore treatment and the dressing scheme, it is necessary to take into account the granulometric composition and morphological features of gold itself and gold-bearing phases. The mineral composition of the samples studied is listed in Table 1, and the results of chemical analysis of the samples, in Table 2.

A mineralogical analysis of sample I demonstrated [5] that the nonmetallic minerals contained in the

sample are mostly represented by quartz in the form of grains of irregular angular shape, which is frequently impregnated with iron hydroxides and, as a result, has reddish color. Sulfides are represented by pyrite, pyrrhotine, chalcopyrite, arsenopyrite, sphalerite, and galenite.

The ore bodies of samples I and II are represented by quartz-vein low-sulfide formations and the embedding hydrothermally modified (quartz-containing, sulfidized) shale.

According to the results of a phase analysis, 14.5% of gold in sample I [5] is the native (amalgamable) phase, 76.8% of the metal is associated with sulfides, and 8.7%, with silicates. In sample II, about 72.9% of gold is in the free state, 4.6% is associated with sulfides, and 0.8%, with quartz and other minerals.

Table 3 lists the granulometric composition of the starting materials and the distribution of gold among fractions.

The results of a sieve analysis of the starting material of sample I demonstrate that the content of gold increases when the grain size becomes smaller, reaching the maximum value (19.4 and 33 g ton^{-1}) for the fractions –0.063+0.050 and –0.050 mm, respectively. However, the yield of these fractions, which are, in fact, concentrates, is extremely low, 4.9%. The amount of gold in coarser fractions decreases to 1–2 g ton^{-1}, but, at the same time, the amount of gold in these fractions is 60% of its total content. This is due to the increased (80%) yield of +0.1-mm fractions, compared with finer fractions. The finely dispersed gold (–1 μm) contained in these fractions is commonly extracted to only an insignificant extent. The main mass of this gold remains embedded in minerals, and more frequently in pyrite (the content of finely dispersed gold in pyrite may be as high as several hundred grams per ton). In the course of flotation dressing, this gold is extracted together with the carrier minerals.

The distribution of gold in the starting sample II is somewhat different. It can be seen from Table 3 that the distribution of gold among fractions is relatively even (10 to 20%). In the –0.1+0.05-mm fraction, the amount of gold is the largest (33.8%), which is accounted for by the low yield of these fractions (13.2%). In a finer (sludge) –0.05-mm fraction, the content of gold decreases, compared with that in the –0.1+0.05-mm fraction, by a factor of 4.7. However, the amount of gold in this fraction does not decrease significantly (9.6%) because of the simultaneous increase in its yield. Most part of gold is distributed among +0.63-mm fractions, which constitute 34% of the whole sample under study. Therefore, subsequent dressing without preliminary weakening or grinding of this fraction will lead to a considerable loss of the valuable component into the dressing tailings.

The aim of this study was, first, to develop a process of ore treatment that would raise the yield of fine fractions containing gold of emulsion-type dissemination and, second, to simultaneously weaken to the maximum possible extent the binding between the mineral, carrier, and metal. The latter will intensify the subsequent procedures for recovery of gold into a commercial product.

The influence exerted by the electrohydraulic impact on the processing properties of particles of gold-containing samples was studied as follows: Mineral slurry with a certain concentration of the solid component (s : l = 1 : 10) and known geochemical properties of the mineral raw material was poured into a discharge chamber of certain volume and treated in various modes of the electrohydraulic impact.

In the course of electrohydraulic treatment, only the number of pulses applied to the slurry was varied, whereas all other parameters remained the same during the experiment: weighed portion being treated, 100 g; treatment duration, 20, 30, and 60 pulses; pulse repetition frequency, 2–3 pulses per second; pulse energy, 80 J; grain size of the starting product, ≤ 2 mm; and working liquid, water. After the electrohydraulic treatment, a sample was extracted from the reactor, and the mineral slurry was subjected to separation. The influence exerted by the electrohydraulic impact was evaluated on the basis of a sieve

analysis and an analysis for the content of gold in the samples before and after the treatment. The content of gold in solid residues was determined by X-ray fluorescence analysis [6]. Each result was obtained for a minimum of three parallel runs. The results of an analysis performed five times for each sample were subjected to statistical processing and are presented here with account of errors.

For more clarity in describing the results of the study, the experimental data in Table 4 are plotted graphically.

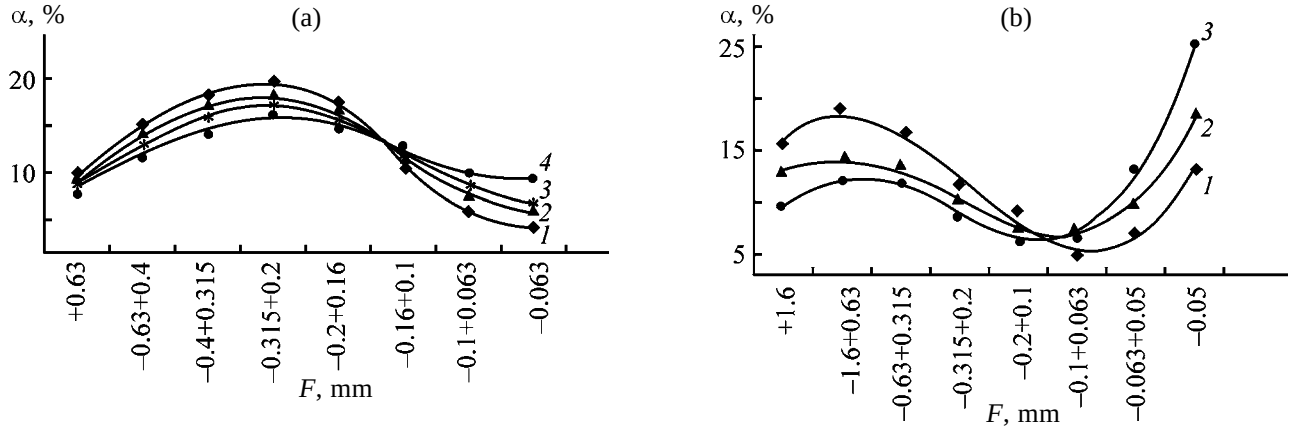

Fig. 1. Granulometric composition of samples (a) I and (b) II before and after electrohydraulic treatment. (α) Yield and (*F*) fraction. Sample: (*1*) untreated and (*2, 3, 4*) treated with 20, 30, and 60 pulses, respectively; the same for Fig. 2.

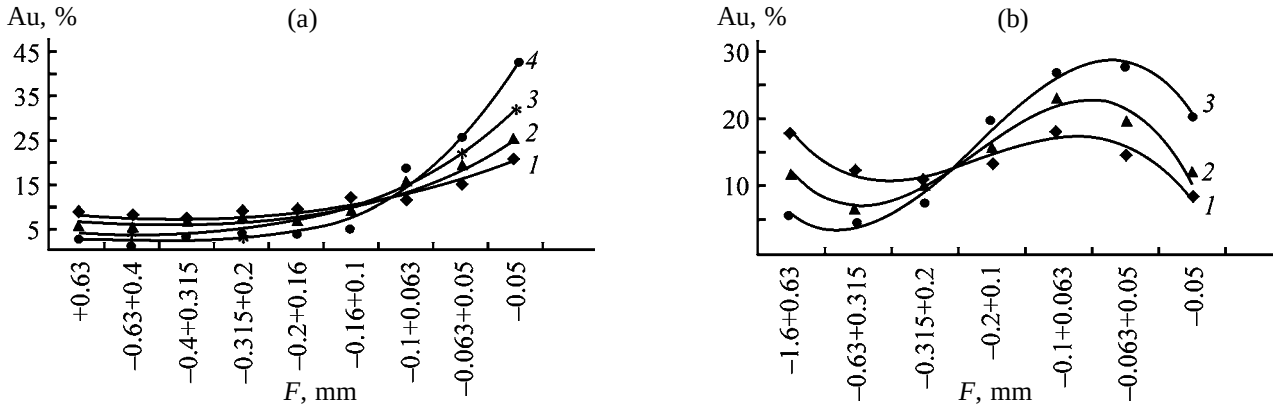

Fig. 2. Distribution of gold among fractions *F* in samples (a) I and (b) II before and after electrohydraulic treatment. (Au) Recovery of gold.

Figures 1a and 1b show how ground ore is distributed among fractions at different intensities of the electrohydraulic treatment. Figures 2a and 2b show how the distribution of gold among fractions depends on the intensity of electrohydraulic treatment.

Electrohydraulic treatment of samples I leads to an insignificant rise in the content of finer fractions in proportion to the increase in the treatment intensity (by 1%, on the average). After treatment with 60 pulses, the content of –0.63+0.16-mm fractions decreases by 12%, and that of –0.1-mm fractions increases by 12%. The coarser +0.63-mm fractions are virtually not ground at all under the action of the electrohydraulic effect. This can be explained as follows: the compression waves formed under the given experimental conditions, as well as the resulting secondary effects, which favor disintegration, have no significant effect on ore particles that belong to the +0.63-mm fraction. In addition, the influence exerted by grinding of the given type of samples is "masked" by the presence of compounds of iron and oxygen on the surface of gold grains. This indicates that the surface of gold grains is covered with films of oxides (hydroxides) of iron (film thickness not exceeding 2 μm). The last statement is clearly illustrated by Fig. 2a.

Figure 2a shows that gold is distributed in proportion to the yields, whose value depends on the intensity of electrohydraulic treatment. As the yield of finer fractions increases, the amount of gold in these fractions grows simultaneously. The richest in gold are –0.10-mm fractions. Similarly to the initial sample, the –0.1-mm fractions in samples treated with 20, 30, and 60 pulses are concentrates containing 61, 66, and 79% of the total amount of gold, respectively. Compared with the initial sample, the yield of these fractions in treated samples increases by factors of 1.5, 1.7, and 2, respectively.

Electrohydraulic treatment of samples II affects the granulometric composition considerably more strongly, compared with samples I. The content of coarser fractions decreases in proportion to the treatment intensity, and the yield of fine fractions, accordingly, increases. The +0.1-mm fractions are ground satisfactorily and their total decreases by 20%, whereas the yield of +0.1-mm fractions increases proportionally.

The type of gold distribution in samples II is similar to that in samples I. The only difference is that gold in samples I is distributed evenly over all fractions coarser than +0.1 mm, whereas the content of gold in samples II decreases when the treatment intensity increases, being redistributed into finer –0.2-mm fractions. This points to a weaker binding between the mineral, carrier, and metal in samples of the gold-containing ore. As a result of electrohydraulic treatment, 22% of gold passes from the +0.2-mm fraction to finer fractions. The content of gold in the –0.063-mm fraction increases twofold.

An analysis of the efficiency of the electrohydraulic treatment of samples I and II demonstrated that the treatment can produce microcracks in mineral products, which, in turn, facilitates the access of the leaching agent to the surface of gold grains. The weakening of concretions makes higher the recovery of Au into productive solutions. The efficiency of activation with electric discharges in a liquid makes it possible to regard the given process as a promising technique for pretreatment of mineral raw materials in ore dressing and recovery of gold by cyanidation or using other leaching agents.

CONCLUSIONS

(1) Electrohydraulic treatment changes the granulometric composition of mineral products. Secondary raw materials (old tailings) are ground to a lesser extent because of the formation of high-strength oxidation products on the surface of particles in a sample.

(2) Electrohydraulic treatment leads to disintegration and weakening of binding between the mineral and the metal, which leads to redistribution of gold from coarser to finer fractions.

(3) Electrohydraulic treatment is more preferable for gold-containing unyielding ores, because a stronger influence on the granulometric composition and gold recovery is observed in this case. This fact is accounted for by the presence of iron hydroxide films on the surface of gold in samples of old tailings, which creates an additional barrier for the electrohydraulic effect.

(4) The ore treatment process studied can be regarded as promising for processing of gold-containing unyielding ores, which are characterized by nonuniform distribution and fine dissemination of gold in the rock-forming minerals.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Damping of the Growth of Titanium Oxide Nanolayer Formed by Molecular Layer Deposition Technique on Oxidized Silicon Surface

V. P. Dorofeev, A. A. Malygin, and S. I. Kol'tsov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received October 28, 2003, in final form, February 2004

Abstract—Ellipsometric data on titanium oxide nanolayers synthesized by molecular layer deposition technique on oxidized Si(100) surface are discussed.

Numerous works [1–12] concern molecular layer deposition (MLD) of titanium oxide nanolayers on the surfaces of dispersed materials and flat supports in a vacuum and in flow systems under atmospheric pressure. Many works on the preparation of titanium oxide layers by ALD (atomic layer deposition) and ALE (atomic layer epitaxy), which are based on the same principles as the MLD technique, have been published recently [13–16]. Nanometer titanium oxide layers can be used in microelectronics for the formation of capacitors and undergate dielectrics for apparatus with minimal component sizes of 90 nm and less, and also for the production of catalytically active materials and sorbents [15, 17–19].

When titanium oxide layers were synthesized by the MLD technique on flat silicon and quartz supports, the dependence of the layer thickness on the number of MLD cycles was linear when the deposition was performed both under atmospheric pressure and in a vacuum [4–7, 9]. According to [5–7, 9], the thickness growth per one MLD cycle was 0.24–0.33 nm, which is close to the size of a titanium oxide octahedron.

The experiments have shown that, at temperatures higher than 200°C, damping of the growth of titanium oxide nanolayer takes place on the surface of single-crystal silicon coated by a layer of silicon oxide. The phenomenon was not described earlier in the literature. In this work we made an ellipsometric study of this process.

Titanium oxide layers were synthesized on single-crystal silicon (KDB-7.5 grade) plates with the (100) orientation. Their surface was coated with a film of silicon oxide of 2–3 nm thickness, which was obtained by silicon oxidation with concentrated nitric acid. It should be noted that the oxide film on silicon was formed in the presence of water without high-temperature treatment of the supports; therefore, maximal hydroxylation of the surface could be expected.

The synthesis was carried out in a vacuum glass installation with a volume of about 400 ml [6]. An MLD cycle included treatment of the plates by $TiCl_4$ vapor, pumping out of the forming hydrogen chloride and excess of $TiCl_4$ vapor, treatment with water vapor, and pumping out of hydrogen chloride and water vapor excess at 160–260°C. The contact time after the addition of $TiCl_4$ vapor was 1 min, and the evacuation time, 2 min. A two–threefold increase in these parameters did not change the thickness of the titanium oxide layers synthesized. The residual gas pressure after 2-min evacuation was about 0.3 Pa. The temperature in the reactor was maintained with an accuracy of ±3°C. The main inner parts of the installation being in contact with the reagents were heated to no less than 120°C.

The formation of titanium oxide layers was monitored by ellipsometry. A null-ellipsometer with a helium–neon laser (λ = 632.8 nm) assembled by a PCSA scheme with a fixed compensator [20] was used. The measurements were carried out by a four-zone technique, which eliminated most of the errors arising from imperfection of the ellipsometer optical scheme [20]. The ellipsometric measurements were carried out in air before and after synthesis of the samples; the incidence angle was 70°.

According to the ellipsometric data, the thickness of a titanium oxide nanolayer depended linearly on the number of MLD cycles at synthesis temperatures

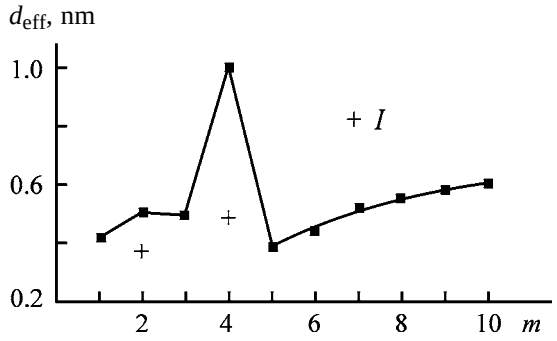

Fig. 1. Effective thickness of titanium oxide film d_{eff} as a function of the number of MLD cycles m on oxidized silicon surface. (*I*) After heating; the same for Fig. 2.

of 160–200°C. The refractive indices of the films were 2.4–2.5, which corresponds to the refractive index of anatase [21].

We have found that, in the range 200–235°C, the ellipsometric parameters of the sample surface remain practically constant after 10 and more (up to 20) MLD cycles. The parameter Δ decreased by 1°45′–2°10′, and the parameter ψ increased on the average by 1′.

According to the ellipsometric data, the increase in the synthesis temperature above 240°C resulted a in significant decrease in the thickness of titanium oxide nanolayers.

The change in the ellipsometric parameter Δ in the range 200–235°C corresponds to the thickness of a titanium oxide layer less than 1 nm; its refractive index can be determined exactly only by immersion ellipsometry [20]. Therefore, we calculated the effective thickness of the films using a preset refractive index n = 2.5 corresponding to anatase [21], which agrees well with an average increase in the ellipsometric parameter ψ by 1′. The maximal effective thickness of a titanium oxide film which was attained in ten and more MLD cycles was 0.60–0.67 nm. According to our calculations, a small error in the determination of the refractive index only slightly affects the calculated film thickness. For example, if we accept n = 2, the calculated film thickness decreases by 10% as compared to n = 2.5.

The effective thickness d_{eff} of a titanium oxide nanolayer synthesized at 225°C, determined by ellipsometry, is shown in Fig. 1 as a function of the number of MLD cycles m. It is seen from Fig. 1 that, in the initial stages of the nanolayer formation (m < 5), its effective thickness is abnormally high and increases nonmonotonically with the number of MLD cycles. The observed abnormally high values of the effective thickness are in agreement with the published data [8, 11, 12] on abnormally large changes in the ellipsometric parameter Δ in the initial stages of the formation of titanium oxide nanolayers. After five MLD cycles, the shape of the function $d_{eff} = f(m)$ changes, probably owing to compaction of the nanolayer.

The effects described are attributable to crystallization of titanium oxide nanolayers. It is mentioned in the monograph [22] that titanium dioxide starts to crystallize in the presence of water even at 60–100°C. The nanolayer effective thickness after five treatment cycles is 0.39 nm, which agrees well with the parameter a = 0.373 nm of the anatase unit cell [23]. It is likely that after five MLD cycles a dense crystalline film is formed, whereas after a smaller number of cycles the crystallization is incomplete. Amorphous and partially crystalline layers have lower density in comparison with crystalline films, and hence they have a larger thickness. In addition, because of the simultaneous presence of dense regions of the crystalline phase and loose regions of the amorphous phase in a film, its structure cannot be adequately described by a model of ideally smooth film with a constant refractive index throughout the surface. Consequently, the calculated effective thickness may be significantly increased, which seems to take place for m = 4, i.e., immediately before the complete crystallization.

To study the compaction of titanium oxide nanolayers, we have carried out experiments on annealing of the samples. We found that, on annealing the samples with m = 2 and m = 4 in a vacuum (300°C, 1 h) the effective thickness of nanolayers decreased to 0.37 and 0.48 nm, respectively (Fig. 1), and remained unchanged on further annealing. No thickness changes were observed on annealing of the other samples. It is likely that the annealing accelerates crystallization, which results not only in compaction of the film, but also in its greater uniformity, which causes a decrease in the effective thickness.

One of reasons for damping of the formation of a titanium oxide nanolayer can be formation of surface groups of the ≡Ti–Cl type, which results in formation of one titanium hydroxide group upon hydrolysis, instead of three groups used for its creation. The dehydroxylation of the sample surface can be another reason.

According to the chemical analysis [1, 3, 10, 16], formation of the ≡Ti–Cl groups is unlikely. At the same time, most of hydroxy groups are removed at 160°C from the titanium oxide surface [22], and at 200°C the main part of coordinated water is desorbed

(however, hydroxy groups and water are not removed completely by evacuation even at 300°C). We can expect that, in the course of formation of a titanium oxide nanolayer, the properties of the modified surface would gradually approach the properties of the surface of bulk titanium dioxide. Therefore, a more probable reason for damping of the growth of titanium oxide nanolayer is low thermal stability of the centers of $TiCl_4$ chemisorption. Special experiments confirmed this assumption. When a titanium oxide layer is synthesized at 225°C on a titanium oxide film with a thickness of 1.1 nm obtained at 185°C, no changes in the ellipsometric parameters are observed. On the contrary, on the titanium oxide layer obtained by ten MLD cycles at 225°C, the thickness of the film linearly depends on the number of cycles at 185°C.

It should be noted that the damping of molecular layer deposition process was found [1, 10] when studying the formation of a titanium oxide nanolayer on the silica gel surface. The authors explained this damping by obliteration of the matrix pore space in the course of the synthesis. It is of interest that, according to [1], the formation of a titanium oxide nanolayer practically ceases after ten MLD cycles, which corresponds to the results of this work.

As the properties of oxidized silicon surface are similar to the properties of amorphous silica, and its pretreatment did not involve heating to high temperatures, we can expect that the properties of this surface are similar to the properties of the silica gel surface. According to monograph [24], silica samples obtained without severe thermal treatment (particularly, silica gels) have significantly higher surface concentration of hydroxy groups (7–8 nm^{-2}) compared to the average concentration of 4–5 nm^{-2} for silica.

Therefore, it is of interest to compare the data on the formation of titanium oxide nanolayers on the oxidized silicon surface and the data obtained for silica gel in [1]. The interrelation between the amount of titanium on silica gel and the effective thickness of titanium oxide nanolayer on silicon is shown in Fig. 2a in the coordinates d_{eff}–$[Ti]_m$, where $[Ti]_m$ is the content of titanium on silica gel after m treatment cycles related to 1 g of anhydrous silica [1] (see table). It is seen from Fig. 2a that the points corresponding to $m \geq 5$ belong to the straight line outgoing from the origin. Thus, the effective thickness of a titanium oxide nanolayer on the silicon surface and the titanium content on the silica gel surface are proportional to each other at $m \geq 5$. The absence of proportionality at $m < 5$ is attributable to a smaller density of these

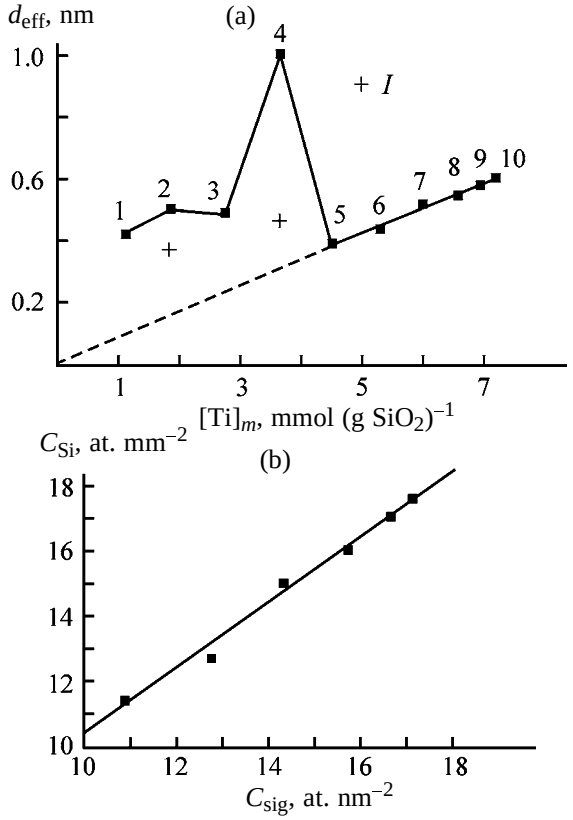

Fig. 2. Correlation of the (a) effective thickness of titanium oxide layer d_{eff} on the silicon surface with titanium content $[Ti]_m$ on the silica gel surface and (b) calculated amounts of titanium atoms per unit surface area of silicon C_{Si} and of silica gel C_{sig} for equal numbers of MLD cycles. (a) Figures at points denote cycle numbers.

layers compared to the density of the layers formed at $m \geq 5$.

As we have found that the thickness of a titanium oxide nanolayer on the silicon surface is proportional to the titanium content on the silica gel surface, it was of interest to compare the amounts of titanium per unit surface area on silicon and silica gel for an equal number of MLD cycles.

The number of titanium atoms per unit surface area of silicon C_{Si} can be calculated by the formula

$$C_{Si} = \frac{d_{eff}\rho}{M_{TiO_2}} N_A, \quad (1)$$

where d_{eff} is the effective film thickness; ρ, film density (which was taken at $m \geq 5$ to be equal to the anatase density of 3.83 g cm^{-3} [21]); N_A, Avogadro constant; and M_{TiO_2} = 79.90 g mol^{-1}, molar weight of TiO_2.

The number of titanium atoms per unit surface area of silica gel can be estimated from the data on the

Chemical composition and specific surface area of titanium-containing silica gel

m	$[Ti]_m$, mmol g^{-1} [1]	S_{sp}, $m^2\ g^{-1}$ [2]	Fraction of SiO_2 in product [1]	$[Ti]_m$, mmol $(g\ SiO_2)^{-1}$ [1]	S_{sp}, $m^2\ g^{-1}$ $(g\ SiO_2)^{-1}$ (our calculation)
0	0	270	0.969	0	279

3	2.16	200	0.784	2.76	255
4	2.73	195	0.744	3.67	262
5	3.21	160	0.710	4.53	225
6	3.63	–	0.683	5.31	–
7	3.95	–	0.659	6.00	–
8	4.21	–	0.641	6.57	–
9	4.41	140	0.633	6.96	221
10	4.51	–	0.629	7.17	–

chemical composition and specific surface area of titanium-containing silica gels [1, 2] (see table). The specific surface area of titanium-containing silica gels significantly decreases during the synthesis [2] (see table). However, the decrease in the sample specific surface area is caused not only by a change in the porous space geometry, but also by the weight gain upon layer deposition [25, 26]. For example, if a film grows on a sample with a flat surface, its surface area will not change; however, the specific surface area will decrease because the surface area would be related not to the initial sample weight, but to the total weight of the starting sample and the film. For this reason, to find true relations of surface areas of titanium-containing silica gels, they were related to the weight of anhydrous silica gel, which remains unchanged during the synthesis (similarly to the values of $[Ti]_m$ referred to 1 g of SiO_2 in [1, 2, 10]). The recalculation was fulfilled by dividing S_{sp} of samples by the fraction of anhydrous silica in them (see table). The resulting S_{sp} values $[m^2\ (g\ SiO_2)^{-1}]$ are given in the table. It is seen that the surface areas of titanium-containing samples referred to the weight of anhydrous silica change upon layer deposition only slightly. For approximate calculations, the average value $S_{av} = 250\ m^2\ (g\ SiO_2)^{-1}$ can be used. In this case, the number of Ti atoms per unit surface area of silica gel C_{sig} can be calculated by the formula

$$C_{sig} = \frac{[Ti]_m N_A}{S_{sp}}, \qquad (2)$$

where $[Ti]_m$ values are expressed in moles per gram of SiO_2.

The relationship between the numbers of titanium atoms per unit surface area of silica gel and silicon is shown in Fig. 2b in the coordinates C_{Si}–C_{sig}. These numbers were calculated by formulas (1) and (2) for equal numbers of MLD cycles starting from $m = 5$. The relationship is reasonably described by the equation $C_{Si} = 0.4 + 1.0C_{sig}$ (rms deviation $\sigma = 0.26$ at. nm^{-2}). Hence, the numbers of titanium atoms per unit surface area of silicon and silica gel for the same number of MLD cycles are virtually the same, which suggests that there is a certain similarity in molecular layer deposition of titanium oxide nanolayer on the oxidized silicon surface and on silica gel.

Earlier [27] we have drawn similar conclusions when comparing the amounts of Cr per unit surface area of chromium oxides synthesized by MLD technique on the silica gel surface and on silicon carbide particles. Silicon carbide is known to be coated with an SiO_2 film with a thickness of up to 10 nm. After the first MLD cycle, the chromium concentrations per unit surface area on silicon carbide and silica gel were almost equal.

CONCLUSIONS

(1) According to the ellipsometric data, the molecular layer deposition of a titanium oxide nanolayer damps in the range 200–235°C. After ten molecular layer deposition cycles, the formation of the nanolayer practically stops. In this case, the nanolayer thickness attains 0.60–0.67 nm.

(2) The initial stage of formation of titanium oxide nanolayer was studied ellipsometrically. An assumption was made that the layer was compacted after five molecular layer deposition cycles.

(3) Taking into account previous data on the synthesis of titanium oxide nanolayers on the silica sur-

face, it was proposed that the processes of molecular layer deposoition on the oxidized surface of single-crystal silicon and silica gel are similar.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

X-ray Phase Analysis of Structure of Water–Salt Systems: NaCl–H_2O and KCl–H_2O

O. N. Pestova, Yu. P. Kostikov, and M. K. Khripun

St. Petersburg State University, St. Petersburg, Russia

Received May 27, 2004

Abstract—Aqueous solutions of sodium and potassium chlorides were studied by a diffraction method. The effect of cations on the structure of water was considered from the viewpoint of this method. The size of supramolecular structures and the number of water molecules per salt formula unit in solution were estimated.

The choice of aqueous solutions of sodium and potassium chlorides as objects of our study was caused by an important role of these systems in natural physicochemical, physiological, and biological processes, in geological research, and also by their wide industrial use [1–3].

It is known that even slight amounts of an electrolyte added to water change its physical and physicochemical properties because of changes in its structure. Presently Frank–Ibsen–Wen model [4] based on a dominating role of free water is used to describe structural changes in moderately concentrated solutions. Influence of electrolyte ions on water is accounted for from the viewpoint of the hydration theory.

In going to concentrated solutions, this approach becomes inapplicable, as the reasoning concerning the intrinsic structure of water in such solutions loses sense. Apparently, to study structures of concentrated solutions, alternative approach and model representations are required, and previously we have developed such a model [5–8]. This approach is based on the comparison of changes in the physical and chemical properties with the shape of the solubility polytherm of a salt. This approach allows us to divide the entire concentration range of the solution existence into zones with various dominating structures (cybotactic groups) corresponding to structures of solid phases crystallizing from the solution upon decreasing temperature: water, a crystal hydrate with a definite composition, or an anhydrous salt.

Results of cryoscopic, Raman-spectroscopic, viscometric, and calorimetric studies of solutions in wide concentration ranges provide indirect information on their structure; they point to structural reorganizations in systems occurring as concentrations of components change. According to the developed theory, such results allow us to make assumptions on the interconversions in a solution. To obtain more comprehensive information about a solution structure and to develop further the model views, we have proposed to use a modification of the X-ray diffraction method. The feature of this experiment consists in the fact that the measurements are carried out in a wide range of 2θ angles and that the result is the dependence of the dispersion intensity on the dispersion angle $I(2\theta)$, whereas when liquid systems are studied by the usual X-ray diffraction method, the scattering under small angles ($2\theta < 6°$) is considered and the diffraction patterns are presented as radial distribution curves $dI(2\theta)$ [9]. In so doing, average distances between particles are estimated.

We pursued different aims when studying solutions by the diffraction method. The method used in this work furnishes new information on the structure of a system as a whole. The X-ray phase experiments have been carried out earlier for several electrolyte solutions [10]. The results of these experiments have shown that this method is sensitive to structural changes in solutions and makes it possible to follow the effect of an electrolyte (as its concentration increases) on the structure of water.

EXPERIMENTAL

To prepare solutions, we used chemically pure grade salts and distilled water. The titration with a solution of mercury nitrate with diphenylcarbazone indicator was used to determine the concentration of chloride ions. Dilute solutions were prepared by volumetric dilution of saturated solutions.

1070-4272/04/7707-1066 © 2004 MAIK "Nauka/Interperiodica"

Diffraction patterns were measured on a DRON-2.0 difractometer with an Ni filter and CuK_α radiation. Mode of the tube operation: I = 8 mA, U = 18 kV, sweep rate 1 deg min^{-1}. A sample was transferred with a syringe into an 1 ml duralumin cell, equipped with a window made of 0.2-mm beryllium foil. The spectra were measured in the range of angles θ from 4° to 24° at room temperature.

The diffraction patterns of pure water and solutions of alkali metal chlorides with various salt concentrations are shown in Figs. 1–3. Narrow lines (five lines) in the region of large angles (2.45, 2.19, 2.07, 1.99, and 1.92 Å) belong to beryllium. In the diffraction pattern of pure water (Fig. 1), a wide and strong peak (halo) is observed at 3.14 Å, and a less intensive halo, at 2.32 Å. Their positions coincide with the positions of maxima of lines in the diffraction pattern of ice of tetragonal symmetry, i.e., the spectrum of water consists of wide lines of ice, which points to the absence of long-range order and the presence of short-range order in the structure of pure water.

The obtained diffraction patterns of solutions of sodium and potassium chlorides show certain regular trends.

An increase in the electrolyte concentration results in a reduction of the intensity of the water halo, its broadening, and shift of its maximum toward larger angles θ. It is indicative of gradual break of the intrinsic structure of water and increasing disorder in solution. The reduction of the halo intensity occurs up to a certain salt concentration, after which the intensity remains practically unchanged.

The data on sodium chloride solutions are shown in Fig. 2.

When the salt concentration increases from 0.35 to 1.97 M, the intensity of water halo decreases fairly sharply; with the further increase in the molarity of sodium chloride, the dependence becomes smoother, and in solutions close to saturation the intensity changes insignificantly. It seems to be indicative of a temporary structural constancy. Despite the sharp decrease in the intensity in dilute solutions, the half-width of the peak (30–31 mm) remains virtually unchanged (compared to that in pure water) up to ~5 M concentration of the salt. This indicates that no appreciable structure break takes place in the sodium chloride solution up to its ~5 M concentration, i.e., the structure existing at that moment appears to be no less ordered than that of pure water. Only at the salt concentration of 4.61 M the half-width of the halo increases (to 34 mm); this concentration corresponds

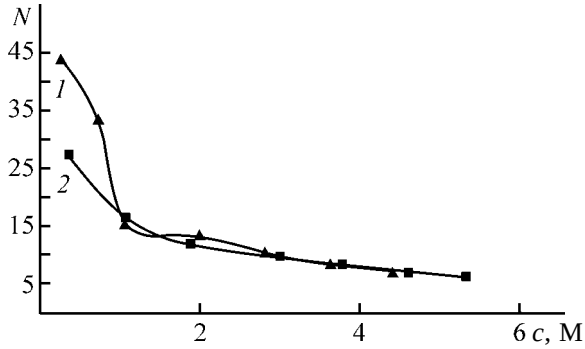

Fig. 4. Variaiton of the number of water molecules *N* per formula unit of (*1*) KCl and (*2*) NaCl with the molar concentration of the salts in solution *c*.

tions is not so sharp as in the case of sodium chloride. However, broadening of the halo is observed already at a minimal salt concentration (Fig. 3). Thus, potassium chloride starts to break the water structure at once.

We have calculated approximate sizes of supramolecular structures dominating in solution from the X-ray diffraction patterns using the Debye–Scherrer formula [12]

$$L = \lambda(B\cos\theta),$$

where λ is wavelength, Å; *B*, half-width of halo, rad; and θ, scattering angle, deg.

The size of associates in pure water is approximately 30 Å.

The size of structures in solutions with posteutectic concentrations can be estimated similarly. For example, the size of structures existing in the 5.32 M solution of sodium chloride is 26 Å, and in the 3.63 M solution of potassium chloride L = 33 Å. We believe that these values are quite reasonable but rather approximate, as the wider the halo and the lower its intensity (which, as a rule, is observed in concentrated solutions), the higher is the error in the *B* determination.

We believe that the composition of such structures (cybotactic groups) determines the composition of crystal unit cells of a substance, i.e., a cybotactic group in a solution is a combined modular structure containing many molecules. To form a crystal unit cell, a suitable environment is necessary, which arises even in a concentrated solution when structurally induced processes become to prevail. However, conditions for the formation of the corresponding environment are realized within fractions of seconds as we deal with a liquid system where chaotic thermal, translation, and rotation motions take place. Therefore, a cybotactic group is an associate having a short lifetime, which is insufficient for congestion of similar groups in the same place and thus for the formation of a solid phase.

The analysis of diffraction patterns allowed us to determine the number of water molecules per salt formula unit in solution according to the formula

$$[(I_w - I_i) \times 55.56/I_w]/c,$$

where I_w is the intensity of scattering in water (in a halo maximum), mm; I_i, intensity of scattering in a sample (in solution), mm; $(I_w - I_i) \times 55.56/I_w$, number of water moles from the water structure consumed for the salt hydration; and *c*, molar concentration of the solution.

The dependence of the number of water molecules per salt formula unit on its molar concentration is given in Fig. 4.

It should be noted that the dependence is not monotonic: the number of water molecules changes more sharply at low concentrations, and at higher concentrations it is smooth, gradually approaching a constant number. This points to the prevalence of the corresponding structure in solution. Figure 4 shows that

there are approximately seven water molecules per formula unit of sodium chloride in the saturated solution. Practically the same value (7–8) was also found for potassium chloride in saturated solution (at 25°C). It should also be noted that in the region of low concentrations the effect of K^+ cations on the water structure is pronounced much more strongly, which is attributable to the negative hydration power of these ions, whereas Na^+ cations are on the border between positive and negative hydration and do not exert pronounced structure-making or structure-breaking effect on water.

CONCLUSIONS

(1) X-ray diffraction patterns show how cations affect the water structure as an electrolyte is concentrated and allow estimation of the number of water molecules per formula unit of a solute and the size of cybotactic groups dominating in the solution.

(2) X-ray diffraction once again revealed a difference in the nature of Na^+ and K^+ ions in the region of dilute solutions, caused by their different hydration power. It is very important that, within the framework of a single experiment, we were able to observe all features of changes in the structure of solutions of such simple salts. It is clearly seen that the distinction in the nature of sodium and potassium ions is completely leveled off in going to high concentrations owing to the M^+–Cl^- ion–ion association and to the origination of microheterogeneity in solutions.

(3) X-ray diffraction is one more tool for studying liquid systems; it furnishes qualitatively new information on the structure of a solution as a whole.

Abstract—The behavior of scandium compounds in going from alkaline solutions to carbonate and hydrocarbonate solutions was studied. The possibility of coprecipitation of scandium(III) complex carbonate with zinc oxide was examined.

Integrated use of mineral raw material and development of low-waste processes become urgent in view of environmental protection. The possibility of scandium recovery from large-volume technogenic deposits from aluminum production is of particular interest. Such valuable components of bauxites as scandium, titanium, zirconium, yttrium, and lanthanides are almost completely concentrated in waste products after pressure leaching. A chemomineralogical analysis supported by laboratory studies has shown that the technology of recovery of scandium compounds from bauxite processing products and of scandium separation from concomitant components is largely simplified when scandium(III), which is weakly bound to macrocomponents, is converted to a carbonate complex. To find the optimal process conditions, we have studied scandium-containing alkaline carbonate and carbonate–hydrocarbonate systems.

Published data on the solubility of scandium(III) hydroxide in alkaline solutions are contradictory, probably owing to distinctions in experimental conditions [1, 2]. The behavior of scandium(III) in solutions of alkali metal carbonates and hydrocarbonates has been studied in more detail [3, 4]. We found no published data on the solubility of scandium(III) compounds in hydrocarbonate–carbonate ($NaHCO_3$–Na_2CO_3) solutions with low content of free alkali, which are required for understanding the scandium(III) behavior in processing of red mud by a soda–alkaline technology.

EXPERIMENTAL

When studying solubility of scandium(III) hydroxide in the above systems, we used chemically and analytically pure grade $NaHCO_3$, Na_2CO_3, NaOH, and ZnO as starting chemicals. Scandium(III) hydroxide was prepared from scandium oxide of the OS-99.0 grade. The scandium content was determined by EDTA titraiton or by photometry with Xylenol Orange as indicator. Zinc was determined quantitatively by complexometric titration with Eriochrome Black T as indicator. The concentrations of carbonates and hydrocarbonates were determined by volumetric titration with Methyl Red and phenolphthalein indicators, and that of free alkali, with phenolphthalein in the presence of barium chloride.

An alkaline solution of Sc(III) was obtained by heating a mixture of Sc_2O_3 and sodium hydroxide in a platinum cup on a sand bath with a minimal amount of water to homogenize the mixture and to increase the reaction surface area, and then the mixture was sintered at 400°C for 6–8 h. The cake was leached with double-distilled water, transferred into hermetically sealed polyethylene vessels, and kept at 18–20°C to reach the equilibrium. The liquid phase was sampled using a centrifuge. Carbonate systems were prepared by mixing scandium(III) hydroxide and the corresponding amount of sodium carbonate in 100 ml of a solution in a glass vessel and keeping it at room temperature to reach the equilibrium.

The IR absorption spectra were taken from samples prepared as mulls in mineral oil. We also used a diffuse reflection attachment. The spectra were obtained on a Perkin–Elmer Fourier IR spectrometer (450–3000 cm^{-1}). The thermal stability of the scandium complex compound was evaluated by differential thermal and thermogravimetric analyses on a Q-1500 derivatograph at a heating rate of 10 deg min^{-1}.

1070-4272/04/7707-1070 © 2004 MAIK "Nauka/Interperiodica"

The curve of scandium(III) solubility in alkaline solutions can have one or two maxima at quite different concentrations of sodium hydroxide, and the maximal solubility also varies over a wide range. The experimental solubility curve largely reproduces the initial branch of the curve given in [1]. We studied the saturation of alkali liquors with scandium(III) for 3 months. Probably, the saturation curve in Fig. 1, which was obtained after 3-month keeping of the solutions, is not equilibrium. Our experiments confirm the published data that the equilibrium between a solution and a solid phase at 18–20°C is attained very slowly (in 3 months and more) and that scandium(III) can form stable colloidal solutions, which complicates the experiment. According to Ivanov-Emin *et al*. [1], the autoclave treatment of a mixture of scandium oxide and sodium hydroxide at 160–180°C results in the reduction of the time required to reach an equilibrium to 20–40 days.

In going from alkaline to carbonate and then to hydrocarbonate solutions, the solubility of scandium(III) hydroxide grows singnificantly. It also grows as the concentration of the hydrocarbonate solutions increases (Fig. 1). The equilibrium in the systems was reached within two weeks. The resulting solubility curves are located somewhat lower than the curves described in the literature; however, in general, they agree well with each other.

As the concentration of hydroxide ions in solution increases, the content of scandium(III) considerably decreases. The influence of the concentration of OH^- ions on the solubility of scandium hydroxide was demonstrated with sodium carbonate solutions containing various amounts of $NaHCO_3$, Na_2CO_3, and NaOH [3]. The solubility sharply decreasesd (approximately from 5 to 2.2×10^{-3} g l^{-1} Sc_2O_3) as the molar ratio Na^+/CO_3^{2-} increased from 1.5 to 3.0. The further increase in the concentration of OH^- ions only slightly increased the solubility: to 5.8×10^{-3} g l^{-1} at Na^+/CO_3^{2-} = 3.5 [3, 4]. These data show that the content of scandium(III) oxide can reach 3 g l^{-1} in carbonate solutions in the presence of OH^- ions (at Na^+/CO_3^{2-} = 2.0–3.0).

Our experiments gave somewhat different results. Solutions were prepared by adding sodium hydroxide to the starting concentrated solution (solution A) containing 80 g l^{-1} of $NaHCO_3$ and 12.8 g l^{-1} of Sc_2O_3 and keeping the solutions at room temperature for 2 weeks. The scandium solubility regularly decreased and reached the minimal value of 7×10^{-3} g l^{-1} of Sc_2O_3 at $Na^+ : CO_3^{2-} = 2$ (Fig. 2). At the molar ratio

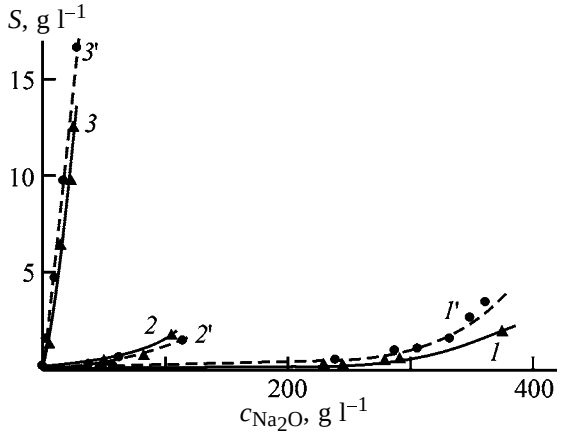

Fig. 1. Soluibility *S* of scandium oxide as a function of Na_2O concentration c_{Na_2O} in solutions of (*1*, *1*') NaOH, (*2*, *2*') Na_2CO_3, and (*3*, *3*') $NaHCO_3$. Data: (*1*–*3*) our experiments, (*1*') form [1], and (*2*', *3*') from [3].

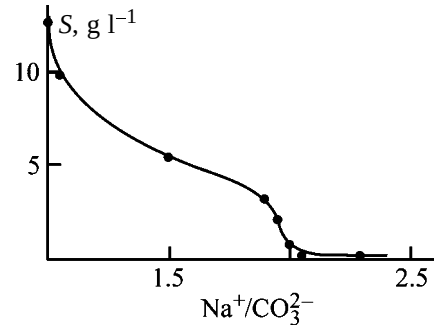

Fig. 2. Solubility of Sc_2O_3 as a function of the molar ratio Na^+/CO_3^{2-} in $NaHCO_3$–Na_2CO_3–NaOH solutions.

$Na^+/CO_3^{2-} < 2$, the solubility of scandium hydroxide grew as the concentration of CO_3^{2-} ions increased owing to the ability of scandium to form complexes. In the presence of even insignificant amount of alkali in the carbonate solution at $Na^+/CO_3^{2-} \geq 2$, scandium carbonate complexes are unstable, whereas scandium hydroxo compounds are poorly soluble and are stable only in the presence of a large excess of NaOH. We note that the scandium(III) concentration in $NaHCO_3$ solutions is much higher than in the carbonate solution with the same concentration of CO_3^{2-}.

We have isolated transparent crystals of the complex scandium carbonate $Na_5Sc(CO_3)_4 \cdot 18H_2O$ as prisms of up to 2 mm length from solution A cooled to 3–5°C and kept for 5–7 days. In time, the crystals grew together to form druses. The structure of this compound was proved by X-ray phase analysis.

We studied the thermal stability of the resulting crystal hydrate using differential thermal and thermogravimetric analyses. The decomposition occurs in several stages; first, 10 mol of water of crystallization is removed on heating to ~150°C, which corresponds

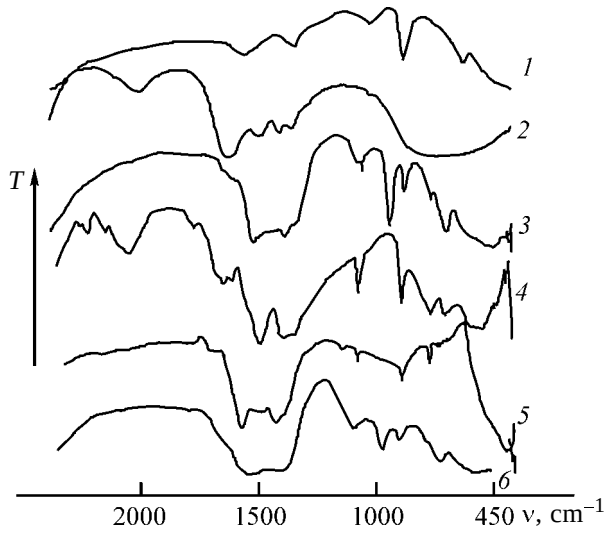

Fig. 3. IR spectra of (*1*) $Sc(OH)_3$ prepared from OS-99.0-grade Sc_2O_3, (*2*) solution A, (*3*) precipitate in equilibrium with solution A, (*4*) $Na_5Sc(CO_3)_4 \cdot 11H_2O$, (*5*) precipitated Zn–Sc concentrate, and (*6*) Zn–Sc concentrate treated with 10% NaOH solution. (*T*) Transmission and (ν) wave number.

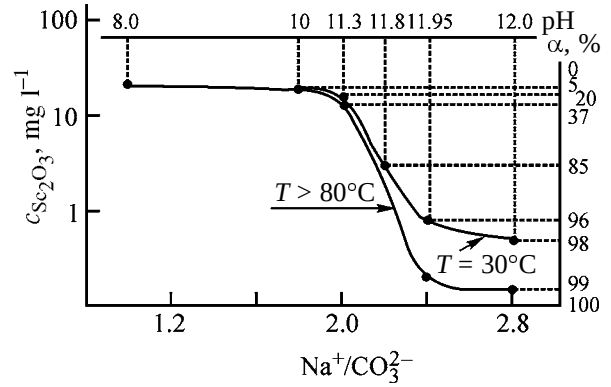

Fig. 4. Precipitation of scandium from solutions as influenced by the Na^+/CO_3^{2-} raito, temperature, and solution pH. Starting solution 1 M $NaHCO_3$, 20 mg l^{-1} of Sc_2O_3, time 2 h. ($c_{Sc_2O_3}$) Sc_2O_3 content and (α) degree of precipitation.

to the weight loss of 10.1%. In the range 230–340°C, the weight loss is 7.1%, and further, up to 430°C, it is 10.7%. Water and CO_2 are lost in these stages simultaneously, and the complex anion is destroyed.

The existence of a complex compound in solutions under study was proved by the IR spectra of solution A and of the precipitate in equilibrium with it. We also carried out potentiometric titration of 1 M solution of $NaHCO_3$ containing 0.87 g l^{-1} of Sc_2O_3. It was shown that scandium(III) ion coordinates four carbonate ligands. Some of these ligands are monodentate and the others are bidentate bridging. In the IR spectra of the hydrocarbonate solution of scandium(III), of the corresponding precipitate, and also of scandium(III) coprecipitated with zinc oxide from the hydrocarbonate solution (Fig. 3), we can distinguish sets of frequencies characteristic for coordinated carbonate groups OCO_2 with the symmetry reduced from D_{3h} to C_{2v}. The band ν_3 (D_{3h}) at 1420–1470 cm^{-1} is split to ν_1 and ν_5 (C_{2v}), with the strongest absorption bands being ν_5 (monodentate) = 1400–1419 and ν_1 (bidentate) = 1506–1558 cm^{-1}. The band ν_5 (bidentate) = 1347–1366 cm^{-1} corresponding to the bidentate coordination of OCO_2 groups is better pronounced in solution. In the lower-frequency region, there is the ν_2 band (C_{2v}) at 1020–1090 cm^{-1} and the ν_1 band, which is inactive in the IR spectra at the D_{3h} symmetry. A broad absorption band of water bending vibrations at ~1640 cm^{-1} is observed in the spectrum of the solution of the complex; it is also well resolved in the spectrum of the crystal hydrate.

Weak absorption bands at 665–675 and 705 cm^{-1} in the spectra of the solid products can correspond to the vibrations of the Sc–O and O–Sc–O bonds, including vibrations that involve oxygen atoms participating in the coordination bond of scandium with water molecules or carbonate groups. It is assumed that a part of carbonate groups in the scandium(III) complex carbonate act as bridging ligands participating in the construction of reticular structures with voids, which can be occupied by water molecules.

By varying the concentration and temperature (taking into account the kinetic factor), we found that the optimal temperature for the complex formation in the saturated hydrocarbonate solution is 40–50°C. We studied the precipitation of scandium from a carbonate–hydrocarbonate solution at various Na^+/CO_3^{2-} molar ratios, solution temperatures, and lower starting concentrations of scandium in solution. As the scandium(III) content in the starting solution and temperature decrease, the pH at which the Sc(III) compound starts to hydrolyze grows, i.e., a somewhat greater consumption of alkali is required and the degree of scandium(III) precipitation from the solution in the time of the experiment slightly decreases (Fig. 4).

To precipitate scandium(III) from carbonate solutions faster and more exhaustively, we suggested to coprecipitate its compounds with basic zinc carbonate. The precipitation was carried out under conditions of complete conversion of the hydrocarbonate solution to the carbonate solution, in the presence of a small excess of alkali. The solubility of the zincate in such solution is insignificant, and scandium(III) is captured by the forming precipitate. It is recommended to carry out the precipitation up to the excess NaOH concen-

tration of 10–25 g l^{-1} at 70–80°C. These conditions allow the residual scandium concentration in the mother solution to be decreased 0.2 mg l^{-1} of Sc_2O_3 [5].

The IR data suggest that scandium(III) is precipitated as a mixture of basic scandium(III) carbonate and the complex $Na_5Sc(CO_3)_4$; no heteronuclear zinc(II)–scandium(III) complexes are detected (Fig. 3). The bands corresponding to the basic carbonate disappear from the spectra of the zinc–scandium concentrate after washing it with a 10% solution of alkali to remove zinc, and the intensity of the bands of the complex decreases, but new bands appear, corresponding to $Sc(OH)_3$ which is insoluble in weakly alkaline solutions. These data show that scandium carbonate complexes do not exist in alkaline medium.

Based on the ability of scandium to form a soluble complex compound with carbonate ions, we developed a scheme of recovering scandium(III) from red mud, which is a waste product of alumina production. The complex formation of scandium(III) with carbonate anions makes it possible to use the equipment of the basic production, which makes the method economically and technologically attractive.

CONCLUSIONS

(1) The solubility of scandium(III) compounds in pure and mixed solutions of sodium hydroxide, carbonate, and hydrocarbonate was studied. It was shown that the solubility of scandium oxide decreases as the content of hydrocarbonate decreases, and when the free alkali appears, it falls down to 2.2×10^{-3} g l^{-1} of Sc_2O_3.

(2) The existence of the scandium complex compound $Na_5Sc(CO_3)_4 \cdot nH_2O$ in the hydrocarbonate solution, in the solid phase in equilibrium with it, and in the precipitate obtained by the coprecipitation of scandium with zinc oxide was proved by IR spectroscopy.

Received July 8, 2003; in the final form, December 2003

Abstract—The physicochemical characteristics of 1,2-dibenzoylhydrazine relevant to precipitation of copper(II) with this reagent were studied.

Symmetrical aliphatic 1,2-diacylhydrazines (DAHs) of the general formula RC(O)NHNHC(O)R (R is C_3H_7–C_5H_{11}) are potentially tetradentate complexing agents suitable for concentration and separation of metals and for wastewater decontamination from nonferrous metals (NMs) by flotation [1] and from Cu(II) by precipitation [2]. DAHs are easily prepared and are characterized by low toxicity and strong complexation with NMs. However, these reagents are coordinated with NMs at pH 9–11 considerably exceeding pH of wastewater (5.5–8.7). It is reasonable to suggest that replacement of an electron-donor alkyl radical in a DAH molecule by an electron-acceptor radical, e.g., phenyl radical, can increase the acidity of this reagent and hence shift its complexation with NMs to lower pH.

In this work we studied the physicochemical characteristics of 1,2-dibenzoylhydrazine (DBH) and its complexation with copper(II).

EXPERIMENTAL

1,2-Dibenzoylhydrazine was prepared by thermal decomposition of the salt $2C_6H_5COOH \cdot N_2H_4 \cdot H_2O$ [3]. The main substance content in DBH prepared by this procedure was no less than 97% as determined by conductometric titration on an OK-102/1 conductometer (Hungary) equipped with an OK-0902P bell-shaped electrode [4]. The optical density of solutions was measured on an SF-26 spectrophotometer and a KFK-2 photocolorimeter; pH was measured on an EV-74 ionometer equipped with glass and silver chloride electrodes. The voltammetric curves of DBH ethanol solutions were obtained in the dc mode on a PU-1 polarograph with a three-electrode cell at room temperature without deaeration. A platinum electrode was used as an indicator electrode, and a platinum plate, as an auxiliary electrode. The potentials were measured relative to a saturated silver chloride electrode. The IR spectra (mulls in Vaseline oil) were recorded on a Specord M-80 IR spectrometer. The thermogravimetric curves were recorded on an MOM (Model Q-1500, Hungary) derivatograph. The copper(II) content in solutions was determined by the extraction-photometric technique using extractable Cu(II) complex with zinc diethyldithiocarbamate [5].

The DBH solubility in water and several other solvents was determined as follows. A portion of DBH was contacted with a solvent for 24 h at 20 ± 0.5°C. An aliquot of the liquid phase saturated with DBH was sampled and dried in a drying oven at 105–110°C, and the resulting dry residue was weighed. In the case of 0.1 M aqueous KOH as solvent, the DBH concentration in saturated solution was determined from its optical density (λ = 240 nm, 1-cm optical cell) using a calibration curve. The DBH solubility in the solvents used was as follows (g l^{-1}): water 0.22, 2-methylbutanol 1.34, ethanol 5.22, *p*-xylene 0.48, chloroform 0.02, and 0.1 M aqueous KOH 9.6. These results show that the DBH solutions in both ethanol and aqueous alkali can be used for precipitation of Cu(II) and as collectors in Cu(II) recovery by flotation.

The first and second DBH ionization constants were determined spectrophotometrically [6]. Figure 1 shows the electronic absorption spectra of aqueous DBH at different pH. The absorption bands of nonionized DBH molecules in water (spectrum *1*) and their ionized species in alkaline solutions (curves *2* and *3*) in the range 300–320 nm considerably differ. In order to calculate pK_{a_1} and pK_{a_2} of DBH, the de-

pendence of the optical density D on pH_{eq} at 325 nm was studied (Fig. 2). Figure 2 shows that the plot of D vs. pH has two inflection points. The inflection points corresponding to the first and second steps of DBH ionization are located within pH ranges 9–9.5 and 10.5–11.0, respectively [see Eq. (1)]:

$$C_6H_5{-}\underset{\underset{O}{\|}}{C}{-}NH{-}NH{-}\underset{\underset{O}{\|}}{C}{-}C_6H_5 \quad (H_2L)$$

$$\overset{K_{a_1}}{\rightleftharpoons} C_6H_5{-}\underset{\underset{O^-}{|}}{C}{=}NH{-}NH{-}\underset{\underset{O}{\|}}{C}{-}C_6H_5 \quad (HL^-)$$

$$\overset{K_{a_2}}{\rightleftharpoons} C_6H_5{-}\underset{\underset{O^-}{|}}{C}{=}NH{-}NH{=}\underset{\underset{O^-}{|}}{C}{-}C_6H_5. \quad (L^{2-}) \qquad (1)$$

The pK_{a_1} and pK_{a_2} calculated by the formulas published in [6] are 9.22 ± 0.04 and 10.8 ± 0.3, respectively. The comparison of these ionization constants with those of aliphatic 1,2-diacylhydrazines, e.g., 1,2-dipentanoylhydrazine (DPH) ($pK_{a_1} = 11.21 \pm 0.04$, $pK_{a_2} = 12.0 \pm 0.3$) shows that DBH is a stronger acid than DPH.

In order to determine the resistance of DBH to hydrolysis, a portion of DBH (0.05–0.08 mmol) was dissolved in 1 M aqueous KOH (50 ml) at 60 ± 0.1°C. At intervals of 1, 2, 3, and 4 h, aliquots (5.0 ml) of the reaction mixture were sampled, and their optical densities were determined at λ = 325 nm in a 1-cm optical cell. We found that the optical density of the DBH alkaline solutions does not change in the first 2 h and then gradually increases (for example, after a lapse of 3 h, the optical density increases by 25%). The DBH hydrolysis was monitored spectrophotometrically at λ = 325 nm, which corresponds to the maximal difference between the optical densities of dibenzoylhydrazine (DBH) and the main expected hydrolysis products: benzoylhydrazine (BH) and potassium benzoate (PB) (Fig. 3). These species were chosen assuming that DBH is hydrolyzed in an alkaline solution by a mechanism identical to that of aliphatic DAH, involving formation of benzoate and hydrazine hydrate as the main products and benzoic acid hydrazide as intermediate [7]. Figure 3 shows that, if DBH were hydrolyzed by the above hypothetical mechanism, the optical density would decrease. However, our experiments showed that base hydrolysis of DBH is accompanied by an increase in the optical density. We believe that this opposite trend is caused, at least in the first stage of hydrolysis, by the redox reaction producing azo compounds:

(*3*) Curve *1* after treatment with the technique of shifting the solubility. Content: Cu(II) 63.5 mg l^{-1}, ethanol solution of DBH 10^{-2} M; ammonia buffer solution: $(NH_4)_2SO_4$ 0.125 M + NH_4OH 0.25 M, V 25 ml, and τ 5 min.

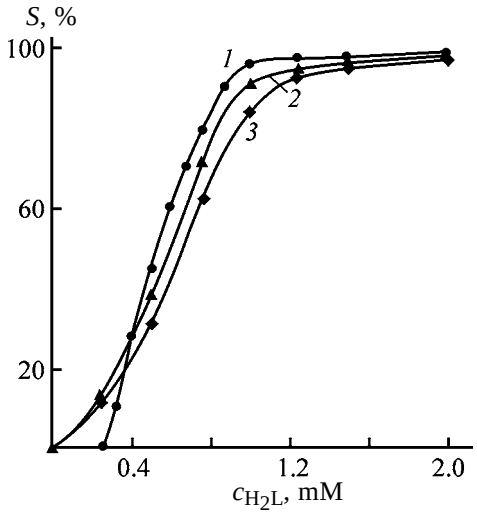

Fig. 5. Degree of precipitation of Cu(II) *S* as a function of DBH and DAH concentration c_{H_2L}. Cu(II) concentration 63.5 mg l^{-1}; ammonia buffer solution: $(NH_4)_2SO_4$ 0.125 M + NH_4OH 0.25 M, *V* 25 ml, and τ 5 min. H_2L: (*1*) DBH, (*2*) DPH and (*3*) dibutanoylhydrazine in ethanol.

$$2C_6H_5\text{–}\underset{\underset{O}{\|}}{C}\text{–NH–NH–}\underset{\underset{O}{\|}}{C}\text{–}C_6H_5 + O_2$$

$$\rightleftarrows 2C_6H_5\text{–}\underset{\underset{O}{\|}}{C}\text{–N=N–}\underset{\underset{O}{\|}}{C}\text{–}C_6H_5 + 2H_2O. \qquad (2)$$

Although the products of this reaction were not identified by us and its true mechanism is unknown, nevertheless, we established that DBH is chemically stable in 1 M aqueous KOH at 60°C for at least the first 2 h. At the same time, DPH under identical conditions decomposes to 40% in the first 3 h [6].

The voltammetric curves of DBH (10^{-2} M) in 1 M aqueous KOH were registered at the cathodic polarization at intervals of 1, 2, 3, 4 and 5 h. We found that the height of polarographic waves decreases with time due to electrochemical oxidation of DBH. The comparison of the voltammetric curves of DBH and DPH [6] shows that these compounds have approximately equal stability to electrochemical oxidation in 1 M aqueous KOH.

Since the poorly soluble complexes of Cu(II) with DBH are floatable only in the persence of a frother, the DBH complexation with Cu(II) was studied by a precipitation technique. Figure 4 shows that DBH precipitates Cu(II) within the wide pH range and the most complete precipitation (up to of 99.8%) is reached within pH 6–10. With increasing ammonia content to 0.5 M (pH ~11), the degree of recovery of Cu(II) decreases to 96% due to the competing formation of soluble Cu(II) ammonia complexes. Addition of $(NH_4)_2SO_4$ to 0.125 M does not noticeably affect the precipitation of Cu(II).

Figure 5 shows the degree of precipitation of Cu(II) as influenced by the content of DBH and aliphatic DAH. The curve obtained with DBH has an inflection point corresponding to Cu(II) : DBH ratio in the precipitate equal to unity. The plot of $\log \varepsilon$ [$\varepsilon = S_i(1 - S_i)$] vs. pH_{eq} shows that the precipitation of copper(II) with DBH in the form of 1 : 1 complex is accompanied by liberation of two moles of [H^+] per mole of DBH, i.e., the precipitated complex contains L^{2-} anions.

The comparison of the precipitation curves presented in Fig. 5 shows that at equal pH DBH (curve *1*) more efficiently precipitates Cu(II) than do aliphatic DAHs (curves *2* and *3*). The efficiency of precipitation of Cu(II) with DAHs from NH_4OH + $(NH_4)_2SO_4$ buffer mixture at pH 9–10 can be increased by adding KOH to increase the degree of DBH ionization [2]. DBH, owing to its high acidity, precipitates 96% of Cu(II) even at pH 5.

Thus, the precipitation of Cu(II) in the form of its complex with DBH can be described by the equation

$$[Cu(NH_3)_4]^{2+} + H_2L \rightleftarrows CuL\downarrow + 2NH_3 + 2NH_4^+. \qquad (3)$$

The residual Cu(II) concentration in the filtered solution (pH 9.4), determined 5, 15, 30, and 60 min after precipitation at Cu : DBH = 1 : 1, was constant. These data show that 5 min is sufficient for ripening of the CuDBH precipitate.

The Cu : DBH ratio in the precipitate was determined by conductometric titration as follows. 10^{-2} M aqueous $CuSO_4$ (5 ml) and distilled water (60 ml) were poured into a 100-ml beaker, and then the ammonia buffer solution was added dropwise until a blue color of Cu(II) ammonia complex appeared. This solution was titrated by adding 0.2-ml portions of 10^{-2} M DBH in alcohol. The curve of conductometric titration has three inflection points corresponding to formation of complexes with Cu : DBH ratios of 2 : 1, 1 : 1, and 1 : 2.

We attempted to isolate the complexes of Cu(II) with DBH from ammonia solutions at Cu : DBH ratios of 1 : 1 and 1 : 2. In these experiments, 10^{-2} or 5×10^{-3} M aqueous $CuSO_4$ (50 ml) was placed in a 250-ml beaker, and 10 M aqueous NaOH (2.8 ml) and 2.5 M aqueous $(NH_4)_2SO_4$ (5.2 ml) were added. Thereafter, while stirring this mixture, 10^{-2} M DBH in ethanol (50 ml) was added to each of these solutions, and the resulting suspensions were allowed to stand for 30 min. The precipitates were filtered off, successively washed on the filter with hot water and ethanol, and then air-dried.

The complexes precipitated at Cu : DBH ratios of 1 : 1 and 1 : 2 have green color and are poorly soluble in water and common organic solvents. Their IR spectra and thermogravimetric curves are identical. In the IR spectra, instead of the absorption bands of NH (3160 cm^{-1}) and C=O (1670, 1635 cm^{-1}) stretching vibrations in the DBH molecule, the absorption bands of the C=N (1520 cm^{-1}) and C–O (1400 cm^{-1}) vibrations appear. These spectroscopic data confirm that Cu(II) in the complexes under consideration coordinates with double-deprotonated DBH molecule (L^{2-}).

The thermogravimetric analysis shows that both 1 : 1 and 1 : 2 complexes are thermally stable up to 325°C. The elemental analysis shows that these complexes have identical copper content. The complexes prepared at Cu(II) : DBH = 1 : 1 and 1 : 2 contain 20.85% and 20.73% Cu(II), respectively, which is close to the calculated copper content in $Cu(C_6H_5OCNNCOC_6H_5)$, 21.06%.

Thus, although conductometric titration shows that in aqueous ammonia the 2 : 1, 1 : 1, and 1 : 2 complexes are formed, only the 1 : 1 complex was isolated. The precipitation of Cu(II) in the form of this poorly soluble complex can be used for quantitative gravimetric determination of Cu(II).

In industrial flotation and precipitation of metals, both the froth products and precipitates are commonly dried and ashed. Therefore, the development of procedures for reuse of the reagents is an important problem [8]. We found that, on treatment of the filtered poorly soluble complex of Cu(II) with DBH with 0.25–2.0 M aqueous H_2SO_4, this complex is readily broken down to give a white crystalline precipitate of DBH and a filtered solution of $CuSO_4$. This solution was collected in a 25-ml volumetric flask, and water was added the mark. A 5-ml aliquot of the filtered solution was sampled, and the Cu(II) content was determined by complexometric titration with EDTA [9]. It was established that the complete DBH regeneration with aqueous H_2SO_4 is reached at H_2SO_4 concentration not lower than 0.5 M.

CONCLUSIONS

(1) Introduction of phenyl radicals into 1,2-diacylhydrazines increases their acidity by two orders of magnitude and enhances their chemical stability in alkaline solutions.

(2) The complexes of 1,2-dibenzoylhydrazine with Cu(II) are formed in ammonia solutions at pH within 5–8 without adding alkali, whereas aliphatic 1,2-diacylhydrazines are coordinated with Cu(II) at pH 9–10.

(3) Owing to low solubility of 1,2-dibenzoylhydrazine in water and aqueous acids, this reagent can be recovered from its complexes with Cu(II) by treatment with 0.5 M aqueous H_2SO_4.

Institute of Phytochemistry, Ministry of Education and Science of the Kazakhstan Republic, Karaganda, Kazakhstan

Received February 11, 2004

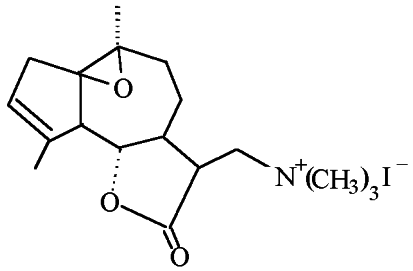
Abstract—The heat of solution of dimethylaminoarglabin methyl iodide $C_{18}H_{28}O_3NI$ at dilutions (mole of salt/mole of water) of 1 : 75000, 1 : 100000, and 1 : 150000 was determined by isothermal calorimetry. The data obtained were used to calculate the standard heat of solution of the compound in an infinitely dilute (standard) aqueous solution. The heats of combustion, melting, and formation of $C_{18}H_{28}O_3NI$ and 33 its analogs were estimated by approximate methods of chemical thermodynamics.

Calorimetric methods, which are the primary source of information in physical chemistry of solutions, are the most commonly used in biochemical thermodynamics [1]. A study of thermochemical and thermodynamic properties of terpenoids is of certain theoretical and practical significance for their controlled synthesis. In this respect, natural sesquiterpene lactones, most of which possess a wide spectrum of biological activity, are of interest [2]. Various pharmaceuticals based on sesquiterpene lactones have been and are being developed. For example, original antitumor preparation Arglabin based on sesquiterpene lactone derived from *Artemisia glabella* Kar. et Kir., growing solely in Central Kazakhstan, was developed and applied in medicine [3]. The Arglabin drug was registered in the Kazakhstan Republic, and its registration in the Russian Federation is in progress.

Thermochemical and thermodynamic properties of sesquiterpene lactones of the general formula $C_{15}H_{18}O_3$ (including Arglabin) and its derivatives have been studied previously [4].

EXPERIMENTAL

In this work, we studied experimentally the enthalpy of solution of dimethylaminoarglabin methyl iodide $C_{18}H_{28}O_3NI$ in water.[1] The structural formula of dimethylaminoarglabin methyl iodide is presented below:



The enthalpy of solution of the compound was studied on a DAK-1-1A automated differential calorimeter at 25°C at dilutions (mole of substance/mole of water) of 1 : 75000, 1 : 100000, and 1 : 150000. The heat of solution was determined in the automatic heat compensation mode. The thermal effects were recorded with a KSP-4 self-recorder and IP-4 precision integrator. The time of the preliminary thermostating of the substance was 2 h. The integrator drift did not exceed three units of the last digit in 100 s. Prior to the experiment, the instrument was calibrated by Joulean heat. To do this, a calibrated voltage was supplied to a built-in heater of the instrument, and the released power was measured. The calibration of the instrument was checked by measuring the heat of solution of triply recrystallized potassium chloride at dilutions (mole of salt/mole of water) of 1 : 1600, 1 : 2400, and 1 : 3200. The average heat of the KCl solution in water (17860 ± 283 J mol^{-1}) agrees well (to within 1.6–2.0%) with the known values of 17577 ± 34 [5] and 17489 ± 371 J mol^{-1} [6].

[1] The compound of the pharmacopoeia purity was prepared at the Laboratory of Terpenoid Chemistry of the Institute of Phytochemistry.

Table 1. Enthalpy of solution of dimethylaminoarglabin methyl iodide in water at various dilutions

$C_{18}H_{28}O_3NI$ weight, g	Q_s, J	ΔH_s^m, kJ mol^{-1}
Dilution 1:75 000		
0.0016	0.100	27.06
0.0017	0.106	26.99
0.0018	0.113	27.17
0.0015	0.093	26.84
0.0015	0.094	27.13
Average ΔH_s^m (1) = 27.04 ± 0.16		
Dilution 1 : 100 000		
0.0011	0.087	34.24
0.0012	0.094	33.91
0.0011	0.086	33.84
0.0012	0.096	34.63
0.0013	0.104	34.29
Average ΔH_s^m (2) = 34.18 ± 0.51		
Dilution 1 : 150 000		
0.0008	0.085	45.99
0.0008	0.084	45.45
0.0009	0.092	44.25
0.0007	0.074	45.76
0.0007	0.074	45.76
Average ΔH_s^m (3) = 45.44 ± 0.86		

The experimental errors and uniformity of their variance were calculated by the methods of mathematical statistics using the Student and Bartlett tests [7]. The results of the calorimetric study are presented in Table 1.

Then, the experimentally obtained enthalpies of dimethylaminoarglabin methyl iodide solution at various dilutions were extrapolated to infinite dilution, and the standard enthalpies of solution of the compound in an infinitely dilute (standard) aqueous solution were calculated. Based on the equation $\Delta H_s^m = fm^{1/2}$ (m is molal concentration), it was established [8] that the dependence of the enthalpy of $C_{18}H_{28}O_3NI$ solution, ΔH_s^m (kJ mol^{-1}), on the molal concentration is described by the relationship

$$\Delta H_s^m = 86.8 - 2206.0m^{1/2}, \quad (1)$$

from which the standard enthalpy of solution of dimethylaminoarglabin methyl iodide in an infinitely dilute (standard) aqueous solution was determined as 86.8 ± 1.2 kJ mol^{-1}.

To calculate the standard enthalpy of formation of $C_{18}H_{28}O_3NI$, its standard heat of combustion was estimated using the Karash and Frost methods [9], which are the most suitable procedures for taking into account contributions of various groups in the molecule to the heat of combustion.

The average enthalpy of combustion of $C_{18}H_{28}O_3 \cdot NI$ in liquid state, calculated by these two methods, is –10 792 ± 134 kJ mol^{-1}.

The $\Delta_f H^0_{298.15}$ of $C_{18}H_{28}O_3NI$(l) was calculated using the average ΔH^0_{comb} value by the Hess cycle based on the reaction

$$2C_{18}H_{28}O_3NI(l) + 47O_2(g) = 36CO_2(g) + 28H_2O(l) + N_2(g) + I_2(g) - \Delta H^0_{comb} \quad (2)$$

to be –300.3 kJ mol^{-1}.

It should be noted that the Karash and Frost methods can be applied solely to calculating the enthalpy of combustion ΔH^0 of liquid hydrocarbons. The required values of $\Delta_f H^0_{298.15}$ of CO_2(g) and H_2O(l) were taken from [10].

Since at standard temperature (298.15 K) the compound studied is in the crystalline state, a need arises to calculate $\Delta_f H^0_{298.15}$ of its solid modification. To do this, the ΔH^0_m values of the compounds were estimated by the empirical equation [11]

$$\Delta H^0_m = 44.4T_m - 4400. \quad (3)$$

The ΔH^0_m value of $C_{18}H_{28}O_3NI$, calculated by Eq. (3), is 16.7 kJ mol^{-1}. From the equation

$$\Delta_f H^0_{298.15}[C_{18}H_{28}O_3NI(s)] = \Delta_f H^0_{298.15}[C_{18}H_{28}O_3NI(l)] - \Delta H^0_m, \quad (4)$$

the standard enthalpy of formation of dimethylaminoarglabin methyl iodide in the crystalline state was calculated as –317.0 kJ mol^{-1}.

The standard enthalpy of formation of $C_{18}H_{28}O_3NI$ in aqueous solution was determined using the standard enthalpy of solution of dimethylaminoarglabin methyl iodide in standard (infinitely dilute) aqueous solution by the equation

$$\Delta_f H^0_{298.15}[C_{18}H_{28}O_3NI(sol., H_2O, stand. state)] = \Delta_f H^0_{298.15}[C_{18}H_{28}O_3NI(s)] + \Delta H^0_s; \quad (5)$$

it was found to be –230.2 kJ mol^{-1}.

Table 2. Standard heats of formation of $C_{18}H_{28}O_3NI$ and its analogs

Compound	$-\Delta_f H^0_{298.15}$, kJ mol^{-1}	Compound	$-\Delta_f H^0_{298.15}$, kJ mol^{-1}
$C_{18}H_{28}O_3NF$	497	$C_{18}H_{28}O_3NNO_2$	283
$C_{18}H_{28}O_3NBr$	294	$[C_{18}H_{28}O_3N]_3PO_4$	1760
$C_{18}H_{28}O_3NCl$	334	$[C_{18}H_{28}O_3N]_4P_2O_7$	2925
$C_{18}H_{28}O_3NClO_4$	309	$[C_{18}H_{28}O_3N]_2CO_3$	1009
$C_{18}H_{28}O_3NClO_3$	288	$[C_{18}H_{28}O_3N]_2C_2O_4$	1172
$C_{18}H_{28}O_3NBrO_3$	276	$C_{18}H_{28}O_3NAlO_2$	1080
$C_{18}H_{28}O_3NIO_3$	431	$C_{18}H_{28}O_3NBO_2$	908
$[C_{18}H_{28}O_3N]_2SO_4$	1251	$C_{18}H_{28}O_3NReO_4$	1016
$[C_{18}H_{28}O_3N]_2SO_3$	970	$C_{18}H_{28}O_3NMnO_4$	752
$[C_{18}H_{28}O_3N]_2SeO_4$	931	$[C_{18}H_{28}O_3N]_2Cr_2O_7$	1890
$[C_{18}H_{28}O_3N]_2TeO_4$	1115	$[C_{18}H_{28}O_3N]_2CrO_4$	1233
$[C_{18}H_{28}O_3N]_2S_2O_3$	1019	$[C_{18}H_{28}O_3N]_2WO_4$	1433
$[C_{18}H_{28}O_3N]_2SeO_3$	829	$[C_{18}H_{28}O_3N]_2MoO_4$	1259
$[C_{18}H_{28}O_3N]_2TeO_3$	859	$C_{18}H_{28}O_3NVO_3$	1083
$[C_{18}H_{28}O_3N]_2S$	319	$C_{18}H_{28}O_3NNbO_3$	1262
$[C_{18}H_{28}O_3N]_2Se$	360	$[C_{18}H_{28}O_3N]_3AsO_4$	1389
$C_{18}H_{28}O_3NNO_3$	388		

The equation

$$\Delta_f H^0_{298.15}[C_{18}H_{28}O_3N^+(\text{sol., } H_2O, \text{ stand. state})] = \Delta_f H^0_{298.15}[C_{18}H_{28}O_3NI(\text{sol., } H_2O, \text{ stand. state})] - \Delta_f H^0_{298.15}[I^-(\text{sol., } H_2O, \text{ stand. state})] \quad (6)$$

was used to calculate the standard enthalpy of formation of the $[C_{18}H_{28}O_3N]^+$ ion in a standard aqueous solution (–174.9 kJ mol^{-1}). The $\Delta_f H^0_{298.15}[I^-(\text{sol., } H_2O, \text{ stand. state})]$ value necessary for calculation was taken from a reference book [10].

The found $\Delta_f H^0_{298.15}[C_{18}H_{28}O_3N]^+$ value in aqueous solution made it possible to calculate the standard heats of formation of the $C_{18}H_{28}O_3NI$ analogs.

A method using the enthalpy increments, $\Delta_f H^i_{298.15}$, for calculating $\Delta_f H^0_{298.15}$ of inorganic salts has been proposed in [12, 13]. The increments, or standard constituents, are convenient for the calculation of thermodynamic properties assuming their additivity. In this case, the thermodynamic property of a substance is determined as the sum of the standard thermodynamic constants of its constituents (in the given case, ions). The standard enthalpy of formation of the crystalline salt was calculated by the formula [12, 13]

$$\Delta_f H^0_{298.15}[Me_m(X_\alpha O_\beta)_n] = m\Delta_f H^0_{298.15}[Me^{n+}(\text{sol., } H_2O, \text{ stand. state})]K + n\Delta_f H^i_{298.15}(X_\alpha O_\beta)^{m-}. \quad (7)$$

To use the given formula, it is sufficient to know the $\Delta_f H^0_{298.15}[Me^{n+}(\text{sol., } H_2O, \text{ stand. state})]$ values. The values of the K parameters (proportionality coefficients) and $\Delta_f H^i_{298.15}(X_\alpha O_\beta)^{m-}$ (the enthalpy increments of the anions) are tabulated in [12, 13]. For the compound $C_{18}H_{28}O_3NI$, scheme (7) can be presented as follows:

$$\Delta_f H^0_{298.15}[C_{18}H_{28}O_3NI(s)] = \Delta_f H^0_{298.15}[C_{18}H_{28}O_3N^+(\text{sol., } H_2O, \text{ stand. state})]K + \Delta_f H^i_{298.15}(I^-). \quad (8)$$

The calculated $\Delta_f H^0$ values for $C_{18}H_{28}O_3NI$ and 33 its analogs are presented in Table 2.

CONCLUSIONS

(1) The standard enthalpy of solution of dimethylaminoarglabin methyl iodide in water was determined by isothermal calorimetry.

(2) Its enthalpies of combustion and melting were calculated. The standard heat of formation of the cation $[C_{18}H_{28}O_3N]^+$ in aqueous solution was determined using the calculated and experimental enthalpies of solution of dimethylaminoarglabin methyl iodide in standard aqueous solution.

(3) The standard heats of formation of $C_{18}H_{28}O_3NI$ and 33 related compounds were calculated using the method of ionic increments.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Kinetics and Mechanism of Thermal Decomposition of Guanidinium Nitrate and Its Mixtures with Ammonium Nitrate

Yu. I. Rubtsov, A. I. Kazakov, D. B. Lempert, and G. B. Manelis

Institute of Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received December 15, 2003; in final form, April 2004

Abstract—The kinetics of heat release in thermal decomposition of guanidinium and ammonium nitrates and their mixtures in the liquid phase in a calorimeter was studied. The kinetic equations of these processes and temperature dependences of the kinetic constants in these equations were evaluated. The oxidation rate constants of guanidinium and ammonium cations with molecular nitric acid in aqueous nitric acid solutions were found; these constants were calculated by solution of the reverse problem for salt melts. The temperatures and ΔH values of melting of the initial salts and their eutectic mixture were determined.

Ammonium nitrate (AN) is widely used in agriculture as nitrogen fertilizer and as oxidant in production of explosives and gas-generating fuel compositions. Modification of AN using various additives to provide the required physicochemical and energy properties of the resulting compositions is urgent, especially for fuels. One of possible ways of modification is addition to AN of other onium nitrates with negative oxygen balance, which thus can act as fuels. Unfortunately, many onium nitrates (hydrazinium, hydoxylammonium, urea, etc.) have poor thermal stability, which hinders their practical use. One of the most stable onium nitrates is, probably, guanidinium nitrate (GN); the mixture of 2 mol AN and 1 mol GN has zero oxygen balance. Initially, all the onium nitrates thermally degrade through equilibrium dissociation to form the initial base and nitric acid. As a rule, the rate of decomposition is determined by the equilibrium constant of dissociation of the nitrate into the base and nitric acid and by the rate of oxidation of the corresponding cation with a nitric acid molecule or by the rate of thermal transformation of the base [1].

In aqueous solution, guanidine is a stronger base (pK 13.6) than ammonia (pK 9.27) [2]. The pK values can strongly change on passing from aqueous solutions to the ionic nitrate melt. However, since the difference in pK in aqueous solutions is very large, we assumed that it cannot be completely leveled off in the melt, and thus the concentration of nitric acid in GN should be significantly smaller than in AN. Data on the rate of oxidation of $CN_3H_6^+$ ion with HNO_3 molecule are lacking. Theoretically, this constant may be noticeably higher than the rate constant of oxidation of NH_4^+ ion, which should significantly increase the rate of GN thermal decomposition. Relatively high melting point of guanidinium nitrate (214°C) indicates that the rate of NG decomposition is lower as compared with AN. Since at relatively high decomposition rate determination of the melting point is virtually impossible, the rate of GN decomposition at 214°C is small. Some data on the rate of hydrolysis of $CN_3H_6^+$ ion at 240–300°C are given in [3]. It was found that the nitrate ion does not participate in transformations at water excess, whereas $CN_3H_6^+$ ion undergoes autocatalytic hydrolysis to form CO_2 and NH_3 with urea intermediate. From the rates of heat release from liquid mixtures of AN and GN, it will be possible to assess the feasibility of their processing, in particular, the feasibility of granulation of these mixtures through the melt, as it is often used for technical AN (fertilizer).

EXPERIMENTAL

In this work we used analytically pure grade guanidinium and ammonium nitrates. The kinetics of heat release in thermal decomposition of GN and AN was studied with a DAK-1-2 differential dynamic calorimeter [4] using sealed glass ampules (2 cm^3 volume) completely accommodated in the working cell of the

1070-4272/04/7707-1083 © 2004 MAIK "Nauka/Interperiodica"

calorimeter and thus having no cold sections. The data on the rate of heat release at thermal decomposition of NA commercially produced as agricultural fertilizer [1] showed that the process rate strongly depends on the free volume of the system, due to the transfer into the gas phase at elevated temperatures of certain fraction of NH_3 formed at reversible dissociation of the nitrate into NH_3 and HNO_3. With NH_3 removal from the melt, the content of HNO_3 in the melt and the rate of thermal decomposition increase. To determine the decomposition rate of the salt with the composition closest to the stoichiometry, the process should be performed at the smallest possible free volume to exclude evaporation of NH_3. However, under these conditions, gaseous products formed by the salt decomposition sharply increase the internal pressure and the ampule can be broken. At 200–230°C, the glass ampule (internal diameter 7–8 mm and wall thickness 1–1.15 mm) withstands internal pressure of up to 2 MPa and is broken at higher pressures. Owing to this reason, our experiments on thermal decomposition of AN were interrupted in the initial stage of the process, and the amount of the released gaseous products and pressure in the ampule were evaluated from the amount of the heat released. For comparison, the kinetics of heat release in decomposition of GN and its mixtures with AN were studied under the same conditions, though the equilibrium guanidine pressure over GN at the experimental temperatures is low and the decomposition rate of pure salt is almost independent of the free ampule volume. As for AN + NG mixtures, this dependence becomes more pronounced with increasing AN content in the mixture.

The phase transition temperatures required to evaluate the possibility of granulation of the AN + NG mixtures through the melt (melting point of the eutectic mixture T_e and temperature of the complete melting of the mixture T_f) were determined from the thermograms recorded on a DAK-1-1 differential calorimeter in the linear heating mode. The experiments began at temperatures lower than T_e, when the mixture components are solid, and finished at T_f, when the heat absorption due to the salt melting was terminated. The temperatures T_e and T_f were determined from the beginning and end of the heat absorption. The rate of heat absorption in these steps changed rapidly; the temperatures of the beginning and end of the process could be determined with ±1% accuracy. The thermal effects of the phase transitions were calculated by integration of the curves of heat absorption registered during melting of the mixture.

The kinetics of the heat release in thermal decomposition of pure GN and AN were studied in the ranges 216.8–247.6 (Fig. 1a) and 201.0–230.7°C, respectively. Comparison of the rates showed that, at 200–230°C, the initial rate of heat release in GN decomposition is lower, compared to AN, by a factor of 2.0–3.5. But this difference is not so large as it should be expected if the difference in pK of CN_3H_5 and NH_3 remained constant on passing to the salt melts and the oxidation rate constants of the corresponding cations were similar. Decomposition of AN proceeds with self-acceleration determined by accumulation of nitric acid in the course of the process. The effect of HNO_3 and H_2O on the AN decomposition was studied previously [5]. The initial decomposition rate of reagent grade AN (W mol^{-1}) is close to that of granulated AN produced as fertilizer, but the degree of self-acceleration is significantly smaller. The resulting rate curves can be described by the following kinetic equation:

$$dQ/dt = k_1 + k_2Q. \quad (1)$$

A similar equation was used previously [5] to describe the kinetics of heat release in AN decomposition, but in this case the self-acceleration began only after release of 400–800 J mol^{-1} because of the presence of organic impurities in the sample oxidizable with HNO_3. The k_1 values from Eq. (1) are given below:

T, °C	201	209.6	216.8	223.6	230.7
$k_1 \times 10^2$, W mol^{-1}	3.5	9.8	18	36	78
$k_2 \times 10^5$, s^{-1}	6.4	8.1	8.9	9.4	10.5

The temperature dependences of the constants k_1 and k_2 are as follows:

$$k_1 = 8.4 \times 10^{20} \exp(-203 \times 10^3/RT),$$

$$k_2 = 0.21 \exp(331.8 \times 10^3/RT).$$

We should note slower self-acceleration and low activation energy of this process. The difference from AN produced as fertilizer is probably due to the impurities, which decrease the hygroscopicity and hinder phase transitions in AN. Moreover, the content of water in the AN samples in question is probably higher than in the fertilizer. We failed to remove water without loss of NH_3 by drying in air of small samples at temperatures ≥100°C; as a result, the content of HNO_3 in the sample and the initial decomposition rate increase. After drying of the sample for 3 h at 105°C, the initial decomposition rate increases by a factor of 4; no acceleration of the process was observed,

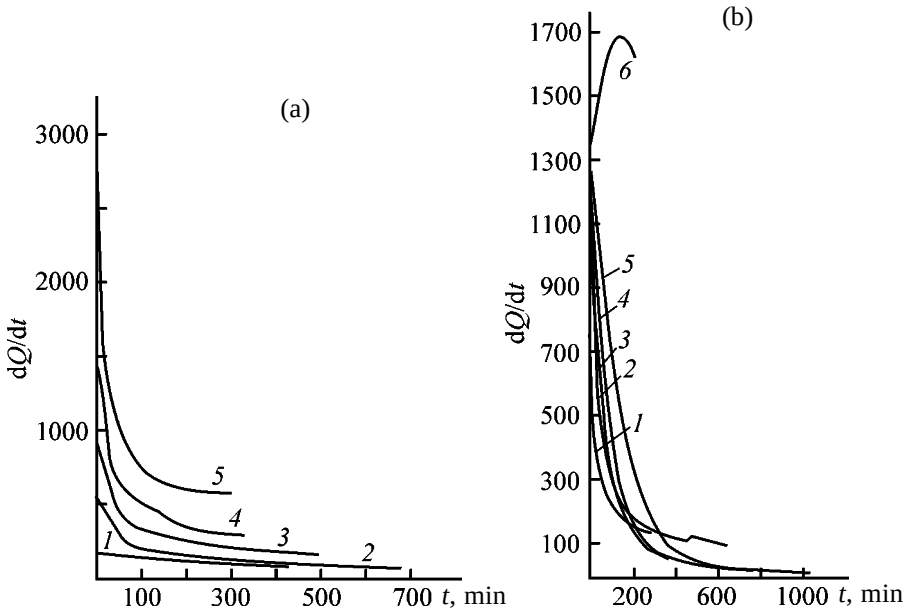

Fig. 1. Kinetic curves of heat release dQ/dt in thermal decomposition of (a) GN and (b) GN + AN mixtures at 223.6°C. (t) Time. (a) Decomposition temperature, °C: (*1*) 216.8, (*2*) 223.6, (*3*) 230.7, (*4*) 239.8, and (*5*) 247.6. (b) Mole fraction N_{AN}: (*1*) 0.147, (*2*) 0.356, (*3*) 0.690, (*4*) 0.810, (*5*) 0.905, and (*6*) 0.955.

because at relatively high initial concentration the acid is not further accumulated. Our results confirmed strong dependence of the rate of AN decomposition on the salt stoichiometry, content of impurities, and experimental conditions, found previously in [1].

The kinetics of heat release in GN thermal decomposition differs from that in AN decomposition; no self-acceleration is observed and the process rate sharply decreases in the course of experiments. This is obviously due to a change in the oxygen balance in GN as compared to AN, with the corresponding changes in the reaction pathways and products of oxidative decomposition. Since one HNO_3 molecule cannot oxidize all the three amino groups and the carbon atom in the $CN_3H_6^+$ molecule, GN is the oxidant-deficient compound. As a result, various bases, including probably NH_3 and CN_3H_5, are accumulated in thermal decomposition and not HNO_3 as in the case of AN. The equilibrium content of HNO_3 will decrease due to the shift in the equilibrium of salt dissociation to the acid and base with increasing total content of bases. As a result, the rate of oxidation with HNO_3 will also decrease. The amount of heat released during the experiments (Fig. 1a) is rather small and comprises 4–12 kJ mol^{-1}. This is significantly smaller than the theoretical heat of GN decomposition (460 kJ mol^{-1}) at complete consumption of oxygen in oxidation and formation of liquid water. The greater fraction of GN remains unchanged, and the rate of its decomposition is very small. This confirms that accumulation of bases (and not GN loss) is the decisive factor responsible for the process deceleration.

Taking into account the above reasons concerning the effect of the reaction products on the process rate, the resulting rate curves of the heat release can be described by the following kinetic equation:

$$\mathrm{d}Q/\mathrm{d}t = k/(b + fQ). \qquad (2)$$

The k/b value determines the initial decomposition rate. The parameters of this equation obtained by linearization of the experimental kinetic curves are given below:

T, °C	216.8	223.6	230.7	239.8	247.6
$k/b \times 10^2$, W mol^{-1}	5.4	16.4	20.4	36.7	79.0
k/f, J mol^{-2} s^{-1}	9.9	17.6	32.2	64.4	143

Their temperature dependences are as follows:

$$k/b = 4.2 \times 10^{16} \exp(-167.2 \times 10^3/RT),$$

$$k/f = 7.9 \times 10^{20} \exp(-179.7 \times 10^3/RT),$$

where k is the rate constant, dimensionless parameter b, the initial content of CN_3H_5 (mole) formed in the reverse dissociation of GN into base and acid; and f, amount of base (mole) formed at release of 1 J heat

due to decomposition of GN (mol J^{-1}); fQ is the dimensionless quantity.

Since in thermal decomposition of AN and GN the salt consumption affects the process rate only in the late stages, it was not taken into account in the kinetic equation. Due to the features of the evaluation procedure, we studied only the initial stages of the process, when the degree of decomposition was lower than 10%.

The rate of AN decomposition sharply increases during the process, whereas the rate of GN decomposition decreases by virtually the same factor. As a result, the difference in the decomposition rates of these salts rapidly increases in the course of the experiment, despite rather small difference in the initial decomposition rates. The period required to attain similar conversion for GN is significantly lower than for AN. For example, after heat release from both salts of 2000 J mol^{-1} at 230.7°C, their decomposition rates differ by a factor of 20, whereas the initial rates differ by a factor of only 3.5.

We studied the kinetics of heat release in thermal decomposition of AN + GN mixtures of various compositions at 223.6°C; at this and the other temperatures studied, all the mixtures are homogeneous liquid solutions. Since the decomposition rate in the salt mixture is determined by the equilibrium dissociation of these salts and all the equilibrium reactions in solutions are often expressed through the mole fractions of components N, the experimental rates of heat release were calculated per mole of solution, i.e., for a mixture with sum of the amounts of components equal to 1 mol. In such a solution, the mole fraction of a certain component equals to its amount in moles. The rate constants for pure AN and GN were also calculated per mole of the compound. The kinetic curves of heat release for AN + GN mixtures are shown in Fig, 1b. As seen, in contrast to the self-acceleration of decomposition of pure AN, the process rate gradually decreases on passing to the mixtures even at mole fraction of GN of 0.1, with a sharper decrease at higher GN content.

For the AN + GN mixture with 2 : 1 molar ratio, the initial rate of heat release (W mol^{-1}) in the 209.6–247.6°C range was measured:

T, °C	$(dQ/dt)_{t=0}$
209.6	0.16
216.8	0.20
223.6	0.86
230.7	0.54
239.8	1.1
247.6	1.7

and its temperature dependence was evaluated:

$$(dQ/dt)_{t=0} = 1.9 \times 10^{13} \exp(-130.0 \times 10^3/RT).$$

As will be shown below, the rate of heat release in the salt mixture is determined by sum of the oxidation rates of NH_4^+ and $CN_3H_6^+$, and its temperature dependence is given by the sum of the two corresponding exponents. Therefore, the temperature dependence presented is obviously formal and correct only in a narrow temperature range; in other temperature ranges, this dependence should change.

In the general form, the initial rate of heat release in decomposition of pure NH_4NO_3 and $CN_3H_6NO_3$ is determined by the salt content and by the rate constant and heat of salt decomposition. If the two salts in the mixture decomposed independently, the initial rate of heat release in the AN + GN mixture (per mole of the mixture) would be determined by the sum of contributions of each salt component to the total heat release, taking into account its content:

$$dQ/dt = k_{AN} Q_{AN} N_{AN} + k_{GN} Q_{GN} N_{GN} = k_{GN} Q_{GN} + N_{AN}(k_{AN} Q_{AN} - k_{GN} Q_{GN}), \quad (3)$$

where k_{AN} and k_{GN}, Q_{AN} and Q_{GN}, and N_{AN} and N_{GN} are the rate constants of decomposition, total heats of decomposition, and mole fractions of the corresponding salts in the mixture.

Thus, constants in Eqs. (1) and (2) can be given as follows:

$$k_1 = k_{AN} Q_{AN}, \qquad k/b = k_{GN} Q_{GN}.$$

The dependence of the rate of the heat release on the AN mole fraction should be linear, and the extreme points should correspond to the initial rates for the pure compounds. The dependence of the initial rate of the heat release in the AN + GN mixtures on the AN mole fraction is shown in Fig. 2. As seen, all the experimental points lie above the straight line connecting the initial rates of the heat release in decomposition of the pure salts. The salts interact with each other in the melt, but the deviations from the straight line are not very large, and the rates of the heat release in the AN + GN mixtures are fairly close from that in AN. These results suggest that the safety in treatment of liquid AN + GN mixtures (e.g., their granulation through the melt) under similar conditions is similar; at least, the difference is smaller than the differences in the rates of heat release for various

batches of commercial AN, differing by an order of magnitude and more. If we take into account that no self-acceleration is observed in the AN + GN mixtures at $N_{GN} > 0.1$ and the rate of heat release gradually decreases, the probability of the runaway should be smaller. At the same time, the specific conditions of the process require specific calculations of its thermal stability.

The data on the kinetics of AN thermal decomposition [1] showed that, at fairly high temperatures and low concentrations of nitric acid (as in the AN melt), this reaction proceeds through oxidation of NH_4^+ with molecular HNO_3 and the kinetic equation can be presented as follows:

$$dQ/dt = k_{NH_4^+} Q_{AN} c_{NH_4^+} c_{HA} V^0_{AN}, \quad (4)$$

where $k_{NH_4^+}$ is the oxidation rate constant of NH_4^+ ($cm^3\ mol^{-1}\ s^{-1}$), Q_{AN} is the heat of AN decomposition ($J\ mol^{-1}$), $c_{NH_4^+}$ and c_{HA} are the concentrations of NH_4^+ ions and HNO_3 molecules (M), and V^0_{AN} is the AN molar volume ($cm^3\ mol^{-1}$).

If we denote the initial concentrations of NH_4^+ ions and HNO_3 molecules as $c^0_{NH_4^+}$ and c^0_{HA}, then

$$k_1 = k_{NH_4^+} Q_{AN} c^0_{NH_4^+} c^0_{HA} V^0_{AN}.$$

Since at the process start $c^0_{NH_4^+} V^0_{AN} = 1$, then

$$k_1 = k_{NH_4^+} Q_{AN} c^0_{HA}.$$

Three series of experiments were performed to determine the $k_{NH_4^+} Q_{AN}$ product. We measured the initial rate of heat release in oxidation of NH_4^+ ions with solutions of nitric acid of various concentrations at 198°C; the initial rates ($W\ mol^{-1}$) obtained are given below:

HNO_3, wt %	20	25	30	32.5
$(dQ/dt)_{t=0}$	3.1	5.9	12.4	10.6

In these experiments, the concentration of NH_4^+ ions in the mixture was much lower than the concentration of HNO_3 molecules; the concentration of nitric acid did not noticeably change during the process. Due to the decrease in the NH_4^+ concentration, the first reaction order was observed. The concentration of nondissociated HNO_3 molecules in the nitric acid solutions was determined from the data given in [6]. Analysis of experimental data showed that the oxidation of NH_4^+ with HNO_3 solutions in the given concentration range proceeds as the first-order reaction with respect to the concentration of HNO_3 molecules. Using the oxidation rates of NH_4^+ ions with 32.5% nitric acid solution at various temperatures

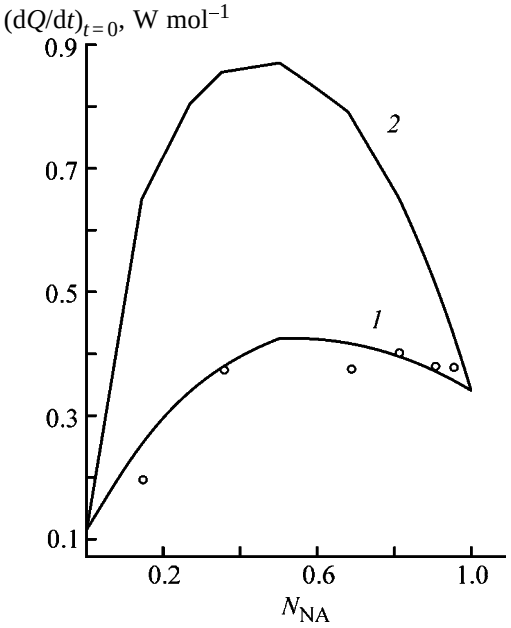

Fig. 2. Initial rate of heat release $(dQ/dt)_{t=0}$ in the AN + GN mixture as a function of the AN mole fraction N_{AN} at 223.6°C. (*1*) Experimental and (*2*) calculated from Eq. (7) using $k_{NH_4^+} Q_{AN}$ and $k_{GN^+} Q_{GN}$ determined for aqueous HNO_3 solutions.

T, °C	183.0	188.0	193.0	198.0
$(dQ/dt)_{t=0}$	1.5	4.7	7.5	10.6

and the data on concentrations of nondissociated HNO_3 molecules [6], we determined the temperature dependence of $k_{NH_4^+} Q_{AN}$ ($W\ cm^3\ mol^{-2}$):

$$k_{NH_4^+} Q_{AN} = 1.0 \times 10^{22} \exp(-150 \times 10^3/RT).$$

It was found [7] that, at lower temperatures, another oxidation mechanism involving N_2O_5 as oxidizing agent is realized.

It could be expected that the mechanism of $CN_3H_6NO_3$ decomposition would be similar and the rate of heat release in its decomposition would be determined by the rate of $CN_3H_6^+$ oxidation with HNO_3 molecule. In the temperature range studied, no thermal transformations of $CN_3H_6^+$ ion are observed in the absence of water. This is confirmed by higher stability of GN in comparison with AN. In this case, the kinetic equation of the process rate ($W\ mol^{-1}$) can be given as follows:

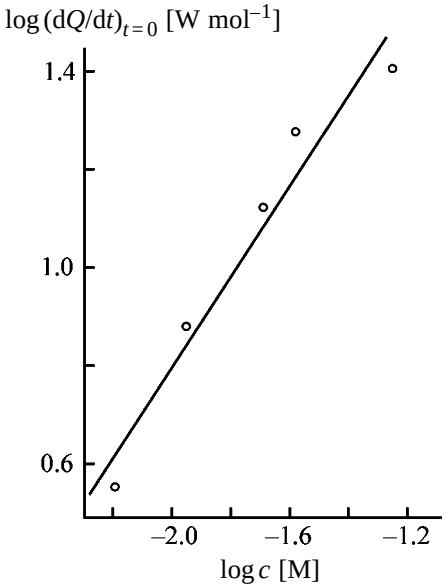

Fig. 3. Logarithm of the initial rate of the heat release $(dQ/dt)_{t=0}$ in oxidation of the $CN_3H_6^+$ ion as a function of the concentration of nondissociated HNO_3 molecules c at 172.4°C.

$$dQ/dt = k_{GH^+} Q_{GN} c_{GH^+} c_{HA} V^0_{GN}. \quad (5)$$

Correspondingly,

$$k/b = k_{GH^+} Q_{GN} c^0_{GH^+} c^0_{HA} V^0_{GN};$$

since at the process start $c^0_{GH^+} V^0_{GN} = 1$,

$$k/b = k_{GH^+} Q_{GN} c^0_{HA}.$$

The symbols and dimensions are similar to those used in Eq. (4), but they refer to guanidinium ion (GH^+) and guanidinium nitrate (GN).

To check this assumption, we studied the kinetic dependences of oxidation of $CN_3H_6^+$ ions with HNO_3 molecules. About 0.01 g (8.3×10^{-5} mol) of GN was placed in an ampule containing about 1.1 g of 20.01–39.03 wt % HNO_3 [$(3.5–6.8) \times 10^{-3}$ mol]. At such a large excess, the loss of HNO_3 in the oxidation does not noticeably alter the initial concentration, and the oxidation is described as a first-order reaction due to the consumption of $CN_3H_6^+$ ions. The concentration of nondissociated HNO_3 molecules in solutions were determined using the data given in [6]. The dependence of the initial rate of heat release (W mol^{-1}) on the concentration of HNO_3 molecules at 172.4°C is shown in Fig. 3; it corresponds to the first-order reaction with respect to molecular HNO_3. We also studied the dependence of the process rate on the concentration of $CN_3H_6^+$ ions in solutions (mol cm^{-3}) at 182.4°C:

$c_{GH^+} \times 10^5$	4.4	8.3	13.6	17.2
$(dQ/dt)_{t=0}$	76.8	73.1	68.4	67.5

In this case, the reaction is also first-order with respect to c_{GH^+} within the experimental error.

We studied the temperature dependence of the initial rate of heat release (W mol^{-1}) in oxidation of GH^+ in the 159.3–182.4°C range at HNO_3 concentration of 39.03 wt %.

T, °C	159.3	164.0	172.4	177.8	182.4
$(dQ/dt)_{t=0}$	17.2	23.4	25.6	50.2	73.1

Using these data and taking into account the concentrations of nondissociated HNO_3 molecules in solution, we obtained the temperature dependence of $k_{GH^+} Q_{GN}$ (W cm^3 mol^{-2}):

$$k_{GH^+} Q_{GN} = 8.4 \times 10^{18} \exp(-112 \times 10^3/RT).$$

Comparison of the independently determined rate constants of heat release in oxidation of NH_4^+ and $CN_3H_6^+$ ions in aqueous nitric acid solutions showed that, at 223.6°C, the rate of $CN_3H_6^+$ oxidation is higher by a factor of 8 than that of NH_4^+ oxidation, and this difference increases with decreasing temperature.

In the AN + GN melt, the rate of heat release can be evaluated as a sum of the oxidation rates of NH_4^+ and $GN_3H_6^+$ ions with molecular HNO_3. The interaction of AN and GN is obviously determined by common salt anion, changes in the equilibrium content of HNO_3 in the mixture in comparison with the initial components, and difference in the oxidation rate constants of NH_4^+ and $CN_3H_6^+$ ions. In this case, the increase in the content of HNO_3 molecules in the mixture in comparison with pure GN, at higher oxidation rate constant of $CN_3H_6^+$, is probably decisive.

If we denote the equilibrium mole fractions of NH_3, HNO_3, and CN_3H_5 as N_{NH_3}, N_{AN}, and N_{GN} and the constants of salt dissociation into base and acid as K_{AN} and K_{GN} and neglect the variations in the mole fractions of salt ions due to dissociation, because the degree of salt dissociation into base and acid is low, then the system of reactions of the reversible dissociation in the salt mixture can be presented as follows:

$$NH_4NO_3 \rightleftarrows NH_3 + HNO_3,$$

$$K_{AN} = N_{NH_3} N_{HA} / N_{AN};$$

$$CN_3H_6NO_3 \rightleftarrows CN_3H_5 + HNO_3,$$

$$K_{GN} = N_G N_{HA}/N_{GN}.$$

Since $b = N_G$ (i.e., mole fraction of the base in the system) and for pure salt $N_G = N_{HA}$ and $N_{GN} \sim 1$ due to small degree of salt dissociation into base and acid, then $b = (K_{GN})^{0.5}$.

Solution of this system for the initial moment in the absence of the reaction products gives the equilibrium mole fraction of HNO_3 in the system:

$$N_{HA} = [K_{AN}N_{AN}/(1 + a)]^{0.5} + [K_{GN}N_{GN}/(1 + a^{-1})]^{0.5},$$

$$a = K_{GN}N_{GN}/K_{AN}N_{AN}. \quad (6)$$

Since $c_{HA} = N_{HA}/V^0$, where V^0 is the molar volume of the salt mixture, and similar expressions can be given for all the system components, the final expression [based on Eqs. (4)–(6)] for the dependence of the initial rate of heat release in the AN + GN mixture on its composition is as follows:

$$dQ/dt = \{[K_{AN}N_{AN}/(1 + a)]^{0.5} + [K_{GN}N_{GN}/(1 + a^{-1})]^{0.5}\}$$

$$\times (k_{NH_4^+}Q_{AN}N_{AN} + k_{GH^+}Q_{GN}N_{GN})/V^0. \quad (7)$$

For pure salts, the mole fraction of salt is 1 and the initial rate of the process can be given as

$$(dQ/dt)_{AN} = k_{NH_4^+}Q_{AN}K_{AN}^{0.5}/V_{AN}^0,$$

$$(dQ/dt)_{GN} = k_{GH^+}Q_{GN}K_{GN}^{0.5}/V_{GN}^0. \quad (8)$$

To a first approximation, considering it as the additive value, the molar volume of the mixture can be calculated as the sum of the molar volumes of the initial salts:

$$V^0 = N_{AN}V_{AN}^0 + N_{GN}V_{GN}^0 = V_{AN}^0 + (V_{GN}^0 - V_{AN}^0)N_{GN}.$$

Using the temperature dependence of the density of liquid AN [8], we calculated $V_{AN}^0 = 56.7$ cm^3 mol^{-1} at 220°C. Since data on the density of liquid GN are lacking, we assumed the densities of AN and GN to be equal, and thus $V_{GN}^0 = 86.5$ cm^3 mol^{-1}.

The K_{GN} and K_{AN} values were calculated from the initial rates of heat release in decomposition of pure AN and GN using the experimental values of $k_{NH_4^+}Q_{AN}$ and $k_{GH^+}Q_{GN}$ (obtained in studying cation oxidation in HNO_3). Now, using all the above data and Eq. (7), we can evaluate the dependence of the rate of heat release in the AN + GN mixture on the AN mole fraction; this dependence is shown in Fig. 2 (curve *2*). As seen, the real rates of heat release are significantly lower than the calculated dependence. Such a difference can be only due to the changes in the oxidation rate constants of NH_4^+ and $CN_3H_6^+$ ions as compared to the values determined in this work for aqueous HNO_3 solutions.

The properties of the melt and aqueous solution of nitric acid are strongly different; the melt is composed virtually exclusively of the ions and has a low dielectric constant (2–4), whereas the aqueous solution contains many HNO_3 and H_2O molecules and its dielectric constant is higher by at least an order of magnitude.Probably, the solvation of cations in these media is different, which, in turn, should affect the rate constants of their oxidation. Changes in $k_{NH_4^+}Q_{AN}$ and $k_{GH^+}Q_{GN}$ should change the constants K_{AN} and K_{GN} [see Eq. (8)], but the initial rates of heat release in the salts are determined with relatively high accuracy. Unfortunately, we failed to determine experimentally the oxidation rate constants directly in the salt melts in question due to the difficulties with dosed supply of 100% nitric acid in the melt and, especially, due to the lack of procedures for quantitative analysis of nitric acid content in these melts. At the temperatures studied, nitric acid can form complexes with the other molten components and partially pass into the gas phase. Hence, the reverse problem was solved: we determined the $k_{NH_4^+}Q_{AN}$ and $k_{GH^+}Q_{GN}$ values (W cm^3 mol^{-2}) from the calculated dependence of the rates of heat release taking into account Eq. (8) provided that all the temperature dependences obtained were preserved:

$$k_{NH_4^+}Q_{AN} = 5.0 \times 10^{22} \exp(-150 \times 10^3/RT),$$

$$k_{GH^+}Q_{GN} = 1.0 \times 10^{19} \exp(-112 \times 10^3/RT).$$

For AN, these values are greater by a factor of 4.7 than those determined experimentally in aqueous acidic solutions, and for GN, by a factor of 1.2. The $k_{NH_4^+}Q_{AN}$ and $k_{GH^+}Q_{GN}$ values obtained by solving the reverse problem should be used to calculate the process rates in the melts, whereas the experimental data obtained previously are correct for aqueous acid solutions.

Using the calculated rate constants of heat release and the initial rates of heat release in pure salts, we obtained the following equilibrium constants of salt

dissociation into base and acid:

$$K_{AN} = 0.89\exp(-107\times10^3/RT),$$

$$K_{GN} = 0.13\exp(-111\times10^3/RT).$$

At 200°C, K_{AN} is greater by a factor of 20 than K_{GN}, which corresponds to the difference in the basicities of NH_3 and CN_3H_5 in the melts of the corresponding salts. Taking into account the fact that in Eq. (2) $b = (K_{GN})^{0.5}$, from the temperature dependences of k/b and k/f for NG decomposition we evaluated the following temperature dependences

$$b = 036\exp(-55.6\times10^3/RT),$$

$$f = 1.9\times10^{-5}\exp(-43\times10^3/RT)\ \ (\text{mol J}^{-1}).$$

To assess the feasibility of granulation or other treatment procedures of the AN + GN mixture through the melt, we determined the melting temperature of the eutectic mixture T_e and the temperature of complete melting of the AN + GN mixture (2 : 1 molar ratio) T_f on a DAK-1-1 calorimeter in the linear heating mode at a heating rate of 5×10^{-3} deg s^{-1}. The sample weights of the AN + GN mixture (2 : 1 molar ratio) were 1.5 and 0.15 g. The experimental temperatures (average of 5 measurements) were independent of the sample weight: $T_e = 126.0\pm1$ and $T_f = 132.5\pm1$°C.

Unfortunately, experimental T_e is close to the temperature of the phase transition AN II → AN I (125–126°C). The rate dependence of the heat release passes through two very closely located maxima; i.e., the phase transition and eutectic melting overlap. Though melting probably begins at temperatures higher than the phase transition by 1–1.5°C, their separation is virtually impossible. To evaluate the possibility of using the AN + GN mixture, it is important that the mixture begins to melt at 126°C, and at lower temperatures it is solid. The total amount of heat absorbed upon melting of the mixture was determined by numerical integration of the experimental curve of heat absorption. The heat of the process per mole of the mixture is independent of the sample weight, and its average value is 10.0±0.4 kJ per mole of the AN + GN mixture. According to published data [9], the enthalpy changes comprise $\Delta H_{pt} = 4.43\pm0.42$ and $\Delta H_m = 5.64\pm0.63$ kJ mol^{-1} for phase transition and melting, respectively.

Since the enthalpy of melting of AN, 6.40 kJ mol^{-1}, was determined long ago [9] and could be inaccurate and for GN such value was unknown, we evaluated the enthalpies of melting of AN and GN on a DAK-1-1 calorimeter using the procedure similar to those used for salt mixtures. We determined that AN melts at 169±1°C, with the enthalpy of melting $\Delta H = 6.35\pm0.63$ kJ mol^{-1}; and these results well agree with published data. For NG, the melting point was 215±1°C, which is close to the value from [10], with $\Delta H = 18.4\pm1.3$ kJ mol^{-1}. To evaluate the possibility of the phase transitions, the GN sample was heated in a DAK-1-2 calorimeter in the temperature range from 25°C to the melting point. Since no peaks of heat release or absorption were found, there are no phase transitions of the first kind in the temperature range studied. The enthalpies of melting of the two similar salts strongly differ, but AN undergoes three phase transitions with heat absorption in the temperature range from 25°C to the melting point; their total effect is 7.14 kJ mol^{-1}, and the total heat absorption (with melting) reaches 13.5 kJ mol^{-1}. Taking into account the differences in the structure and weight of the cations, this value well agrees with the enthalpy of melting of GN, for which the melting is not preceded by phase transitions.

Using the enthalpies of melting of AN and GN determined and considering the enthalpy of melting of the AN + GN mixture to be the additive value, we calculated for this mixture $\Delta H_m = 10.0$ kJ mol^{-1}. Probably, the difference with the experimental value of 4.4 kJ mol^{-1} is due to the changes in the enthalpy of the liquid phase as compared to the initial liquid salts; it is probably the heat of mixing.

Based on the Schroeder equation [1] describing changes in the melting temperature of one component upon addition of another one, assuming that the solution of these components is ideal, and using the above ΔH values of the salts studied, we calculated the melting diagram of the AN + GN mixture, but it poorly agrees with the experimental T_e and T_f. This fact suggests strong deviation of our system from the ideal solution. Since for ideal solution the heat of mixing is zero, our experimental results indicate strong interaction of ions in the molten salt mixture, which is greater than that in the melts of the pure components.

Our experimental data show that granules of the eutectic AN + GN mixture can be prepared though the melt using any known procedure of granulation of AN and fertilizers on its basis with sufficient safety level, because the rates of heat release in thermal decomposition of these mixtures are close to that observed with AN.

CONCLUSIONS

(1) The rate of heat release in thermal decomposition of $CN_3H_6^+$ and NH_4^+ nitrates and their mixtures in the liquid phase is determined by the oxidation rate of the corresponding cations with molecular HNO_3.

(2) The rate constant of $CN_3H_6^+$ oxidation is greater than that of NH_4^+ both in aqueous solutions of nitric acid and in molten salts. This difference decreases on passing from aqueous solutions with high dielectric constants to the melts with small dielectric constants.

(3) The difference in the basicity of NH_3 and CN_3H_5 strongly decreases on passing from aqueous solutions of nitric acid to melts, and the equilibrium constant of guanidinium nitrate dissociation in the melt is smaller than that of ammonium nitrate by a factor of only 20.

(4) The rates of heat release in thermal decomposition of the mixtures of ammonium and guanidinium nitrates are close to those observed with ammonium nitrate. At guanidinium nitrate content of 10 wt % and greater, no self-acceleration of the process is observed, and thus the known procedure of granulation of AN and fertilizers on its basis with sufficient safety level can be used to prepare solid granules from the molten salt mixture.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Aging of Whey Gels in the Presence of Organic Colloids

S. G. Kozlov, A. Yu. Prosekov, and A. S. Sorochkina

Kemerovo Technological Institute of Food Industry, Kemerovo, Russia

Received December 22, 2003; in final form, April 2004

Abstract—Effects of organic colloids on gelation of curds and aging of whey gels are studied. The influence of some physicochemical factors on the predicted macrokinetic characteristics of whey gels is revealed.

The questions of structurization in disperse systems, as applied to various branches of industry, were considered in works of many leading research schools [1–4]. The theoretical concepts developed by them can find use in technology of structured foodstuffs of desired consistency. Agents supporting the consistency are used primarily in production of foodstuffs with unstable structure, which should remain homogeneous throughout the storage period [5, 6]. There are diverse agents modifying the rheological characteristics of such foodstuffs, including natural, synthetic, and bacterial ones.

Gels represent highly dispersed systems with a liquid dispersion medium, consisting of a fluid-filled framework forming a structure from dispersed solids. Gels are classified with two-phase systems with highly developed interface between a continuous or finely dispersed phase of a suspended solid and an aqueous (or aqueous-organic) phase, which also can be continuous or partially dispersed. A solid is commonly regarded as a fibrous structure. It can consist of poorly soluble compounds, for example, proteins, or thread-like crystals, like the silica or crystalline cellulose gels. The structural stability depends on the structure of the continuous phase network, so that the system as a whole exhibits many properties of a solid, regardless of the state of aggregation of the dispersion medium and dispersed phase themselves.

Aging results in degradation of the gel structure, which is accompanied by irreversible deterioration of the rheological characteristics (molecules of a gelator flocculate, providing immobilization of the dispersion medium). In aging, a monodisperse gel passes into a quasicontinuous body formed as a result of broken dispersity. The main cause of this transition is break of the structural stability, accompanied by mutual approach of the colloid particles.

In analysis of this phenomenon, it is advisable, first, to determine the kinetic parameters of the yield stress and the amount of the liberated functional groups, and, second, to evaluate the effect of process factors on the evolution of the strength of the gels formed.

The composition of the samples studied in this work was as follows (%): gelator [agar 1.2, or pectin 0.8, or agaroid 2.5, or gelatin 2.5, or methyl cellulose (MC) 1.5, or starch 2.5], sucrose 30, and whey as the rest. The acidity was adjusted to pH 4.0–4.2 with citric acid.

EXPERIMENTAL

The rheological behavior of the gels was studied on a Rheotest-2 instrument (GDR) [7] at 20°C. The shear stress τ (Pa) was estimated by Eq. (1):

$$\tau = z\alpha, \quad (1)$$

where z is the cell constant (Pa) and α, scale reading.

The effective viscosity η (Pa s) was determined by Eq. (2):

$$\eta = \tau/j, \quad (2)$$

where j is the shear rate (s^{-1}).

The flow curves were reproduced by the Herschel–Bulkley equation (3):

$$\tau = \tau_0 + kj^n, \quad (3)$$

where τ_0 is the yield stress (Pa) at a given shear rate gradient; k, the consistency factor (Pa s) characterizing the viscosity of the material at $j = 1\ s^{-1}$; and n, flow index characterizing the flow behavior.

The molecular weight of the gelators was determined by HPLC with Hewlett–Packard columns. In

1070-4272/04/7707-1092 © 2004 MAIK "Nauka/Interperiodica"

the first columns, the exhaust rate was 0.008, and in the second column, 0.0166 ml s^{-1}. Calibration was performed on a Dawn F laser nephelometer.

The relative content of functional groups (carboxy, methoxy, aldehyde, hydroxy, and amine) was determined using standard procedures. The initial content was accepted in all the cases to be 100%.

The relative content of free carboxy groups C_f (%) was determined by titration of a weighed portion of the gel with 0.1 N NaOH in the presence of Hinton reagent until development of red coloration [8]. Then C_f was estimated by Eq. (4):

$$C_f = \{(0.45a/G)_S[(0.45a/G)_N]^{-1}\} \times 100, \quad (4)$$

where a is the volume of the titrant consumed (ml); G, sample weight (g); and 0.45, conversion rate (1 ml of 0.1 N NaOH corresponds to 0.0045 g of COOH). The indices S and N refer to the sample after storage and the reference sample, respectively.

The relative content of the ether groups C_e (%) was determined by Eq. (5):

$$C_e = \{(0.45b/G)_S[(0.45b/G)_N]^{-1}\} \times 100, \quad (5)$$

where b is the volume of the titrant consumed for the second titration (ml).

The relative content of the acetyl groups C_{Ac} (%) was determined according to the procedure described in [8] using Eq. (6):

$$C_{Ac} = \{(43.04C/100G)_S[(43.04C/100G)_N]^{-1}\} \times 100, \quad (6)$$

where C is the difference between the titrant volume consumed for titration of the sample and that in the blank experiment (ml); and 43.04 is the equivalent weight of the acetyl groups.

The relative content of the methoxylated carboxy groups C_m (%) was estimated with correction for the acetyl groups by Eq. (7).

$$C_m = C_e + C_{Ac}. \quad (7)$$

The total content of the carboxy groups C_o (%) was estimated as

$$C_o = C_m + C_f. \quad (8)$$

The relative content of the amino groups C_a (%) was determined by titration according to Dudenkov's method [9] using Eq. (9):

$$C_a = [(mP)_S/(mP)_N] \times 100, \quad (9)$$

where m is the volume of 0.1 N NaOH consumed for titration (ml) and P, conversion factor.

The aldehyde groups was determined by the method based on the reaction with fuchsinsulfurous acid with formation of a colored product [10]. The hydroxy groups were determined by the neutralization method [11].

The samples were stored for 15 days under temperature- and humidity-controlled conditions.

Table 1 shows how the aging influences the mechanical characteristics of the gel structures, which is significant for the systems studied.

The results show that the trends in evolution of the yield stress do not depend on the gelator used. In the initial period (data printed bold), the gel structure strengthened. For agar, agaroid, pectin, MC, and

* Period of time in which the gel reaches its maximal strength/onset of aging.

starch, this period was 120, 72, 15, 20, 3, and 4 h, respectively. In this period, the strength increased by 58.5, 30.7, 45.6, 19.5, 33.6, and 28.5%, respectively, as compared to the initial sample. Evidently, the relative increase in the strength is controlled by the nature of interaction between the compounds composing the dispersion medium and the hydrated gelator.

The effect of structurization is promoted by the polymeric compounds of whey (for example, whey proteins promote cross-linking). Such a structurization is accompanied by transition of the thixotropic gel into a nonthixotropic structure and, finally, results in formation of a 3D matrix with infinitesimal number of "free nodes" containing the dispersion medium weakly bound to the gelator.

The structurization period in whey gels was followed by their aging. Two competitive processes were observed during aging. They were reflected in an elastic strain slowly decayed in time and also in a steady-rate plastic viscous flow. In this period, the number of broken bonds was higher than the number of newly formed bonds, as demonstrated by the rheological data.

For agar and agaroid, we observed a distinctly pronounced transition from the state characterized by the maximal strength to the state of degradation. This was not the case for pectin, gelatin, MC, and starch. In particular, the transition period in the systems with the indicated gelators was 24–216, 10–120, 3–5, and 2–96 h, respectively, depending on the nature of intermolecular interactions in these systems.

It is well known that the properties of gels strongly depend on the temperature. Therefore, we studied the temperature effect on aging of whey gels. As parameters characterizing this effect we selected the time in which the gel reaches its maximal strength and the time until the onset of degradation (aging). The results are given in Table 2.

In all the systems, we observed a decrease in the strength of whey gels with increasing temperature. For agar, agaroid, pectin, gelatin, and MC, the transitions were not observed at all at temperatures of 35–40, 30–35, 25–30, 20–25, and 10–15°C, respectively. This is due to increasing thermal motion of molecules, which have rotational radius insufficient for the system to acquire more stable state. Increasing temperature reduced the time to the onset of aging of the gel, caused by increase in the kinetic energy of the system as a result of heating.

It is significant that some of the organic colloids allowed preparation of the dispersions only at definite temperatures.

For example, methyl cellulose at 5–10°C after 3 h, in which structurization was completed, started to change its rheological behavior so that the process could be referred to as aging.

For some of the gels, after completion of the process we observed no structurization stage at all. In this case, aging started in a rather short time (shorter than after 1 day of storage).

The observed trends are caused by several factors, change in the relative molecular weight of the organic colloids being one of the most significant (Table 3). The results show that increase in the relative molecular weight is typical of the gelators in the initial hours of storage of whey gels. The longest time in which the relative molecular weight increased was observed with agaroid. This is due to the fact that agaroid had the minimal relative molecular weight, which increased in

the course of the sol–gel transition as a result of completion of the formation of adsorption layers at the organic colloid–dispersion medium interface.

The shortest period of time in which the relative molecular weight changed was observed for gelatin (~2 h). This fact can be attributed to the specific features of formation of the solvation shells in gelatin: potential sites of cross-linking in the polymer chain of gelatin were blocked because of a larger number of the interfacial layers. Thus, the maximal increase in the relative molecular weight of about 50% was found in agaroid, and the minimal increase (only 0.8%), in gelatin.

Analysis of the results obtained revealed the following general trends:

(1) The stabilizer is experienced to hydrolysis under the effect of certain internal and external factors;

(2) the integrity of the solvation shells is broken as a result of formation of structural defects under the effect of components of the gels;

(3) the activation barrier of aging is overcome at elevated temperatures.

Generally, aging of a gel is an irreversible process whose rate is controlled by the composition, temperature, and other factors.

The aging is described by Eq. (10):

$$\tau = \tau_0 \exp[(U_0 - \nu P)/k_B T], \quad (10)$$

where τ is the bond breakdown stress in the gel; τ_0, preexponential factor; U_0, true (initial) activation energy of degradation; ν, structural factor; k_B, Boltzmann constant; P, breaking stress; and T, temperature (K).

According to Eq. (10), degradation of a gel is a temperature-dependent process. With increasing temperature, the energy barrier U_0 of breaking of the bonds is overcome, as demonstrated by the liberation of functional groups of the gelators, which were directly involved in the sol–gel transition (Table 4).

The results obtained allowed evaluation of the relative contributions of different functional groups of the gelators to formation of whey-based dispersions. However, it should be pointed out that, in this case, they can be involved in formation of new types of bonds, as was demonstrated, for example, by data on the relative contents of functional groups in the gelatin-based gel.

Generally, gelatinous systems based on curds are classified with quasistable systems. In storage, the particles composing a 3D structure are reoriented, and the liquid phase is liberated (most of gels tend to break the structure). In such multicomponent systems as whey, aging proceeds less intensively as a result of partial absorption of the dispersed phase by other components of the gel through physicochemical interactions leading to formation of new bonds, thus preventing the transition into an absolutely stable state with separation into several individual phases.

CONCLUSIONS

(1) Addition of organic colloids enhances the stability of whey gels.

(2) Structural stability of the gels decreases with increasing temperature of the process.

(3) In storage, the relative molecular weight of the hydrocolloids changes as a result of hydrolysis, distortion of the solvation shells, and overcoming of the energy barrier of degradation.

SORPTION AND ION-EXCHANGE PROCESSES

Mercury(II) Sorption on Nickel(II) Hydroxide: Influence of Halide Ion Concentration and pH of the Solutions

O. V. Nagornyi, A. S. Kolyshkin, and V. V. Vol'khin

Perm State Technical University, Perm, Russia

Received November 25, 2003

Abstract—Sorption of Hg(II) on β-$Ni(OH)_2$ was studied as influenced by chloride ion concentration and pH of the solutions, affecting the Hg(II) speciation. The sorption mechanism was considered.

Mercury(II) compounds are biologically hazardous. Mercury and its compounds are concentrated naturally by soil particles and mineral suspension and are accumulated in bottom sediments. Accumulation and transfer of mercury in the nature is largely controlled by adsorption [1].

Sorption is used to remove mercury compounds from aqueous solutions. Leikin *et al*. [2] used organic anion-exchangers as sorbents for negatively charged mercury halide complexes. Sorption of mercury(II) on natural minerals, kaolinite [3], goethite [4], and quartz [5], was studied.

Although many minerals can adsorb mercury compounds, only synthetic inorganic sorbents are efficiently used at present to remove mercury compounds from aqueous solutions. More than 90% of Hg(II) is removed with freshly prepared hydrated iron(III) oxide from aqueous solutions with pH from 5 to 8.6 [6]. A number of new inorganic sorbents including those for anionic complexes have been developed to date [7]. Nickel(II) hydroxide [8] and double nickel hydroxides with other metals [9] have relatively high anion-exchange capacity for Hg(II) complexes. Therefore, the study of synthetic inorganic sorbents for Hg(II) is an urgent problem.

The diversity of mercury species present in aqueous solutions complicates selection of inorganic sorbents for Hg(II). For example, in aqueous solutions containing Cl^- anions, Hg(II) exists in the form of the following aqua, hydroxoaqua, and mixed hydroxoaquachloride or chloride complexes: Hg^{2+}, $HgOH^+$, $Hg(OH)_{2(aq)}$, $Hg(OH)_3^-$, $HgCl^+$, $HgCl_{2(aq)}$, $HgOHCl_{(aq)}$, $HgCl_3^-$, $HgCl_4^{2-}$ [1, 4, 10, 11]. Formation of cationic, neutral, and anionic mercury(II) species can result in incomplete mercury sorption from aqueous solutions. Neutral and anionic Hg(II) species are stable mainly at pH close to that of natural waters [1]. In this case, anion exchangers can be used as the sorbents. However, to determine the mechanism of Hg(II) sorption on metal hydroxides exhibiting anion-exchange properties, additional studies are required.

The aim of this work was to determine the influence of Cl^- concentration and pH of the solution on Hg(II) sorption on nickel(II) hydroxide and to propose the sorption mechanism.

Nickel(II) hydroxide exists in α- and β-modifications. In this work we studied β-$Ni(OH)_2$. Both modifications have the layered brucite structure. The interlayer spacings in β-$Ni(OH)_2$ lattice are broadened owing to incorporation of H_2O molecules (c = 0.80 nm); the brucite layers in β-$Ni(OH)_2$ lattice are closer (c = 0.46 nm) [12]. The α-modification is unstable and is unsuitable as a sorbent.

β-$Ni(OH)_2$ was prepared by exchange reaction of aqueous solution of $Ni(NO_3)_2$ with NaOH taken in a 5% excess. The resulting precipitate was washed with distilled water and granulated by freezing. To remove NO_3^- impurity, the granulated material was treated with 0.1 M NaOH for a long time. The NO_3^- content in the solid phase was determined by IR spectroscopy.

The sorption experiments under dynamic conditions were performed by the conventional methods [13].

Aqueous Hg(II) solutions were prepared from $Hg(NO_3)_2 \cdot H_2O$. Mercury halide complexes were synthesized by addition of aqueous solutions of KCl, KBr, and KI. All the salts were of analytically pure grade. The Hg(II) content in the solution was determined by absorption of the mercury complex with Crystalline Violet at λ = 605 nm using a KFK-2MP photocolorimeter [14].

The relative content of different Hg(II) species formed at various concentrations of free Cl^- was cal-

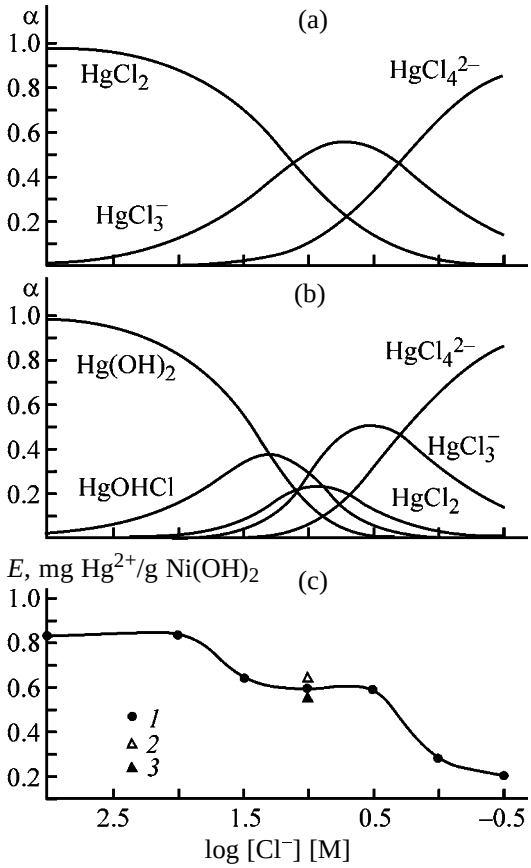

Fig. 1. (a, b) Mole fractions of Hg(II) species in solutions α and (c) sorption capacity of β-$Ni(OH)_2$ for Hg(II) *E* as functions of $[Cl^-]$. pH: (a) 5; (b) 9; (c) (*1*) ~5; (*2*) 7.8, kept for more than 24 h; and (*3*) 8.3, kept for more than 24 h.

culated from the equilibrium constants of the following reactions [15]:

$$Hg^{2+} + OH^- \rightleftarrows HgOH^+, \quad \log K = 10.6;$$

$$Hg^{2+} + 2OH^- \rightleftarrows Hg(OH)^0_{2(aq)}, \quad \log K = 21.8;$$

$$Hg^{2+} + Cl^- \rightleftarrows HgCl^+, \quad \log K = 7.2;$$

$$Hg^{2+} + 2Cl^- \rightleftarrows HgCl^0_{2(aq)}, \quad \log K = 14.0;$$

$$Hg^{2+} + 3Cl^- \rightleftarrows HgCl_3^-, \quad \log K = 15.1;$$

$$Hg^{2+} + 4Cl^- \rightleftarrows HgCl_4^{2-}, \quad \log K = 15.4;$$

$$Hg^{2+} + Cl^- + OH^- \rightleftarrows HgClOH^0_{(aq)}, \quad \log K = 18.1.$$

The results of these calculations for a solution with pH 5 are shown in Fig 1a. The dependence of the sorption capacity of β-$Ni(OH)_2$ for Hg, *E* [mg Hg^{2+}/g $Ni(OH)_2$], on the Cl^- concentration varied in the same range is shown in Fig. 1c. The total Hg(II) concentration in each solution was 10^{-3} M.

The dependence of the relative concentration of Hg(II) species in the solution on $[Cl^-]$ does not correlate with the dependence of the sorption capacity of β-$Ni(OH)_2$ for Hg(II) on $[Cl^-]$. This was due to the difference in the pH of solutions used for the calculation and the experimental pH of the working solutions. When the initial solution passed through a sorbent bed, its pH increased to 8.5–9.0. We recalculated the dependence of the relative concentrations of Hg(II) species on $[Cl^-]$ at pH 9. The results are presented in Fig. 1b.

Comparison of the calculated and experimental dependences allows the following conclusions. The maximal sorption capacity *E* was observed in the $[Cl^-]$ range from 10^{-3} to 10^{-2} M, when $Hg(OH)_2$ and HgOHCl were formed. When these complexes started to transform into $HgCl_3^-$ and $HgCl_4^{2-}$, the first drop of *E* [from 20 to 15 mg Hg^{2+}/g $Ni(OH)_2$] occurred. At $[Cl^-]$ higher than $10^{-0.5}$ M, the sorption capacity *E* decreased again from 15 to 7–6 mg Hg^{2+}/g $Ni(OH)_2$. Under these conditions, hydroxo complexes $Hg(OH)_2$ and HgOHCl disappeared completely. Then *E* remained constant at the level of 5.0–5.5 mg Hg^{2+}/g $Ni(OH)_2$.

To explain these results, let us consider possible mechanisms of Hg(II) sorption by metal hydroxides.

Anionic complexes $HgCl_3^-$ and $HgCl_4^{2-}$ can be adsorbed by the ion-exchange mechanism:

$$\equiv Ni{-}OH + HgCl_3^- \rightleftarrows \equiv Ni{-}ClHgCl_2 + OH^-.$$

Halide anions Cl^-, Br^-, and I^-, being in equilibrium with $HgHal_3^-$ and $HgHal_4^{2-}$, are absorbed by the same mechanism. Previously we showed that chloride ions are exchanged with equivalent amount of OH groups of metal hydroxides. This process, however, makes an insignificant contribution. The sorption in the absence of Hg hydroxo complexes occurs by the anion-exchange mechanism.

An increased sorption capacity for hydrolyzed Hg(II) species is due to the different sorption mechanism. Sarkar *et al*. [3] showed that M–O–Hg bridges (where M is metal ion of the metal hydroxide) are formed in this case. Sorption of Hg(II) hydroxo complexes involves formation of surface intraspheric complexes ≡MOHgCl or $MOHgOHCl^-$, with the formation of the latter complex being more thermodynamically favorable. For example, log *K* of formation of ≡AlOHgCl and $\equiv AlOHgOHCl^-$ complexes in adsorption of Hg(II) on gibbsite is 6.64 and –0.50, respectively.

Thus, hydrolyzed Hg(II) species such as HgOHCl are sorbed on nickel(II) hydroxide owing to formation

Sorption of Hg(II) on Ni(II) hydroxide from solutions containing Cl^-, Br^-, and I^-

Anion	E, mg Hg^{2+}/g $Ni(OH)_2$	Hg(II) desorption, %
Cl^-	17.8	31
Br^-	10.1	51
I^-	2.42	98

of the surface intraspheric complex ≡NiOHgCl. At the same time, HgOHCl is not the major mercury species at almost any concentrations of chloride ions in the solution. We suggest that the concentration of this complex remains approximately constant during the sorption (buffer effect). The only question is the rate of this process. We found that formation of HgOHCl is completed during passage of the solution through an ion-exchange column. The sorption capacity did not noticeably change after an Hg(II) solution was allowed to stand at pH 7.8 and 8.3 prior to sorption for additional time (see Fig 1b, points *2* and *3*, respectively).

The decrease in E at $[Cl^-] > 10^{-2}$ M remains unclear. We suggest that the presence of different anionic species in the solution interferes with the sorption via formation of Ni–O–Hg bonds. A change in the composition of the Hg(II) complex and a decrease in the equilibrium constant of its formation are also possible.

The results of this work show that Hg(II) sorption on Ni(II) hydroxide from solutions containing Br^- and I^- should decrease owing to formation of $HgHal_3^-$ and $HgHal_4^{2-}$ complexes. This assumption is confirmed by the experimental data presented in the table. The working solutions contained 10^{-3} M Hg(II) and 10^{-1} M Hal^-. Mercury was desorbed with 0.1 M NaOH. The data on Hg(II) sorption from a chloride solution are included in the table for comparison.

In the presence of Br^- and I^- in the solution, the probability of the ion-exchange sorption of Hg(II) increases and formation of intraspheric surface complexes is suppressed owing to stabilization of $HgBr_3^-$ and $HgBr_4^{2-}$ (pK 19.7 and 21.0, respectively) and especially HgI_3^- and HgI_4^{2-} (pK 27.6 and 29.8, respectively). As the contribution of ion-exchange sorption of Hg(II) by nickel(II) hydroxide increases, the fraction of desorbed mercury increases. In the experiments with chloride and bromide solutions, the Hg(II) desorption is 4.9–5.2 mg Hg^{2+}/g $Ni(OH)_2$, which correlates with the E vs. $[Cl^-]$ dependence (Fig. 1c). Chloride and bromide anions can be involved in the ion exchange. The equilibrium Hal^- concentrations in the solutions in the course of the sorption decrease in the following order: $Cl^- > Br^- > I^-$. Our experimental results show that the surface intraspheric Hg(II) complexes are stable in 0.1 M NaOH.

CONCLUSIONS

(1) The dependence of Hg(II) speciation in solutions with pH 5.0 and 9.0 on the Cl^- concentration was calculated.

(2) The dependence of the sorption capacity of β-$Ni(OH)_2$ for Hg(II) on $[Cl^-]$ was measured experimentally.

(3) The sorption capacity of β-$Ni(OH)_2$ for Hg(II) correlates with that calculated for solutions with pH 9.

(4) Ionic Hg(II) complexes can be absorbed by β-$Ni(OH)_2$ owing to exchange with OH groups of the hydroxide. The sorption mechanism of hydroxo Hg(II) complexes involves formation of surface intraspheric complexes like MOHgHal.

SORPTION AND ION-EXCHANGE PROCESSES

Recovery of Cadmium(II) Ions with a Sulfur-Containing Carbon Sorbent

L. A. Zemskova, V. A. Avramenko, V. V. Chernykh, V. N. Kustov, and Yu. M. Nikolenko

Institute of Chemistry, Far Eastern Division, Russian Academy of Sciences, Vladivostok, Russia

Received May 14, 2003; in final form, March 2004

Abstract—The sorptive properties of a sulfur-containing sorbent, selective with respect to cadmium(II) ions in extraction from aqueous solutions, including process solutions, were studied.

Heavy metal ions (mercury, chromium, cadmium, zinc, lead, copper, and nickel ions) are usually removed from wastewater using reagent treatment methods involving precipitation with hydroxides or sulfides. In the latter case, a more profound purification is attained, since the solubility of heavy metal sulfides is considerably lower than that of hydroxides and carbonates [1]. An alternative, rather efficient method of the removal of heavy metal ions from solutions, especially at their low concentrations, is sorption on, e.g., activated carbon (AC) [2]. Therefore, a possibility can be considered of using sorption on activated carbon materials (ACMs) to remove cadmium and cobalt ions whose concentration in wastewater is very low compared to other heavy metal ions [1]. In addition, sorption on ACMs can be the final stage of the purification of industrial wastewater. For example, use of AC after sulfide precipitation decreases the residual concentration of zinc and cadmium ions by approximately 50% [2].

Fibrous carbon materials (FCMs) show promise for extraction of heavy metal ions, since they combine filtering and sorptive properties, high specific surface area, and developed porosity. However, FCMs are rather expensive. In addition, their sorption capacity with respect to heavy metal ions is relatively low. Therefore, treatment of large volumes of industrial wastewater containing heavy metal ions requires a large number of relatively cheap and readily available sorbents. In this connection, using technogenic wastes as sorbents is of particular interest. They should exhibit selectivity with respect to heavy metal ions, being group reagents of a sort with respect to the given class of metals. Among sorbents intended, e.g., for concentrating mercury ions the most promising are S,N-containing sorbents, whose selectivity is higher than that of their N,O-containing analogs [3]. In this connection, spent activated carbons containing both elemental sulfur and surface sulfides, which are used as sorbents, e.g., for treatment of natural gas or gases in cellulose production, may be of interest [4].

In this work, modified sulfur-containing fibrous carbon sorbents obtained from waste of textile production and a commercial carbon fiber were studied and tested for recovery of cadmium ions from solutions of various concentrations and compositions.

EXPERIMENTAL

Sulfur-containing carbon fibers were prepared by treating activated carbon fiber, obtained from natural fibers, at 600°C in a mixture of an inert gas (nitrogen), hydrogen sulfide, and water vapor (sorbent I), or in a mixture of an inert gas and hydrogen sulfide (sorbent II) [5]; alternatively, they were prepared by impregnating an activated fiber with a sulfur solution in turpentine with subsequent drying (sorbent III). The Aktilen-V commercial carbon fiber (sorbent IV) with a specific surface area of 700 $m^2 g^{-1}$ and a pore volume of 0.400 $cm^3 g^{-1}$ was also used for comparison.

The sorption was performed in the static mode at continuous agitation for 2 days (a Type 357 shaker with a water bath, ELPAN plant, Poland, 150 rockings per minute) from the initial solutions containing 100, 80, 60, 40, and 20 mg l^{-1} Cd(II). The solutions were prepared by volumetric dilution of the stock solution containing 100 mg l^{-1} Cd(II) and 700 mg l^{-1} Ca(II). $CdCl_2 \cdot 2.5H_2O$ (analytically pure grade) and anhydrous $CaCl_2$ (pure grade) were used as the starting compounds for preparing the stock solution. The volume of the solutions studied was 25 ml, and the

1070-4272/04/7707-1100 © 2004 MAIK "Nauka/Interperiodica"

weight of the fiber portions, 0.025 g. The content of Cd(II) in the solutions after sorption was determined by atomic absorption spectroscopy (AA-780 spectrometer, Nippon Jarrell Ash). The amount of sorbed Cd(II) was calculated from the difference in its content in the solutions before and after sorption. The sorption kinetics was studied with sorbent I having the maximal sorption capacity (SC) from the solutions containing 10 and 4.3 mg l^{-1} Cd(II), prepared by dilution of stock solution, and with sorbent III.

The spectra of core electrons were measured on an ES-2401 commercial X-ray photoelectron spectrometer (AlK_α radiation). The chamber of the analyzer was evacuated to 7×10^{-8} mm Hg. The energy scale of the spectrometer was calibrated by the Au4$f_{7/2}$ peak (binding energy E_b 84.0 eV). Gold was sputtered in the sample pretreatment chamber of the spectrometer. Experimental spectra were treated by the method described in [6, 7]. The measured binding energies were reproduced to within 0.2 eV, and the error of determination of the relative concentrations of the elements was no more than 20%.

The isotherms of the Cd(II) sorption on sulfur-containing carbon sorbents I–III are shown in Fig. 1 in comparison with those on Aktilen-B (IV). The sorption capacities of sorbents I and II, obtained in different series of the experiments, fall within the area between curves *1* and *2*. Curve *1* reflects the Cd(II) sorption on the samples of sorbents I and II having the highest sorption capacity. The graphs show that, despite scatter of values, sulfur-containing carbon sorbents I and II have the higher sorption capacity compared to sorbent III containing elemental sulfur and to commercial activated fiber IV.

The isotherms are described by the Freundlich equation:

$$a = bc^{1/n}, \quad (1)$$

where a is the equilibrium concentration of Cd(II) in the sorbent (sorbent capacity SC) (mg g^{-1}); c, equilibrium concentration of Cd(II) in the solution (mg l^{-1}); and b and n, constants.

The values of b and n for the sorbents, as calculated from data in Fig. 1, are presented below:

Sorbent	b	n
I	19.2	5.7
II	12.5	6.3
III	0.52	1.4
IV	0.82	1.8

Comparinson of the capacities for Cd(II) in aqueous solutions, exhibited by sulfur-containing sorbents I and II and by oxidized carbons [8], shows that these values are comparable. At the same time, in sorption of ions from multicomponent mixtures, the sorption capacities differ considerably. Therefore, the sorption capacity was determined from the solutions containing a mixture of cadmium and calcium salts to confirm the selectivity.

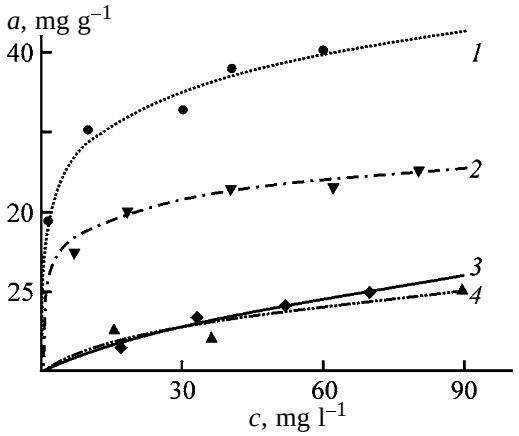

Fig. 1. Isotherms of the Cd(II) sorption from aqueous solutions in the presence of excess Ca(II) ions. (*a*) Equilibrium concentration of Cd(II) on the sorbent and (*c*) equilibrium concentration of cadmium in the solution. Sorbent: (*1*) I, (*2*) II, (*3*) III, and (*4*) IV.

As known, a certain correlation exists between sulfide and oxohydrate sorbents. The role of aqua, OH groups, and O atoms in sulfides can be played, respectively, by H_2S and HS groups and S atoms. In the general case, numerous kinds of sorption events are possible with sulfides; however, these are surface processes determining the colloidal and chemical properties of sulfides [9].

Assuming that the selectivity by Cd(II) of carbon-containing sorbents I and II is due to the nature of the sulfur-containing groups on the sorbent surface, we studied the sorbent samples by X-ray photoelectron spectroscopy (XPES).

Examples of the C1*s* and S2*p* experimental photoelectron spectra for sorbent I are shown in Fig. 2. In the S2*p* electron range, two peaks with binding energies E_b of 164.1 ± 0.2 and 168.3 ± 0.2 eV are present. The E_b values allow peaks to be assigned to bridging sulfur (C–S–H, C–S–C, or C–S–S–C) and to SO_2 groups, respectively [10, 11]. It was found that the S content in the sorbents studied is 1–3%, and most of it is incorporated in bridging groups (Fig. 2b).

The difference in the sorption capacities of sorbents I and II, on the one hand, and sorbent III, on the other

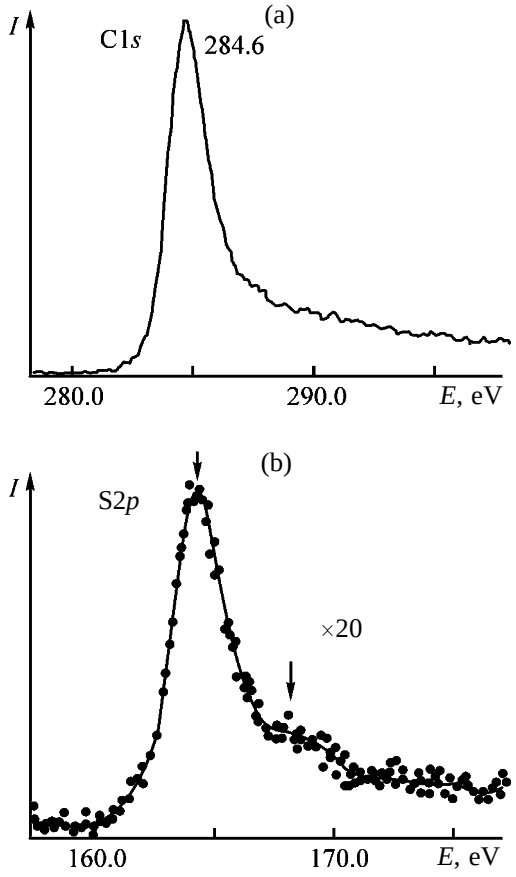

Fig. 2. C1*s* and S2*p* X-ray photoelectron spectra of sorbent I. (*I*) Intensity and (*E*) binding energy. Spectrum: (a) experimental and (b) experimental and after smoothing.

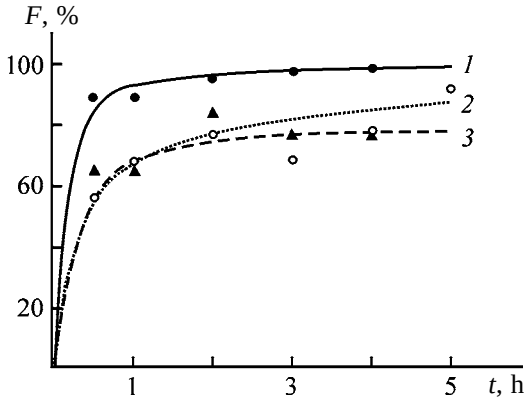

Fig. 3. Cd(II) sorption vs. time of contact with the sorbent *t*. (*F*) Ratio of the sorbed Cd(II) amount to the maximum amount sorbed in 24 h. Sorbent: (*1*, *2*) I and (*3*) III. c_0, mg l^{-1}: (*1*, *3*) 4.3 and (*2*) 10.

hand, indirectly confirms that sorbents I and II do not contain elemental S (Fig. 1).

For sorbent I, whose capacity under the static conditions is the highest, we studied the kinetics of Cd(II) sorption. Figure 3 shows that sulfur-containing carbon sorbent I sorbs more than 50% of the maximum value (attained during 24 h of sorption) in the first 0.5 h and more than 90–98% of Cd(II), within 5 h.

The rate constant k was calculated from the slope of the straight line in the $\log c$–t coordinates, in accordance with the equation of the first-order irreversible reaction transformed into the form

$$\log c = \log c_0 - 0.434tk, \quad (2)$$

where c_0 and c are the initial and current concentrations of Cd(II) in the solution (mg l^{-1}) and t is time (s) [12].

The obtained rate constant of the Cd(II) sorption by sorbents I and III are as follows.

Sorbent	c_0, mg l^{-1}	$k \times 10^{-4}$, s^{-1}
I	4.3	1.273
	10	0.480
III	4.3	0.510

Sulfur-containing carbon sorbents I and II were used under the laboratory and pilot-plant conditions for the purification of industrial water containing 0.6 mg l^{-1} Cd(II). The total salt content in the water was 2.5 g l^{-1}, and the content of hardness salts, 10 mg-equiv l^{-1}. In industrial water treatment, we used a radial filter containing 1 kg of fibrous sorbent (a mixture of sorbents I and II). The flow rate was 200 l h^{-1}. 180 m^3 of industrial water was purified during the test. The residual concentration of Cd(II) in the purified water was less than 0.001 mg l^{-1}.

CONCLUSIONS

(1) The study of fibrous carbon sorbents containing 1–3% sulfur showed that the selective properties of sorbents I and II are due to the presence of sulfide and hydrosulfide groups and C–S–C and C–S–S–C bridging groups.

(2) Treatment of multicomponent process solutions containing 0.6 mg l^{-1} Cd(II) with sorbents I and II decreases the cadmium concentration in the purified water to less than 0.001 mg l^{-1}.

Abstract—The electrodeposition of copper–tin alloy from a sulfate electrolyte containing $CuSO_4 \cdot 5H_2O$, $SnSO_4$, H_2SO_4, and benzyl alcohol was studied.

The Cu–Sn alloy containing 10–20 wt % Sn (yellow bronze) is applied as protective, protective-decorative, and antifriction coating [1, 2]. Numerous electrolytes were proposed for the electrodeposition of Cu–Sn alloy, among which cyanide–stannate electrolytes have found the widest industrial application [1, 2]. At the same time, these electrolytes have a number of drawbacks such as toxicity and high working temperature.

Sulfate bronzing electrolytes, which more completely meet the process requirements, being less toxic, comparatively cheap, and simple in preparation and service and operating at room temperature, are considered today to be the most promising. Of specific interest are sulfate electrolytes for obtaining lustrous Cu–Sn coatings. However, the electrolytes developed for obtaining lustrous coatings operate at low current densities i_c and require pretreatment [3–5].

In this work we studied the electrodeposition of Cu–Sn alloy from a sulfate electrolyte in the presence of benzyl alcohol (BA). This additive is used in electrolytes to obtain Sn, Sn–Sb, and Sn–Bi lustrous coatings [6–8].

The study was performed in an electrolyte containing $CuSO_4 \cdot 5H_2O$ 30–50 g l^{-1}, $SnSO_4$ 30–50 g l^{-1}, H_2SO_4 70–120 g l^{-1}, and BA 1–10 ml l^{-1}. Copper foil was used as material for cathodes, on which a 9–15-μm-thick alloy layer was deposited. Anodes were made of bronze (85 wt % Cu and 15 wt % Sn), copper, and tin. The alloy was analyzed by the method described in [2]. The content of Sn^{2+} in the electrolyte was determined by iodometric titration [9]. The Sn^{4+} content in the electrolyte was calculated by the difference between the total content of tin and the Sn^{2+} content [9]. The copper(II) content in the electrolyte and that in the alloy were determined electrogravimetrically at direct current [2]. The X-ray diffraction analysis of Cu–Sn deposits was done on a DRON-2 diffractometer (CuK_α radiation). The polarization curves were recorded on a P-5827 potentiostat in the potentiodynamic mode at a linear potential sweep rate of 2 mV s^{-1}. A mercury sulfate electrode was the reference. In this study, all potentials are given relative to standard hydrogen electrode. The current efficiency by the Cu–Sn alloy was determined by the electrogravimetric method from the results of the electrolysis in the galvanostatic mode. The electrodeposition was performed at 18–20°C with and without stirring the electrolyte.

Data on how the BA concentration affects the outward appearance of the coatings depending on the current density (electrolyte composition, g l^{-1}): $CuSO_4 \cdot 5H_2O$ 30–50, $SnSO_4$ 30–50, and H_2SO_4 90) showed that the widest i_c interval (3–5 A dm^{-2}) for obtaining lustrous coatings is attained at an alcohol concentration of 2–4 ml l^{-1}. Outside this concentration range, dull or semilustrous coatings were obtained. It was established that the outward appearance of the coatings was also affected by the H_2SO_4 concentration in the electrolyte. At an H_2SO_4 concentration of 70–80 g l^{-1}, the coatings obtained were semilustrous (i_c = 3–5 A dm^{-2}), and the electrolyte operation was unstable. With acid concentration increased to 90–120 g l^{-1}, lustrous coatings were obtained at i_c = 3–5 A dm^{-2}. It should be noted that only stirring ensured formation of quality lustrous coatings in all the electrolytes studied. The coatings obtained without stirring were dull and rough.

The chemical analysis of the lustrous coatings obtained showed that, in this case, the Cu–Sn electrolytic alloy is formed. The influence of i_c on alloy the composition was studied. It was found that, with in-

1070-4272/04/7707-1104 © 2004 MAIK "Nauka/Interperiodica"

creasing current density, the Cu content in the alloy decreased (Fig. 1, curve *1*), with the current efficiency by the alloy being as high as 95.0–96.8% (Fig. 1, curve *2*).

We studied the influence of $CuSO_4 \cdot 5H_2O$ and $SnSO_4$ concentrations on the alloy composition. The table shows that the Cu content in the alloy increases with increasing $CuSO_4 \cdot 5H_2O$ concentration (at a constant $SnSO_4$ concentration) and decreases with increasing $SnSO_4$ concentration (at a constant $CuSO_4 \cdot 5H_2O$ concentration).

Variation of the H_2SO_4 concentration within 90–100 g l^{-1} does not affect the alloy composition. At higher acid concentrations (110–120 g l^{-1}), the Cu content in the alloy increases by 1–2%.

The polarization measurements were performed in the electrolytes for Cu, Sn, and Cu–Sn electrodeposition. We found that BA inhibits electrodeposition. Figure 2 shows that, in a BA-containing electrolyte, the cathodic polarization curve of the Cu–Sn deposition lies between the polarization curves of the Cu and Sn deposition at i_c = 1–3.8 A dm^{-2} and at more positive potentials at higher current densities (i_c > 3.8 A dm^{-2}) (Fig. 2, curves *1–3*).

To determine the rate of the Cu and Sn electrodeposition, we calculated in this study the partial polarization curves. The calculation was performed taking into account the alloy compositions at various i_c values, current efficiencies by the alloy, and electrochemical equivalents of Cu, Sn, and Cu–Sn [10]. As seen, the rate of the Cu deposition into the alloy is considerably higher than that of the Sn deposition (Fig. 2, curves *1*', *2*').

The analysis of the cathodic polarization curves of the individual metal deposition and of the partial curves shows that, as compared to separate deposition, Cu is deposited into the alloy with an overpolarization, and Sn, with a considerable depolarization (Fig. 2, curves *1*, *1*' and *2*, *2*').

The overpolarization in deposition of ions of a more electropositive metal cannot be explained in terms of the thermodynamics [1], since the maximal work spent for the alloy formation upon the deposition of both electropositive and electronegative metals is positive. Evidently, the overpolarization at Cu electrodeposition into the alloy is associated with the presence of BA in electrolyte, which decreases the process rate owing to adsorption on the electrode. Apparently, the depolarization in the Sn deposition into the alloy results from a decrease in its partial

energy released upon formation of intermetallic compounds in bronzes [1]. This is confirmed by the analysis of the alloy phase composition. It was found that the alloy formed in formation of yellow bronze con-

sisted of CuSn and $Cu_{31}Sn_8$ intermetallic compounds.

The electrochemical stability of a bronzing electrolyte was studied in the course of prolonged electrolysis with bronze and copper anodes. It was found that, with increasing amount of the passed electricity, the concentration of the Sn^{2+} ions in the electrolyte decreases, whereas the Sn^{4+} concentration increases (Fig. 3, curves *1*, *2*). The Cu^{2+} content in the electrolyte varies insignificantly, and the Cu content in the alloy increases (Fig. 3, curve *3*). It should be noted that, in the course of the electrolysis with bronze anodes, the Sn^{2+} concentration in the electrolyte and the alloy composition vary to a lesser extent than in the course of the electrolysis with Cu anodes.

To ascertain why the content of Sn^{2+} ions in the electrolyte decreases considerably and the Sn^{4+} content increases, we took the anodic polarization curves. It was found that the potential of a bronze anode at i_a = 1–5 A dm^{-2} lies in the range of potentials from 0.36 to 0.38 V, and that of a copper anode, in the range from 0.32 to 0.47 V, i.e., they both are more positive than the standard potential of the oxidation of Sn^{2+} to Sn^{4+} (0.16 V) [11]. The data presented show that the oxidation of Sn^{2+} to Sn^{4+} with subsequent hydrolysis and precipitation of metastannic acid suspension are responsible for the low electrochemical stability of the bronzing electrolyte with respect to Sn^{2+}, with both bronze and copper anodes. With tin anodes, the dissolution potential at i_a = 1–5 A dm^{-2} varies from –0.18 to –0.10 V, i.e., the potential of the Sn anode acquires more negative values than the potential of the Sn^{2+} oxidation to Sn^{4+}, which makes this oxidation on the anode infeasible. At the same time, it is not reasonable to use tin anodes for the electrodeposition of yellow bronze, since in this case the Sn^{2+} concentration in the electrolyte increases considerably and the Cu^{2+} concentration decreases. A decrease in the Sn^{2+} concentration in the electrolyte is due to its contact deposition onto tin anodes when switching off the current. The Sn anodes can be used for adjusting the composition of the sulfate electrolyte both to increase the Sn^{2+} concentration in the electrolyte and to decrease the concentration of Cu^{2+} if its excessive amount is accumulated.

Thus, we developed a sulfate electrolyte for obtaining lustrous Cu–Sn coatings (yellow bronze). The electrolyte contains $CuSO_4 \cdot 5H_2O$ 30–50 g l^{-1}, $SnSO_4$ 30–50 g l^{-1}, H_2SO_4 90–100 g l^{-1}, and BA 2–4 ml l^{-1}; i_c = 3–5 A dm^{-2}.

The current efficiency is 95–98%. The tin content in the alloy is 11–18 wt %. Anodes are made of bronze (85 wt % Cu and 15 wt % Sn). The process is performed at 18–20°C at stirring and continuous filtration of the electrolyte. After passing 25–30 A h l^{-1} of electricity, the Sn^{2+} and Cu^{2+} concentrations require correction. Adjustment of the BA concentration is performed on the basis of spectrophotometric analysis data [6].

CONCLUSIONS

Electrodeposition of Cu–Sn alloy is performed at 18–20°C with stirring and continuous filtration of the electrolyte containing $CuSO_4 \cdot 5H_2O$ 30–50 g l^{-1}, $SnSO_4$ 30–50 g l^{-1}, H_2SO_4 90–100 g l^{-1}, and benzyl alcohol 2–4 ml l^{-1}.

Abstract—A scheme for preparing high-purity lithium hydroxide monohydrate from technical-grade lithium carbonate is suggested.

The basic stage in preparation of $LiOH \cdot H_2O$ from Li_2CO_3 is transformation of solid Li_2CO_3 into a LiOH solution. In this case, the throughput of the conversion process and its energy consumption, as well as the concentration and purity of the resulting LiOH solution largely determine the quality of the product obtained, its production cost, and the efficiency of the method as a whole.

Of the known techniques for preparing LiOH from Li_2CO_3, the method based on the reaction of Li_2CO_3 with lime milk $Ca(OH)_2$ is mainly used in practice [1, 2]. Despite the simplicity of this method and use of low-cost and readily available raw materials, it has a number of important disadvantages. For example, to obtain high-quality $LiOH \cdot H_2O$, it is necessary to impose stringent requirements on the purity of the starting components. In view of the low solubility of $Ca(OH)_2$, the technique in question is also characterized by low yield of LiOH into solution and large loss of Li^+, associated with the necessity for washing and settling of voluminous precipitates of $CaCO_3$.

To raise the yield of LiOH and improve the purity of the $LiOH \cdot H_2O$ obtained, it has been suggested to use, instead of $Ca(OH)_2$, a more soluble compound, $Ba(OH)_2$ [2]. However, the given method is also largely characterized by the same disadvantages. Moreover, $Ba(OH)_2$ is more expensive than $Ca(OH)_2$.

A method for obtaining LiOH by hydration of its oxide formed in thermochemical dissociation of Li_2CO_3 in a vacuum was suggested in [2]. However, the low rate of Li_2CO_3 decomposition gives no way of using this technique in the industry.

In recent years, electrochemical methods using ion-exchange membranes have found wide use in manufacture of high-purity alkali metal hydroxides [3–9].

For example, a method is known for preparing LiOH from Li_2CO_3 in a two-chamber electrolyzer with a cation-exchange membrane, lead anode, and iron cathode [8].

In [9], it was suggested to prepare LiOH from solid Li_2CO_3-containing wastes by bringing them in contact with water and subsequent separation of the clarified liquid phase. A lithium-containing solution is passed through the central chamber of a three-chamber electrolyzer, and a LiOH solution is obtained in the cathode chambe, and a solution of a mixture of acids, in the anode chamber. The circulation of the starting solution leads to desalting of the liquid in the central chamber, and this liquid is recycled into the dissolution stage.

The above-mentioned electrochemical methods for conversion of Li_2CO_3 into LiOH exhibit important advantages over chemical production techniques, because they make it possible to directly obtain high-purity LiOH at lower loss of Li^+. Therefore, development of a process for obtaining high-purity $LiOH \cdot H_2O$ by membrane electrolysis shows promise. However, the low output capacity and high energy consumption by electrochemical conversion, which is due to low solubility of Li_2CO_3 in water, is an important disadvantage in setting up a large-scale production.

The above disadvantages can be eliminated by preliminarily converting Li_2CO_3 into a well-soluble lithium salt. In this case, the solubility of the salt in water, electrical conductivity of its solution, and the nature of anodic reactions and products formed will

1070-4272/04/7707-1108 © 2004 MAIK "Nauka/Interperiodica"

largely determine the efficiency of membrane electrolysis.

The most suitable salt is Li_2SO_4, which is due not only to its high solubility, but, to a considerable extent, also to specificity of the anodic processes that occur in electrolysis of a Li_2SO_4 solution.

The main anodic reaction in electrolysis of the sulfate solution proceeds to give O_2 and H_2SO_4 as products, which makes it possible to use readily available and inexpensive lead anodes. In addition, the evolving O_2 presents no problems with its utilization, and H_2SO_4 generated in the anolyte is easily neutralized with Li_2CO_3, with its conversion into Li_2SO_4.

In addition to the electromembrane conversion of Li_2CO_3 into a LiOH solution, it is necessary to solve, in developing a process for production of high-purity $LiOH \cdot H_2O$, the problem of removal of Na, Ca, Mg, Al (halides and sulfates) impurities, and also SiO_3^{2-} ions, contained in Li_2CO_3. Solving this problem required a number of experimental studies and predetermined the goals of this work. Among the issues studied were the following: electrochemical conversion $Li_2SO_4 \rightarrow LiOH$ with determining the main technical and economical characteristics of the process and factors affecting the yield and qualitative composition of the conversion-produced LiOH; evaporation of the conversion-produced LiOH solution, crystallization of $LiOH \cdot H_2O$ from this solution, distribution of impurities among the liquid and solid phases, and washing of the resulting $LiOH \cdot H_2O$ crystals to remove mother liquor; and carbonation of mother liquors after evaporation as applied to utilization of Li^+ from these solutions.

EXPERIMENTAL

In the study was used technical-grade Li_2CO_3 manufactured by the SQM company (Chile) and containing about 1% impurities. The starting Li_2CO_3 solution was prepared from chemically pure grade crystalline lithium sulfate and distilled water.

The electrochemical conversion was studied in a galvanostatic mode on a laboratory setup whose main part is a membrane electrolyzer in the form of a filter-press apparatus with a stainless steel cathode and lead anode. The interelectrode space of the electrolyzer is separated by an MK-40 cation-exchange membrane into the anode and cathode chambers. The working area of the membrane and electrodes was the same and equal to 0.78 dm^2.

The rate of solution circulation in all the experiments was 0.15 l min^{-1}. The thickness of the electrode chambers was varied from 2 to 16 min, and the concentration of H_2SO_4 in the anolyte, from 0 to 87 g l^{-1}. The concentration of the resulting LiOH was in the range from 10 to 85 g l^{-1}, and the current density, from 5.2 to 15.4 A dm^{-2}. The process temperature depended on the current load and varied in the range 30–40°C.

In the experiments, the main parameters of the electrolysis process (transfer of Li^+ ions into the cathode chamber, current efficiency, electrolyzer voltage, and specific electric power consumption) were determined. In addition, the qualitative and quantitative composition of the conversion-produced LiOH and the influence exerted on these parameters by the anolyte composition were found.

The rate of transfer of Li^+ ions into the cathode chamber, ΔP_{Li^+}, (g Li h^{-1} dm^{-2}), was determined from changes in the concentration of Li^+ ions, or in the equivalent concentration of OH^- ions in the catholyte (the negligible content of impurity ions in the catholyte was disregarded), and from changes in its volume in unit time, using the formula

$$\Delta P_{Li^+} = \frac{\Delta V_c \Delta c_{Li^+}}{\tau S_m} \times 0.292,$$

where ΔV_c is the change in the catholyte volume in a time τ (l); Δc_{Li^+}, the change in the concentration of LiOH in the time τ (g l^{-1}); τ, the time of electrolysis (h); S_m, the membrane area (dm^2); and 0.292, the recalculation factor.

The current efficiency η (%) was calculated by the formula

$$\eta = \frac{\Delta P_{Li^+} F}{j E_{Li^+}} \times 100,$$

where j is the current density (A dm^{-2}); F = 26.8, the Faraday constant (A h); and E_{Li^+} = 7, the chemical equivalent of lithium (g).

The specific energy expenditure was determined using the formula

$$W = \frac{Uj}{\Delta P_{Li^+}},$$

where W is the specific expenditure of electric power (W h g^{-1} Li), and U is the electrolyzer voltage (V).

The crystallization of $LiOH \cdot H_2O$, including the stage of its washing, was studied with conversion

solutions of LiOH. A solution was evaporated to a LiOH concentration in solution of 170–180 g l^{-1}. Then, the evaporated solution was cooled in a closed flask to room temperature and the crystals formed were rapidly filtered off. The product was dried in a desiccator at room temperature and then analyzed for the content of impurities and subjected to washing.

The mother liquor, which is a saturated solution of LiOH with impurities, was recycled into the stage of evaporation and crystallization, and so on. This yielded, each time, crystals and mother liquors increasingly contaminated with impurities. A total of five different samples were obtained.

The resulting $LiOH \cdot H_2O$ samples were, each separately, washed to remove impurities with a pure saturated solution of LiOH in accordance with a scheme of three-stage batch washing with phase mixing; the l : s ratio was 1 : 1 for each stage.

The washed $LiOH \cdot H_2O$ samples were dried, and the residual content of impurities in them was determined.

A mother liquor formed after crystallization, which is a saturated LiOH solution contaminated with Na, K, and Ca ions, was placed in a vessel for carbonation, into which CO_2 was fed from a cylinder at a rate of 0.3 l min^{-1} through a gas-distribution unit. The carbonation was performed in the bubbling mode to pH 12.3 to prevent formation of lithium hydrocarbonate.

The resulting suspension was separated by filtration, after which the precipitate was washed on the filter with a threefold volume of distilled water, dried in a desiccator, and analyzed for the content of impurities.

The conventional analytical techniques were used in the study. The concentration of Li, K, and Na ions was determined by the spectral method on a Philips AAS-SP-9 atomic-absorption spectrophotometer [10]; that of calcium and magnesium ions, by EDTA titration [11]; that of OH^- and H^+ ions, by titration with a 0.1 N solution of HCl or KOH, respectively [12]; and that of chloride ions, by mercurimetric titration, with nitroprusside as indicator [13]. Sulfate ions were determined in solutions with their concentration exceeding 1 g l^{-1} by volumetric EDTA titration [14], and in cases when the concentration of these ions was lower than 1 g l^{-1}, by the nephelometric method on a KFK-1 photocolorimeter [12]. The accuracy of determination was 5%. The formation of PbO_2 in the system under study was monitored as follows. The precipitate was filtered off and then boiled, together with the filter, in a mixture of HNO_3 with H_2O_2, with the whole amount of PbO_2 quantitatively dissolved. The concentration of lead in solution was determined by EDTA titration, with Xylenol Orange as indicator, at pH 5.5 [15]. The concentrations of Cl_2 and O_3 in the gas phase were determined by photocolorimetry on a KFK-2MP instrument [16].

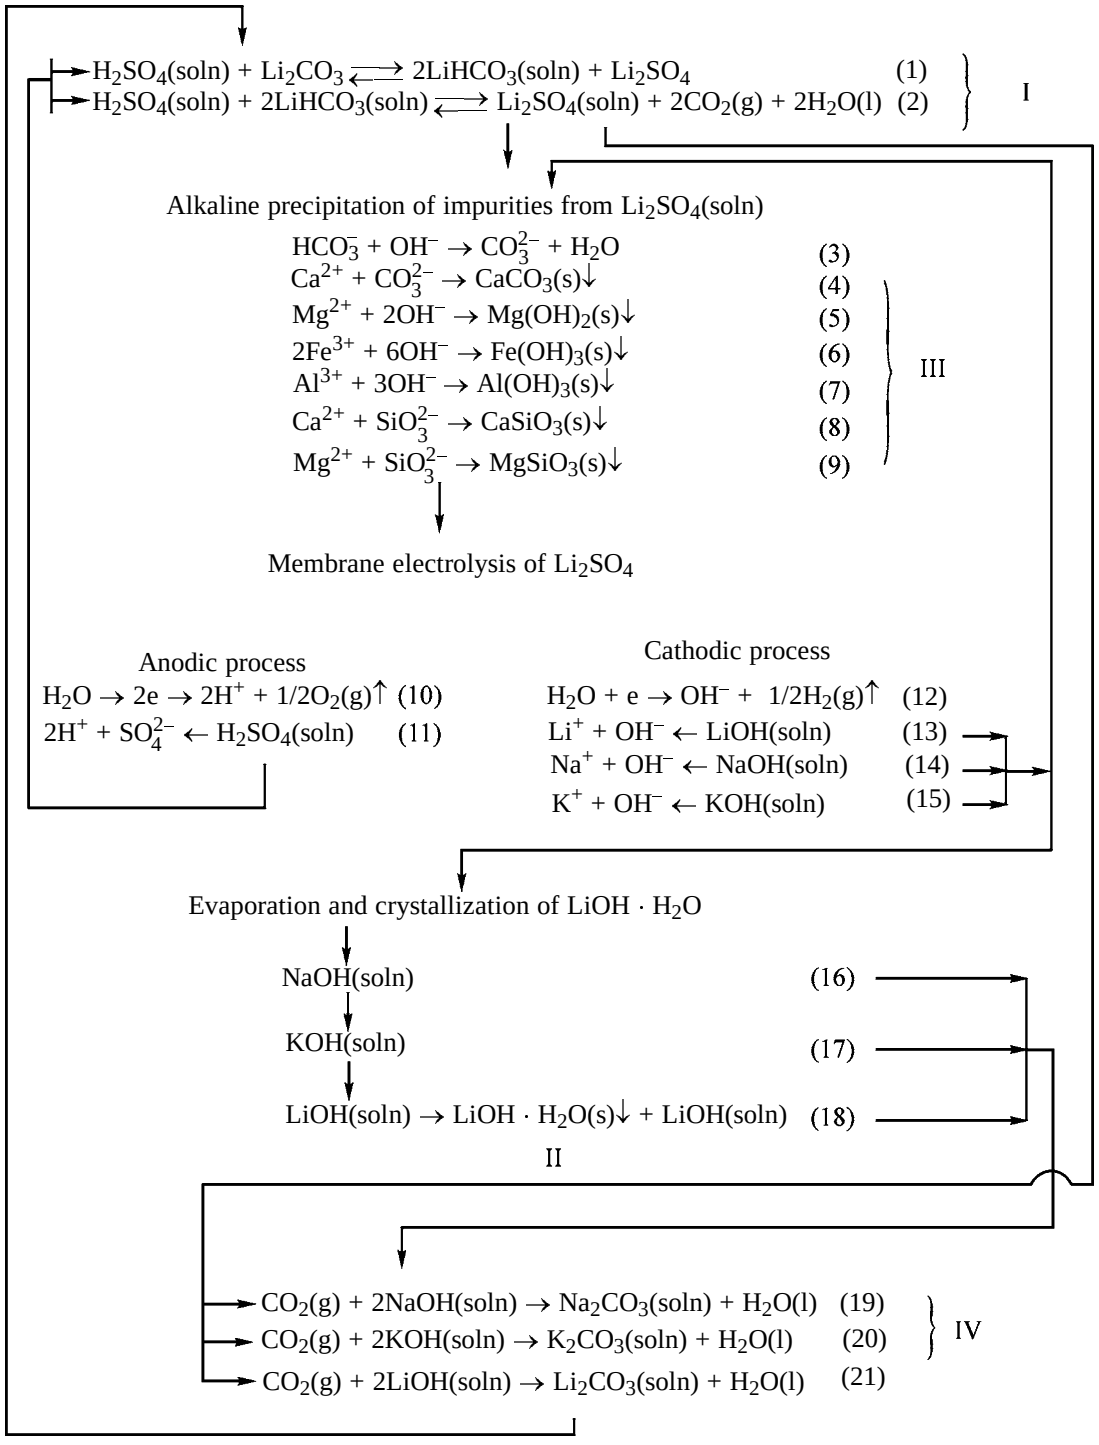
The procedure for obtaining high-purity $LiOH \cdot H_2O$ from technical-grade Li_2CO_3 is shown in Scheme 1.

According to the scheme suggested, a Li_2SO_4 solution is obtained from H_2SO_4 and Li_2CO_3 [reactions (1), (2)]. In the process, impurities of Na^+, K^+, Ca^{2+}, Mg^{2+}, Al^{3+}, Fe^{3+}, SiO_3^{2-}, and Cl^- ions will also pass into solution from technical-grade Li_2CO_3. Some of these impurities can impair the quality of the resulting LiOH solution and disturb the course of electrolysis to the point of its complete termination. This primarily refers to cations that tend to form poorly soluble compounds on coming in contact with alkali formed in the cathode chamber. Therefore, prior to delivering the Li_2SO_4 solution to electrochemical conversion, it should be alkalized to pH 11–12 in order to precipitate these impurities in the form of poorly soluble compounds [reactions (4)–(9)]. The purified Li_2SO_4 solution is fed into the anode chamber of the electrolyzer. In the course of electrolysis, water is oxidized electrochemically at the anode to give gaseous O_2 and H^+ ions by reaction (10).

The cathode space is filled with a dilute LiOH solution, with the electrochemical reduction of water occurring at the cathode to give gaseous H_2 and OH^- ions by reaction (12). The cation-exchange membrane separating the cathode and anode spaces of the electrolyzer ensures free transfer of cations (mainly Li^+) from the anode space of the electrolyzer into its cathode space under the action of an electric field and precludes transfer of anions. As a result, a fairly pure LiOH solution concentrates in the cathode chamber [reaction (13)]. The main ingredients that contaminate LiOH will be Na^+ and K^+, which are present in the anolyte and cannot be removed from the anolyte in the stage of its alkaline purification preceding the electrolysis. Therefore, these cations will also freely pass, together with Li^+ cations, into the cathode chamber and thereby contaminate the product [reactions (14), (15)].

The thus obtained LiOH solution containing a certain amount of Ba^+ and K^+ impurities is delivered to the stage of evaporation and crystallization of $LiOH \cdot H_2O$ and is, in part, used to alkalize the Li_2SO_4 solution before the electrochemical conversion.

Scheme 1



Chemical reactions that occur in preparing high-purity $LiOH \cdot H_2O$ from technical-grade lithium carbonate.

The required degree of purification of the final product to remove Na^+ and K^+ can be achieved by crystallization of $LiOH \cdot H_2O$ from an evaporated LiOH solution [reactions (16)–(18)]. In the crystallization of $LiOH \cdot H_2O$, Na^+ and K^+ ions must mainly remain in the mother liquor because of the higher solubility of NaOH and KOH and, up to their certain content in the solution being evaporated, must not affect the purity of the $LiOH \cdot H_2O$ crystals obtained. In this case, the resulting $LiOH \cdot H_2O$ crystals should

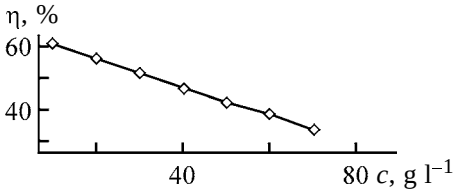


Fig. 1. Current efficiency η vs. LiOH concentration *c*.

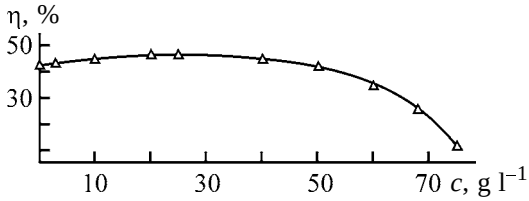

Fig. 2. Current efficiency η by conversion LiOH vs. the H_2SO_4 concentration *c* in the analyte.

be washed with the condensate for more complete removal of the mother liquor from their surface.

In order to prevent the loss of Li^+, it is advisable to treat spent washing solutions and mother liquors with carbon dioxide evolved in reaction (2). It is necessary to separate the poorly soluble Li_2CO_3 from the liquid phase, which contains mostly Na_2CO_3 and K_2CO_3 [reactions (19)–(21)]. The carbonate mother liquors formed after separation of Li_2CO_3 can be used in the industry, e.g., for neutralization of wastewater, or in installations for water softening.

The main characteristic of any process is the specific energy expenditure necessary for obtaining the target product. The specific energy expenditure in electrolysis is determined by the electrolyzer voltage and current efficiency by the target product. The electrolyzer voltage is largely determined by the electrical conductivity of the electrolyte, which, as a rule, depends on its concentration. In studying the electrochemical conversion of Li_2SO_4 into LiOH, the optimal Li_2SO_4 concentration in the solution delivered to the conversion stage was determined to be 180–230 g l^{-1} [17]. To this concentration corresponds the maximum electrical conductivity of approximately 0.09 S cm^{-1}, which, combined with the relatively low viscosity, ensures the minimum energy expenditure for overcoming the ohmic and hydrodynamic resistances in the given process. It was established experimentally that changing the thickness of chambers of the electrolysis cell in the range 2–8 mm has virtually no effect on the loss of voltage in electrolysis of a Li_2SO_4 solution with a concentration of 200 g l^{-1} in the current density range studied. In the elementary cell, the chamber thickness was taken to be 4 mm, which enables one, on the one hand, to simplify to the maximum possible extent the fabrication of an electrolyzer of the filter-press type, and, on the other, to construct apparatus with a high output capacity and relatively small dimensions.

The concentration of LiOH in the cathode chamber affects the loss of voltage in an elementary cell of the electrolyzer only at LiOH concentrations of up to 40–45 g l^{-1}.

A much stronger influence is exerted by the concentration of LiOH obtained on the current efficiency by LiOH, whose value directly determines the specific energy expenditure.

The dependence of the current efficiency on the concentration of the LiOH being obtained, shown in Fig. 1, indicates that the transfer of Li^+ ions linearly decreases as the content of Li^+ ions in the catholyte becomes higher. This leads to a proportional rise in the specific expenditure of electric power. The minimum specific expenditure of electric power for electrochemical conversion corresponds to concentrations of LiOH obtained equal to 20–25 g l^{-1}. However, obtaining a more concentrated LiOH solution is advantageous as regards energy saving in evaporation of a solution of conversion LiOH in production of $LiOH \cdot H_2O$.

Rough feasibility studies demonstrated that, as regards lowering to the maximum possible extent the total energy expenditure for obtaining $LiOH \cdot H_2O$ as a commercial product, the optimal concentration of conversion LiOH is 40–50 g l^{-1}. In this case, the concentration of the acid in the anolyte does not exert, in a rather wide range (up to 50 g l^{-1} of H_2SO_4), any noticeable influence on the cathode current efficiency by LiOH (Fig. 2). A moderate increase in the acidity even improves the process parameters because of a certain enhancement of the transfer of Li^+ ions and the corresponding increase in the current efficiency (by approximately 5%). The possible reason is that, when the acidity of the anolyte increases, H^+ ions neutralize OH^- ions in the membrane or in the near-membrane layer on the anode side to give water. The reaction between H^+ and OH^- ions, which are charge carriers, is compensated for by an increase in the fraction of current transported by Li^+ ions. The optimal concentration of H_2SO_4 in the anolyte in production of LiOH is in the range 15–40 g l^{-1}. Impurity ions constantly delivered into the anolyte with Li_2CO_3 in the neutralization of the acid cannot affect the process parameters to any noticeable extent because of their insignificant content in the anolyte.

In addition to the parameters described above,

those affecting the feasibility of electrolysis include the current density, which determines the specific output capacity of the process. The dependences in Figs. 3 and 4 clearly demonstrate that raising the current density leads to an increase in the electrolyzer voltage (Figs. 3, 4) and to the corresponding rise in the specific energy expenditure (Fig. 4, straight line *2*). At the same time, raising the current density leads to a proportional increase in the rate of transfer of Li^+ ions, ΔP_{Li^+}, i.e., in the specific output capacity of the process (Fig. 4, straight line *1*). For example, a threefold increase in the current density leads to an identical increase in the specific output capacity of the process, whereas the energy expenditures grows by only 36.6%. It was also established that the current density does not affect significantly the qualitative composition of the LiOH obtained. The electrolysis is more efficient at higher current densities, because the component of the production cost, associated with the capital cost and running expenses, decreases in this case. This conclusion is also supported by the fact that the concentration polarization of the electrodes and membranes, which makes shorter their service life, is not observed at the current densities studied. This is indicated by the stable current efficiency by LiOH and by the sufficiently high chemical and corrosion resistance of the membranes and electrodes, observed in the course of the study.

The main disadvantage of MK-40 membranes is their high permeability to OH^- ions, which leads to low current efficiency. At the same time, these membranes enable production of LiOH that is virtually free of any foreign anions. The main impurities that pass from Li_2CO_3 into a LiOH solution in electrochemical conversion are Na^+ and Ca^{2+} ions, whose concentrations in the 2 M LiOH solution obtained in a stationary electrolysis mode are 35–40 and 12–15 mg l^{-1}, respectively. A decrease or increase in the concentration of LiOH does not affect their relative concentration in solution. The study performed demonstrated that, as expected, the concentration of Ca^{2+} ions in alkali can be diminished to 2–4 mg l^{-1} by purifying the anolyte by the carbonate–alkaline method. No transfer of lead ions into the LiOH solution was observed in the course of electrolysis.

The parameters characterizing the purification of $LiOH \cdot H_2O$ by evaporation, crystallization, and washing of the crystals obtained to remove the remainder of contaminated mother liquor are listed in Tables 1 and 2.

Table 2 shows that the maximum content of Na^+ ions in the $LiOH \cdot H_2O$ samples obtained, at which high-purity $LiOH \cdot H_2O$ can be obtained by their washing to remove mother liquor (residual content of $Na^+ \le 0.002$ wt %), is about 0.06 wt %. As seen from Table 1, the concentration of Na^+ ions in a LiOH solution from which $LiOH \cdot H_2O$ with a residual sodium content $c \le 0.06$ wt % can be obtained should not exceed 1.4 g l^{-1}.

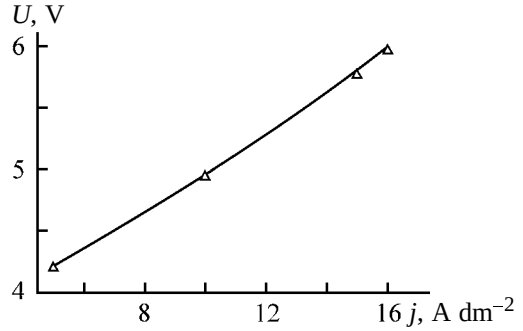

Fig. 3. Voltage U vs. the current density j in production of LiOH.

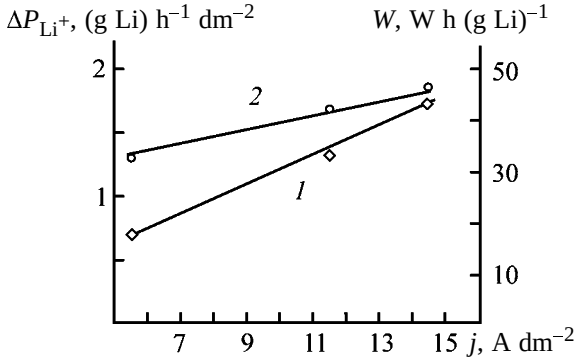

Fig. 4. (*1*) Rate of transfer of Li^+ ions and (*2*) specific energy expenditure W vs. the current density j in production of a LiOH solution. (ΔP_{Li^+}) Specific transfer of Li^+ ions to the cathode chamber.

As expected, Ca^{2+} is removed by washing to a considerably lesser extent than Na^+, and, therefore, the maximum content of Ca^{2+} impurity in the $LiOH \cdot H_2O$ samples delivered to the washing stage should not exceed 0.003 wt % for $LiOH \cdot H_2O$ of required purity as regards Ca^{2+} ions (residual content of Ca^{2+} $c \le 0.001$ wt %) to be obtained. In this case, the concentration of Ca^{2+} in a LiOH solution from which $LiOH \cdot H_2O$ with a residual content of Ca^{2+} $c \le 0.003$ wt % can be obtained should not exceed 0.05 g l^{-1}. Provided that the concentration of Ca^{2+} in the starting solution of conversion LiOH is lowered to 2–4 mg l^{-1} by its alkaline–carbonate removal from the anolyte delivered to electrolysis, it may be stated that Ca^{2+} is not an impurity component that determines the quality of $LiOH \cdot H_2O$ produced by the technique suggested.

Table 1. Characteristics of starting solutions and crystalline $LiOH \cdot H_2O$ samples obtained from these solutions

Sample no.	LiOH solution	Solution volume, l	c_{LiOH} in solution, g l^{-1}	Na^+ content		Ca^{2+} content	
				in solution, g l^{-1}	in $LiOH \cdot H_2O$, wt %	in solution, g l^{-1}	in $LiOH \cdot H_2O$, wt %

In order to test the process on an enlarged scale, a pilot batch of the product was prepared from lithium carbonate of Chilean manufacture.

In the process, 8.5 l of a conversion solution of LiOH with an average concentration of 45 g l^{-1} was obtained. The average concentrations of the main impurities in the resulting solution are as follows (mg l^{-1}): Na^+ 70, Ca^{2+} 15, CO_3^{2-} 300. The contents of other impurities (Pb, Fe^{2+}, Mg^{2+}, SO_4^{2-}, Cl^-) were either an order of magnitude lower than that of Na^+ and Ca^{2+}, or these impurities could not be detected at all by the analytical methods used.

Table 3. Composition of Li_2CO_3 manufactured by SQM (Chile) and of $LiOH \cdot H_2O$ obtained

Main substance and impurities	Content, wt %	
	Li_2CO_3	$LiOH \cdot H_2O$
Li_2CO_3	99.0	0.6*
Cl^-	0.02	0.1×10^{-3}
Na^+	0.12	2×10^{-3}
K^+	0.05	0.2×10^{-3}
Ca^{2+}	0.04	$\leq 4 \times 10^{-3}$
Mg^{2+}	0.011	$\leq 1 \times 10^{-3}$
SO_4^{2-}	0.1	$\leq 0.1 \times 10^{-3}$
Fe_2O_3	0.03	$\leq 1 \times 10^{-3}$
Insolubles	0.02	–
Pb	–	–

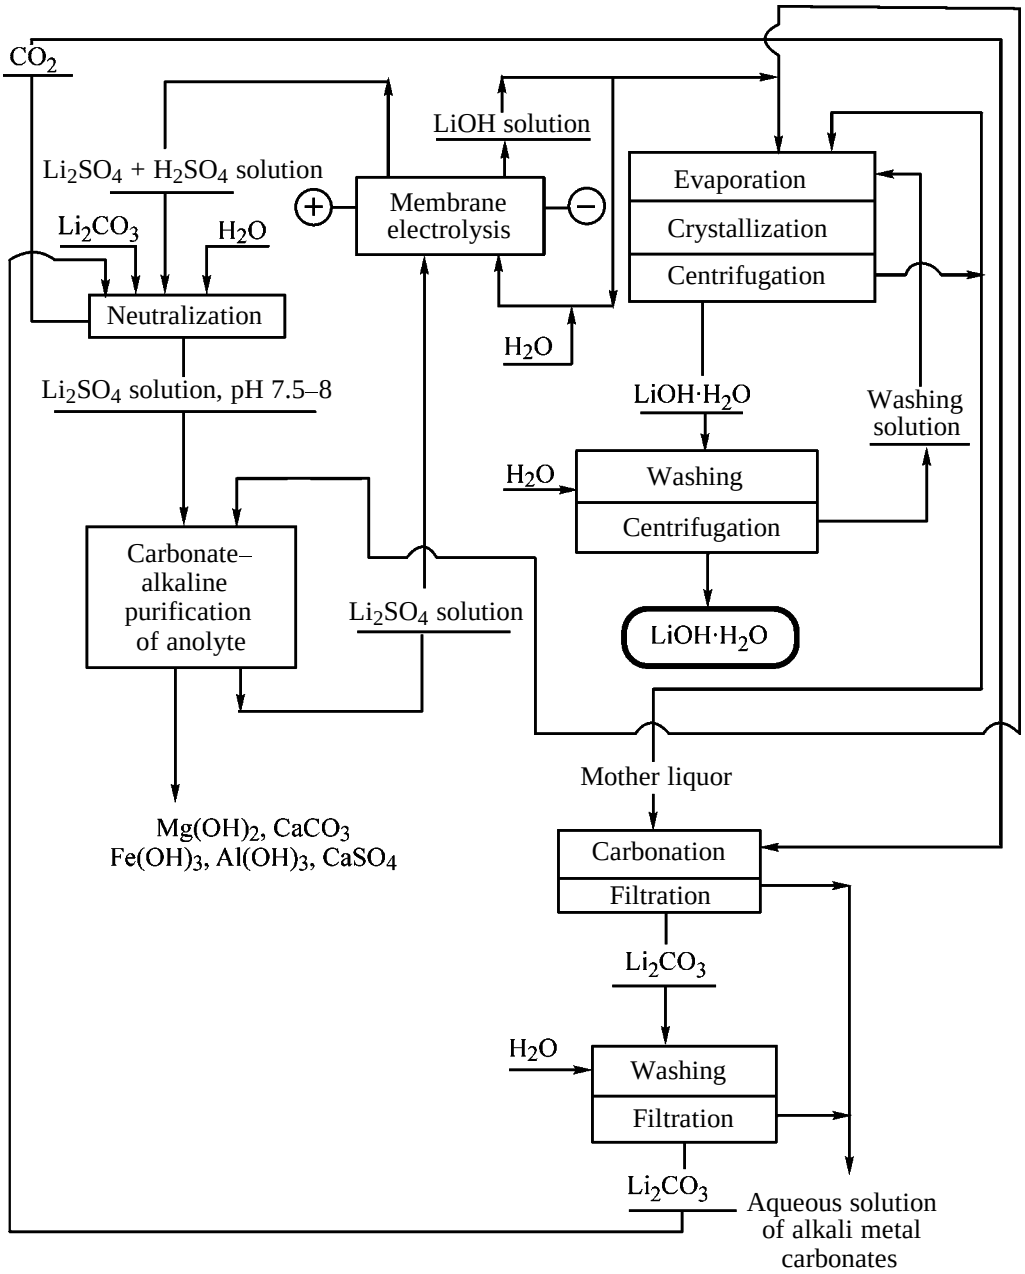
* The product contains a CO_3^{2-} impurity because of its storage conditions.

It follows from Table 3 that the quality of $LiOH \cdot H_2O$ satisfies the requirements of GOST (State Standard) 8595–83 (LGO-1 brand) in all the parameters except the content of Ca^{2+}.

The increased content of Ca^{2+} (~0.004 wt % against 0.001 wt % required by GOST) can be brought to satisfactory values by preliminary alkaline–carbonate purification of the anolyte delivered to electrolysis.

A study of the carbonation of alkaline mother liquors obtained after evaporation and crystallization, which cannot be used to produce commercial $LiOH \cdot H_2O$ because of the high content of impurities, demonstrated sufficiently high efficiency of this process for utilization of Li^+. Li_2CO_3 obtained by carbonation

Scheme 2



Flowsheet for production of high-purity $LiOH \cdot H_2O$.

contains only 0.007 wt % Na^+ and 0.043 wt % Ca^{2+}, which allows its recycling into the stage of electrochemical conversion. It was established that the main part of Ca^{2+} passes into the solid phase of Li_2CO_3 and cannot be removed by subsequent washing. Part of Na^+ ions (88%) remains in solution, and 12% Na^+ coprecipitates with Li_2CO_3, and this Na^+ can be completely removed by washing.

A calculation of the conversion of Li_2CO_3 into $LiOH \cdot H_2O$ of LGO-1 brand demonstrated that the loss of Li^+ without utilization from mother liquors formed in crystallization of $LiOH \cdot H_2O$ is 5.4%. With utilization of Li^+ from mother liquors by their carbonation and recycling of Li_2CO_3, the loss of Li^+ is about 1%.

The results obtained were used to develop a technique for manufacture of high-purity $LiOH \cdot H_2O$ from Li_2CO_3 by membrane electrolysis (Scheme 2). The technique was patented in the Russian Federation [18].

CONCLUSIONS

(1) The experimental study of production of $LiOH \cdot H_2O$ from technical-grade Li_2CO_3 by membrane electrolysis via Li_2SO_4 demonstrated that the use of a sulfate solution of Li^+ makes it possible to perform the process in an intensive mode at high current densities and allows use of lead anodes and MK-40 cation-exchange membranes of domestic manufacture.

(2) The use of these materials in a practical implementation of the process of electrochemical conversion demonstrated their high stability and efficiency. The technique is distinguished by an integrated approach to solution of the problem of use of technical-grade Li_2CO_3 and, in particular, that of Chilean manufacture. It yields high-purity $LiOH \cdot H_2O$ with a minimum amount of reagents used and does not produce any toxic waste.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

N-Phenacylpyridinium Bromides as Acid Corrosion Inhibitors

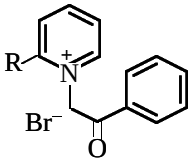
R. I. Yurchenko, I. S. Pogrebova, T. N. Pilipenko, and T. E. Shubina

Kiev Polytechnic Institute, National Technical University of Ukraine, Kiev, Ukraine

Received March 11, 2004

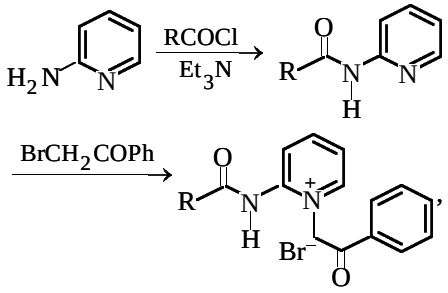
Abstract—The inhibiting effect of *N*-phenacylpyridinium bromides with the amide group in the pyridine ring on corrosion of carbon steel in 3 M sulfuric acid is studied. A relationship between the nature of substituents at the amide group and the corrosion-protective properties of the compounds studied is revealed. Compounds demonstrating high protection efficiency in acid solutions at elevated temperatures are found.

In the previous work [1] we demonstrated that the corrosion-protective efficiency of *N*-phenacylpyridinium bromides (**I**)



at 20 and 40°C can be characterized as the correlation between the inhibiting factor γ and σ_c^0 constants of the substituent R. At higher temperatures (60 and 80°C), they demonstrate considerably higher inhibiting efficiency, depending on the nature of the substituent. As the temperature increased from 20 to 60°C, the inhibiting factor of the compound with the NH_2 group increased by a factor of 8 (from 23.7 to 200.3), while that of the compound with the acetyl group, by a factor of 35 (from 7.6 to 262.8). Such a difference in the increase of the inhibiting efficiency between these compounds is due to the fact that, at the elevated temperature, the metal surface more actively interacts with the $COCH_3$ group as compared to the amino group under the same conditions. Therefore, for further study of the relationship between the structure of *N*-phenacylpyridinium bromides and their corrosion-protective properties, we selected compounds bearing carbonyl substituents at the position 2 of the pyridine ring. These are the amides 2-benzoylamino-1-(2-oxo-2-phenylethyl)pyridinium bromide (**II**), 2-(3-phenylacryloyl)amino-1-(2-oxo-2-phenylethyl)-pyridinium bromide (**III**), 2-(4-methoxybenzoyl)amino-1-(2-oxo-2-phenylethyl)pyridinium bromide (**IV**), 2-(2-furylcarbonyl)amino-1-(2-oxo-2-phenylethyl)pyridinium bromide (**V**), 2-(2-tetrahydrofurylcarbonyl)-amino-1-(2-oxo-2-phenylethyl)pyridinium bromide (**VI**), 2-(thienylcarbonyl)amino-1-(2-oxo-2phenylethyl)pyridinium bromide (**VII**), 2-(3-(2-furyl)-acryloyl]amino-1-(2-oxo-2-phenylethyl)pyridinium bromide (**VIII**), 2-(1-adamantoyl)amino-1-(2-oxo-2-phenylethyl)pyridinium bromide (**IX**), and 2-octadecanoylamino-1-(2-oxo-2-phenylethyl)pyridinium bromide (**X**).

These compounds bearing three and, in some cases, even four reactive centers capable of interacting with the metal surface are of particular interest for further investigation of the effect of intramolecular synergism in corrosion-protective action of organic compounds. They were synthesized by the reaction of 2-aminopyridine with the corresponding acid chlorides, followed by alkylation of the resulting amides with ω-bromoacetophenone:



where R = C_6H_5 (**II**), $C_6H_5CH{=}CH$ (**III**), 4-$CH_3C_6H_4$ (**IV**),

 (**V**),  (**VI**),  (**VII**),

 (**VIII**),  (**IX**), $CH_3(CH_2)_{16}$ (**X**).

The structures of the products were confirmed by IR and ^1H NMR spectra.

EXPERIMENTAL

A mixture of 0.02 mol of appropriate acid chloride, prepared from the acid and thionyl chloride, 0.02 mol of 2-aminopyridine, 0.22 mol of triethylamine, and 20 ml of anhydrous benzene was refluxed for 3 h. Then benzene was removed in a vacuum (water-jet pump), and the residue was treated with water. Solid amides were separated, and oily amides were extracted with benzene. The resulting benzene solutions were dried over anhydrous sodium sulfate, and benzene was removed in a vacuum (water-jet pump). Equimolar amounts (0.0015 mol) of the amides thus obtained and ω-bromoacetophenone were refluxed with 15 ml of ethyl acetate for 3 h. The reaction mixture was treated with diethyl ether, and a solid (**II**, **V**, **VIII**, or **IX**) was separated. In the case of oily products, the solvent was removed by decantation, and the residue was washed with ether and dried in a vacuum (water-jet pump). The yields (%) and melting points (°C) of compounds **II**, **V**, **VIII**, and **IX** are as follows: **II** 80, 176–179; **V** 75, 210–212; **VIII** 72, 180–181; and **IX** 82, 237–240.

The corrosion-protective properties of compounds **II**–**X** were studied at their concentration of 1×10^{-2} M by determining the inhibiting factor γ and protection rate *Z* of 08KP steel in 3 M H_2SO_4 at 20, 40, 60, and 80°C using the gravimetric method. The results are summarized in Table 1.

Since substitution of the hydrogen atom of the amino group by an acyl residue is accompanied by a decrease in the electron-donating power of this group, it could be expected that the compounds in hand would demonstrate lower protective efficiency at room temperature as compared to their unsubstituted analogs. Indeed, we found that, on passing from **I** (R = NH_2) to amide **II**, the inhibiting factor considerably decreases not only at 20 or 40°C, but also at higher temperatures. Evidently, in this case, the processes blocking the negative electron induction of the benzamide group and promoting protective action do not occur.

Different behavior was observed for the other amides, whose acyl residue contains (in addition to the phenyl group or in its place) such substituents as an ethylene bridge (compound **III**), *p*-methoxy group (**IV**), heterocyclic systems: furan, tetrahydrofuran, and thiophene rings (compounds **V**–**VII**), or a vinyl group and a furan ring (**VIII**). The inhibiting factor of these compounds at all the temperatures studied was considerably higher as compared not only to amide **II**, but also to the compound with an NH_2 group. Increase in the protective rate was observed also with substitution of the phenyl group in **II** by a bulky adamantyl group (compound **IX**) or stearic acid residue (**X**). Following [1–4], enhancement of the inhibiting action in compounds **II**–**VIII** is caused to a considerable extent by immediate participation of the substituents R in adsorption, and, in amides **IX** and **X**, by either the shielding effect of the adamantyl and octadecyl groups or small electron-donating effects characteristic of these groups [2–5].

For compounds **I**, **II**, and **V**–**VII** we have made quantum-chemical calculations of the charge distribution in the molecules (Table 2). The geometry was optimized by the B3LYP method [6] with the standard basis 6-31G using the GAUSSIAN program pack [7]. All the stationary points were fixed on the basis of full analysis of normal modes of harmonic vibrations, where NIMAG = 0 corresponds to the minima on the potential energy surfaces for all the optimized structures. The results showed that, on passing from **I** (R =

Table 2. Effective charges q on the heteroatoms of the compounds

* Effective charges q in **I** (R = NH_2): –0.57072 (O^1), –0.35093 (N^2), and –0.80152 (N^3).

NH_2) to compounds **II** and **V**–**VIII**, the negative charge on the nitrogen atom N^3 at the pyridine ring decreases to about the same level (somewhat higher value was obtained for **II**). This fact and also practically equal charges on the oxygen atoms of the acyl groups in these compounds suggest that the value of the negative charges on the amide nitrogen and oxygen atoms is not the factor determining the inhibiting factor of the compounds studied, and the observed differences in their protective characteristics are caused, without question, by the nature of substituents R.

The calculation data showed that, in amides **V**–**VII**, the oxygen atoms of the furan and tetrahydrofuran rings bear negative charges, and the sulfur atom of the thiophene ring, a positive charge, which is responsible for different mechanisms of interaction of the heterocyclic fragments in the indicated compounds with the metal surface. Adsorption of the oxygen-containing heterocyclic structures on the metal proceeds via the nucleophilic oxygen atoms. Therefore, the larger negative charge localized on the oxygen atom of the tetrahydrofuran ring is responsible for somewhat higher protective performance of **VI** as compared to amide **V**. In compound **VII** containing a thiophene ring, specific adsorption on the steel surface can occur by virtue of formation of back coordination bond with electron transfer from the metal to the sulfur atom, thanks to its ability to accept electrons on *d* orbitals.

The electrocapillary curves obtained on mercury in 3 M H_2SO_4 at 20°C in the presence of some of the compounds studied showed that these compounds are readily adsorbed on both negatively and positively charged electrode surfaces (maximum in the electrocapillary curve slightly shifted toward positive values). This suggests the possibility that oppositely charged reactive centers of the compounds participate in the adsorption and that their presence induces a positive adsorption jump of the potential.

The voltammetric measurements made in the presence of compounds **V** and **IX** revealed that they are corrosion inhibitors of a mixed type. Being adsorbed on a negatively charged surface of corroded steel, these compounds inhibit both the anodic and cathodic corrosion processes. Comparison of the experimental and theoretical (calculated from the kinetic equations [8]) inhibiting factors showed that, in the presence of some of the compounds, inhibition of acid corrosion of steel at 40 and 60°C proceeds by the coupled energy-blocking mechanism. However, making such calculations at 20°C is complicated by the occurrence of a mixed hydrogen–oxygen depolarization in their presence.

As the temperature increased from 20 to 60°C, the inhibiting factor of amide **II** increased by a factor of 6, and that of compounds **II**–**X**, by a factor of 11–22, which is higher by a factor of 1.5–3.6 than the inhibiting factor of the unsubstituted compound at the

same temperature. Such an enhancement of the protective properties of the indicated compounds is due to increase in the contribution of the specific adsorption via the carbonyl group of the phenyl residue, and also to more effective participation of the acylamide groups in adsorption. With further increase in the temperature, the protective activity of the most of these compounds slightly decreases, which, as known, is a result of a high renewal rate of the surface of corroded steel, retarding adsorption of the inhibitor.

It should be pointed out that the inhibiting factors of the compounds in hand at 20 and 40°C only slightly differ from each other, suggesting that the effect of substituents in the acyl groups is leveled off under these conditions. As the temperature rises to 60–80°C, interaction of these compounds with the metal surface considerably increases, and the differences in their inhibiting activity become more pronounced. For example, at 20°C, the inhibiting factors of compounds **III** and **IV** differ by about unity (or by a factor of 1.04), while at 60°C, this difference becomes equal to 366 (or by a factor of 2). The difference between **IV** and **V** is 6 (1.37) at 20°C and 414 (2.31) at 60°C. The reason is that, at low temperatures, the same reactive centers are responsible for adsorption of all the amides studied, and the substituents R have only insignificant effect. At higher temperatures, more favorable conditions for effective participation of the substituents are realized, whose different structure provides their different contributions to the corrosion-inhibiting activity of the molecule as a whole.

CONCLUSIONS

(1) *N*-Phenacylpyridinium bromides bearing an amide group in the pyridine ring are highly efficient acid corrosion inhibitors. The inhibiting factor of these compounds depends on the nature of substituents in the acyl group, insofar as they can directly participate in the interaction with the metal surface.

(2) High inhibiting value of *N*-phenacylpyridinium bromides is a result of a combined action of all the reactive centers of the molecules, which is particularly pronounced at elevated temperatures. The inhibiting factor of the compounds is as high as 300–700, and the protective rate of steel, 99.7–99.9%.

CATALYSIS

Oxidation of Carbon in the Presence of Catalysts Based on Cesium Lanthanum Vanadate

Abstract—Some kinetic aspects of the catalytic oxidation of carbon with atmospheric oxygen and nitrogen oxide NO in the presence of catalysts based of cesium lanthanum vanadate were studied. The influence exerted by a promoter, cesium sulfate, and its content on the course of catalytic reactions was analyzed.

Recently, the interest of researchers has been attracted by catalytic oxidation of carbonaceous substances (carbon black) with oxygen and with nitrogen oxides. These reactions are of practical importance for treatment of effluent gases in thermal power engineering, metallurgy, building, and at garbage incineration plants. The interest is due to the fact that fume gases contain, in addition to other toxic components, carbon black, nitrogen oxides, and residual oxygen. These reactions can be used to neutralize exhausts of diesel engines and to decrease the exhaust smoke emission. Discharges of carbon black are dangerous because of the carcinogenic compounds it contains. Deposits of carbonaceous substances impair the efficiency of thermocatalytic neutralizers. There exist complex oxide catalysts that markedly accelerate the oxidation of carbon black with the residual oxygen, and some of these can be used to oxidize carbonaceous substances via reduction of nitrogen oxides to molecular nitrogen.

Carbon can be oxidized in the presence of solid or partly molten catalysts [1–7], with complex compounds of vanadium distinguished by their high catalytic activity. The activity of, e.g., lanthanum vanadate increases dramatically when alkali metal ions are incorporated into its structure, with the catalytic activity the higher, the larger the atomic mass of a metal [2, 3]. In addition, the promoting effect is exhibited by alkali metal salts and, in particular, Cs_2SO_4 introduced into the catalyst composition. The mechanism of catalysis of the reactions mentioned above is rather complicated; to similar types of interactions can be referred processes occurring in catalytic gasification of coal and other carbonaceous substances [8]. Steam–oxygen gasification is catalyzed by compounds of alkali metals, e.g., by their carbonates. The activity of alkali metal compounds also increases in going from lithium to cesium. A similar behavior has been observed for carbon oxidation with nitrogen oxide N_2O [9].

Thermocatalytic devices for neutralization of waste gases [10], working in the continuous or batch mode, should ensure a virtually complete burning-out of the carbon black absorbed. Carbon black substances of different origins have different structure and composition [11]. However, finer structures are stronger than more complex ones, and, therefore, deposits of diesel carbon black are mainly composed of formations not larger than 5–10 μm in size. The particles may contain incompletely burnt oils, mineral components of additives to combustive-lubricating materials, products formed in wear of the piston and cylinder, etc. [10]. Impurities of this kind diminish the effective oxidation surface of carbon black and hinder access of oxidizing agents into pores, so that the particles are only oxidized on their surface.

The kinetic parameters of combustion of various carbonaceous substances strongly differ [12]. For dust-like particles of various coals, the overall activation energy E of combustion in air varies from 75 to 170 kJ mol^{-1}. Very strongly (by several orders of magnitude) differ the pre-exponential factors K_0 in the Arrhenius equation, obtained for these reactions. Determining the kinetic parameters is experimentally difficult. The individual specific features of materials lead to a wide scatter of points in experimental dependences. However, despite this circumstance, empirical equations relating E and K_0 have been derived. To higher activation energies correspond greater values of K_0. There exists an opinion that K_0 is proportional to the number of active centers on the carbon surface [12]. As their number grows, the energy of each center

1070-4272/04/7707-1121 © 2004 MAIK "Nauka/Interperiodica"

decreases, which leads to an increase in the activation energy. It has been suggested to use as a parameter describing the process the specific surface rate of reaction with carbon, K_S^C [12]. This quantity depends on whether the process is kinetically or diffusion-controlled. It is related to the concentration of O_2 in the gas medium, relative amounts of the forming oxides CO and CO_2, etc. It is commonly believed that, for carbonaceous particles of size not exceeding 10 μm, reactions at their internal surfaces at low temperatures are not important, and the overall combustion rate is determined by the kinetics of the chemical reaction between O_2 and carbon. If carbon combustion occurs within a bed, the key importance is acquired by diffusion processes, and E decreases severalfold [12].

For the properties of samples in modeling of reactions with gases to be reproducible, a certain type of a carbonaceous material is chosen [9, 12], e.g., activated carbon. In this study, experiments were performed with activated carbon ground to 10 μm, which makes the samples similar in particle size and specific surface area of particles to carbon black. The presence of mineral substances in the carbon makes the experimental conditions close to reality. An attempt was made to carry out a comparative analysis of kinetic features of the process of carbon oxidation by atmospheric oxygen and nitrogen oxide NO in the presence of a cesium lanthanum vanadate catalyst with a monazite structure, promoted with various amounts of Cs_2SO_4.

EXPERIMENTAL

Powder catalysts were synthesized using $La(NO_3)_3 \cdot 6H_2O$, $CsNO_3$, KNO_3, and $AgNO_3$ (all of chemically pure grade), NH_4VO_3 of pure grade, $Cu(NO_3)_2 \cdot 3H_2O$, and polyvinyl alcohol of 11/2 brand. $Cs_xLa_{1-x}VO_{4\pm y}$ ($x = 0-0.5$) was synthesized by pyrolysis of polymer–salt formulations [13, 14]. A 5–10% solution of polyvinyl alcohol in distilled water was prepared on a water bath and prescribed amounts of $La(NO_3)_3 \cdot 6H_2O$ and $CsNO_3$ were dissolved in this solution. Ammonium vanadate was dissolved in water under heating, and the resulting solution was mixed with a separate portion of the aqueous solution of polyvinyl alcohol and with an aqueous-polymeric solution of the nitrates. A gel prepared using the methods described in [15, 16] was dried in a thin layer under an infrared lamp and subjected to pyrolysis and then to calcination (4 h at 600°C). The product obtained was analyzed on a DRON-1.5 diffractometer with CoK_α radiation using the JCPDS file. To introduce the promoter, cesium sulfate Cs_2SO_4, an aqueous–alcoholic solution of a technical-grade reagent was prepared, and the catalyst powder was impregnated with a prescribed volume of this solution and then dried at 90°C. Other samples were also prepared by pyrolysis of polymer–salt compositions from the appropriate salts [13, 17].

The catalyst (S_{sp} = 8–15 $m^2\ g^{-1}$) was ground in an agate mortar and mixed in a mass ratio of 4 : 1 with a preliminarily ground activated carbon of BAU brand [18] ($S_{sp} \approx 100\ m^2\ g^{-1}$, ash content 4 wt %). The ash contained oxides of aluminum, iron, silicon, and other metals (microimpurities). The catalytic activity in carbon oxidation by atmospheric oxygen was determined gravimetrically in an open reactor, with the layer of a mixture of a powdered catalyst with carbon placed in ceramic boats. Oxidation of carbon with nitrogen oxide NO was studied in a similar manner in a flow-through quartz reactor through which NO obtained in a reaction of a concentrated solution of $NaNO_2$ or KNO_2 and a solution of $FeSO_4$ acidified with hydrochloric acid (all reagents of chemically pure grade) was passed at a flow rate of 30 ml min^{-1}. The first solution was added dropwise to the second.

To determine the optimal composition of the catalyst, $Cs_xLa_{1-x}VO_{4\pm y}$ (x = 0 to 0.5; monazite structure), and $M_{0.1}La_{1.9}Cu_{0.95}V_{0.05}O_{4\pm y}$ (M = K, Cs), which belong to the K_2NiF_4 structural type, were synthesized as single-phase samples. The introduction of alkali metals changed the constants of the crystal lattice of the K_2NiF_4 type. On introducing the larger cesium ion, these constants were 0.2% greater than those upon substitution of lanthanum with potassium. The activity of multicomponent compounds was evaluated in carbon oxidation with atmospheric oxygen, with step-by-step isothermal (20 min) exposures of the reaction mixtures in the temperature range from 100 to 600°C. As a reference sample served carbon without a catalyst or with addition of indifferent substances of mass equal to that of the catalyst. The nominal reaction ignition temperature T_{ig} was determined from the temperature dependences of the degree of carbon burning-out. The activity of $Cs_xLa_{1-x} \cdot VO_{4\pm y}$ exceeded (T_{ig} = 300–310°C) that of $M_{0.1}La_{1.9}Cu_{0.95}V_{0.05}O_{4\pm y}$. An analysis of the activity of catalysts of the last type confirmed its relationship with the atomic mass of the alkali metal ion incorporated into the structure. For the composition containing Cs^+ or K^+, the ignition temperatures were 330 and 340°C, respectively. For samples without a catalyst, the ignition temperature was 410°C. It was found that the optimal catalyst composition is

$Cs_{0.3}La_{0.7}VO_{4\pm y}$, and just this composition was used in further experiments. A higher content of Cs^+ commonly gives no additional increase in the catalytic activity. A heterogeneous catalyst [17, 19, 20] of the empirical formula $Ag_{0.25}La_{0.75}MnO_{3\pm y}$ (T_{ig} = 360°C), which exhibits high activity in oxidation of CO and organic compounds, was also inferior in activity to $Cs_{0.3}La_{0.7}VO_{4\pm y}$.

In studying the kinetics of carbon oxidation, isothermal experiments were performed in the practically important working temperature range of catalysts, 300–400°C. As promoter for $Cs_{0.3}La_{0.7}VO_{4\pm y}$ served Cs_2SO_4. The conversion was determined at exposures ranging from 5 min to 1–1.5 h. At a relatively short duration of an experiment, the time of heating of the samples exerts a noticeable influence, and there is an induction period of the reaction, associated with the sorption of O_2 on the carbon surface. It was confirmed in the course of the study that addition of Cs_2SO_4 to the catalyst markedly raises the rate of carbon oxidation with oxygen and lowers the ignition temperature of the reaction (Table 1, Fig. 1). In carbon oxidation in the kinetic mode at the external surfaces of grains, the dependences of the conversion α on time τ at isothermal exposures must be described by the equation of a "collapsing sphere"

$$[1 - (1 - \alpha)^{1/3}] = k\tau, \quad (1)$$

where k is the rate constant.

On the whole, the experimental data can be described, within the experimental error, by the above equation, which is confirmed by data processing in the coordinates of reduced time. However, deviations from this dependence are observed in some cases at relatively high conversions, with the conversion found to be somewhat lower than the calculated value. This may be due to existence in the final stage of residues of the coarsest or difficultly oxidizable particles, because the carbon powders used were not exactly monodisperse and homogeneous: they were produced from raw materials of natural origin. Moreover, a certain contribution may come from carbon particles with nonspherical shape. Such particles are similar to stable chains in carbon black. For formations of this kind, the time dependence of the conversion is described by the equation of a "collapsing cylinder," which also leads to a certain decrease in the rate of the overall oxidation process:

$$[1 - (1 - \alpha)^{1/2}] = k\tau. \quad (2)$$

For practical implementation of oxidation of carbonaceous particles in gas flows, it is advisable to bring them in contact with solid surfaces at a sufficiently high velocity, e.g., with a special baffler for disintegration of ensembles of particles. Further, to determine the kinetics of carbon oxidation in more detail, it would be appropriate to perform experiments with monodisperse powders. The carbon combustion observed could also be described using the equation of a first-order reaction with respect to carbon

$$\ln[1/(1 - \alpha)] = k\tau. \quad (3)$$

A calculation of the rate constants of the combustion reaction by Eqs. (1) and (3) gave similar results.

Table 1. Ignition temperature of carbon oxidation

Sample no.	Sample composition	Ignition temperature T_{ig}, °C	
		air	NO
1	Carbon	410	500
2	Carbon + catalyst	300–310	380
3	Carbon + catalyst + promoter, wt %:		
	1	350	480
4	5	290	440
5	10	270	360

In the presence of catalysts based on cesium lanthanum vanadate, the overall rate constant of carbon oxidation, K, was higher (Table 2), compared with the case of their absence. The values of E for carbon oxidation in the presence of catalysts for sample nos. 2–5 are in good agreement with the data obtained by other authors [12]. Consequently, it may be considered that the oxidation mode is close to that of burning of separate particles in a gas medium; the preexponential factors also conform to this model.

Introduction of 1 wt % Cs_2SO_4 dramatically changes the properties of the catalyst: E and T_{ig} increase (Tables 1, 2; Figs. 2, 3). Also strongly grows the pre-exponential factor, with the result that the rate of carbon oxidation, on the whole, increases. The phenomenon observed can be attributed to changes in the nature of the phases present in the catalyst and the extent of contact with carbon particles at the boundary of the catalyst. As the content of Cs_2SO_4 in the catalyst increases, the activation energy of combustion becomes lower, as also does the ignition temperature. In the presence of 10 wt % Cs_2SO_4 (Table 2), E has a value characteristic of burning in a bed. For noncatalytic carbon oxidation, the E obtained has

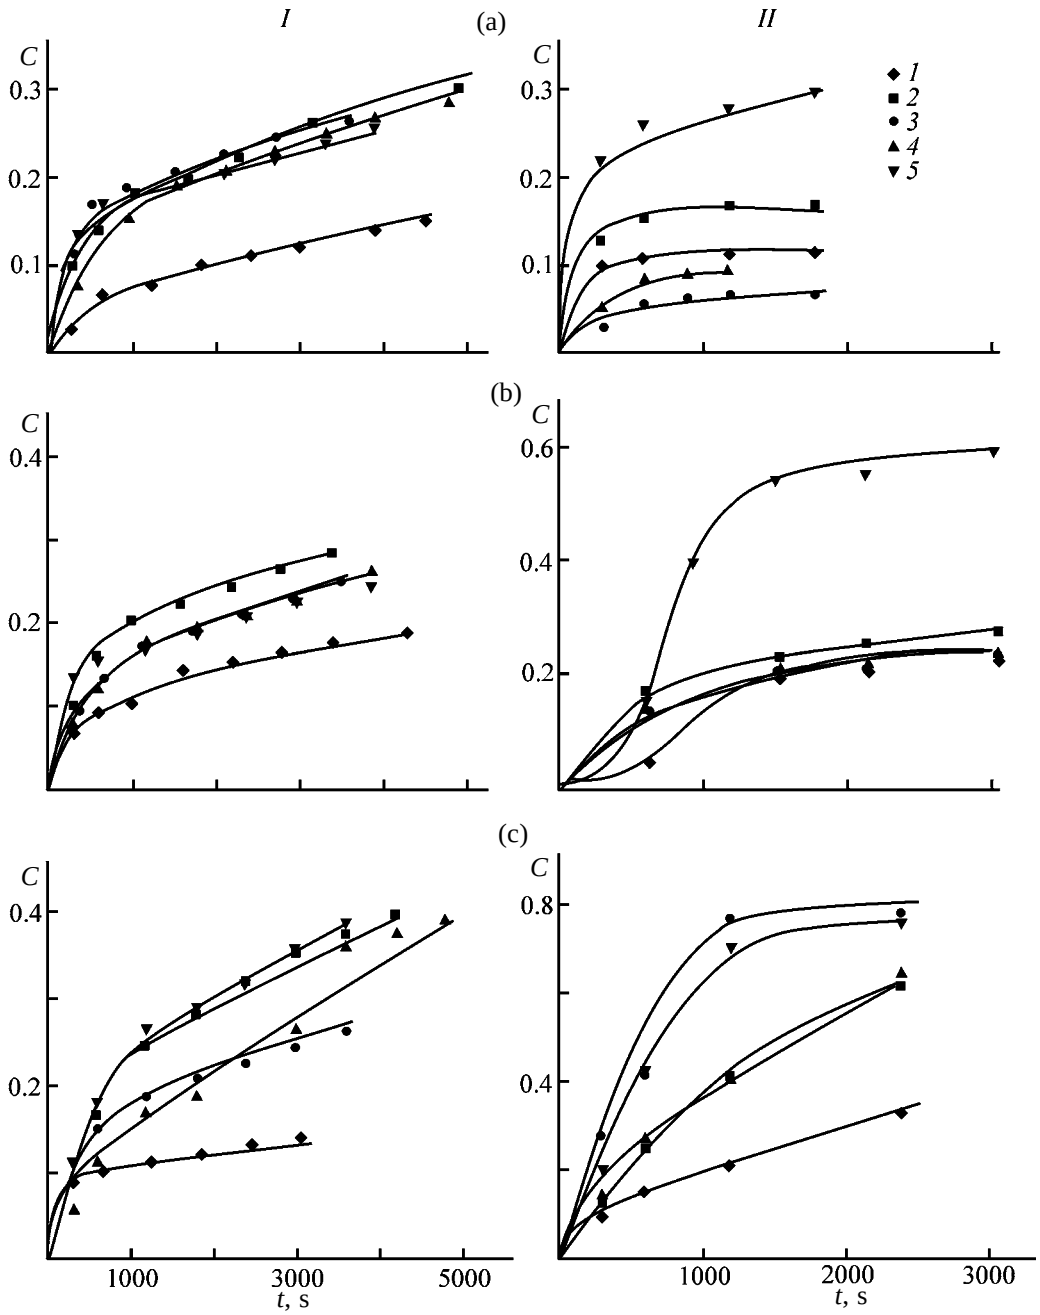

Fig. 1. Examples of the dependences of the extent of carbon removal, *C*, on the process duration *t* in oxidation with (*I*) nitrogen oxide and (*II*) atmospheric oxygen. Temperature (°C): (a) 300, (b) 350, and (c) 400. Sample: (*1*) without catalyst, (*2*) carbon with catalyst without promoter, (*3*) carbon with catalyst containing 1 wt % promoter, (*4*) the same with 5 wt % promoter, and (*5*) the same with 10 wt % promoter.
