INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Kinetics of the Reaction of Cubic Boron Nitride with a Melt of Sodium Hydroxide

A. V. Lapshin, A. M. Germanskii, and S. P. Bogdanov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received October 9, 2003

Abstract—Kinetics of the reaction of cubic boron nitride with a melt of sodium hydroxide in the temperature range 380–480°C was studied. Kinetic parameters of the reaction were determined.

Intermediate products of the synthesis of cubic boron nitride (CBN), so-called cakes, are polydisperse mixtures of two polymorphic modifications of hexagonal graphite-like boron nitride (HBN) and CBN [1]. Crystals of cubic boron nitride are extracted from intermediate products in two stages. In the first stage, a cake is treated with an acid to remove compounds of the metal initiating the synthesis, after which the residue of nonrecrystallized HBN is removed by treatment with a melt of alkali [2]. The CBN extraction in the second stage is based on the difference in rates of reactions of CBN and HBN with a melt of alkali. The degree of CBN decomposition in this reaction, yielding ammonia and the corresponding metal borate, increases as the sample grain size decreases. For example, at 400°C and process duration of 30 min, a CBN micropowder with the particle size from 5 to 3 μm (5/3) decomposes to 55%, and that with the particle size of 250/200, only to 6%. At 700°C, a 5/3 micropowder and also samples with the main fraction particle size from 50 to 40 μm decompose completely, whereas CBN with the particle size of 100/80 and 250/200 decompose to 90 and 88%, respectively. Thus, the treatment with a melt of alkali, which is used to remove HBN during enrichment of the primary product of the synthesis with CBN, even at low temperatures results in considerable losses of this expensive material, especially of its small-size fractions [3].

Furthermore, the following data on the reaction of CBN with alkali melts are available in the literature. According to [4], edges of CBN crystals with nitrogen atoms on the surface have a higher activity in reactions with a KOH melt than edges with boron atoms. However, quantitative characteristics of CBN chemical stability were not given in that work. Mishina and Filonenko [5] have correlated the observed cracking of CBN bicrystals on etching by a KOH melt with the presence of a mass defect on grain boundaries; however, it seems more probable that this phenomenon results from the chemical decomposition of impurities segregating on interfaces. Thus, according to [6], the degradation of CBN crystals on their etching by an alkali results from the chemical decomposition of HBN inclusions contained in the crystals and of impurities captured during their growth. At the same time, it is known [2] that the content of impurities (in particular, of carbon and oxygen) on the surface of LO-grade CBN crystals is higher than in LKV-grade crystals having a more perfect structure and also higher strength and crack resistance. Therefore, we can conclude that the chemical stability of CBN toward an alkali melt depends on both the shape of crystals and the state of their surface.

Such conclusion seems to be important, because wearing of tools equipped with CBN crystals depends on their chemical interaction with a material under treatment and with the environment [7]. Klimenko *et al.* [7] have found that chemical compounds consisting of elements of contacting materials and environment arise in the region of the contact between CBN and the material under treatment. It is probable that the parameter of CBN chemical inertness to oxidants can serve as one of criteria in selection of a type of CBN to be used as a tool material.

We failed to find in the literature a quantitative description of the kinetics of CBN reactions with melts of alkalis. At the same time, the knowledge of the kinetic relationships of the process is required to improve the process for the enrichment of primary products of the CBN synthesis.

The aim of this work was to determine the rate constants of the CBN reaction with an NaOH melt.

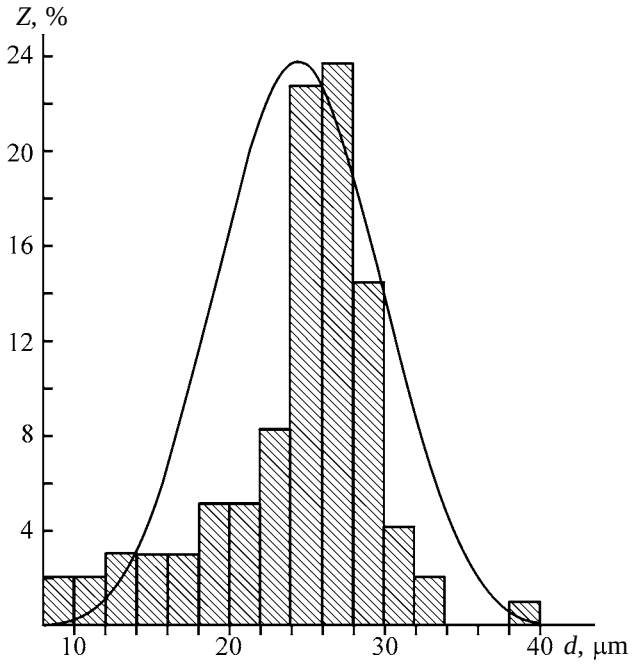

Fig. 1. Particle-size distribution of B-3 28/20 CBN powder. Mean size 24.48 μm; number of particles 97; specific surface area 200.03 $m^2 kg^{-1}$. (*Z*) Proportion of particles and (*d*) equivalent diameter.

EXPERIMENTAL

We used the following CBN samples: LKV-40 grinding powder and LM micropowder [OST (Branch Standard) 2MT 79-2–88]; B-5 grinding powder (amber) and B-3 micropowder synthesized using lithium and magnesium initiators, respectively (Borei corporation, St. Petersburg); Borazon V-500 and Borazon-I grinding powders (General Electric, the United States); and EBN 20-30 micropowder (EID Ltd, the United Kingdom). The samples were treated with NaOH [GOST (State Standard) 4328–77].

A preliminary study of products of the reaction between CBN and an NaOH melt (1 : 1 by weight) by the X-ray phase analysis has shown that they contain residual CBN and the borate Na_3BO_3, which agrees well with the data of [3, 4]. This allows us to state that this reaction is described by the equation

$$BN + 3NaOH \rightarrow Na_3BO_3 + NH_3\uparrow.$$

We studied the chemical reaction of CBN with an NaOH melt on an installation allowing continuous recording of variation in time of the total weight of an NaOH melt and a CBN sample under isothermal conditions. Before the measurements, the melt of alkali was heated to the required temperature in an SShOL-1.1.6/12-M3-U42 shaft furnace, then a CBN sample was placed in the crucible with the melt, and the weight variation during the reaction was recorded with an ADV-200M analytical balance arranged over the furnace. The temperature was determined with an accuracy of ±1°C with a TL-3 thermometer (GOST 21 593) arranged over the melt surface. The reaction time was measured with a stopwatch; the treatment duration was 1 h. The weight of the non-decomposed CBN residue was determined in each experiment.

To determine the rate constants of the reactions of various CBN types with NaOH, we used the generally accepted initial-rate method, according to which the slopes of the initial portions of the concentration vs. time plots correspond to the initial rates at certain initial concentrations and reaction surface areas [8].

The rate constant *K* ($kg\ s^{-1}\ m^{-2}$) of the boron nitride reaction with an NaOH melt was determined using the main equation for topochemical processes given in [9–11] in various forms:

$$d\alpha/d\tau = KS_{sp}c_{NaOH}^{n}, \quad (1)$$

where $\alpha = (m_0 - m_\tau)/m_0$ is the degree of conversion; m_τ, CBN weight (g) to an instant τ; m_0, initial CBN weight (g); S_{sp}, specific surface area of CBN powder ($m^2\ g^{-1}$); c_{NaOH}, NaOH concentration ($g\ g^{-1}$); and *n*, reaction order.

Provided that the NaOH concentration is constant, Eq. (1) in an integral form for spherical particles is converted to the form

$$1 - (1 - \alpha)^{1/3} = \frac{K\tau c_{NaOH}^{n}}{R_0\rho}, \quad (2)$$

where R_0 is the initial particle radius (m), and ρ is the particle density ($g\ cm^{-3}$).

In all the experiments, we took NaOH in a 50-fold excess as compared to the stoichiometric amount of CBN (the weight of NaOH exceeded the weight of a CBN sample by a factor of 50 and more). Therefore, when calculating the degree of conversion by Eq. (2) in the whole range of its variation (from 0 to 1), we accepted $C_{NaOH} \approx 1$ in the case of the reaction with pure NaOH and as a constant value for the reaction with NaOH containing Na_3BO_3.

The initial specific surface area was determined by the Video-Test method [12] from the size distribution of powder particles (Fig. 1).

The reaction conditions and rate constants with the corresponding errors are given in the table. The ex-

perience of using this technique for studying the kinetics of reactions of other BN modifications with an alkali melt has shown that the error in the rate constants is caused mainly by the temperature variation during the experiment [13]. Therefore, we estimated the error taking into account the known temperature dependence of the rate constant

$$K = K_0 \exp(-E_a/RT).$$

For the reaction of B-5 CBN with a melt as an example, we show the characteristic kinetic curves in Fig. 2 together with the kinetic curves calculated by Eq. (2) with the constants obtained. It is seen that the experimental and calculated data on the degree of CBN sample transformation in the reaction with a melt coincide within the limits of the experimental error; therefore, this process is limited by the reaction on the interface.

To determine the reaction order in Eq. (1), we found experimentally the rate of the reaction of LM 28/20 CBN with an NaOH melt containing 10 mol % Na_3BO_3 (C_{NaOH} = 0.738 g g^{-1}) at 440°C. Using these data (the rate was 1.5×10^{-4} s^{-1}) and also the known rate constant of the CBN reaction with a pure NaOH melt at the same temperature, we have calculated the reaction order to be 3.5.

The apparent activation energy of the reaction was determined by the Arrhenius equation. The Arrhenius plot for the grinding powder is linear. The coefficients of the Arrhenius equation for B-5 were found to be as follows: K_0 = 8.2 ± 0.6 kg s^{-1} m^{-2}, E_a = 92.3 ± 12.9 kJ mol^{-1}. The obtained value of the apparent activation energy additionally proves the fact that the reaction is kinetically controlled.

The dependence of $\ln K$ on $1/T$ for a B-3 micropowder is shown in Fig. 3. The fracture of the curve can be accounted for as follows. The relatively high specific surface area of the powder contacting with the melt determines the high reaction rate. As the process is exothermic, the steady-state heat removal from the reaction zone is not ensured. The heat evolution leads to a considerable heating in the zone of the melt–particle contact, and the actual reaction temperature appears to be higher than the temperature detected by a thermometer arranged above the melt surface. Therefore, the determination of the activation energy for micropowders is possible only in the region of temperatures lower than 420°C and requires additional experiments to be carried out.

The data obtained on the degree of CBN decomposition in its reaction with an NaOH melt are in good agreement with the data of [3], where the degree of decomposition of CBN with the particle size of 100/80 upon treatment with NaOH at 400°C for 1 h was 11.2%, and at 460°C and the treatment time of 30 min it was 25%. According to our data, the degree of the decomposition of B-5 grinding powder at 420°C and the treatment time of 50 min was 13.7%, and at 460°C and the treatment time of 30 min it was 20.6%. The degree of the decomposition of an LKV-40 100/80 powder upon treatment with a melt at 420°C for 1 h was 11.1%.

Experimental and calculated rate constants of the reaction of CBN with an NaOH melt

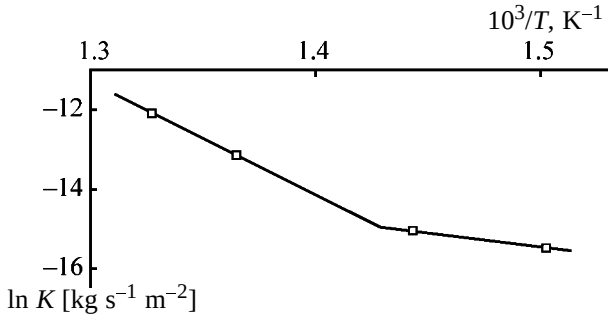

Fig. 3. Rate constant K of the reaction of B-3 28/20 CBN with an NaOH melt as a function of temperature T.

It should be noted that the rate constants of the reactions of various types of CBN with an NaOH melt allow us to judge their chemical inertness at the same temperature. The powders can be ranked in the following order with respect to the chemical stability at low temperatures (less than 420°C): B-3 > LKV-40 > B-5 > LM. The difference in the inertness of various CBN types toward an alkali melt seems to be associated with variations in the defectiveness of their structure, in the development of a microrelief, and in the chemical composition of their surface. It was impossible to determine within the framework of this study what factor was of crucial importance in each particular case. It is probable that such a parameter of chemical stability as the rate constant of the reaction with a corrosive medium can serve as one of criteria for the selection of a CBN type to be used as a tool material. The values of the constants obtained can be used to simulate mathematically the enrichment of intermediate products in the synthesis of abrasive CBN grains using, e.g., the algorithm from [14].

CONCLUSIONS

(1) Rate constants of reactions of various types of cubic boron nitride with an NaOH melt at various temperatures were estimated. The apparent activation energy of the process was determined.

(2) The $\ln K$–$1/T$ dependence for micropowders deviates from linearity. This phenomenon was attributed to the pronounced exothermic effect caused by a high specific surface area of the powders.

(3) Various types of cubic boron nitride differ from each other in the stability to an NaOH melt.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Fusibility of Formulations Based on Phases of the System Constituted by Spinel, Mullite, and Aluminum Titanate

Abstract—A set of physicochemical analytical methods was applied to study fusion and crystallization of magnesia–alumina spinel, aluminum titanate, mullite, and their binary and ternary formulations. The feasibility of elucidating phase transformations that occur when phases containing ions with variable oxidation level are fused in an inert gas medium was analyzed.

Of particular interest in developing heat-resistant refractory formulations are materials based on phases of the system $MgO–Al_2O_3–TiO_2–SiO_2$, in which a triangle formed by three refractory phases stands out. These phases are magnesia–alumina spinel, aluminum titanate, and mullite, each of which possesses unique properties. In particular, magnesia–alumina spinel combines high melting point (2135°C) with enhanced resistance to the action of slag melts and high-temperature strength [1, 2]. Owing to the shape of its crystals and low thermal expansion coefficient, mullite improves the heat resistance and makes higher the softening onset temperature of refractories under mechanical load [1, 3]. Aluminum titanate is one of a few materials with negative thermal expansion coefficient, which makes it promising as a base for structural ceramics [3, 4]. However, data on fusibility and phase relationships in the above-mentioned three-component system are virtually lacking.

The aim of this study was to establish the minimum temperature at which a melt appears in the triangle $MgAl_2O_4–Al_6Si_2O_{13}–Al_2TiO_5$ and to determine how the melting occurs.

The melting points of solid phases and crystallization temperatures of melts were determined by high-temperature differential thermal analysis (DTA) [5]. The high-temperature DTA can be performed either in a vacuum or in an inert gas. In this study, the analysis was carried out in helium. To reveal the extent of the reducing influence exerted by the inert gas medium on the behavior of the basic phases in melting–crystallization, a thermodynamic analysis of the stability of the spinel, mullite, and aluminum titanate under partial oxygen pressure of 0.1 Pa at 730–2130°C was made using the thermodynamic characteristics of solid and liquid phases represented in the IVTANTERMO database and reported in [6]. It was found that the magnesia–alumina spinel is stable over the entire temperature range studied, mullite is unstable in the inert medium at temperatures above 1730°C and decomposes into the constituent oxides, and aluminum titanate is unstable below 1300°C and above 1700°C and decomposes into TiO_2 and Al_2O_3. The results obtained are in agreement with the data of [7, 8].

In view of the aforesaid, it was necessary, to attain the formulated goal, to verify the adequacy of high-temperature DTA in an inert gas as applied to oxide compounds containing ions with variable oxidation level. For this purpose, the process of melting of the individual phases (spinel, mullite, and aluminum titanate) and binary systems delimiting the triangle under consideration was studied.

The tetrahedrization of the system $MgO–Al_2O_3–TiO_2–SiO_2$ was given by Berezhnoi in [9]. Data on the structure of the phase diagrams of the systems constituted by spinel and aluminum titanate, spinel and mullite, and mullite and aluminum titanate were reported in [10–13].

The section from spinel to aluminum titanate in the system $MgO–Al_2O_3–TiO_2$ is quasi-binary with a eutectic containing 45 wt % $MgAl_2O_4$ and eutectic temperature of no less than 1730°C [10, 11].

The system constituted by the spinel and mullite has a eutectic that contains 24.7 wt % spinel and melts at 1810°C [12].

The section from aluminum titanate to mullite in the ternary system $Al_2O_3–SiO_2–TiO_2$ is not quasi-

* γ_{true} is the true density; α, coefficient of linear thermal expansion; H_μ, microhardness.

binary because of the presence of corundum, but has eutectic nature [13]. The minimum temperature of the melt appearance corresponds to the melting temperature of the reaction point (1710°C) [13]. The eutectic contains 48 wt % mullite.

The position of the eutectic in the ternary system constituted by the spinel, aluminum titanate, and mullite was estimated theoretically to be at (mol %) 37 spinel, 55 aluminum titanate, and 8 mullite, using the method developed on the basis of geometric thermodynamics, taking into account changes in the Gibbs energy of a mixture of components [14, 15].

The high-temperature DTA was performed on a VTA-981 derivatograph calibrated against the melting points of well-known substances in helium of A brand [TU (Technical Specification) 6-21-12–94], with temperature raised at a rate of 80 deg min^{-1}. The samples studied were melted in molybdenum crucibles. The temperature corresponding to the onset of a thermal effect was determined at the bending point of a curve. In those cases when the bending of the differential curve was smooth, the beginning or end of an effect was determined as the point of intersection of the baseline with the tangent to the corresponding branch of the peak.

X-ray diffraction patterns were obtained at room temperature on a DRON-3 installation with CuK_α radiation at scanning rate of 2 deg min^{-1}. The X-ray phase analysis consisted in phase identification by comparing the interplanar spacings d/n, measured in the X-ray diffraction patterns, and the corresponding relative intensities I/I_0 of diffraction peaks with the reference values from the ASTM database, using the Ident 4 software package.

The microstructure and microhardness of samples were studied on polished sections. Images of the microstructure of the samples, obtained in reflected light, were analyzed on an EPIQANT automated image analyzer connected to a video camera, which made it possible to view images on the monitor screen. The microhardness of the formulations was measured with a PMT-5M microhardness meter equipped with an FOM-2 photoelectric ocular micrometer. The thermal expansion coefficient was determined on a DKV-5A quartz dilatometer, using sintered samples in the form of 45 × 5 × 5-mm prisms. The pycnometric density was measured in accordance with GOST (State Standard) 2211–65.

As starting materials for solid-state syntheses of the spinel, mullite, and aluminum titanate we used powdered technical-grade alumina (TU 6-09-3916–75), basic magnesium carbonate $m MgCO_3 \cdot Mg(OH)_2 \cdot nH_2O$ (TU 6-09-01-353–78) (characterized by calcination loss of 57.28%), TiO_2 (TU 6-09-05-03-37–75), and quartz glass (GOST 9428–73), taken in amounts corresponding to the stoichiometry of the desired products. Aluminum titanate was synthesized using corundum obtained by firing of technical-grade alumina at 1750°C.

Mixtures of starting compounds were subjected to joint grinding in a vibration mill with corundum balls at balls : material ratio of 4 : 1 to particle size of 4–6 μm. The powders obtained were used to prepare briquettes, which, after drying at room temperature for 48 h, were calcined in air in an electric furnace with molybdenum disilicide heaters at heating rate to the final temperature of 10 deg min^{-1}. Data on the heating modes used are listed in Table 1.

The calcined briquettes were crushed, ground, and recalcined under the same conditions. The completeness of synthesis was judged from XPA data.

Samples for measuring the thermal expansion coefficient and microhardness and preparing polished sections were obtained by compacting powders with particle size of 4–6 μm, which were moistened with a 5% aqueous solution of polyvinyl alcohol to 4% moisture content under a pressure of 50 MPa, with subsequent drying at room temperature for 24 h and calcination at 1600°C for 1 h.

The characteristics of the compounds synthesized, which are listed in Table 1, are in good agreement with published data on the properties of the phases under study [1, 16, 17].

Mixtures of the compounds synthesized, taken in prescribed ratios (Tables 2, 3), were used for DTA. The phase transformations that occurred in melting were judged from the results of XPA (Figs. 1, 2).

Derivatograms of the compounds synthesized are shown in Fig. 3. The fact that the onset temperatures of the effects that can be interpreted as melting and

crystallization do not coincide in a single heating–cooling cycle, which is characteristic of some of the formulations under consideration, can be attributed either to overheating of the mixture in melting or to overcooling of a melt in crystallization. It is known [7] that oxide melts tend to be overcooled, and, therefore, preference was, as a rule, given to onset temperatures of the melting effects. To obtain more reliable results, two heating–cooling cycles were performed for each formulation. Visual inspection of the samples after DTA revealed that crystalline samples containing aluminum titanate turned black. The color of the other crystallized melts was light gray.

In melting of the magnesia–alumina spinel, complete melting could not be achieved. The onset temperature of melting, recorded in the thermogram, was 2090°C, with no other effects revealed.

In melting of mullite, the endothermic peak has a rather complex structure (Fig. 3a). The onset of melting is recorded at 1845°C; a clearly pronounced superposition of two endothermic effects that begin at 1885

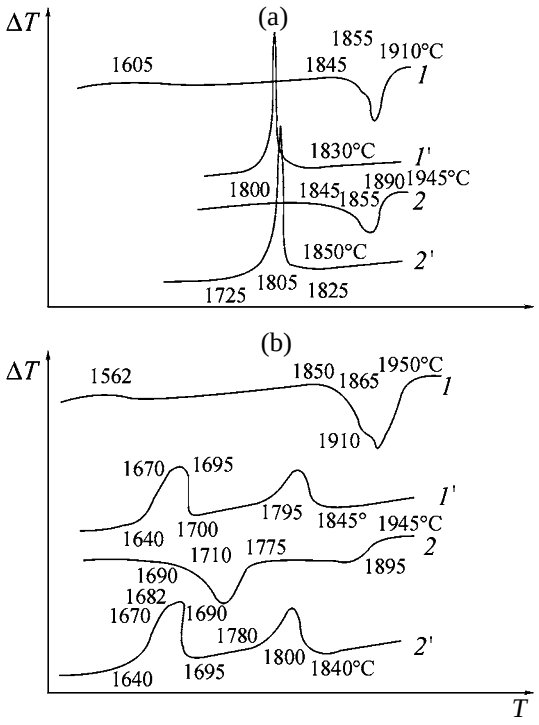

Fig. 3. Thermograms of the synthesized samples of (a) mullite and (b) aluminum titanate. (*T*) Temperature and (Δ*T*) difference between the temperatures of the sample and reference. (*1*, *2*) First and second heating and (*1*', *2*') first and second cooling, respectively.

and 1910°C is observed. In a second heating, the general pattern was preserved, but the peaks were broadened somewhat and the onset temperature of the high-temperature effect slightly decreased (to 1890°C). In cooling, most part of heat is released in both cycles in a narrow temperature range (about 20°C). This is presumably due to the occurrence of crystallization by the reaction mechanism, according to which the primarily formed aluminum oxide reacts with the melt to give mullite [13]. XPA data for a melted sample confirm the assumption made.

In the first heating of aluminum titanate, an endothermic effect that is a superposition of three effects with onset temperatures of 1850, 1870, and 1910°C was recorded (Fig. 3b). However, already the subsequent cooling reveals a group of exothermic effects at lower temperatures. This indicates that the phase composition of aluminum titanate changes significantly in melting–crystallization in an inert gas medium, which is confirmed by the results of XPA indicating that oxides of the general formula TiO_{2-x}, corundum, and anosovite solid solution based on aluminum titanate are present in the crystallized sample. The experimentally obtained phase transformation temperatures of 1690 and 1850°C are in agreement with published data [18].

The results of DTA for two- and three-component formulations are listed in Tables 2 and 3; XPA data, in Figs. 1 and 2; and results of microstructural studies, in Fig. 4.

It follows from the results obtained that the temperature at which a melt appears in the mullite–spinel system is 1815 ± 10°C, with the minimum difference between the solidus and liquidus temperatures observed for a mixture composed of 50 mol % spinel and 50 mol % mullite. Only two phases can be seen in polished section images [19]. The presence of a pronounced dendrite structure in a sample containing equal amounts of spinel and mullite also gives reason to state that this composition is close to the eutectic composition. An X-ray phase analysis of melted formulations and microhardness measurements (15 200 and 8800 MPa) did not reveal any phases except mullite and spinel.

The solidus temperature in the system constituted by aluminum titanate and spinel is 1745 ± 15°C. An X-ray phase analysis of melted samples did not reveal any foreign phases. Presumably, aluminum titanate does not decompose in the first heating in the presence of spinel (under the experimental conditions) because of its stabilization by the spinel [20]. A microstructural analysis of the formulations revealed eutectic colonies in a sample with 25 mol % spinel, on which a fine spherical porosity, characteristic of eutectics, and colonies with dendritic structure can be seen [18].

The DTA curves of the formulations constituted by aluminum titanate and mullite contain three groups of peaks each, for all the compositions studied. The low-temperature effects correspond to the minimum temperature of appearance of a melt, equal to 1715 ± 20°C for the given system, which is close to the temperature reported in [13]. The intermediate heat effects are, in all probability, associated with reactions between solid phases and the melt. The X-ray diffraction patterns of the formulations under study (Figs. 3a and 3b) show, in addition to the initial phases, the presence of corundum in all the samples (reflections with *d*/*n* 0.208 and 0.255 nm). Measurements of the microhardness of the formulations also revealed the presence of corundum (21 000 MPa), mullite (8800 MPa), and aluminum titanate (6100 MPa). Thus, it was confirmed that the system in question is not quasi-binary. Analysis of the microstructure of the formulations under consideration shows that eutectic colonies are

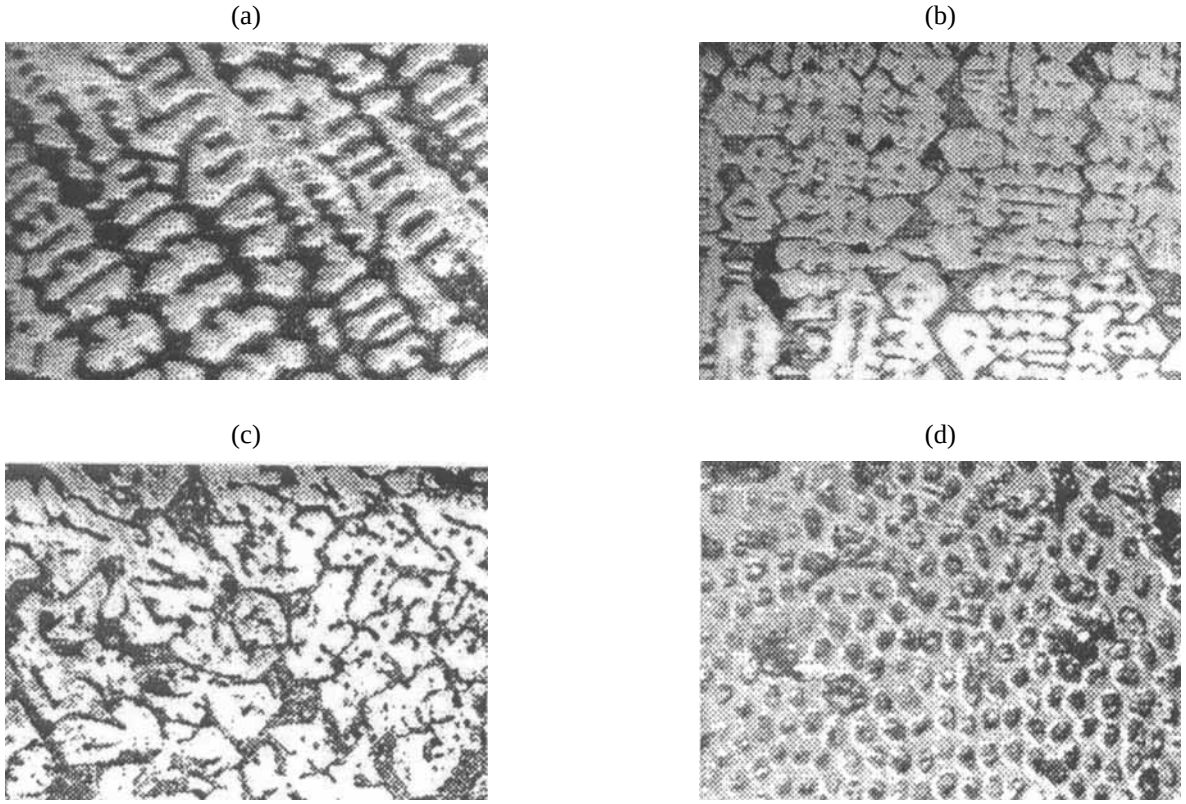

Fig. 4. Photographs of the microstructure of melted samples. Composition (mol %): (a) 70 Al_2TiO_5, 22.5 $Al_6Si_2O_{13}$, and 7.5 $MgAl_2O_4$; (b) 70 Al_2TiO_5, 15 $Al_6Si_2O_{13}$, and 15 $MgAl_2O_4$; (c) 70 Al_2TiO_5, 7.5 $Al_6Si_2O_{13}$, and 22.5 $MgAl_2O_4$; (d) 57 Al_2TiO_5, 34 $Al_6Si_2O_{13}$, and 9 $MgAl_2O_4$. Magnification: (a) 300, (b, c) 100, and (d) 400.

present in the sample containing 25 mol % mullite [19]. This formulation is close in composition to that corresponding to the point of intersection of the conode passing through the apex corresponding to corundum and the reaction point with the tie line connecting aluminum titanate and mullite in the system Al_2O_3–SiO_2–TiO_2.

The satisfactory agreement between published data on the fusibility of the individual phases and the binary systems constituted by spinel and mullite, aluminum titanate and spinel, and aluminum titanate and mullite in helium gave reason to expect that the given technique would be applicable to ternary formulations.

As points to be studied in the ternary system under consideration were chosen those corresponding to the calculated eutectic composition and to the compositions of the equimass, equivolume, and equimolar formulations, with the first two of these latter being so close that they can be regarded as virtually the same composition (Table 3). In addition, compositions with 70 mol % aluminum titanate and varied content of spinel and mullite were studied, and also some others. The results of DTA of the ternary formulations are listed in Table 3.

It follows from the data obtained that the minimum temperature of appearance of a liquid phase in the system under study, 1645 ± 15°C, is virtually composition-independent. An X-ray phase analysis of multiple-phase formulations (Fig. 2) demonstrated the presence of mullite, aluminum titanate, and spinel in all the compositions, and indications of the presence of corundum in samples with high content of aluminum titanate and mullite.

It can be seen from the microstructures of melted samples, shown in Fig. 4, that these samples have structure characteristic of eutectic colonies. Combined with the results of DTA and XPA, this gives reason to believe that the composition completely fusible at the above-mentioned minimum temperature lies near the point corresponding to the composition (mol %) 55 Al_2TiO_5, 8 $Al_6Si_2O_{13}$, and 37 $MgAlO_4$.

At the same time, the fact that the DTA curves obtained for compositions in the region adjacent to the Al_2TiO_5–$Al_6Si_2O_{13}$ side contain more than two thermal effects associated with melting–crystallization processes, taken together with the results of XPA, indicates that the plane constituted by aluminum titanate, mullite, and spinel in the system MgO–Al_2O_3–

SiO_2–TiO_2 cannot be regarded as strictly quasi-ternary.

CONCLUSIONS

(1) The applicability of high-temperature differential thermal analysis in an inert medium to systems containing metal oxides with variable oxidation levels was demonstrated in an experimental study of fusibility of refractory phases in the system $MgAl_2O_4$–$Al_6Si_2O_{13}$–Al_2TiO_5.

(2) A set of physicochemical analytical methods was used to establish that the minimum temperature at which a melt appears in the system under study is 1645 ± 15°C.

(3) The plane constituted by aluminum titanate, mullite, and spinel in the system MgO–Al_2O_3–SiO_2–TiO_2 is not quasi-ternary.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Production of Magnetic Supports Coated with Silica Layer from Dispersed Cobalt and Zinc–Nickel Ferrites

S. S. Airapetyan and A. G. Khachatryan

Yerevan State University, Yerevan, Armenia

Received March 12, 2003

Abstract—The possibility of obtaining dispersed powders of cobalt and zinc–nickel ferrites with particle size of 1–4 μm by thermal treatment of the corresponding oxalates was analyzed. Changes in porous characteristics of the ferrites obtained in their thermal treatment were studied.

Sorbents and supports with magnetic properties have their specific application fields, with the isolation and purification of substances of this kind, including those biologically active, carried out using a magnetic field. The use of sorbents and supports depends on whether soft- or hard-magnetic is a given material.

The sorption properties of sorbents and supports are determined by functional groups deposited onto the surface of one or another layer (of either organic or inorganic origin). Sorbents and supports with magnetic properties are commonly obtained using finished magnetic materials with certain unchanging magnetic characteristics.

In some cases, it is appropriate to use semifinished magnetic materials and, in particular, powders of various ferrites whose thermal treatment is not completed (as shown below, such materials show a certain extent of porosity), which is due to specific features of methods used to deposit a protective coating or a layer with necessary functional groups onto the surface of ferrites. This poses the question of control over the properties of the starting magnetic materials. In the authors' opinion, synthesis of magnetic materials to be used as a magnetic component of magnetic sorbents and supports may become a key issue.

Up to now, magnetite of both natural [1] and synthetic origin [2] has been most frequently used as the magnetic constituent of the systems mentioned above.

Commonly, magnetic sorbents and supports are synthesized by embedding magnetic materials in various macromolecular compounds: agarose and polyamide gel [1, 3], ion-exchange resins [4], etc. In some cases, coatings of organic origin restrict the possible application field of such systems. Therefore, magnetic supports with inorganic coatings become the most promising [5].

The possible promising magnetic materials for obtaining sorbents and supports with magnetic properties are dispersed ferrite powders. The magnetic properties of ferrites are widely diverse and can be controlled in the course of synthesis. Moreover, ferrites may be soft- or hard-magnetic.

In some cases, it is important to know what structural transformations occur in ferrite particles in their thermal treatment. Ferrites of various metals, which are of interest mainly as magnetic materials, are commonly obtained by sintering of metal oxides at high temperature (about 1000°C and more) [6, 7].

EXPERIMENTAL

Dispersed powders of cobalt(II) ferrite and mixed zinc–nickel(II) ferrite were obtained by thermal treatment of powders of the corresponding oxalates under the process conditions listed in the table. Similar results are obtained in precipitation of mixed oxalates of iron(II) and cobalt(II). The oxalates were synthesized by adding concentrated solutions of Me^{2+} (M = Fe, Co, Ni, Zn) to a dilute (0.2–0.4 N) solution of oxalic acid under continuous agitation. After the solution became turbid, the agitation was stopped, the suspension was kept for additional 40–50 min, and then the oxalate powder was separated from the mother liquor by filtering and dried with acetone on the filter.

A silica layer was deposited onto the surface of the ferrite powders obtained by a procedure described in [5]. Powdered cobalt(II) ferrite was suspended under continuous agitation in distilled water heated to the

8	0.4	250	Fe 0.80, Ni 0.20, Zn 0.20	2.0

boiling point. To the resulting suspension was added dilute water glass (2.0 wt % in terms of SiO_2, silicate ratio $M \geq 3$), with the volume of the initial suspension maintained constant. After the whole calculated amount of the water glass solution was introduced, the heating was terminated, and the suspension obtained was cooled to room temperature and washed with distilled water on the filter. The resulting powder was dried at 150°C and subjected to thermal treatment at 800–1000°C.

The sorption volume of pores in ferrite samples obtained under various thermal treatment conditions was found from benzene sorption [8].

The porous characteristics of the materials obtained were determined by the BET procedure on a Micromeritics Accusorb 2300A instrument.

It is known [9] that, in obtaining highly dispersed materials, it is necessary to mix reagents in the following order: more concentrated solutions are to be added to a dilute solution. The tendency toward a decrease in the particle size of the resulting powdered oxalates is observed with increasing concentration of oxalic acid and decreasing concentration of solutions of bivalent metals (see table).

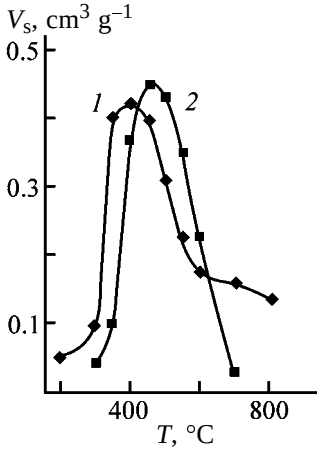

Fig. 1. Sorption volume V_s of pores in (*1*) cobalt and (*2*) zinc–nickel ferrites vs. thermal treatment temperature T.

The oxalates obtained in run no. 4 (see table) and a mixed oxalate of iron and cobalt, synthesized following the same scheme, were used to study the influence exerted by the temperature of thermal treatment on the porosity of ferrites obtained on their base.

Figure 1 shows how the sorption volume of pores in samples of cobalt ferrite (curve *1*) and zinc–nickel ferrite (curve *2*) depends on the temperature of their thermal treatment. It can be seen that the maximum pore volume is observed in samples of these ferrites upon their thermal treatment at 400–500°C. With increasing temperature, the pore volume falls steeply.

A sample of zinc–nickel ferrite has virtually no porosity upon thermal treatment at 600°C, whereas cobalt ferrite behaves somewhat differently. In this sample, residual porosity is still preserved at a temperature of 800–900°C. It is assumed that the presence of zinc oxide ensures fast particle sintering and, as a result, the porosity of zinc–nickel ferrite particles disappears rapidly.

Of particular interest is the fact that thermal treatment of oxalates yields porous ferrite powders (at 400–500°C) that can provide a good adhesion of a film being deposited to the surface. Ferrites with a silica coating were calcined at 800–1000°C for 4–5 h. The presence of silica in the ferrite powder prevents total shrinking of the skeleton, with the result that the samples obtained show a certain amount of porosity.

Deposition of thin inorganic coatings on the surface of magnetic powders makes it possible to obtain magnetic sorbents and supports with a minimum amount of ballast and completely shielded surface.

Ferrites subjected to thermal treatment at 400°C

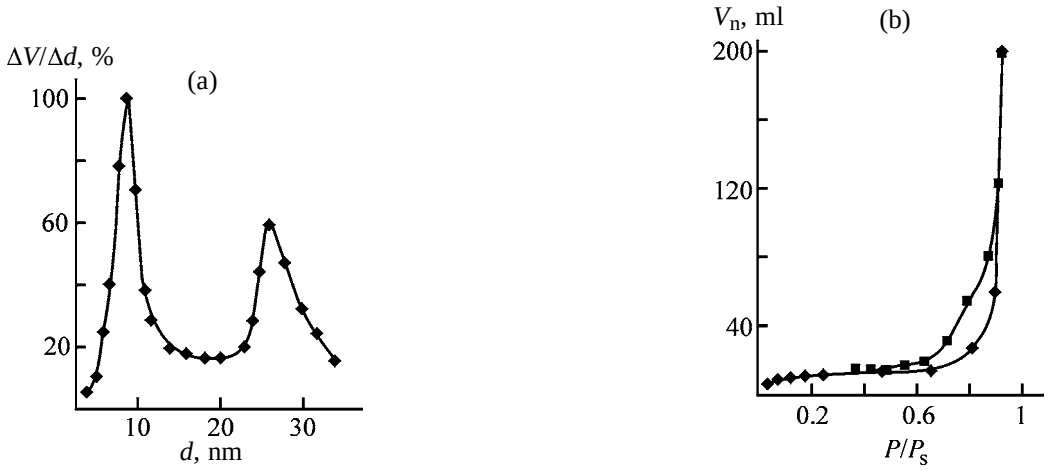

Fig. 2. (a) Pore distribution $\Delta V/\Delta d$ with respect to size d and (b) isotherm of capillary condensation of nitrogen, V_n, on porous cobalt ferrite.

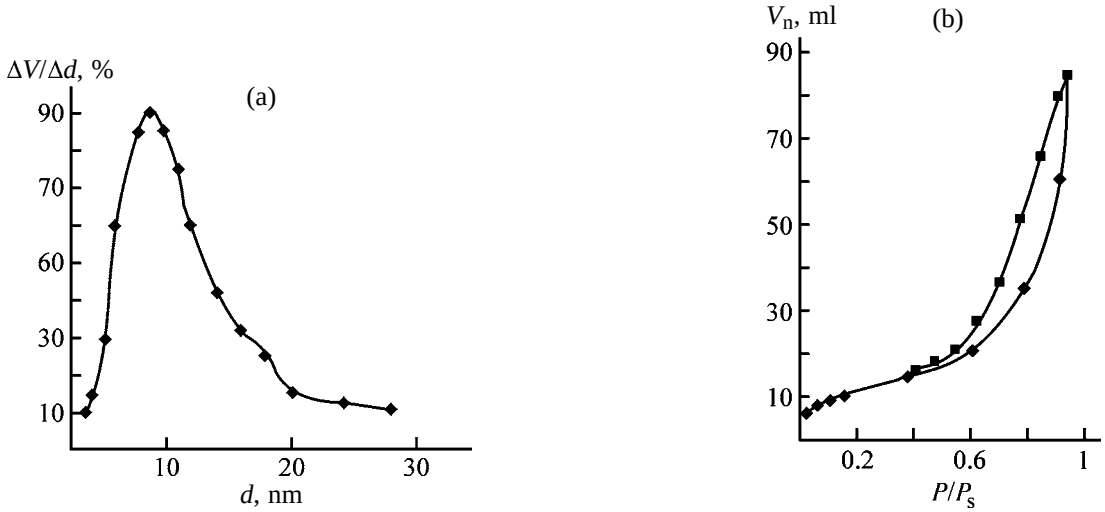

Fig. 3. (a) Pore distribution $\Delta V/\Delta d$ with respect to size d and (b) isotherm of capillary condensation of nitrogen, V_n, on porous cobalt ferrite coated with 15 wt % silica.

were used to produce magnetic supports coated with layers composed of silica.

In contrast to the case of silica deposition onto the surface of nonporous ferrite particles, that onto the surface of porous ferrite particles proceeds at a higher rate. It was demonstrated experimentally that about 20 wt % silica can be deposited onto the surface of the above ferrites thermally treated at 400–500°C. The porosity of the ferrite particles makes it possible to vary the amount of silica deposited onto their surface.

Figures 2a and 2b show isotherms of capillary condensation of nitrogen on porous cobalt(II) ferrite and the pore size distribution for this ferrite sample.

Figure 3 shows isotherms of capillary condensation of nitrogen on cobalt ferrite coated with silicon dioxide (15 wt %) and the pore size distribution for this material.

The pore size distributions were calculated from the desorption branch of the hysteresis loop in the isotherm of capillary condensation.

Interestingly, the initial cobalt ferrite sample shows biporosity, with average pore sizes of 9 and 26 nm. The average pore diameter in cobalt ferrite coated with 15 wt % silica is 9 nm.

It follows from Fig. 3 that the biporosity virtually disappears upon deposition of silica onto the cobalt ferrite surface. It seems strange that the number of coarse pores decreases to a greater extent than that of fine pores. Presumably, the fine pores become in-

accessible to the silica being deposited, since, in a solution with silicate ratio M = 3.25, sodium silicate is hydrolyzed to give colloid varieties of silica, which have limited access into fine pores. Therefore, the major part of silica being deposited remains in coarsely porous regions of the porous ferrite.

CONCLUSIONS

(1) Thermal treatment of mixed oxalate yields porous ferrite particles. The largest pore volume (0.40–0.45 $cm^3 g^{-1}$) is observed in the case of thermal treatment of oxalates in the temperature range 400–500°C.

(2) It is shown that a silica coating can be deposited onto the surface of porous ferrites. In this case, the biporosity of the initial porous ferrite disappears, with the coarse parts of pores diminishing to a greater extent.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Structure Formation and Conduction of Nanosized Nickel Oxide in Porous Glass

V. N. Pak, O. Yu. Solomatina, T. M. Burkat, and I. Yu. Tikhomirova

Herzen Russian State Pedagogical University, St. Petersburg, Russia

Received April 16, 2003

Abstract—Nickel(II) oxide was deposited on the surface of a porous glass in the amount of 0.5–7.0 mmol g^{-1} by impregnation of the glass with an aqueous solutions of $Ni(NO_3)_2$, followed by decomposition of the salt at 673 K. The size features of the formation of the oxide structure were characterized by the data of optical and X-ray photoelectron spectroscopy and by measurements of density and electrical conductivity.

Transition metal oxides are used for preparing a wide range of electrical materials, from high-ohmic dielectrics to high-temperature superconductors. The intensive development of the chemistry and physics of nanosized functional components and devices for electronics poses a problem of directional synthesis and study of special properties of oxide systems devoid of a formed band structure [1–5]. Of special interest is the specificity of electron exchange and transfer in the case of a small number of atoms (10^{15}–10^{16} at cm^{-2}) making up oxides of *d* elements in the initial stage of filling a surface of typical dielectric supports [1–3, 6, 7]. Apart from its own importance, the study of the electrical conduction should reveal forms of existence and size features of the supported oxides.

To continue our previous studies [6–11], in this work we have studied in the same context the state and electrical conduction of nanosized nickel(II) oxide in porous glass (PG). The technique of the nickel oxide deposition by impregnation of PG with $Ni(NO_3)_2$ aqueous solutions, followed by removal of water and decomposition of the salt at 673 K, appeared the most accessible and reliable. The many-time repetition of these operations using solutions of various concentrations allowed us to smoothly control the oxide content in the glass. The changes in the oxide state in a series of NiO/PG systems were monitored by optical and X-ray photoelectron spectroscopy and by measurements of the density and electrical conductivity.

EXPERIMENTAL

To find specific features of early stages of filling of the PG silica surface with nickel oxide, we carried out experiments using glasses obtained by known techniques [12–14] as laminas of the size $10 \times 10 \times 1$ mm with the following structural parameters: pore radius r_p = 10 nm, porosity ε = 0.30 $cm^3\ g^{-1}$, and specific surface area S_{sp} = 46 $m^2\ g^{-1}$. For the aim of this work it was essential that the developed surface and porosity of the glass provided a possibility for reliable control of the weight of an oxide synthesized in it. The impregnation of PG with $Ni(NO_3)_2$ solutions was intended to ensure the maximal and reproducible filling of the pore space with the electrolyte. The actual molar amount of the salt introduced in a PG (and consequently of nickel oxide *Q*) per gram of the glass linearly correlates with the concentration of the impregnating solution *c* and volume of pores in the glass ε:

$$Q = c\varepsilon\gamma, \quad (1)$$

where $\gamma < 1$ is a coefficient reflecting the deviation from an ideal filling.

We determined the actual γ value as the ratio of the nickel oxide content introduced in the PG, which was measured by the gravimetric method, to its limiting value calculated by Eq. (1) under the condition $\gamma = 1$. Numerous experiments have shown poor efficiency of the impregnation of glass laminas by immersing in solutions, as in this case γ values did not exceed 0.6–0.7. The impregnation of the glass at the expense of capillary rise of a liquid in through pores appeared to be much more complete and reproducible. In this case, the solution was taken up through one of parallel plate surfaces of a lamina, providing free displacement of air through another surface. This mode provided an average value γ = 0.9 describing in essence the frac-

tion of the total pore volume in which an $Ni(NO_3)_2$ solution was distributed during the capillary impregnation.

Gradual building up of nickel oxide mass in PG can be achieved by repeated impregnation–thermolysis operations using $Ni(NO_3)_2$ solutions of various concentrations (Fig. 1). A series of NiO/PG systems with nickel oxide content Q from 0.5 to 7.0 mmol per gram of the porous glass (hereinafter, mmol g^{-1}) was obtained by this technique.

Samples of NiO/PG were insufficiently transparent to be studied in transmitted light. The optical electronic spectra in the visible range (400–800 nm) were obtained using powders of specially prepared NiO/PG samples; the spectra were recorded in the diffuse reflection mode on an SF-10 double-beam spectrometer with a spherical photometer using the initial PG as a reference. The X-ray photoelectron spectra were taken on an ES-2401 instrument using MgK_α excitation radiation with the energy of 1253.6 eV in a band of removal of inner Ni $2p$ electrons.

Electrical measurements were carried out on direct current using the circuit and instruments described earlier [6–11]. Plates of NiO/PG were placed between pinching (with a constant pressure of 200 g cm^{-2}) electrodes having the form of massive copper disks with polished silver-coated surfaces. In this way we measured the currents passing across the laminas, i.e. along the walls of PG channels with NiO distributed on their surface. The specific electrical conductivity was calculated for the NiO/PG systems taking into account actual sizes of the laminas without recalculation to the nickel oxide content and corrections for the porosity.

The data on the weight loss during the thermal decomposition of $Ni(NO_3)_2$ in PG at 673 K reliably pointed to the formation of NiO on the surface. Characteristic changes in the diffuse reflection spectra accompanying the thermolysis are shown in Fig. 2. The spectrum of the deposited salt is well resolved; the absorption maximum at γ = 710 nm corresponds to one of three bands characteristic of Ni^{2+} cations in the octahedral oxygen surrounding. The maximum corresponds to the spin-allowed electronic transition $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ [15]. The band shape suggests that the second maximum corresponding to the transition $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ is close to 400 nm, which also agrees with the published data (λ = 395 nm [15]). We failed to observe the third d–d transition $^3A_{2g} \rightarrow {}^3T_{2g}(F)$ with $\lambda > 1000$ nm because of the limited working range of the spectrometer. The octahedral nickel(II) coordination with oxygen atoms is retained in all stages of the salt thermolysis (Fig. 2). However, in the process, the absorption in the central part of the visible range rapidly progresses. Thus, even upon depositing the first "portions" of NiO, a broad structureless band covering the whole visible range is formed. Nevertheless, we can judge the presence of nickel(II) in the composition of $[NiO_6]$ polyhedra by a weak maximum at 700 nm. The nature of the observed spectrum broadening is not quite clear and may be due to both strengthening of vibronic coupling in the solid phase and partial $3d_\pi$–$2p_\pi$ conjugation of electrons along Ni–O–Ni bonds in small nickel oxide clusters.

The measured pore volume and density of deposited nickel oxide in the series of NiO/PG systems (Fig. 3) suggest that the free volume would monotonically decrease as the NiO content in the glass increases. This trend is, indeed, observed experimentally; however, it is clearly seen that the rate ε of the

decrease is not constant, and bends in the ε–*Q* dependence are clearly seen. The data of reliable measurements of the NiO weight and volume allow us to make a physically justified estimation of its density

$$\rho = Q/(\varepsilon_0 - \varepsilon), \quad (2)$$

where ε_0 and ε are the volumes of pores of pure and oxide-containing glasses, respectively.

Thus, in the case of a particular sample we obtain the value of density averaged over all types of variously sized oxide formations actually existing in the sample. Building up NiO to the content Q = 2 mmol g^{-1} takes place with preservation of a low density (approximately 4 g cm^{-3}); in the range 2–4 mmol g^{-1}, the density increases to 6.5 g cm^{-3}, after which it continues to increase less noticeably, gradually approaching the reference value of ρ = 7.45 g cm^{-3} for bulk NiO. The results obtained suggest that the state of deposited NiO considerably changes when its content increases.

Measurements of the electrical conductivity σ (Fig. 3) furnish important information on the character of filling of the PG surface with nickel oxide. The shape of the log σ–*Q* dependence is in good agreement with trends in variation of the free volume and density, clearly confirming the presence of stages of oxide growth. In the initial stage, separate nickel-containing polyhedra and(or) their small ensembles (clusters) are fixed on the silica surface. The lowest measurable conductivity appears only when the content of nickel oxide Q = 1.5 mmol g^{-1} is reached, causing origination of primary "channels" of through conductivity. The subsequent small increase in the oxide content to Q =2.0 mmol g^{-1} is accompanied by a jump of σ, which in general agrees with the concept of electrical conduction of small-size systems [1–3, 6–10, 16] and characterizes a high probability of the layer-by-layer filling of the silica surface with nickel-containing polyhedra. It should be noted that, in this case, the content of poorly conducting oxide is low, so the detection of a clear step on the log σ–*Q* plot is rather indicative. The preferential two-dimensional structure of the forming oxide layer is confirmed by an estimate of its effective thickness, which, to a first approximation, can be represented as

$$h = Q/\rho S_{sp}. \quad (3)$$

Thus obtained value h = 8 Å (at Q = 2.0 mmol g^{-1}) closely corresponds to the size of the nickel-containing polyhedron [NiO_6]. The prolongation of

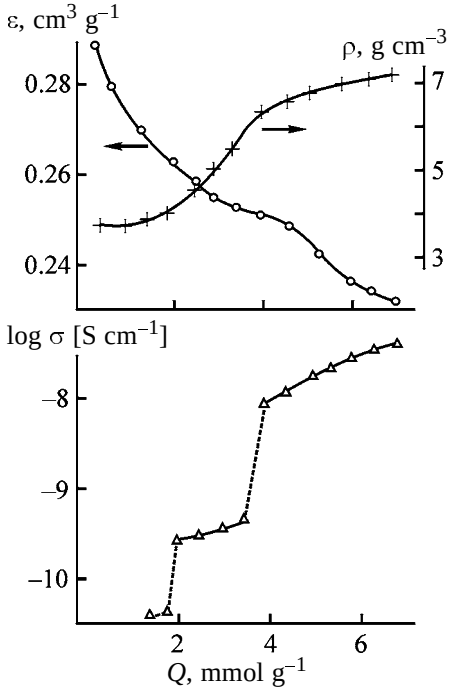

Fig. 3. Variations of the pore volume ε, specific electrical conductivity σ of modified PG, and density ρ of synthesized nickel oxide with increasing nickel oxide content Q in the glass.

supermonolayer growth ensures slow rate of the conductivity growth in the middle segment, Q = 2–3.5 mmol g^{-1}, corresponding to a considerable increase in the density of the synthesized nickel oxide; this is followed by the second jump of σ in the narrow range of oxide content 3.5–4.0 mmol g^{-1}. Further on (Q > 4 mmol g^{-1}), ρ and σ grow monotonically.

The following explanation of the observed experimental relationships seems to be the most probable. The conventional monolayer of nickel-containing polyhedra formed in the first stage is fixed directly on the walls of through channels of a glass and actually is surface nickel silicate. This is responsible for a low "packing density" of the polyhedra and their separation in space, determining the extremely low electrical conductivity. Formation of the second layer of [NiO_6] polyhedra is accompanied by a considerable density increase, which corresponds to the possibility of gradual formation of a structure with the parameters (bond length and bond angles) approaching those for NiO. The completion of this process in the range Q = 3.5–4.0 mmol g^{-1} is accompanied by strengthening of collective electronic interactions in the dense oxide layer and, correspondingly, by a sharp growth of the conductivity. The results obtained allow us to rule out formation of the island (three-dimensional) oxide structure, as at the achieved PG surface filling the islands would inevitably remain separate, remote from

Position of maxima in the X-ray photoelectron spectra of NiO/PG systems in the band of ionization of nickel inner 2*p* levels

Q, mmol g^{-1}	E_b, eV	
	$2p_{1/2}$	$2p_{3/2}$
1.54	876.3	859.5
2.10	876.0	859.0
2.96	875.8	858.7
4.10	875.4	858.2
5.20	875.1	858.0
6.00	874.9	857.9

each other, which contradicts the well pronounced steps in the $\log\sigma$–Q plot in the region of the formation of conventional oxide monolayers. Most likely, the formation of multiple "bridging" Ni–O–Ni bonds in the course of joining of polyhedra in a tangential direction appears energetically preferential as compared to the normal (relative to the surface) direction of the growth.

The dimensional features of changes in the steric and electronic structure of nickel oxide in the course of "step-by-step" increase in its content in a PG are reflected in the X-ray photoelectron spectra. The strongest bands of electron removal from filled shells of nickel atoms correspond to its 2*p* electrons [17]. It should be noted that, according to the published data [17], in the case of NiO the binding energy of 2*p* electrons varies within relatively wide limits of

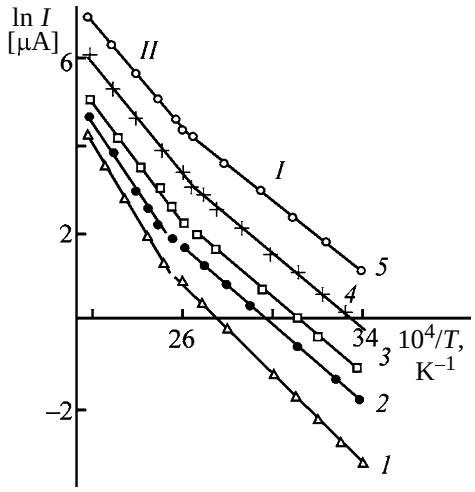

Fig. 4. Temperature dependence of current *I* measured at the voltage of 10 V across laminas of PG containing nickel oxide. NiO content (mmol g^{-1}): (*1*) 4.1, (*2*) 4.5, (*3*) 5.2, (*4*) 5.6, and (*5*) 6.0.

$E_b(2p_{1/2})$ = 871–874 eV. Hence, when studying spectra of NiO/PG systems, the most informative is the binding energy variation with increasing content of the deposited component, rather than the absolute value of the energy. In particular, the increase in E_b is definitely treated as an evidence of the increase in the positive effective charge of metal atoms [17]. The spectra obtained contain two bands of the $2p_{3/2}$ and $2p_{1/2}$ states in the region of removal of nickel inner 2*p* electrons with a distance of about 17 eV between their maxima (see table). The maximal binding energies E_b are observed in the first stage of filling of the glass surface with the oxide ($Q \le 2$ mmol g^{-1}), which is caused by a considerable positive effective charge of nickel atoms in the structure of the surface silicate. An increase in the oxide content over the conventional monolayer is accompanied by a noticeable and uniform shift of the 2*p*-electron maxima to lower energies. In spite of significant shifts of the spectra, they remain two-component, suggesting the electron density redistribution inside the oxide layer as a whole in the direction of lower effective charges of nickel atoms. Thus, the spectral manifestation of the electron-acceptor effect of silica [18, 19] becomes weaker as the weight of the deposited component increases.

Returning to the results of electrical conductivity studies, we note that it has a clear electronic character. In fact, if nickel or oxygen ions took part in the electricity transmission, the samples would be polarized owing to the appearance of an internal field directed against the applied field. In none of the experiments we have observed the emergence of polarization potentials or residual currents after cutting off the external voltage. The linearity of the voltammetric characteristics of all NiO/PG samples in a wide voltage range also suggests the absence of ion transfer. On the whole, relatively low values of σ (Fig. 3) allow us to rule out metal–metal exchange interactions by overlap of the 3*d* orbitals of nickel atoms [6, 7]. The above-mentioned $3d_\pi$–$2p_\pi$ electronic conjugation through Ni–O–Ni "bridges" seems to be the most probable conduction mechanism.

The temperature activation of currents *I* measured across laminas of modified glasses with the density of deposited oxide ρ = 6.4–6.9 g cm^{-3} is shown in Fig. 4. In the range of low temperatures, 293–473 K, the $\ln I$–T plots are of the same shape, which confirms similar structures of the conducting layers and similar features of the electricity transfer. The presence of two activation segments *I* and *II* can result from the fact that, in the vicinity of 380 K, the amplitudes of thermal vibrations are reached, ensuring accelerated

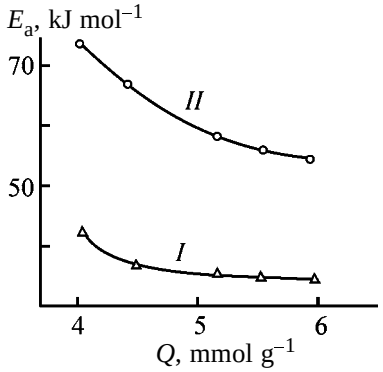

Fig. 5. Influence of NiO content in PG Q on the activation energy E_a calculated for two segments of temperature dependences of conductivity.

growth of the conductivity at the expense of increased electronic conjugation of Ni–O–Ni bonds. The activation energies E_a calculated for the two linear segments of the $\ln I$–T plots are shown in Fig. 5. It is evident that a small decrease in E_a is practically completed in the range of the deposited oxide content Q = 4–6 mmol g^{-1}. This result agrees well with the trends in the density variation (Fig. 3) and confirms the gradual formation and stabilization of structural parameters of a nickel oxide layer on the PG silica surface.

CONCLUSIONS

(1) Variations in the density, electrical conductivity, and optical and X-ray photoelectron spectra of nanosized nickel oxide, accompanying increase in its content on a silica surface, were studied. Based on the results obtained, a probable model of step filling of the porous glass surface was suggested. The process involves formation of a monolayer of nickel silicate in the first stage and uniform building up of predominantly two-dimensional NiO layer in further stages.

(2) Spectroscopic features of nanosized nickel oxide and well-pronounced jumps of the electrical conductivity, corresponding to the phases of its growth on the silica surface, reflect the manifestation of $3d_\pi$–$2p_\pi$ electron conjugation through Ni–O–Ni bonds.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Gas-Sensitive Properties of SnO_2-Based Thin Films Obtained from Film-Forming Solutions

N. V. Postovalova, S. A. Kuznetsova, A. I. Ivanov, and V. V. Kozik

Tomsk State University, Tomsk, Russia

Received July 8, 2003

Abstract—Gas-sensitive properties of SnO_2 thin-film materials doped with antimony(III) with respect to the reducing gases CO, CH_4, and H_2 were studied. The materials were obtained from film-forming solutions of Sn(II) and Sb(III) complexes with acetylacetone.

Environmental protection is one of global problems. First of all it concerns atmosphere pollution, which is determined by emission levels of carbon, sulfur, nitrogen, and heavy metal oxides, radionuclides, and cancerogenic polyaromatic hydrocarbons [1]. Thin-film materials based on SnO_2 with semiconductor properties [2] are widely used as gas-sensitive components for the determination of these combustible and toxic gases in air. It is known that these materials are mainly produced by sputtering; however, these coatings have some drawbacks [3]. Therefore, it is appropriate to perform studies aimed to enhance the SnO_2 sensitivity to gases, which depends on the film structure and composition. Thus, it is necessary to search for new methods of synthesizing film-forming systems, allowing preparation of films with specified structure and composition.

Here we consider the gas-sensitive properties of thin films of tin dioxide doped with antimony. The films were obtained from film-forming solutions of Sn(II) and Sb(III) complexes with acetylacetone as an organic ligand.

EXPERIMENTAL

Film-forming solutions based on complex compounds (FFSCCs) were prepared by dissolving tin(II) chloride (0.297–0.273 M), antimony(III) chloride crystal hydrate (2.9×10^{-3}–2.63×10^{-2} M), acetylacetone (0.6 M), and hydrochloric acid (0.4 M) in alcohol (96 wt %). The antimony content (1, 6, and 9 at. %) in SnO_2 films was chosen on the basis of the published data [4]. Antimony-free FFSCC compositions and the processes occurring in these FFSCCs were considered in detail in [5].

Films of SnO_2–Sb were obtained by centrifugation on an MPW-340 centrifuge (4000–4500 rpm), dried for 1 h in a desiccator at 333 K, and annealed in a muffle furnace at 873 K. Three 1-h annealings were performed to stabilize the electrophysical parameters. Single-crystal silicon was used as support.

The electrical resistance of the films was measured with an E6-13A teraohmmeter in air and in CO and CH_4 atmospheres at 299–673 K. Platinum contacts were used. The ratio of the resistance in air and resistance in a gas was taken as the value of adsorption response R_a/R_g to the action of the CO, CH_4, and H_2 gases. The activation energy of charge carriers E_a was calculated by the procedure described in [6]. The film thickness and refractive index were determined by ellipsometry (LEF-3M). The film composition was determined by X-ray phase analysis on a DRON-3M diffractometer (CuK_α radiation, Ni filter).

The X-ray patterns, interpreted as in [7], show that introduction of antimony(III) into an SnO_2 film results in a shift of interplanar spacings (Table 1), but the rutile-type structure of SnO_2 is preserved. The shift can be caused by formation of a solid solution based on SnO_2.

Table 1. X-ray diffraction parameters of SnO_2–Sb films

c_{Sb} = 1 at. %		c_{Sb} = 9 at. %		SnO_2 [7]

The films obtained from these film-forming solutions are conducting. Their thickness is 46–68 nm. Table 2 shows that the electrical resistance and activation energy of charge carriers regularly decrease as the concentration of antimony dopant increases from 1 to 9 at. %. As shown in [4], the rise of the electrical conductivity owing to dopant transition from lattice points to the grain surface is caused by the lifting of the compensation effect of oxygen donor vacancies in SnO_2 by Sb(V) impurity centers.

The conductivity of the films depends not only on the activation energy of charge carriers and their concentration, but also on the structure, which can be judged from the refractive index *n*. Films containing 1 at. % Sb have the lowest *n* value of 1.69. The refractive index of SnO_2 films obtained from antimony-free FFSCC is 1.89 [5], and that of Sb_2O_3 is 2.05 [8]. Such a low *n* value of the SnO_2 film containing 1 at. % Sb antimony suggests its defectiveness. Such films have a fairly high surface resistance of 10^6 Ω. Samples containing 9 at. % Sb have higher $n = 2.13$ and a relatively low surface resistance of about 10^{-3} Ω.

To study the behavior of the films in CO, CH_4, and H_2 atmospheres, we have chosen samples with sharply different physical properties. As seen from Fig. 1, the R_a/R_g ratio increases with temperature. The R_a/R_g curves for SnO_2 film containing 1 at. % Sb have two maxima in CO (curve *1*) and CH_4 (curve *2*) atmospheres: in the low-temperature region at 393 K and in the high-temperature region at 573 K. The low-temperature maximum is caused by surface reactions of oxygen adsorbed on the film with reducing gases, which results in delocalization of electrons [4]. The second peak in the R_a/R_g curves is related to the formation of new chemical bonds corresponding to double-charged tin (SnO) [9]. In contrast to SnO_2, SnO is a narrow-band-gap semiconductor, and, consequently, its presence can lead to a significant change in the electrical conductivity. This film shows no response to hydrogen.

As seen from Fig. 2, R_a/R_g for the SnO_2 film doped with 1 at. % Sb depends on the gas concentration. Its maximal sensitivity corresponds to the CH_4 concentration of 10 vol % ($T = 574$ K). The temperature dependences of R_a/R_g of SnO_2 films doped with 9 and 1 at. % Sb are different (Fig. 1, curves *1* and *2*). No pronounced peaks are observed in the CH_4 atmosphere (Fig. 1, curve *3*). An insignificant sensitivity peak was found for CO concentration of 5 vol % (493 K). It becomes better pronounced after keeping the film for 2 days at the CO concentration of 40 vol % (Fig. 3). The low sensitivity of SnO_2 films doped with 9 at. % Sb is attributable to blocking of the surface states of adsorbed oxygen by a large amount of antimony [5].

Table 2. Properties of SnO_2–Sb* films

c_{Sb}, at. %	E_a, eV	*n*	*R*, Ω

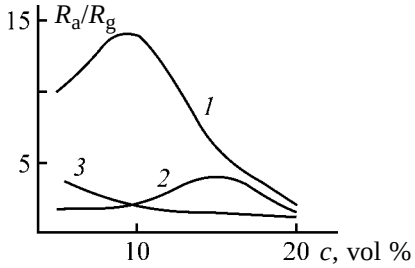

Fig. 2. Adsorption response R_a/R_g of SnO_2 films doped with 1 at. % Sb as a function of concentration *c* of (*1*, *2*) CH_4 and (*3*) CO. Temperature (K): (*1*) 574 and (*2*, *3*) 393.

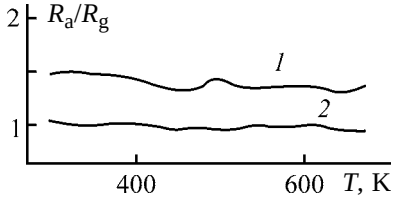

Fig. 3. Temperature dependence of the adsorption response R_a/R_g of SnO_2 films doped with 9 at. % Sb to CO. CO concentration (vol. %): (*1*) 40 and (*2*) 5.

CONCLUSIONS

(1) High-resistance thin SnO_2 films doped with Sb (1, 6, and 9 at. %) were prepared by centrifugation on

silicon supports from film-forming solutions based on tin(II) and antimony(III) complexes with acetylacetone.

(2) The sample containing 1 at. % Sb shows the greatest adsorption response to the reducing gases CO and CH_4. The low-resistance sample containing 9 at. % Sb does not show such a behavior. The films are stable and are able to operate at relatively low temperatures. Their gas-sensitive properties compare well with those of thin-film materials prepared by more laborious and expensive techniques. It is proposed to use the films obtained as components sensitive to CO and CH_4 in the presence of H_2.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Iteration Methods for Calculating Physicochemical Properties of Molecular Inorganic Compounds

I. B. Sladkov and M. V. Uchaneva

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received May 26, 2003

Abstract—Iteration schemes for highly reliable prediction of physicochemical properties of molecular inorganic compounds were proposed.

The most reliable prediction of physicochemical properties of molecular liquids is achieved using methods based on the thermodynamic similarity theory. These methods use relationships between the physicochemical properties expressed in the dimensionless form. Passing to dimensionless values requires data on the critical parameters of substances. Therefore, the above methods employ critical parameters as input data. Because the experimental data on the critical constants are rather limited, the calculation methods of their determination have became practically significant. First, this concerns the molecular inorganic compounds that have found wide practical application [1] but are, however, little studied.

Reliable data on the critical parameters can be obtained by the iteration methods. These methods involve successive approximations to obtain the closest agreement between the required parameter and other previously known physicochemical properties of a substance. The fact that not only the critical parameters but also other physicochemical properties of a substance can be determined in the course of iteration is a significant advantage of the iteration methods.

In this study we developed an iteration scheme for highly reliable prediction of the critical parameters of molecular inorganic compounds. It is based on relationships employing the determining criterion, which reliably describes the thermodynamic similarity of any molecular inorganic compounds. The latter is referred to as the factor of the complexity of intermolecular interaction (or ψ-factor) and is considered in detail in [1].

Let us list the equations used in the iteration scheme proposed (iteration 1). For the critical temperature and critical pressure, we used the equation obtained by integrating the Clausius–Clapeyron equation between the boiling and critical temperatures [2]. In this case, the pressure varies from a value at the boiling point P_b to a value at the critical point P_{cr}. In the literature [3], this equation is known as the van der Waals equation

$$\ln(P_{cr}/P_b) = f(T_{cr}/T_b - 1). \quad (1)$$

The parameter

$$f = \Delta H_b/(RT_{cr}) \quad (2)$$

is referred to as the generalized constant, because its variations from substance to substance lie within very narrow limits. ΔH_b is the enthalpy of vaporization at the boiling point.

To leave only one unknown parameter (critical temperature) in Eq. (1), the known relationship for the critical pressure is used:

$$P_{cr} = RT_{cr}/(8b), \quad (3)$$

where b is the van der Waals constant.

Then, Eq. (1) becomes

$$\ln[RT_{cr}/(8bP_b)] = f(T_{cr}/T_b - 1). \quad (4)$$

The critical temperature appearing in the expression for f can be calculated by the equation [1]

$$T_{cr} = T_b + 0.89(T_b)^{0.92+0.2\psi}, \quad (5)$$

where ψ is the factor of the complexity of intermolecular interaction.

The ψ factor is the determining criterion of thermodynamic similarity, which extends the applicability of

Iteration 1 (set of data for 60 substances)**	0.9	2.2	1.1
Iteration 2 (set of data for 50 substances)***	1.6	2.4	2.0

* Averaged (in the absolute value) for the whole set of substances.
** For any molecular inorganic compounds.
*** For nonpolar and weakly polar substances.

the correlations obtained using the similarity theory [1]. After that, f can be calculated by the equation

$$f = \Delta H_b/\{R[T_b + 0.89(T_b)^{0.92+0.2\psi}]\}$$

and considered constant in Eq. (4).

Taking into account the dimensionalities of b ($cm^3\ mol^{-1}$) and P_b (MPa), we obtain the following expression for the critical temperature:

$$T_{cr} = T_b[(1/f)\ln(10.255T_{cr}/b) + 1]. \quad (6)$$

We start the iteration from calculation of the complexity factor

$$\psi = 0.1\ln T_b - 0.122\ln V_b + 0.006$$

and the van der Waals constant [1]

$$b = mV_b + n,$$

where $m = 1.27$ and $n = -6$ if $\psi \le 0.1$; $m = 1$ and $n = 11$ if $\psi \ge 0.1$; V_b is the molar volume at the boiling point ($cm^3\ mol^{-1}$).

The van der Waals constant b ($cm^3\ mol^{-1}$) can be calculated from the given values of m and n.

The critical temperature, to a first approximation, is calculated by Eq. (5) and, as a second approximation, by Eq. (6).

If the difference between the obtained T_{cr} values is less than the preset accuracy (e.g., 0.001), then we go to calculating the other critical parameters. Otherwise, we return to Eq. (6) using the specified T_{cr} value.

After the critical temperature is determined, the critical pressure should be calculated from Eq. (1):

$$P_{cr} = P_b \exp[f(T_{cr}/T_b - 1)]. \quad (7)$$

The critical volume can be calculated by the Benson equation [4]:

$$V_{cr} = V_b(2.4 + 0.1833\ln P_{cr}]. \quad (8)$$

The iteration is suitable for calculating critical parameters of any molecular inorganic compounds, from nonpolar to strongly polar substances.

The accuracy of the method proposed in this work (iteration 1) was verified on a set of data for 60 substances, including hydrides (B_2H_6, CH_4, GeH_4, SnH_4, NH_3, and N_2H_4), fluorides (CF_4, PF_3, MoF_6, WF_6, UF_6, and PtF_6), chlorides (CCl_4, $SiCl_4$, $GeCl_4$, $SnCl_4$, $TiCl_4$, BCl_3, PCl_3, PCl_5, $BiCl_3$, $SbCl_3$, S_2Cl_2, $MoCl_5$, and HCl), bromides (BBr_3, $SnBr_4$, $GeBr_4$, PBr_3, $AsBr_3$, and $SbBr_3$), iodides (BI_3, SiI_4, and SnI_4), mixed halides ($SiCl_3F$, $SiCl_2F_2$, $SiClF_3$, CBr_2F_2, $CBrF_3$, PCl_2F, $PClF_2$, $SiBr_2Cl_2$, $SiBrCl_3$, and $NClF_2$), hydrohalides ($CHClF_2$, $SiHCl_3$, $SiHBr_3$, and NHF_2), oxohalides (PCl_3O, PBr_3O, SCl_2O, SOF_2, $SeCl_2O$, WCl_4O, VCl_3O, and ClO_3F), and oxides (CO, SO_2, OsO_4, and H_2O). Among these compounds are 10 strongly polar substances (SO_2, NH_3, H_2O, and others).

All the input data were taken from [1]. The calculated and experimental values of the critical parameters (critical temperature T_{cr}, critical pressure P_{cr}, and critical volume V_{cr}) are given in Table 1 to demonstrate the accuracy of the iteration method proposed. The data presented show that the iteration method proposed is highly reliable for predicting the critical parameters.

It should be noted that the method proposed has two essential advantages. First, it employs only accessible input data (boiling point of a substance, its molar volume, and the enthalpy of vaporization at the boiling point). Second, it is suitable for any molecular inorganic compounds, from nonpolar and weakly polar substances to strongly polar substances and associated liquids.

The iteration method based on the minimal number of the experimental input data is important for little studied substances. We developed the iteration scheme (iteration 2) using the boiling point as the only experimental input parameter. The molar volume and the enthalpy of vaporization at the boiling point, apart from the critical parameters, can be determined by this method.

This iteration employs the following relationships between the physicochemical properties of molecular inorganic compounds [1]: (1) $\Delta S_b = 88$ (Trouton rule), (2) $\theta = T_b/T_{cr} = 0.772 - 12.27/\Delta S_b$, (3) $T_{cr} = T_b/\theta$,

(4) $V_b = 116\prod^{1/2}/T_b^{0.3} + 0.5$, (4) $b = 1.27V_b - 6$, (5) $P_{cr} = 1.039T_{cr}/b$, (6) V_b (second approximation) = $85T_{cr}P_{cr} + 2$, (7) $\Delta H_b = T_b[73 + 2.09\ln(T_bM/V_b)]$, and (8) ΔS_b (second approximation) = $\Delta H_b/T_b$.

If the difference between the calculations of ΔS_b by steps 1 and 8 is smaller than a preset accuracy (e.g., 0.001), then the calculation is finished. Otherwise, the calculation by step 1 is performed again, with the new value assigned to ΔS_b.

The iteration converges sharply (the number of steps does not commonly exceed three). The iteration can be applied to nonpolar and weakly polar substances. To judge whether the compound under study belongs to such substances, it is sufficient to compare its boiling point and parachor $\prod$. For nonpolar and weakly polar substances, the following inequality [1] is fulfilled:

$$T_b < 100\prod.$$

The iteration was verified with 50 molecular inorganic substances. It employs the minimal number of easily accessible input data (boiling point) and ensures quite reliable prediction of the critical parameters (see table). Moreover, the iteration can predict the increased number of properties. Apart from the critical parameters, it can also determine (with the mean average error given in parentheses) the molar volume of a liquid at the boiling point (1.7%) and the enthalpy of vaporization at the boiling point (2.2%).

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Kinetic Characteristics of Xylitol Crystallization from Aqueous-Ethanolic Solutions

V. V. Vyglazov

St. Petersburg State Forestry Engineering Academy, St. Petersburg, Russia

Received July 10, 2003

Abstract—The kinetics of xylitol crystallization from aqueous-ethanolic solutions as a function of the initial solution supersaturation, solvent composition, and temperature was studied. The effect of solvent composition on the rate of the xylitol bulk crystallization was considered.

Among sugar substitutes, an important role belongs to pentahydric aliphatic polyol, xylitol, prepared by reductive transformation of *D*-xylose [1]. Inclusion of xylitol in the list of food additives (E 967) [2] and confirmation of its anticarious properties extended applications of this polyol. The main branches of xylitol use are food production, perfumery, pharmaceutics, and chemistry.

The technology of food xylitol production consists of the following main stages: hydrolysis of hemicellulose polysaccharides of pentosan-containing plant raw materials (birch wood, cotton husk, corn cob shanks); pentosan hydrolyzate preparation for hydrogenation; hydrogenation of xylose solution; purification and concentration of xylitol solution; and xylitol crystallization. Crystallization is an important stage of xylitol production, since in many respects it determines the yield and quality of the target product. The possibilities of increasing the xylitol yield and quality by optimization of the known technology of xylitol crystallization from concentrated aqueous solutions are practically exhausted.

The method of xylitol separation including preliminary crystallization from supersaturated aqueous solution and subsequent crystallization in the ethanol–water mixture is more efficient [3]. The optimum mode of xylitol crystallization can be determined from the data on the process statics and kinetics. Previously, on the basis of the solubility data, we developed a model of the statics of xylitol crystallization from aqueous-ethanolic solutions [4]. In this work, we studied the kinetics of polyol crystallization.

EXPERIMENTAL

The xylitol crystallization from aqueous-ethanolic solutions was studied as a function of the degree of solution supersaturation (characterized by supersaturation coefficient *S*), solvent composition, and temperature at a constant stirring rate of 100 rpm. Xylitol crystallization was studied under the isothermal conditions at 5, 25, and 40°C. The compositions of water–ethanol mixtures were taken with regard to probable values of the liquid-to-solid ratio *M* [i.e., the ratio of 95.3% ethanol weight to the weight of dry substances of the crystallizate (massecuite)]. It was 60–90 vol % (or 53.9–87.5 wt %) with respect to ethanol, which corresponds to the $0.10 < M < 0.50$ range used in industrial xylitol crystallization. The initial supersaturation was reached by heating. The degree of supersaturation was selected with regard to polyol solubility [4] by the formula $S = c_{in}/c_s$, where *S* is supersaturation coefficient and c_{in} and c_s are the xylitol initial concentration and solubility (g per 100 g of the solvent), respectively.

Food xylitol used [TU (Technical Specifications) 64-10-04–89] was preliminarily recrystallized and dried to the moisture content of 0.03%. The xylitol purity determined by GLC [5] was 99.9%, mp of crystals 93.5–94.0°C. The solvent was prepared by mixing of ethanol (rectificate) with distilled water at 20°C. The refractive indices of water–ethanol mixtures prepared agree with data of [6]. Xylitol crystallization was performed in a three-necked flask equipped with a stirrer and thermometer. The temperature was controlled with 0.1°C accuracy.

Crystallization was monitored through a change in the refractive index of a liquid phase sample. Preliminarily, the n_D^T–c_{et} calibration plots were built for each ethanol concentration and temperature. A linear dependence n_D^T–c_{et} was observed for the concentration range corresponding to supersaturated metastable state of the solution. This is characteristic also for other

1070-4272/04/7701-0026 © 2004 MAIK "Nauka/Interperiodica"

substances [7]. The error in determination of xylitol concentration in aqueous-ethanolic solution by the refractive index was 0.05 g per 100 g of the solvent, which corresponds to the interval from ±0.25 (in 60% ethanol) to ±2 rel% (in 90% ethanol) at 5°C.

The crystalline products obtained were examined microscopically to estimate the granulometric composition. Linear dimensions of a large number of particles (>60) were measured under a microscope equipped with a special scale. Each crystal was measured along two mutually perpendicular directions, and the average value L was taken as its linear size. Microscopic analysis allowed determination of the size distribution of particles in the fraction (%) [8].

The data on xylitol crystallization under various conditions in the form of typical kinetic curves are shown in Fig. 1. The xylitol solubility c_s at fixed temperature and solution composition is shown by a dashed line. The analysis of the kinetic curves showed that the increase in the ethanol concentration c_{et} in the intercrystallite liquor of the xylitol suspension accelerates xylitol separation into the solid phase. For example, at 25°C, xylitol crystallization proceeds by a factor of 11 faster in 90% than in 60% ethanol (Table 1). The time of decrease in the degree of solution supersaturation from 1.86 to 1.10 was taken as the time of xylitol crystallization.

The initial period of xylitol crystallization is satisfactorily described by the equation [9]

$$J = K_N c_{in}^n, \quad (1)$$

where J is the nucleation rate; K_N, nucleation rate constant; c_{in}, initial xylitol concentration (g per 100 g of solvent); and n, nucleation order.

When the crystallization has an induction period, Eq. (1) transforms into Eq. (2):

$$\log t_{ind} = K_{ind} - n\log(c_{in}/c_s), \quad (2)$$

where t_{ind} is the induction period (min); K_{ind}, induction period constant; and c_s, xylitol solubility (g per 100 g of solvent).

The slope of the linear dependence of $\log t_{ind}$ on $\log(c_{in}/c_s)$ is equal to the nucleation reaction order n; the latter changes for xylitol from n = 7 at c_{et} = 60 vol % and 5°C to n = 30 at c_{et} = 90 vol % and 40°C.

The rate of xylitol nucleation increases with increasing temperature and c_{et}, especially at M > 0.3, which is connected with changes in the mixed solvent structure. Extrapolation of the linear dependences described by Eq. (2) to the range of greater supersaturation, where t_{ind} = 1, allows evaluation of maximum supersaturations S_{lim} characterizing the upper boundary of metastability and determination of the region of stability of xylitol solutions as a whole. In

Table 1. Duration of xylitol crystallization t from aqueous-ethanolic solutions*

c_{et}, vol %	t, min, at indicated temperature, °C		
	5	25	40
60	285	345	930
70	110	122	380
80	70	80	117
90	25	32	85

* c_{et} is the ethanol concentration in water–ethanol mixture; the same for Table 2.

Table 2. Fractional composition of xylitol crystals at various crystallization temperatures

c_{et}, vol %	Content, %, of crystals of indicated size, mm					
	>0.15	<0.15	>0.15	<0.15	>0.15	<0.15
	5°C		25°C		40°C	
60	82	18	58	42	54	46
70	66	34	50	50	41	49
80	40	60	42	58	18	82
90	0	100	0	100	5	95

60% ethanol, S_{lim} changes from 2.99 at 5°C to 2.12 at 40°C, and in 90% ethanol, from 2.40 at 5°C to 1.86 at 40°C. The decrease in the width of the metastable zone with increasing c_{et} satisfactorily agrees with the theory connecting a decrease in S_{lim} with decreasing solvent permittivity (ε_{H_2O} = 82.1 and $\varepsilon_{C_2H_5OH}$ = 25.0 at 20°C [11]).

The second stage of bulk xylitol crystallization from aqueous-ethanolic solutions involves direct formation of crystalline precipitates. At fairly high solution supersaturation, when the rate of back dissolution from the surface of growing crystals can be neglected and the surface area after attaining the maximal rate of the process changes insignificantly, the expression derived from the chemical kinetics equation for heterogeneous reactions [9]

$$\Delta t = A - B\log(c/c_s), \quad (3)$$

is valid. Here $\Delta t = t - t_{ind}$, $A = (1/K_1)\log(c_{in}/c_s)$, $B = 1/K_1$, t is the total time of observation (min), and K_1, the rate constant of xylitol crystal growth (min^{-1}).

The applicability of Eq. (3) to xylitol crystallization from aqueous-ethanolic solutions is confirmed by the linear dependence of $\log(c/c_s)$ on the crystallization time Δt (Fig. 2).

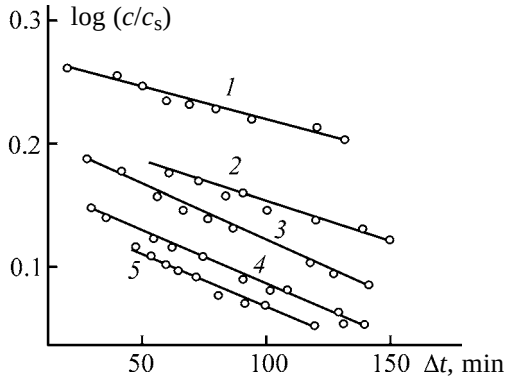

Fig. 2. Logarithm of the degree of supersaturation of xylitol aqueous-ethanolic solutions c/c_s as a function of crystallization time Δt at various temperatures. c_{et} (vol %): (*1*, *2*) 60, (*3*) 70, and (*4*, *5*) 80. Temperature (°C): (*1*, *5*) 25 and (*2*–*4*) 5.

The first order of the crystallization reaction under isothermal conditions shows that the xylitol crystallization rate is limited by the rate of diffusion of polyol molecules to the surface of growing crystals.

It was found that, as the ethanol concentration in the mixed solvent is increased, e.g., from 80 to 90 vol %, the xylitol crystallization rate increases by a factor of approximately 3 (K_1 increases from 1.7×10^{-3} to 4.9×10^{-3} min^{-1}). For c_{et} = 80–90 vol %, the linear dependence of $\log(c/c_s)$ on Δt keeps at S 1.1–1.3, and for c_{et} = 60–70 vol %, at S = 1.2–1.5.

These S values characterize the width of the first zone of metastability in the xylitol–ethanol–water phase diagram. In this region of supersaturation, already existing crystals grow without formation of new crystallization centers, which is very important for the technology of xylitol crystallization.

A microscopic estimation of the fractional composition of xylitol crystals prepared in kinetic experiments showed that the crystal size substantially depends of c_{et} and T (Table 2). At c_{et} < 80 vol %, larger crystals are formed.

Under industrial conditions, massecuite crystals should be capable of further growth in the ethanolic solution characterized by supersaturations corresponding to the first metastable zone.

To prevent the secondary nucleation, ethanol should be introduced into the crystallizing system gradually. To obtain larger crystals, the c_{et} value in the intercrystalline liquor should not exceed 80 vol % (Table 2).

CONCLUSIONS

(1) A study of xylitol crystallization as a function of the degree of the initial solution supersaturation,

solvent composition, and temperature revealed the main kinetic characteristics of this process: maximal supersaturation of solutions in the form of the first and second metastability boundaries, induction period, nucleation reaction order, and the rate constant of xylitol crystal growth.

(2) The data obtained were used to choose the optimum mode of xylitol crystallization on the laboratory and semicommercial scale and were taken into consideration when designing the crystallization apparatus.

SORPTION AND ION-EXCHANGE PROCESSES

Ion-Exchange Properties and IR Spectra of Natural Clinoptilolite Modified with Titanium Hydroxophosphates

V. S. Aleksandrova, O. P. Zykova, and E. Ya. Markiv

Institute of Sorption and Endoecological Problems, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received July 22, 2002; in final form, March 2003

Abstract—A method for modification of a natural zeolite, a clinoptilolite-containing tuff, with compounds based on titanium phosphate is suggested. The results obtained in a comparative study of sorption of heavy metal ions on the initial and modified clinoptilolite are presented. The modifying effect of an additive is discussed on the basis of IR and X-ray fluorescence spectroscopic data.

The selectivity of a natural zeolite, clinoptilolite, toward ions of heavy and transition metals makes promising its use for recovery of these elements from aqueous solutions, industrial wastewater, and potable water. However, the clinoptilolite-containing material is rarely used in practice in its natural form, being, as a rule, subjected to additional chemical pretreatment to improve its sorption, mainly ion-exchange properties [1].

The most widely used method for directed modification of a zeolite sorbent is cation-exchange modification, which consists in that the polycationic natural material is transformed into a monocationic (H^+, Na^+, Ca^{2+}, NH_4^+, etc.) form [2].

In contrast to the commonly accepted approach [2], in this work we examined the possibility of improving the performance of natural clinoptilolite by chemical grafting of a modifying agent with good sorption and selective properties. We believe that the most promising in this regard are compounds based on titanium hydroxophosphates [3].

EXPERIMENTAL

As starting sorbent we took samples of a clinoptilolite-containing tuff from the Sokirnitskoe deposit (Transcarpathia). The modification was performed by impregnating the polycationic matrix with a 1 M aqueous solution of $TiCl_4$ in 1 M HCl (pH 0) with subsequent drying and further treatment with a 1 M H_3PO_4 solution. The resulting sorbent was washed with distilled water to remove excess acid and salts and dried at 100–110°C.

An analysis of the elemental composition of the surface layer of the modified clinoptilolite samples by X-ray fluorescence spectroscopy (VG ESCA-3 spectrometer with reference for determining the core electrons, C1*s* line 284.4 eV) demonstrated that the Ti : P ratio is within the range (1 : 3)–(1 : 1). The observed scatter is probably due to inhomogeneity of the starting natural material.

Sorption experiments were carried out under dynamic conditions on a filtering column 0.8 cm in diameter with the sorbent bed height of 10 cm (0.5–1.0-mm fraction) and sorbent charge volume [1 c.v. (column volume)] of 5 cm^3. The filtration rate was chosen to be 2.0 m h^{-1} (100 cm^3 h^{-1}, i.e., 20 c.v. h^{-1}). Model solutions containing 1–2 mg dm^{-3} of copper(II), lead(II), and cadmium(II) ions were prepared from potable tap water with total hardness of 3.7–4.2 mg-equiv dm^{-3}, which contained (mg dm^{-3}) 60–65 Ca^{2+} ions, 10–15 Mg^{2+} ions, and 0.3 iron ions; pH 6.8–7.1. Preliminary studies revealed that no precipitation of heavy metal ions occurs in the working range of concentrations ($\leq 10^{-5}$ M) and pH values (6.8–7.1). The results obtained are in agreement with the data of [3–5].

A comparative analysis of the output curves of sorption of copper(II), cadmium(II), and lead(II) ions, which were obtained on natural and modified clinoptilolite under the same conditions, demonstrated that the degree of recovery of these elements with a modified sorbent is 2–2.5 times that with the natural material. Data on the influence exerted by modification on the sorption of Cd^{2+}, Cu^{2+}, and Pb^{2+} ions in the dynamic mode are presented in Fig. 1. It can be seen that, even on the background of a manyfold excess

1070-4272/04/7701-0030 © 2004 MAIK "Nauka/Interperiodica"

(by a factor of 50–100 for Ca^{2+} only) of alkaline-earth elements present in tap water, the degree of recovery of the ions under study is sufficiently high. In this case, as also in the case of titanium hydroxophosphates, the ions can be arranged in the order of increasing degree of recovery as follows: Cu ≤ Cd < Pb.

To reveal how the modifying agent is bound to the natural zeolite, at what centers the modification occurs, and what is reason for higher sorption of heavy metal ions on the sorbent obtained, we examined the IR spectra of the starting clinoptilolite and its modified form before and after sorption of ions. Samples were in the form of KBr pellets or a mull in mineral oil. The weighed portions taken for preparing KBr pellets were chosen so that the bands under study were peaked at 80–20% transmission. The spectra were recorded on a Carl Zeiss Specord M80 instrument in the spectral range 4000–400 cm^{-1}. Since the spectral manifestation of the processes that occur on the surface is diffuse, the method of baseline and internal reference [6] was used to ensure the adequacy of the analysis performed. As the internal reference we chose the band associated with bending vibrations of water (ν ~1635 cm^{-1}) [7]. Its shape, position, and intensity are virtually the same for all of the samples studied (Fig. 2).

It is known [7] that the strongest absorption in the IR spectrum of clinoptilolite is observed in the range 900–1300 cm^{-1}. This absorption is due to intra- and extratetrahedral asymmetric stretching vibrations of O–Si(Al)–O bonds. The absorption bands in the range 400–8500 cm^{-1} range are attributed to symmetric stretching and bending vibrations of structural groups of the aluminum–silicon–oxygen framework. An isolated absorption band peaked at ν ~1635 cm^{-1} is due to bending vibrations of sorbed water, and a broad medium-intensity band of complex shape at ν ~3400 cm^{-1} is associated with stretching vibrations of hydroxy groups [7].

The results obtained in mathematical processing of the spectral data in the region of absorption associated with stretching vibrations of the O–H bonds (2900–4000 cm^{-1}) and the main absorption band of the zeolite framework (850–1550 cm^{-1}) are shown in Figs. 3 and 4, respectively. As seen from Fig. 3, modification of clinoptilolite with titanium hydroxophosphate leads to a decrease in the intensity of the high-frequency (3600–3800 cm^{-1}) wing of the absorption band associated with stretching vibrations of hydroxy groups possessing basic properties [8–10].

The modification of clinoptilolite also manifests itself in an increase in the intensity and halfwidth of the main absorption band of O–Si(Al)–O bonds, peaked at ν ~1075 cm^{-1} (Fig. 4). Figure 4 also shows the difference of the optical densities of the modified and unmodified forms of clinoptilolite, which is a

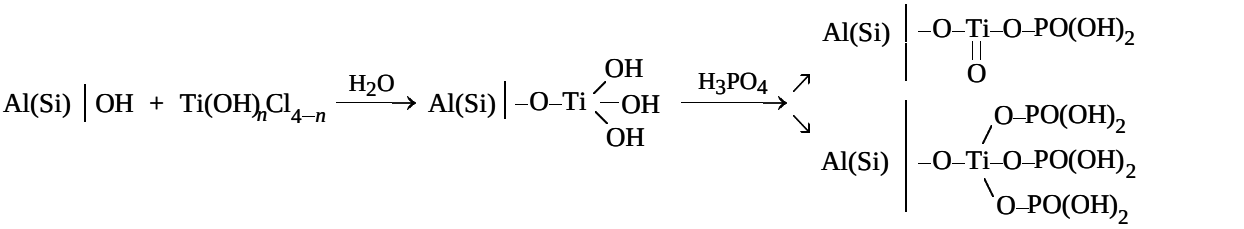
curve with two clearly pronounced peaks. The low-frequency peak at ν ~1020 cm^{-1} is related to absorption of the modifying agent, since the main absorption band in the IR spectrum of amorphous titanium hydroxophosphate is recorded in this spectral range. The high-frequency peak (with ν ~1150 cm^{-1}) arises in the spectral range of absorption by strong aluminum–silicon–oxygen bonds of the zeolite framework. The appearance of additional O–Si(Al)–O bonds upon modification indicates that the bonding between clinoptilolite and the modifying agent is covalent.

The decrease in the amount of hydroxy groups of basic nature (Fig. 3, 3600–3800 cm^{-1}), with simultaneous appearance of additional O–Si(Al)–O bonds (Fig. 4, ν ~1150 cm^{-1}), points to the active role of these groups in the formation of covalent bonds between the modifying agent and the starting zeolite.

Figure 3 also shows that the intensity of the low-frequency wing of the absorption band associated with OH groups with pronounced protonogenic properties increases substantially in the course of modification. After the modified clinoptilolite is used as sorbent for ion recovery, the intensity of the low-frequency wing of the absorption band associated with the OH groups responsible for the acid properties of the surface decreases. This decrease is shown for the example of sorption of lead(II) ions in Fig. 3, curve *3*. The decrease (compared with the modified sample before sorption) in the intensity of the low-frequency component responsible for the acid properties of the surface points to the cationic mechanism of sorption. Here, only the following detail of interest should be noted: the stronger the hydrogen in the protonogenic OH group is covalently bound to oxygen (3500–3150 cm^{-1} range), the lower its reactivity toward cations [curve *3* occupies an intermediate position between the absorption curves of the starting clinoptilolite (*1*) and its modified form (*2*)]. With increasing ionic component in the bonding between hydrogen and oxygen (2700–2500 cm^{-1} range), all the protonogenic groups acquired in modification are "consumed" for sorption of lead(II) ions (curve *3* coincides with curve *1* of the starting clinoptilolite). It should also be noted that OH groups are not involved at all in cation sorption: the high-frequency wing (3800–3600 cm^{-1} range) of the absorption band of OH groups of modified clinoptilolite before sorption of lead(II) ions (curve *2*) completely coincides with that upon sorption of these ions (curve *3*).

The following should be taken into account when analyzing the reaction of the modifying agent with the surface of clinoptilolite: (a) IR data (role of basic hydroxy groups in grafting of the modifying agent); (b) the fact that titanium tetrachloride even at pH 0 is hydrolyzed in aqueous sulfuric acid solutions to give hydroxochlorides and hydroxo complexes [11], which form poorly soluble titanium hydroxophosphates in their subsequent reaction with phosphoric acid [3]; (c) elemental ratio Ti : P in the surface layer. Then this reaction can be represented as the following scheme:



where n = 0, 1, 2, and 3.

Additional sorption of cations on modified clinoptilolite is due to protons of grafted dibasic groups of phosphoric acid, with different dissociation constants [5]. The ionization of phosphoric acid groups mainly by the first step at working pH values of 6.8–7.1 predetermines the involvement of three equivalent protonogenic groups in the ion exchange.

CONCLUSIONS

(1) A new, highly efficient sorbent for heavy metal ions, with sorption characteristics exceeding those of the initial sorbent, was obtained by modifying a natural zeolite, clinoptilolite, with titanium hydroxophosphate.

(2) The results of IR studies, X-ray fluorescence spectroscopy, and sorption measurements led to a conclusion that the modification of clinoptilolite consists in grafting to its surface of titanium hydroxophosphate compounds with increased concentration of OH groups, which can exchange their protons for cations of heavy metals. It is the additional contribution of this cation exchange to the ion exchange commonly observed in natural zeolites that gives rise to improved sorption properties of modified clinoptilolite samples.

CATALYSIS

Development of a Supported Catalyst for Decomposition of Spent Sulfuric Acid

N. A. Dobrovinskaya, E. I. Dobkina, and S. M. Kuznetsova

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received May 8, 2003

Abstract—A technology for manufacture of a high-strength catalyst for decomposition of spent sulfuric acid is presented.

One of the most difficultly utilizable industrial wastes is spent sulfuric acid (SSA), which is mainly composed of H_2SO_4 and organic or inorganic impurities and water. More than one third of spent sulfuric acid is produced by oil refining and petrochemical industries.

The domestic and foreign experience demonstrates that the most efficient method for SSA utilization is thermal decomposition of sulfuric acid wastes to SO_2 in a fluidized bed of a thermally stable wear-resistant catalyst [1, 2]. This method is versatile, since it can be used to decompose SSA of various qualitative and quantitative compositions. The catalyst operation under the process conditions is affected not only by the fluidized bed mode, but also by temperature and high corrosive activity of the medium. Therefore, stringent requirements are imposed upon catalysts for SSA decomposition. This, in the first place, refers to such a constituent of the catalysts as supports.

It has been shown [2, 3] that the most effective catalysts for thermolysis of sulfuric acid are Fe_2O_3, V_2O_5, CuO, and Cr_2O_3. The activity of a catalyst is determined not only by its chemical composition, but also by the surface area accessible to reagents, i.e., by its pore structure.

It is virtually impossible to directly use metal oxides in high-temperature processes such as thermolysis of sulfuric acid. This is due to the fact that their initially not-too-large specific surface area decreases rapidly because of the agglomeration of fine particles to give coarser aggregates. As a result, the activity of such catalysts decreases in the course of time. The performance of a catalyst and its thermal stability can be raised by distributing a metal oxide over the surface of an appropriate porous support.

In [3], SiO_2 (silica gel, diatomite, Aerosil) and γ-Al_2O_3 were tested as supports for iron oxide catalysts. These supports are not inert toward decomposition of sulfuric acid. It has been demonstrated that silica gel is the most active in the process in question, apparently because of its more developed surface. For example, the activity of the Fe_2O_3 catalyst on SiO_2 is approximately 3 times that of Fe_2O_3 on γ-Al_2O_3. However, after 45 h of operation, the specific surface area of the catalyst on silica gel decreased by a factor of approximately 12, and that of the catalyst supported by aluminum oxide, by a factor of only 4. The predominant pore radius changed from 6–10 to 80–400 nm in the first catalyst, and from 8–10 to only 10–30 nm in the second. Apparently, the higher melting point of γ-Al_2O_3 results in that its microstructure changes in catalyst operation at a considerably slower rate, compared with that of silica gel, i.e., the thermal stability of γ-Al_2O_3 is higher.

It should be remembered here that phase equilibrium conditions may change in objects including small-size particles. One of manifestations of this effect is the depression of the melting point of dispersed particles, which can be described by the equation [5]

$$T = T_m(1 - 2\omega\Delta\alpha/R\theta_m), \quad (1)$$

where T_m is the melting point of a bulk sample; ω, volume per particle; $\Delta\alpha$, change in the surface energy across the interface; R, particle radius; and θ_m, heat of melting.

It follows from Eq. (1) that the smaller the particle radius, the stronger the depression of its melting point. In a real catalyst, which contains particles of various size, finer particles will undergo melting earlier, the melt will fill spaces between coarser particles, and solid–liquid agglomeration will begin [5–7].

According to Hüttig [5], the onset temperature of agglomeration is about 0.45 of the melting point:

$$T_{\text{onset aggl.}} \cong 0.45T_m. \quad (2)$$

Table 1. Parameters of aluminum oxide

Fraction, mm	ρ_{bulk}, kg m^{-3}	S_{sp}, m^2 g^{-1}	Π_{wear}, %	V_w, cm^3 g^{-1}	Na_2O	Fe_2O_3
					wt %	
1.5–2.0	640	128	0.1	0.48	0.05	0.05
0.8–1.0	710	250	0.2	0.90	0.02	0.05

To synthesize thermally stable catalysts, it is advisable to use substances whose agglomeration onset temperature exceeds the process temperature. When considering silica gel (T_m = 1725°C) and aluminum oxide (T_m = 2050°C) in this regard, preference should be given to the latter.

Thermocatalytic decomposition of SSA, and especially that in a fluidized bed, imposes specific requirements upon a catalyst to be used, with account of the very severe operation conditions (corrosive medium, high temperature, collisions and friction of grains). Therefore, it is the support and only the support that can ensure high stability of a catalyst under these conditions. Such a support should possess, in addition to the necessary macrostructure, high mechanical strength that is preserved during a long service life.

Silica gel, whose porous structure is transformed significantly, fails to meet this requirement even in the initial period of its operation. As for other alternative supports of silicate nature, such as diatomite, Aerosil [6], aluminosilicate, and zeolite [6], all of these show the same shortcomings as silica gel. Under the reaction conditions, they undergo intensive agglomeration, lose their strength, and their active component is carried away, with the resulting loss of activity. All this gives no way of considering silicate materials to be promising supports of catalysts for thermal decomposition of SSA.

As regards the strength and thermal stability of aluminum oxide, it may be stated that they depend on a variety of factors, which can be combined in a single notion of preparation conditions. These include both the synthesis of Al_2O_3 itself and its further modification to obtain the required properties.

EXPERIMENTAL

Fabrication of a support for a catalyst for SSA decomposition was based on the best, for the case in question, properties of aluminum oxide and silica gel. As starting material was taken spherical granulated γ-Al_2O_3 whose main parameters are listed in Table 1 (bulk density ρ_{bulk}; specific surface area S_{sp}; wear resistance Π_{wear}; pore volume for water V_w; content of Na_2O and Fe_2O_3 impurities).

Since aluminum oxide rapidly loses its strength in SSA decomposition under the action of water and SO_3 vapors, it was of interest to protect its surface from the influence of these factors. In this case, SiO_2 may prove to be a good modifying agent because of its chemical stability under the conditions of SSA decomposition. There have been several reports [8, 9] on the strengthening, hydrophobizing, and protective action of film coatings based on polyorganosiloxanes. Among monomeric oxygen-containing organosilicon compounds, the most widely used in practice are pure esters of orthosilicic acid, especially tetramethoxysilane and tetraethoxysiliane (TEOS). Organosilicon–aluminum compounds containing an Si–O–Al group are of particular interest, since they are models of highly stable compounds, aluminosilicates, which widely occur in the Earth's crust.

The binding of hydrophobic films to materials is a result of their interaction with the reactive groups of the surface. For example, treatment of inorganic materials that contain a surface Al–OH group with silicon-functional organic compounds yields a firmly adhering film that covers the surface being treated as a monomolecular layer. The film is so thin that it does not close even the finest pores of the material [8].

Silicon dioxide was deposited by treating the starting spherical γ-Al_2O_3 with ethyl ester of orthosilicic acid, TEOS. A weighed portion of aluminum oxide was placed in a glass reactor with a reflux condenser and a thermometer. A calculated amount of TEOS and a diluent were charged into the same reactor to liquid to solid ratio l : s = 1.15–1.20, so that aluminum oxide was completely covered with the solution. Since TEOS undergoes deep hydrolysis in water, to the point of formation of a sol of silicic acid, ethanol, which can be mixed with TEOS in any ratio, was used as diluent. The presence of a solvent favored more uniform deposition of SiO_2 onto the support surface. The filled reactor was heated on a sand bath to 80–

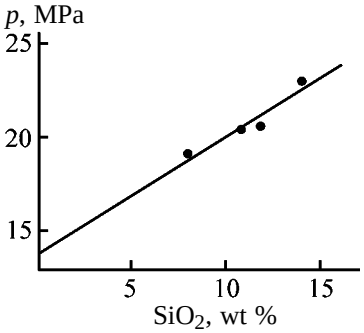

Fig. 1. Crushing strength *P* of a support calcined in an air flow vs. the amount of deposited modifying agent SiO_2.

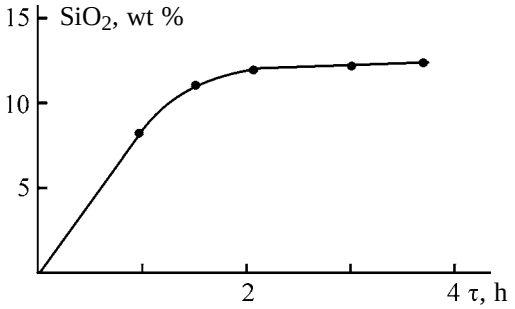

Fig. 2. Amount of deposited SiO_2 vs. the treatment duration τ.

85°C and kept at this temperature for 1–3 h. After the siliconizing was over, the support was discharged and dried at room temperature in the course of 8–10 h. The dried support contained in its pores a small amount of diethyl ether, which was completely burned out in the subsequent calcination of the sample in an air flow at 500–550°C.

The necessary amount of TEOS was approximately determined with account of the amount of SiO_2 (%) to be deposited:

$$V_{TEOS} = m_{SiO_2}/m_{AlO_3}$$

$$= m_{SiO_2} M_{TEOS} G_{Al_2O_3}/(100 - m_{SiO_2}) M_{SiO_2} \rho_{TEOS}, \quad (3)$$

where V_{TEOS} is the calculated volume of TEOS (ml); m_{SiO_2} and $m_{Al_2O_3}$, amounts of substances (%); M_{TEOS} and M_{SiO_2}, molecular masses of TEOS and silicon dioxide; $G_{Al_2O_3}$, weighed portion of aluminum oxide (g); and ρ_{TEOS}, TEOS density (g cm^{-3}).

To determine the amount of the actually deposited SiO_2, siliconized samples were subjected to chemical analysis. To find the optimal amount of the modifying agent, a set of γ-Al_2O_3 samples with varied content of SiO_2 was prepared. Tests demonstrated that modification markedly improves the strength characteristics of the support, with its crushing strength increasing virtually in direct proportion to the amount of the modifying agent deposited (Fig. 1). It was found that, in the case of calcination of samples treated with TEOS in a muffle furnace, their strength is 2–3 MPa lower than that in calcination at the same temperature in an air flow.

This can be explained by taking into account the fact that the ether is oxidized with an increase in volume. In calcination in an air flow, most part of the ether, which is highly volatile, is carried away from its pores at the very beginning of heating, when the oxidation rate of the ether is low and its combustion actually occurs outside a support grain. In the case of the "stagnant" zone of a muffle furnace, some part of diethyl ether has enough time to be oxidized directly within the support pores. The products formed in the process exert a disjoining effect on its structure, so that some contacts of the structure disintegrate and the strength of the support decreases. Thus, to obtain catalysts with the highest strength, it is advisable to use supports calcined in an air flow. The results of experiments demonstrated that it is impossible to deposit more than 16–18 wt % SiO_2 by the procedure suggested. Attempts to raise the content of SiO_2 by longer treatment of aluminum oxide with TEOS failed to produce any significant results. As seen from Fig. 2, the greatest amount of SiO_2 is deposited in the first 1.5–2 h of treatment. Extending the duration of siliconizing to 3–3.5 h made it only possible to deposit additional ~0.5 wt % SiO_2.

Originally, this fact was attributed to the possible consumption of the whole amount of TEOS. Therefore, one of samples was subjected to three successive treatments (for 1.5 h each), every time in a fresh TEOS solution in ethanol.

This method made it possible to raise the content of SiO_2 in the sample to a somewhat greater extent than in the case of a longer single treatment. However, in this case also, the gain was too small in relation to expenditure. For example, the first siliconizing run produced 11 wt % SiO_2 on the Al_2O_3 surface, whereas the contributions of the second and third runs were only 3.3 and 1.9 wt % SiO_2, respectively.

The limitations on the amount of deposited SiO_2 can only be attributed to the presence on the surface of Al_2O_3 of a limited number of functional groups that can react with TEOS by the molecular layer deposition mechanism [10]. A certain increase in the content of SiO_2 upon several successive siliconizing runs can be accounted for by the fact that, after all the available surface OH groups are spent, there remains

a fraction of unshielded Al_2O_3 surface containing aluminum ions with unsaturated coordination. These ions are Lewis acid centers [1]. Thus, the limit on the amount of SiO_2 directly bound to the Al_2O_3 surface depends on specific features of the surface of aluminum oxide, which, in turn, is a function of process parameters of Al_2O_3 synthesis.

A study of the silicon distribution in a siliconized sample by X-ray fluorescence microanalysis demonstrated that this distribution is uniform across the entire grain. Figure 3 shows typical concentration profiles of aluminum and silicon along the grain diameter, obtained with an electron-beam microprobe.

However, this method tells nothing about how silicon is distributed with respect to the Al_2O_3 phase. Comparison of the concentration ratios c_{Si}/c_{Al} of silicon and aluminum, calculated using results of chemical analysis and data on elemental composition, furnished by X-ray photoelectron spectroscopy (XPS), confirms the surface distribution of silicon on Al_2O_3 (Table 2).

The XPS technique yields information about the qualitative and quantitative elemental composition of the surface layer (with thickness of several nanometers, usually 2–5 nm) of the sample, whereas the conventional chemical analysis determines the content of an element related to the whole bulk of the sample under study. The clearly overestimated XPS data, compared with the results of chemical analysis (Table 2), suggest that silicon is concentrated just in the surface layer of the sample. This fact, in combination with the data of X-ray fluorescence spectroscopy (Fig. 3), demonstrates that silicon is rather uniformly distributed over the entire external and internal surface of Al_2O_3.

The whole body of the data obtained suggests that the increase in the sample strength is due to strengthening of a number of individual contacts via deposition of SiO_2 at connection points of grains with Al_2O_3.

To make a final choice of a support, catalysts were synthesized both on the initial and on the siliconized γ-Al_2O_3. Iron and copper oxides were used as active components of the catalyst for SSA decomposition.

The catalysts for carrying out this process in a fluidized bed were prepared by impregnating a support with solutions of salts of the active components at 90°C in the course of 3 h with intermittent agitation. The liquid to solid phase ratio was taken to be 1.5. The samples obtained after the impregnation and separation of the solid phase from the liquid were dried at 110°C and then calcined at 700–800°C for 3 h. The calcination temperature was chosen with account of the working temperature of the catalyst.

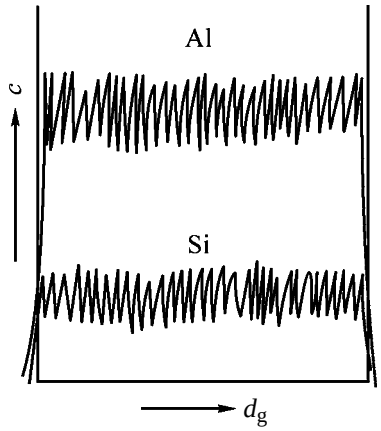

Fig. 3. Aluminum and silicon concentration profiles c along the diameter d_g of a siliconized support grain.

It is known that finely grained catalysts should be used to obtain an effective fluidized bed. The experience of numerous researchers shows that, with a catalyst supported by 0.8–1.0-mm Al_2O_3 fraction, thermal decomposition of SSA is kinetically controlled. Since virtually the entire surface of the catalyst works in this case, its composition should be uniform across the whole grain to improve its performance to the maximum possible extent. Such a uniformity is also important in connection with the abradability of the catalyst in the fluidized bed. Therefore, it is important to reveal how the distribution of active components is affected by siliconizing.

To determine the influence exerted by the support and method of its impregnation on the distribution of the active components in a catalyst grain, two sets of samples were fabricated: set 1 on the starting γ-Al_2O_3 and set 2 on siliconized γ-Al_2O_3. In both sets, aqueous solutions of iron and copper nitrates, $Fe(NO_3)_3 \cdot 9H_2O$ and $Cu(NO_3)_2 \cdot 3H_2O$, with concentrations of 150 and 100 g l^{-1}, respectively, were used as impregnating media. The methods of impregnation

Table 2. Content of silicon in siliconized aluminum oxide

Sample no.	c_{Si}/c_{Al} ratio	
	surface	bulk

2	0.42	0.17

Table 3. Methods of impregnation and content of active components, CuO and Fe_2O_3, in catalyst samples

Set 1, support γ-Al_2O_3			Order of impregnation	Set 2, support γ-Al_2O_3 + 15 wt % SiO_2		
sample no.	CuO	Fe_2O_3		sample no.	CuO	Fe_2O_3
	wt %				wt %	
1-1	5.42	–	$Cu(NO_3)_2$	2-1	5.40	–
1-2	–	5.85	$Fe(NO_3)_3$	2-2	–	5.00
1-3	2.82	5.30	Simultaneously from a solution of $Fe(NO_3)_3$ and $Cu(NO_3)_2$	2-3	3.46	4.15
1-4	4.17	5.63	Successively (1) $Fe(NO_3)_3$, (2) $Cu(NO_3)_2$	2-4	4.20	4.86
1-5	5.36	4.23	Successively (1) $Cu(NO_3)_2$, (2) $Fe(NO_3)_3$	2-5	5.32	3.71

and the results of a chemical analysis of the samples obtained are listed in Table 3.

Measurements of the strength of the samples obtained demonstrated that it corresponds to the strength of the supports used, being equal to 13.0–14.2 MPa for samples of set 1 and 20.5–22.0 MPa for samples of set 2.

The results of chemical analyses are very close for the samples of both sets and give no way of making choice in favor of one of the two supports. However, a study of these samples revealed the following remarkable pattern. The distribution of copper in catalysts 1-1 and 2-1 is virtually uniform across a grain of each of the supports, whereas the concentration profiles of iron along the grain diameter are strongly different in samples 1-2 and 2-2 (Fig. 4). In "pure" γ-Al_2O_3, this distribution is of typical "crust" nature, whereas in the siliconized sample it is nearly uniform. The same characteristic features are observed for the distribution of active components in binary catalysts (Fig. 5).

The nonuniform distribution of iron is, in contrast to that of copper in pure γ-Al_2O_3, a consequence of the ability of iron(III) hydroxide, which appears in the impregnating solution through hydrolysis of $Fe(NO_3)_3$, to form a colloid system. In this case, the size of aggregates of $Fe(OH)_3$ sol particles is in the range 1–100 nm [12]. If account is taken of the fact that the predominant pore radius of the Al_2O_3 used is

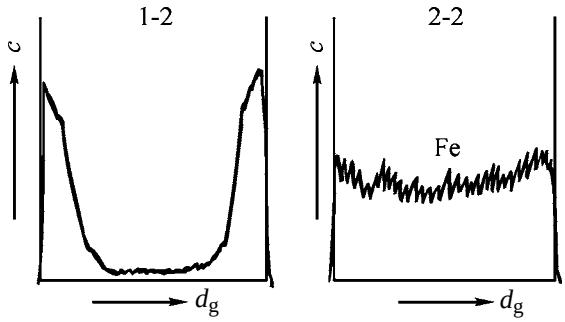

Fig. 4. Iron concentration profiles c along catalyst grain diameter d_g (Table 3).

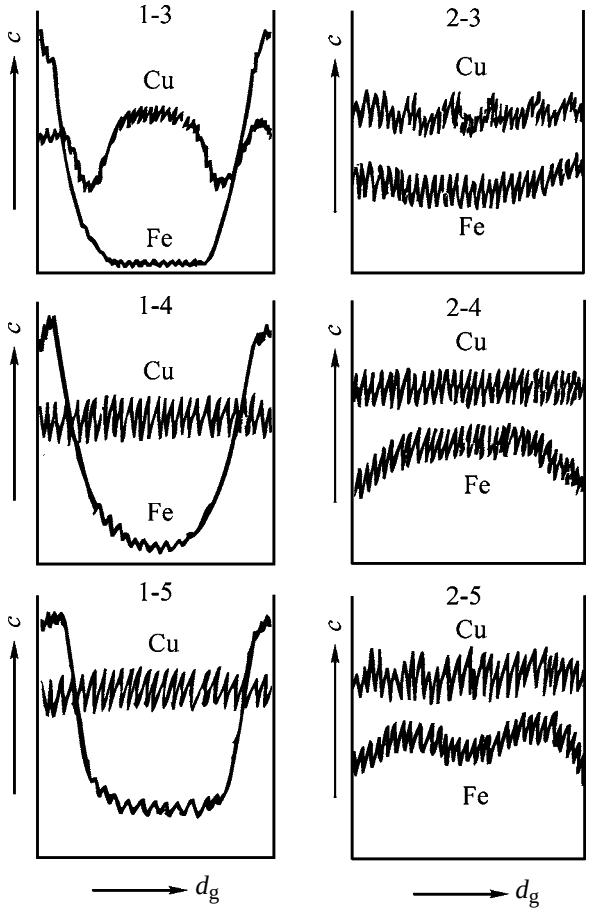

Fig. 5. Iron and copper concentration profiles c along catalyst grain diameter d_g (Table 3).

6–10 nm, it becomes understandable why iron hydroxide cannot penetrate inside a grain. The finest colloid particles penetrate into the accessible pores and block the way for other, coarser particles. The situation is aggravated by a sol–gel transition that occurs as a result of heating in the course of impregnation. In this case, the main part of $Fe(OH)_3$ deposited is concentrated in the surface layer of grains in the form of a ring (Fig. 4, sample 1-2). If the impregnating $Fe(NO_3)_3$ solution is sufficiently concentrated, a thick layer of $Fe(OH)_3$ is accumulated on the outer surface of a support grain. In thermal treatment of the sample, this layer is converted to an Fe_2O_3 layer which is poorly bound to the substrate and is easily lost even in charging into apparatus, not to mention the operation in a fluidized bed.

In the case of binary samples fabricated by impregnation with a solution that contains two salts simultaneously, formation of coarse colloid particles of $Fe(OH)_3$ hinders uniform distribution of copper (Fig. 5, sample 1-3). In this case, the total content of CuO in sample 1-3 is lower than that in samples 1-1, 1-4, and 1-5 (Table 3), in which the copper compound is deposited from solutions that contain no other cations. If a support is first impregnated with an $Fe(NO_3)_3$ solution and calcined, after which copper(II) nitrate is deposited, then, in the absence of $Fe(OH)_3$, copper is distributed uniformly (Fig. 5, sample 1-4), as in the case of a "pure" support. If impregnations are performed in reverse order, the iron concentration profile changes somewhat (Fig. 5, sample 1-5), but its distribution is still far from being uniform.

To obtain a uniform distribution of iron, it is, apparently, necessary to preclude formation of a colloid solution, i.e., to suppress hydrolysis occurring by the reaction

$$Fe(NO_3)_3 + H_2O = Fe(OH)_3 + HNO_3.$$

This equilibrium can be shifted to the left by introducing a strong acid into the reaction zone. However, this may exert disintegrating influence on aluminum and thereby impair its strength. The problem was resolved by siliconization of the support.

An IR study of pyridine adsorption onto the surface of pure and siliconized γ-Al_2O_3 made it possible to establish the nature of acid centers present on the surface. Only Lewis acid centers are present on the surface of Al_2O_3. Siliconizing leads to appearance of additional Brønsted centers, whose amount is the greater, the larger amount of SiO_2 is bound to the surface of Al_2O_3.

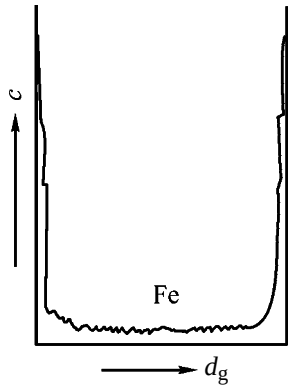

Fig. 6. Iron concentration profile c along the diameter d_g of α-Al_2O_3 grain.

Comparison of the iron concentration profiles in catalysts based on pure and siliconized γ-Al_2O_3 (Figs. 4 and 5) suggests that it is the presence of Brønsted acid centers on the support surface in samples of set 2 that is responsible for the uniform distribution of iron across a grain.

This conclusion is confirmed by the iron distribution on porous corundum α-Al_2O_3 (Fig. 6). The corundum was obtained by calcination of the starting γ-Al_2O_3 at 1300°C for 3 h. Similarly to pure γ-Al_2O_3, α-Al_2O_3 has no Brønsted acidity. Of interest is the fact that, despite the very large pore size in this sample (100–1000 nm), only trace amounts of iron can be introduced inside its grains in the form of a thin concentrated ring on the grain surface. Such a distribution of iron is favored by the visually observed process of coagulation of the $Fe(NO_3)_3$ sol, which occurs in α-Al_2O_3 impregnation with exceedingly high intensity and leads to clogging of even so coarse pores.

In impregnation of siliconized γ-Al_2O_3, nothing, apparently, prevents the occurrence of $Fe(OH)_3$ hydrolysis in the bulk of the impregnating solution. However, the forming $Fe(OH)_3$ aggregates approach the surface exhibiting a Brønsted acidity and experience there its peptizing effect. In this case, coarse colloid particles of $Fe(OH)_3$ disintegrate into finer particles, which freely penetrate into the support pores.

Thus, the advantage of siliconized γ-Al_2O_3 over a pure support is not limited to an increase in mechanical strength. One more important advantage is that active components can be uniformly deposited throughout the catalyst grains.

To find the optimal impregnation method, kinetic characteristics of the catalysts of set 2 were studied on

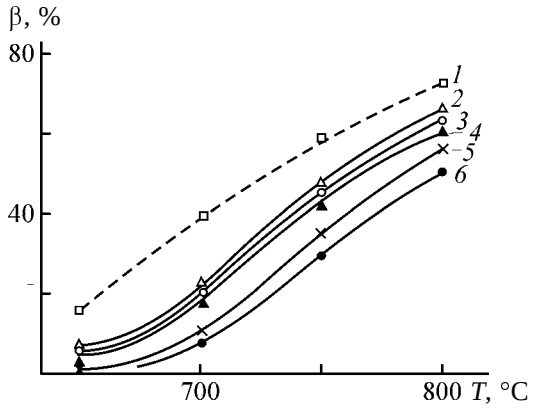

Fig. 7. Degree β of sulfur trioxide SO_3 decomposition on various catalysts vs. temperature *T*. Catalyst: (*1*) platinum, (*2*) 2-3, (*3*) 2-4, (*4*) 2-1, (*5*) 2-5, and (*6*) 2-2 (Table 3).

a laboratory installation in a process that models the thermocatalytic decomposition of SSA. The results obtained are presented in Fig. 7. For comparison, the activity of a platinum catalyst is shown in the same figure.

As for single-component samples, contrary to the existing opinion, the catalyst based on copper oxide much exceeded in activity the iron oxide catalyst (Fig. 7, samples 2-1 and 2-2).

Among the binary catalysts, the highest activity was observed for sample 2-3 fabricated by simultaneous impregnation with a solution of salts of both metals. Catalysts 2-4 and 2-5, which contain an even greater amount of active components than sample 2-3 (Table 3) and are characterized by a similar distribution of these components across a grain (Fig. 5), but were fabricated by successive impregnation have lower activity than catalyst 2-3 (Fig. 7, samples 2-3, 2-4, and 2-5).

An XPS study of the samples demonstrated that the active components are formed in the form of copper ferrite, with a minor amount of free oxides CuO and Fe_2O_3.

The enhanced activity of ferrites, compared with that of individual oxides, is known [6]. Taking into account this fact, it can be assumed that the highest activity of sample 2-3 is due to the existence of the optimal conditions for formation of the copper ferrite phase in simultaneous impregnation of the support with a solution of two salts.

CONCLUSIONS

(1) A catalyst for utilization of spent sulfuric acid with low content of organic impurities was developed. It was established that it is advisable to use copper and iron oxides supported by siliconized γ-Al_2O_3 as active components.

(2) Electron microprobe analysis was applied to study the distribution of the active components in a catalyst grain.

(3) The optimal method for depositing active components consists in simultaneous impregnation of a support with a solution of iron and copper salts. In this case, copper ferrite, which exhibits enhanced catalytic activity, is formed in the final stage of catalyst fabrication, its calcination.

Abstract—The procedure for cleaning polycrystalline fibers of electrolytic silver used as a catalyst for gas-phase oxidation of ethylene glycol to glyoxal was developed with the aid of X-ray photoelectron spectroscopy.

Unsupported compact metals are used as catalysts of some important industrial reactions. The typical feature of the catalytic reactions performed under rigid conditions is segregation of impurities on the catalyst surface. These impurities can partially or completely poison the catalyst. As a result, the behavior of the catalytic system at varied external parameters (temperature and pressure of reactants) becomes irreproducible. As a rule, the catalyst is contaminated by the impurities contained in the initial material used for the catalyst production or by impurities introduced in the course of the catalyst production. The problem of the surface cleanness arises for both pilot and industrial catalysts. Measurements of physicochemical properties of contaminated compounds can be incorrect. Purification of these samples under rigorous conditions (calcination, etching, etc.) can also make their properties worse.

Silver is one of widely used metallic catalysts for preparing ethylene oxide [1], formaldehyde, acetaldehyde, and glyoxal [2] by heterogeneous oxidation. Practically important vapor-phase oxidation of ethylene glycol into glyoxal is catalyzed by both compact and supported silver [3].

The best catalyst for glyoxal synthesis is polycrystalline silver fiber prepared by electrolysis of a silver chloride melt [4]. This catalyst has a unique nano- and microstructure stable to reactive chemical media at 800–900 K. The results of the study of these silver catalysts prepared by the electrolytic procedure make a great contribution to the theory of heterogeneous catalysis with metals. Fibrous silver catalysts should be free of process and other impurities. However, investigation of their surfcae by surface-sensitive methods shows the presence of various impurities.

In this work, the states of surface atoms and the chemical composition of the surface of silver fiber samples taken in different steps of their preparation, purification, and application as catalysts were studied by X-ray photoelectron spectroscopy (XPS). Based on the experimental data, a nondestructive procedure for cleaning the surface of silver crystals with preservation of their morphological and structural features was proposed. As determined by XPS, the surface of the silver catalyst treated under actual catalytic conditions is almost free of impurities.

EXPERIMENTAL

Filamentary silver crystals were prepared by electrolysis of an $AgNO_3$ melt in an open electrolysis bath with a rotating cathode (T = 543–560 K, 32–34 wt % $AgNO_3$ in a KNO_3–$NaNO_3$ melt) [4]. A scanning electron microscopic (SEM) study shows that these samples consist of silver needles with a smooth surface (Fig. 1), which are formed by topochemical processes occurring in the course of electrolysis of the melt of metal nitrates. Silver crystals formed under these conditions have a developed dendrite structure with a great number of surface defects [4].

The chemical composition of the surface of silver catalyst was studied by XPS using a VG ESCALAB spectrometer. The spectra were recorded by the procedure described in detail in [5–7].

Electrons were emitted from the samples under the action of soft AlK_α X-ray radiation. The free path of the electrons λ was in the range 20–30 Å depending on their energy, which allowed the study of the sample surface to a depth of 3λ, i.e., 60–90 Å.

The samples were fixed in air in a holder with a

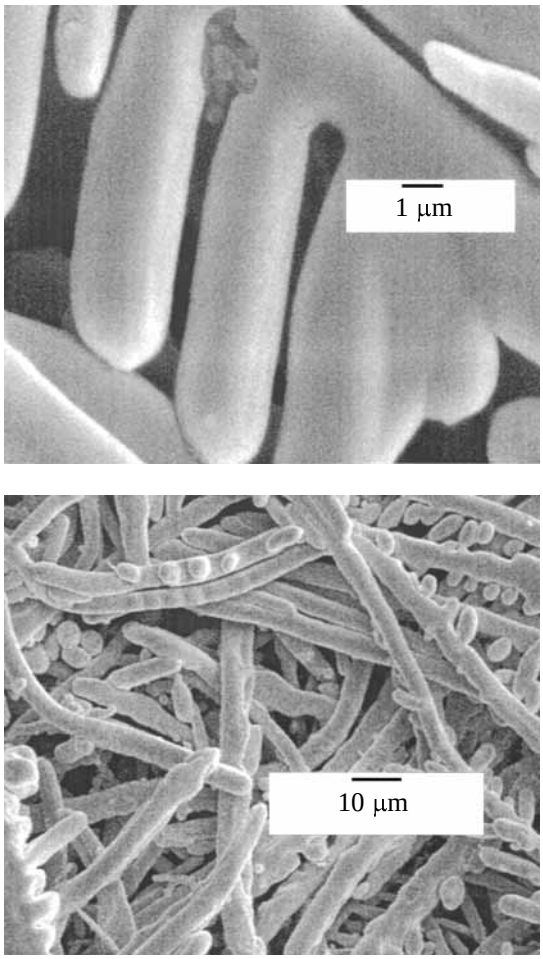

Fig. 1. Surface morphology of silver crystals prepared by electrolysis of $AgNO_3$ melt (SEM pattern).

conducting two-side scotch tape stable in a vacuum. Prior to recording XPS spectra, the samples were evacuated in a pretreatment chamber to a residual pressure of $P = 10^{-2}$ mPa. Then they were moved into the analyzer chamber and evacuated to the residual pressure of about 10^{-4} mPa. The main background gases were CO, CO_2, and H_2O.

The spectral data were treated with the aid of the conventional graphical packages and CALC special original software. To estimate the chemical composition quantitatively, the precision spectra of the most intense bands of the elements were recorded. The concentration ratio of the elements in the samples was determined from the integral intensities of the bands of definite atomic levels, taking into account the tabulated empirical factors of atomic sensitivities [8].

Silver samples (2 cm catalyst bed) were treated in a flow catalytic reactor with a mixture of EG (ethylene glycol), O_2, N_2, and H_2O in different molar ratios. The reactor made from stainless steel tube 15 cm long and 2 cm in diameter was connected with a contact condenser arranged below the catalyst bed. The reaction products were analyzed chromatographically [9].

The total XPS spectra of one of the silver fiber samples is shown in Figs. 2*I*a, and the detailed spectra, in Figs. 2*I*b and 2*I*c. The spectrum of the initial sample prepared by the electrolytic procedure contains the bands of bismuth, zinc, chlorine, and copper impurities along with the major bands of silver, carbon, and oxygen.

Carbon and oxygen are present in all the silver samples and are not considered as impurities for catalytic oxidation of organic molecules. Chlorine can be removed by preliminary heating of the catalyst in an oxygen atmosphere, or it disappears in the course of the catalytic process. Other impurities, Bi, Cu, and Zn, cannot be removed by the redox treatment. In the course of the catalytic processes, their concentration on the silver surface increases owing to diffusion of these elements from the bulk of the catalyst (Fig. 2*I*, curve *2*). In addition, sodium appears on the catalyst surface.

The concentration ratios of these elements were determined by XPS assuming that they are uniformly distributed in the catalyst (Table 1). As seen from Table 1, these ratios are relatively high. It should be noted that the metal impurities are accumulated on the silver surface owing to their segregation and under the action of the oxidative media promoting capture of metal atoms and their oxidation. As a result, the impurity/silver concentration ratio on the surface increases by a factor of 5–6. Thus, as seen from Table 1, large area of the surface of the initial samples is coated by impurity metals. In the course of the catalytic reaction, almost the whole surface can be coated with these impurities, and the catalyst can be partially and completely deactivated.

Thus, effective cleaning of the crystal surface with preservation of the unique morphological and defective structure of silver fiber is an urgent problem. In this case, etching of the surface with nitric acid does not furnish the desired result, since the impurities are present not only on the surface but also in the bulk of the sample.

To remove impurities from the sample, we treated its surface with hydrofluoric acid. This acid does not react with silver and selectively dissolves the impurities. The treatment was performed as follows.

(1) Filamentary silver crystals are sintered with an organic filler at 923 K for 3 h in an air flow to form

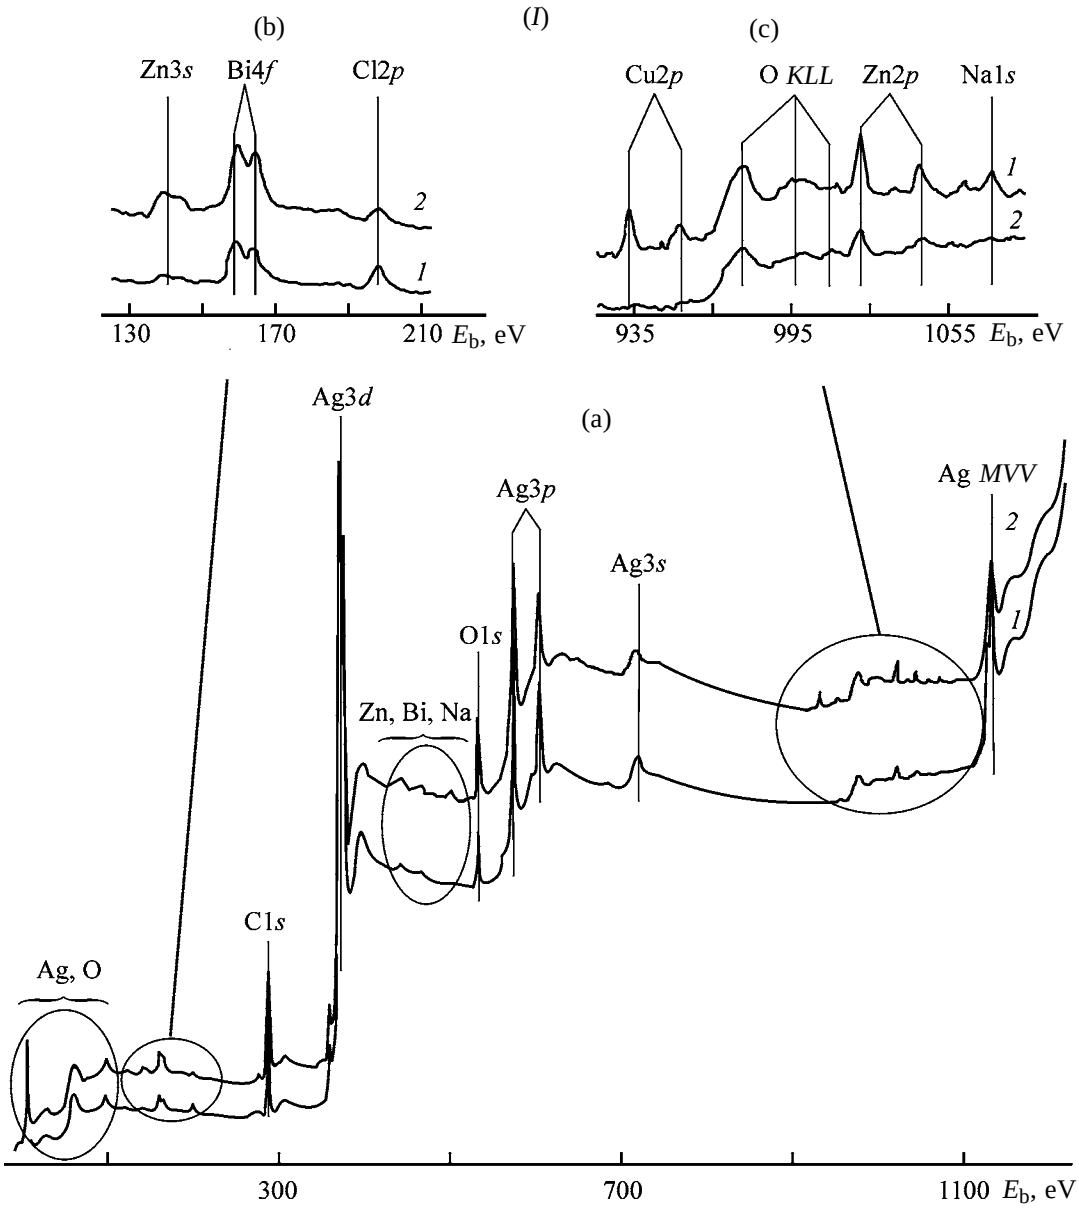

Fig. 2. (a) Total XPS recorded and (b, c) fragments of these spectra containing characteristic bands of the surface impurities. (E_b) Binding energy. (*I*) (*1*) initial silver crystals and (*2*) silver treated with an $O_2 : N_2 : EG : H_2O = 1.0 : 10.0 : 1.0 : 3.4$ reaction mixture; (*II*) (*1*) initial silver crystals, (*2*) silver surface treated with hydrofluoric acid (40 wt %, 1 h, $T = 353$ K), and (*3*) silver treated with HF and then $O_2 : N_2 : EG : H_2O = 1.0 : 10.0 : 1.0 : 3.4$ reaction mixture.

granules of equal size. As noted above, on heating, the impurities are segregated on the catalyst surface, which favors their more complete removal from the sample.

(2) Granulated silver catalyst is treated with 40% aqueous HF at 353 K for 1 h with continuous stirring.

(3) The cleaned catalyst is washed with double-distilled water and calcined at 873 K for 3 h.

We used various acids (HCl, CH_3COOH, and HF) to remove the metal impurities. All the examined acids remove Zn and Cu. However, appreciable amount of Bi is present on the surface after treatment with HCl and CH_3COOH (Table 1). In addition, the content of sodium atoms (common impurity in HCl) and chlorine increases after the treatment with hydrochloric acid probably owing to formation of difficulty soluble AgCl.

Treatment with hydrofluoric acid meets to the greatest extent the requirements to silver cleaning. The

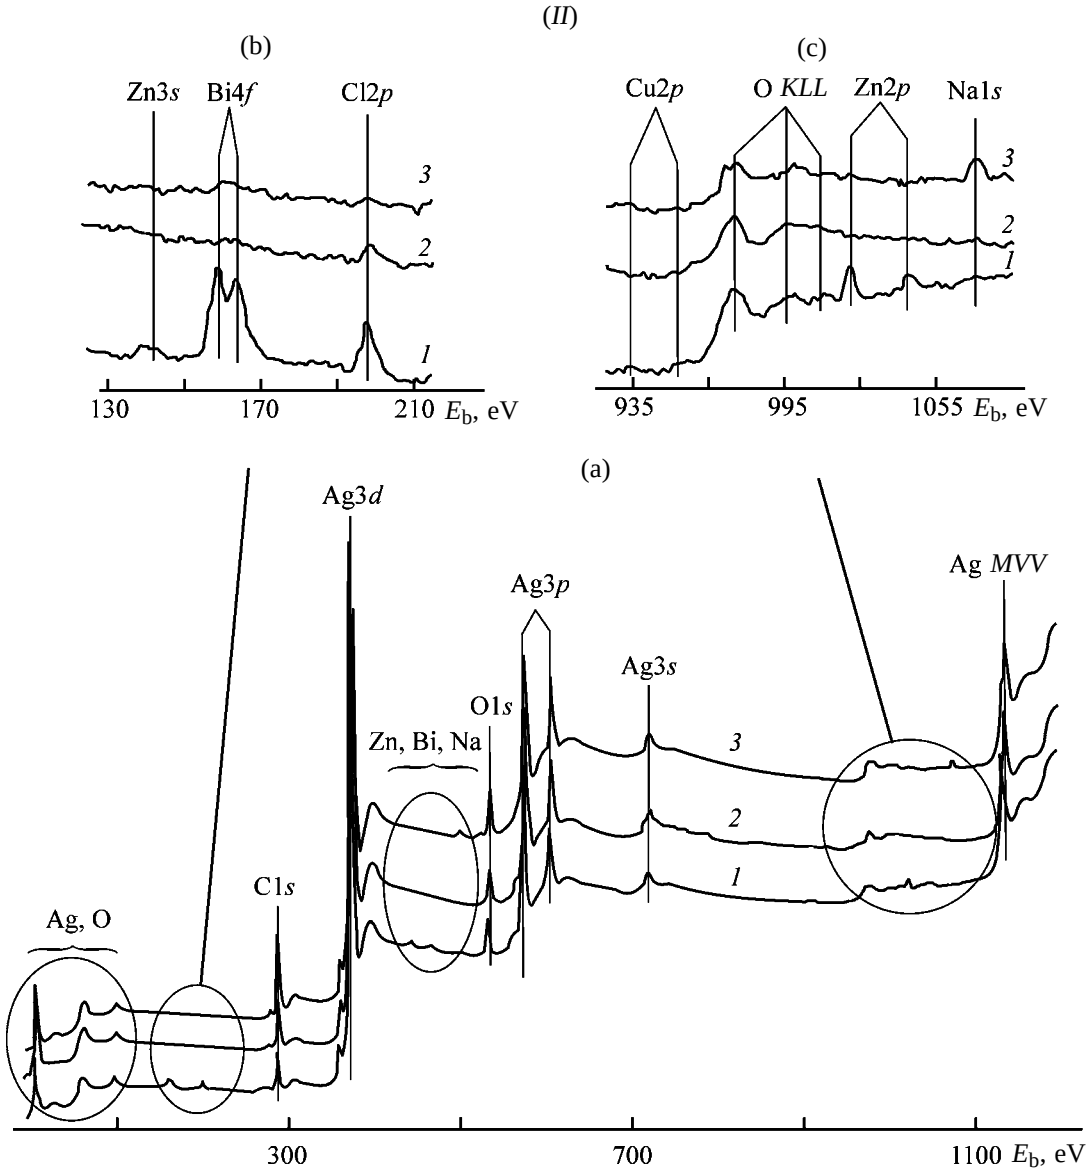

Fig. 2. (Contd.)

Table 1. Relative atomic concentrations of elements on the surface of fibrous silver

Silver sample	Relative atomic concentration*						
	Bi	Cl	C	O	Cu	Zn	Na
Initial	0.10	0.25	1.26	0.59	0.00	0.11	0.00

Treated with the reaction mixture after cleaning the surface	0.00	0.00	2.6	0.64	0.00	0.00	0.10

* Per silver atom.

Table 2. Main parameters of partial oxidation of ethylene glycol to glyoxal in the presence of cleaned fibrous silver

T, K	EG : O_2 : N_2 : H_2O molar ratio	EG conversion, %	Selectivity of glyoxal formation, %
227	1.0 : 1.0 : 10.0:3.4	81.4	49.9
277	1.0 : 1.0 : 0.0 : 3.4	89.3	62.8
227	1.0 : 1.12 : 30.0 : 5.2	87.7	38.65
277	1.0 : 1.12 : 30.0 : 5.2	89.0	58.7

XPS spectrum recorded in a wider energy range after the treatment with hydrofluoric acid (Fig. 2*II*, curve *1*) contains neither fluorine bands nor bands of new impurity elements. The bands of zinc and bismuth virtually completely disappeared after the treatment. As seen from the XPS spectra (Fig. 2*II*), the impurities of the above elements were not accumulated on the surface of the treated sample after its use as a catalyst of vapor-phase oxidation of ethylene glycol (723–923 K, 4–5 h).

The activity and selectivity of cleaned fibrous silver catalysts (Table 2) are high and are comparable with those reported in [10].

CONCLUSION

Precision analysis of the chemical composition of the surface of compact silver catalysts was performed by surface-sensitive X-ray photoelectron spectroscopy. A number of impurity elements were detected. To remove these impurities, the procedure involving treatment with hydrofluoric acid and preserving the unique defective and morphological structure of filament silver crystals was developed. The cleaned catalysts are thermally stable and exhibit high activity and selectivity in glyoxal synthesis.

Received July 21, 2003

Abstract—Effect of mechanical treatment of peat on the yield of the major fractions (polysaccharides, polyphenols, water-soluble compounds, and humic acids) and catalytic activity of humic substances in oxidation processes is studied. Conditions of formation of substances with the maximal antioxidant and initiating activities are determined. The antioxidant and initiating activities of the polysaccharide and humic fractions is studied, in relation to the structure and iron content.

Humic substances obtained from peat, coals, and sapropel are bioactive. Their physiological action is associated with the effect on the photosynthesis and oxygen, protein, and carbohydrate exchange kinetics [1, 2]. Attempts were made to link the bioactivity of humic substances to their reactivity toward free radicals and also to their structural features, e.g., the hydrophilic to hydrophobic group ratio in humic acid macromolecules [3]. However, results obtained by various authors are not always consistent, most likely, because of an inhomogeneity of the chemical composition of preparations studied, which depends on the starting raw material and preparation, isolation, purification, and bioactivity characterization procedures.

It is clear that study and application of bioactive humic compounds cannon be realized without solving such problems as recovery of humic substances from raw materials, their separation into fractions, and physicochemical characterization. One of the most efficient methods for preparation of humic substances at the maximal yield of water-soluble fractions is mechanical activation of peat in the presence of chemicals. The composition of the resulting products with respect to the major classes of bioactive agents depends on the mechanochemical conditions [4]. The catalytic properties of the products may be characterized using oxygen electroreduction. The inhibiting activity of a compound in this reaction can be considered as a measure of such a performance characteristic as the antioxidant activity, which is important in view of application of the compound as a protector against oxidative degradation of polymers, asphaltization of fuel, rancidity of fats, and, maybe, aging of living organisms and tumorogenesis. The activity of growth stimulants depends on their ability to initiate oxidation. Expansion of the spectrum of compounds used as inhibitors of promoters of oxidation is a topical scientific and practical problem.

In this work we studied the catalytic effect of humic substances obtained using mechanochemical activation on oxygen electroreduction.

EXPERIMENTAL

Humic substances were extracted from two kinds of peat collected from the Tomsk oblast: valley wood peat of the Tagansk deposit (degree of degradation 5%; ash content 3.7%) and high-moor dust peat of the Temnoe deposit (ash content 25.5%). Effect of the mechanochemical treatment procedure on the composition and properties of the resulting humic substances was studied using a VTsM-10 flow planetary mill activator with 10-mm steel balls developed by the Institute of Solid State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk. The ball acceleration was 180 $m\ s^{-2}$ and treatment time, 2 min. The samples studied in this work were as follows. Sample nos. 1, 6: initial peat; nos. 2, 7: peat mechanically activated (dispersed) in the absence of chemicals; nos. 3, 8: peat mechanically activated in the presence of the cellulolytic enzyme celloviridine (CV) (0.5%); nos. 4, 9: peat mechanically activated in the presence of 3% NaOH; and nos. 5, 10: peat mechanically activated in the presence of 3% NaOH + 0.5% CV.

From the initial and activated peat samples we extracted water-soluble compounds (WS), polysaccharides, polyphenols, and humic acids (HA). Chemical transformations in the separated HA fractions were monitored by ^{13}C NMR. Metals were determined by X-ray fluorescence spectroscopy.

The catalytic activity of the fractions with respect to oxygen electroreduction was determined voltammetrically [5]. Current-voltage curves were obtained over the voltage range 0–2.0 V on a polarograph in alkaline solutions at pH 10–12 (direct-current or differential pulse voltammetry mode; scan rate 20 mV s^{-1}). To determine the initial peak current of oxygen, corresponding to its solubility in a given solvent, we measured the voltammogram of the supporting electrolyte in the absence of a humic substance. Then the electrolyte was purged with an inert gas under pressure to remove oxygen from the solution, and the voltammogram of the supporting electrolyte was registered in the absence of oxygen in the solution. A solution containing a humic substance was added to a fresh portion of the electrolyte, and the proportional change in the oxygen electroreduction current was measured. The differential pulse voltammetry allows determination of the concentration at a level of 10^{-6}–10^{-7} mg l^{-1} to within 10%.

Mechanical activation in a planetary mill alters the content, physicochemical properties, and reactivity of the major components of peat. The degree of the observed transformations and their trends depend on the botanical type of peat and activation conditions. The yields of humic components at various mechanical activation conditions are given in Table 1. Analysis of the group composition of the initial and activated peat samples revealed that, irrespective of the type of peat and activation conditions, the content of water-soluble compounds increases by a factor of 6–15. Similar trends were observed also in the yield of humic acids from various types of peat: mechanical activation in the absence of the reagent increases and the reaction with NaOH decreases the HA content.

The carbohydrate and polyphenol fractions and humic acids representing polyconjugated systems with a wide spectrum of functional groups [4] are expected to be highly reactive. Being introduced in the model system, they act as initiators or inhibitors, changing the oxygen electroreduction rate. The direction of oxygen electroreduction depends on pH, metal salts, structural features of the components, and intermolecular interactions between them.

We plotted the difference of the oxygen reduction current density $I/(I_{lim} - I_{res})$ as a function of the concentration of a humic component in the solution. The resulting curves (Fig. 1) mostly consist of two sections corresponding to groups of different activity. The activity factors of these groups K_1 and K_2 can be evaluated from the slopes of the corresponding sections:

$$K = \frac{\Delta I/(I_{lim} - I_{res})}{\Delta c},$$

where ΔI is the difference of the running oxygen reduction current density with addition of an organic additive; I_{lim}, limiting oxygen reduction current in the absence of additives; I_{res}, residual current in the deoxygenated solution at a constant potential; and Δc, difference of the organic additive concentration.

The results show that the polyphenol, polysaccharide, WS, and HA fractions differently affect the cath-

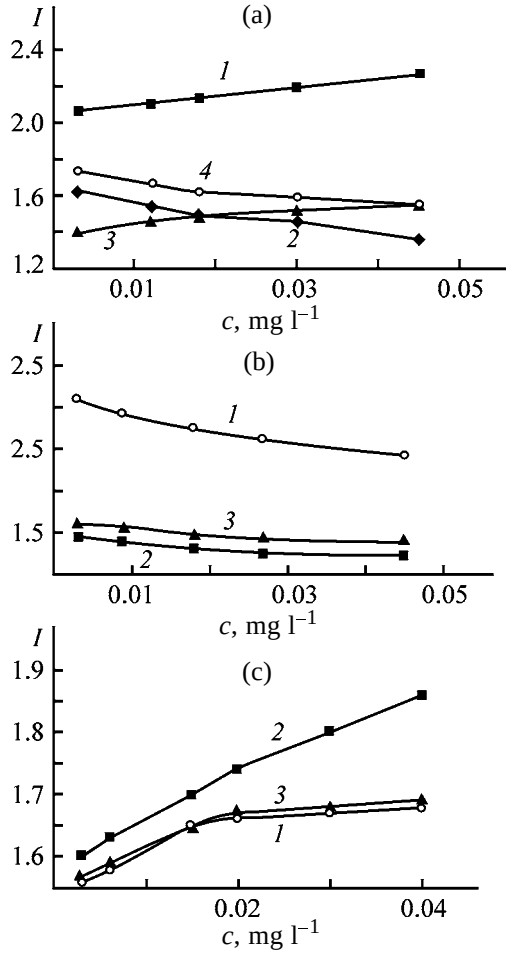

Fig. 1. Current density I of oxygen reduction as a function of the concentration c of (a) polysaccharides, (b) polyphenols, and (c) humic acids. Samples: (*1*) initial, (*2*) dispersed (mechanically activated in the absence of reagents), (*3*) activated in the presence of celloviridine, and (*4*) initial sample of polysaccharides treated with EDTA.

odic current. The polysaccharide fractions separated from the initial peat and that treated with NaOH (Fig. 1a, curves *1*, *3*) and all the HA fractions (Fig. 1c) increase the reduction current, while the polyphenol (Fig. 1b) and WS fractions decrease it. The initiating and inhibiting effects are most clearly pronounced at the humic fraction concentration of 0.01–0.02 mg l^{-1}. The cathodic current decreases with increasing c. Evidently, at low c, the degree of association of humic substances is low, and free active group can contribute to redox reactions.

The catalytic activity factors of humic components separated from the initial and mechanically activated peat samples are given in Table 2. For polysaccharides, activation increases the K values. Among the fractions separated from the initial samples, the maximal initiating activity is observed in polysaccharides from valley peat. The activity of polysaccharides depends on the mechanical treatment procedure. Dispersion and mechanical activation in the presence of celloviridine produce structural transformations in polysaccharides, increasing the antioxidant properties. In this case, the antioxidant activity of polysaccharides from disperse high-moor peat considerably exceeds that of polyphenols. Base hydrolysis enhances the initiating properties of the polysaccharide fractions from both valley and high-moor peats. The change in their catalytic activity seems to be associated with redistribution of WS components: base hydrolysis results in a strong increase in the polyphenol fraction, whereas the polysaccharide fraction decreases.

It is well known that most of native antioxidants are of the phenolic nature (substituted phenols, polyphenols, flavonoids, etc.). Among the mechanically treated samples, the total of the WS and polyphenol fractions separated from both kinds of peat inhibits oxygen electroreduction (antioxidant activity is higher in polyphenols from high-moor peat). Mechanical activation decreases the antioxidant activity of polyphenols, irrespective of the mechanical treatment conditions, except for mechanical activation with the enzyme in the presence of NaOH (sample nos. 5 and 10). The combined WS fractions (total of polysaccharides and polyphenols) demonstrate a synergistic effect, i.e., under various treatment conditions, their antioxidant activity is higher as compared to polyphenols. The WS fraction from high-moor peat shows higher antioxidant activity that that from valley peat. Base hydrolysis considerably increases the activity of the latter.

The HA fraction demonstrates the initiating properties in all cases, regardless of the mechanical activation conditions. The maximal catalytic activity of humic components was observed at their concentration of 0.001–0.003 wt %. With increasing concentration above the indicated value, the cathodic current changes only slightly (Fig. 1c). In all cases, except base hydrolysis, we observed an increase in the activity factors of humic acids. The maximal activity was shown by humic acids from disperse peats.

Catalytic properties of humic components are probably due to the presence of some metals, particularly iron, in them. The X-ray fluorescence analysis revealed (Table 1) that iron dominates in the HA fraction as compared to Mn, Ti, Ca, and Si compounds. Mechanochemical treatment results in redistribution of iron among the fractions (Table 1). However, as we demonstrated previously [6], a decrease in the iron content by a factor of 2–10 through acid treatment has

no effect on the catalytic activity of humic acids. Furthermore, Table 2 shows that the highest catalytic activity is shown by humic acids from high-moor peat having lower iron content.

To elucidate the contribution of iron to the catalytic activity, humic components were treated with EDTA. It was suggested that EDTA as a strong complexing agent for Fe(III) should suppress its catalytic activity. After treatment with EDTA, polysaccharides demonstrated a clearly pronounced inhibiting action. Therefore, removal of Fe(III) decomposes the associates in the polysaccharide fraction, making free functional groups with the inhibiting activity. As for HA fractions, their initiating activity remained practically unchanged after treatment with EDTA (Table 2).

Catalytic properties of humic acids depend on the features of their structure which includes carboxy groups, phenolic hydroxy groups, and quinoid fragments. In alkaline solutions, it is typical of humic acids to form a great amount of semiquinone radicals highly active in oxidation reactions [7]. The ^{13}C NMR analysis (Table 3) shows that mechanochemical activation of peats alters the structural characteristics of humic acids. For peat of both kinds, we observed a decrease in the fraction of alkyl carbons and increase in the amount of oxygen-containing fragments $C_{alk}O$ of various natures, which is most clearly pronounced in high-moor peat after mechanical dispersion and treatment with the enzyme. In the samples after base hydrolysis, the dealkylation is less pronounced. The

composition of oxygen-containing groups in humic acids depends on the treatment conditions. The amount of carbohydrate fragments increased in all the mechanically activated samples, which can be attributed to break of the glycoside bonds. The amount of the methoxy groups remained virtually unchanged, as well as the aromatic core structure (Fa) in both types of peat. Dispersion and mechanical treatment with celloviridine increase the amount of the carboxy groups in humic acids, except for the case of base hydrolysis (sample nos. 4, 9). In the latter case, we observed a considerable decrease in the fraction of carboxy groups at the expense of formation of the carboxylate ions.

Finally, removal of iron strongly affects the catalytic activity of the polysaccharide fractions, but only slightly, that of the HA fraction.

CONCLUSIONS

(1) The fraction composition of peat can be altered by mechanochemical treatment. The content of polysaccharides can be varied from 0.2 to 4.4%; that of polyphenols, from 1.1 to 6.1%; that of water-soluble compounds, from 1.3 to 9.1%; and that of humic acids, from 3.1 to 10.5%.

(2) Base hydrolysis enhances the antioxidant action of the polyphenol and water-soluble fractions.

(3) The polysaccharide fraction separated from valley peat, after removal of iron by treatment with EDTA, demonstrates the highest inhibiting activity. Base hydrolysis eliminates the antioxidant action of this fraction because of redistribution of functional groups among the water-soluble fractions.

(4) The inhibiting activity of humic acids is independent of treatment conditions and removal of iron, being controlled by the structural features of their macromolecules.

CATALYSIS

Catalytic Oxidation of Cyclohexane with Ozone–Oxygen Mixtures

Abstract—Selective oxidation of cyclohexane with ozone in the presence of chromium(0) hexacarbonyl and sodium naphthenates–Cr(III) mixtures was studied.

Since cyclohexane is an intermediate of caprolactam oxidation, an increase in the selectivity of cyclohexane oxidation to cyclohexanone [1] is an urgent problem.

Previously we showed [2] that noncatalytic oxidation of cyclohexane to cyclohexanone with ozone is more selective that industrial oxidation of cyclohexane with atmospheric oxygen to form a mixture of cyclohexanol and cyclohexanone.

The selectivity of oxidation of alkanes and cycloalkanes to the corresponding carbonyl compounds appreciably increases in the presence of catalysts of heterolytic decomposition of hydroperoxides, such as chromium(III) and chromium(VI) compounds [3–5]. The catalytic effect in the course of high-temperature liquid-phase oxidation of alkanes and cycloalkanes in manifested mainly in the step of hydroperoxide decomposition. When the process is performed at low temperature in the presence of a strong oxidizing agent (O_3 and O_2), variable-valence metal compounds can appreciably affect the mechanism of chain initiation, propagation, and termination and the contribution of radical and nonradical pathways. To control the selectivity of these processes, the features of the mechanism of these steps should be determined.

The procedures for oxidizing cyclohexane and for analyzing the reaction products were described previously [2, 3].

Cyclohexane ozonolysis was performed at 20–60°C in the presence of 2×10^{-2}–2×10^{-3} M stearates, naphthenates, and acetylacetonates of Co(II), Co(III), Cr(III), Mn(II), and $Cr(CO)_6$ as catalysts. The typical kinetic curves of accumulation of the oxidation products are shown in Fig. 1. The classes of compounds formed in this reaction are identical to those formed in oxidation of cyclohexane with ozone–oxygen mixtures. The kinetics of the overall cyclohexane consumption is of the first order irrespective of the catalyst (Figs. 2, 3). This is confirmed by the constancy of the accumulation rates of cyclohexanol, cyclohexanone, cyclohexyl hydroperoxide, and the acids in cyclohexane ozonolysis in the presence of cobalt(II) stearate (Fig. 1). Hence, the selectivity of formation of the target product (cyclohexanone) is almost constant

in the examined conversion range (~10%). In the presence of $Cr(CO)_6$, the accumulation rates of the hydroperoxide, alcohol, and ketone are also constant in the first oxidation steps (Figs. 1–3). The kinetic curve of accumulation of the acids is nonlinear. However, since the content of these acids in less than 0.05 M, the contribution of this pathway is insignificant and has small effect on the kinetic curve of cyclohexane consumption.

Chromium hexacarbonyl catalyzes the oxidation, whereas $CoSt_2$, $Mn(acac)_3$, and $CrSt_3$ appreciably inhibit the cyclohexane ozonolysis. Clearly, this is not due to homolytic or heterolytic catalytic decomposition of cyclohexyl hydroperoxide. First, at 20–40°C cyclohexyl hydroperoxide is relatively stable to thermocatalytic decomposition [4, 5]. Second, the steady-state concentration of cyclohexyl hydroperoxide in the course of cyclohexane ozonolysis is low owing to its fast consumption in the reaction with ozone (catalysis of this reaction is possible). The inhibiting effect is most likely due to reaction of the peroxy radicals with the catalyst. The rate constant of the reaction between the peroxy radicals and 3*d*-metal compounds is high [6]. The catalysis with $Cr(CO)_6$ and $Co(acac)_3$ can be related to their reaction with ozone, cyclohexane, and its oxidation products.

The selectivity of cyclohexanone formation is maximal in the presence of $Cr(CO)_6$. We studied the rate and selectivity of cyclohexane ozonolysis as influenced by the temperature, ozone concentration, and catalyst. The apparent activation energies of the overall cyclohexane consumption and cyclohexanone formation, determined by varying the reaction temperature in the range 20–60°C, are 34.5 ± 3 and 27.5 ± 2.5 kJ mol^{-1}, respectively, and are close to those of the noncatalytic process. The noticeable difference in the activation energies under conditions of consecutive and parallel reactions suggests a strong temperature effect on the reaction selectivity, which is confirmed experimentally (Figs. 4a, 4b).

The experimental kinetic curves measured at different concentrations of ozone and the catalyst and at different temperatures are shown in Figs. 2 and 3, respectively. The ozone concentration and the temperature have the strongest effect on the reaction rate. As the ozone concentration increases by a factor of 2 (from 2 to 4 vol %), the cyclohexane consumption accelerates by a factor of 2.4 {20°C, [O_3] = 2–4 vol %, [$Cr(CO)_6$] = 2×10^{-4} M}. Hence, bimolecular nonchain reaction of cyclohexane with ozone [1] is accompanied by chain oxidation of cyclohexane or decomposition of ozone with acceleration of initiation and progress of cyclohexane ozonolysis. The dependence of the rate of cyclohexane (RH) oxidation with ozone in CCl_4 at 22°C on [RH], [O_3], and [O_2] is described by the equation [7]

$$v = 3.2 \times 10^{-3}[RH][O_3] + 0.3[RH]^{1/2}[O_3]^{3/2} + 0.75[RH][O_3]^2/[O_2]_{gas}.$$

The third component of this equation is responsible for chain decomposition of O_3 [7] under the action of cyclohexyl radicals. The chain propagates by the equation $R^{\cdot} + O_3 \rightarrow RO^{\cdot} + O_2$, $RO^{\cdot} + RH \rightarrow ROH + R^{\cdot}$ and is terminated by the reaction $R^{\cdot} + O_2 \rightarrow RO_2^{\cdot}$ provided that the reaction between two cyclohexylperoxy radicals is faster than the reaction of RO_2 with ozone. In this case (no solvent, bubbling reactor, [RH] ≫ [O_3] ~ [O_2]), cyclohexyl radicals are almost

quantitatively oxidized to cyclohexylperoxy radicals. However, in the first steps of cyclohexane ozonolysis [7], the major oxidation product, cyclohexanol, is rapidly converted into cyclohexanone by the nonchain mechanism. The reaction of cyclohexylperoxy radicals with ozone and quadratic chain termination with the peroxy radicals should be taken into account in the kinetic equation of cyclohexane consumption by the chain mechanism. The experimental kinetic curves of cyclohexane consumption in $\ln(c/c_0)$–τ coordinates (c_0 and c are the initial and current cyclohexane concentrations, respectively; τ is the reaction time), measured in the first reaction step at low cyclohexane conversion (up to 8%) and small contribution of the chain pathway, are almost linear (Figs. 2, 3). The effect of $Cr(CO)_6$ concentration is significantly weaker. As $[Cr(CO)_6]$ increases from 2×10^{-5} to 2×10^{-3} M (20–60°C), the rate of cyclohexane consumption increases by more than 30% as compared to the noncatalytic reaction. As shown above, the mechanism of ozonolysis of saturated hydrocarbons is radical chain.

Catalytic oxidation of cyclohexane with ozone occurs also by the radical chain pathway. To gain insight into the mechanism of this process, we studied accumulation of the main reaction products. To determine the influence of various catalysts [mainly $Cr(CO)_6$] on the yield of each product, we measured the dependence of the selectivity of its formation on the hydrocarbon conversion. The reaction selectivity was taken as the ratio of the concentration of a definite reaction product to the total concentration of the reaction products.

The dependences of the total selectivity of formation of each product on the hydrocarbon conversion in catalytic ozonolysis of cyclohexane at $[O_3]$ = 4 vol %, 40°C, and the catalyst concentration of 2×10^{-4} M are shown in Figs. 4a and 4b. As the conversion increases, the selectivity of formation of the hydroperoxide and cyclohexanol linearly decreases, as a rule, and that of cyclohexanone formation increases owing to conversion of cyclohexanol and cyclohexyl hydroperoxide into the ketone. When the conversion is lower than 10%, the selectivity of cyclohexanone formation ranges from 69 to 73% without catalyst and reaches 81% in the presence of $Cr(CO)_6$. In addition, in the presence of $Cr(CO)_6$, the yield of cyclohexyl hydroperoxide and cyclohexanol decreases more sharply with increasing cyclohexane conversion. Hence, $Cr(CO)_6$ catalyzes the conversion of these compounds into cyclohexanone. An ozone–chromium(III) stearate system also exhibits high catalytic activity with respect to cyclohexanone (Fig. 4a). In this case, the ketone yield is as high as 70% at 6.5% conversion. When chromium(III) acetate poorly soluble in the reaction mixture is used, the selectivity of the ketone formation does not exceed 31%, but the selectivity of the hydroperoxide formation reaches 48%.

The catalytic effect of ozone–$CoSt_2$, ozone–$Co(acac)_3$, and ozone–$Mn(acac)_3$ systems on the selectivity is considerably lower than that of the ozone–chromium(III) and ozone–chromium(0) systems. In the presence of $Mn(acac)_3$, cyclohexane is rapidly converted into the acids and ε-caprolactone and the total yield of peroxides grows with increasing cyclohexane conversion. This dependence passes through a maximum.

Although the selectivity of cyclohexanone formation is maximal in the presence of the ozone–$Cr(CO)_6$ catalytic system, the selectivity and rate of the reaction considerably change in the examined temperature range (20–60°C). Cyclohexane ozonolysis with ozone–air mixtures containing 2% ozone is slow. In 4 h, the hydrocarbon conversion is as low as 2.2%, and the selectivity of cyclohexanone formation reaches 42–51%. Under these conditions, the catalyst affects the ratio of the main classes of the ozonolysis products. The selectivity of the cyclohexanone formation in the presence of 2×10^{-5} M $Cr(CO)_6$ is relatively high (up to 65%). The total yield of the hydroperoxides slightly grows with increasing catalyst concentration.

This is the case at elevated temperatures (60°C). Under these conditions, the selectivity of cyclohexanone formation is no higher than 60%. At 60°C, the conversion of cyclohexanol and cyclohexyl hydroperoxide into cyclohexanone and parallel conversion of cyclohexanone into the acids and lactone are accelerated. The almost optimal conditions of catalytic ozonolysis of cyclohexane are as follows: $[O_3]$ = 4 vol %, 40°C, $[Cr(CO)_6] = 2 \times 10^{-4}$ M, cyclohexane conversion 7–10%. The ketone yield reaches 81%. Ozone–sodium naphthenate, chromium(III) naphthenate, and ozone–chromium(III) naphthenate catalytic systems [8, 9] provide 85–90% selectivity of the ketone formation at the cyclohexane conversion of 5.3–6.5%.

Thus, as the cyclohexane conversion increases, the selectivity of formation of the main reaction products (R'C=O, ROOH, and ROH) is constant, decreases, or increases depending on the reaction conditions (temperature, concentrations of ozone and the catalyst). At low temperature (20°C), the selectivity of formation of these products decreases with increasing ozone

concentration owing to acceleration of the consumption of the alcohol and hydroperoxide. The selectivity of the ketone formation grows with increasing cyclohexane concentration. At 60°C, cyclohexanone oxidation is accelerated and the selectivity of its formation remains constant in the whole examined conversion range. The selectivity of formation of acids and esters increases. In the course of cyclohexane ozonolysis at 40°C in the presence of the ozone–$Cr(CO)_6$ catalytic system, the total selectivity of cyclohexanone formation regularly increases, the selectivity for the hydroperoxide and alcohol decreases, and the selectivity for the acids is constant. In the presence of ozone–NaNph–$Cr(Nph)_3$ (Nph is the naphthenate anion) catalytic system, the total selectivity of formation of cyclohexanol and cyclohexanone mixture is high [10]. To gain deeper insight into the mechanism of cyclohexane oxidation, let us consider the transformation of the catalyst, hydroperoxide, alcohol, and ketone under these conditions.

The rate constant of reaction of ozone with Co(II), Fe(II), Mn(II), and Cr(III) acetates is higher by 2–3 orders of magnitude than that of reaction of ozone with cyclohexyl hydroperoxide [1, 3, 11]. Ozone reacts with the catalysts by the reaction [12]

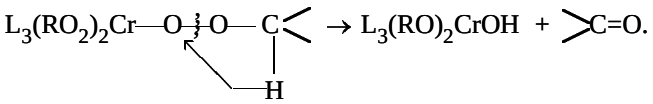
$$O_3 + M(II) \rightarrow M(III) + O_2 + O^- \text{ (or } O_3^-).$$

Negatively charged oxygen atom rapidly reacts with a proton of the acid present in the reaction mixture to form ·OH radical. In addition, the reaction of a saturated hydrocarbon with ozone [1] yields R· and ·OH radicals. Hydroxy radicals oxidize the reduced form of a variable-valence metal:

$$\cdot OH + M(II) \rightarrow M(III) + {}^-OH.$$

The oxidation potential of Me(III)/Me(II) is sufficient for Me(III) to oxidize hydroperoxides, alcohols, and ketones. If the activation energy of the reaction of the initial or intermediate compound with the oxidized form of the catalyst is high, more active ·OH radical can initiate the oxidation. In addition, in the course of cyclohexane oxidation with an ozone–air mixture, variable-valence metal carboxylates in the oxidized or reduced forms coordinate the oxygen-containing reaction products (ROOOH, ROH, R'C=O). The overall rate of catalytic ozonolysis of cyclohexane should depend on the stability of these complexes, and the selectivity of ketone formation, on the ratio of the rates of formation and consumption of these complexes. The main sources of cyclohexanone in noncatalytic ozonolysis of cyclohexane are unstable hydrotrioxide, cyclohexanol, cyclohexyl hydroperoxide, and $RO_2^{\cdot}$ radical [1].

Let us consider the influence of $Cr(CO)_6$ catalyst on the conversion of the above intermediates of cyclohexane ozonolysis. In the presence of chromium compounds, cyclohexyl hydroperoxide is selectively converted into cyclohexanone mainly by the nonradical mechanism [4]. Indictor *et al*. showed [5] that Cr(III) is oxidized with the hydroperoxide to Cr(VI). Antonovskii suggests [13] that the O–O bond of the peroxy ester is homolytically ruptured to form the ketone



As found in [4], decomposition of *tert*-butyl hydroperoxide in the presence of Cr(III) acetylacetonate is described by the scheme

$$Cr(III) + yt\text{-BuOOH} \rightleftarrows \text{Complex},$$

$$\text{Complex} \rightarrow Cr(III + l) + y(t\text{-BuO}^{\cdot} + {}^-OH),$$

$$Cr(III + l) + Cr(III) \rightarrow Cr(VI) + Cr(l),$$

where y is the stoichiometric coefficient, and l is an integer equal to the change in the chromium oxidation state.

Bibichev [14] also suggests that the selective conversion of a secondary hydroperoxide into the ketone in the presence of chromium(III) stearate also passes through formation of the complex $Cr(St)_3 \cdot n$ROOH, where $n > 1$. When a hydroperoxide molecule is coordinated to the Cr(III) atom, the electron density from the α-oxygen atom of the hydroperoxide is transferred to the *d* orbital of Cr(III). As a result, the O–O bond of the hydroperoxide is weakened and then homolytically ruptured to form alkoxy and hydroxy radicals. The liberated OH radical, without escaping into the bulk of solution, can attack the C–H bond of the coordinated hydroperoxide to form the ketone and water by the molecular (cryptoradical) mechanism.

The apparent rate constant of cyclohexyl hydroperoxide decomposition in the presence of 2×10^{-4} M $Cr(CO)_6$ is $7.6 \times 10^7 \exp(-67\,000 \pm 2000)/RT$ min^{-1}. If the steady-state concentration of ROOH is 0.1 M, the rate constant of cyclohexanone formation from hydroperoxide at 40°C is 0.0046 mol l^{-1} h^{-1}. Hence, the contribution of the catalytic decomposition of cyclohexyl hydroperoxide to cyclohexanone formation is no higher than 2 and 8.2% at 40 and 60°C, respectively, i.e., is low.

The steady-state concentration of hydrotrioxide at 20°C is 2.2×10^{-3} M. The strength of the O–O bond in this compound is close to that in cyclohexyl hydroperoxide. Hence, the contribution of the catalytic decomposition of the hydrotrioxide to the overall process can be neglected. Both inner- and outer-sphere coordination of cyclohexyl hydroperoxide is typical of 3*d* transition metals [15]; however, coordination-saturated $Cr(CO)_6$ can form only outer-sphere complexes with ROOH [$Cr(CO)_6 \cdot ROOH$]. Chromium hexacarbonyl is stable up to 120–140°C. Since carbonyl groups in $Cr(CO)_6$ are substituted by the dissociative mechanism with a high activation energy (ΔE_a = 163 kJ mol^{-1}), occurrence of these reactions under our conditions is unlikely.

Carbonyl ligands are strongly bonded to the chromium atom in $Cr(CO)_6$. The donor–acceptor σ bond in carbonyls is formed by interaction of the *d* orbital of the metal, e.g., $d_{x^2-y^2}$, with *n* electrons of CO on the *sp*-hybrid σ_n orbital. The carbonyl group donates the α-electron pair localized on the carbon atom. The dative π bond in carbonyls is formed by donation of the electron density form *d* orbitals of the metal, e.g., d_{xy}, to unoccupied antibonding π orbitals of CO.

However, zero-valent chromium in $Cr(CO)_6$ is rapidly oxidized with ozone to Cr(III) and Cr(VI). A sharp band at 336 nm typical for Cr(III) appears in the electronic absorption spectra of $Cr(CO)_6$ solutions in $CHCl_3$ and cyclohexane (1.2×10^{-3} M) after bubbling of an ozone–oxygen mixture for 0.5–1 min ($[O_3]$ = 4 vol %, 25°C). As determined by ESR, the steady-state concentration of Cr^{5+} [18] is very low. Hexavalent chromium was qualitatively determined by the reaction with diphenylcarbazide [19].

The overall process of $Cr(CO)_6$ oxidation with ozone can be described by the following reactions:

$$Cr(CO)_6 + mO_3 \xrightarrow[-CO,\ -CO_2,\ -O_2]{} Cr(III)L_3 + 3O^{\cdot-},$$

$$O^{\cdot-} + H^+ \overset{K_e}{\rightleftarrows} {}^{\cdot}OH, \quad K_e = 10^{12} \text{ [3]},$$

$${}^{\cdot}OH + Cr(III) \rightarrow Cr(IV) + {}^{-}OH,$$

$${}^{-}OH + H^+ \rightleftarrows H_2O,$$

$$Cr(III) + RO_2^{\cdot} \rightarrow Cr(IV) + RO_2^-,$$

$$Cr(IV) + O_3 \rightarrow Cr(V) + O^- + O_2,$$

$$Cr(III) + O_3 \rightarrow Cr(IV) + O^- + O_2,$$

$$Cr(V) + O_3 \xrightarrow[-O_2]{} Cr(VI) + O^-,$$

$$RO_2^- + H^+ \rightarrow ROOH.$$

It is known [20] that Cr(VI) selectively oxidizes alcohols to carbonyl compounds:

$$Cr(VI) + ROH \rightarrow R{=}O + Cr(IV).$$

Probably, Cr(IV) is reduced to Cr(III) with cyclohexanol hydroxy hydroperoxide or the hydroxyperoxy radical  exhibiting redox properties [6]. In addition, reactions between chromium atoms in different oxidation states are also possible. The steady-state concentration of cyclohexanol in the products of catalytic ozonolysis of cyclohexane is low (Fig. 4). The cyclohexanol yield in the course of the ozonolysis decreases owing to its conversion into cyclohexanone [21, 22].

Probably, the fact that the total yield of cyclohexanol and cyclohexanone and the concentration ratio of these products vary a wide range (Fig. 4) is due not only to the catalysis of the alcohol oxidation to the ketone with Cr(VI). Special experiments show slow consumption of cyclohexanol and cyclohexanone in the course of cyclohexane ozonolysis catalyzed with $Cr(CO)_6$ in a bubbling reactor. Slow consumption of cyclohexanol is caused by its self-accociation. We suggest that the increased cyclohexanol yield in the presence of chromium-containing catalysts is due to a change in the reactivity of the peroxide and alkoxy radicals in the chromium(III) coordination sphere. The transformations of these radicals in the course of cyclohexane ozonolysis are discussed in [1].

CONCLUSION

Ozone–chromium(0) hexacarbonyl, ozone–chromium(III) naphthenate–sodium naphthenate, and chromium(0) hexacarbonyl–cyclohexyl hydroperoxide systems are catalytically active in cyclohexane oxidation. In the presence of these catalysts, the selectivity of formation of cyclohexanol–cyclohexanone mixture and of the target product, cyclohexanone, is high.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Cathodic Deposition of Copper from Dilute Solutions

Received May 22, 2003

Abstract—The cathodic deposition of copper onto stationary and smooth rotating disc electrodes from dilute aqueous solutions [copper(II) concentration up to 100 mg l^{-1}] was studied.

In extraction and dressing of polymetallic sulfide ores, a large amount of stripping rock dumps, lean ores, and dressing tails containing heavy metal sulfides are formed. In the course of prolonged exposure to atmospheric oxygen, sparingly soluble heavy metal sulfides are gradually oxidized with formation of well soluble compounds, sulfites and sulfates, which enter subdump, pit, and mine waters as a result of natural leaching. The volumes of their formation at each plant are between $(50–100) \times 10^3$ and $(5–6) \times 10^6$ m^3 yearly and depend on seasonal and weather conditions. The content of heavy metals in subdump waters is also dependent on seasonal and weather conditions and varies from a few milligrams to 1 g and more per liter, which exceeds by several orders of magnitude the maximum permissible concentration (MPC). The approximate composition of the subdump, mine, and pit waters is given in Table 1. Presently, most of mining plants have no water treatment facilities, and the above waters enter natural reservoirs without any purification.

The sewage from mining plants can be purified by chemical, physicochemical, and biological methods [1–5]. However, all the above methods have drawbacks impeding their application.

A promising method is direct electrolysis (cathodic deposition), which allows recovery of metals from aqueous solutions in the form of target products. It is also important that the electrolysis involves no chemicals. This makes it possible to develop low-waste and wasteless processes [6]. However, the electrodeposition of metals from the sewage from mining plants involves a number of problems caused by complex composition of the wastewaters and low concentration of target components. Among the main problems is intensification of the electrolysis, since electrodeposition of metals from dilute solution is limited by the transport processes.

One of the simplest methods to intensify the electrodeposition of metals is the use of a fast flow of electrolyte in the interelectrode space [7–10]. Porous and cellular cathodes made of carbon fibers also make the process more intense owing to increased deposition area [11–15]. One more way to intensify the electrolysis is the use of fluidized cathodes [15]. However, ensuring fluidization conditions requires special expensive equipment and involves additional power consumption.

We believe that the most efficient method for intensifying cathodic deposition of metals from dilute solutions is the use of a smooth rotating cathode, which makes it possible to lift diffusion restrictions and recover metals at a rate sufficient for commercial application.

Table 1. Content of ions in subdump and mine waters from UOMPP*

In this work, the influence of various factors on the cathodic deposition of copper onto a smooth rotating electrode was studied to estimate the potentialities of this method.

EXPERIMENTAL

The features of the cathodic deposition of copper on a stationary electrode were studied by taking chronopotentiometric curves in a YaSE-2 temperature-controlled three-electrode cell with separated electrode compartments. A platinum plate was the working electrode, a silver chloride electrode was reference, and a platinum wire, auxiliary electrode. The study was performed in the galvanostatic mode with the use of an automated potentiostatic-galvanostatic device.[1] The current efficiency (CE) of the cathodic deposition of copper was determined from the ratio of the lengths of the plateaus corresponding to deposition and dissolution potentials of copper in the cathodic and anodic chronopotentiograms.

The features of copper deposition on a smooth rotating electrode were studied in a specially designed cell (Fig. 1). The electrolyzer was polarized in the galvanostatic mode with a stabilized B5-49 voltage and current source. The voltage and current values were controlled with a B7-27 A/1 digital voltmeter. The time of the cathodic deposition of the metal was measured with a stopwatch. The rate of rotation of the disc cathode was measured and adjusted with a tachometer. The cathode was a stainless steel disc, and the anodes were made of the lead–antimony alloy. The cathode area was 160 cm^2. Prior to the test, the cathodes were trimmed with an emery paper (no. 0) and washed in the electrolyte to be studied. The amount of copper deposited on the cathode, CE, and the degree of recovery (DR) were calculated from difference in the copper content in the electrolyte before and after the electrolysis.

The electrolysis time was always chosen so that the amount of the electricity passed corresponded to 100% of the initial copper content.

The model solutions of subdump and mine waters were prepared from chemically pure grade reagents and distilled water. The copper concentration in solutions was determined by direct complexometric titration.

Because copper is an electropositive metal, the rate of the copper deposition will be determined by the ratio of the rates of only two processes: copper deposition and hydrogen evolution. The dissolution of copper from the electrode surface under the action of corrosion is virtually absent.

The preliminary tests showed that, in electrodeposition of copper on a stationary electrode from dilute solutions (Fig. 2), the current efficiency strongly depends on the density of the polarizing current. The acceptable level of CE for solutions containing 0.1 and 1.0 mg l^{-1} copper(II) is attained at a current density of about 0.1 mA cm^{-2}. For the solution containing 0.01 mg l^{-1} copper(II), the acceptable current efficiency in electrodeposition of copper was attained at the current densities as low as 0.01–0.05 mA cm^{-2}.

[1] The device was developed at the laboratory of electrochemistry, Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences.

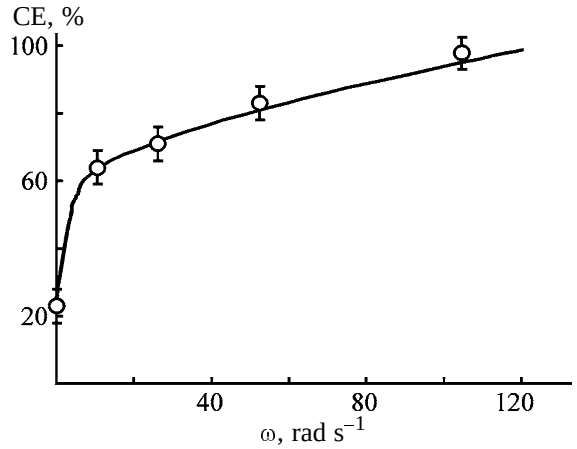

Fig. 3. Current efficiency CE vs. cathode rotation rate ω. Supporting electrolyte 0.5 M Na_2SO_4, i = 0.5 mA cm^{-2}, $c_{Cu^{2+}}$ = 100 mg l^{-1}, pH 3.

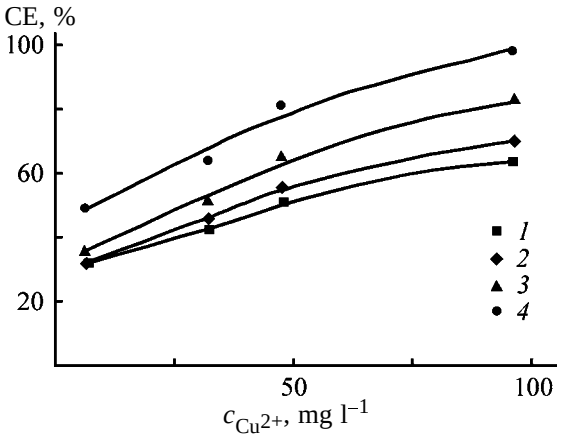

Fig. 4. Current efficiency CE vs. the concentration of copper ions $c_{Cu^{2+}}$ in electrolyte at various rates of rotation of the electrode. Supporting electrolyte 0.5 M Na_2SO_4, i = 0.5 mA cm^{-2}, pH 3. Electrode rotation rate, rad s^{-1}: (*1*) 10.5, (*2*) 26, (*3*) 52.3, and (*4*) 105.

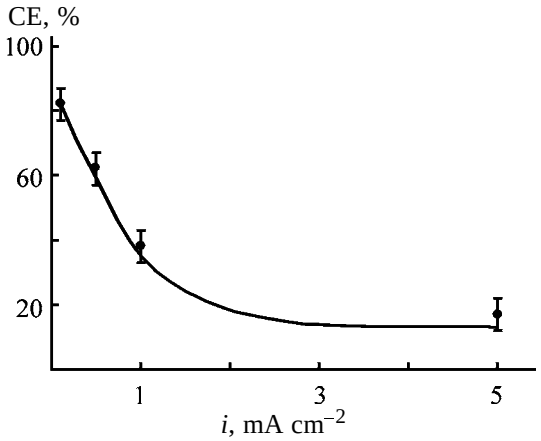

Fig. 5. Current efficiency CE by copper in deposition onto a rotating cathode vs. current density i. Supporting electrolyte 0.5 M Na_2SO_4, ω = 52.3 rad s^{-1}, $c_{Cu^{2+}}$ = 100 mg l^{-1}, pH 5.

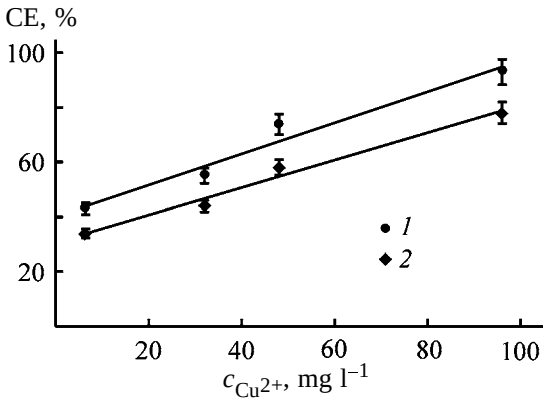

Fig. 6. Current efficiency CE of copper cathodic deposition vs. copper(II) concentration in solution $c_{Cu^{2+}}$ at various pH. Supporting electrolyte 0.5 M Na_2SO_4, i = 0.5 mA cm^{-2}, ω = 52.3 rad s^{-1}. Electrolyte pH: (*1*) 3 and (*2*) 5.

It should be noted that, owing to alkalization of the near-electrode layer upon hydrogen evolution at the cathode, copper(II) hydroxide flakes always appeared on the cathode upon copper deposition. Therefore, the copper deposition from dilute solutions onto a stationary electrode can occur in a quantitative yield only at a very low rate (i < 0.1 mA cm^{-2}), unacceptable for commercial applications.

The current efficiency of the copper deposition on the rotating electrode is considerably higher than on the stationary electrode (Fig. 3). With increasing rotation rate, CE increases to virtually 100%, which for solutions containing 100 mg l^{-1} Cu^{2+} is achieved at a rotation rate of 105 rad s^{-1}. As shown above, copper can be deposited in the form of hydroxides without stirring and at a low rotation rate owing to alkalization of the near-electrode layer of the electrolyte. As a result, the Cu^{2+} concentration on the electrode surface decreases, and the ratio of rates of the copper deposition and hydrogen evolution changes. Increasing the rotation rate decreases the concentration of the cathodically formed alkali. Therefore, $Cu(OH)_2$ is formed to a lesser extent or is not formed at all, which results in increased CE.

With decreasing copper(II) concentration in the solution, the current efficiency decreases also (Fig. 4). For example, at $C_{Cu^{2+}}$ decreased by an order of magnitude, CE decreases by 50%.

The current efficiency of the copper deposition on the rotating electrode, as on the stationary electrode, strongly depends on the polarizing current density (Fig. 5). For example, at the Cu^{2+} concentration in

Table 2. Composition of subdump, mine, and pit waters before and after electrolysis

Object	pH	Content of metal cations, mg l^{-1}			
		Cu	Zn	Fe	Mn
Mine water (UOMPP):					
before electrolysis	6.0	2.45	3.83	0.25	2.06
after electrolysis		0.74 (70)*	2.33 (39)	0.04 (84)	0.04 (98)
Subdump water:					
before electrolysis	2.5	83	582	–	76
after electrolysis		0.1 (99.98)	582 (0)	–	42 (45)

Note: * The degree of recovery (%) is given in parentheses.

solution of 100 mg l^{-1}, pH 5, and rotation rate of 52.3 rad s^{-1}, as the current density is increased from 0.1 to 2 mA cm^{-2}, CE sharply decreases from 82 to 22%; as the current density is increased further, CE decreases insignificantly.

The solution pH plays an important role in electrodeposition of metals. On the one hand, it is responsible for the form in which the metal exists in a solution, and, on the other hand, CE by hydrogen is higher at lower pH. Upon cathodic deposition of copper from neutral solutions of copper(II) sulfate, a sharp increase in pH in the near-cathode layer is observed even at low current densities, which leads to the precipitation of copper hydroxides [16]. As expected, as pH is decreased from 5.0 to 3.0, CE by copper increases by 10–20% on the average in the case of a rotating electrode also (Fig. 6).

In all cases, precipitation of copper hydroxide flakes was not observed on the rotating cathode, though the cathodic deposits obtained at various current densities, pH values, and rotation rates markedly differed in quality.

It can be readily seen from the comparison of the data obtained on stationary and rotating electrodes that the use of a rotating cathode allows the rate of copper electrodeposition to be increased by a factor of 5–10, with CE increasing by 70% in the process.

The data obtained were confirmed in tests on the copper deposition from subdump and mine waters of the Uchaly Ore Mining and Processing Plant (UOMPP). The experimental results show that the degree of copper deposition from subdump and mine waters is 98 and 70%, respectively.

CONCLUSIONS

(1) It was shown by an example of the cathodic deposition of copper that the current efficiency achieved with a rotating electrode is higher than that with a stationary electrode.

(2) The use of a rotating cathode allows the rate of copper electrodeposition from dilute solutions to be increased 5–10-fold, with the high current efficiency retained.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrochemical Recovery of Silver from Secondary Raw Materials

O. G. Gromov, A. P. Kuz'min, G. B. Kunshina, E. P. Lokshin, and V. T. Kalinnikov

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received April 3, 2003

Abstract—Electrolysis of silver in 95–84 wt % sulfuric acid with addition of 40 g l^{-1} of silver sulfate was studied at electrolyte temperature of 40°C. The optimal conditions of silver electrolysis in 84–85 wt % sulfuric acid were determined. Semicommercial tests of the electrochemical recovery of silver from silver coatings on copper, brass, aluminum, and steel articles were performed.

The market demand poses an acute problem of recovery of noble metals from scrap and electronic waste by new economically efficient and environmentally clean technologies. It is known [1] that the electrochemical recovery of noble metals from solutions of complex composition is one of the most economically efficient techniques. However, the existing schemes for processing of secondary raw materials are not always effective because of the low noble metal recovery, high power consumption, and, occasionally, poor environmental characteristics. For example, electrolytic recovery of silver from a silver coating on copper base [2] involves two stages of electrolytic processing. In the first stage, the solder is dissolved in a sulfamic electrolyte, with lead, tin, and zinc deposited at the cathode in the form of powders. In the second stage, the copper-containing base is dissolved in a sulfuric acid electrolyte, with copper powder obtained at the cathode and copper concentrated in the anode slime. The disadvantages of this technique are high power consumption and impossibility of obtaining high-purity silver.

In electrolytic recovery of silver from a silver coating on iron base [3], silver is anodically dissolved in an electrolyte containing 86 vol % concentrated sulfuric acid, 12 vol % ethanol, and 2 vol % mononitrobenzene at 40°C, voltage of 8 V, and current density of 12 A dm^{-2}. The disadvantages of this technology are the presence of strongly toxic aromatic compounds (mononitrobenzene, in particular) and the necessity for subsequent recovery of silver from the electrolyte solution.

The aim of this study was to examine selective recovery of silver from electrotechnical scrap by electrolysis in concentrated sulfuric acid to give high-purity silver metal as the final product.

EXPERIMENTAL

As starting materials we used 95 wt % H_2SO_4 and Ag_2SO_4, both of pure grade, and 6 cm^2 plates of metallic silver, St.3 steel, 1Cr18Ni9Ti stainless steel, and glassy carbon. The electrochemical cell had the form of a glass vessel 50 mm in diameter and 80 mm high, charged with 50 cm^3 of sulfuric acid and Ag_2SO_4 additive. The cathode and anode were placed at a distance of 40 mm and connected to an unconventional dc power supply providing current of 0–30 A, with voltage continuously variable in the range 0–5 V. To maintain the electrolyte temperature at 40–50°C, the cell was placed in an electric furnace. The phase composition of the products obtained was determined by X-ray phase analysis on a DRON-2 diffractometer with CuK_α radiation and graphite monochromator.

Initially, a plate of metallic silver was used as the anode, and a glassy carbon plate, as the cathode. The voltage across the power supply terminals was 1.5 V under no-load conditions; the electrolyte temperature, 40°C; and the concentration of Ag_2SO_4 in sulfuric acid, 40 g l^{-1}. On applying voltage to the cell, the current changed stepwise to 0.6–0.7 A and then decreased to a constant value of 0.4–0.35 A. A silver deposit of black color was formed at the cathode, with small gas bubbles seen on the surface of this deposit. After 3–5 min, the cathode silver turned lighter, and a lilac cloud appeared in the electrolyte near the upper part of the cathode and then, gradually, occupied the whole volume of the electrolyte.

1070-4272/04/7701-0062 © 2004 MAIK "Nauka/Interperiodica"

It was established that the amount of silver obtained at the cathode is 17–18% relative to that dissolved at the anode, with the quantity of electricity passed through the electrolyte being equivalent to the mass of silver dissolved at the anode, i.e., there are no side processes at the anode. The electrolysis product contained, in addition to metallic silver, a black substance. This substance was isolated by dissolving metallic silver in 20% nitric acid. An X-ray phase analysis demonstrated (Fig. 1) that this substance is a mixture of $Ag_8S_3SO_4$ and Ag_2S. The compound $Ag_8S_3SO_4$ can be represented as $3Ag_2S \cdot Ag_2SO_4$. The formation of these compounds in electrolysis can be explained as follows. It is known [4] that silver used as the cathode material reduces hot concentrated sulfuric acid to SO_2, which is readily reduced electrochemically to the sulfide ion S^{2-}. S^{2-} ions react with silver cations to give Ag_2S. In this case, freshly deposited cathodic silver exhibits high chemical activity and partly reacts with concentrated sulfuric acid at relatively low temperature. This reaction yields silver sulfide at the cathode as follows:

$$2Ag + 2H_2SO_4 = Ag_2SO_4 + SO_2 + 2H_2O, \quad (1)$$

$$SO_2 + 2e = S^{2-} + O_2\uparrow, \quad (2)$$

$$2Ag - 2e + S^{2-} = Ag_2S. \quad (3)$$

When combined, these reactions constitute the overall reaction

$$4Ag + 2H_2SO_4 = Ag_2S + Ag_2SO_4 + 2H_2O + O_2\uparrow. \quad (4)$$

The forming silver sulfide is partly dissolved in the electrolyte via reaction with silver sulfate, which is readily soluble in concentrated sulfuric acid, to give double compounds $nAg_2S \cdot Ag_2SO_4$, where n = 1–3. At n = 3, the compound precipitates and is mixed with peeled-off cathodic silver.

By gradual dilution of sulfuric acid, it was found that, at its concentration $c \le 85$ wt %, electrolysis of silver proceeds without any change in the color of the electrolyte, with white deposit of silver formed at the cathode. The mass of the cathodic silver corresponds to the mass of silver dissolved at the anode. The cathodic silver contains no Ag_2S impurity, i.e., reaction (4) does not occur. All the subsequent studies were performed with 84–85% H_2SO_4.

It is inappropriate to use glassy carbon, which is an excellent catalyst for reduction of H_2SO_4, as cathode material in electrolysis of silver. To select a cathode material, plates of Cr18Ni9Ti stainless steel, St.3 steel, and silver were tested. The best result was obtained with metallic silver: a dense layer of finely crystalline silver was formed on the cathode. With St.3 steel used as the cathode material, silver cementation occurred on the steel surface, with simultaneous formation of iron sulfate, which is insoluble in H_2SO_4 of the given concentration and results in that the cathode silver has the form of a very loose, readily peeling layer. In the case of stainless steel, silver cementation also occurred, but a rather dense layer of cathodic silver was formed in the course of electrolysis. The stainless steel cathode is nearly as good as that made of metallic silver. The disadvantages of this cathode are the partial consumption of Ag_2SO_4 dissolved in sulfuric acid and the possible contamination of the electrolyte with iron and alloying components.

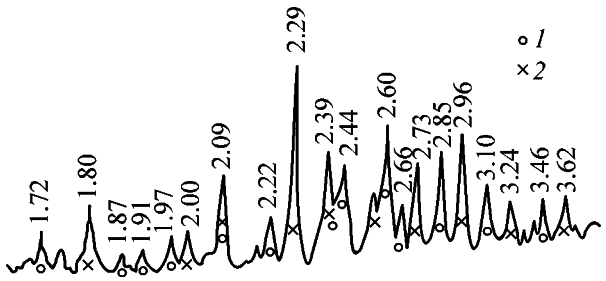

Fig. 1. X-ray diffraction pattern of the black product obtained in electrolysis of silver in concentrated H_2SO_4: (*1*) Ag_2S and (*2*) $Ag_8S_3SO_4$.

With a stainless steel cathode and silver anode, the optimal conditions of silver electrolysis in 84% H_2SO_4 were determined. The intensity of electrolysis was evaluated by the current flowing through the electrolyte. Figure 2a shows the current as a function of the Ag_2SO_4 content in the electrolyte at a working voltage of 1.5 V and electrolyte temperature of 40°C. It was found that a loose, X-ray amorphous deposit of silver is formed at an Ag_2SO_4 concentration of 15 g l^{-1}, and a dense finely crystalline deposit of silver, at 30 g l^{-1}. At Ag_2SO_4 concentration of 40 g l^{-1}, the current is lower and, on cooling the electrolyte to room temperature, Ag_2SO_4 partly precipitates. The recommended Ag_2SO_4 concentration in the electrolyte is 30 ± 5 g l^{-1}.

The dependence of the electrolysis intensity on the electrolyte temperature was studied at a working voltage of 1.5 V and Ag_2SO_4 concentration in the electrolyte of 30 g l^{-1}. It was found that electrolysis virtually does not occur at all at room temperature, since the current strength is 0.05–0.06 A. The plot of the current strength vs. the electrolyte temperature has an inflection point at 40°C (Fig. 2b). Taking into account

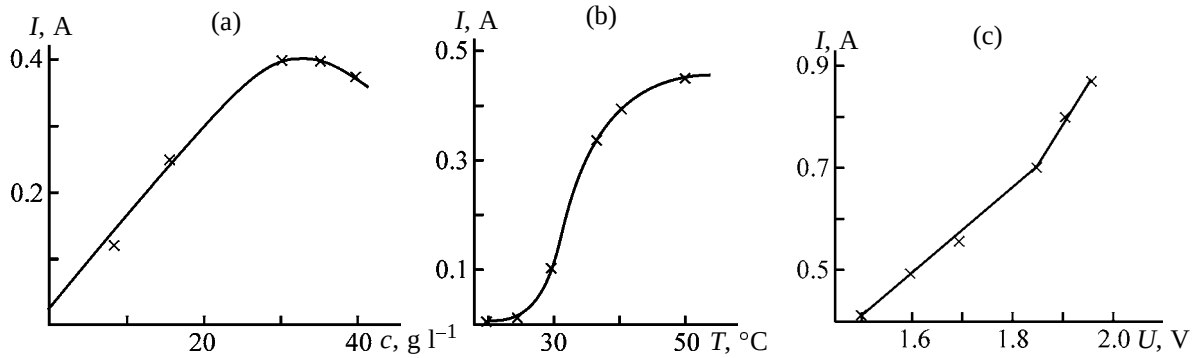

Fig. 2. Current strength I vs. (a) Ag_2SO_4 concentration c in the electrolyte, (b) electrolyte temperature T, and (c) initial voltage U.

the fact that the probability of reaction between the cathodic silver and H_2SO_4 increases with temperature, the optimal electrolyte temperature was taken to be 40 ± 5°C.

The dependence of the electrolysis intensity on the working voltage was studied at the optimal electrolyte temperature and Ag_2SO_4 content (Fig. 2c). As the voltage increases from 1.5 to 1.85 V, the dc current grows proportionally, and at 1.9 V the current starts to rise more steeply and gas evolution begins at the cathode and anode. This can be attributed to electrochemical decomposition of water at voltages of 1.9 V and higher. Consequently, the working voltage should not exceed 1.85 V.

The silver-containing electronic scrap is composed of various articles with silver coatings on copper, brass, bronze, aluminum alloys, and stainless steel. A study of the behavior of these materials as an anode yielded the following results. On submerging a copper plate in the electrolyte, silver cementation occurs. On switching on the voltage, the current increases stepwise to 0.2 A and then, after 10–15 s, falls to zero. This can be accounted for by the anodic dissolution of cemented silver, which terminates when the plate is completely coated with a thin layer of copper sulfate, which is insoluble in the electrolyte. With brass and bronze, the process occurs in a similar way. In the case of stainless steel, its surface is also coated with a protective layer, whose composition was not determined. With plates of aluminum alloys, there is no silver cementation and the current is zero on applying voltage to the cell, since the surface of these alloys is coated with a protective film of aluminum oxide from the very beginning.

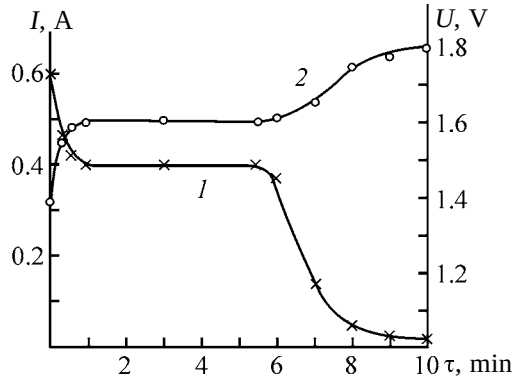

Fig. 3. (*1*) Current I and (*2*) working voltage U vs. electrolysis duration τ.

Since some of silver-plated articles are partly coated with POS 61 solder, its behavior in electrolysis was also studied. For this purpose, a copper plate was completely coated with the solder. On submerging this plate in the electrolyte, there is no silver cementation, and, on switching on the voltage, the current is zero. A similar result was obtained with Sn and Pb plates. This means that the surface of the solder, Sn, and Pb is coated with protective films of the corresponding oxides.

Thus, the presence of Cu, Sn, Pb, Fe, and Al has no effect on the electrolysis of silver, since these metals are passivated.

In studying the electrochemical recovery of silver from silver coatings, the articles to be processed, suspended on a copper wire, were used as the anode. The voltage across the power supply terminals was 1.8 V under no-load conditions. Figure 3 shows typical dependences of the current and working voltage on electrolysis duration. It is noteworthy here that the current rises steeply and the voltage falls on closing the electric circuit. Then, during 1 min, the current decreases and the voltage increases somewhat and remains constant until the article surface starts to be freed of the silver coating. After that, the voltage starts to increase, and the current, to decrease steeply. The electrolysis was terminated when the current reached a value of 0.01 A. The articles were with-

Process conditions and results obtained in electrolysis of silver coatings*

* Article surface after electrolysis shows no traces of silver coating and no signs of corrosion.

drawn from the electrolyte, washed with water, and dried in air. An inspection with an MBS-1 microscope (25 × magnification) revealed that the silver coating was completely removed and there were no indications of corrosion on the article surface. The cathodic silver was easily detached from the cathode. The studies performed demonstrated that, with the parameters chosen, electrolysis provides selective dissolution of the silver coating, with simultaneous deposition of metallic silver from the electrolyte at the cathode.

Semicommercial tests of the electrochemical recovery of silver from silver coatings were carried out on an electrolyzer shown schematically in Fig. 4. The electrolyzer casing, which is a metallic (Cr18Ni9Ti stainless steel) tank 180 mm in diameter and 260 mm high, served as the cathode. Silver-plated articles, taken in amount of 1–3 kg, were placed in the anode basket suspended within the casing on a copper rod. As the anode basket served a fluoroplastic vessel 115 mm in diameter and 155 mm high. The cylindrical surface and the bottom of the vessel were perforated (aperture diameter 10 mm) so that the openings occupied 75–80% of the surface. The silver obtained was scraped off the cathode and separated from the electrolyte by decanting and then by centrifuging on a TsLS-3 centrifuge. The results listed in the table demonstrate that the duration of electrolysis is 0.6–1.4 h, depending on the type and amount of the charge with articles; silver coatings are anodically dissolved completely and selectively, which is indicated by their total absence on the article surface after electrolysis; the whole amount of silver dissolved is deposited at the cathode, which is confirmed by the 99% recovery of silver into the final product. It was found that the silver powder obtained is composed of metallic silver with purity of 99.9 wt % and impurity content (wt %): Cu 0.03, Sn 0.01, Pb 0.01, Fe 0.006, and Al 0.02.

CONCLUSIONS

(1) A study of silver electrolysis in sulfuric acid with concentration of 95 wt % and addition of 40 g l^{-1} Ag_2SO_4 at electrolyte temperature of 40°C demonstrated that the electrolysis proceeds with metallic silver and Ag_2S deposited at the cathode.

(2) It was shown that Ag_2S is not formed at the cathode at sulfuric acid concentrations $c \le 85$ wt %.

(3) The optimal silver electrolysis conditions in sulfuric acid with concentration of 84–85 wt % were determined: Ag_2SO_4 content in the electrolyte 30 ± 5 g l^{-1}, initial voltage 1.85 V, and electrolyte temperature 40°C.

(4) It was established that Cu, Sn, Pb, Fe, and Al are passivated under these conditions at the anode

because of the formation on their surface of protective films composed of the corresponding sulfates or oxides.

(5) Semicommercial tests of the method suggested for electrochemical recovery of silver from silver coatings on copper, brass, aluminum, and steel articles were carried out. Metallic silver with 99.9 wt % purity was obtained with the average degree of recovery of 99.0%.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Gas Evolution and Absorption in a Sealed Nickel–Zinc Battery with Nickel Oxide Electrode Fabricated from Spherical Nickel Hydroxide

Rigel' Battery Company, Open Joint-Stock Company, St. Petersburg, Russia

Received July 22, 2003

Abstract—The range of variation of the barometric parameters of a sealed nickel–zinc battery with nickel oxide electrode made of spherical nickel hydroxide was studied under the conditions of cycling and exposure in charged and discharged states.

Interdependent functioning of nickel oxide (NOE) and zinc electrodes in a nickel–zinc (NZ) system is complicated by the oxygen and hydrogen evolution occurring on the electrodes, when their potentials are in the region of thermodynamic instability of water. Unbalance of main and side processes on the counter-electrodes leads to unbalance between the degrees of their charging. The balance can be maintained for a long time only in a sealed battery owing to efficient methods of recombination of released gases.

Formation of a sealed nickel–zinc (SNZ) battery is based on positive results achieved in study and exploitation of sealed nickel–cadmium (SNC) and sealed lead–acid (SLA) batteries. The most efficient method of the recombination of accumulating gases in NZ battery, which has found practical application, involves the ionization of oxygen on the zinc electrode and the oxidation of hydrogen on the NOE [1].

Presently, SNZ batteries based on this principle use a porous zinc electrode with gauze or a foamed-metal support and a metal-ceramic nickel oxide electrode (MC NOE), which ensure insignificant gas evolution and necessary gas recombination.

The oxygen ionization in chemical alkaline power sources is well studied for the case of a sealed nickel–cadmium battery. It was established in [2, 3] that the rate of the electrochemical recovery of oxygen on the cadmium electrode reaches 5–8 mA cm^{-2}. At limited rate of its delivery into the pores of cadmium electrode, this process is diffusion-controlled. The most important result of these works is a conclusion that the ionization current can be increased considerably by creating conditions for displacement of a part of electrolyte from the electrode pores under the pressure of gas penetrating through separator pores.

The rate of the oxygen ionization on zinc (0.1–0.2 mA cm^{-2}) [4] is less than that on cadmium. A study of the current variations on a half-immersed electrode showed that the dependences typical of diffusion mode are not implemented on the zinc electrode. Apparently, the process occurs by the mixed mechanism.

The conditions of gas delivery to the counterelectrode are more complex in SNZ battery than in SNC battery, which apply microporous separators to impede growth of zinc dendrites. At the same time, though the rate of oxygen ionization on the zinc electrode is low, the balance between the evolved and absorbed oxygen at a low internal gas pressure can be ensured during each cycle (charging, pause, discharge, and pause) by optimizing the battery design and applying efficient charging methods [5]. In this case, in batteries with MC NOE, 60–70% of oxygen is absorbed during charging, and the rest, during the subsequent periods of a cycle.

The interaction of hydrogen with NOE was mainly studied in a nickel–hydrogen battery and at a pressure higher than that in SNZ battery. The voltammetric method was used to show that hydrogen is oxidized at a marked rate only on the charged NOE, whereas on the discharged NOE the oxidation rate is virtually zero [6].

A study of the dynamics of hydrogen accumulation in the SNZ battery showed that the pressure can be stabilized depending on the ratio of the rates of its evolution on the zinc electrode and absorption upon

interaction with NOE [7]. With hydrogen pressure in the gas volume of the battery increased from 1×10^2 to 2.5×10^2 kPa, the rate of its oxidation on the MC NOE increased by a factor of more than 3, in fundamental agreement with the conclusions of [2, 3].

In view of recent development of new materials such as spherical nickel hydroxide and foamed metal supports, it seemed appropriate to use the compacted electrodes fabricated from these materials in NZ batteries [8].

EXPERIMENTAL

To determine the internal pressure appearing in using such electrodes, we studied in this work the gas absorption and evolution in a sealed NTs-25 nickel–zinc battery, in which NOE on foamed nickel (FN) support was used instead of MC NOE. The battery design, including electrode thickness, zinc electrodes, number of electrodes, set of separators, and electrolyte volume, was the same as in a battery with MC NOE. The electrolyte used had the volume V = 90 cm^3 and contained (M) KOH 7 and LiOH 1. At the same time, because the active paste of the FN-supported NOE was denser, the ratio of theoretical capacities of the negative and positive electrodes in a battery with FN-supported NOE was 2.2 : 1 instead of a 3 : 1 ratio in a battery with MC NOE (theoretical capacity of negative and positive electrodes is 112 and 50 A h, respectively).

We studied two types of NTs-25 batteries containing different corrosion inhibitors: 1% HgO and 0.25% PbO (type I) and 2% CdO and 1% PbO (type II).

The batteries were formed during two cycles in the modes recommended in [9]. The discharge capacity imparted in the first and the second cycles was 18 and 35–36 A·h, respectively, and the coefficient of utilization of the active paste was 54–58%. Later on, manometers or valves with an opening pressure of 2×10^2 kPa were mounted on the cycled batteries. The charging capacity was 26–24.5 A h, which corresponds to the rated capacity of sealed NTs-25 battery with MC NOE. The discharge was done with a current of 0.2C = 5 A and sometimes with a current of 1C = 25 A (C is rated capacity).

The obtained data on the barometric parameters of the sealed NTs-25 batteries were recalculated to the volumes of evolved and absorbed gases, based on the internal gas volume of the battery (80 cm^3). The proportions of oxygen and hydrogen were determined from pressure drops in various periods of the cycle using previously obtained data on hydrogen evolution on the zinc electrode in batteries with MC NOE having the same negative electrodes and containing the same corrosion inhibitors [4, 7].

The peculiar features of the processes in the batteries studied can be judged from variations of the gas pressure in them in cycling (Fig. 1) and during the pauses (Fig. 2).

The barometric data presented in Fig. 1 belong to the steady-state conditions, which are well reproduced from cycle to cycle. The value and character of pressure variations in batteries of types I and II differ essentially. This is associated with the different hydrogen evolution, because, except for the inhibitor composition in the zinc electrode, the oxygen evolution on the NOE and the conditions of oxygen absorption on the zinc electrode were the same in both cases.

In type I batteries containing the HgO and PbO additives, the pressure increases only slightly with charging and does not exceed a value of 1×10^2 kPa even when the subsequent charging is done in the intense mode with a current of 1.0C (Fig. 3). In this case, the gas evolution in the different cycles is 45–

Evolution and absorption of oxygen and hydrogen in sealed NTs-25 batteries during different periods of the cycle

Cycle period	Oxygen volume, cm^3			Hydrogen volume, cm^3					
	types I and II			type I			type II		
	evolved	absorbed	accumulated	evolved	absorbed	accumulated	evolved	absorbed	accumulated
Charging	80–120	40–70	40–60	15–25	–	–	80–100	–	–
Pause		30–35	–		10–15	–	60–80	–	–
Discharge		15–20	–		5–10	–	–	40–70	–
Pause		5–10	0		0–5	0	–	0–5	80–100

70 cm^3, including 15–25 cm^3 of hydrogen (see table). The oxygen evolution in charging (80–100 cm^3) minus the oxygen absorption during this period (50–60%) is less by 20–25% than gas evolution in a battery with MC NOE charged under the similar conditions [5]. In the subsequent periods of each cycle, including pause, discharge, and pause, the oxygen is ionized virtually completely, which is confirmed by the gas analysis.

Hydrogen released in charging is absorbed during the time of residence of the battery without current (pause) and during the discharge, but absorption is incomplete. Its residual pressure (of about 0.4×10^2 kPa) corresponds to a value established when batteries of this type reside without current in both charged and discharged states (Fig. 2).

The hydrogen accumulation in charging is larger by a factor of 4–5 in the type II batteries containing CdO and PbO than in the type I batteries (see table, Fig. 1). Figure 1 shows that the hydrogen evolution also increases during the pause between charging and discharge, since the gas evolution in the course of this period exceeds the volume of ionizing oxygen. This result is also consistent with the data of Fig. 2.

A main decrease in the hydrogen pressure, considerably dependent on its value in the battery, occurs in the course of discharge. The gas pressure increases from cycle to cycle to a constant value, with the maximum pressure established within $(2.7–2.8) \times 10^2$ kPa (Fig. 4). This corresponds to a value established in this type of batteries without current in both charged and discharged states (Fig. 2).

Thus, the value of the maximum pressure in a cycled SNZ battery is determined by hydrogen accumulation, which depends on the efficiency of inhibitors in the zinc electrode and on the structure of active paste of NOE, which determines the surface area accessible to hydrogen oxidation.

The effect of the NOE structure on hydrogen recombination can be estimated by comparing the character of pressure variations in cycling for sealed NTs-25 battery of type I and for batteries with MC NOE and a zinc electrode containing the same inhibitors (1% HgO and 0.25% PbO) (Fig. 5). Whereas in the type I battery studied here the pressure initially increases, then decreases to a value of 1×10^2 kPa after cycling for a short time, and then varies within $(1–0.4) \times 10^2$, in a battery with MC NOE both the maximal and the final (minimal) pressures increase gradually to a constant value of $(2.3–2.7) \times 10^2$ kPa to the 50–60th cycle.

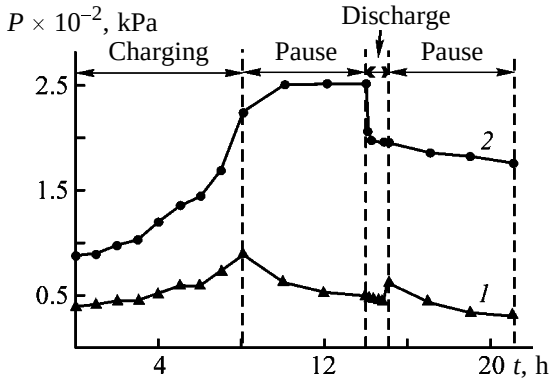

Fig. 3. Variation of the gas pressure P in sealed NTs-25 batteries of types (*1*) I and (*2*) II during cycling at the discharge current of 1.0*C*.

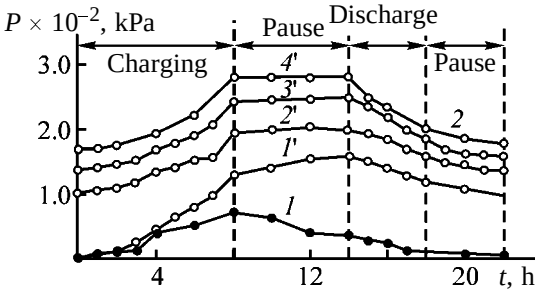

Fig. 4. Variation of the gas pressure P in sealed NTs-25 batteries of type II in succesive cycles (*1'*–*4'*), as compared to the type I battery (*1*).

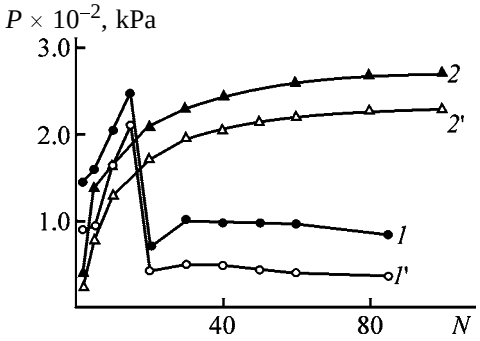

Fig. 5. Variation of the (*1*, *2*) maximal and (*1'*, *2'*) minimal gas pressures in the sealed NTs-25 type I batteries (*1*, *1'*) with NOE on FN support and (*2*, *2'*) with MC NOE electrode during cycling. (*P*) Pressure and (*N*) number of cycles.

The pressure increase in the start of cycling of a battery with MC NOE is associated with insufficient value of the internal surface area of those gas sections of a dosed NOE which are accessible to hydrogen oxidation. As the gas pressure increases, the displacement of electrolyte from the MC NOE, which has the gradual porometric characteristic, is observed starting from coarser pores. As a result, the NOE reveals the properties of a self-dosing electrode. In this period, the rate of the hydrogen oxidation increases and at a certain pressure reaches the evolution rate.

In the NOE with an FN support, unlike MC NOE, small closed pores formed in compacting 1–10-μm spherical particles prevail. The displacement of the electrolyte from these pores is made difficult, especially in the initial cycles, while the electrode surface after compaction is smooth. Therefore, the battery pressure increases stepwise during several cycles, reaches a value of 2×10^2 kPa, at which a valve opens, and after 20 cycles, as active paste becomes loosened, decreases to a constant value, depending on the rate of hydrogen evolution, which is determined by the performance of the corrosion inhibitor in the zinc electrode.

With hydrogen evolution as large as 2–3 cm^3 per 1 A h during one cycle, most of hydrogen can recombine. Apparently, the residual amount giving a pressure of $(0.4-0.6) \times 10^2$ kPa corresponds to the equilibrium concentration established in a contact with nickel(III) hydroxide without current.

If corrosion inhibitors are less efficient (as in type II batteries), only a part of hydrogen, released during the cycle in an amount of 5–8 cm^3 per A h, recombines, and hydrogen accumulates in the battery. In this case, the pressure increase associated with the specificity of NOE structure is sharper than in the battery with MC NOE (Figs. 4, 5). The pressure stabilizes in the range $(2.2–2.7) \times 10^2$ kPa, which corresponds to the steady-state value for the open-circuit state of the discharged or charged battery (Fig. 2).

CONCLUSIONS

(1) A sealed nickel–zinc battery with a nickel oxide electrode fabricated from spherical nickel hydroxide on a foamed nickel support has the barometric parameters dependent on the performance of corrosion inhibitors in the zinc electrode.

(2) The oxygen evolution in charging is 4–5 cm^3 per 1 A h of rated capacity, of which about 60% is absorbed during charging and the rest, during the cycle (discharge and pause). The maximum value of the oxygen pressure does not exceed 1×10^2 kPa. At hydrogen evolution as large as 2–3 cm^3 per 1 A h during one cycle, most of it is absorbed at the total gas pressure varied within $(1.2–0.4) \times 10^2$ kPa. At larger hydrogen evolutions, the pressure increases to a constant value of $(2.3–2.8) \times 10^2$ kPa, at which a battery with nickel oxide electrode passes from the dosed state to the self-dosing state.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrolytic Deposition of Molybdenum Oxide from Aqueous Solutions at Room Temperature

V. M. Nagirnyi, R. D. Apostolova, A. S. Baskevich, and E. M. Shembel'

Ukrainian State University of Chemical Engineering, Dnepropetrovsk, Ukraine

Received April 24, 2003

Abstract—The conditions of electrolytic deposition of molybdenum oxide from aqueous solutions at room temperature were studied and the optimal parameters of electrolysis, which provide deposits with necessary physical and structural characteristics, were chosen.

Previously, we demonstrated the possibility of synthesizing molybdenum oxide quantitatively with rather high current efficiency by cathodic deposition from aqueous solutions of ammonium molybdate $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ at 80–85°C [1]. The deposits obtained, which were tested in a secondary lithium cell in the form of ballast-free and composite ("pasted") cathodes, were distinguished by satisfactory discharge characteristics and cyclability, which indicates that the materials obtained by the method under consideration are promising [2]. However, the issues concerning the electrolytic deposition of molybdenum oxide from an aqueous solution of its salt at low temperature, i.e., under common electrolysis conditions, remained unconsidered. The low-temperature conditions are rather attractive, as considerably simplifying the electrolysis.

Here we report the results of studies in this area. We found no data of this kind in the literature. The electrochemical characteristics of the materials in question, which are an independent issue, were beyond the scope of this study.

The investigation was performed using the procedure described in [1]. As object of the study we used 0.005, 0.01, 0.02, 0.04, and 0.08 M $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ solutions with pH 6.0 and 9.0. All the experiments were conducted at 22 ± 2°C. The efficiency of the cathodic process was evaluated by the conditional current efficiency (CE_{cond}) calculated with account of the results of X-ray diffraction analysis. According to these data, the phase composition of the deposits is mostly described by the formula of nonstoichiometric molybdenum oxide $Mo_4O_{11}\cdot nH_2O$, which contains 2.75 atoms of oxygen per atom of molybdenum, i.e., is an intermediate oxide compound between the pentavalent, Mo_2O_5, and hexavalent, MoO_3, molybdenum oxides. To a first approximation, it can be regarded as doubled molybdenum pentoxide $2Mo_2O_5$ in which the atoms of molybdenum and oxygen are structurally bound in the above ratio. The reaction of Mo_2O_5 formation at the cathode can be represented as

$$2MoO_4^{2-} + 6H^+ + 2e \rightarrow Mo_2O_5 + 3H_2O.$$

Hence,

$$E = [Mo_2O_5]/2\times 26.8 = 272/2\times 26.8 = 5.07\ \text{g (A h)}^{-1}.$$

Since dehydration at 250°C for 7–10 h affects the weight of the deposits only slightly, compared with the initial weight after electrolysis (0.15–0.2 mg per 2.0–2.5 mg of deposit), the water component was disregarded, which is quite acceptable for CE_{cond} calculation.

The CE_{cond}–I_c dependences are shown in Fig. 1 for different ammonium molybdate concentrations and solution pH values. The dependences exhibit extrema at the points corresponding to current densities of 2.5 and 2.0 mA cm^{-2}, respectively, for the solutions with pH 6.5 and 9.0. The conditional current efficiency grows with the concentration of ammonium molybdate in solution increasing from 0.005 to 0.02 M and markedly decreases in solutions with higher concentrations (Fig. 1, curves *1*–*5* and *1*', *3*', and *5*' for pH 6.5 and 9.0, respectively). All the curves are characterized by descending portions gradually falling to a certain minimum value, which depends only slightly on the current density, with the corresponding portions of the curves nearly merging together for solutions with concentrations higher than 0.01 M (pH 6.5). The same behavior is observed for the dependences of the limiting values of CE_{cond} on the solution concentration at different pH values, shown in Fig. 2.

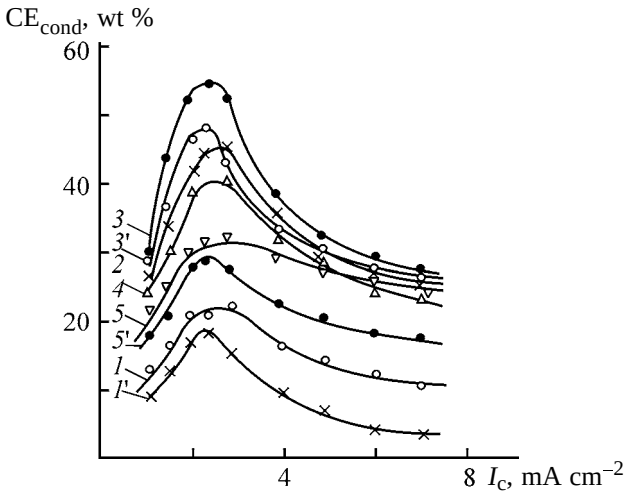

Fig. 1. Conditional current efficiency CE_{cond} by moybdenum oxide vs. the current density I_c in electrolysis of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ solutions at 20°C. Solution concentration, M: (*1*, *1*') 0.005, (*2*) 0.01, (*3*, *3*') 0.02, (*4*) 0.04, and (*5*, *5*') 0.08. pH: (*1*–*5*) 6.5 and (*1*', *3*', *5*') 9.0.

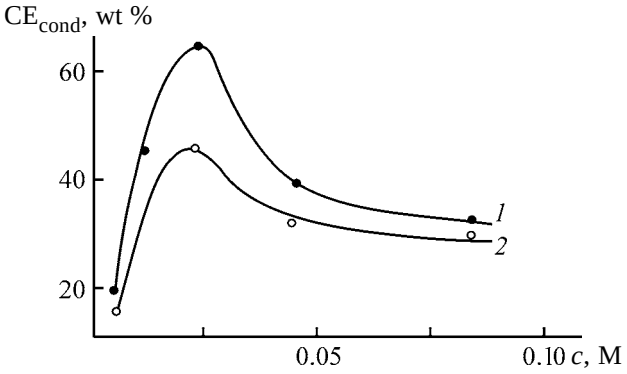

Fig. 2. Maximal value of the conditional current efficiency CE_{cond} vs. the solution concentration c at 20°C. pH: (*1*) 6.5 and (*2*) 9.0. I_c, mA cm^{-2}: (*1*) 2.5 and (*2*) 2.0.

Thus, the shape and relative positions of the curves are largely determined by the concentration and pH value of the solutions used. The rise in CE_{cond} with increasing solution concentration at its relatively low values (0.005–0.02 M) is due to enhanced diffusion of molybdate ions toward the cathode and higher hydrogen overvoltage. This overvoltage is lower in solutions with higher pH (9.0), in agreement with the data of [3]. This results in the corresponding increase in the rate of hydrogen evolution and lowering of the CE_{cond} by the cathode deposit, which to a certain extent accounts for the fact that the CE_{cond} decreases at high ammonium molybdate concentrations in solution ($\geq$0.04 M) (Figs. 1, 2). Apparently, the parallel rise in the concentration of ammonium ions in solution is responsible for their accumulation in the near-cathode layer and to its corresponding alkalization, which, in the end, results in leading acceleration of the hydrogen evolution. As for the equalization of the values of CE_{cond} at high current densities and their coincidence for the solutions with high ammonium molybdate concentration (pH 6.5), this is presumably due to the attainment of close, and independent of electrolysis parameters, ratios of the rates of hydrogen evolution and cathodic deposit formation.

The data presented are in satisfactory agreement with the current–voltage characteristics of the process under study (Fig. 3). The overall I_c–E dependences have the form of steeply ascending branches of a concave parabola, whose position with respect to the cathode potentials depends on the concentration and pH value of the solution and the type of substrate. At the same pH values, the cathodic polarization markedly increases as the salt concentration in solution becomes lower (Fig. 3, curves *1* and *2*). Correspondingly, at the same concentration and pH of the solution, the potential on the cathode surface preliminarily coated with a solid oxide layer is considerably higher than that of the initial steel surface (Fig. 3, curves *1*, *1*' and *3*, *3*'). Raising the solution pH (all other conditions being the same) leads to a decrease in the cathodic polarization of the initial surface of the stainless steel support and, contrariwise, to an increase in the polarization of the surface preliminarily coated with an oxide layer (Fig. 3, curves *1*, *3* and *1*', *3*').

Comparison of the overall and partial curves of cathodic deposit formation and hydrogen evolution (Fig. 3, curves *1*" and *1*'") shows that hydrogen evolution is the potential-determining process in the overall cathodic process. This is also indicated by the run of the partial curve of oxide deposition. This curve reaches the limiting plateau, which is independent of the cathode potential, at relatively low current densities. This results in that, with increasing polarizing current, the relative rates of oxide deposition and hydrogen evolution change continuously in favor of the latter, which also follows from the CE_{cond}–I_c dependences considered above. Hence, the lower the overvoltage and the higher the rate of hydrogen evolution, the lesser the extent of polarization of the cathodic process. For example, the hydrogen overvoltage on the initial surface of the cathode is relatively low and the corresponding overall curves are arranged in the order of decreasing cathode potentials for processes with higher hydrogen evolution rates. This is clearly seen when curves for solutions with higher and lower pH values and salt concentrations are compared (Fig. 3, curves *3* and *1*, and *1* and *2*). These curves are characterized by higher current efficiency by hydrogen in the former case. On a surface preliminarily coated

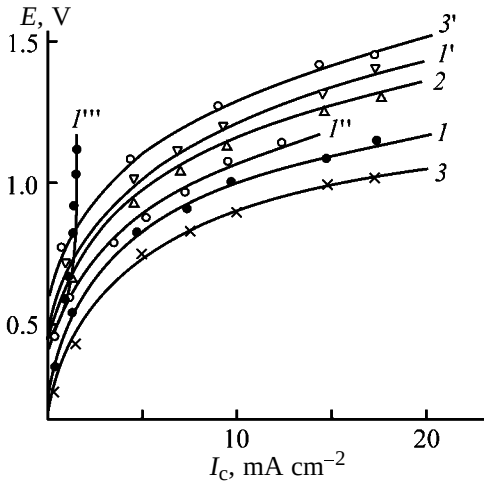

Fig. 3. Cathode potential E vs. the current density I_c in electrolysis of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ solutions at 20°C. Cathode: 12Cr18Ni9Ti steel. Solution concentration, M: (*1*, *1*', *1*'', *1*''') 0.04 [(*1*') on a film of molybdenum oxide; (*1*'', *1*''') partial curves of hydrogen evolution and molybdenum oxide deposition, respectively], (*2*) 0.02, and (*3*, *3*') 0.04 [(*3*') on a film of molybdenum oxide]. pH: (*1*, *1*', *1*'', *1*''', *2*) 6.5 and (*3*, *3*') 9.0.

with a solid molybdenum oxide layer, the hydrogen overvoltage increases substantially, which leads to an adequate enhancement of the cathodic polarization (Fig. 3, curves *1*, *1*' and *3*, *3*').

Nearly irrespective of the electrolysis conditions, the resulting molybdenum oxide deposits are obtained on the smooth surface of a stainless steel support as compact semilustrous black coatings with bluish tint, without any deviations in the external appearance. Oxide coatings up to 25 μm thick, dried at room temperature, exhibit satisfactory adhesion to the support surface and good mechanical stability (they sustain sample bending by 180° without cracking at the bending line). On being heated in air to 180–250°C, coatings thicker than 5–7 μm tend to undergo brittle failure and are easily removed when touched with hand. At the same time, thermal treatment at this temperature removes the crystallization water and makes more ordered the structure of the material, which may exert positive influence on its electrochemical characteristics. According to X-ray diffraction analysis, the phase composition of the deposits mainly corresponds to the formula Mo_4O_{11} with inclusions of the Mo_9O_{23} phase. On heating in air to above 60°C, the phase composition of the deposits changes fundamentally, with transition to single-phase MoO_3.

CONCLUSION

High-quality molybdenum oxide deposits are formed as compact uniform coatings up to 25 μm thick and more, exhibiting satisfactory mechanical stability and adhesion to the base, with sufficiently high current efficiency on a substrate made of 12Cr18Ni9Ti stainless steel from ammonium molybdate solutions with concentration of 0.005 to 0.08 M at 20±2°C, pH 6.5–9.0, and cathode current density of 1.5–7.5 mA cm^{-2}. Dispersed deposits may also be formed.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Selective Recovery of Nonferrous Metal Cations from Wastewater with Weakly Basic Anion Exchangers

P. N. Chelnakova and V. A. Kolodyazhnyi

Obninsk State Technical University of Atomic Power Engineering, Obninsk, Kaluga oblast, Russia

Received February 13, 2003

Abstract—Selective recovery of transition metals (Ni^{2+}, Cu^{2+}, and Cr^{2+}) with weakly basic anion exchangers from aqueous solutions simulating naturally mineralized water was studied. The exchange capacity of anion exchangers for these cations was determined. The technique for efficient resin regeneration was developed.

Due to corrosion of construction materials of atomic reactors, the wastewater formed in operation of nuclear power plants can contain traces of radionuclides, in particular, radioactive isotopes of transition metals (Ni^{2+}, Co^{2+}, Cr^{3+}, etc.) [1, 2]. These low-level wastes (10^{-4}–10^{-5} Ci l^{-1}) must be concentrated to obtain small volumes of solid or liquid waste. The ionic contaminants can be efficiently removed and concentrated with ion-exchange resins, in particular, cation exchangers [3–5]. Ion exchangers were widely used also for neutralization of wastewater and wash waters from electroplating production, in which the metal content varies from tens to thousands of milligrams per liter [6–9]. However, in the presence of cations of natural mineralization (in particular, Na^+, K^+, Ca^{2+}, and Mg^{2+}), the exchange capacity of resins for target metals sharply decreases, and conditioning of regeneration solutions is hindered. Therefore, we must choose such ion exchanger which would allow selective recovery of the transition metals. The comparative analysis of the complexing power of resins was published in [10]. It was noted that anion exchangers containing electron-donor groups sorb cations of transition metals due to formation of coordination bonds.

In this work we examined the possibility of removal of transition metals from aqueous solution containing cations of natural mineralization with complexing anion exchangers. The main attention was given to the choice of such a resin that would have sufficiently high sorption capacity and could be regenerated with obtaining highly concentrated solution of the target metals (radionuclides), from which the target metals could be quantitatively recovered in the form of metals or their appropriate compounds.

EXPERIMENTAL

In our experiments, we used the model solutions prepared by dissolution of copper(II), nickel(II) and chromium(III) salts in distilled and tap water. The water hardness was varied from 4 to 6 mg-equiv l^{-1}. The metal concentration was varied from 50 to 2000 mg l^{-1}.

The metal ion content in solutions was determined spectrophotometrically on an SF-46 spectrophotometer. Before determination, the transition metal ions were converted into colored complexes with the following reagents: lead diethyldithiocarbamate for Cu^{2+}, diphenylcarbazide for Cr^{3+} (after preliminary conversion of Cr^{3+} into chromate anion), and dimethylglyoxime (in the presence of bromine as oxidant) for Ni^{2+} [11]. The water hardness was determined by complexometric titration [12]. The acidity of solutions was measured on an EV-74 ionometer.

The spent anion exchangers were regenerated by metal elution with 30–40% aqueous H_2SO_4. After removal of the metals, the anion exchangers were treated with alkali and then washed with water.

Under static conditions, the sorption experiments were carried as follows. A weighed sample of an anion exchanger was placed into a flask (250 ml), and an aqueous solution of a transition metal salt was added. This mixture was kept for 2–4 days at intermittent stirring. After the equilibrium was attained, the residual metal concentration was determined.

The sorption of transition metals under dynamic conditions was studied by passing of their model solutions through a column packed with the anion exchanger until the transition metal concentration be-

* c_0 is the Cu^{2+} and Ni^{2+} concentration in solution, c_e is the residual (equilibrium) Cu^{2+} and Ni^{2+} concentration, g is the sorption capacity, and η is the degree of metal recovery.

came equal at the inlet and outlet of the column. In these experiments, the height of the anion exchanger bed was 12.2 cm, and the volume of the swollen resin was 46.4 ml. The metal content in the eluate at the outlet of the column was determined at regular intervals.

In order to choose an anion exchanger ensuring both the selective sorption of the transition metals under consideration in the presence of salts of natural mineralization and the maximal sorption capacity for them, the sorption of the metals at their concentration of 100 mg l^{-1} was studied under static conditions. The results of these experiments are listed in Table 1.

The sorption capacity of the resin for metals g (mg-equiv g^{-1} of dry resin) was calculated by the equation

$$g = V(c_0 - c_e)/(Em), \quad (1)$$

where V is the sorbate volume (l), E is the metal mg-equivalent (31.75 and 29.5 mg for Cu^{2+} and Ni^{2+}, respectively), and m is the dry resin weight (g).

The degree of metal recovery η (%) was calculated by the equation

$$\eta = (c_0 - c_e)/c_0. \quad (2)$$

Among anion exchangers tested by us, the maximal sorption capacity for transition metals under consideration is exhibited by weakly basic AM-7 and AN-221 polyfunctional resins. These resins were used in all the experiments. We found that, under identical experimental conditions, Cr^{3+} cations are identically sorbed on both weakly and moderately basic anion exchangers. For example, in sorption of Cr^{3+} from its solutions in both distilled and tap water with the initial concentration $c_0(Cr^{3+})$ 250 mg l^{-1} on AM-7, AN-221, AN-31 resins, their sorption capacity was 0.9 mg-equiv g^{-1}. The strongly basic AV-17 anion exchanger does not noticeably sorb Cr^{3+}.

Table 1 shows that the salts of natural mineralization do not noticeably affect the sorption recovery of Ni^{2+} and Cu^{2+}. The degree of sorption of Cu^{2+} and Ni^{2+} on weakly basic resins reaches 97 and 88%, respectively. These data show that the resins tested ensure selective recovery of the transition metals concerned.

We believe that transition metal cations are sorbed on weakly basic anion exchangers by coordination of the electron-donor groups of the resin (–NH_2, =NH, and ≡N) with metal cations by the donor–acceptor mechanism [10]. Thus, in sorption of transition metals, the anion exchanger acts as macromolecular complexone:

$$\equiv N\colon + \square M^{n+} \longrightarrow \equiv N\colon M^{n+}.$$

In order to determine the maximal sorption capacity of the anion exchangers for metal cations, the sorption of the metals was studied as a function of their concentration. Aqueous solutions of the transition metals were prepared in both distilled and tap water. All the sorption experiments were carried out under static conditions. An accurately weighed sample of the anion exchanger was placed in an aqueous solution of the transition metal salt and kept for approximately

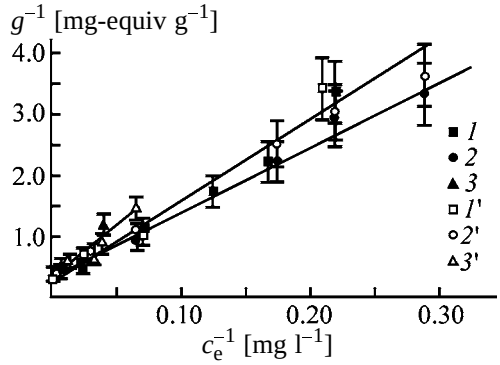

Fig. 1. Sorption of transition metal cations on weakly basic anion exchangers under static conditions as a function of the reciprocal equilibrium metal concentration in the solution. (*g*) Sorption capacity and (c_e) equilibrium metal concentration in the solution. Solvent: (*1*–*3*) tap water and (*1*'–*3*') distilled water. Fig. 2. Sorption of Cu(II) ions from (*1*) distilled and (*2*) tap water on AN-221 anion exchanger under dynamic conditions. (*c*) Cu(II) concentration in the eluate and (*V*) sorbate volume.

48 h. Thereafter, the equilibrium metal concentration in the sorbate was determined. From these data, the static sorption capacity of the resin for transition metals was calculated by Eq. (1). The experimental results on sorption of Ni^{2+}, Cu^{2+}, and Cr^{2+} depending on the equilibrium metal concentration were analyzed in terms of the Langmuir theory [13]

$$g = \alpha c_e/(1 + \beta c_e), \quad (3)$$

where g is the sorption capacity of the resin (mg-equiv g^{-1} dry resin), c_e is the equilibrium metal cation concentration in the solution (mg l^{-1}), and α and β are the empirical constants.

Equation (3) shows that sorption in the coordinates $1/g$ vs. $1/c_e$ is a straight line:

$$1/g = \alpha/\beta + 1/\alpha c_e. \quad (4)$$

Figure 1 shows that the experimental data on sorption of transition metals on anion exchangers are fairly well fitted to the Langmuir equation. These data show also that, in the limits of the determination error, the cations of natural mineralization do not interfere with sorption of the transition metals, i.e., the transition metals can be selectively removed from the initial solution. In sorption of the transition metals from tap water, the maximal sorption capacity of anion exchangers for these metals calculated by Eq. (4) at $c_e \to \infty$ was as follows (mg-equiv g^{-1} resin): Ni^{2+} (AN221) 2.05 ± 0.20, Cu^{2+} (AM-7) 3.5 ± 0.30, and Cr^{3+} (AM-7) 2.86 ± 0.25.

These calculated maximal sorption capacities reasonably agree with their experimental values: Ni^{2+} (AN-221) 1.9, Cu^{2+} (AM-7) 3.42, and Cr^{3+} (AM-7) 3.12 mg-equiv g^{-1} resin. Comparison of the experimental and calculated sorption capacities shows that the maximal sorption capacity of the resins for transition metal cations can be calculated from the data of sorption experiments by the Langmuir equation.

In sorption under static conditions, the equilibrium metal content in the sorbate was attained within three days. Under these conditions, the selective recovery of the transition metals was reached. In sorption under industrial conditions, the equilibrium sorption of metals must be attained within a period required for passing purified water through ion-exchange column. This time is considerably shorter then the time of attainment of the equilibrium sorption. Therefore, we studied the selectivity of sorption of the transition metals [by example of copper(II)] under dynamic conditions. In these experiments, Cu^{2+} solutions in tap and distilled water were passed through a column packed with AN-221 anion exchanger in the OH form. The elution velocity was 1.08 m h^{-1}. Figure 2 shows the output curves (Cu^{2+} content in eluate vs. eluate volume). The characteristics of Cu^{2+} sorption under dynamic conditions are listed in Table 2.

Table 2 shows that the sorption capacity of AN-221 anion exchanger for Cu^{2+} under dynamic conditions is considerably less than that under static conditions. We believe that this decrease in the sorption capacity is caused by the fact that the time of the sorbate–resin contact is insufficient for attainment of the sorption equilibrium. Therefore, we can suggest that, on optimization of the sorption column length, the sorption capacity can significantly increase. Our experimental

Table 2. Characteristics of Cu^{2+} sorption from its solutions in distilled and tap water on AN-221 anion exchanger*

				mg cm^{-3} swollen resin		mg-equiv cm^{-3} swollen resin	
Distilled	1150.5	330	1025.9	8.2	22.1	0.26	0.70
Tap	1139.3	340	1089	8.3	23.5	0.26	0.74

* (c_0) Cu^{2+} concentration in the initial solution, (V_b) eluate volume by the moment of Cu^{2+} breakthrough, (Σm) Cu^{2+} weight in the resin saturated with Cu^{2+}, (m) sorption capacity of the resin for copper(II) by the moment of Cu^{2+} breakthrough, and (g) sorption capacity of resin at complete resin saturation with Cu^{2+}, respectively.

data show that the efficiency of copper(II) recovery from both tap and distilled water is virtually identical (within the limits of determination error). This fact shows that salts of natural mineralization do not interfere with copper(II) sorption under dynamic conditions.

In order to regenerate the anion exchanger, aqueous H_2SO_4 was passed through a column at a flow velocity of 1.05 m h^{-1} and the metal concentration in the eluate was determined at a certain intervals. We found that the optimal regeneration is reached in washing the column with aqueous H_2SO_4 of the concentration $c \geq 30$ wt %. The degree of regeneration was determined as the ratio of the weight of copper(II) contained in the regeneration solution Σm_r to the total weight of copper(II) sorbed on the anion exchanger Σm (Table 2). After completion of regeneration, the anion exchanger was washed successively with water and alkali to convert the resin to the OH form. Figure 3 shows the degree of resin regeneration η, the copper(II) content in the regeneration solution Σm_r, and the copper(II) concentration in the regeneration solution c as functions of aqueous sulfuric acid volume passed through the column.

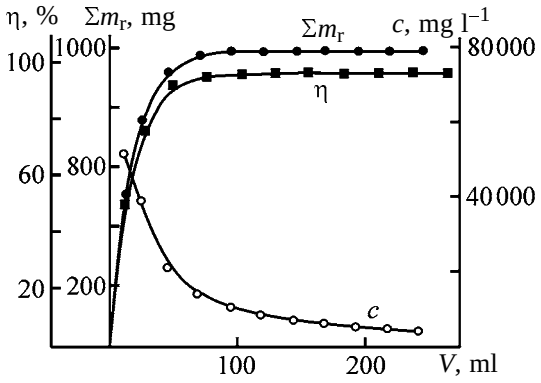

Fig. 3. Regeneration parameters of AN-221 anion exchanger as functions of the sulfuric acid volume V passed through column. (η) Degree of regeneration, (Σm_r) copper(II) content in regeneration solution and (c) copper(II) concentration in the regeneration solution.

Figure 3 shows that the degree of regeneration η > 90% is reached on passing approximately one volume of 30% H_2SO_4 through one volume of resin. Under these conditions, the regeneration solution contains more than 40 g l^{-1} of copper(II). Owing to such a high copper concentration, the utilization of the regeneration solutions becomes expedient from practical and economical viewpoints. Copper can be recovered from this regeneration solution by electrolysis. In our experiments, the regeneration solution (250 ml) was electrolyzed at the current strength of 5 A and voltage of 3 V. On electrolysis for 2 h, 7.4 g of copper was recovered (current efficiency 62%) and the copper concentration in the regeneration solution decreased from 30 to 0.1 g l^{-1}. After such a treatment, the regeneration solution was repeatedly used for regeneration of the anion exchanger saturated with copper(II).

Thus, our sorption experiments under dynamic conditions showed suitability of anion exchange for wastewater treatment to remove copper(II). This technique allows the selective recovery of copper(II) and obtaining of highly concentrated copper-containing solutions suitable for utilization.

CONCLUSIONS

(1) The sorption of copper(II), nickel(II), and chromium(III) from model solutions on anion exchangers was studied under static conditions. In sorption recovery of the nonferrous metals, the AN-221 and AM-7 weakly basic anion exchangers in the OH form exhibit the highest selectivity, and the salts of natural mineralization do not interfere with sorption.

(2) The sorption of copper(II) on AN-221 weakly basic anion exchanger under dynamic conditions and regeneration of this resin with aqueous H_2SO_4 were studied. The salts of natural mineralization do not in-

terfere with sorption. On treatment of copper-containing solutions with the anion exchanger, the residual copper content does not exceed the maximum permissible concentration.

(3) The weakly basic anion exchangers can be used for selective recovery of nonferrous metals from industrial wastewater.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Deep Purification of Aqueous Solutions To Remove Iron(III) with Carbonate-Containing Industrial Waste

T. G. Lupeiko, M. O. Gorbunova, and E. M. Bayan

Rostov State University, Rostov-on-Don, Russia

Received June 13, 2002; in final form, June 2003

Abstract—The possibility of using a carbonate-containing industrial waste in purification of aqueous solutions to remove iron(III) ions to below the maximum permissible concentration was analyzed. The sorbent capacities were calculated for iron(III) solutions with various initial concentrations. The influence exerted by the time, temperature, anionic composition of iron(III) salt solutions, and other factors on sorption was assessed.

The problem of purification of industrial wastewater that contains metal ions has always been, and still is rather topical in view of their adverse effect on the environment and human health. Of particular interest in this regard is the possibility of using solid industrial wastes as sorbents for heavy metals. To advantages of this method can be referred the ready availability and low cost of the sorbent (waste) and the environmental expediency of its use.

Previously, the composition and physicochemical properties of wastes formed in water treatment at heat and power plants have been studied for the example of the Rostov Heat and Power Plant no. 2 (TETs-2); it was shown that the slime mainly contains calcium and magnesium carbonates, is homogeneous and finely dispersed, has relatively constant composition, and is chemically and radiologically safe [1]. It has also been shown that the waste under study exhibits sorption capacity and can be successfully used to purify aqueous solutions to remove toxic ions of copper [2] and chromium [3].

This study is concerned with the possibility of purification of aqueous solutions to remove iron(III) ions, which can be found most frequently in industrial wastewater. The sorbent suggested is based on calcium and magnesium carbonates. When it is placed in the water medium, an excess amount of OH groups is formed because of the partial hydrolysis of the anion, which is confirmed by the fact that the pH of solutions of the waste is 8.7 [3]. Industrial wastewater from electroplating shops, including iron-containing solutions, is acidic and contains anions of strong acids (Cl^-, SO_4^{2-}, NO_3^-), i.e., Fe^{3+} is present in wastewater in the form of aqua hydroxo complexes formed in hydrolysis of the cation. Therefore, addition of the industrial waste to acid solutions of iron must enhance the hydrolysis, with iron hydroxide, which is the least soluble under the given conditions, formed and carbon dioxide evolved, by the scheme

$$Fe^{3+} \xrightarrow[-H^+]{HOH} Fe(OH)^{2+} \xrightarrow[-H^+]{HOH} Fe(OH)_2^+ \xrightarrow[-H^+]{HOH} Fe(OH)_3\downarrow,$$

$$CO_3^{2-} \xrightarrow[-OH^-]{HOH} HCO_3^- \xrightarrow[-OH^-]{HOH} H_2CO_3 \longrightarrow H_2O + CO_2\uparrow.$$

Thus, it would be expected that the carbonate-containing waste will allow deep purification of aqueous solutions to remove iron ions. In this case, the low solubility product of $Fe(OH)_3$ (6.3×10^{-38} [4]) will result in that the residual concentration of iron will not exceed the maximum permissible concentration (MPC) equal to 0.5 mg l^{-1} [5].

EXPERIMENTAL

In this work we studied the sorption capacity of a carbonate-containing waste in sorption of iron(III) from solutions with various initial concentrations and analyzed the influence exerted by the sorption time, temperature, and other factors on the degree of iron(III) recovery and sorbent expenditure.

The concentration of iron(III) was determined complexometrically by the commonly accepted procedure [6] to within 0.2%. For low concentrations, a spectrophotometric technique with *o*-phenanthroline was used [5]. The optical density was measured on a KFK-2MP photometer to within 4%. The acidity of the solutions

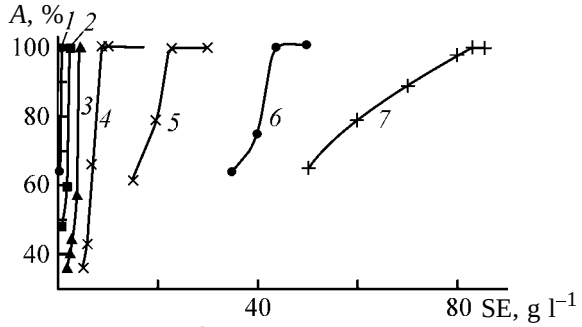

Fig. 1. Degree of Fe^{3+} recovery, *A*, vs. sorbent expenditure SE. Fe^{3+} concentration in solution, mg l^{-1}: (*1*) 200, (*2*) 500, (*3*) 1000, (*4*) 2000, (*5*) 5000, (*6*) 10000, and (*7*) 20000.

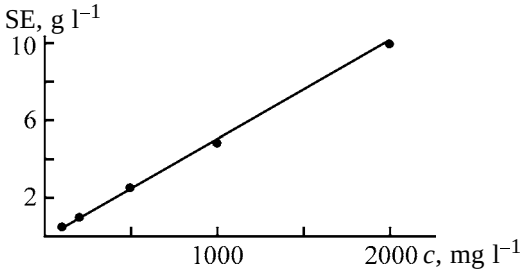

Fig. 2. Optimal sorbent expenditure SE vs. Fe^{3+} concentration *c* in the initial solution.

used was monitored potentiometrically with an I-120M pH meter to within ±0.05 pH units. Model solutions were prepared from a concentrated $FeCl_3$ solution with account of the Fe^{3+} content in wastewater from various industries. The solutions were strongly acidic, which is also characteristic of real wastewater [7]. The sorbent fraction used had particle size of 0.25–0.50 mm, which mainly constitutes the powdered industrial waste [3].

The range within which the content of iron(III) in industrial wastewater varies is rather wide: from several milligrams per liter at nonferrous metallurgical plants to tens of grams per liter at shops for etching of ferrous metals. Therefore, the optimal sorbent expenditure was determined for solutions with different concentrations. For this purpose, a weighed portion of the sorbent was placed in 100 ml of a solution to be purified, kept at 25°C. The amount of sorbent taken for Fe^{3+} precipitation was varied from 0.1 to 8 g (i.e., from 1 to 80 g l^{-1}). The sorption was carried out under static conditions with agitation in the course of 15 min, a time sufficient for the sorption process to be complete. The concentration of Fe(III) in a solution was determined before and after its contact with the sorbent, and the degree of metal recovery was calculated from the difference of the initial and residual concentrations. As the optimal sorbent expenditure was taken the minimum amount of the sorbent that was necessary under the given conditions for iron(III) to be removed to below MPC_{Fe}.

Effect of concentration $c_{Fe^{3+}}$ and pH of the initial $FeCl_3$ solution on expenditure and capacity of the sorbent

$c_{Fe^{3+}}$, mg l^{-1}	pH	Expenditure, g l^{-1}	Capacity, mg g^{-1}
100	2.41	0.5	200
200	2.37	1.0	200
500	2.32	2.5	200
1000	2.11	4.8	208
2000	1.83	10	200
5000	1.63	23	217
10000	1.40	44	227
20000	1.05	83	241

Apparently, the sorbent expenditure becomes higher as the initial content of iron(III) in solution increases (Figs. 1, 2). For example, purifying to below MPC_{Fe} requires 0.5 g l^{-1} of the sorbent for a solution with the initial iron concentration of 100 mg l^{-1} and 80 g l^{-1} for that with the concentration of 20 g l^{-1}. The optimal values of the sorbent expenditure and capacity are listed in the table.

For solutions with not-too-high iron(III) concentration, the sorbent capacity is 200 mg of Fe^{3+} per gram of the sorbent. With increasing iron content, the sorbent capacity grows somewhat, which is presumably due to the formation of a larger amount of difficultly soluble metal hydroxide and to the noticeable contribution to sorption from iron(III) ions additionally coprecipitated on the hydroxide. The dependence of the optimal sorbent expenditure on the Fe^{3+} concentration in the starting solution was processed using the least-squares technique with the use of the experimental data obtained (Fig. 2). In the concentration range 100–2000 mg l^{-1}, the plot can be interpreted as a straight line with 99.9% probability, which makes it possible to calculate the optimal sorbent expenditure for solutions with intermediate concentrations.

As would be expected, the pH values of the initially strongly acidic solutions being purified increased upon their contact with the sorbent (Fig. 3). This process was accompanied by evolution of carbon dioxide. In this case, the higher the iron(III) concentration in solution and the lower the pH of the starting solution, the stronger the gas evolution. It is also noteworthy that pH exceeds 4.5 in filtrates with Fe^{3+} content below the MPC_{Fe} level. This is due to the fact that, in weakly acidic, neutral, and alkaline media ($4.1 < pH < 14$), iron mainly exists in the form of a

difficultly soluble hydroxide, $Fe(OH)_3$ [4]. Hence follows that, indeed, purification of aqueous solutions to remove Fe^{3+} ions is based on their neutralization with a carbonate-containing waste, which leads to mutual enhancement of hydrolysis of the carbonate component of the sorbent and the iron salt to the point of precipitation of iron(III) hydroxide and evolution of carbon dioxide.

To evaluate the influence exerted by the time of contact between a solution being purified and the sorbent on the sorption process, weighed portions of the sorbent (0.25 and 1.0 g) were placed in 100 ml of a solution with the initial Fe^{3+} concentration of 500 and 2000 mg l^{-1}, respectively. The time of sorption was varied from 1 to 10 min. At the iron concentration of 500 mg l^{-1}, 2 min is sufficient for recovery of the metal to the MPC level. With increasing concentration of Fe^{3+} in solution, the sorption duration grows to become 3 min at 2000 mg l^{-1} (Fig. 4). As seen from the data presented, the purification of aqueous solutions to remove Fe^{3+} ions is complete much earlier, compared with ions of other metals. For example, the optimal time of sorption is 60 min for a 10 g l^{-1} copper(II) solution [2]. In all probability, this is due to the fact that, in the case of Cu^{2+}, there exist a number of phases with close solubility products, which can be formed in sorption and in the accompanying processes of neutralization, hydrolysis, etc. In the first stage, when the pH values are relatively low, only the least soluble, under the given conditions, phases are formed. Then, in the course of prolonged neutralization, these phases are converted into other, still less soluble phases, and this solid $\rightarrow$ solid transition cannot be fast. Thus, the fast sorption of iron(III) is apparently related to a simple mechanism of the process, which, in turn, is due to the presence of the $Fe(OH)_3$ phase, predominant in the solubility product in a wide pH range.

In order to study the influence exerted by the sorbent particle size on the extent of purification, three sorbent fractions were used: 0.1–0.25, 0.25–0.5, and 0.5–1.0 mm. The sorption was carried out from a solution with iron(III) concentration of 2 g l^{-1} under static conditions with agitation, in the course of 15 min. It was found that Fe^{3+} ions are removed to the greatest extent at particle size of 0.1–0.25 mm (Fig. 5). In all probability, this is due to higher solubility of finer particles in an aqueous solution and larger working surface area of the sorbent. Taking into account the fact that the sorbent is mainly composed of the 0.25–0.5-mm fraction, preliminary grinding of the sorbent is advisable. However, it was difficult to determine in this study which of the following two ways is more economically efficient: to grind the sorbent, with its expenditure thereby diminished, or to use its greater amounts without preliminary grinding.

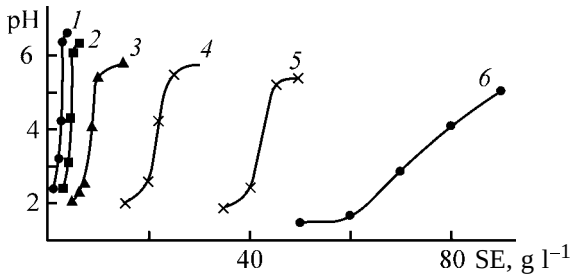

Fig. 3. Solution pH vs. sorbent expenditure SE. Fe^{3+} concentration in solution (mg l^{-1}): (*1*) 500, (*2*) 1000, (*3*) 2000, (*4*) 5000, (*5*) 10 000, and (*6*) 20 000.

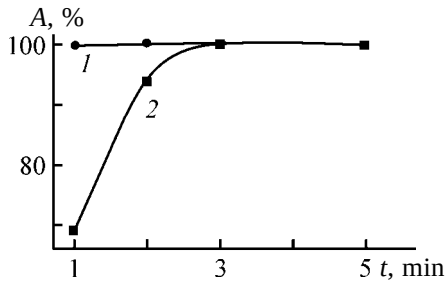

Fig. 4. Degree of Fe^{3-} recovery, *A*, vs. time *t*. Fe^{3+} concentration in solution (mg l^{-1}): (*1*) 500 and (*2*) 2000.

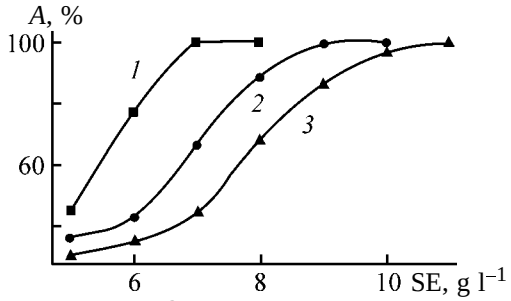

Fig. 5. Degree of Fe^{3+} recovery, *A*, vs. sorbent expenditure SE. Sorbent particle diameter (mm): (*1*) 0.1–0.25, (*2*) 0.25–0.5, and (*3*) 0.5–1.0.

The influence of the solution temperature on sorption was studied with a 2000 mg l^{-1} iron solution at a sorbent expenditure of 8 g l^{-1} (amount of sorbent somewhat smaller than the optimal value) and time of static sorption equal to 15 min. As seen from Fig. 6, sorption is markedly more effective at higher temperatures. This can be attributed to enhancement of hydrolysis and to an increase in the solubility of carbonates contained in the sorbent, which is also confirmed by more vigorous evolution of carbon dioxide. Thus, purification of the starting solution with 2 g l^{-1}

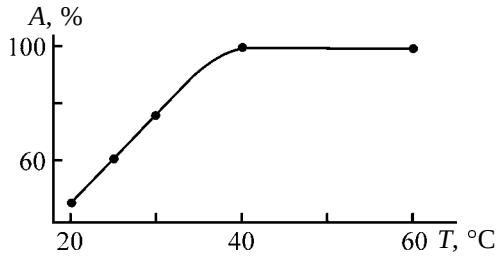

Fig. 6. Degree of Fe^{3-} recovery, *A*, vs. solution temperature *T*.

of iron(III) requires 10 g l^{-1} of the sorbent at 25°C (Fig. 2), whereas, upon heating to 40°C, 8 g l^{-1} of the sorbent is sufficient, i.e., the sorbent expenditure is lower in Fe^{3+} sorption from heated solutions.

In view of the fact that industrial wastewater has varied anionic composition, we analyzed the influence exerted on sorption by the anion component. It was found that processes of purification of chloride, nitrate, and sulfate solutions to remove Fe^{3+} occur in much the same way, with the sorbent capacities coinciding.

The results presented here indicate that the carbonate-containing industrial waste under study can well be used for purification of acid aqueous solutions (e.g., wastewater) to remove iron(III) ions. Moreover, the pH values of purified solutions conform to sanitary regulations concerning purified wastewater.

CONCLUSIONS

(1) The possibility of using a carbonate-containing sorbent for deep purification of aqueous solutions to remove Fe^{3+} ions was demonstrated.

(2) It was confirmed that the main mechanism of sorbent operation is neutralization of strongly acidic solutions with precipitation of Fe^{3+} in the form of a difficultly soluble hydroxide.

(3) The optimal time of contact of the sorbent with a solution being purified and sorbent expenditure for iron(III) salt solutions with various initial concentrations were determined, and the optimal sorbent capacity was calculated to be about 0.2 g of Fe^{3+} per gram of the sorbent.

(4) The sorbent expenditure is lower at finer dispersity of sorbent particles and in the case of sorption from heated solutions.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Use of Carbonate-Containing Industrial Waste for Treatment of Aqueous Solutions To Remove Nickel(II) Ions

T. G. Lupeiko, E. M. Bayan, and M. O. Gorbunova

Rostov State University, Rostov-on-Don, Russia

Received July 15, 2003

Abstract—The possibility of using a carbonate-containing industrial waste formed in water-treatment units of thermal power plants for treatment of aqueous solutions to remove nickel(II) ions was analyzed. The influence exerted by the time, temperature, and other factors on the degree of recovery of nickel(II) ions and sorbent expenditure was established. The possibility of separating nickel(II) and iron(III) ions simultaneously present in solution, using the waste under study, was demonstrated.

One of burdensome, large-tonnage wastes produced by thermal power plants is the carbonate-containing precipitate formed at shops for chemical water treatment. The suspended precipitate (slime) is periodically removed to slime collectors, which occupy large area and affect adversely the natural landscape and water-bearing horizons. The water-treatment waste can be used as raw material in manufacture of unfired bricks and as additive in production of ceramic articles and fertilizers. The waste is used most massively in landscape leveling and reclamation of strip pits. Despite the active search for various methods for utilizing slime and diminishing its amount, the problem is far from being resolved.

Previously, the composition and physicochemical properties of wastes formed in water treatment have been studied for the example of the Rostov heat and electric power plant TETs-2, and it was shown that the slime mainly contains calcium and magnesium carbonates, is homogeneous and finely dispersed, has relatively constant composition, and is chemically and radiologically safe [1]. It has also been shown that the waste under study has sorption capacity and can be successfully used to purify aqueous acid solutions to remove iron, copper, and chromium ions [2, 3].

This study is concerned with the possibility of treatment of aqueous solutions to remove nickel(II) ions, which can be found most frequently in wastewater of electroplating shops and are very toxic. Particularly dangerous are spent concentrated nickel-plating solutions (electrolytes) whose discharge to sewage disposal plants can disrupt their operation. Moreover, a great amount of the valuable metal is lost. In this study, we examined the possibility of recovering nickel(II) ions with a carbonate-containing industrial waste.

EXPERIMENTAL

Model solutions were prepared from $NiCl_2 \cdot 6H_2O$ of chemically pure grade; their concentration corresponded to the content of Ni^{2+} ions in wastewater from various plant shops [4]. The sorption was performed under static conditions as follows. A weighed portion of the sorbent (slime) with particle size in the range 0.25–0.50 mm was added to 100 ml of a solution to be purified, with a concentration c_{in} (mg l^{-1}) (calculated in terms of nickel). The resulting mixture was agitated for a time τ (min), and then the solutions were filtered. The pH value and the Ni^{2+} concentration in solution were determined before and after a solution was brought in contact with the sorbent, and the degree of recovery of the metal was determined from the difference of its initial and residual concentrations. The Ni^{2+} concentration was found by a spectrophotometric method with dimethylglyoxime, using the commonly accepted procedure [5]. The optical density was measured on a KFK-2MP photometer to within 5%. The acidity of the solutions used was monitored potentiometrically with an I-120M pH meter to within ± 0.05 pH units.

The content of nickel in industrial wastewater varies widely, and, therefore, the optimal sorbent expenditure was found for solutions with various concentrations c_{in} of 115, 50, 25, 10, and 1 mg l^{-1}. The sorption was carried out at 20°C for 60 min (Table 1, Fig. 1a).

As seen from Table 1, 95% degree of recovery is achieved for a solution with the initial Ni^{2+} concentration of 115 mg l^{-1} at the sorbent expenditure of 50 g l^{-1}. For solutions with lower initial concentration of nickel(II), sufficiently high degree of purification is obtained at lower amounts of the sorbent. For example, 10 g l^{-1} of the sorbent is sufficient for 97% recovery of the metal from a solution with c_{Ni} = 25 mg l^{-1}, and 4 g l^{-1}, for 95% recovery of nickel(II) from a solution with c_{Ni} = 10 mg l^{-1}.

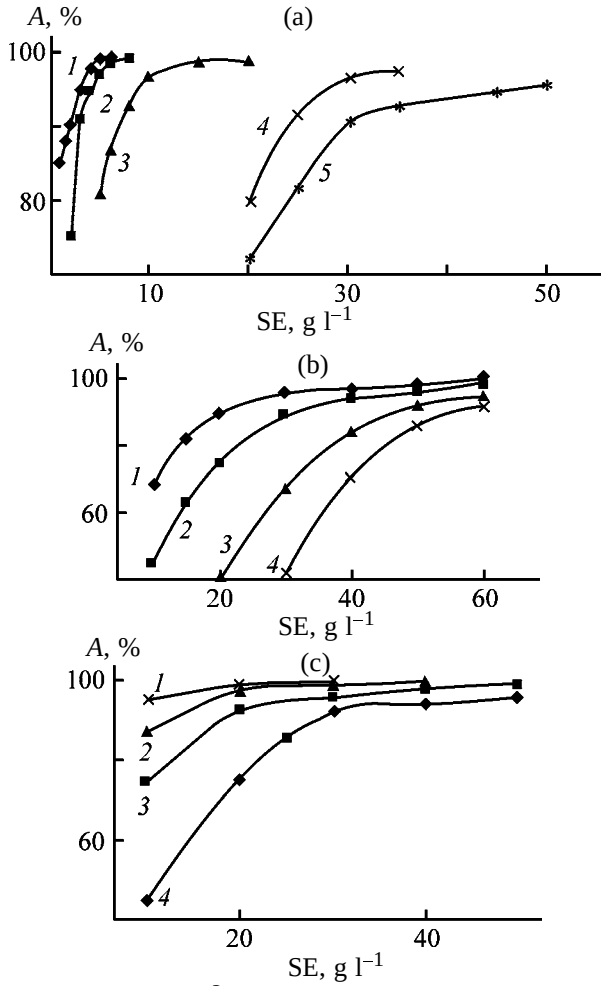

Fig. 1. Degree of Ni^{2+} recovery, *A*, vs. sorbent expenditure SE. (a) Nickel concentration in solution (mg l^{-1}): (*1*) 1, (*2*) 10, (*3*) 25, (*4*) 50, and (*5*) 115. (b) Particle diameter (mm): (*1*) 0.1–0.25, (*2*) 0.25–0.5, (*3*) 0.5–1.0, and (*4*) 1.0–2.0. (c) Temperature (°C): (*1*) 20, (*2*) 40, (*3*) 60, and (*4*) 80.

Analysis of data on the pH values of the starting and purified solutions shows that the sorption is accompanied by neutralization and alkalization of the initially acid solutions. It was noticed that the pH value of the purified solutions conforms to sanitary regulations concerning purified wastewater. The maximum degree of nickel recovery is achieved at pH > 8. Apparently, this is due to hydrolysis of the carbonates contained in the slime, which is confirmed by evolution of carbon dioxide. The higher the concentration of nickel ions and the lower the initial pH of a solution being purified, the more vigorous are the dissolution of the carbonate-containing waste and the gas evolution. The sorption capacity is, apparently, also related to exchange of magnesium(II) ions for nickel(II) in an aqueous solution to give a less soluble nickel carbonate in accordance with their solubility

products: $SP_{MgCO_3} = 2.1 \times 10^{-5}$, whereas $SP_{NiCO_3} = 1.3 \times 10^{-7}$. Formation of nickel carbonate via decomposition of calcium carbonate is unlikely, since $SP_{CaCO_3} = 3.8 \times 10^{-9}$.

In view of the aforesaid, nickel sorption (removal from the solution bulk) can be represented as a set of several reactions.

(1) Partial dissolution of the sorbent with subsequent formation of hydroxide anions

$$CO_3^{2-} + H_2O \rightleftarrows HCO_3^- + OH^-,$$

$$HCO_3^- + H_2O \rightleftarrows OH^- + H_2CO_3,$$

$$H_2CO_3 \rightarrow H_2O + CO_2\uparrow.$$

(2) Formation on the sorbent surface and near it of poorly soluble nickel hydroxide

$$Ni^{2+} + H_2O \rightleftarrows NiOH^+ + H^+,$$

$$NiOH^+ + H_2O \rightleftarrows Ni(OH)_2\downarrow + H^+.$$

The mutual enhancement of hydrolysis of the nickel(II) salt and the carbonate component of the sorbent results in that carbon dioxide is evolved and a precipitate of poorly soluble nickel hydroxide is formed.

(3) Formation on the sorbent surface and near it of poorly soluble nickel carbonate

$$MgCO(s) + Ni^{2+} \rightarrow NiCO_3(s) + Mg^{2+}.$$

In addition, nickel(II) ions can be adsorbed on the surface of an undissolved sorbent and on freshly formed particles. Thus, the interaction with the carbon-containing waste consists in "mild" neutralization of acid solutions and ends in self-adjusting establishment of a weakly acid medium, which rules out excessive alkalization of solutions. In this regard, the waste acts as a material self-adjusting the pH value. In this case, the process itself is constituted by precipitation of nickel(II) hydroxide, exchange interactions that lead to carbonate and mixed hydroxo carbonate phases, and, presumably, adsorption of nickel(II) by the amorphous particles formed and particles of an undissolved sorbent. Since the equilibration process is long, the initially formed solid phases are nonequilibrium and are further transformed into equilibrium phases (similarly to the previously studied sorption of Cu^{2+} [2]).

The above interactions provide nickel recovery from aqueous solutions. However, in view of the low efficiency of this process, it is to be optimized by adjusting its conditions. For this purpose, the influence exerted on the process by various factors was studied.

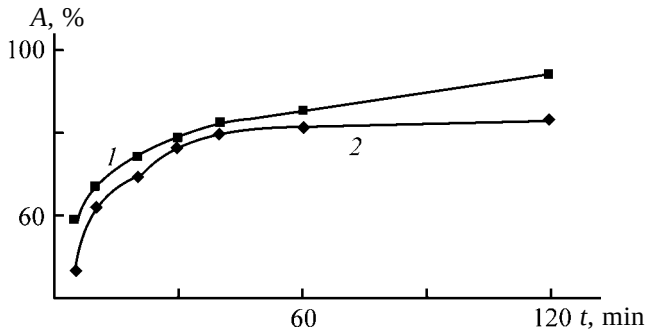

Fig. 2. Degree of Ni^{2+} recovery, A, vs. time t. Sorption conditions: (*1*) $c_{Ni} = 200$ mg l^{-1}, SE = 50 g l^{-1}; (*2*) $c_{Ni} = 25$ mg l^{-1}, SE = 5 g l^{-1}.

Since an air-dry slime sample is a powder with various particle diameters [1], the study was commenced with assessment of the influence exerted on the efficiency of nickel recovery by dispersity of sorbent particles. For this purpose, the main fractions of a carbonate-containing waste with grain sizes of 0.1–0.25, 0.25–0.5, 0.5–1.0, and 1.0–2.0 mm were used. The sorption was performed from solutions with nickel(II) concentration of 100 mg l^{-1}, at sorption time of 30 min. As expected, the degree of sorption is higher, and the sorbent expenditure is lower, with finely dispersed fractions, e.g., 0.1–0.25 mm (Fig. 1b). In all probability, this is due to easier dissolution of finer particles in the aqueous solution and larger working surface area of the sorbent. However, at high sorbent expenditure, which is necessary for achieving >90% nickel(II) recovery, the particle size affects the process only slightly, because the solution is supersaturated with the slime. Moreover, use of a finely dispersed fraction makes difficult the separation of the sorbent contaminated with nickel from the purified solution. Therefore, the sorbent fraction with grain size of 0.25–0.5 mm, whose content in the sorbent exceeds 45% [3], was used in further experiments.

An important specific feature of the process is that the sorption equilibrium is attained slowly (Fig. 2), even though the major part of the metal is recovered already during the first several minutes. For example, for a solution with $c_{in} = 200$ mg l^{-1} (curve *1*), the main part of nickel(II) (58%) is sorbed at the sorbent expenditure of 50 g l^{-1} during the first 5 min. For a solution with the initial concentration of 25 mg l^{-1} (curve *2*), more than 60% of the metal is recovered at the sorbent expenditure of 5 g l^{-1} in 10 min. In this

Table 2. Stage-by-stage purification of solutions. Duration of each purification stage 5 min

c_{in}, mg l^{-1}	First stage of purification		Second stage of purification		DR, %
	SE, g l^{-1}	c_{res}, mg l^{-1}	SE, g l^{-1}	c_{res}, mg l^{-1}	
200	50	72	30	1.44	99
100	20	32	15	0.38	99
25	5	11	5	0.41	98

case, sorption proceeds actively during the first hour, and then the process passes into a less intensive stage, with virtually complete recovery (99%) achieved in 3 days. If a markedly greater amount of sorbent, e.g., 10 mg l^{-1}, is taken for a solution with c_{in} = 25 mg l^{-1}, more than 90% of nickel(II) is recovered in the first 5 min.

In view of this fact, the optimal sorption conditions for achieving a high degree of purification are to be chosen depending on the task to be accomplished. For example, at low sorbent expenditure, the time of contact with a solution being purified should be relatively long, and fast and efficient purification is achieved at a large excess of the sorbent. Taking into account the low cost of the sorbent, the second way seems to be more efficient. Also possible is stage-by-stage purification of solutions. This is particularly important for strongly concentrated solutions, for which "rough" purification will be the first stage, and, if necessary, additional purification, the second stage. Table 2 illustrates a possible course of stage-by-stage purification. As for the choice of conditions and modes of treatment of particular real kinds of wastewater from electroplating shops, it is determined, in the first place, by their qualitative and quantitative composition and the task to be accomplished at a plant (rough purification of spent concentrated electrolytes or fine purification of wastewater).

One more result of interest was that the expenditure of the carbonate-containing sorbent is markedly lower in sorption from hot solutions. In this case, the precipitation of nickel(II) ions is markedly accelerated and a high degree of purification is achieved. For example, upon heating to 40°C, nickel ions are virtually completely removed from a solution (c_{in} = 100 mg l^{-1}) in the presence of 40 g l^{-1} of slime in 15 min, and if the sorption is carried out at 80°C, 95% recovery of nickel requires a 5 times smaller amount of the sorbent (SE = 50 g l^{-1} at 20°C and 10 g l^{-1} at 80°C (Fig. 1c). In all probability, the higher efficiency of purification in sorption from hot solutions is due to increased solubility of the slime and to enhanced hydrolysis of its constituents, such as calcium and magnesium carbonates. This conclusion is confirmed by more vigorous evolution of carbon dioxide from hot solutions.

The qualitative and quantitative compositions of industrial wastewater strongly vary, and, therefore, the influence exerted by various ions on the sorption of nickel(II) was analyzed. A study of sorption from sulfate, chloride, and nitrate solutions revealed that changes in the anionic composition of solutions have virtually no effect on the sorption of nickel(II). At the same time, the presence of metal cations strongly affects the amount of sorbent necessary for solution purification, since the sorbent is also consumed for recovery of other metals. The influence of cations was studied for the example of iron, which is a cation that most frequently occurs in wastewater. Taking into account the fact that sorption of nickel(II) proceeds successfully only at a sufficiently high expenditure of the sorbent (Table 1) and iron(III) is sorbed virtually instantaneously at low sorbent consumption [sorbing capacity 200 mg iron(III) per 1 g sorbent], it is possible to separate solutions that contain these ions. This is particularly important in nickel plating of iron articles, when the nickel-plating electrolyte is contaminated with iron(III) ions. Table 3 lists the results of sorption from solutions containing nickel(II) and iron(III) ions in ratios of 1 : 2, 1 : 4, and 1 : 6, i.e., solutions with c_{in}^{Ni} = 100 mg l^{-1} and c_{in}^{Fe} = 200, 400, and 600 mg l^{-1}, respectively. The sorption was carried out from acid solutions (pH 2–3) for 5 min. As seen from Table 3, 90% of nickel remains in a solution that initially contained a mixture of aqua ions of the metals in a ratio Ni : Fe = 1 : 6 upon complete precipitation of iron(III). For less concentrated solutions, precipitation of iron(III) with virtually zero loss of nickel(II) is possible.

Finally, it should be noted that, under certain conditions, the carbonate-containing waste formed in water treatment at thermal power plants can be used for recovery of nickel(II) ions from dilute and concen-

Table 3. Separation of solutions containing Ni(II) and Fe(III) ions

SE, g l^{-1}	Degree of metal recovery, %					
	Ni : Fe = 1 : 2		Ni : Fe = 1 : 4		Ni : Fe = 1 : 6	
	Fe(III)	Ni(II)	Fe(III)	Ni(II)	Fe(III)	Ni(II)
1.0	76	0	–	–	–	–

3.0	–	–	100	1.6	77	5.8
4.0	–	–	–	–	100	9.9

trated solutions, and also for partial or virtually complete separation of mixed solutions that contain both Ni(II) and Fe(III) ions.

CONCLUSIONS

(1) The possibility of using the slime formed in water-treatment units of thermal power plants for purification of aqueous solutions to remove nickel(II) ions was demonstrated.

(2) The optimal process duration and sorbent expenditure were found for solutions with various concentrations. Several purification schemes were suggested.

(3) It was established that the sorbent expenditure decreases as the temperature of a solution being purified is raised, sorption duration is made longer, and more finely dispersed sorbent fraction is used.

(4) The possibility of partly or virtually completely separating mixed solutions that contain various amounts of Ni(II) and Fe(III) with the use of the waste was demonstrated.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Interrelation between Self-Diffusion, Viscosity, and Optical Properties of Organic Liquids

I. V. Skomorokhov and V. I. Skomorokhov

Tupolev Kazan State Technical University, Kazan, Tatarstan, Russia

Received May 16, 2003

Abstract—The possibility of general correlation analysis of the self-diffusion coefficients and dynamic viscosity coefficients of low-molecular-weight liquid organic nonelectrolytes was studied. An attempt was made to obtain common dependences suitable for calculating the self-diffusion and viscosity coefficients.

Optical methods of investigations, in particular, refractometry, are widely used in physicochemical analysis. Refractometric constants are closely related to many physical properties of substances. Combined measurements of optical and other properties of liquids reveal their interrelation.

There are virtually no published data on a correlation between the kinetic coefficients characterizing the mass and momentum transfer processes, on the one hand, and refractometric constants, on the other. Only Suryanarayana [1] estimated the dynamic viscosity coefficient of liquids η, mPa s^{-1}, from the refractive index n:

$$\eta = C\left[\frac{(n_D^{20})^2 - 1}{(n_D^{20})^2 + 2}\right], \quad (1)$$

where C is the proportionality coefficient with the dimensionality identical to that of η, and n_D^{20}, refractive index for the D line of sodium (λ = 589.3 nm) at 20°C.

There are no published data on interrelation between the self-diffusion coefficients (SDCs), characterizing the thermal (random) motion of molecules in liquids, and the refractometric constants.

Figure 1 presents the D vs. n_D^{20} plots constructed for the experimental self-diffusion coefficients D available from the literature. It is seen that the data for isomeric homologs and liquids from different homologous series cannot be fitted by a single correlation curve.

General correlation analysis is possible only for liquids from the same group (homologous series). For example, for liquid *n*-alkanes from pentane to decane, we obtained the following linear equation:

$$D = an_D^{20} + b, \quad (2)$$

where a = –77.36 (–79.62) and b = 110.23 (113.55) for T = 293.15 (298.15 K). The SDCs calculated by this equation and those measured experimentally differ by less than 5%.

With lengthening molecular chain of *n*-alkanes, Eq. (2) gets nonlinear (Fig. 1, curve *1*). Regular trends in variation of the SDCs with the refractive index along a homologous series are also exhibited by primary alcohols C_1–C_8 (Fig. 1, curve *2*) and cyclanes, namely, *cyclo*-C_5, *cyclo*-C_6, and methyl-*cyclo*-C_6 (Fig. 1, curve *3*). No common equation directly interrelating D and n_D^{20} parameters of liquids from different classes was revealed.

The light wave affects the mobility of the charges (electrons and nuclei in atoms) constituting the molecule. As a result, molecules of liquid nonpolar dielec-

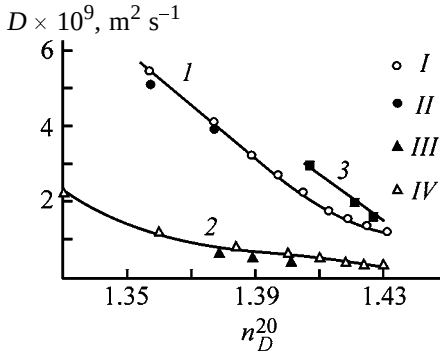

Fig. 1. Correlation of D with n_D^{20} for selected organic liquids at 293.15 K: (*1*) (*I*) *n*-C_5–*n*-C_{17} and (*II*) *iso*-C_5, *iso*-C_6; (*2*) (*III*) primary alcohols C_1–C_8, (*IV*) *iso* alcohols C_3–C_5, and (*3*) cyclanes.

trics get polarized, acquiring a dipole moment $\vec{\mu} = \alpha\vec{E}$. Here, μ is the dipole moment of the molecule, D; $\vec{E}$, electric field strength, V m^{-1}; and α, polarizability, characterizing the electric-field-induced deformability of the molecule, D m^4 V^{-1}.

The equation for molar polarization corrected for the dipole interaction of molecules in the limit of a very weak field has the form [2, 3]

$$\frac{\varepsilon - 1}{\varepsilon + 2} = \frac{4}{3}\pi n\alpha[1 + S(n, T)], \quad (3)$$

where n is the number of molecules per unit volume (numerical density) in the same limit, m^{-3}, and $S(n, T)$, a function of the numerical density and temperature.

We will introduce the designation $n_0 = (4/3)\pi n\alpha$ into Eq. (3) and thus obtain

$$\frac{\varepsilon - 1}{(\varepsilon + 2)n_0} - 1 = S(n, T). \quad (4)$$

Transfer of particles in liquids is, essentially, a sequence of their random displacements. Diffusion motion of a particle in a medium is usually characterized by an rms displacement $\langle r^2\rangle$ from the initial position within the time $\Delta\tau$. In the three-dimensional space, the rms displacement is defined as follows [4, 5]:

$$\langle r^2\rangle = 6D\Delta\tau. \quad (5)$$

Under isobaric conditions, the rms displacement of a molecule within a certain time interval $\Delta\tau$, like the $S(n, T)$ functional, is a function of the numerical density and temperature. Therefore, SDC can be expressed as

$$D = \frac{\langle r^2\rangle}{6\Delta\tau} = f(n, T). \quad (6)$$

Comparison of Eqs. (4) and (6) suggests that the self-diffusion coefficient can be expressed as a function of the left-hand side of Eq. (4), which is the molar polarization P_m

$$D = \varphi\left[\frac{(\varepsilon - 1)}{(\varepsilon + 2)}\frac{M}{\rho}\right]\varphi(P_m). \quad (7)$$

where φ is the function designation; M, molecular weight, kg mol^{-1}; ρ, density of liquid, kg m^{-3}; and ε, dielectric permittivity (dimensionless).

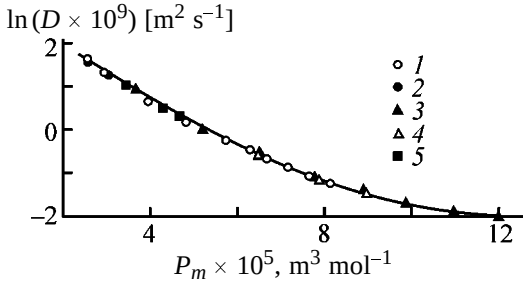

Fig. 2. Common dependence of D on P_m for organic liquids: (*1*) *n*-C_5–*n*-C_{17}; (*2*) *iso*-C_5, *iso*-C_6; (*3*) primary alcohols C_1–C_8; (*4*) *iso* alcohols C_3–C_5; and (*5*) cyclanes.

To test the hypothesized existence of a correlation between the self-diffusion coefficient and molar polarization, we took advantage of the SDCs, densities, refractive indices [6–9], and dielectric permittivities [10] of liquids from various homologous series.

We constructed the $\ln D$ vs. P_m plots for the experimental SDCs of liquid *n*-alkanes (C_5–C_{17}), isopentane, isohexane (with the dipole moment $\mu = 0$ and association number $\psi = 1$), as well as for diethyl ether and diisopropyl ether ($\mu > 0$, $\psi = 1$), benzene, toluene, *m*-xylene, cyclopentane, cyclohexane, methylcyclohexane ($\mu \sim 0$, $\psi > 1$), and homologous series of primary alcohols (C_1–C_8), 2-propanol, and 3-butanol ($\mu > 0$, $\psi > 1$). These points are well fitted by a common curve (Fig. 2).

Comparison with Fig. 1 clearly shows that general correlation analysis of the experimental SDC values in the $\ln D$ vs. P_m coordinates is advantageous.

The molar polarization of liquids whose dielectric permittivity $\varepsilon \neq (n_D^{20})^2$ was calculated by the formula

$$P_m = \frac{(\varepsilon - 1)}{(\varepsilon + 2)}\frac{M}{\rho}, \quad (8)$$

and that of liquids with $\varepsilon = (n_D^{20})^2$, by the formula

$$P_m = \psi R_d, \quad (9)$$

where ψ is the correction for association of the molecules, which is equal to the association number determined using the viscosities [11], and R_d, molar refraction determined by the equation

$$R_d = \frac{(n_D^{20})^2 - 1}{(n_D^{20})^2 + 2}\frac{M}{\rho}. \quad (10)$$

By regression analysis, we obtained the analytical expression describing most adequately the experimental self-diffusion coefficients D, m^2 s^{-1}, for the

liquids studied at 293.15 K:

$$D = 10^{-9}\exp(a_1P_m^2 + b_1P_m + c_1), \quad (11)$$

where $a_1 = 2.791 \times 10^{-4}$ mol^2 cm^{-6}, $b_1 = -8.157538 \times 10^{-2}$ mol cm^{-3}, $c_1 = 3.5155$ for nonpolar and weakly polar liquids (alkanes, cyclanes, aromatic hydrocarbons); and $a_1 = 2.4006 \times 10^{-4}$ mol^2 cm^{-6}, $b_1 = -7.31926 \times 10^{-2}$ mol cm^{-3}, $c_1 = 3.16715$ for polar liquids (primary alcohols); P_m has the dimensionality of cm^3 mol^{-1}.

The discrepancies (per cent) between the SDCs calculated by Eq. (11) and determined experimentally were estimated at 6.6 (maximal) and 2.36 (average) for alkanes, cyclanes, and aromatic hydrocarbons, respectively; and 3.7 (maximal) and 1.63 (average) for primary alcohols.

Unfortunately, the limited number of the experimentally determined SDCs for organic liquids prevents more comprehensive analysis; there are no SDCs for polar molecules of fatty acids and esters having high intrinsic dipole moments ($\mu > 2$ D).

Thus, with lacking experimental SDCs for organic liquids, Eq. (10) can be recommended for calculating these parameters.

We also studied how the dynamic viscosity coefficients (DVCs) vary with the molar refraction and molar polarization of *n*-alkanes and primary alcohols. The experimental viscosities were represented in the $\eta M^{2/3}$ vs. R_d, $\ln\eta$ vs. P_m, and $\ln\eta$ vs. R_d coordinates. The most precise correlation was obtained in the case of the $\ln\eta$ vs. P_m coordinates.

By parabolic regression we obtained equations for calculating the viscosities η, mPa s, of liquid *n*-alkanes,

$$\eta = \exp(a_2P_m^2 + b_2P_m + c_2), \quad (12)$$

with the parameters $a_2 = -2.7358 \times 10^{-4}$ mol^2 cm^{-6}, $b_2 = 8.06 \times 10^{-2}$ mol cm^{-3}, $c_2 = -3.3875$, and viscosities of primary alcohols,

$$\eta = \exp(a_3R_d + c_3), \quad (13)$$

with the parameters $a_3 = 5.62 \times 10^{-2}$ mol cm^{-3} and $c_3 = -2.227$; P_m and R_d have the dimensionality of cm^3 mol^{-1}.

The relative mean deviations of the DVCs calculated by Eqs. (12) and (13) from those determined experimentally were estimated at 0.875 and 1.73% for nonassociated alkanes and associated alcohols, respectively. The average deviation was calculated as the ratio of the sum of the absolute values of the relative deviations for all the N processed experimental points to their number

$$\delta_{mean} = \frac{\sum_{n=1}^{N}|\delta_i|}{N}, \quad (14)$$

where δ_{mean} is the average relative deviation of the calculated DVCs from the experimental data; δ_i, relative deviation for individual experimental points; and N, number of points.

The maximal deviations of the calculated DVCs from the experimental data were estimated at 1.6 and 4.75% for *n*-heptane and primary alcohols, respectively. The maximal deviation $\max\{\delta_i\}$, %, corresponds to the largest deviation among those calculated by the formula

$$\max\{\delta_i\} = \left[\frac{(\eta_{i,calc} - \eta_{i,exp})}{\eta_{i,exp}}\right] \times 100, \quad (15)$$

where $\eta_{i,calc}$ is the viscosity calculated by Eqs. (12) or (13), and $\eta_{i,exp}$, the experimental viscosity.

In view of the fact that the SDCs and DVCs can be precisely described by similar dependences, we can estimate the rotational component of the activation energy of viscous flow $E_{rot} = E_\eta - E_{trans}$ for *n*-alkanes by the equation

$$A_\eta A_D T\exp(E_{rot}/kT) = \exp[(a_1 + a_2)P_m^2 + (b_1 + b_2)P_m + (c_1 + c_2)], \quad (16)$$

where k is the Boltzmann constant; E_{rot}, rotational component of the activation energy of viscous flow; A_η and A_D, pre-exponential factors in the equations for SDC and DVC [12], respectively; constants a_1, a_2, b_1, b_2, c_1, and c_2 are identical to those in Eqs. (11) and (12).

CONCLUSIONS

(1) A correlation was established between the self-diffusion coefficients D and molar polarization P_m of liquid low-molecular-weight organic nonelectrolytes, $\ln D = f(P_m)$, as well as between their dynamic viscosity coefficients η and molar polarization, $\ln\eta = f(P_m)$. These correlations yield common dependences suitable for calculating the self-diffusion [Eg. (11)] and dynamic viscosity [Eqs. (12) and (13)] coefficients.

(2) For a series of homologous substances, common dependences can be obtained for the refractive index.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Tetrafluoromethane by Graphite Fluorination with Elemental Fluorine

Abstract—Formation of high-temperature inverse wave of the filtration combustion of graphite fixed bed in fluorine was studied. Scientific principles of the industrial process of the tetrafluoromethane synthesis from graphite and fluorine were developed.

Tetrafluoromethane (TFM), CF_4, is widely used in the industry for plasma-chemical production of integrated circuits, as refrigerant, flame inhibitor, etc. [1]. The annual world consumption of TFM is about 1000 t today, which determines urgency of the development of its commercial synthesis.

Various methods of TFM preparation are known: fluorination of methane, its chloro and fluoro derivatives, silicon carbide, and polyfluoroethylene with elemental fluorine and fluorination of tetrachloromethane with various inorganic fluorides [1]. However, the synthesis from the elements is the most promising; fluorine is a commercial product, and electrode graphite, which is characterized by high purity and appropriate physicomechanical properties, can be used as a carbon material.

It was found [2–11] that, depending of fluorination conditions and kind of carbon raw material, the products of fluorine reaction with carbon are liquid, solid, and gaseous substances:

$$C(s) + F_2(g) \rightarrow (CF)_n(s) + CF_4(g) + C_2F_6(g) + C_3F_8(g) + C_4F_{10}(g) + C_5F_{12}(g) + \ldots \quad (1)$$

It was shown in [8, 9] that, at 1000–1500°C, TFM is the single product of the fluorine reaction with graphite. At lower temperatures, hexafluoroethane, octafluoropropane, and higher-molecular-weight perfluorinated carbons are also formed. At the temperatures lower than 500°C, fluorographite $(CF)_n$ is the main product. At temperatures lower than 100°C, fluorine does not react with graphite, as indicated in numerous papers.

The TFM formation in the fluorine reaction with carbon is accompanied by a heat release (932 kJ mol^{-1}) sufficient for graphite heating up to the required temperatures. Powdered graphite has effective heat conductivity of about 10^{-2} W m^{-1} K^{-1}. The filtration combustion mode is realized when fluorine is passed through a heated graphite bed. The combustion wave has inverse structure, since graphite burns out completely, and all the reaction heat is distributed in the graphite bed below the reaction zone along the gas flow direction. In the inverse wave of the filtration combustion, the zone of fluorine uptake is narrower than the zone of highly heated graphite. Therefore, unreacted graphite is subject to prolonged heating before it appears in the reaction zone, and, as a result, volatile impurities (e.g., sulfur) are eliminated. This fact favors preparation of high-purity TFM. It should be noted that, in the inverse wave of the filtration combustion, fluorine breakthrough through the reaction zone is excluded, and thus complete fluorine conversion is provided [12].

As mentioned above, at temperatures lower than 500°C, solid fluorocarbon $(CF)_n$ is the single reaction product [10, 11]. On heating above 500°C, it decomposes to form C_2F_6, C_3F_8, C_4F_{10}, etc. [10, 11]. Therefore, to obtain pure TFM, the thermal interaction of the graphite packing in the fluorine-containing area with heat-bearing surfaces should be excluded. This can be realized by feeding fluorine directly into the graphite bed depth.

However, at the reactor startup, fluorine is (in the simplest case) fed into the graphite bed at room temperature, and, in the course of formation of the high-temperature synthesis wave, fluorographite initially

1070-4272/04/7701-0092 © 2004 MAIK "Nauka/Interperiodica"

accumulates, which then decomposes to form C_2F_6, C_3F_8, C_4F_{10}, etc. In addition, since fluorographite is a thermolabile condensed compound, its accumulation is undesirable from the viewpoint of safety of the reactor functioning. Thus, the stage of formation in the graphite packing with the initial temperature of 10–20°C of a high-temperature wave (1000–1500 K) in which the synthesis proceeds is the most important for production of maximally pure CF_4 in an industrial reactor and the process safety.

We found no studies of carbon ignition in fluorine. Such important characteristics of the industrial process as the time of ignition delay and time of attainment of the reactor operating mode ensuring production of pure TFM (at the content of fluorocarbon impurities no more than 0.1%) are virtually unknown.

In this work, we determined the conditions of formation of a high-temperature wave of filtration combustion of graphite or its mixtures with activated birch charcoal in fluorine and a method for safe and reliable reactor startup.

EXPERIMENTAL

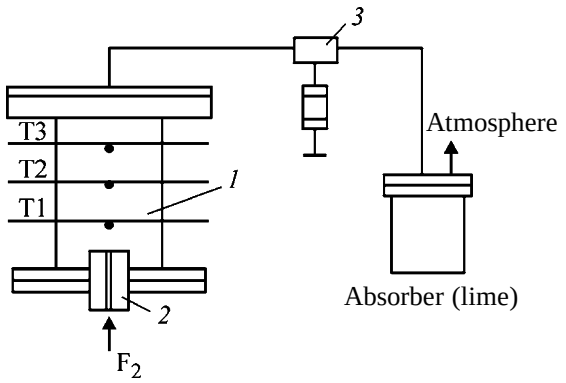
To study the combustion process, we developed a laboratory device (see figure).

A graphite powder was charged into a cylinder (*1*) with an inner diameter of 68 mm and height of 164 mm. Fluorine was fed into the reactor through a thick-walled copper nozzle (*2*). In the reactor volume 700 mm in diameter, Chromel–Alumel thermocouples T1–T3 without protective cases were placed. The distance (along the vertical) between the nozzle outlet and thermocouple junction was 14 mm, and the distance between the thermocouple junctions, 30 mm.

In the experiments, the constant fluorine consumption was preset, and samples of the reaction gas for chromatographic analysis on a katharometer were taken from a sampler (*3*) with a syringe. In addition, the fluorine breakthrough through the sampler (*3*) was monitored. A KI aqueous solution was used as an indicator.

Formation of the high-temperature zone of the synthesis was judged from the thermograms obtained. The time interval from the beginning of fluorine introduction to attainment of the temperature of 400°C near the junction of thermocouple T1 was considered as the ignition delay time t_{id}.

Fluorine and an F_2 + HF mixture[1] were used as



Scheme of the laboratory device for studying carbon combustion in fluorine.

fluorinating agents, and ground VAZ grade graphite (TU 48-20-54–84) produced by the MEZ (Moscow Electrode Plant) Joint-Stock Company and a mixture of 90% graphite and 10% activated birch charcoal (ABC), as carbon raw materials.

The first series of experiments was performed with VAZ graphite and fluorine. The initial graphite and graphite already used in high-temperature synthesis of CF_4 were used. The results of measurements of the ignition delay time as influenced by fluorine consumption are listed in Table 1. The nozzle outlet diameter *d* and the linear velocity of the fluorine flow at the nozzle outlet also presented. It should be noted that the high-temperature reaction zone could not be formed with spent graphite.

The results of chromatographic analysis of the reaction gas samples, qualitative monitoring of the fluorine breakthrough, and measurement of temperature as a function of time from the beginning of fluorine feeding are given in Table 2.

It follows from Tables 1 and 2 that heat accumulation and ignition proceed in the area between thermo-

* After the use in high-temperature synthesis of CF_4.

couples T2 and T3, and, as a result, a counterwave of the filtration carbon combustion in fluorine is formed. It propagates upwards the flow, is stabilized in the region of fluorine outlet from the nozzle, and transforms into the inverse wave. The counterwave of carbon combustion in fluorine propagates in the filtration mode; there is no fluorine breakthrough beyond the reaction front. The wave linear velocity between thermocouples T2 and T1 is 900 mm h^{-1} with respect to the level of 600°C.

The time of ignition delay of the initial graphite is several hundreds of seconds. In this time, carbon polyfluoride is accumulated, which then decomposes with formation of gaseous fluoroalkanes containing CF_4. Under the laboratory conditions, after the first 900 s of the synthesis, the product containing 99.5 vol % CF_4 was prepared. The main impurities were C_2F_6 and C_3F_8.

To control the possibility of shutdown and startup of the industrial reactor of the TFM synthesis after cooling the reaction zone, we made experiments with graphite treated with fluorine in the high-temperature zone and found that, under laboratory conditions at the initial temperature of 15°C, such graphite was not ignited.

Hence, to obtain pure TFM and provide stable reactor startup, special measures are required to intensify the ignition.

One of the methods of the ignition intensification is adding certain amount of activated charcoal to the graphite packing. The charcoal has substantially larger specific surface area as compared to graphite and provides higher reaction rate. We performed a series of experiments with graphite + ABC mixture using the above method. The results are given in Tables 1 and 2.

The time of ignition delay for freshly prepared graphite + ABC mixture was 250 s at fluorine flow rate of 40 $cm^3 s^{-1}$; there was fluorine breakthrough through the graphite bed. After 700 s of the synthesis, pure CF_4 was not obtained; the hexafluoroethane impurity was 0.6 vol %. In the case of spent mixture and at fluorine flow rate of 15 $cm^3 s^{-1}$, no ignition was observed.

The above facts show that the time of the ignition delay with ABC as initiator decreases, but the problem of the startup period (accumulation of thermolabile carbon polyfluoride under the synthesis conditions) remains. In addition, the spent graphite + ABC mixture, similarly to pure graphite, has startup characteristics differing from those of the freshly prepared mixture.

Using ABC as initiator in an industrial reactor may have the following substantial disadvantage. In the case of faster ABC burn-out as compared to graphite, the ABC in the region of fluorine feeding into the carbon bed can get exhausted after prolonged reactor functioning, which worsens the reactor startup parameters (time of ignition delay, time of attaining the steady-state mode).

In this work, we suggest the following method of the reactor startup. At startup, a gas forming with fluorine a self-igniting pair is introduced into the graphite bed coaxially to the fluorine flow. After formation of high-temperature (> 1000 K) zone, owing to heat liberated in oxidation of this gas with fluorine, feeding of the gas is turned off, and the TFM synthesis is performed.

Taking into account high reactivity of fluorine, readily available methane, propane, ethylene, etc. can be used as a gaseous fuel.

Among the above gases, ethylene is the most reactive with respect to fluorine, since in the fluorine–ethylene system a branched chain reaction mechanism is realized [13]. Therefore, in laboratory trials of this method, we used a mixture consisting of 85 vol % H_2 and 15 vol % ethylene and VAZ graphite (initial and spent). The nozzle for feeding fluorine and gas fuel consists of two coaxial tubes. Fluorine was fed through the axial channel, and a mixture consisting of hydrogen and ethylene, through the ring channel.

Table 3. Time t_{350} at various flow rates of fluorine W_{F_2} and ethylene + hydrogen mixture W_{mix}, d = 0.85 mm

Mixture	W_{mix}, $cm^3 s^{-1}$	W_{F_2}, $cm^3 s^{-1}$	U_{F_2}, $m s^{-1}$	t_{350}, s
$H_2 + C_2H_4$	13	26	46	188
	13	13	23	270
$C_3H_8 + C_4H_{10}$	3.7	26	46	128
	1.8	14	25	173

The gaseous fuel was fed for 10 s, and then fluorine feeding at a preset flow rate was started. When the temperature near the thermocouple T2 junction reached 350°C, feeding the gaseous fuel was stopped, while feeding fluorine with the preset flow rate was continued.

The time intervals between the beginning of fluorine feeding and attainment of 350°C near the thermocouple T2 junction, t_{350}, for various flow rates of fluorine and gas mixture are listed in Table 3. The compositions of the reaction products after stopping feeding of the ethylene + hydrogen mixture and measurement of the temperature of the graphite bed are listed in Table 4.

At the instant of fluorine feeding into the graphite bed, thermocouple T1 recorded a jump of temperature from the initial value to more than 1300°C, after which it burnt down. Thermocouples T2 and T3 recorded smooth temperature rise, and after approximately 5 min, thermocouple T2 recorded the temperature of 150–300°C.

Table 4 shows that, after stopping the supply of the gaseous fuel, a stable high-temperature inverse wave of the CF_4 synthesis is formed in the graphite bed. The time interval from stopping the gaseous fuel feeding to obtaining pure CF_4 (more than 99.9 vol %) does not exceed 500 s.

No fluorine breakthrough through the graphite bed was observed. All experiments of this series were performed with graphite that worked in the high-temperature zone of the synthesis.

Thus, the use of gaseous fuel allows stable startup of the wave reactor of TFM synthesis without ac-

* No F_2 breakthrough.

cumulation of carbon polyfluoride in the reactor in the starting period.

Fluorine produced at electrolysis plants contains impurities of HF, N_2, and O_2. To reveal the effect of HF on the TFM synthesis, we made experiments with an F_2 + 9 vol % HF mixture simulating electrolysis gas produced by the Angarsk electrolysis chemical combine and found that HF does not affect the starting characteristics and the composition of the synthesis products.

Propane–butane mixture is the most widespread commercial gaseous fuel. Therefore, we performed some experiments on its use to obtain high-temperature zone of TFM synthesis. The scheme of the laboratory device and experimental procedure were the same as above. The results are presented in Tables 3 and 4.

Thermocouple T1 at the instant of fluorine feeding recorded a temperature jump from the initial value to that higher than 1300°C. The pattern of formation of the high-temperature zone was similar to that observed with ethylene–hydrogen mixture.

The above data show that, under the industrial conditions, startup of the reactor of the TFM synthesis from electrode graphite and F_2 in the mode of the inverse wave of the filtration combustion is the most reliable when a gaseous fuel is used. In this case, the process can be organized so as to minimize accumulation of carbon polyfluoride in the reactor volume in the time of formation of the high-temperature zone and ensure the time of attainment of working conditions not exceeding 10 min. The propane–butane mixture can be recommended as the most readily available.

CONCLUSIONS

(1) A laboratory device was developed, and conditions of formation of high-temperature wave of filtration combustion in fluorine of graphite and its mixtures with activated birch charcoal were studied.

(2) At temperatures higher than 1000°C, tetrafluoromethane is the single product of fluorine reaction with graphite.

(3) At the initial temperature of the bed of graphite (or its mixture with activated birch charcoal) of 20°C, the ignition process is instable, and formation of the high-temperature zone of the synthesis depends of the fluorine flow velocity and carbon raw material history.

(4) The method of formation of the high-temperature synthesis zone with a gaseous fuel, which forms with fluorine a self-igniting pair in the graphite bed, was suggested and experimentally examined. This method allows formation of a stable wave of graphite filtration combustion in fluorine. Propane–butane mixture can be recommended for industrial use.

Received June 19, 2003

Abstract—A procedure was developed for preparing partially fluorinated dialkyl ethers by the reaction of hexafluoropropylene with aliphatic and polyfluorinated alcohols in the presence of KOH. On treatment with concentrated sulfuric acid, these ethers form alkyl esters of acids, and on treatment with KOH, alkenyl ethers.

The problems in development of new ozone-friendly solvents are largely determined by the need in replacement of Freon 113, widely used as solvent. The main drawback of this Freon is that hydrocarbon oils are limitedly or poorly soluble in it, and organofluorine and organosilicon liquids are insoluble. Major efforts in this direction have not led to success. Orlov *et al.* [1] suggested as one of alternatives hexafluorocyclobutane, which is an efficient solvent for various azeotropic compositions. This compound can be prepared on the commercial scale from dichlorohexafluorocyclobutane, which, in turn, is obtained by dimerization of trifluorochloroethylene. At the same time, partially fluorinated dialkyl ethers are also of interest. The 3M company developed Freon HFE 7110, $CH_3OCF_2CF_2CF_2CF_3$, but it also has certain drawbacks, whereas tetrafluoroethyl difluoromethyl ether $CHF_2CF_2OCHF_2$ can replace Freon 11 as a foaming agent in production of foamed plastics and can be used in microelectronics in dry etching instead of perfluorocarbons [2]. Ethers like $C_4F_9OCH_3$ (bp 61°C), $(CF_3)_2CFCF_2OC_2H_5$, and others, used for extraction of lavender essential oils, showed good performance with respect to the quality of the extracted product and the purity of the oils obtained therefrom [3]. These ethers were used as solvents in chemical reactions, in particular, in synthesis of amides derived from fluoropolyalkyl ethers for magnetic reproducing media [4] and in oxidation of tetrafluoroethylene [5].

Partially fluorinated ethers were prepared by reactions of hexafluoropropylene with alcohols in the presence of alkali [6, 7] or with metal alcoholates in toluene [8], dioxane [9], or methanol [10]. Polyoxaalkylene glycols add to hexafluoropropylene in the presence of water traces across the olefin double bond; the resulting adducts are used as compression, motor, and vacuum oils [11]. Fully fluorinated dialkyl ethers prepared by reactions of octafluoroisobutylene with alcohols, followed by further electrochemical fluorination in anhydrous HF, e.g., $(CF_3)_2CFCF_2OC_nF_{2n+1}$, are used as solvents for cleaning electronic circuits, as refrigerants, as foaming agents, and as polymerization media [12–14].

The goal of this study was to develop a commercially acceptable procedure for synthesis of partially fluorinated dialkyl ethers from available and relatively cheap hexafluoropropylene and to examine the possibilities of using these ethers as ozone-friendly solvents and as intermediates in organofluorine synthesis.

When gaseous hexafluoropropylene is passed at 20–40°C through alcohols containing catalytic amounts of sodium alcoholates or alkalis (the reaction can also be performed in a pressure vessel), the alcohol adds across the double bond. The reaction pathway only slightly depends on the conditions. The byproducts are alkenyl ethers formed by substitution of the terminal fluorine atom at the double bond by alkoxy groups and alkyl 2,3,3,3-tetrafluoropropionates; their amount does not exceed 5% (cf. data from [15]):

$$CF_3CF{=}CF_2 \xrightarrow[ROH]{5\%\ KOH} CF_3CHFCF_2OR$$

$$+\ CF_3CF{=}CFOR + CF_3CHF{-}\underset{OR}{\overset{O}{\langle\!\!\langle}},$$

VIII	5.10 (H^2, $^1J_{HF}$ 45, $^2J_{HF}$ 7) 4.36 (H^4, $^2J_{HH}$ 7.1), 1.34 (H^5, $^2J_{HH}$ 7.1)	120.5 (C^1, $^1J_{CF}$ 281.9, $^2J_{CF}$ 27.8), 84.1 (C^2, $^1J_{CF}$ 199.2, $^2J_{CF}$ 35.6), 63.0 (C^4), 13.2 (C^5)	86.5 (F^1, 8, 12), –42.2 (F^2, 45, 10)

The reaction involves the attack of the alkoxy anion at the carbon atom of the hexafluoropropylene double bond, with generation of the intermediate carbanion. This species abstracts the proton from the solvent to form the main reaction product **I**–**IV**. Stabilization of the carbanion by elimination of the fluoride ion from the α-position (from the CF_2 fragment) yields the product of formal substitution of fluorine at the double bond (compounds **V**, **VI**). The hydrogen fluoride released in the process reacts with the alkali, and water participates in formation of the addition product and can induce hydrolysis of both by-products **V**, **VI** and target products **I**–**IV**. This is suggested by isolation of HF from the mixture of reaction products and formation of alkyl 2,3,3,3-tetrafluoropropionates **VII** and **VIII**:

$$CF_3CF{=}CF_2 \xrightarrow{RO^-} [\,CF_3\bar{C}F\,CF_2OR\,]$$

$$\xrightarrow{H^+} CF_3CHF\,CF_2OR \xrightarrow{H_2O}$$

$$\xrightarrow[-F^-]{} CF_3CF{=}CFOR \xrightarrow{H_2O} CF_3CHF{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}OR\,.$$

Indeed, heating of **I** and **II** with concentrated sulfuric acid at 40°C for 1 h, followed by treatment of the reaction mixture with water, causes formation of compounds **VII** [6] and **VIII** in quantitative yield, and heating with solid KOH in dioxane affords **V** and **VI**:

$$CF_3CHF\,CF_2OR \xrightarrow[(2)\ H_2O]{(1)\ H_2SO_4} CF_3CHF{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}OR$$

$$CF_3CHF\,CF_2OR \xrightarrow[\text{Dioxane}]{KOH} CF_3CF{=}CFOR\,,$$

where R = Me or Et.

The structures of the new compounds were confirmed by ^{1}H, ^{13}C, and ^{19}F NMR (Table 1), IR, and mass spectrometry.

For partially fluorinated dialkyl ethers, telomeric alcohols, and partially fluorinated carboxylic acid ester, we evaluated the toxicological parameters. The results are listed in Table 2. It is seen that the compounds belong to hazard class III (moderately toxic) or IV (weakly toxic substances).

Table 2. Some toxicological parameters of organofluorine compounds

Compound	LD_{50}	LD_{100}	Hazard class
	mg kg^{-1}		
$CF_3CHFCF_2OCH_2CF_2CHF_2$	5000		IV

$CF_3CHFC(O)OCH_2H_5$	5000		IV

EXPERIMENTAL

The ^1H, ^{13}C, and ^{19}F NMR spectra were recorded on a Bruker WP 400 SY spectrometer (400, 100, and 188 MHz, respectively) relative to internal HMDS and C_6F_6 (J_{CH} was not measured). The IR spectra were taken on a Specord M-80 spectrometer (CCl_4), and the mass spectra (ionizing electron energy 70 eV), on a Hewlett–Packard G 1800 A GCD gas chromatograph with a mass-selective detector [30 m × 0.25 mm capillary column coated with a 0.25-μm layer of 5% diphenylsiloxane–95% dimethylsiloxane copolymer (HP-5); carrier gas helium, 1 ml min^{-1}; vaporizer temperature 280°C; column temperature schedule: 50°C, 2 min; heating to 280°C at a rate of 10 deg min^{-1}; 280°C, 5 min]. The progress of all the reactions was monitored by ^{19}F NMR spectroscopy. The reaction mixtures were analyzed on an LKhM 72 chromatograph (15% SE-30, SKTF-803, QF-1 on Chromosorb W, 4000 × 4-mm column).

The characteristics of the new compounds and analytical data are listed in Table 3.

Synthesis of partially fluorinated dialkyl ethers. (1) A 100-ml flask equipped with a magnetic stirrer, a thermometer, a tube for input of gaseous reactants, and a reflux condenser was charged with 40 ml of absolute methanol, and 1 g of sodium metal was added in portions at room temperature. After complete dissolution of sodium, gaseous hexafluoropropylene was passed at a rate chosen so as to minimize the breakthrough of the gas. The process was performed for 1.5 h, after which the reaction mixture was poured into 300 ml of water and shaken; the lower organic layer was separated and dried over CaCl2. The mixture was analyzed by ^{19}F NMR spectroscopy and gas chromatography–mass spectrometry. The mixture was distilled with collection of the 54–55°C fraction (33 g).

(2) A similar flask was charged with 50 ml of an alcohol (methanol, ethanol, isopropanol, 2,2,3,3-tetrafluoropropanol) and 5 g of KOH. A flow of gaseous hexafluoropropylene was passed at atmospheric pressure; in the process, the mixture warmed up from 20 to 40°C. After the heat release ceased, passing of hexafluoropropylene was stopped, the mixture was poured into 400 ml of cold water and shaken, and the lower organic layer was separated, washed with 100 ml of water, and dried over $CaCl_2$. The products were distilled and analyzed.

(3) A 100-ml rotating autoclave was charged with 10 ml of methanol and 11.2 g of solid KOH; then the autoclave was sealed, and 30 g of hexafluoropropylene was condensed into it through a valve. The autoclave was heated at 50°C for 1 h (the pressure rose to 4 atm), cooled, and opened; the contents were poured into water. Compound **I** was obtained; yield 34.2 g (94%), bp 54–55°C.

Table 3. Characteristics of partially fluorinated dialkyl ethers and analytical data

* $[M^+]$.

Hydrolysis of partially fluorinated dialkyl ethers. (1) A 20-ml flask equipped with a magnetic stirrer and a reflux condenser was charged with 15 g of **I** (with **II**, the procedure was similar), and 15 g of concentrated sulfuric acid was added. The mixture slightly warmed up. Then the mixture was heated with stirring for 1 h at 40°C and poured onto 50 g of ice; the organic layer was separated, washed with water, and dried over $CaCl_2$.

By this procedure, we prepared 10 g of compound **VIII** to be used in the subsequent studies as intermediate.

(2) A similar flask was charged with 27 g of SbF_5, and 15 g of **II** was added in portions with stirring, so as to avoid warming up above room temperature. The mixture was stirred at room temperature for 1 h and poured into 50 g of ice; the organic layer was separated, washed with cold water, and dried over $CaCl_2$. The product was distilled, with collection of the fraction boiling at 95–96°C; yield 8 g.

Reaction of KOH with partially fluorinated dialkyl ethers. A 100-ml flask equipped with a magnetic stirrer, a thermometer, and a reflux condenser was charged with 40 g of **I** (with **II**, the procedure was similar) and 50 ml of dry dioxane, after which finely divided KOH was added in portions with stirring at room temperature. The mixture warmed up. Then the mixture was heated with stirring for 2 h at 40°C, and the reaction products were distilled off. Compound **V**: yield 82%, bp 51–52°C, n_D^{20} 1.3208, d_4^{20} 1.3601 (published data [8]: bp 51.5°C/743 mm Hg, n_D^{20} 1.2970, d_4^{20} 1.3595); **VI**: yield 78%, bp 71–72°C, n_D^{20} 1.3210, d_4^{20} 1.2930 (published data [8]: bp 71–72°C/743 mm Hg, n_D^{20} 1.3103, d_4^{20} 1.2884).

CONCLUSIONS

(1) The possibility of preparing partially fluorinated dialkyl ethers by reaction of hexafluoropropylene with alcohols (methanol, ethanol, isopropanol, 2,3,3,3-tetrafluoropropanol) in the presence of KOH was examined. These ethers are formed by addition of an alcohol across the double bond in hexafluoropropylene.

(2) Partially fluorinated dialkyl ethers are converted to alkyl 2,3,3,3-tetrafluoropropionates by treatment with concentrated H_2SO_4 and to alkyl pentafluoropropenyl ethers by treatment with KOH.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Ozonolysis of Methylcyclohexanols and Methylcyclohexanones

A. M. Syroezhko and O. Yu. Begak

Received March 20, 2003

Abstract—Ozonolysis of isomeric methylcyclohexanols and methylcyclohexanones was studied.

Oxidation of methylcyclohexane with ozone–oxygen mixtures involves formation of isomeric methylcyclohexanols (MCHLs) and methylcyclohexanones (MCHNs), which subsequently transform into acids and esters. Previously we studied ozonolysis of cyclohexanol [1], cyclohexanone [2], and 1-methylcyclohexanol [3].

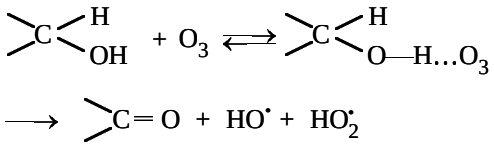
Here we consider ozonolysis of secondary alcohols (MCHLs) and the corresponding isomeric MCHNs. The oxidation and analytical procedures are described in [4].

In ozonolysis of methylcyclohexane (MCH), the accumulating secondary and tertiary alcohols are actively consumed. For example, the rate of ozonolysis of 2-methylcyclohexanol grows from 8.3×10^{-3} to 22.2×10^{-3} mol l^{-1} min^{-1} as the temperature is increased from 40 to 100°C ([O_3] = 4 vol %).

Ozonolysis of secondary MCHLs yields the corresponding isomeric MCHNs (see table), hydroxy hydroperoxides, hydrogen peroxide, esters, and acids [5, 6]. The composition of the acids was studied in detail in [7–9]. The selectivity of ozonolysis of isomeric MCHLs is higher compared to their oxidation with oxygen [6, 10–18]; the yields of the target products are given in the table.

Recombination of hydroperoxy radicals and their reaction with ozone can yield hydroxyalkoxy radicals, which isomerize to form mono- and dicarboxylic acids [19–22]. The acids are also formed by reaction of hydroxy hydroperoxides derived from MCHLs with ozone [6, 15, 16]. The $RO^{\cdot}$ radical is also a source of acids at elevated temperatures. It is formed from the adduct $2ROH \cdot H_2O_2$ [18] with the activation energy of 19 kJ mol^{-1}. In the developed ozonolysis of isomeric MCHLs, the accumulating MCHNs are actively oxidized into acids [20–22] and lactones.

The abnormally high reactivity of ozone toward nonassociated primary and secondary alcohols [8, 9], along with the reactivity of ozone with alcoholic C–H bonds, discussed in this paper, may also be due to concerted detachment of hydrogen from the alcoholic hydroxy group with ozone [23]:



Yield of ozonolysis products of secondary MCHLs* ([O_3] = 4 vol %)

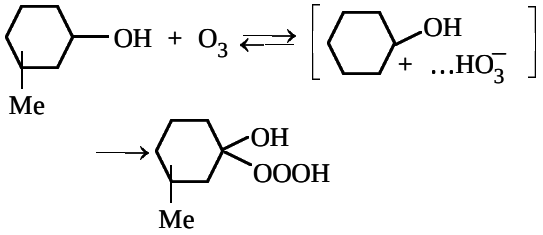
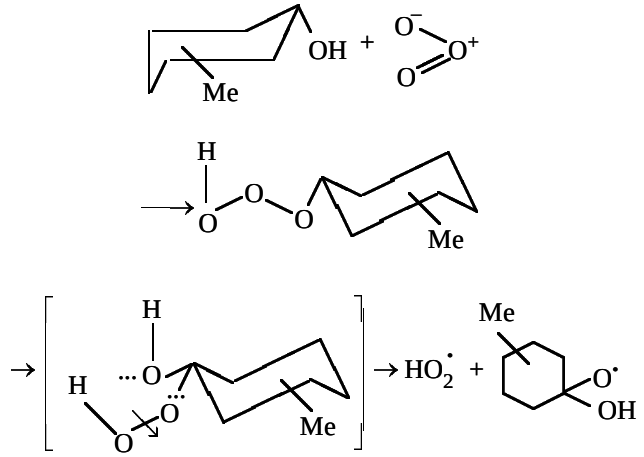
* Major products: 4-MCHL, β-methyladipic acid and 4-methylcyclohexanone; 2-MCHL, ε-ketoenanthic acid and 2-methylcyclohexanone; and 3-MCHL, sum of α- and β-methyladipic acids and 3-methylcyclohexanone.

1070-4272/04/7701-0102 © 2004 MAIK "Nauka/Interperiodica"

This reaction is exothermic (ΔH –46 kJ mol^{-1} [23]) at the C–H bond energy of 360 kJ mol^{-1}. Simple hydrogen detachment from the C–H group is endothermic (ΔH 40 kJ mol^{-1}). Most probably, ozone reacts with alcohols not only by the radical mechanism discussed above, but also by the mechanism of 1,3-dipolar insertion. The primary molecular product, MCHL hydrotrioxide, can be formed by the mechanism of the hydride ion transfer, with formation of an intermediate ion pair:

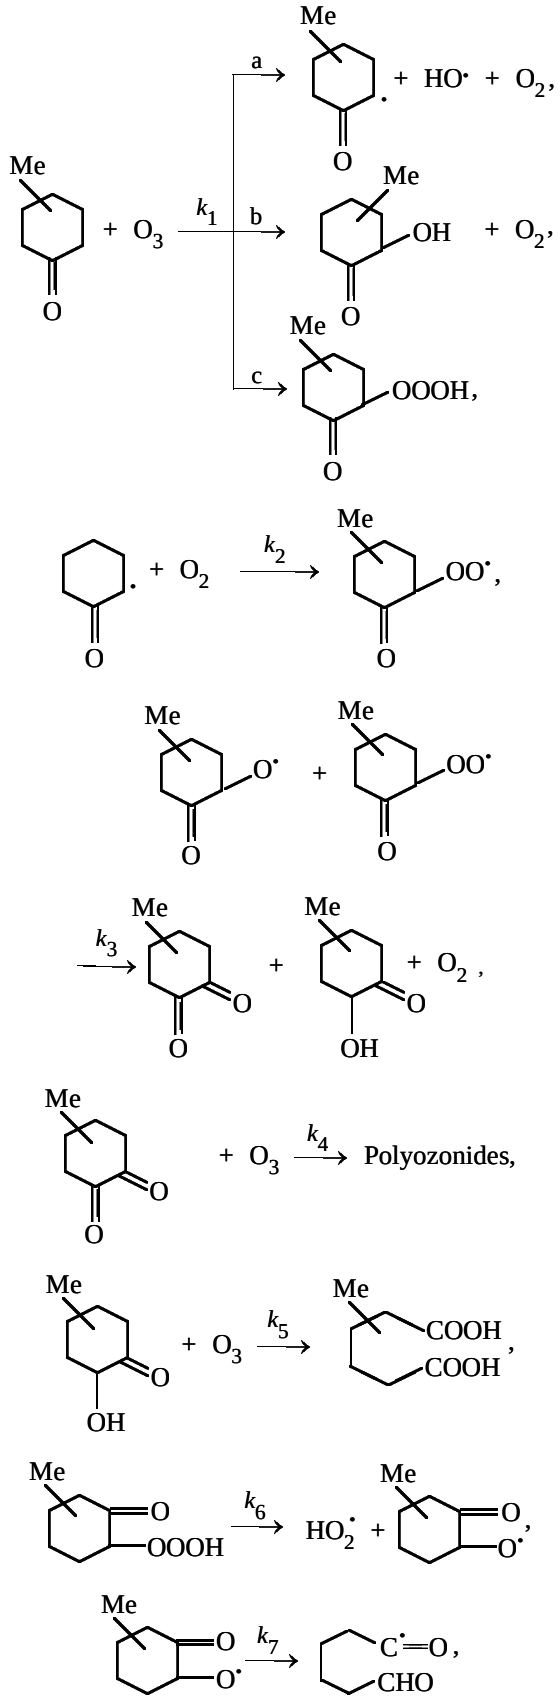


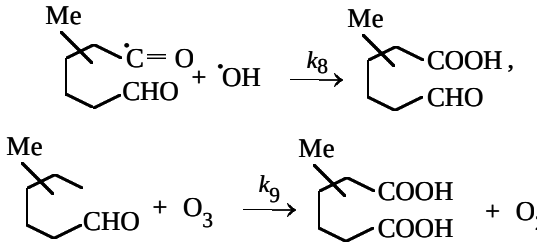
In ozonolysis of methanol, the activation energy of formation of the related ion pair is about 5 kJ mol^{-1} [24]. The ionization potential and hence the probability of formation of ion pairs are determined by the structure and concentration of the starting alcohols and by the polarity of the medium. In formation of the intermediate cyclohexanol hydrotrioxide or isomeric secondary MCHLs, the transition state will be stabilized owing to formation of a relatively stable six-membered ring:



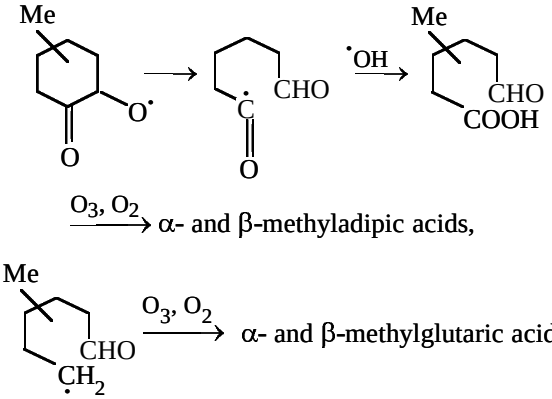
The mechanisms of ozonolysis of cyclohexanone and isomeric MCHLs are similar [2]. The major reaction products are lactones and acids. α-Keto hydrotrioxide, polyozonides, and isomeric methyl-1-hydroxycyclohexan-2-ones and methyl-1,2-cyclohexanediones are accumulated in smaller amounts.

The mechanism of their formation is schematically shown below:





At lower temperatures (15–20°C), the yield of lactones reaches 52% [25]. As the temperature is elevated (40–80°C), the reaction selectivity with respect to acids grows by 12–16% compared to oxidation with oxygen. Ozonolysis of 4-methylcyclohexanone yields mainly β-methyladipic and β-methylglutaric acids [20–26]. In acidic products of 3-methylcyclohexanone ozonolysis, the major components are α- and β-methyladipic and α-methylglutaric acids [6]. In ozonolysis of 2-methylcyclohexanone, the major acidic products are α-methyladipic, ε-ketoenanthic, and caproic acids. Formation of acids [15, 21] at elevated temperatures presumably occurs via isomeric α-keto oxy radicals tending to isomerize with ring opening:



Ozonolysis of MCHNs is more selective than their oxidation with oxygen [14].

CONCLUSIONS

(1) Ozonolysis of isomeric secondary methylcyclohexanols to the corresponding isomeric methylcyclohexanones is more selective than oxidation with atmospheric oxygen.

(2) Ozonolysis of isomeric methylcyclohexanones mainly yields lactones and acids: monocarboxylic, dicarboxylic, and keto carboxylic.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polyacrylonitrile–Fullerene C_{60} System as Laser Radiation Limiter

Abstract—Fullerene-containing media, including polyacrylonitrile and acrylonitrile copolymers, were tested as candidates for application in protective devices for optical limitation of the laser radiation energy generated by a YAG-Nd laser.

Development of laser technologies makes urgent protection of eyes and optical devices against laser radiation. In review [1] we discussed in detail the mechanism of limitation by fullerenes and their derivatives. Janot *et al*. [2] found (like previously for porphyrins [3]) that the energy absorption depends on the strength of interaction between the fullerene molecules.

Guldi and Prato [4] reported that, upon absorption of an energy quantum, the monomeric form of fullerene occurs in the excited state within several hundreds of microseconds, and in the aggregated form the lifetime of the excited state sharply decreases to <1 μs. As revealed by light and neutron scattering studies [5, 6], in the majority of organic solvents C_{60} exists as aggregates occurring in equilibrium with the monomeric form. The energy-absorbing power of fullerene is increased by conversion to the monomeric form. To this end, Guldi and Prato [4] suggested incorporation of fullerene into regular structures such as zeolites, porous silicate matrices, or micelles or its functionalization by linking with various species (low- or high-molecular-weight) forming covalent bonds. Such modification affects the electronic structure of fullerene and decreases its energy-absorbing power. An increase in the number of the monomeric C_{60} molecules in solution upon derivatization compensates the energy intensity loss. Fullerene associates can disaggregate without disturbing the electronic structure via formation of nonvalence bonds in complex, e.g., fullerene–polymer, compounds [7, 8].

Chemically and thermally stable polymers like commercial polyacrylonitrile (PAN) and acrylonitrile copolymers [9], as well as polyamido acids (films, fibers), can be made suitable for creation of protective devices by incorporating fullerenes into their composition. In this work, we studied the energy-absorbing properties of fullerene-containing polymers and copolymers of acrylonitrile (AN), including composites, differing in the composition and synthesis procedure.

EXPERIMENTAL

Polyacrylonitrile (a-PAN) and copolymers of AN with methacrylate (AN–MA) and butyl acrylate (AN–BA) with the acrylate content of up to 10% were synthesized by anionic polymerization, via the action of alkoxides. Low-temperature homogeneous polymerization in dimethylformamide (DMF) yields polymers of AN with a narrow molecular-weight distribution pattern [10], having the stereoblock microstructure [11]. They are characterized, in particular, by enhanced thermal stability compared to the PAN synthesized by radical polymerization (r-PAN). Anionic polymerization allows preparation of AN–acrylate copolymers with the desired composition, as well as partially cyclized polyacrylonitrile (c-PAN), in which up to 40% of the nitrile [–C≡N] groups are converted into imine [>C=N–] groups, forming ladder structures [12].

Covalently bound fullerene C_{60} was incorporated into a-PAN, in particular, via deactivation of "living" polyacrylonitrile chains by introducing a fullerene solution in toluene to terminate polymerization [13].

The polymers under study, except for c-PAN, are able of film and fiber formation. Consequently, the energy-absorbing properties of these polymers were

1070-4272/04/7701-0106 © 2004 MAIK "Nauka/Interperiodica"

studied mostly with their films. The latter were obtained by casting on cover glasses a combined solution of the polymer and fullerene prepared by mixing the solutions of the components that were prepared beforehand; the films were dried at 20°C.

Figure 1 shows schematically the YAG-Nd laser-based experimental setup for studying optical limitation of the laser radiation energy by fullerene-containing media. The working parameters of the setup are as follows: radiation wavelength λ = 532 nm, pulse length 10 ns, pulse energy 0.35 J, and density of incident radiation energy 0–4 J cm^{-3}.

The samples under study were (a) solutions of a straight polymer or of a polymer doped with C_{60} in DMF (we used cells with a 3-mm liquid layer) and (b) polymer films differing in the composition and C_{60} content.

Figures 2a and 2b show how the energy density of the radiation that passed through the sample E_{out} varies with the energy density of the incident radiation E_{in}. The onset of nonlinear transmission for DMF solutions of a-PAN–C_{60} and c-PAN–C_{60} is approximately at E_{in} = 0.5 J cm^{-2}.

The compositions of the samples studied by us and their laser radiation limitation properties are summarized in the table.

For comparison, we present the energy-absorbing properties of solutions of a-PAN (run no. 1) and c-PAN (run no. 3), as well as of the AN–BA film (run no. 8) without fullerene. Clearly, a-PAN solution and AN–BA film absorb nearly a half of the incident laser beam energy. In the case of the solution of c-PAN containing conjugated >C=N–C=N– double bonds (run no. 3), absorption is somewhat greater [11].

These functional groups not only impart a yellow-brown color to the polymer but also are responsible for participation of c-PAN in various complex formation reactions. In solutions of c-PAN, the existence of such structures favors mutual arrangement of the macrochains, yielding crystalline structures in the polymer in the course of removal of the solvent. The same moieties in c-PAN are, evidently, responsible for interaction of the polymer with C_{60} and for its disaggregation. This is confirmed by the fact that, upon introduction of C_{60} into c-PAN (run no. 4), the incident laser energy decreases 20-fold.

Significant nonlinear energy absorption was observed in the case of the a-PAN–C_{60} solution (run no. 2). In this experiment, we studied a-PAN containing covalently bound fullerene. The polymer was prepared by introducing a toluene solution of fullerene during "living" polymerization of AN to terminate the propagating chains, which resulted in its covalent bonding. The part of the C_{60} introduced that has not reacted with the anionic reactive center can interact with a-PAN by the complex formation mechanism.

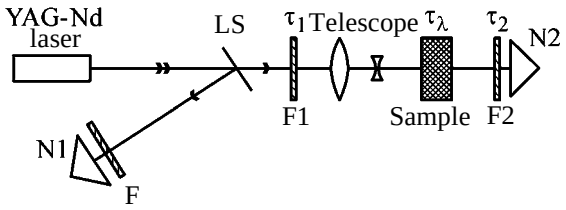

Fig. 1. Schematic of the setup for studying the dynamic range of optical limitation of laser radiation: (LS) light splitter, (F, F_1, F_2) filters, and (N_1, N_2) energy meters.

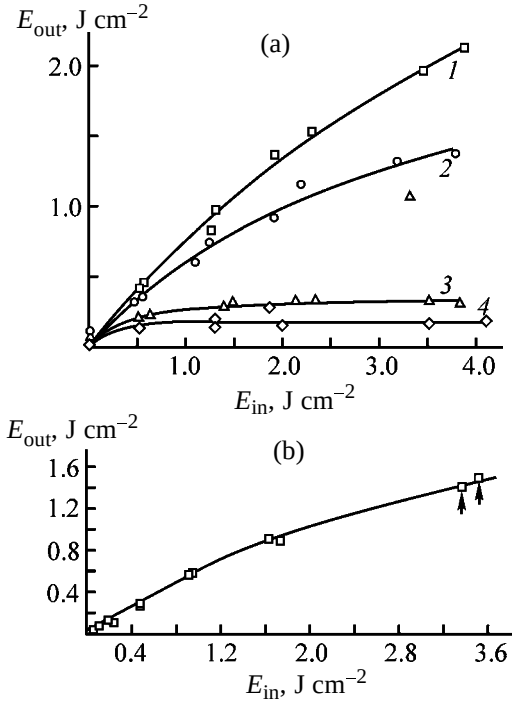

Fig. 2. Radiation energy density at the outlet E_{out} vs. the radiation energy density at the inlet E_{in}. Run no.: (a) 1, (*2*) 3, (*3*) 2, and (*4*) 4; (b) 7. (a) (*1*) a-PAN, (*2*) c-PAN, (*3*) a-PAN–C_{60}, and (*4*) c-PAN–C_{60}; (b) r-PAN–C_{60}. *T*, %: (a) (*1*) 80, (*2*) 69, (*3*) 53, and (*4*) 48; (b) 80.

Studies of the film coatings obtained from the combined solutions of a-PAN–C_{60} and r-PAN–C_{60} (run nos. 5–7) revealed weak optical limitation for these films (Fig. 2a). Evidently, under the actual conditions of combining the polymer (high-viscosity solutions) and fullerene, the components did not interact efficiently. This means that the energy of interaction between the polymer chains was higher than in the

* Transmission $T = E_{out}/E_{in}$; T_{in} is transmission of the sample at small E_{in}; T_{non}, transmission under nonlinear absorption; K_{abs} and K_{rel}, absolute and relative limitation coefficients, respectively; $E_{in.f.}$, energy density at which the sample fails.

** *S* is solvent (*N*-methyl-2-pyrrolidone); AA, acrylic acid; and PAA PM, polymer derived from diaminodiphenyl ether and pyromellitic acid.

case of the polymer–fullerene system. It is known [8] that the PAN macromolecules in solutions exhibit a tendency to cross-linking and gelation.

By changing from PAN to copolymers of AN with acrylates less prone to intermolecular interaction of chains in solutions, it is possible to obtain their films with C_{60} able of more efficient limitation of laser radiation (run nos. 9–14). This suggests that, in these systems, fullerene is significantly disaggregated. However, composite films based on AN–acrylate copolymers are less thermally stable than PAN-based films. The limiting failure energy for these films tended to increase with decreasing C_{60} content in them. This was accompanied by enhancement of the optical-limitation power of the films. Thus, introduction of fullerene in amounts exceeding that sufficient for efficient interaction with the polymer increases the number of C_{60} aggregates and decreases both the transparency and thermal stability of the films. These properties of the films are also deteriorated by incomplete removal of the solvent (run nos. 12, 13) which imparts plasticity to the films.

We intended to enhance the thermal stability of the films prepared from AN–acrylate copolymers by introducing a commercial polymer, polyamido acid, in the solution preparation stage. For comparison, we prepared films from the combined solutions of the polymer of diaminodiphenyl ether and pyromellitic acid (PAA PM) with fullerene C_{60} in DMF. These films (run nos. 18, 19) exhibited a good strength but poor optical properties. Poor nonlinear-optical properties of these films are, evidently, due to chemical reactions of fullerene with the functional groups of amido acids.

To strengthen the AN–BA-based films, we additionally introduced the AN–AA copolymer prepared by partial hydrolysis of a-PAN (degree of hydrolysis 5–10%). The thermal stability of such composite films (run nos. 15–17) actually tended to increase, with certain energy capacity being preserved.

CONCLUSIONS

(1) Fullerene-containing composites based on polyacrylonitrile and acrylonitrile copolymers with alkyl

arcylates offer promise for preparing materials suitable for creation of laser-radiation-protecting devices.

(2) Acrylonitrile–alkyl acrylate copolymers afford more uniform, than homopolymers, distribution of C_{60} fullerene in the composites owing to weakening of interchain interaction.

(3) A relatively low content of C_{60} (0.5%) in composites with copolymers affords optimal limitation properties, with the transparency and thermal stability of the films being preserved.

Abstract—Chromatographic characteristics of adamantyl silicone stationary phase were studied.

Adamantane derivatives attract steady interest caused by specific structure of their hydrocarbon framework and also by their biological activity [1, 2]. The structure and hydrophobicity (lipophilicity) of adamantane provide favorable conditions for its transport through biological membranes. Linking of adamantyl radical to organic compounds modifies their biological activity, in many cases enhancing it. It was found [3, 4] that adamantyl radical affects hypoglycemic, antitumor, immunodepressive, antibacterial, and other types of biological activity. Much promise is shown by polymeric materials based on adamantane, characterized by high thermal stability, resistance to corrosive media, and high hardness [5]. Adamantane derivatives are of some interest as a model in solving many problems in theoretical chemistry, such as the influence of the electronic structure and topology of molecules on physicochemical characteristics and influence of induction and steric factors on the reactivity and stability of compounds. However, many problems related to the reactivity, biological activity, structure, and its correlation with physicochemical characteristics of framework compounds, especially with their chromatographic behavior, are not completely understood. Chromatographic characteristics of some adamantane derivatives as sorbates in gas–liquid and liquid chromatography were studied [6–8], but data on the use of sorbents and stationary phases based on adamantane are virtually lacking. There are only evidences that introduction of adamantane fragment into stationary phases should enhance their selectivity, at least with respect to polynuclear aromatic hydrocarbons [9]. In this connection, we studied in this work the chromatographic characteristics of adamantyl silicone stationary phase under conditions realized in capillary gas chromatography.

EXPERIMENTAL

The experiments were performed on a Halls-311 gas chromatograph equipped with a flame-ionization detector in the isothermal mode at temperatures from 100°C to 200°C with the interval of 20°C. The vaporizer temperature was varied from 150°C to 250°C. The analysis was carried out on a steel capillary column (22 m × 0.22 mm) with cross-linked alkyladamantane (film thickness d_f = 0.2 μm). Nitrogen was used as a carrier gas with the flow division at the column inlet of 1 : 60. To characterize the column, we studied the chromatographic retention of various organic substances. Solid substances were introduced into the chromatograph in the form of solutions in ethanol or toluene. The retention indices (RIs) were evaluated by the Kovats formula [10]. The experimental indices averaged over 7–10 values are listed in Table 1. The reproducibility of RI was 1–2 index units (i.u.). The contribution of alkyl to retention $\delta I(R)$ for substances under consideration was evaluated by the scheme $\delta I(R) = I(R_{n+1}) - I(R_n)$, where $I(R_{n+1})$ and $I(R_n)$ are RIs of the neighboring homologs [11]. The differential molar free energy of sorption ΔG was evaluated according to [12]. The Rohrschneider polarity factors were determined from the experimental data by the well-known procedure [10]: x = 0.132, y = 0.993, z = 0.543, and s = 0.210. The selectivity factor of the stationary phase and separation factor for estimation of the *meta–para* selectivity were evaluated by the relationships given in [11].

According to the resulting values of Rohrschneider factor, the phase in hand is nonpolar and its chromatographic characteristics should be close to those of Apiezon-L (Ap-L) or silicones OV-1 and SE-30. To

characterize the properties of adamantyl silicone we studied the chromatographic retention of some representatives of various classes of organic compounds. As follows from Table 1, RIs virtually regularly vary with variation of the molecular weight of sorbates. At the same time, since chromatographic method is based on high sensitivity to differences in the thermodynamic characteristics of sorption of substances, caused by molecular structure of stationary phase and sorbate, the RI values adequately reflect their structural features.

As follows from Fig. 1, the correlation between RI and molecular weight of normal alcohols can be approximated by a linear dependence with the correlation factor of 0.998.

The features of chromatographic retention of organic compounds of various types are the most clearly pronounced in consideration of homomorphism factors and differences in RIs of substances with polar and nonpolar stationary phases. In this case, functional groups, rings, and hydrocarbon radicals can act as homomorphs.

As known, within homologous series of organic compounds, the RIs increase; according to the well-known Kovats rule, the increments of CH_2 δI should be approximately 100 i.u. for a nonpolar stationary phase. For nonbranched alkanes, the experimentally determined contribution of methylene unit to RI on adamantyl silicone is 100 i.u. The contribution to the free energy of sorption was approximately –2 kJ mol^{-1}, decreasing to –1.55 kJ mol^{-2} as the temperature was increased to 200°C. As a whole, for adamantyl silicone ΔG grows with increasing molecular weight of sorbates.

As follows Table 2, $\delta I(CH_3)$ of linear alcohols is in the range 90–100 i.u., somewhat decreasing with increasing temperature. As for normal alkanes, the contribution to the sorption energy $\delta(\Delta G)$ is approximately –2 kJ mol^{-1} and varies from –1.27 to –1.46 kJ mol^{-1} at 200°C. The dependence of ΔG of 1-propanol on operating temperature is shown in Fig. 2. The dependences for other members of this homologous series are similar.

For benzene homologs, the contribution of methylene unit is approximately 90 i.u., as for Apiezon-L.

The increment of CH_3 groups depends on their number and relative positions in the benzene ring. With increasing number of methyl groups, alkylbenzene molecule remains planar and, hence, can be oriented in the sorbent surface in the manner optimal for sorption [13]. Lengthening of alkyl chain results in nonplanar orientation of the alkylbenzene molecule; therefore, as a rule, the retention of monoalkylbenzenes is worse than the retention of polyalkylbenzenes with the same number of carbon atoms in the substituent.

In particular, for toluene, *m*-, and *p*-xylenes, $\delta I(CH_3)$ at 160°C is in the range 100–160 i.u., while for *o*-xylene this value is significantly greater (from 130 to 140 i.u.). The contribution to the sorption energy is from –2.72 to –2.37 for *o*-xylene and from –2.19 to –1.87 kJ mol^{-1} for *m*- and *p*-xylenes depending on temperature. The similar trends take place with other compounds with vicinal arrangement of methyl groups on both polar and nonpolar stationary phases. The vicinal arrangement of methyl groups causes an increase in the internal energy of the molecule; therefore, the contribution of neighboring methyl groups to the energy of dispersion interaction with the stationary phase is greater than that in the case of more remote arrangement of these groups [14]. Heating increases the *meta*–*para* selectivity of adamantyl silicone, with the contributions of methyl groups to RI somewhat decreasing and becoming different for *ortho*-, *meta*-, and *para*-positions, 98, 54, and 77 i.u., respectively, and the contributions to ΔG of sorption of sorption becoming essentially different: –153, –0.84, and –1.20 kJ mol^{-1} (it should be noted that for normal alkanes this value is practically constant and varies in the homologous series by no more than 0.1–0.2 kJ mol^{-1}). Weaker retention of the *para* isomer in comparison with *meta*-substituted derivatives may be due to the fact that, in symmetrical arrangement of substituents, the benzene ring somewhat rises over the sorbent surface [13]. Heating enhances this process, which is apparently favored by the presence of bulky adamantyl fragment in the stationary phase. It should be noted that nonmonotonic variation of RI with

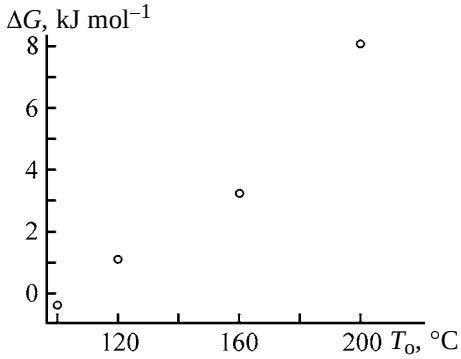

Fig. 2. ΔG of 1-hexanol as a function of operating temperature T_o. Stationary phase is adamantyl silicone, r = 0.982.

p-Nitrotoluene	418	–	429	–8.47				

temperature (nonconstancy of temperature increment dI/dt) is fairly frequently observed in chromatographic analysis of representatives of various homologous series and is apparently caused by the difference in the energy equivalents of one unit of the index ΔG_{iu}, determined according to [15], and nonlinear variation of this value with increasing RI [16].

It is well known that cyclization significantly increases RI on both polar and nonpolar stationary phases. As follows from Table 1, in passing from hexane to cyclohexane, RI on adamantyl silicone increases by 60–80 i.u. (on Apiezon-L, by 96 i.u.), which is equivalent to addition of one methylene unit in the homologous series. Passing from decane to adamantane results in increase in RI by 120–140 i.u., which is somewhat greater than the increment of the methylene unit. In this case, the sorption energy varies from –1.56 to –3.35 kJ mol^{-1}. Substitution of the benzene ring for a saturated six-membered ring does not result in significant variations in the retention with the adamantane phase, similar to Apiezon. In passing from benzene to naphthalene and then to anthracene, RIs on Apiezon-L significantly increase and are 686, 1309, and 1869 i.u., respectively. On the adamantane stationary phase, these variations are not so great: for these compounds, RIs are 677, 1080, and 1104. It is believed that in this case the steric effect of the adamantane fragment of the stationary phase becomes significant. This is suggested by the fact that, for adamantane, RI on adamantyl silicone is somewhat lower than that on Apiezon (1119 and 1216 i.u., respectively).

The contributions of functional groups to retention with adamantyl silicone are different depending on the nature of the group (Table 3). Contrary to retention on Apiezon-L, the contribution of the OH group of adamantyl silicone stationary phase δI is greater for linear (260–280 i.u., and 204–240 i.u. on Apiezon-L) and cyclic alcohols (228 and 204 i.u., respectively). On methyl silicone SE-30, the contribution of OH groups is 240–260 i.u. It is believed that linear alcohols are retained on adamantyl silicone predominantly owing to formation of a hydrogen bond between the OH group of alkanols and silanol groups of the stationary phase. Apparently, the presence of adamantane fragment is favorable for redistribution of the electron density in molecules of the stationary phase. It was shown previously that 1-adamantyl radical exhibits strong induction increasing the effective negative charge on the oxygen atom bonded to adamantyl [17]. It is likely that this effect results in strengthening of the hydrogen bond of alcoholic hydroxyl with the stationary phase.

For phenol on adamantyl silicone, $\delta I(\text{OH})_{\text{i.u.}}$ decreases in comparison with Apiezon-L (290 and 335 i.u., 337 i.u. on methyl silicone phase), which is apparently caused by the predominant contribution of phenyl radical, interacting nonspecifically with the adamantyl fragment of the stationary phase, to adsorption. For phenol homologs, the contribution of OH group is governed by its position relative to alkyl.

In particular, for 2-methylphenol δI(OH) on adamantyl silicone is 265, and for 3- and 4-methylphenol, 286. For Apiezon, these values are 347 and 379 i.u., and for methyl silicone, 250 and 280. In other words, the contribution of functional group located in *ortho*-position to methyl is less than that for *meta*- and *para*-positions remote from the alkyl. Similarly, the contribution of the CH_3 group in 2-methylphenol is less (73 i.u.) than that in 3- and 4-methylphenols (96 i.u.), which is caused by intramolecular interaction of methyl with hydroxyl in *ortho*-position. Similar trends are observed for other vicinal substituents and functional groups [18]. For example, the contribution of nitro group to retention of *ortho*-nitrotoluene is less (401 i.u.) compared to *para*-nitrotoluene (429 i.u.). For nitrobenzene, this value is 420 i.u. The contribution of OH group of alkylphenols to the adsorption energy does not noticeably vary with heating from 100 to 160°C and decreases by nearly 1.5 kJ mol^{-1} at 200°C, being practically equal to the contribution of OH group of phenol.

The value of δI(OH) of 1-adamantanol is much less and equal to 140 i.u. The contribution of OH group to the adsorption energy is less than the contribution of phenolic and cyclohexanol OH groups by a factor of almost 2 and less than the contribution of OH groups in linear alkanols by a factor of 3. This is largely due to the steric effect of adamantane fragments, present in molecules of both the stationary phase and sorbate and hindering participation of hydroxy group in retention.

The results of this study show that adamantyl silicone exhibits a fairly high selectivity in separation of structural isomers. The selectivity factor of adamantyl silicone varies from 0.53 to 0.73 depending on temperature. In estimation of the *meta–para* selectivity of this stationary phase, the separation factor is 1.18 (for comparison, the selectivity of some liquid crystals with respect to *meta–para* isomers is 1.03–1.09 [19]). The selectivity in separation of isomers of 1-methyl-1,2-dicyclopropylcyclopropane, whose *cis* and *trans* isomers are not always separable on standard stationary phases, is equal to 1.1. High selectivity of adamantyl silicone manifests itself in separation of homologs of normal alkanes and alkylbenzenes (α 2, 1.9), which was used in analysis of naphtha hydrocarbons. These studies also suggest enantioselectivity of this phase, since adamantyl cross-linked with silicone apparently can form chiral cavities. However, this suggestion calls for further investigations.

Thus, our results show that retention of sorbates of various structures with adamantyl silicone is governed by dispersion interactions, which depend essentially on deformability of molecules and, hence, their volume. According to additivity of the free energy of interaction, an increase in the molecular size by one methylene unit results in virtually equal increase in dispersion forces, which is reflected in the equality of contributions of alkyls to the retention and sorption energy. At the same time, it is evident that the presence of the adamantane fragment in molecules of the stationary phase results in redistribution of the electron density in its silanol groups and strengthening of interaction of electron-acceptor functional groups of sorbates with the stationary phase. This is confirmed by an increase in the contribution of these groups to retention with adamantyl silicone in comparison with methyl silicone and Apiezon-L. Apparently, the stationary phase studied can be suitable for solving chromatographic problems and for studying the structure of sorbates and intermolecular interactions of these sorbates.

CONCLUSIONS

(1) The retention indices of primary alcohols, aromatic hydrocarbons, alkylphenols, and some adamantane derivatives and the thermodynamic characteristics of their sorption with adamantyl silicone were compared to the respective characteristics of known silicone stationary phases.

(2) The selectivity of adamantyl silicone phase in separation of low-boiling naphtha hydrocarbon fraction and isomers of 1-methyl-1,2-dicyclopropylcyclopropane was shown. The possible enantioselectivity of the phase was suggested.

Abstract—Formation of a polymeric coating in the course of preparation of polymer-containing silica gel as influenced by preliminary activation of the surface of nonporous silica gel with vinylchlorosilane was studied.

Nonporous silica gel supports with various grafted functional groups find expanding application in chromatography and immobilization of biopolymers [1, 2]. Before coating of the solid support or sorbent with a polymeric layer, its surface is activated by various procedures. Active centers formed by grafting of organic compounds on the support surface containing –OH groups allow their subsequent polymerization modification with various functional groups. Such active centers, which affect the kinetics of the initiator degradation and monomer polymerization [3, 4], can be prepared by grafting of compounds with unsaturated bonds, e.g., vinylchlorosilanes (VCSs) and vinyltrichlorosilanes, to the hydroxyl-containing support surface [5–8]. Polymerization in these systems is initiated by the agent occurring in the monomer bulk or sorbed on the surface of modified solid support [3–8].

Formation of a continuous polymeric coating protecting the support surface is urgent for preparing packing materials for high-performance liquid chromatography (HPLC). Uncontrolled cross-linking during deposition of the polymeric coating can deteriorate the chromatographic properties of the packing materials.

In this work we studied nonporous silica gel microspheres to eliminate the effect of structural features of the matrix (in particular, support porosity) on the polymeric coating deposition.

EXPERIMENTAL

As starting compounds for preparing packing materials with a polymeric coating we used nonporous microspheric silica gel with a particle size of 2 μm and residual pore volume of no more than 0.03 $cm^3\ g^{-1}$; it was prepared by the procedure given in [1]. The surface of this material was modified with VCS and octadecylchlorosilane (ODCS) with additional silanization with trimethylchlorosilane (TMCS) according to published procedure [9].

Copolymer of octadecyl methacrylate (ODMA) and methyl methacrylate (MMA) was used as polymeric material. The ODMA–MMA copolymer was prepared and deposited on the silica gel surface according to [10] using dicumyl peroxide initiating agent.

The HPLC analysis was performed on a Gilson device equipped with a double-beam UV detector (λ = 254 nm) using acetonitrile–water mobile phase (3 : 7 volume ratio). The tests were performed with 4.6×50- and 4.6×33-mm columns.

We used chemically pure grade reagents and chromatographic grade acetonitrile, water, and uracil–pyridine–phenol–toluene test mixture.

The sorption capacity factor of the material with respect to toluene can be determined as

$$k = (\tau_t - \tau_u)/\tau_u,$$

where τ_t and τ_u are the retention times of toluene and uracil, respectively (min).

The chromatographic parameters of the columns packed with nonporous supports (2 μm particle size) and different content of the polymeric coating are listed in the table. The particle surface was not preliminarily modified with VCS. The chromatographic properties of the columns packed with nonporous silica gel microspheres modified with ODCS (C_{18}) are given for comparison.

Let us consider the chromatographic properties of

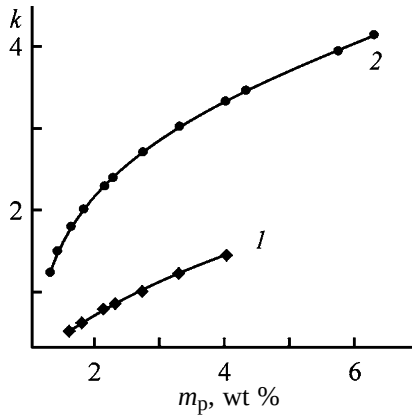
the columns packed with microspheric silica gel containing C_{18} phase as a reference. The data given in the table show that, in the course of polymerization modification without VCS pretreatment, the continuous polymeric coating is formed only when the polymer content does not exceed 2 wt %. It should be noted that this content of the polymer on the nonporous surface significantly exceeds the amount required to form a monomolecular layer. Slight rise of k to 1.21 corresponds to the increase in the content of the polymeric coating to 3.1 wt % relative to the support weight. The main chromatographic properties of the columns packed with nonporous supports (2 μm particle size) preliminarily modified with VCS and differing in the content of the polymer coating are also listed in the table.

The mandatory requirement to the resulting polymer-containing composites is complete shielding of all the silanol groups on the support surface, eliminating two major disadvantages of silica matrices: high solubility in alkaline medium and so-called "silanol" interaction on the surface.

At complete shielding of the silanol groups, the retention time of pyridine is shorter than that of phenol (see table). Although the polymeric coating completely shields all the surface silanol groups, in some cases secondary cross-linking is observed, which is illustrated by increasing sorption capacity factor k with respect to toluene. This increase in k with increasing content of the polymeric coating confirms the fact that the polymeric coating with certain porosity is formed on the vinylated surface.

The sorption capacity factor increases with increasing content of the polymer (see figure). As seen from the comparison of dependences *1* and *2*, a continuous polymeric coating is formed in the course of deposition of the polymer layer on the silica gel surface pre-



Sorption capacity factor with respect to toluene k as a function of the content of the polymer deposited m_p. Polymer (*1*) without VCS modification and (*2*) preliminarily modified with VCS.

liminarily modified with VCS. In this case, an increase in k with increasing polymer amount is less pronounced than without VCS pretreatment. The chromatographic parameters of the columns, obtained in this case, are similar to those for the columns packed with microspheric nonporous supports modified with ODCS (k values are nearly equal).

Since it is believed that k increases owing to the appearance of additional surface, then it can be concluded that secondary pores are formed in the course of silica gel coating with the polymer. It should be noted that the polymerization initiator (dicumyl peroxide) passes from the pentane solution to the support surface simultaneously with ODMA–MMA oligomer.

Secondary pores on the surface of a support preliminarily modified with VCS are formed as follows. In the course of polymerization on the surface containing vinyl groups, the sections with double bonds react first, because oligomers and silanol groups are less reactive. These vinyl-containing sections on the support surface become the centers of cross-linking of the oligomer fragments, forming a network which gives rise to secondary porosity. Simultaneously, free radicals are generated by thermal degradation of the initiator:

$$\mathrm{ROOR} \rightarrow 2\mathrm{RO}^{\bullet} \text{ and } \mathrm{ROOR} \rightarrow \mathrm{ROO}^{\bullet} + \mathrm{R}^{\bullet}.$$

These free radicals primarily attack the sections with double bonds and generate a large amount of free radicals on the support surface, causing random cross-linking of oligomeric fragments and formation of the porous polymer. Due to the high rate of the radical formation and random linking of oligomers with surface groups, a porous polymeric layer is formed instead of a continuous coating. Moreover, linking of separate oligomeric fragments with each other is hindered, because the main fraction of the initiator is consumed in the opening of the double bonds. It should be noted that, since cross-linking proceeds only with vinyl-containing sections of the support surface, the vinyl-free surface sections remain uncoated.

When the support surface was not preliminarily modified with VCS, the oligomeric fragments of copolymers react with radicals first. Oligomeric fragments are cross-linked, and the degree of additional polymerization is greater than in the above case. In the latter case, the polymer most likely covers silica gel particles and does not interact with their surface. The efficiency of additional polymerization is lower, which causes formation of a more uniform and relatively nonporous polymeric coating. With increasing polymer content, k also grows, but this trend is less pronounced than in the previous case.

CONCLUSIONS

(1) Preliminarily activation of the silica gel surface with vinylchlorosilane provides formation of secondary pores.

(2) The polymeric coatings with decreased porosity can be obtained without preliminary modification when the secondary porosity is insignificant.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Activating Mixing in Preparation and Modification of Polymeric Composites

V. P. Britov, V. V. Bogdanov, O. O. Nikolaev, and A. E. Tubolkin

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 4, 2003

Abstract—The concept of activating mixing as a procedure for preparing and modification of polymeric composites was developed. A new classification and generalized parameters of mixing, characterizing conditions of the energy supply to polymeric composition through the device working elements, were proposed. The dependence for determining the treatment modes providing controllable development of chemical transformations in a polymer system, which is invariant with respect to treatment modes and working installation, was obtained.

Formation and modification of polymeric composites by mixing is one of the ways for preparing new materials. Theoretically valid approach to this process was formulated in the middle of the past century [1]. It was suggested that laminar mixing increases the interface area of the components under the shear strain.

Since that time, despite considerable amount of works on various aspects of mixing (technology, installations, procedures to evaluate the system state, quantitative evaluation of the process performance), the phenomenological concept of the process remained unchanged. One of the reasons of this lag in the theoretical interpretation of the processes occurring during mixing was due to the concept of the process objective taken *a priori.*

Until recently, mixing was considered as a process whose "objective is transformation of the initial system, characterized by the ordered distribution of the components, into a system with disordered random distribution" [1].

This concept is obviously restricted [2], as seen from the following example. An active filler is added to a system in which the polymeric matrix is a mixture of elastomers. The required set of the material properties is provided only at the optimal distribution of the filler between the phases. In this case, "optimal distribution" is not identical with the uniform distribution of the filler in the entire system, because the filler content ensuring the highest strengthening is specific for each polymer.

The restriction of the classical concept of the mixing objective is confirmed by the analysis of the other polymeric systems. For example, in polymer engineering (as in other chemical processes) mixing should also be performed in single-component systems. In this case, mixing provides formation of the temperature-uniform material. In particular, a set of devices for rubber treatment is known, which provide heating and temperature uniformity in the material (cold-feeding screw machines).

The known classification of mixing processes should be also refined. These processes are often classified by the phase composition of the working medium and the process kind. As regards the phase composition, mixing can be performed in liquid, viscous-flow, and powder states [3]. In preparation of polymeric composite materials (PCMs), processes of the second group (viscous-flow mixing) are used most widely. However, only a few processes fit in the above classification. In the strict sense, these are only processes based on mixing of two thermoplastic components in a melt. A thermoplastic material is mixed with a rubber when one of the components (rubber) occurs not only in the viscous-flow but also in the hyperelastic state.

The real PCM preparation is based on mixing of powdered and high- and low-viscosity components added in the specific order and in definite time. Preparation of rubber stocks is the most typical example. Hence, we should consider not the process occurring in the viscous-flow state, but mixing of the components in different physical and phase states.

At present, the process results are not taken into account in classification, though the definitions such as "homogenization" and "dispersion" are used. It is

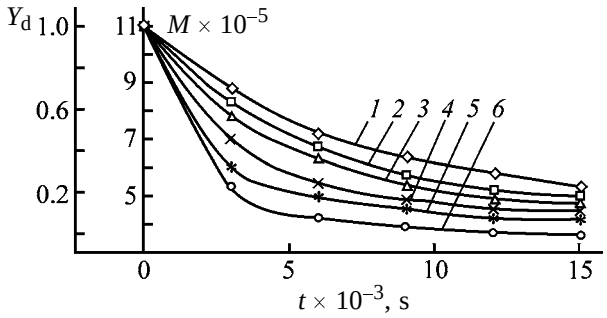

Fig. 1. Kinetic curves of NR degradation. (Y_d) Degree of degradation, (M) molecular weight of the polymer, and (t) time. H_0 (mm): (*1, 4*) 2; (*2, 5*) 1.5, and (*3, 6*) 1. φ_w: (*1, 3*) 0 and (*2, 4–6*) 0.3.

assumed that, in the first case, only the uniform distribution of particles is attained, whereas in the second case this is accompanied by a decrease in the component particle size. The above subdivision was made about 40 years ago [4], it seems valid, but separation of these processes in practice is very difficult. For example, the majority of compositions with addition of various components are prepared using impeller and rotary mixers in which the dispersion of the components is accompanied by homogenization of the entire system.

The most serious disadvantage of the existing approach to the mixing process is that it is considered as a combination of physical processes, whereas occurrence of chemical reactions due to the mechanical impact on the polymers in the course of their treatment is well known [5]. At present, a great body of data on mechanochemical transformations in polymers is available, but it is still not systemized. Moreover, due to the absence of the general criterion of the external effect on a polymer, it is difficult to compare the data given by different authors. In most cases, this effect is evaluated by changes in a separate process parameter, e.g., transition number through the rolls gap, grinding time in mills, etc. This approach does not take into account the process modes and design parameters of the installation in their combination, though they affect the material simultaneously [6].

Mechanochemical transformations in polymers are often described by an equation characterizing changes in the molecular weight with time proposed by Baramboim [5]:

$$M_t = (M_0 - M_\infty)\exp(-kt) + M_\infty, \quad (1)$$

where M_t is the current molecular weight at time t, M_0 is the initial molecular weight of the polymer, M_∞ is the limiting molecular weight of the smallest chain section, and k is a constant.

Casale and Porter [6] believed that constant k depends on the chemical nature of the polymer and packing density of its chains and determines the rate of mechanical degradation. Hence, k is a function of the polymer properties and is independent of the treatment conditions. However, k depends not only on the polymer nature, but also on the conditions of the energy supply to the material. The nature of the medium and temperature mode of dispersion are important but insufficient parameters to characterize the process conditions. Certain changes in the shear rate will cause changes in the shear stress and degradation rate in the system. This fact is confirmed by the data of the same authors on the relationship between the kinetics of ultrasonic degradation and experimental conditions.

This assumption was also confirmed by our experiments illustrating the development of mechanical degradation processes in natural rubber (NR). The kinetic dependences of NR degradation under various treatment conditions (H_0 is the minimal gap between the rolls) on the rolls with a wedge intensifying attachment [3] and without it are shown in Fig. 1. The depth of the wedge dipping is $\varphi_w = 0.3$ and $\varphi_w = 0$, respectively. As seen, the parameter k changes with changes in the treatment conditions. Thus, comparison of the data on mechanical degradation of similar polymers under different experimental conditions is meaningless, because different results will be obtained at different treatment modes. At the same time, comparison of the parameters of mechanical degradation obtained at rigidly fixed treatment modes is also impossible because of differences in the mixer design, providing different parameters of the mechanical field affecting the given material.

Thus, novel criteria allowing comparison of various polymers using parameters of mechanical degradation are required; moreover, these criteria should be invariant with respect to the treatment modes and design features of the installations.

We believe that classification of mixing processes by their effect on the mixed materials is the most promising. In this case, the objective of mixing (as a main procedure for PCM preparation) is to provide the optimal conditions in which the most valuable properties of the material (depending on its composition) will be manifested. For this purpose, new processes and equipment should be developed. Mixing should be organized so that the energy supplied to the components will initiate their chemical interactions

hindered under the other conditions or accelerate these reactions. Obviously, we consider only the components between which these reactions can proceed.

Practical problems which could be solved in this case are (1) development of new high-performance processes for preparing common compositions from viscous chemically reactive components and (2) preparation of new materials in the course of initiation of mechanochemical transformations and(or) controllable chemical modification of the polymers.

We suggest the term "activating" to define mixing under the conditions of initiated and controllable mechanochemical transformations.

The activating mixing differs from the other mixing modes (including those accompanied by mechanochemical transformations) in that in this case, along with increasing interface area between the components, the corresponding chemical reactions in the system are directly initiated or their rate considerably increases.

Activating mixing also differs from the other types of mechanical treatment causing mechanochemical effects (e.g., ultrasonic) by the specific effect of the mechanical field (shear strain), which increases the interface area between the components.

Thus, homogenization and dispersion mixing and the other mechanical procedures initiating chemical transformations can be considered as particular cases of activating mixing. This assumption can be illustrated using the classical Arrhenius equation in which the reaction rate constant K is determined by two variables (activation energy E_a and space steric factor pz):

$$K = pz e^{-E_a/RT}, \quad (2)$$

where z is the factor proportional to the collision number between the interacting particles.

At activating mixing, the reacting compounds obtain certain energy and the activation barrier of chemical reactions decreases. Moreover, during treatment some portion of mechanical energy is transformed in the heat, which also increases the reaction rate.

Finally, under the effect of stresses and shear rates, causing dispersion and homogenization, the interface area between the components increases and, thus, the probability of favorable mutual orientation of components (parameter pz) promoting the chemical reaction also increases. The latter condition of the activating mixing is advantageous as compared with the other modes of mechanochemical initiation and makes it efficient for practical implementation.

Our concept of the activating mixing allows the following classification of processes by the result of their effect on the mixed component.

Simple homogenizing mixing is a process that decreases the concentration heterogeneity in the system without chemical transformations. Mixing of granulated polymers with powdered or granulated additives without changes in the particle size and preparation of temperature-uniform media are the examples of this process.

Simple dispersion mixing is a process that causes breakdown of the disperse phase agglomerates in the system without chemical transformations These processes include formation of oil–water emulsions, breakdown of agglomerates of inert fillers in rubbers, etc.

Homogenizing mixing is a process that decreases the concentration heterogeneity in the system and is accompanied by chemical transformations that are not initiated in the course of the given process. Mixing of liquid media able of chemical reaction is an example of the process.

Dispersion mixing is a process that causes breakdown of the disperse phase agglomerates in the system and is accompanied by chemical transformations that are not initiated in the course of the given process.

Activating mixing is a process of initiation of chemical transformations in the system accompanied by its homogenization and dispersion of the separate phases.

It is advisable to describe each of the above processes by its own parameters (generalized parameters) of the external effect on the material.

The homogenizing mixing can be described using the common concept of the shear strain γ and its variance, which are directly related to the interface area between the components [3].

As for dispersion mixing, along with shear strain, we should evaluate the shear stresses τ appearing in the system and causing dispersion of one polymer in a another, breakdown of filler agglomerates, etc.

To develop the generalized parameters of activating mixing, we used the available experimental data on mechanochemical transformations in polymers processed on different installations. The correlation between the intensity of mechanical energy supply and the rate of mechanical degradation during treatment of rigid carbon-chain polymers (e.g., polystyrene, polyvinyl acetate, and polymethyl methacrylate) in a vibrating mill was found in [5]. With some assumptions, the strike energy of the grinding bodies of cer-

tain generalized weight is taken to be proportional to $(\alpha f)^2$, where α and f are the amplitude and frequency, respectively.

It was found that the rate constant of degradation is proportional to $\log(\alpha f)^2$. This suggests that

$$k_d = \log[(\alpha f)^2/(\alpha_0 f_0)^2], \quad (3)$$

where $\alpha_0 f_0$ is the certain deformation limit at which the rate constant of degradation decreases to zero.

For this process, it is convenient to use the energy E (J m^{-3}) per unit volume of the medium (energy density) as a criterion of the external effect:

$$E = 2\pi^2\rho(\alpha f)^2. \quad (4)$$

The process described above is physically similar to the process of shearing flow as predominant in both mixing and the other process of the polymer treatment.

It is known that the greater the internal friction (determined by the internal friction coefficient, or viscosity μ, Pa s), the greater the shear stress τ (Pa) required to preserve the steady-state motion in a laminar flow with a constant rate gradient γ' (s^{-1}); the relationship of these parameters is shown by the Newton equation $\tau = \mu\gamma'$. The energy intensity of the solution motion in a laminar flow per unit volume Y (W m^{-3}) is determined by the following equation:

$$Y = \mu\gamma'^2. \quad (5)$$

The amount of energy supplied to the material in certain time t (commonly, the period of the material treatment), or the density of the strain energy, can be given as

$$E = \mu\gamma'^2 t. \quad (6)$$

Equation (6) can be presented by various expressions:

$$E = \mu\gamma'^2 t = \mu\gamma'\gamma' t = \mu\gamma'\gamma = \tau\gamma, \quad (7)$$

where $\gamma = \gamma' t$ is the shear strain.

The density of the strain energy can be expressed in various dimensions: $U = E V_m$ [J mol^{-1}, cal mol^{-1}]; $U = EM_{av}/\rho$ [J mol^{-1}] = $0.24EM_{av}/\rho$ [cal mol^{-1}], where V_m and M_{av} are the average molar volume and average molecular weight, respectively. In this case, the value of the external mechanical effect can be compared with the energy of chemical bond.

It can be readily shown that the parameters in Eqs. (3) and (7) are physically identical. In the case of unidimensional motion, the rate gradient U/H can be used instead of the strain rate $d\gamma/dt$, i.e., the strain and shear rate correspond to the amplitude and frequency of the external mechanical field, respectively.

Thus, we proposed two generalized parameters to characterize the activating mixing, namely, the density of the strain energy and its intensity.

The possibility of using the intensity of the shear energy to analyze the mechanical degradation was first proposed in [6], but this parameter was not applied to mixing procedures, polymer treatment, and setup utilized. Hence, it was advisable to verify our generalized parameters with experimental data.

The tests were carried out using laboratory devices (Weissenberg rheogoniometer, Brabender plastograph) and industrial equipment (roller-bending machine, rotary mixers, vibrating mills, rotary-pulsating units). The resulting materials were analyzed by IR and UV spectroscopy, sol–gel analysis, and the other methods allowing evaluation of the molecular weight and molecular-weight distribution. In the course of the tests, we studied the relationships between the generalized parameters of the external effect on the system and parameters of mechanochemical transformations determined independently. The degree of mechanical degradation was studied using a dimensionless parameter (degradation index):

$$I_d = \frac{M_0 - M_t}{M_0 - M_\infty}. \quad (8)$$

In Fig. 2, our experimental data (see Fig. 1) are shown in the "degradation index–strain energy density" coordinates. The kinetic dependences of the index of mechanical degradation of natural rubber fall on a common straight line described by the following equation:

$$I_d^* = 1 - I_d = \frac{M_0 - M_t}{M_0 - M_\infty} = e^{-k^*\tau\gamma}, \quad (9)$$

where k^* is the degradation rate constant.

The curves of mechanical degradation of some other rubbers, obtained by similar procedure, are also shown in Fig. 2. Mutual position of the kinetic curves in the I_d^*–$\tau\gamma$ coordinates allows comparison of the rates of mechanical degradation of various polymers irrespective of the conditions of their treatment. In this case, k^* describes only the material properties. Thus, by determining the dependences of the parameters of

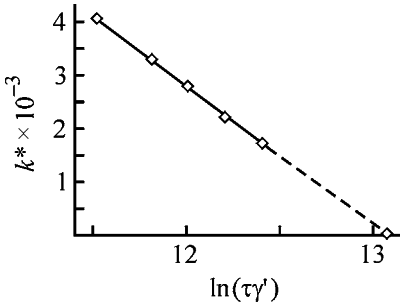

Fig. 3. Rate constant of degradation as a function of the intensity of mechanical effect $\tau\gamma'$.

mechanical degradation on $\tau\gamma$, we can obtain a correlation for a given material that is invariant with respect to the treatment modes and design features of the installation. At the same time, even significant density of the strain energy is not sufficient to cause mechanical degradation. The other necessary requirement is the energy supply. Actually, $\tau\gamma$ can be realized in an infinite period, with no mechanical degradation. This is due to the dispersion of the supplied mechanical energy through the polymer chains; this phenomenon was analyzed by Enikolopov [7]. The author studied ultrafast reactions in solids and formulated the following conclusion: At relatively low loading rates, the contribution of the elastic strain is negligible (1%) as compared to the total strain. As a result, at small shear rates in the working zone of the installation, the elastic energy accumulated in a solid is small. With increasing loading rate, the contribution of the elastic strain grows.

The above results can also be applied to our systems, because the polymer, irrespective of its molecular weight, can be considered as solid at certain intensity of the mechanical field. This fact explains the requirement of high shear rates at mechanochemical modification of polymers, reclaim of rubber crumbs from tire crushing, etc.

In practice, the required intensity of the strain effect can be determined as follows. First, the dependence of the degradation rate constant k^* on the logarithm of the shear stress intensity $\tau\gamma'$ is plotted, and then, extrapolating the resulting curve to the zero rate, the $\tau\gamma'$ value required to initiate the degradation is determined (Fig. 3).

Our theoretical results on the activating mixing were used in the development of processes for physicochemical modification of conducting siloxane compounds [8] and medical-purpose preparations [9]. However, it should be noted that the above processes are accompanied by predominantly physical transformations.

CONCLUSIONS

(1) Traditional concepts on the objective, nature, and classification of the mixing process were significantly refined. Classification of the mixing procedure based on the results of its effect on the mixed materials is the most valid. In accordance with this classification, the following mixing modes were distinguished: simple homogenizing, simple dispersion, homogenizing, dispersion, and activating mixing.

(2) The generalized parameters of the activating mixing characterizing the conditions of the energy supply to the material are the strain energy density and its intensity.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Control of Penetration of Macroglobules from Polymer Solution into the Bulk of a Porous Solid

N. V. Volkova, D. N. Emel'yanov, T. S. Kiseleva, and Yu. M. Ananicheva

Lobachevsky Nizhni Novgorod State University, Nizhni Novgorod, Russia

Received November 11, 2002; in final form, April 2003

Abstract—Penetration of poly(butyl methacrylate) macroglobules into solid porous samples of chalk, clay, cement, and cement–river sand mixtures was studied as influenced by the macroglobule size.

Important aspects in impregnation and reinforcement of porous solids (particularly, loose materials typical of historical and cultural monuments) are the depth of penetration and uniformity of distribution of the fixing agent (e.g., polymer) in the bulk of these solids. Naturally, the above-mentioned characteristics will be governed by the properties of the impregnating solution and, above all, by the polymer macroglobule size.

The aim of this work was to study penetration of poly(butyl methacrylate) (PBMA) macroglobules from solutions in solvents of different solvency into the bulk of solid porous samples such as models of historical and cultural monuments. Poly(butyl methacrylate) is widely used for conservation and restoration of art monuments made of various materials [1].

EXPERIMENTAL

We studied suspension PBMA [TU (Technical Specifications) 6-01-240–76] with the molecular weight $M = 3.5 \times 10^5$. As solvents for PBMA served toluene, *o*-xylene, acetone, butanol, and isopropanol. The quality of the solvents with respect to the polymer used was estimated by comparison of their solubility parameters δ [2] summarized in the table below. The table shows that, in changing from toluene to alcohols, the difference in δ increases. This means that, along this series, the quality of the solvent with respect to PBMA tends to deteriorate. The quality of the solvent was also worsened by introducing a precipitating agent for PBMA [3.5 to 10.5% (hereinafter, wt %) distilled water] into isopropanol. In this case, worsened solubility of PBMA in the mixed solvent was evidenced by increased turbidity of the solution, which was estimated nephelometrically.

The rms distance between the ends of the PBMA macromolecule in θ-solvent, isopropyl alcohol, was calculated by the Flory–Fox formula [3]

$$(\bar{h}_\theta^2)^{3/2} = \frac{[\eta]_\theta \bar{M}}{\Phi}, \quad (1)$$

where Φ is the Flory constant; $\bar{M}$, viscosity-average molecular weight of PBMA; and $[\eta]_\theta$, intrinsic viscosity of the PBMA solution in θ-solvent (isopropanol), l g^{-1}, measured at the θ-temperature of 21.5°C [2].

The swelling coefficient α^3 of the macroglobule and the rms distance $(\bar{h}^2)^{1/2}$, nm, between the ends of the macromolecule in different solvent were calculated by the formula

$$\alpha^3 = \frac{[\eta]}{[\eta]_\theta} = \frac{(\bar{h}^2)^{3/2}}{(\bar{h}_\theta^2)^{3/2}}. \quad (2)$$

Influence of the solubility parameter δ on the intrinsic viscosity $[\eta]$ of the PBMA solutions, swelling coefficient α^3 of the macroglobule, and rms distance between the ends of the PBMA macromolecule $(\bar{h}^2)^{1/2}$ [δ_{PBMA} = 8.70 (cal cm^{-3})$^{1/2}$]

Solvent	δ, (cal cm^{-3})$^{1/2}$	α^3	$(\bar{h}^2)^{1/2}$, nm	$[\eta]$, l g^{-1}
Toluene	8.97	5.30	46.0	0.080
o-Xylene	9.03	5.53	46.7	0.083
Acetone	9.74	2.53	36.0	0.038
Butanol	10.77	1.67	31.3	0.025
Isopropanol*	–	1.0	26.4	0.015

* For propanol, δ = 12.06 (cal cm^{-3})$^{1/2}$.

1070-4272/04/7701-0124 © 2004 MAIK "Nauka/Interperiodica"

The polymer content in the solutions was varied from 1 to 16%.

As solids we used $10 \times 10 \times 100$-mm cement–sand samples (CSSs), as well as $10 \times 10 \times 80$-mm pressed chalk (TU 458-15-14–89) and clay samples. The cement–sand samples were prepared by mixing grade 400 Portland cement [GOST (State Standard) 10178–85, particle size from 50 (65%) to 150 (7%) μm] with river sand [average particle size from 100 (5%)–300 (25%) to 400 (20%)–500 (15%) μm] in 18 ml of distilled water. The sand content in the samples was varied from 0 to 90%. The samples were molded at room temperature for 14 days. Clay samples were prepared by room-temperature molding, through mixing fine clay particles [from 1 (28%) to 60 (61%) μm in size] in 18 ml of water, followed by drying to constant weight at 200°C. Next, the pore size of the solid samples was estimated. To this end, we measured the rate of penetration of isopropanol into the sample pores. Then, the average pore radius r_{av}, nm, was calculated by the Washburn equation [4].

The pore radius of the solid samples r_{av}, nm, was estimated at 0.63, 0.48, 0.14, and 1.80 for chalk, clay, CSS-0, and CSS-90, respectively (the figure at the CSS designation corresponds to the river sand percentage).

The porous samples were impregnated until complete saturation with the polymer solutions in closed vessels, by immersing samples, suspended by wires from their face side, by 1 cm of their height in the impregnating liquid. Next, the samples were dried at room temperature under slow solvent evaporation. The uniformity of distribution of the polymer in the bulk of the porous samples was monitored by the procedure from [5]. It is underlain by the fact that the water absorption in the open pore space of the solid sample varies with the extent of pore filling with the penetrated polymer.

The solvent quality will, above all, affect the size of the polymer macroglobule. Grosberg and Khokhlov [6] found that, with deteriorating solvent quality, the macromolecular globule gets contracted. The volume occupied by the macromolecule decreases by a factor of several tens. The table below shows that, in changing from "good" (*o*-xylene or toluene) to "bad" (butanol or isopropanol) solvents, the rms distance between the ends of the PBMA macromolecule decreases by a factor of 1.5–2.

It could be expected with a good reason that, the smaller the globule, the easier and faster its penetration into pores (capillaries) of a solid. However, our

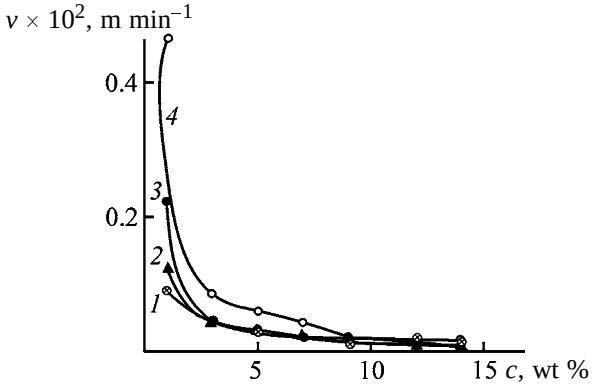

Fig. 1. Influence of the PBMA concentration c in the impregnating solutions in different solvents on the rate of their capillary rising v in CSSs containing 90% river sand. (*1*) Isopropanol, (*2*) butanol, (*3*) *o*-xylene, and (*4*) toluene.

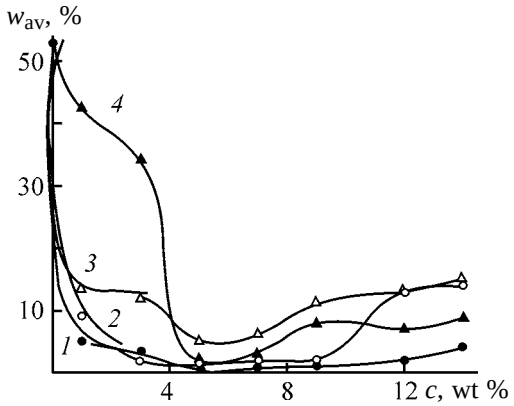

Fig. 2. Average water capacity w_{av} of CSSs containing 90% river sand as a function of the concentration of the impregnating solution c. (*1*) *o*-Xylene, (*2*) acetone, (*3*) butanol, and (*4*) isopropanol.

study showed that the rate of the capillary rising of the solution is larger (Fig. 1) and the degree of penetration of the polymer into CSSs with larger pores is greater (Fig. 2) when the PBMA macroglobules occur in the swollen state. The degree of penetration of the polymer into pores of solid samples was estimated from the amount of water w, %, able of penetration into the sample pores that remained open after impregnation with the polymer. The larger the amount of water absorbed by the sample, the lesser the amount of the polymer it contains. Evidently, in the case of loose globules, the globules extend and get oriented along the flow under the influence of the capillary pressure of absorption. This favors faster and deeper penetration of the globule into the sample pores.

When penetrating into surface pores of the sample, compressed PBMA macroglobules in isopropanol, evidently, plug them, thus preventing further penetration of PBMA into porous solids. This assumption is

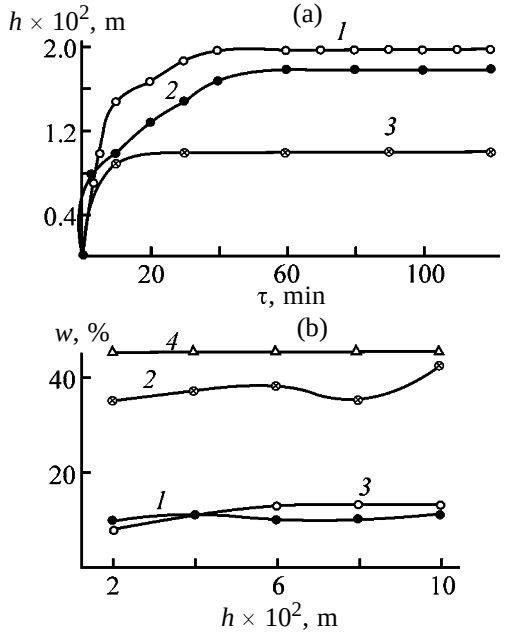

Fig. 4. (a) Kinetic curves of the capillary rising *h* of 3% PBMA solutions into cement samples and (b) variation of the moisture capacity *w* of the samples impregnated with 3% PBMA solutions along their height *h*. (τ) Time of rising of PBMA solutions into the samples, min. (*1*) *o*-Xylene, (*2*) isopropanol, (*3*) butanol, and (*4*) samples untreated with PBMA solution.

confirmed by Fig. 3 which suggests that the moisture capacity of the CSSs impregnated with PBMA solutions in *o*-xylene (a "good" solvent) is virtually invariant along the sample height. This means that the polymer is uniformly distributed over the sample. At the same time, the samples impregnated with PBMA solutions in butanol (a "bad" solvent) are characterized by a much lower moisture capacity of that segment of the sample through which impregnation was performed, compared to that at the opposite end. This suggests that the polymer is nonuniformly distributed over the CSS height and is, most probably, concentrated primarily in the surface pores. Evidently, the internal pores occurring in the middle part of the sample remained unimpregnated with the polymer. This is also confirmed by the fact that the moisture capacity of the samples impregnated with PBMA solutions in butanol significantly exceeds that of the samples impregnated with PBMA solutions in *o*-xylene.

In the case of impregnation of solid samples having small pores, the difference in the rates of rising of solutions in solvents with low and high solvency is virtually leveled off (Fig. 4a). The polymer is uniformly distributed along the height of the samples from both "bad" and "good" solvents (Fig. 4b). However, the degree of its penetration into the sample from the *o*-xylene solution significantly decreases, approaching that of the polymer penetrating from solutions in "bad" solvents. Thus, in both cases the polymer occurs in the surface pores of solids. Penetration of the polymer into sample pores is evidenced by a significant decrease in the moisture capacity relative to the untreated sample.

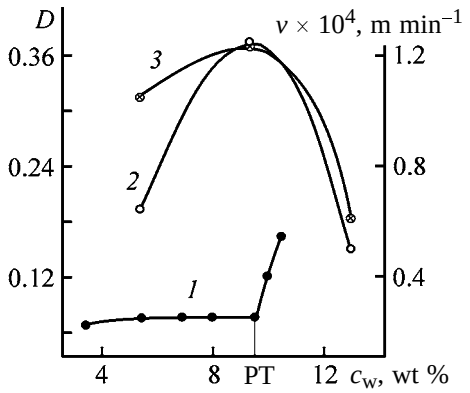

Fig. 5. (*1*) Optical density *D* of 2% PBMA solution and (*2*, *3*) rate of capillary rising of solutions *v* into (*2*) clay and (*3*) chalk samples as functions of the water content c_w in mixtures with isopropanol. (PT) Precipitation threshold for the polymer.

When a precipitating agent is added to a "bad" solvent for PBMA (e.g., water to isopropanol), the macroglubules get contracted, and the solution becomes turbid. We found that, in this state, the rate of impregnation of solid clay and chalk samples with small pores sharply increases (Fig. 5). Decrease in the rate of impregnation of the clay and sand samples after passing the precipitation threshold can be explained by formation of large agglomerates from adhering globules.

Thus, the penetrability of the pores of a solid with large pores by the polymer can be increased by converting the macroglobules into the swollen state. In the case of samples with small pores, the globules should be compressed to the maximal extent.

CONCLUSIONS

(1) In changing from good (*o*-xylene, toluene) to bad (butanol, isopropanol) solvents, the rms distance between the ends of the poly(butyl methacrylate) molecule decreases by a factor of 1.5–2.

(2) The rate of the capillary rising of the poly(butyl methacrylate) solution is higher, and the penetration depth and uniformity of distribution of the polymer within the bulk of a solid with large pores is greater in the case of a swollen globule, i.e., that penetrating from a good solvent.

(3) For samples with small pores, the impregnation rate and uniformity of distribution of poly(butyl methacrylate) along the sample height is independent of the quality of the solvent: The polymer occurs in the surface pores of the samples. Impregnation of the samples with small pores sharply accelerates upon contraction of poly(butyl methacrylate) globules.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

IR and NMR Study of the Structure of Dextran Polyaldehyde

A. L. Neishlos, E. V. Novikova, B. V. Passet, and A. V. Moskvin

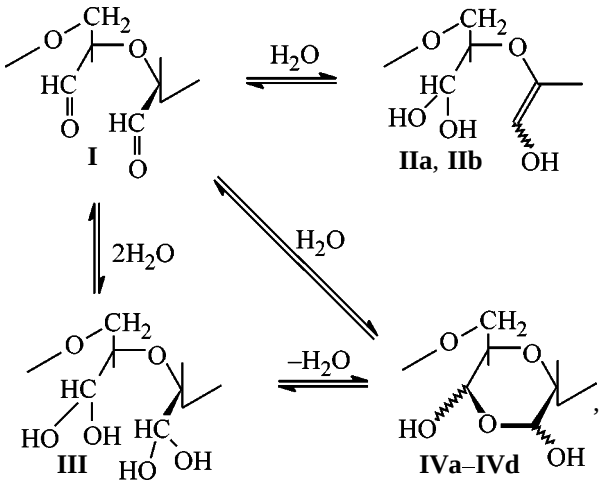
St. Petersburg State Chemical and Pharmaceutical Academy, St. Petersburg, Russia

Received January 24, 2003

Abstract—The structure of samples of dextran polyaldehyde synthesized at various pH was studied by IR and ^{13}C NMR spectroscopy and PM3 semiempirical quantum-chemical method.

As shown previously [1], the structure of dextran polyaldehyde (DPA) depends on the synthesis conditions, in particular, pH value in oxidation of dextran with sodium metaperiodate. Since DPA is used for production of polymeric drugs, its conformity to the standards is one of the important conditions of synthesis. Therefore, the aim of this work was to study the structure of the DPA samples described in [1] by modern physicochemical methods.

It was suggested [2–4] that the DPA samples recovered from a solution with the certain pH can occur in various forms:

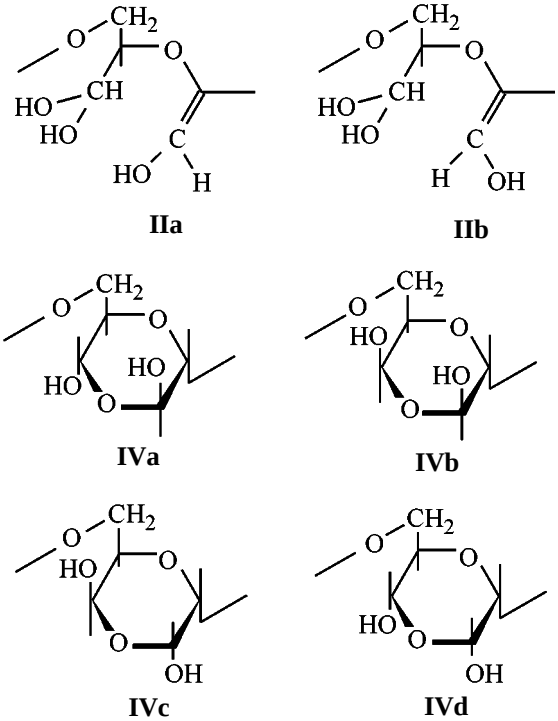


where **I** is aldehyde form, **IIa** and **IIb** are aldoenol forms, **III** is hydrated form, and **IVa**–**IVd** are hemiacetal forms.

Solid samples of DPA were prepared by oxidation of dextran with sodium metaperiodate at pH from 2.78 to 5.34 and isolated from the solution by the procedure described in [1].

Quantum-chemical evaluation of molecules of **I**–**IV** were carried out by semiempirical PM3 method using the GAMESS software [5]. The ^{13}C NMR spectra of solid samples were recorded on a Chemagnetic spectrometer operating at 74.7 MHz with magic angle spinning at 3.6 kHz. The spectra were interpreted using the ACD software. The IR reflection spectra were recorded on a Perkin–Elmer Fourier spectrophotometer.

To determine the energetically more favorable DPA forms, we calculated quantum-chemically the enthalpies of formation of structures **I**–**IV**, $\Delta_f H_0^0$, in a vacuum at 0 K and determined the heat effects of mutual transformations of these forms, $\Delta_r H_0^0$ (Table 1). For **II** and **IV**, the enthalpies of formation of their stereoisomers **IIa, IIb**, and **IVa**–**IVd** were evaluated:



According to quantum-chemical calculations, in the

Table 1. Enthalpies of formation of various DPA forms $\Delta_f H_0^0$ in a vacuum at 0 K and heat effects of their mutual transformations $\Delta_r H_0^0$ (results of PM3 calculations)

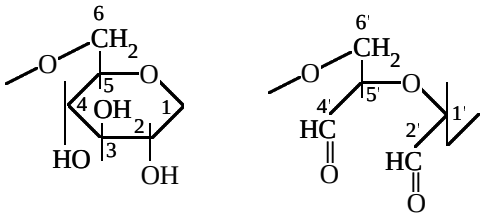
DPA form	$\Delta_f H_0^0$, kJ mol^{-1}	Transformation	$\Delta_r H_0^0$, kJ mol^{-1}
I	–830.645	**I → II**	–9.167
IIa	–1053.632	**I → III**	–103.982
IIb	–1063.860	**I → IV**	–71.261
III	–1382.723	**III → IV**	–32.721
IVa	–1125.954		
IVb	–1118.075		
IVc	–1113.874		
IVd	–1116.407		

gas phase hydrated DPA forms **II**–**IV** are more favorable than nonhydrated form **I**. The most probable is hydrated form **III**, and the least probable, aldoenol form **IIb**. Among the considered hemiacetal structures, the most favorable is **IVa**.

The ^{13}C NMR data for DPA samples and the initial dextran are presented in Table 2. The lines in the spectra of dextran were assigned according to published data [6, 7].

The numbering of the carbon atoms of monosaccharide units in the initial dextran and various forms of its oxidation products **I**–**IV** is presented below.

In the ^{13}C NMR spectra of DPA samples, the signals of $C^{1'}$–$C^{5'}$ atoms are shifted upfield relative to the corresponding signals in the spectrum of dextran.



This is usually observed in spectra of carbohydrates substituted in position 2, 3, or 4 [7].

According to the ^{13}C NMR spectra, oxidation of dextran proceeds across the C^2–C^3 and C^3–C^4 bonds, and there are no signals in the range 70.2–71.7 ppm corresponding to the signal of $C^{3'}$.

The aldehyde form **I** in the samples studied is apparently absent, since in the ^{13}C NMR spectra there are no signals in the region of 200 ppm characteristic of the –CHO group.

In the spectra of the DPA sample prepared at pH 2.78 and 4.88, there are signals in the region of 122.1 and 122.7 ppm, respectively, corresponding to the signal of $C^{2'}$ of aldoenol **II**; however, the signal of $C^{1'}$ in the region of 150 ppm is absent.

In the ^{13}C NMR spectra of all the DPA samples synthesized in the pH range 2.78–5.34, there are signals in the range 87.9 and 92.4–93.3 ppm, corresponding to the signals of $C^{2'}$ and $C^{4'}$ of hydrated **III** or hemiacetal **IV** forms.

Thus, the ^{13}C NMR spectra show that the DPA samples prepared at pH from 2.78 to 5.34 are mix-

* Calculated with the ACD software.

tures of hemiacetal, hydrated, and (at pH 2.78 and 4.88) aldoenol forms.

The IR reflection spectra were interpreted according to published data [8]. In the IR spectra of all the DPA samples, the stretching modes ν(C–C) and ν(C–O) of nonoxidized dextran ring were observed in the range 950–1080 cm^{-1}.

The IR reflection spectra of the samples synthesized at pH 2.57, 2.78, 4.86, and 5.34 show that aldehyde form **I**, manifested as a sharp band at 1700 cm^{-1}, was present in small amounts only in the samples prepared at pH 5.34. In the spectra of the other DPA samples, the absorption bands in this range are much less strong. In addition, water, which is always present in polysaccharides, absorbs in this range, hampering determination of aldehyde groups by IR spectroscopy.

In all the samples, the absorption bands at 1610 and 1500 cm^{-1} were found, suggesting the presence of aldoenol form **II**, whose content is maximal in the sample synthesized at pH 4.88. Certain decrease in the intensity of these bands in the sample with pH 5.34 is apparently due to a decrease in the total amount of oxidized units [1].

The maximum content of hydrated form **III** is observed in the sample prepared at pH 2.57. In its IR spectrum, there are strong absorption bands in the range 1250–1310 cm^{-1}. In the samples synthesized at higher pH its content decreases, and in the sample prepared at pH 5.34 hydrated form **III** is absent.

Thus, the IR spectra of DPA samples prepared by oxidation of dextran at various pH show that solid DPA is a mixture of hydrated form **III** with a small content of aldoenol form **II** and, at pH 5.34, of aldehyde form **I**.

CONCLUSIONS

(1) Dextran polyaldehyde prepared by solid-phase oxidation of dextran at pH < 5.34 contains no aldehyde form **I** and exists predominantly in the form of a mixture of hydrated **III** and hemiacetal **IV** forms.

(2) The content of hydrated form **III** in the samples of dextran polyaldehyde decreases with increasing pH from 2.57 to 4.88.

(3) Aldoenol form **II** is present in all the samples prepared at pH 2.57–5.34, and its content increases with pH.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Antioxidative Stabilization of Polyethylene Glycol in Aqueous Solutions with Herb Phenols

V. M. Mikhal'chuk, T. V. Kryuk, L. V. Petrenko, O. A. Nelepova, and A. N. Nikolaevskii

Donetsk National University, Donetsk, Ukraine

Received September 28, 2001

Abstract—The effect of compounds extracted from herbs on oxidation of polyethylene glycol in aqueous solutiuons was studied.

Polyethylene glycols (PEGs) of various molecular weights, which show no biological activity and are not involved in metabolism, are used in drug and cosmetic formulations [1].

Polymers based on ethylene oxide are characterized by high concentration of $-CH_2-$ groups in which the C–H bond is relatively labile owing to the presence of adjacent ether oxygen atoms. These substances are readily oxidized with atmospheric oxygen [2], which negatively affects the physiological and toxicological properties of drugs based on them. Therefore, PEG-based systems should be stabilized against oxidation. Data on antioxidative stabilization of PEG aqueous solutions are lacking, which makes urgent the studies of PEG oxidation in aqueous solution and the search for optimal inhibitors (InH) of the polymer oxidation.

Preliminary studies of the kinetics of oxygen uptake with 30% solutions of PEG in water and chlorobenzene showed that, in contrast to saturated hydrocarbons and carbon-chain polymers, PEG is oxidized at a high rate ($>5 \times 10^{-6}$ mol l^{-1} s^{-1}) even at 70–90°C. In the initial steps, the oxidation develops with autoacceleration, and the oxygen uptake grows in proportion to time squared; the kinetic curves are linearized in the parabolic coordinates (Fig. 1), which corresponds to the known equation of polymer autooxidation [3]:

$$\Delta O_2 = \frac{\alpha \sigma k_2^2 k_3 [RH]^3}{8k_6} t^2 = \Phi t^2,$$

where ΔO_2 is the amount of oxygen taken up by the polymer; Φ, autoacceleration factor; k_2, k_3, and k_6, rate constants of chain propagation, branching, and termination, respectively; σ, probability of escape of free radicals in breakdown of hydroperoxy groups; and α, yield of hydroperoxide based on the oxygen taken up.

In the course of oxidation, the rate of oxygen uptake monotonically grows, reaches a maximum, and then decreases (Fig. 1). A maximum or plateau in the time dependence of the oxidation rate is due to attainment, at certain instant, of a steady-state concentration of hydroperoxide, primary oxidation product, whose thermal decomposition results in branching of the oxidation kinetic chains [3]. As the temperature is elevated and the PEG content in solution is increased from 30 to 50%, the maximal oxidation rate V_{max} and the autoacceleration factor (Table 1), as expected, grow. An increase in the oxygen partial pressure from 0.02 to 0.1 MPa has virtually no effect on the kinetics

of oxygen uptake (Fig. 1). Our results show that oxidation of the polymer in aqueous solution can be considered as a kinetically controlled degenerate branched process.

Oxidation of PEG in aqueous solution is characterized by lower Φ and V_{max} compared to oxidation in chlorobenzene at the same temperature and polymer concentration (Fig. 1). This is due to solvation of PEG [4]. A water molecule forms a hydrogen-bonded radical complex with a peroxy radical,

$$RO_2^{\cdot} + H_2O \rightarrow ROO^{\cdot}\cdots HOH,$$

which is less reactive in chain propagation and termination than nonsolvated $RO_2^{\cdot}$.

Despite relatively low reactivity in water of radicals leading the oxidation chains, PEG is oxidized much faster than hydrocarbons. For example, medical Vaseline oil is oxidized at a noticeable rate only above 200°C [5]. As inhibitors of PEG oxidation, we tested phenols from herb extracts. Such compounds efficiently inhibit oxidation of liquid hydrocarbons, in particular, ethylbenzene [6], and are readily soluble in aqueous systems, in contrast to traditional inhibitors of oxidation of nonpolar hydrocarbons (sterically hindered phenols, aromatic amines, etc.).

The inhibiting power of phenolic antioxidants is usually evaluated by the rate constants of the reaction

$$RO_2^{\cdot} + PhOH \xrightarrow{k_7} ROOH + PhO^{\cdot},$$

which are determined under conditions of initiated oxidation at constant rate of generation of $RO_2^{\cdot}$ radicals. For the system under consideration, it seems impossible to determine the rate constant k_7 of phenol-inhibited oxidation of PEG experimentally, since autooxidation of PEG occurs even at relatively low temperatures (<70°C), and even at high concentrations of an initiator, azobis(isobutyronitrile) ($>1 \times 10^{-2}$ M), the oxygen uptake occurs under conditions of mixed initiation. This is indicated by the absence of linear concentration dependences of the induction periods τ of PEG oxidation in the presence of antioxidants. For example, the induction period in the kinetic curves of the oxygen uptake becomes longer on adding increasing amounts of syringic acid (Fig. 2a), but the $\tau = f([InH])$ dependence shows a pronounced curvature (Fig. 2b) characteristic of phenol-inhibited oxidation

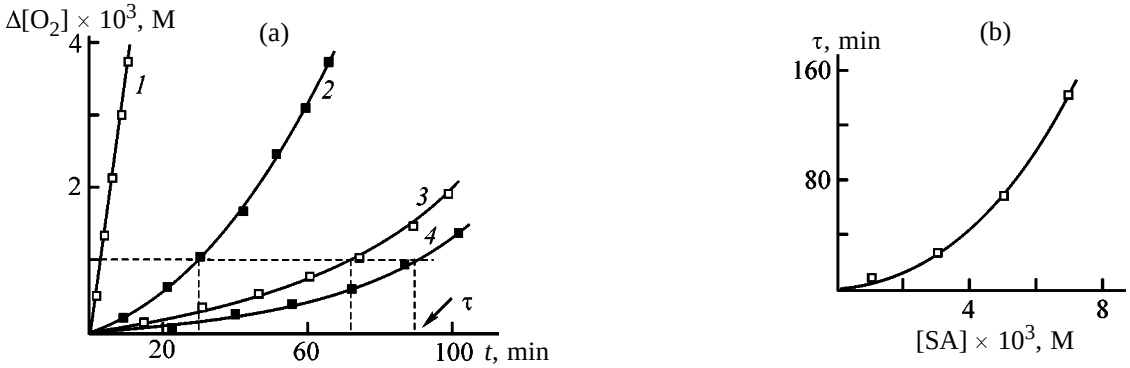

Fig. 2. (a) Kinetic curves of oxygen uptake with 30% PEG solution in water at (*1–3*) 75 and (*4*) 90°C in the presence of (*1–3*) azobis(isobutyronitrile), (*2, 3*) syringic acid, and (*4*) a mixture of syringic acid with phloroglucinol; (b) induction period of initiated oxidation of PEG as a function of syringic acid concentration [SA]. ($\Delta[O_2]$) Amount of oxygen taken up by the polymer, (τ) induction period of oxidation, and (*t*) time. of polymers in the autoaccelerating mode [3]. Therefore, the antioxidative performance of the phenols in hand can be assessed only by the autoacceleration factor and maximal autooxidation rate.

Experiments on the effect of herb phenols on the autooxidation kinetics revealed pronounced antioxidative power of these compounds with respect to PEG. Addition of ethyl gallate, phloroglucinol, syringic acid, and caffeic acid decreases the autoacceleration factor. Furthermore, additions of carboxyl-containing phenols considerably decrease the maximal oxidation rate (Table 1). The phenols in hand can be ranked in the following order with respect to the antioxidative power: ethyl gallate < phloroglucinol < syringic acid < caffeic acid.

As shown in [6], the same compounds are also effective antioxidants for ethylbenzene, which suggests that the stabilizing effect of phenols in polar and nonpolar media is similar. At the same time, data of [6] show that the antioxidative performance of the phenols in hand in aqueous solution is lower than in a nonpolar hydrocarbon medium. For example, in oxidation of PEG and ethylbenzene in the presence of syringic acid under similar experimental conditions (initiator concentration 1×10^{-2} M, 75°C), the 60 min induction period of oxygen uptake is attained at the inhibitor concentration of 5×10^{-3} and 1.5×10^{-5} M, respectively. The lower antioxidative performance of the inhibitors in water may be due to solvation of both phenols and peroxy radical of the polymer [4].

The higher stabilizing performance of carboxyl-containing phenols (syringic and caffeic acids) is, apparently, due to the fact that the antioxidants inhibit the PEG oxidation not only by reacting with peroxy radicals, but also by participating in some other reactions inhibiting the oxidation. The presence of an acid group in InH molecules suggests that such reaction may be decomposition of the primary products of the polymer oxidation. It is known [4] that decomposition of many organic hydroperoxides under the influence of Brønsted acids yields molecular products (alcohols, ketones, aldehydes, acids) incapable of leading the radical-chain oxidation process, which results in the reaction deceleration.

To confirm the assumption that the antioxidative effect of phenols containing acid groups is due to decomposition of hydroperoxides effected by these compounds, we examined the effect of inhibitors on decomposition of the hydroperoxide derived from PEG. We found that ethyl gallate and phloroglucinol containing no COOH groups do not activate the hydroperoxide decomposition. In the presence of syringic and caffeic acids, the hydroperoxide decomposes at a rate exceeding 10^{-6} mol l^{-1} s^{-1} even at 37°C. In the process, the kinetic curves of consumption of hydroperoxy groups are linearized in the coordinates of a second-order reaction with the correlation factor of 0.997 (Fig. 3). At the same time, the rate constant of the bimolecular reaction, calculated at different initial concentrations of the hydroperoxide and syringic acid (from 1×10^{-3} to 1×10^{-2} M) in the temperature range 37–57°C, takes different values depending on reactant concentrations (Table 2). This fact suggests that decomposition of PEG hydroperoxide, apparently, occurs via preliminary complexation and is described by the general relationships of acid decomposition of hydroperoxides following the Michaelis–Menten scheme [7]:

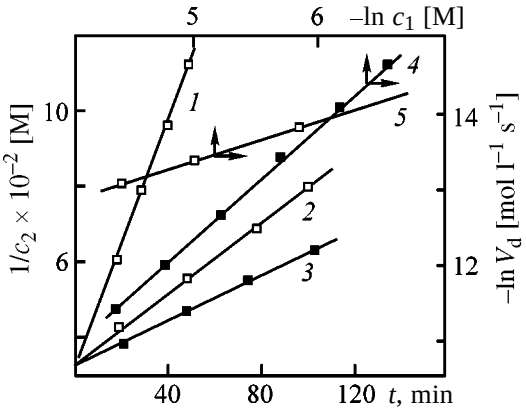

Fig. 3. (*1–3*) Variation with time of the concentration of PEG hydroperoxide in the course of its decomposition in the presence of 5×10^{-3} M syringic acid; initial rate of the hydroperoxide decomposition as a function of the (*4*) hydroperoxide and (*5*) syringic acid concentrations. Temperature, °C: (*1*) 57, (*2*, *4*, *5*) 47, and (*3*) 37. (V_d) Rate of hydroperoxide decomposition, (c_1) hydroperoxide or syringic acid concentration, (c_2) hydroperoxide concentration, and (t) time.

$$\mathrm{ROOH} + \mathrm{H^+} \underset{}{\overset{K_e}{\rightleftharpoons}} \mathrm{ROOH \cdots H^+} \xrightarrow{k_d} \mathrm{H^+} + \text{products}.$$

In this case, the hydroperoxide decomposition rate at $[\mathrm{ROOH}] \ll [\mathrm{H^+}]$ is described by the equation

$$V = \frac{k_d K_e [\mathrm{ROOH}][\mathrm{H^+}]}{1 + K_e[\mathrm{H^+}]},$$

where K_e is the complexation constant, and k_d is the rate constant of hydroperoxide decomposition.

This equation shows that the hydroperoxide decomposition is a first-order reaction with respect to the hydroperoxide, and the reaction order with respect to the catalyst can vary from 0 to 1 depending on K_e.

Table 2. Rate constants k_d of decomposition of PEG hydroperoxides (HP) in aqueous solution in the presence of syringic acid (SA)

5	1.6	2.8	1.6
7	2.1	3.7	3.1
10	3.3	8.7	5.8
[SA] = 5×10^3 M			
[HP] $\times 10^3$, M:			
1	0.28	0.28	0.75
3	0.48	1.1	–
5	1.4	3.2	3.0
7	3.4	3.7	5.0
10	4.9	6.2	7.3

Since the integral method is insufficiently sensitive for reliable determination of the reaction order, we calculated the reaction orders with respect to each component using the LeGore differential method [8]. We found that the dependence of the initial reaction rate on the initial concentration of additives is linearized in the $\ln V = f(\ln c)$ coordinates with the slopes of 0.8–1.2 for the hydroperoxide and 0.6 for syringic acid (Fig. 3), i.e., the order with respect to the hydroperoxide is close to unity, and that with respect to the catalyst is less than unity. Hence, indeed, PEG hydroperoxides decompose in aqueous solutions in the presence of carboxy phenols via formation of a complex.

From the temperature dependence of the rate constant of the reaction of syringic acid with PEG hydroperoxide, we determined the reaction activation energy E_a. The values of the rate constants and E_a (98 kJ mol^{-1}) allow comparison of the activating effect of syringic acid with that of such effective catalysts of organic peroxide decomposition as, e.g., quaternary onium salts, for which k_d varies in the range 10^{-4}–10^{-5} l mol^{-1} s^{-1}, and the activation energy of decomposition of cumyl hydroperoxide is 74–95 kJ mol^{-1} (depending on cation) at a catalyst concentration of 0.1 M [9]. Thus, the carboxy phenols studied in this work efficiently decompose hydroperoxides in aqueous solution.

Since decomposition of hydroperoxides in aqueous solutions in the presence of Brønsted acids mainly occurs without generation of active radicals [4], the phenols studied in this work probably decelerate various steps of PEG oxidation (chain propagation and branching). Addition to the polymer of compounds scavenging $RO_2^{\bullet}$ radicals and decomposing hydroperoxides ensures simultaneously small length and small number of kinetic chains. As a result, both functional groups protect each other from fast consumption and, acting in combination, provide prolonged protection of the polymer [3], i.e., an "internal synergism" of the functional groups of the stabilizer is observed. At the same time, enhancement of the antioxidative power of such inhibitors is due to the fact that the functional group that suppresses degenerate chain branching decreases the autoinitiation rate. As a result, syringic and caffeic acids exceed in the antioxidative power phloroglucinol and ethyl gallate.

When typical radical acceptors are introduced together with an inhibitor capable simultaneously of interacting with $RO_2^{\bullet}$ and decomposing hydroperoxides, the mutual effect of the stabilizers can be both synergistic and antagonistic. For example, in the presence of mixtures of ethyl gallate or phloroglucinol with syringic acid, the induction period in the kinetic curves of the oxygen uptake increases (Fig. 2a). The greatest stabilizing effect is attained on adding a mixture of phloroglucinol with syringic acid. In this case, an increase in τ is accompanied by a decrease in the oxidation rate in deep steps. These effects are the most pronounced at the component ratio from 30 : 70 to 70 : 30.

EXPERIMENTAL

Our experiments were performed with pure grade PEG, H–$(OCH_2CH_2)_n$–OH, molecular weight 3000, purchased from Merck (Germany), mp 55–58°C, hydroxyl number 34–43, and with products of its autooxidation at 120°C containing hydroperoxy groups in concentrations of 0.1–1.1 $\times 10^{-2}$ M. Decomposition of the hydroperoxides was performed under argon at 37–57°C. The inhibitors listed in Table 1 were used without additional purification (Merck, chemically pure grade). The content of ROOH groups was determined by iodometric titration. The rate of the oxygen uptake at its partial pressure of 0.10 and 0.02 MPa was determined on an automatic laboratory unit with the sensitivity of 1.0×10^{-6} mol l^{-1} s^{-1}.

CONCLUSIONS

(1) The kinetics of oxygen uptake with polyethylene glycol of molecular weight 3000 in aqueous solu-

tion at temperatures above 70°C are typical of radical-chain processes with degenerate chain branching.

(2) Carboxy phenols catalyze decomposition of hydroperoxides in aqueous solution. The reaction involves complexation of the reactants; the reaction order is 1 with respect to the hydroperoxide and 0.6 with respect to the catalyst.

(3) Herb phenols decomposing hydroperoxides are antioxidants of combined effect: They terminate kinetic chains of oxidation and simultaneously suppress degenerate branching. As a result, these compounds efficiently inhibit oxidation of polyethylene glycol in aqueous solutions: The autoacceleration factor in oxidation decreases by a factor of 3–5, and the maximal rate of the oxygen uptake by the polymer, by a factor of 3–4.

Received July 10, 2003

Abstract—The effect of nitrosodurene as a source of stable nitroxyl radicals on radical copolymerization of styrene with methyl methacrylate and butyl acrylate was studied.

An urgent problem of the polymer chemistry is development of efficient methods for controlling the growth of the polymeric chain with the aim to prepare macromolecular compounds of required structure and molecular weight, and hence with the required set of properties [1–5]. This goal can be accomplished, in particular, by the use of stable radicals or other active additives as chain-terminating agents. In polymerization of styrene, the most widely used chain-terminating agents are stable nitroxyl radicals, e.g., 2,2,6,6-tetramethylpiperidinyl-1-oxyl (TEMPO) and its derivatives [1, 3, 4, 6]. These agents are effective only at elevated temperatures (100–150°C). Therefore, to perform controlled polymerization under the conditions similar to those of the industrial process, it seems very promising to use, along with traditional radical initiators, active additives generating stable nitroxyl radicals directly in the polymerization system (*in situ*). Suitable additives for this purpose are nitroso compounds and nitrones, which can react with polymeric radicals to give sterically hindered nitroxyl spin adducts acting as chain-terminating agents [7–10]. The controllable mode is ensured in this case under milder temperature conditions, similar to those of commercial synthesis of vinyl polymers (50–80°C).

From the practical viewpoint, it is particularly interesting to develop efficient methods for controllable synthesis of copolymers under the conditions of radical initiation, since copolymerization plays a crucial role in production of polymeric materials with preset properties.

In this work we studied how nitrosodurene (ND) as a source of stable nitroxyl radicals affects the radical copolymerization of styrene (ST) with methyl methacrylate (MMA) and butyl acrylate (BA). On the one hand, these monomers have similar relative activities (r_1 = 0.52 and r_2 = 0.46 for the ST–MMA pair; r_1 = 0.76 and r_2 = 0.19 for the ST–BA pair [11]) and have an azeotropic point. On the other hand, the reactivities of ST, BA, MMA, and the corresponding propagating radicals are essentially different. In this connection, it is of both theoretical and applied interest to study regular trends in copolymerization of these monomers.

EXPERIMENTAL

The monomers were purified as described in [12] by repeated washing with 5–10% alkali solution, washing with distilled water to neutral reaction, drying over $CaCl_2$, and distillation at reduced pressure. Nitrosodurene was prepared by the procedures described in [13–15]. The physicochemical constants of the compounds agree with published data. The polymerization kinetics was monitored gravimetrically, dilatometrically [12], and thermographically [16]. The samples were prepared as follows: A monomer was placed in glass ampules, degassed by three freeze–pump–thaw cycles, and polymerized at a residual pressure of 1.3 Pa. Copolymerization of ST with MMA and of ST with BA was studied at the monomer molar ratios of 53 : 47 and 77 : 23, corresponding to the azeotropic compositions. The intrinsic viscosity of ST–MMA and ST–BA copolymers was determined in chloroform by dilution at 25°C [17]. The molecular-weight distribution (MWD) of ST–MMA and ST–BA was analyzed by gel permeation chromatography (GPC) on an installation equipped with a set of five Styrogel columns with the pore diameter of

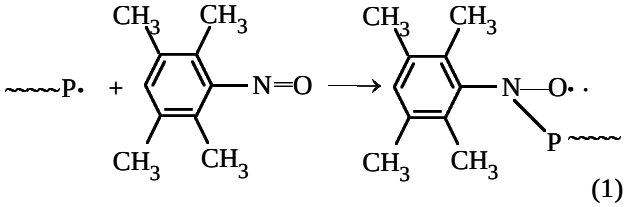
1070-4272/04/7701-0136 © 2004 MAIK "Nauka/Interperiodica"

1×10^5, 3×10^4, 1×10^4, 1×10^3, and 250 Å (Waters, the United States). An R-403 differential refractometer (Waters) was used as detector; the eluent was tetrahydrofuran. Close-cut polystyrene fractions were used as references for calibration [18]. The molecular weights of ST–MMA and ST–BA copolymers was calculated using polystyrene references. The composition of the copolymers was determined by IR (Specord 75 IR) and UV (Perkin–Elmer Lambda 25) spectroscopy.

The effect of ND on copolymerization of ST with acrylic monomers was studied with azeotropic compositions, i.e., with monomer mixtures at which the ratio of the monomeric units in the copolymer is equal to the initial monomer ratio [11]. The use of such mixtures allowed us to eliminate the possible effect exerted by variation of the composition of the monomer mixtures on the copolymerization kinetics and molecular-weight characteristics of the products.

We found that addition of 0.2 mol % ND results in total degeneration of the gel effect in ST–MMA and ST–BA copolymerizations. With ND, in contrast to copolymerization in the presence of TEMPO as chain-terminating agent [6], the total reaction time increases only slightly. This is illustrated by differential curves shown in Fig. 1 for copolymerization of ST with MMA, initiated with azobis(isobutyronitrile) (AIBN), as example.

The initial portions of the kinetic curves of homo- and copolymerization, plotted on the basis of dilatometric data, show that introduction of ND in various concentrations causes appearance of an induction period (Table 1), which is due to reaction of ND with the initiator radicals and macroradicals to form a stable spin adduct terminating propagation of the polymeric chain:



(1)

In homopolymerization of ST and its copolymerization with MMA, additions of ND do not affect significantly the initial reaction rate, and it remains comparable with the copolymerization rate on AIBN (Table 1). It should be noted that, according to the data obtained, the initial rate of ST–MMA copolymerization is controlled by the step of addition of ST to the macroradical. In ST–BA copolymerization, addition of 0.2 mol % ND gives rise to a considerably longer induction period (~230 min) than in the ST–MMA system (~40 min). The initial rate of the ST–BA copolymerization decreases under the influence of ND (relative to copolymerization in the presence of AIBN) more significantly than that of the ST–MMA copolymerization (Table 1).

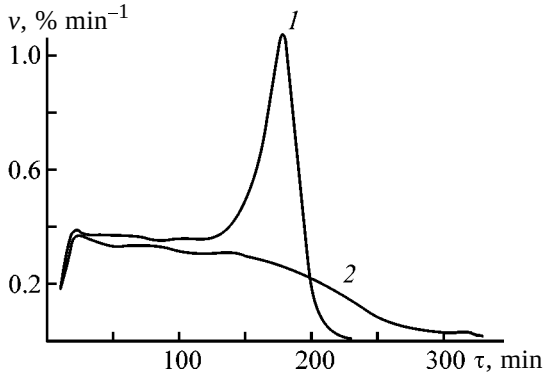


Fig. 1. Differential kinetic curves of ST–MMA copolymerization in the presence of ND at 70°C. Initiator AIBN, 0.8 mol %. (*v*) Polymerization rate and (τ) polymerization time. ND concentration, mol %: (*1*) 0 and (*2*) 0.2; the same for Fig. 2.

Study of the molecular-weight characteristics of the ST–MMA and ST–BA copolymers prepared shows that, in the presence of ND, the intrinsic viscosity of the samples linearly grows with conversion (Figs. 2a, 2b). At the same time, the copolymers prepared in the presence of AIBN without addition of ND are characterized by spontaneous uncontrollable growth of the intrinsic viscosity and molecular weight *M* with the conversion. The number-average molecular weights of the copolymers, calculated from the GPC data, also linearly grow with conversion in the entire conversion range in the case when the copolymers were prepared

in the presence of ND as chain-terminating agent (Fig. 3).

Figures 4a and 4b show how the MWD of copolymers prepared in the presence of the system ND–AIBN at a fixed concentration of the nitroso compound varies with conversion. It is seen that, with increasing conversion, the mode steadily shifts toward higher molecular weights and MWD becomes broader. However, the polydispersity coefficients remain considerably lower than those of the copolymers prepared in the presence of AIBN without ND (Table 2). The observed increase in the polydispersity of the polymer prepared in the presence of ND may be due to occurrence of bimolecular chain termination, along with the mechanism involving ND. As the ND concentration in the system is relatively low, the probability of dimerization of the propagating radicals seems to be fairly high, resulting in formation of the "dead" polymer and increased polydispersity.

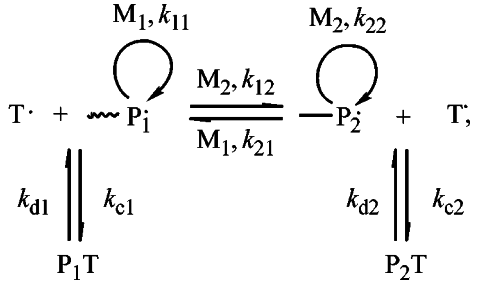
The composition of the synthesized copolymers at various conversions was studied by IR and UV spectroscopy. At the molar ratio of the monomers ST : MMA = 53 : 47 and ST : BA = 77 : 23, under the conditions of our experiments, the composition of the copolymer is similar to that of the starting mixture (Table 3). Thus, ND as a source of stable nitroxyl radicals acting as chain-terminating agents does not affect the composition of copolymers of ST with acrylic monomers. On addition of ND, the conditions remain azeotropic up to high conversions.

Our experimental results—degeneration of the gel effect, linear growth of the intrinsic viscosity and number-average molecular weight with conversion, relatively narrow molecular-weight distribution of the copolymer—suggest realization of the reversible inhibition mechanism in copolymerization of ST with MMA and BA in the presence of ND as a source of stable nitroxyl radicals ($T^{\cdot}$):



where M_1 and M_2 are the molecules of the monomers, MMA (or BA) and ST, respectively; $T^{\cdot}$ is the nitroxyl radical generated by Eq. (1); $P^{\cdot}$ is the propagating radical; k_{d1} and k_{d2} are the rate constants of dissociation of adducts P_1T and P_2T, respectively; k_{c1} and k_{c2} are the rate constants of recombination of nitroxyl radical $T^{\cdot}$ and macroradicals $P_1^{\cdot}$ and $P_2^{\cdot}$, respectively; k_{11}, k_{22}, k_{12}, and k_{21} are the rate constants of chain propagation (addition of the corresponding monomer to the corresponding macroradical).

CONCLUSIONS

(1) Nitrosodurene as a source of stable nitroxyl radicals acting as chain-terminating agents does not affect the composition of copolymers of styrene with acrylic monomers.

(2) Nitrosodurene can efficiently control the kinetic parameters of copolymerization of styrene with butyl acrylate and methyl methacrylate at relatively low temperatures (70°C), similar to those used in commercial synthesis of polymers.

(3) Addition of nitrosodurene to the polymerization system results in degeneration of the gel effect, uniform growth of the molecular weight of the copolymers, and shift of the molecular-weight distribution curves toward higher molecular weights with increasing conversion.

Abstract—Grafting of octafluoropentyl acrylate to polycaproamide PCA-6 in the presence of *tert*-butyl hydroperoxide containing 0.87–1.33% fluorine was studied. The specific feature of radical grafting of the polyfluorinated acrylate is participation of terminal groups of PCA-6 macromolecules.

Fluoro acrylates are grafted under conditions of plasma treatment to the surface of polycaproamide (PCA-6), enhancing its fire resistance [1]. Furthermore, the material modified with polyfluorinated compounds acquires hydrophobic and dust-repelling properties [2]. However, radical grafting of monomers to a polycaproamide thread decreases its strength [3, 4].

As polyfluorinated monomer we chose octafluoropentyl acrylate $H(CF_2CF_2)_2CH_2OC(O)CH=CH_2$ (**I**), which is prepared from octafluoropentyl alcohol [5], a by-product in production of tetrafluoropropyl alcohol used in CD production. We intended to develop a procedure alternative to that described in [1]. We believed that radical grafting of **I** to the PCA-6 surface in the presence of commercially available initiator $(CH_3)_3COOH$ (**II**) should occur under mild conditions and with a fairly high selectivity owing to the polar structure of **I**, electrophilic character of the reaction of radicals with polyfluorinated fragments, and nucleophilic properties of polycaproamide radicals and radicals generated from hydroperoxide **II**.

Our goal was grafting of polyfluorinated acrylate **I** to the surface of PCA-6 thread under conditions of minimal homopolymerization of the monomer and preparation of the high-strength modified thread.

EXPERIMENTAL

Acrylate **I** was prepared by the method described in [5]; bp 85°C at 40 mm Hg, n_D^{20} 1.3462, d_4^{20} 1.4460. Samples of polycaproamide (14.54 tex) thread, 1.2–1.5 m long, were placed in a 1% solution of hydroperoxide **II** in acrylate **I** (1 : 75 excess of the monomer) and heated at 80°C for 1–4 h, with the analysis for the fluorine content in the thread and determination of physicomechanical properties of the thread performed every hour.

The fluorine content in modified PCA-6 was determined potentiometrically with an F-selective electrode. For this purpose, the sample was catalytically burnt in an oxygen atmosphere, the combustion products were dissolved in distilled water, and the potential was measured. Then the pF value ($pF = -\log[F^-][M]$) corresponding to this potential was found from the calibration plot. The physicomechanical parameters of the initial and grafted thread samples were determined with an RM-3 machine.

Thermal decomposition of hydroperoxides results in generation of alkoxy and hydroxy radicals, which abstract a hydrogen atom from a substrate or add to the C=C double bond of an unsaturated compound [6]. Experiments with model compounds [7, 8] showed that the hydrogen atom in the $-NH(CH_2)_5C(O)-$ fragment is abstracted from the α-position relative to the NH group. The arising macroradical **III** subsequently reacts with polyfluorooctyl acrylate **I** (which is facilitated by the electrophilic character of the terminal CH_2 group) to form transition state **IV**. It is stabilized by the polyfluorinated ester group and by the terminal NH group, which is associated with the ester group. As a result, copolymer **VI** is formed as final product:

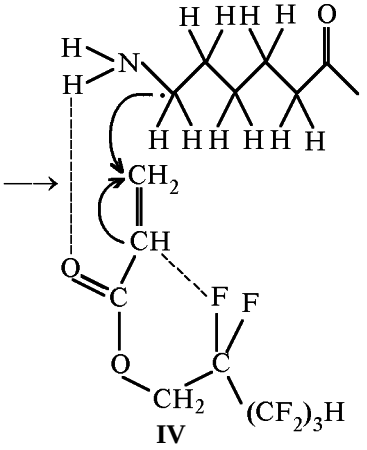
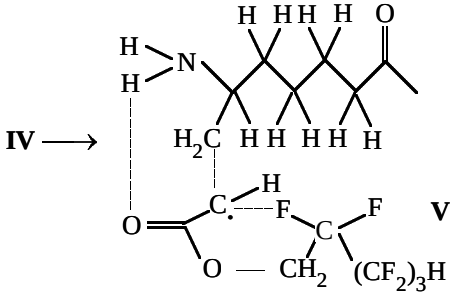
4	9.7	21.8	8.7

R = $(CH_3)_3C–O^{\cdot}$, $^{\cdot}CH_3$, $^{\cdot}OH$.

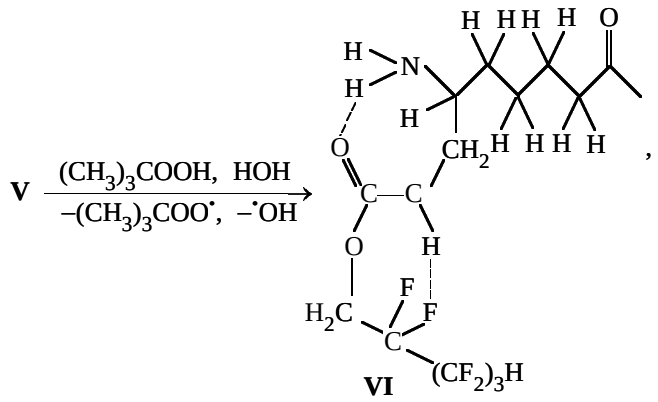
III + CH_2=CH–C(O)$OCH_2(CF_2CF_2)_2H$



IV



In radical **V**, the unpaired electron density is delocalized with the participation of the ester group and fluorine atoms. Radical **V** participates in radical chain transfer in reactions with the hydroperoxide and with water molecules associated with PCA-6. The reaction of radical **V** with a new molecule of the polyfluorinated monomer can be prevented by shielding of the radical center with the difluoromethylene group, whereas hydroxyl-containing reagents (hydroperoxide, water), associating with the fluorine atoms of the CF_2 group and radical center, are effective chain-transfer agents:



VI

A specific feature of the observed grafting of polyfluorinated acrylate **I**, in contrast to grafting of nonfluorinated acrylates, is that the thread strength grows rather than decreases (see table).

This trend may be due to the above-considered grafting mechanism involving terminal groups of PCA-6 macromolecules. The cyclic (due to associative interactions) structure of the forming terminal groups suggests the possibility of stronger molecular orientation in the amorphous phase of the polymer, which usually enhances the strength. The participation of the terminal groups in the radical grafting is suggested by the fact that grafting for 4 h does not result in a significant increase in the fluorine content in PCA-6 as compared to grafting for 2 h:

Grafting time, h	Fluorine content, %
2	0.87
3	1.19
4	1.33

Another specific feature of grafting of acrylate **I** to PCA-6 is that the homopolymer is not formed in significant amounts under the grafting conditions (the starting monomer was isolated by vacuum distillation). This is due to active reactions of macroradicals **III** with radicals generated from the polyfluorinated monomer, resulting in cross chain termination. This is consistent with the data of [8] according to which the ratio of the rate constants of polymeric chain propagation and chain termination decreased by a factor of 2 when polymerization of methyl methacrylate was performed in the presence of a model compound containing an –$NH(CH_2)_5C(O)$– fragment.

CONCLUSION

A specific feature of radical grafting of octafluoropentyl acrylate to a polycaproamide thread in the pres-

ence of *tert*-butyl hydroperoxide is active participation of terminal groups of polycaproamide in the process, which results in enhancement of the thread strength, probably due to higher degree of molecular orientation in the amorphous phase of the polymer as a result of formation of cyclic associates.

Abstract—A procedure was developed for graft polymerization of dimethylaminoethyl methacrylate onto polycaproamide using a redox system whose components are added to the reaction mixture sequentially. A scheme of radical graft polymerization of dimethylaminoethyl methacrylate onto polycaproamide was suggested. The properties of the copolymers were studied. The materials based on modified polycaproamide show promise as chemisorbents.

Purposeful modification of existing macromolecular compounds is the most promising line in development of a wide set of polymeric materials for various purposes. One of the main procedures for chemical modification of macromolecular compounds, including manmade fibers, is synthesis of graft copolymers of appropriate composition. Graft polymerization allows wide variation of the chemical composition, structure, and properties of polymers. Therefore, development of highly efficient and environmentally sound processes for production of graft copolymers derived from polycaproamide (PCA), one of the most abundant manmade polymers, remains an urgent problem.

In graft polymerization onto PCA, the regular structure of the polymer backbone remains intact [1], and the grafted polymer is distributed on the surface of the modified fiber, which enhances the adhesiveness between the fibers and improves the efficiency of the subsequent processing.

The commercially implemented procedure for production of graft copolymers of PCA with poly(dimethylaminoethyl methacrylate) (PDMAEMA) in the form of KM-A1 chemisorption fiber using polycaproamide fiber peroxidized with atmospheric oxygen and a solution of copper sulfate [2, 3] does not ensure production of fibers with the sufficiently high sorption capacity (1.0–1.5 mg-equiv g^{-1}); the degree of grafting does not exceed 25–30%.

Another procedure for preparing a PCA graft copolymer [4, 5] involves preliminary activation of the polycaproamide fiber with a 0.5–2% solution of hydrogen peroxide in the presence of a copper salt (10.2–10.4 wt % Cu^{2+} relative to the reaction mixture) at 50–80°C for 30–60 min. As a copper-containing compound we used copper sulfate. The activated polycaproamide fiber is treated with a 20% DMAEMA solution at 20–30°C for 60–120 min. After grafting completion, the fiber is washed to remove the monomer and homopolymer by treatment with ethanol in a Soxhlet apparatus for 12 h, with subsequent drying.

The drawbacks of this procedure are relatively low content of the grafted polymer (no more than 40–45%) and formation of an undesirable by-product, PDMAEMA (homopolymer), complicating the subsequent processing of the fiber and decreasing the efficiency of graft polymerization.

Our goal was to intensify the existing commercial batch process. To increase the amount of the grafted polymer and enhance the sorption capacity, we developed a procedure for preparing graft copolymers with the Cu^{2+}–H_2O_2 redox system (with copper ions introduced in the form of aqueous copper sulfate solution). The fiber was activated in steps. First, the fiber peroxidized with atmospheric oxygen was treated with a copper sulfate solution, then hydrogen peroxide was added, and the fiber activation was continued.

EXPERIMENTAL

The raw material was ready staple polycaproamide fiber. It is prepared from polycaproamide fiber production waste: substandard textile and cord threads, which are stored and, when accumulated in sufficient amounts (approximately every 2–3 months), are processed on a staple unit.

To prepare the peroxidized PCA, the starting fiber was treated for 5 h with hot (70°C) air in a dryer.

1070-4272/04/7701-0144 © 2004 MAIK "Nauka/Interperiodica"

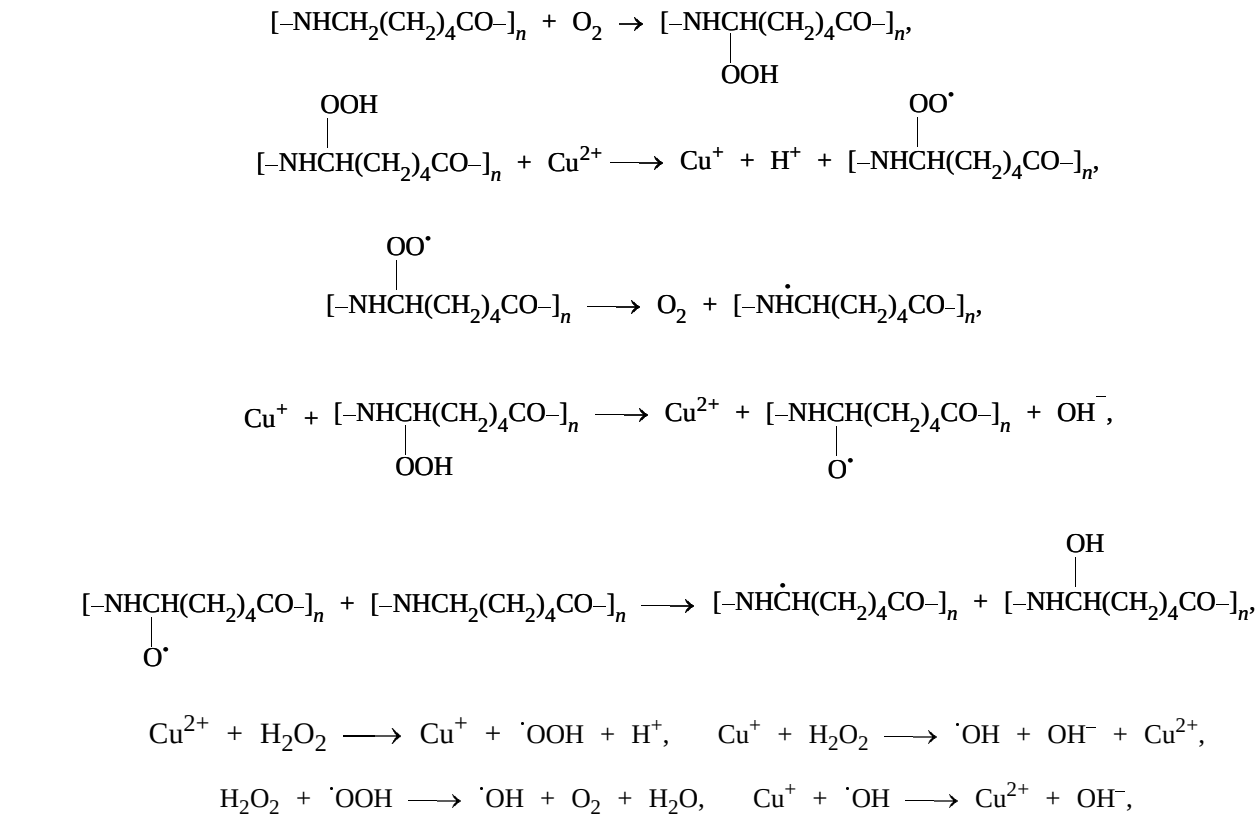
The same amount of hydroperoxy groups (10^{-3} wt % relative to the fiber) is formed in storage of PCA fiber in air for 60–120 days [6]. The latter procedure for preparing peroxidized fiber is more appropriate for industrial conditions, as it involves no expenditures, and production of modified fibers is performed today in the batch mode.

The fiber peroxidized with atmospheric oxygen was placed in a flask, and 0.04–0.05% (relative to the fiber weight) aqueous solution of copper sulfate was added at room temperature. Fifteen minutes later, an aqueous H_2O_2 solution was added in amount corresponding to the H_2O_2 content of 0.20–0.25% relative to the fiber weight. The H_2O_2 solution was added in portions over a period of 15 min at 1-min intervals; the subsequent fiber activation was performed for 25–30 min. The activated PCA was thoroughly washed with water to remove excess H_2O_2 and copper sulfate and then squeezed. After that, it was treated with 20% aqueous DMAEMA in a temperature-controlled flask equipped with a reflux condenser for 20–30 min at 45–55°C. After grafting completion, the polymer was treated with ethanol in a Soxhlet apparatus to remove the monomer and homopolymer, dried, and weighed.

The fact that the PDMAEMA content in the modified fiber is higher than that attained previously [3, 5], in combination with published data on decomposition of H_2O_2 and hydroperoxy groups of PCA with variable-valence metal ions, suggests that our activation procedure makes reactive not only the sections of PCA macromolecules containing hydroperoxy groups, but also the sections that remained unaffected by atmospheric oxygen. Such a result cannot be attained by introducing Cu^{2+} and H_2O_2 simultaneously. In this case, the reaction primarily occurs between the components of the redox system, so that the sections of PCA molecules that contain no peroxy groups are not activated.

If the copper ions are added first, this induces decomposition of the hydroperoxy groups of the fiber with generation of active macroradicals, and the subsequent addition of H_2O_2 activates the sections of macromolecules that contain no hydroperoxy groups. Thus, the amount of active centers in PCA capable of graft polymerization grows, resulting in increased amount of the grafted polymer.

In the case of sequential addition of the components of the redox system, the reaction will probably follow the scheme



RUSSIAN JOURNAL OF APPLIED CHEMISTRY Vol. 77 No. 1 2004

Table 1. Static exchange capacity (SEC) of the PCA–PDMAEMA graft copolymer

* (*H*) Humidity and (c_g) gas concentration.
** 65–70% PDMAEMA.

$$[\text{–NHCH}_2(\text{CH}_2)_4\text{CO–}]_n + {}^{\bullet}\text{OH} \longrightarrow [\text{–NHC}^{\bullet}\text{H}(\text{CH}_2)_4\text{CO–}] + \text{H}_2\text{O},$$

$$[\text{–NHC}^{\bullet}\text{H}(\text{CH}_2)_4\text{CO–}] + \text{H}_2\text{C}{=}\underset{\displaystyle \text{CH}_3}{\underset{|}{\text{C}}}\text{–COO}(\text{CH}_2)_2\text{N}(\text{CH}_3)_2 \longrightarrow [\text{–NHCH}(\text{CH}_2)_4\text{CO–}]_n,$$

$$[\text{H}_2\text{C–}\underset{\displaystyle \text{COO}(\text{CH}_2)_2\text{N}(\text{CH}_3)_2}{\underset{|}{\text{C}}}(\text{CH}_3)\text{–}]_m\ .$$

Separate introduction of the components of the redox system increases the amount of the grafted polymer, so that it becomes feasible to reach the desirable level of 65–70%.

The content of PDMAEMA obtained by graft polymerization was monitored gravimetrically and by the content of tertiary nitrogen, which was determined from variation of the amount of HCl consumed for binding of tertiary nitrogen in the test samples. The results are listed in Table 1.

To evaluate the performance of PCA–PDMAEMA copolymers as chemisorption materials, we prepared filtering units from the modified polycaproamide fiber containing 65–68% PDMAEMA by processing the fiber into a needle-punctured material 1.2 cm thick, with the fiber packing density of 0.15 $g\ cm^{-3}$.

The chemisorption properties were evaluated by the capability of the ion exchanger to sorb acidic gases (HCl, SO_2, HF) on passing the gas–air mixture containing these gases in varied concentrations through the fibrous filter at a rate of 1.4×10^{-4} $m^3\ s^{-1}$ (0.5 $m^3\ h^{-1}$). The characteristics of the sorption power of the material under dynamic conditions are given in Table 2 in comparison with the data for filtering units from KM-A1 fiber (PDMAEMA content 20–25%).

Table 2 shows that, as the content of the grafted polymer is increased to 65–68%, the sorption power grows, on the average, by 30%. The static exchange capacity of the fiber prepared by our procedure (65–70% PDMAEMA) is as high as 2.8–3.2 mg-equiv g^{-1}.

An important characteristic determining the performance of a chemisorbent is variation of the static

Table 3. Variation of properties of the modified polycaproamide fiber (65–68% PDMAEMA) in the course of service

Parameter	Fiber		
	initial	after 20 sorption–regeneration cycles	after 30 sorption–regeneration cycles
SEC, mg-equiv g^{-1}	3.0	3.0	3.0

Wear resistance, cycles	29.2	29.2	29.0
Elongation at break, %	78	78	79

exchange capacity and mechanical properties in the sorption–desorption cycles. The chemisorbent was regenerated with 2% aqueous NaOH solution.

Table 3 shows that both the static exchange capacity and the mechanical properties of the fiber remain unchanged after 20–30 sorption–regeneration cycles, i.e., the fiber shows high stability toward regenerating agents.

CONCLUSIONS

(1) A promising procedure for preparing polycaproamide–poly(dimethylaminoethyl methacrylate) graft copolymer was suggested. The procedure involves sequential addition of the components of the redox system; it ensures increased (65–70%) content of poly(dimethylaminoethyl methacrylate) in the modified fiber and more efficient production of the chemisorption fiber.

(2) The chemisorbent obtained from the modified fiber shows high sorption power, high resistance to repeated regeneration, and long service life.

Received May 16, 2003

Abstract—Structurization in cellulose triacetate modified with trifluoroacetic acid vapor and its effect on the optical activity are studied.

Liquid–crystal (LC) cellulose triacetate (CTA) solutions in trifluoroacetic acid (TFAA) are used for preparing highly oriented films and fibers with improved mechanical characteristics [1, 2]. The anisotropic state is realized only at high (>25%) polymer concentration [3, 4]. Preparation and processing of such concentrated solutions are difficult because of high viscosity of mesomorphic phases [5]. Therefore, development of new processes allowing formation of a highly ordered polymeric matrix through realization of LC state in the system CTA–TFAA is a topical problem.

Previously we demonstrated that an oriented structure in cellulose acetates could be obtained by exposing the polymer to vapor of a solvent in which the polymer forms a lyotropic mesophase [6, 7]. In this case, orientational transformations manifest themselves in, e.g., spontaneous elongation of acetate fibers [6], which can be attributed to transition of the polymer–solvent system into the LC state [8], and also in sustained induced optical anisotropy and decreased grain-boundary angle in acetate films [7], etc. The effect of mesogenic vapor on the structure of condensed (films, fibers) and powdered polymers appeared to be identical: the samples are characterized by abnormal sorption and swelling curves, not obeying the Fick's law [9], and the intensity of their X-ray diffraction peaks increases [10].

It should be pointed out that exposure to vapor of a solvent capable of forming mesophases with cellulose derivatives affects the optical activity of the cellulose esters, suggesting structural changes not only at the supramolecular, but also at the conformation level [7, 9, 11]. In this case, the effect of a solvent vapor on the structure of a cellulose ester is considerably more pronounced as compared to that initiated by the same solvent added in the equivalent amount as liquid [9, 11].

By now, a great body of knowledge is gained on cellulose and its esters as polymers with increased chain rigidity, and there is a steady intense interest in these materials. However, the fact that cellulose acetates, like many natural organic polymers, demonstrate the optical activity varying over a wide range [7, 9, 11] was not given due attention in polymer design. Our recent results showed that it is the optical asymmetry that could be the key point in designing polymers with desirable 3D structure [12], having not only preset, but even some unique characteristics [13].

In [14] we reported the effect of small TFAA additions on the properties of concentrated cellulose acetate solutions. In this work we studied the effect of TFAA vapor on the structure and optical activity of powdered CTA.

EXPERIMENTAL

In the experiments we used the initial and modified samples of powdered CTA, and also solutions and films on its basis.

We employed commercial wood CTA used for producing triacetate fiber (Khimvolokno Joint–Stock Company, Engels, Russia). The characteristics of the polymer are as follows: granule size 4–6 mm, bulk density 1.28 g cm^{-3}, bound acetic acid content 61.2%, and viscosity-average molecular weight 7.5×10^4. For dissolution of the samples we used the conventional process solvent, a 90 : 10 mixture of methylene chloride with ethanol (both of analytically pure grade).

1070-4272/04/7701-0148 © 2004 MAIK "Nauka/Interperiodica"

The bulk polymer was modified by isobaric-isothermal exposure to a solvent vapor at 5–35°C in a hermetically sealed vessel partly filled with a solvent. As a sorbate we used the dipolar amphiprotic solvent, trifluoroacetic acid (analytically pure grade) [15]. Cellulose triacetate was placed on a 2-mm sieve arranged 5 cm above the solvent table. The vapor uptake was determined gravimetrically on a WT torsion balance to within 0.0002 g. The TFAA uptake varied from 0.5 to 100 wt %. The samples of the polymer were taken as it was saturated with the solvent vapor.

The optical rotation of 0.5 g l^{-1} solutions of the initial and modified CTA samples was measured to within 0.04° on an SM-2 circular polarimeter at λ_{Na} = 589 nm and 25°C [16]. The light source was a DNAS18-04-2 lamp.

The polymer films were prepared from 7 wt % solutions by coating onto a preliminarily degreased smooth glass surface in a dust-controlled box. Formation was carried out at room temperature and the same solvent removal rate for all the samples. The film thickness was measured with a TIB-2 thickness gauge to be 100–150 μm. The strength [tensile strength σ_t (MPa)] and elastic properties [elongation at break ε_b (%)] of the CTA films were determined to within 3% on a 2148R-5 tensile-testing machine according to GOST (State Standard) 17316–71.

Differential thermal analysis was performed over the temperature range 200–400°C on a DSC-D differential scanning microcalorimeter at a heating rate of 8 deg min^{-1} with calcined alumina as a reference. The peak positions were registered to within 2° with a KSP-4 logger at a paper speed of 720 mm min^{-1}. X-ray diffraction patterns were obtained on a DRON-3 diffractometer (FeK_α radiation) over the range 2θ = 5°–30°.

Previously we demonstrated [9] that sorption on cellulose acetates of vapor of specific solvents capable of forming lyotropic mesophases with the polymers does not obey the Fick's law. Also the system CTA–TFAA vapor is characterized by abnormal swelling curves (Fig. 1a). At low temperatures, the kinetic curves of sorption pass through extrema (curve *1*), and at room temperature, they are S-shaped (curve *2*). High sorption capacity of CTA for TFAA vapor does not allow equilibrium saturation to be attained even at lowered temperature; swelling is unrestricted and is followed by polymer dissolution. Over the entire experimental temperature range we observed a sorption/desorption hysteresis. Desorption proceeds at a higher rate, and the desorption curve (curve *3*) is no longer abnormal, lying under the swelling curve.

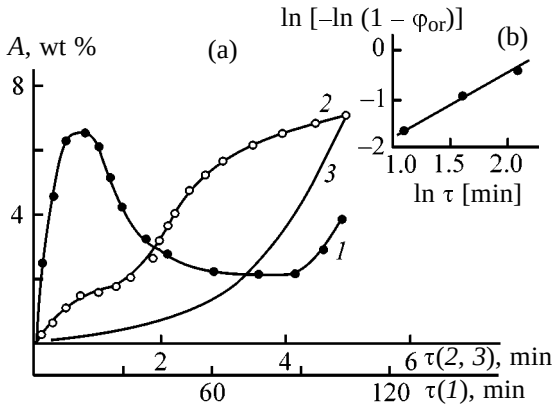

Fig. 1. Kinetic curves of TFAA vapor sorption/desorption on CTA: (a): (*1*) sorption at 8°C, (*2*) sorption at 20°C, and (*3*) desorption at 20°C; (b) descending branch of curve *1* plotted in the coordinates of the Avrami equation. (*A*) Uptake of TFAA vapor, (τ) time, and (1 – φ_{or}) fraction of disordered polymer.

It is known that abnormal kinetics of sorption may be caused by various factors, including structural transformations occurring in the polymer matrix in the course of diffusion of a low-molecular-weight component [17, 18]. To elucidate structural transformations in CTA, initiated by uptake of TFAA vapor, the descending branch of the kinetic curve of swelling (Fig. 1a, curve *1*) was plotted in the coordinates of the Avrami equation (Fig. 1b) [17]. The parameter *n* characterizing the structurization mechanism in the polymer–solvent system was estimated from this equation to be 1.4, suggesting that some orientational transformations occur in the polymer matrix in the presence of TFAA. Similar results were obtained by Azizov and Sadykova [19] for the system cellulose acetate–nitromethane, which, like TFAA, is a mesogenic solvent for cellulose acetates. They suggested orientation of the macromolecules in the course of nitromethane vapor uptake, resulting in modification of the initial polymer structure. Furthermore, they presented abnormal swelling curves similar to those obtained in this work. These curves were interpreted using the concept of structural transitions in the system cellulose acetate–nitromethane proposed by us in [6].

Comparison of two systems (cellulose acetate–nitromethane and CTA–TFAA) appears to be logical, as both systems form lyotropic mesophases [3] under similar conditions [1, 20]. In both systems, formation of anisotropic structures follows the initial gelation [4, 21]. In both systems, an alteration of the optical activity of a cellulose ester was observed [7, 9] as well as initiation of orientational processes accom-

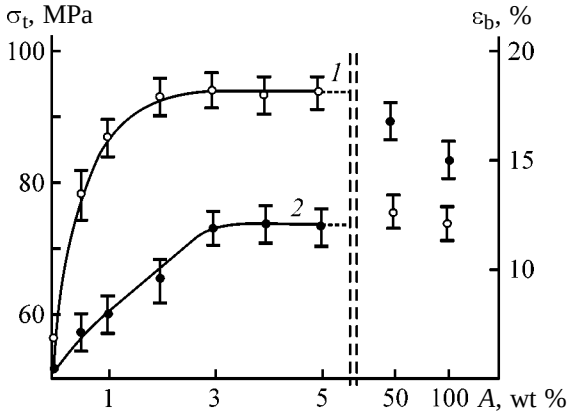

Fig. 2. (*1*) Tensile strength σ_t and (*2*) elongation at break ε_b of CTA films as functions of the TFAA uptake *A*.

panied by considerable improvement of the mechanical characteristics [2, 22]. Finally, both nitromethane and TFAA have an active polar group, high dipole moments, and similar Hildebrand solubility parameters [15, 23]. All the aforesaid allow expansion of the concept proposed in [9] to the system CTA–TFAA vapor. Thus, TFAA vapor uptake modifies the CTA structure. The extrema or inflection points in the kinetic curves (Fig. 1a) reflect alterations in the swelling mechanism. Let us analyze curve *1*. Note first that, in the incompletely acetylated CTA used ($\gamma < 3$), both inter- and intramolecular hydrogen bonds occur, despite the predominance of the acetate groups in the glucopyranose units over the hydroxy groups [24]. The initial stage of polymer swelling (uptake of the first portions of TFAA in amount of no more than 6–8 wt %) involves a break of the intermolecular H bonds. In this case, nonassociated macromolecules, by virtue of their intrinsic rigidity and thanks to the newly realized flexibility, tend to take thermodynamically favorable straightened conformations. Such a self-orientation results in compaction of the polymer chains and, correspondingly, in partial desorption of the solvent, as demonstrated by the decline in curve *1*. Further uptake proceeds in the already modified polymer and is followed by CTA dissolution. The plateau in the curve could be referred to the equilibrium of these two processes. Uptake of the first small amounts of TFAA vapor results in degradation of the system of intermolecular contacts restraining the macrochain flexibility. At the same time, the system of intramolecular hydrogen bonds responsible for high rigidity of the macromolecules is retained. All these factors allow the macromolecules to be oriented [6, 9] up to formation of mesophases [3, 8].

Swelling of a polymer in a solvent vapor is mostly a complex process involving not only a break of intermolecular bonds, but also simultaneous interaction of the solvent with functional groups (specific solvation). Since the sorption capacity of cellulose acetates for TFAA is considerably higher than that for nitromethane, the first of the indicated processes in the system CTA–TFAA vapor can be realized separately only at low temperatures or in a short time corresponding to the uptake of a small amount of the solvent. Therefore, the S-shaped curve obtained at 20°C (Fig. 1a, curve *2*) is a resultant of the structurization and solvation processes. Nevertheless, the inflection points in the swelling curve, the sorption/desorption hysteresis (curve *3*), and the induced optical anisotropy observed previously [7] in acetate films—all these findings suggest dominating structurization in the system with formation of a more ordered polymer matrix.

In further experiments, modified CTA samples were obtained by exposure to TFAA vapor at room temperature. It should be pointed out that CTA samples after uptake of less that 10–15 wt % of TFAA did not differ in their appearance from the initial polymer, in contrast to the case of uptake of 50 wt % of TFAA and more. In the latter cases, the samples represented highly concentrated, transparent, gel-like solutions, which readily formed thin layers on shearing or putting pressure with an object-plate. Such systems are optically anisotropic in a polarized light, demonstrating an iridescent fluorescence.

From modified CTA, we formed films. As a reference we used a film formed from unmodified CTA. Experiments showed that structural transformations induced by TFAA uptake had a strong effect on the mechanical characteristics of the polymer films (Fig. 2). The tensile strength σ_t and elongation at break ε_b of modified CTA films were considerably higher than those of the reference. As the amount of absorbed TFAA increased to about 3 wt %, the mechanical characteristics increased, approaching maximal values. Further increase in the extent of modification ($A > 3$ wt %) no longer affected σ_t and ε_b. For the films formed from CTA after uptake of 50 and 100 wt % of TFAA, we observed certain decrease in σ_t as compared to the films with *A* from about 3 to 5 wt %, but ε_b was found to be higher in the TFAA-rich films. Compared to the reference, the tensile strength and elongation at break of such TFAA-rich films are higher by 30–40 and 200–220%, respectively. In the films with TFFA uptake of 3–5 wt %, the maximal σ_t and ε_b values are higher by 65 and 120%, respectively. These are somewhat unexpected results, since increasing strength of films mostly results in decreasing elasticity, and vice versa. How-

ever, we also observed similar increase in the strength and elastic characteristics in acetate fibers prepared from the polymer modified with TFAA vapor under the same conditions [25]. In this case, the TFAA uptake of 2–3 wt % was sufficient to reach the maximal tensile strength and elongation at break.

The results show that mechanical characteristics of the films correlate with structural transformations in the polymer. These characteristics increase with uptake of small (up to 3–4 wt %) amounts of the solvent vapor, which corresponds to orientational transformations of the macromolecules (Fig. 1, section of curve *2* extending to the inflection point). Note that similar trends were observed in the system cellulose diacetate–nitromethane [25]. It may be suggested that simultaneous increases in σ_t and ε_b in the modified CTA films are caused by the formation of highly ordered domains in the polymer matrix, which, on the one hand, favors increase in the strength and, on the other hand, does not prevent from increase in the elasticity of a film, as such domains do not form a continuous oriented matrix.

The orientational effect of TFAA on the CTA structure was also supported by direct structural methods. Figure 3a shows the X-ray diffraction patterns of the triacetate films. For the modified CTA films, the intensity and area of the peak at $2\theta = 20°–21°$ increase, and those of the peak at 10°–11° decrease. In this case, the total area of the peaks decreases against the reference, giving an additional evidence in favor of the fact that structural transformations occurring in the polymer matrix under the effect of TFAA vapor do not prevent from orientation of the macromolecules, but hinder crystallization of the polymer. Note also that the modified samples are characterized by a higher (by 15°C) decomposition temperature (Fig. 3b).

It is well known that natural polysaccharides, among them cellulose, are optically active. Previously we demonstrated [9, 11] that exposure of cellulose acetates to vapor of a solvent, capable of forming lyotropic mesophases with these polymers, produces strong effects on both their structure and optical activity. The specific optical rotation [α] appeared to be changed in the course of modification of CTA with TFAA vapor.

The unmodified CTA dissolved in a mixture of methylene chloride and ethanol has a negative [α] (–50°, Fig. 4). The absolute [α] values of modified samples are considerably higher. With increasing TFAA uptake, [α] decreases below –200°, which is higher in the absolute value by a factor of 4 than that of the unmodified sample.

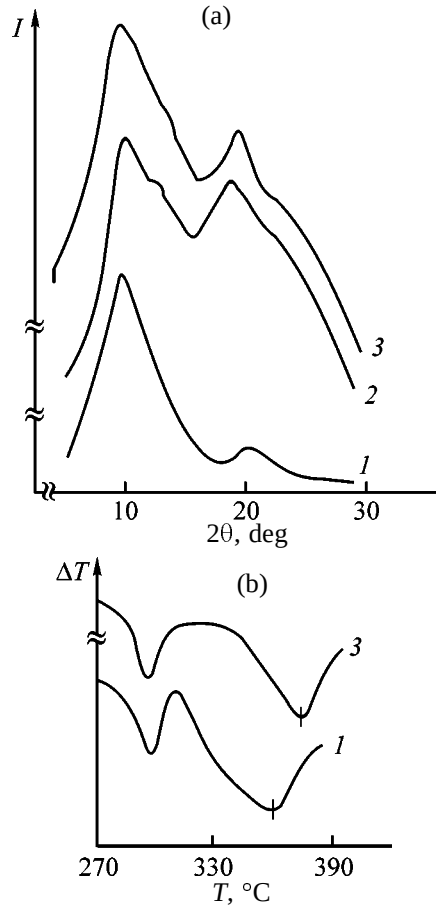

Fig. 3. (a) X-ray diffraction patterns and (b) DTA curves of TCA films: (*1*) reference and (*2*, *3*) TFAA-modified CTA films containing 1 and 3 wt % TFAA, respectively. (*I*) Intensity, (2θ) Bragg angle, (*T*) temperature, and (Δ*T*) difference in the temperature of the test and reference samples.

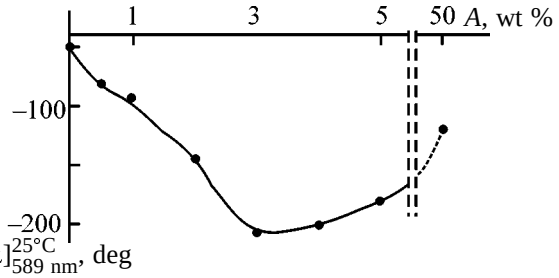

Fig. 4. Specific optical rotation $[\alpha]^{25°C}_{585\,nm}$ of CTA solutions in a mixture of methylene chloride and ethanol as a function of TFAA uptake *A*.

Note that the observed dependence of the specific optical rotation of CTA in the process solvent on the TFAA uptake (Fig. 4) is similar to the concentration dependence of [α] of CTA in TFAA, which was obtained by Meeten and Navard in studying the formation of mesophases in this system [4]. It was demonstrated in the cited work that, with increasing CTA

concentration in TFAA, the negative [α] decreases until the anisotropic transition. In other systems cellulose acetate–mesogenic solvent, the mesophases formed also demonstrated higher absolute values of [α] [3].

Finally, our results show that a strong increase in [α] is typical of the CTA samples modified with small (<3 wt %) amounts of the sorbate vapor (Fig. 4). It is the uptake of such a small amount of TFAA that produces the essential structural transformations (Fig. 1) and improvement of the mechanical characteristics of the films (Fig. 2). It is known that the optical rotation in cellulose esters is controlled by their molecular structure [16], particularly, by the presence of chiral centers in the glucopyranose units and their spatial arrangement, which, in turn, promotes strong inter- and intramolecular hydrogen bonding, and, finally, by the conformation of macromolecules. Uptake of small amount of TFAA initiates a break of intermolecular, but not intramolecular H bonds, providing, as suggested in [3], optimal conditions for highly oriented LC structures to be realized on the basis of cellulose and its derivatives. Furthermore, such an uptake promotes spatial rearrangements in the macromolecules or other structural subunits, strongly changing the optical activity of the polymer. Maybe this is one of the necessary conditions for transition of an optically active polymeric system into LC state. Further uptake of TFAA vapor proceeds with the already modified polymer, which is accompanied by solvation of unbound functional groups. In this case, the induced [α] no longer changes significantly. Similar interrelation between the optical activity and structural ordering was observed also for other natural polymers, e.g., collagen and gelatin [26, 27].

CONCLUSIONS

(1) Modification of cellulose triacetate with trifluoroacetic acid vapor as a mesogenic agent for cellulose derivatives opens the door for directed design of polymers with not only highly ordered, but also even differently organized 3D structure. It is of particular importance that the maximal effects on the structure and optical activity are attained at low TFAA uptake.

(2) The fact that the performance characteristics of the modified cellulose triacetate films are determined by the specific features of the "induced" 3D structure of the ester allows preparation of materials with a controlled structure and desired properties.

CHEMISTRY OF FOSSIL FUEL

Flash Pyrolysis and Kinetic Parameters of Decomposition of Oil Shales

Kh. M. Kerimov

Azerbaijan State Petroleum Academy, Baku, Azerbaijan

Received December 6, 2002; in final form, October 2003

Abstract—Flash pyrolysis of oil shales and distribution of the organic matter in the volatile products and solid residue at various pyrolysis temperatures were studied. The concentrations of aliphatic hydrocarbons and naphthenes + arenes in the volatile products were determined.

Inevitable exhaustion of traditional power resources calls for a search for new sources of hydrocarbon raw materials. Among materials showing promise in this respect are oil shales [1].

The assortment of substances produced by shale processing includes tens of items, without taking into account wastes that can be processed. From the viewpoint of energy production, the most important component of shale oils is the organic matter; its base is kerogen. Kerogen is mainly recovered from the inorganic matrix by pyrolysis. Alternative procedures (extraction, biochemical methods) are less suitable for commercial application [2].

Pyrolytic decomposition of oil shale kerogen involves a set of parallel and consecutive reactions following the scheme

$$\text{Kerogen} \xrightarrow[E_1, A_1]{k_1} \text{gas, bitumen} \xrightarrow[E_2, A_2]{k_2} \text{gas, tar, coke,} \quad (1)$$

where k_1 and k_2 are the rate constants, min^{-1}; E_1 and E_2 are the activation energies, kJ mol^{-1}; and A_1 and A_2 are the preexponential terms (min^{-1}) of the corresponding reactions.

Ballice *et al.* studied decomposition of kerogen thermogravimetrically [3] and concluded that the process occurs in two steps: decomposition of kerogen proper at 300–375°C and secondary decomposition and condensation processes at 375–500°C.

The kinetics of thermal decomposition of kerogen is described by a first-order equation

$$\mathrm{d}x/\mathrm{d}\tau = kf(x), \quad (2)$$

$$x = \frac{m_0 - m_\tau}{m_0 - m_f}, \quad (3)$$

where m_0, m_τ, and m_f are the initial, intermediate, and final sample weights, respectively (mg); k is the rate constant, min^{-1}; and x is the degree of decomposition.

Since

$$\mathrm{d}\ln k/\mathrm{d}T = E/RT^2,$$

and, for first-order reactions, $f(x) = 1 - x$, Eq. (2) can be written as follows:

$$\frac{\mathrm{d}x}{\mathrm{d}T}\frac{\mathrm{d}T}{\mathrm{d}\tau} = A\exp(-E/RT)(1 - x), \quad (4)$$

or

$$\frac{\mathrm{d}x}{\mathrm{d}T} = (A/b)\exp(-E/RT)(1 - x), \quad (5)$$

where $b = \mathrm{d}T/\mathrm{d}x$.

Integration of Eq. (5) gives

$$\ln\{[(E + 2RT)/T^2]\ln[1/(1 - x)]\} = \ln(AR/b) - E/RT. \quad (6)$$

This equation is the Chen–Nuttall equation [4]. The kinetic parameters of oil shale decomposition can be determined by the Coats–Redfern graphical method [5]. The activation energy can be determined from the slope of the straight line plotted in the coordinates $-\ln[-\ln(1 - x)/T^2]$ vs. $1/T$ [3].

In this work, to evaluate the kinetic parameters of decomposition of oil shales from the Dzhangichai deposit, we used a combination of the above methods. From the values of x [Eq. (3)] for definite temperatures, we calculated E by the Coats–Redfern method. These values of E were substituted in Eq. (6), and the preexponential term was determined.

EXPERIMENTAL

The Fischer analysis was performed on a standard installation by the ISO-647 procedure [6]. The elemental analysis of the initial shales and of the tar and residue formed from them was performed according to [7] on an LECO CHNS-932 apparatus. The results are listed in Table 1.

Samples of oil shales were finely divided in a laboratory mill prior to flash pyrolysis. The fraction with the particle size less than 0.1 mm was taken for the experiments; it was dried in a nitrogen atmosphere at 105°C to constant weight.

The scheme of the experimental installation for flash pyrolysis is shown in Fig. 1. A reactor, 120 cm high and 5 cm i.d., is made from stainless steel of grade 316. The dosing unit is arranged in the upper part of the reactor. The temperature of the pyrolysis zone in the lower part of the reactor is controlled with a digital temperature-control unit. The solid residue is collected on the metallic filter arranged in the lower part of the pyrolysis zone. The middle part of the reactor was kept at 300°C for the sample preheating. To prevent condensation of high-molecular-weight hydrocarbons in a flow of decomposition products, the sampling unit arranged after the pyrolysis zone was kept at 200°C. Nickel–chromium thermocouples were used for controlling and measuring the temperatures in the heated zones of the reactor.

In flash pyrolysis, shale samples were placed in the sample inlet unit. Pyrolysis was performed in a nitrogen flow (80 ml min^{-1}) at 450, 500, 550, 600, and 650°C. After attainment of the required temperatures in all the heated zones, the shale sample was input into the pyrolysis zone by turning the arm of the sample inlet unit. The reference, 0.507 vol % neopentane in N_2, was introduced at a flow rate of 20 ml min^{-1} into the flow of products going out from the pyrolysis zone. Samples of products leaving the reactor were taken into evacuated glass ampules. The sampling procedure and chromatographic analysis of the multicomponent vapor–gas mixture are described in [8].

The pyrolysis products were analyzed on a Hewlett–Packard HP 6890 capillary gas chromatograph equipped with a flame-ionization detector. A 100 m × 0.25 mm capillary column was coated with methyl silicone OV-1. The carrier gas was hydrogen, flow rate 25 ml min^{-1}. The detector temperature was 350°C, and the injector temperature, 290°C. The column temperature schedule was as follows: –80°C, 5 min; heating at a rate of 30 deg min^{-1} to –30°C; –30°C, 1.5 min; heating at a rate of 25 deg min^{-1} to 0°C; 0°C, 2 min; heating at a rate of 10 deg min^{-1} to 25°C; 25°C, 1 min; heating at a rate of 10 deg min^{-1} to 280°C; 280°C, 3 min.

Table 1. Elemental analysis and Fischer analysis of oil shales

Component	Content, wt %

The mixture components were identified with a computer by comparing the retention times with the data stored in the memory.

For each temperature, we determined the weight of the solid residue, treated it with 5 M HCl, washed with water on a filter to neutral reaction for chloride ions, and dried to constant weight at 105°C. The solid residue free of mineral carbon was analyzed for C and H on an LECO CHNS-932 apparatus [7]. The yield of volatiles was determined as the weight loss of the sample dry matter. The degree of decomposition of the organic matter X (wt %) was determined by the formula

$$X = \frac{(G_1 - G_2) \times 100}{G_1 (B/100)}, \quad (7)$$

Fig. 1. Fig. 4. Distribution of organic carbon: (α) yield and (*T*) temperature. (*1*) Volatiles and (*2*) solid residue.

At all the temperatures studied, the products are formed at a maximal rate (Fig. 2) within the first minutes, after which the rate decreases, which may be due to a decrease in the concentration of the initial organic matter of shale and occurrence of slow reactions of secondary decomposition. Integration of the kinetic curves allowed determination of the amounts of products that could be analyzed by our procedure. Figure 3 shows that the major products are alkanes and olefins. As the pyrolysis temperature is increased, the yield of alkanes grows, the yield of alkenes passes through a maximum at 550°C, and the amount of naphthenes + arenes varies insignificantly.

The yield of volatiles determined as the dry matter weight loss for each temperature was used to evaluate the degree of decomposition of the shale organic matter by formula (7). Figure 4 shows that, with increasing pyrolysis temperature, the total yield of volatiles increases, reaches a maximum at 550°C, and then

Table 2. Characteristics of the solid residue and composition of volatiles

650	8.27	0.40	1.72	45.3

slightly decreases. At higher temperatures, the volatiles get enriched in aliphatic hydrocarbons. Whereas at 450°C aliphatic hydrocarbons make up 31.5 wt % of volatiles, at 650°C their content reaches 45.3 wt % (Table 2). Apparently, elevated temperatures promote condensation, as evidenced by the C/H ratio in the solid residue. Table 2 shows that, as the pyrolysis temperature is increased from 450 to 650°C, the C/H ratio increases by a factor of almost 1.5.

The TGA data (Fig. 5) show that the weight loss occurs in four steps. Moisture is removed at 120–200°C. The peak at 440°C is assigned to pyrolysis of kerogen. The weight loss at 520°C is due to secondary decomposition and condensation of the heavy fraction of kerogen decomposition products. The weight loss at temperatures above 650°C is due to decomposition of the mineral matrix (primarily carbonates).

To determine the kinetic parameters, we assumed that the decomposition occurs as a first-order reaction with respect to the kerogen concentration. Separate application of the Chen–Nuttall method requires setting of an assumed value of the activation energy to calculate the left part of Eq. (6), after which repeated regression analysis is performed until the desired accuracy of the activation energy and preexponential term is attained. The Coats–Redfern method is simple and allows relatively accurate determination of E. The use of E determined by this procedure in the Chen–Nuttall equation eliminates the need in the repeated calculations.

Using the conversions calculated by Eq. (3), we constructed the plot of $-\ln[-\ln(1 - x)/T^2]$ vs. $1/T$ (Fig. 6). Two linear portions with different slopes suggest the occurrence of two different reactions in the temperature range 300–520°C. Primary reactions of kerogen decomposition occur at 280–380°C, and secondary decomposition processes, at 380–520°C, which is in good agreement with data of [2–5].

The activation energies of the primary (E_1) and secondary (E_2) reactions are 13.95 and 29.86 kJ mol^{-1}, respectively. The calculated activation energies were used to determine the preexponential terms for the primary (A_1) and secondary (A_2) reactions by formula (6): 0.21 and 4.58 min^{-1}, respectively.

The low activation energy E_1 of the kerogen decomposition suggests that the primary decomposition reactions yielding bitumen (pyrolysis tar) and gases involve cleavage of relatively weak chemical bonds in the shale organic matter. The decomposition and condensation of primary pyrolysis products occur with a higher activation energy E_2 at temperatures above 380°C, yielding the final decomposition products.

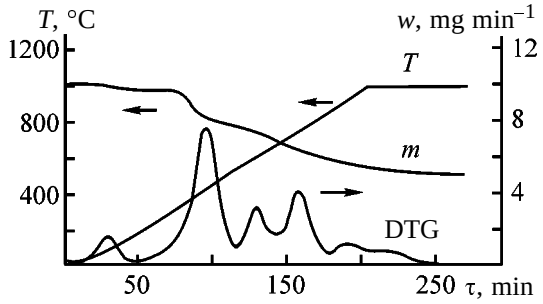

Fig. 5. Thermogravimetric analysis of shale: (T) temperature, (m) weight of residue, (w) decomposition rate, and (τ) time.

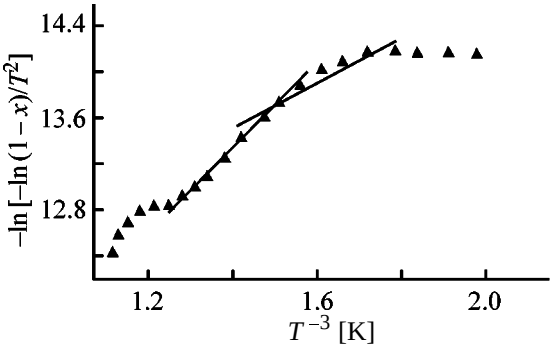

Fig. 6. Analysis of the thermogravimetric data by the combined Coats–Redfern/Chen–Nuttall method. (T) Temperature.

CONCLUSIONS

(1) A study of flash pyrolysis of oil shales from the Dzhangichai deposit showed that, as the temperature is increased, the yield of volatile products passes through a maximum at 550°C, with the relative content of aliphatic hydrocarbons in the volatiles growing and the yield of naphthenes and arenes varying insignificantly.

(2) The occurrence of two consecutive decomposition reactions was revealed, and their kinetic parameters were determined.

ACKNOWLEDGMENTS

The study was performed at the Engineering Faculty, EGE University, Izmir, Turkey, under financial support of NATO-PC TUBITAK.

Abstract—The chemical structure of asphaltene compounds from the semicoking tar of coal belonging to the G17 processing group was studied in detail.

Detailed data on the chemical composition of semicoking tars formed under conditions excluding to a maximal extent high-temperature pyrolysis furnish information about the native structure of fragments of coal organic matter (COM), their genetic relationship with the initial biomaterial, and pathways of its biogeochemical transformation in the course of coal formation. Knowledge of the specific features of the chemical structure of various COM components is important for wide involvement of coals in production of synthetic fuel, raw materials for organic and petrochemical synthesis, and metallurgical coke.

Asphaltenes (APs) are the least studied components of tars formed by thermal degradation of coals, which is due to relatively high molecular weight and polyfunctional composition of these compounds [1–7].

In this work we studied the chemical structure of APs from the semicoking tar of G17 coal from the Kuznetsk coal fields.

EXPERIMENTAL

Characteristics of the coal: moisture content W^d = 2.9, ash residue A^c = 8.7, yield of volatiles V^{daf} = 36.6% of air-dry coal; elemental composition, %: C 80.8, H 5.7, N 1.0, O 11.7, S_{tot} 0.8. Yield of semicoking tar (% COM) 15.1; its chemical group composition, % of anhydrous tar: organic bases 1.15; carboxylic acids 0.85; phenols 18.96; hydrocarbons 32.9; neutral oxygen-, nitrogen-, and sulfur-containing compounds 25.11; asphaltenes 8.6; resinous substances and losses 12.43 [8].

AP characteristics: molecular weight M = 277.5; elemental composition, %: C 77.8, H 8.2, N 2.6, O 11.4; functional composition, g-equiv mol^{-1}: phenolic groups 0.42, quinoid groups 0.40, keto groups 0.27, alcoholic groups 0.38, alkoxy groups 0.22, and heterocyclic oxygen 0.76.

The IR spectra of APs contain bands (ν, cm^{-1}) of the following fragments: aromatic rings (3030–3080, 1600, 1500, 1440–1465), with the increased intensity of the bands at 1600 and 1500 suggesting the presence of fused aromatic systems; CH_2 groups (stretching modes: 2840, 2940, 2925, 2850; bending modes: 720–740, 970, 1470), with the high intensity of these bands suggesting high content of hydrogenated rings; phenolic hydroxyls (3580–3670, 1140–1230, 1310–1410); methoxy (2850) and quinoid (1645, 1665, 1675, 1745) groups; cyclic and naphthenic alcohols (1030–1120, 1260–1350, 3630–3700); oxygen- and nitrogen-containing heterocycles (1565, 1500, 1015–1030, 845–870, 740–800).

Emission spectrum and X-ray fluorescence analyses revealed the following elements in the AP mineral matter: Fe, Mg, Al, Si, Ti, Ni, Sn, Sb, V, Mn, Cr, Zn, Zr, Pt, Rh, Ge, Ga, Hg, Pb, Na, K, Ca, Co, and Nd.

The whole set of IR, UV–Vis, emission, and X-ray fluorescence spectroscopic data and results of elemental, quantitative functional, and structural-group analyses and cryoscopic measurements allows a conclusion that the APs from G17 coal semicoking tar are a complex mixture of compounds of high molecular weight, containing various oxygen-containing functional and alkyl groups and organometallic structures.

To examine the structure of AP components in more detail, we separated APs into two fractions: those soluble (1) and insoluble (2) in boiling acetone. Fraction 1 after separation from fraction 2 was cooled to room temperature and thus was separated into frac-

1070-4272/04/7701-0159 © 2004 MAIK "Nauka/Interperiodica"

tions 1.1 and 1.2 soluble and insoluble in cold acetone, respectively.

By adsorption liquid chromatography on silica gel ASKM, fraction 1.1 was separated into fractions 1.1.1, 1.1.2, and 1.1.3, eluted with benzene, acetone, and acetic acid, respectively. Fractions 1.1.1, 1.1.2, and 2 were further separated by preparative thin-layer chromatography (TLC) on standard Silufol plates (20 × 20 cm) activated at 105–110°C, with the following optimal eluent systems (the volume ratio is given in parentheses): fraction 1.1.1, hexane–diethyl ether–acetone (5 : 5 : 1); fraction 1.1.2, chloroform–hexane–acetone (50 : 10 : 2); and fraction 2, trichloroethylene–diethyl ether–benzene–acetone–acetic acid (3 : 3 : 3 : 2 : 1).

The AP fractions isolated by fractional dissolution in acetone, adsorption liquid chromatography, and preparative TLC were studied by a set of physicochemical methods; from the results obtained, the molecular and hypothetical structural formulas of APs were calculated.

Fraction 1.1 is major (78.0 wt % of the initial APs); the amounts of its subfractions 1.1.1, 1.1.2, and 1.1.3 are, respectively, 44.2, 31.8, and 2.0 wt %. The yield of APs insoluble in boiling acetone (fraction 2) is 19.5 wt %.

The molecular weight of AP fractions varies from 205 (1.1.1) to 398 (2). AP compounds insoluble in boiling acetone (fraction 2) are characterized by lower aromaticity, which is confirmed by the relative intensity of the IR absorption bands (cm^{-1}) of aromatic (3030–3080, 1500, 1600, 1440–1464) and naphthenic (2840, 2925, 720–740, 970, 1470) rings. Fraction 1.1.2 is rich in phenolic components; the content of alcoholic hydroxyls is maximal in fractions 2 and 1.2. Asphaltenes insoluble in boiling acetone (fraction 2) are characterized by the highest content of methoxy groups and heterocyclic oxygen.

From fraction 1.1.1, we isolated 21 compounds with the molecular weight varying from 157 to 283; C content, from 77.7 to 86.1%, H content, from 7.1 to 12.2%, O content, from 1.9 to 14.1%; H/C ratio, from 1.05 to 1.70; and degree of aromaticity, from 0.20 to 0.60. The following functional groups are prevailing (g-equiv mol^{-1}): quinoid (0.20–1.24), keto (0.30–0.72) groups, and oxygen heterocycles (0.25–1.27); the content of naphthenic alcohols is significant.

Structures with the linear fusion type (hydrogenated benzo- and dibenzofuran, benzofluorene, and benzofluorenone derivatives) prevail in fraction 1.1.1; also, structures linked via –CO– groups were identified.

From fraction 1.1.2, we isolated 23 components; their molecular weight varies from 196 to 405; C content, from 68.6 to 86.2; H content, from 6.7 to 12.8; O content, from 1.0 to 23.3%; H/C ratio, from 1.09 to 1.78; and degree of aromaticity, from 0.15 to 0.58. The H/C ratio and the IR data indicate that the components of this eluate are naphthenoaromatic compounds, and some of them are even fully hydrogenated. The main functional groups revealed (g-equiv mol^{-1}) are as follows: phenolic (0.32–1.86), quinoid (0.10–0.80), and alcoholic (0.31–1.06).

Fraction 1.1.2 consists of highly condensed compounds containing mainly three or four rings, although even components with six fused rings are detected. The fusion is almost exclusively angular. We identified methyl homologs of perhydrophenanthrene and octahydrophenanthrol, and also compounds with oxygen and nitrogen atoms incorporated in five-membered heterocycles of the furan and pyrrole type (in the condensed state), substituted with phenolic and alcoholic groups. A distinctive feature of eluate 1.1.2 is relatively low content of keto groups.

Asphaltenes insoluble in hot acetone (fraction 2) were separated into 15 components. Their molecular weight varies from 257 to 589; C content, from 62.5 to 77.7; H content, from 7.6 to 10.8; N + O content, from 12.0 to 28.0%; H/C ratio, from 1.25 to 1.92; and degree of aromaticity, from 0.07 to 0.48.

According to the results of emission spectrum and X-ray fluorescence analyses, the metals present in the initial APs are mainly concentrated in this fraction. Apparently, the metals are partially incorporated in organic complexes containing phenolic and quinoid groups and nitrogen heterocycles.

The AP components from fraction 2 mainly consist of fragments of two or three fused rings (aromatic, hydrogenated, O- and N-heterocyclic), linked with each other via –O–, $–CH_2–$, –CO–, and –NH– groups. The high molecular weight and long linear chain of the compounds are responsible for their low solubility in the majority of organic solvents.

To confirm the structural features of APs, we subjected each fraction to pyrolysis at 800°C and 3 s residence time of vapor in the heated zone; the AP vapor was diluted with Ar (1 : 25). The liquid products were analyzed by capillary gas–liquid chromatography.

In the liquid pyrolysis products of fraction 1.1.1, we detected diphenyl, naphthalene, its methyl and

dimethyl homologs, diphenylene oxide, and derivatives of fluorene, benzene, quinoline, and isoquinoline; pyrolysis of fraction 1.1.2 yielded naphthalene, phenanthrene and its alkyl homologs, diphenyl, dibenzanthracenes, benzo- and dibenzofurans, phenol, cresols, dimethylphenols, and naphthols; pyrolysis of fraction 2 yielded diphenyl, diphenylene oxide, and carbazole.

These facts convincingly prove that the suggested structural formulas are largely adequate to the major components of the initial APs.

CONCLUSIONS

(1) A scheme was suggested for separation of asphaltenes from G17 coal semicoking tar, involving extraction and adsorption liquid and preparative thin-layer chromatography. It allows isolation of a large number of close-cut fractions.

(2) Asphaltenes contain compounds with cyclic fragments linked via bridging groups or fused in the linear or angular mode, including alicyclic, aromatic, and heterocyclic fragments substituted with various oxygen-containing functional groups and alkyl chains.

BRIEF COMMUNICATIONS

Phase Separation of Ternary Liquid Systems Tetradecane–Cyclohexanone–Lanthanide(III) Nitrate Solvates with Tri-*n*-butyl Phosphate

A. K. Pyartman, A. V. Kudrova, and V. A. Keskinov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received May 6, 2003

Abstract—The phase separation diagrams of ternary liquid systems tetradecane–cyclohexanone–lanthanide(III) nitrate solvates with tri-*n*-butyl phosphate {$[Ln(NO_3)_3(TBP)_3$, Ln is Nd or Sm} at T = 298.15 K were studied.

Extraction of rare-earth metals(III) (REM) with tri-*n*-butyl phosphate (TBP) in hydrocarbon diluents is widely used in industrial recovery and separation of REM [1]. When saturating extractant with REM, the organic phase can be separated into two phases, one of which is enriched in $Ln(NO_3)_3(TBP)_3$. This phenomenon was thoroughly studied for actinides [2]. The phase diagrams of the ternary systems tetradecane–cyclohexanone–lanthanide(III) nitrate solvates with tri-*n*-butyl phosphate {$Ln(NO_3)_3(TBP)_3$, Ln is Nd or Sm} were not studied by now. Such data are required for choosing the diluent and the extractant composition ensuring homogeneity of the organic phase in REM extraction with TBP.

The density of organic phases was determined pycnometrically at 298.15 K. The organic components used in our experiments were as follows: TBP distilled under vacuum (ρ = 0.9727 g cm^{-3}), cyclohexanone (ρ = 0.9502 g cm^{-3}), and tetradecane (ρ = 0.7592 g cm^{-3}). The solvates $Ln(NO_3)_3(TBP)_3$ were prepared by triple contact of TBP with Ln(III) nitrate aqueous saturated solution [3]. The solvate concentration in the organic solutions was 1.08–1.12 M (ρ = 1.2745 ± 0.0012 g cm^{-3}). The binodal curves were obtained by improved Alekseev's visual technique [3]. The $Ln(NO_3)_3(TBP)_3$ concentration in the organic solutions was determined by complexometric titration [4]. The compositions of coexisting phases were determined from the weight fraction of $Ln(NO_3)_3(TBP)_3$ in the ternary phase by the technique reported in [5]. We found that, on mixing all the components of the ternary system, the total volume differs from the sum of volumes of the separate components by no more than ±0.2 vol %. Our experimental results were presented as the phase diagrams (Fig. 1) built in the form of the first Roozeboom's triangle. The determination error of the weight fraction of the components did not exceed ±(0.001–0.002).

The phase diagrams and the data listed in the table show that the components of the binary systems $Ln(NO_3)_3(TBP)_3$–$C_{14}H_{30}$ and $(CH_2)_5CO$–$C_{14}H_{30}$ have limited mutual solubility. The $Ln(NO_3)_3(TBP)_3$–$C_{14}H_{30}$ mixtures are separated into two liquid phases. Phases I and II are enriched in $C_{14}H_{30}$ and $Ln(NO_3)_3 \cdot (TBP)_3$, respectively. The $Ln(NO_3)_3(TBP)_3$ solubility in $C_{14}H_{30}$ (weight fraction 0.081) is virtually independent of particular lanthanide. The $(CH_2)_5CO$–$C_{14}H_{30}$ mixtures are also separated into two liquid phases. In this case, phase I is virtually pure tetradecane containing less than 0.001 (wt fraction) of cyclohexanone, and binary phase II contains $C_{14}H_{30}$ (wt fraction 0.339) and $(CH_2)_5CO$ (wt fraction 0.661).

The phase diagrams of the system $Ln(NO_3)_3 \cdot (TBP)_3$–$(CH_2)_5CO$–$C_{14}H_{30}$ contain the region *B* of homogeneous solutions and the two-phase region *A*. These regions are separated by the binodal curve. The ternary mixtures related to region *A* are separated into two liquid phases like the binary system $Ln(NO_3)_3 \cdot (TBP)_3$–$C_{14}H_{30}$. Phase I is the solution of lanthanide nitrate solvate in $C_{14}H_{30}$, and phase II is the equilibrium ternary solution. The point on the binodal curve corresponding to a solution with approximately equal content of each component is the critical point of the ternary system. This point is practically independent of particular lanthanide (see table).

Our results show that, in extraction of lanthanide nitrates of the cerium group with TBP solution in

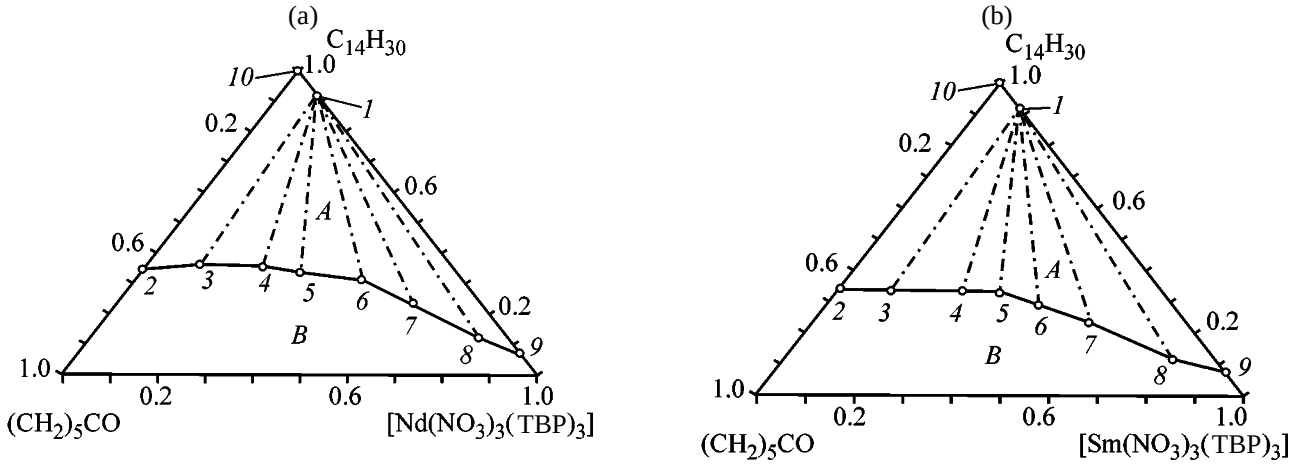

Fig. 1. Phase diagrams of the ternary systems $Ln(NO_3)_3(TBP)_3$–$(CH_2)_5CO$–$C_{14}H_{30}$, Ln is (a) Nd and (b) Sm, at T = 298.15 K. (*A*) Region of coexistence of two liquid phases, (*B*) region of homogeneous solutions, (*2*–*9*) points on the binodal curve, and (*5*) the point on the binodal curve corresponding to the critical composition of the ternary system (ternary system containing equal amounts of each component).

Composition of coexisting phases in the system $Ln(NO_3)_3 \cdot (TBP)_3$–$(CH_2)_5CO$–$C_{14}H_{30}$ at T = 298.15 K

cyclohexanone–tetradecane mixture, the saturation of the extractant with lanthanide nitrate results in phase separation of the organic extract. To prevent this negative phenomenon deteriorating extraction, the tetradecane weight fraction in the mixed diluent should not exceed 0.30 – 0.35.

CONCLUSIONS

(1) $Ln(NO_3)_3(TBP)_3$–$C_{14}H_{30}$ mixtures are two-phase systems. Phase I is enriched in $C_{14}H_{30}$ and phase II, in $Ln(NO_3)_3(TBP)_3$. The $Ln(NO_3)_3(TBP)_3$ solubility in $C_{14}H_{30}$ is practically independent of particular lanthanide(III). Binary $(CH_2)_5CO$–$C_{14}H_{30}$ mixtures also separate into two liquid phases. Phase I is virtually pure tetradecane containing less than 0.001 (wt fraction) of cyclohexanone, and phase II consists of $C_{14}H_{30}$ (wt fraction 0.339) and $(CH_2)_5CO$ (wt fraction 0.661).

(2) The ternary mixtures belonging to region *A* separate into two liquid phases. Phase I is the solution of lanthanide nitrate solvate in $C_{14}H_{30}$, and phase II is the ternary solution containing all the components of the system, $Ln(NO_3)_3(TBP)_3$–$(CH_2)_5CO$–$C_{14}H_{30}$.

(3) To prevent phase separation of the organic extract in extraction of lanthanide nitrates with TBP solution in the cyclohexanone–tetradecane mixture, the tetradecane weight fraction in the mixed diluent should not exceed 0.30 – 0.35.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Academician Georgii Grigor'evich Urazov (to 120th Anniversary of His Birthday)

G.G. Urazov, one of the closest associates and disciples of Academician N.S. Kurnakov, made a major contribution to the development of physicochemical analysis of metallic systems, organization of the domestic aluminum industry, study of natural salts and salt equilibria, nonferrous metallurgy, and training of specialists in chemical technology and nonferrous metallurgy.

Georgii Grigor'evich Urazov was born on January 6 (18), 1884, in Shatoi village of the former Terskaya oblast (North Caucasus) into the family of a physician. He received his secondary education at Yerevan classical education gymnasium, from which he graduated with gold medal in 1903. In the same year, having passed a competition of school-leaving certificates, he was admitted to the metallurgical department of St. Petersburg Polytechnic Institute. Among those who taught chemical sciences at that time were such well-known scientists as N.S. Kurnakov (1860–1941), N.A. Menshutkin (1842–1907), and V.A. Kistyakovskii (1865–1952); courses of lectures on metallurgy were delivered by A.A. Baidakov (1870–1946), M.A. Pavlov (1863–1958), and V.E. Grum-Grzhimailo (1864–1928). The laboratory of general chemistry, headed by Kurnakov, possessed all the necessary equipment for study of physicochemical properties of metallic and other systems. The laboratory comprised three departments: thermal analysis and metallography, electrical measurements and calorimetry, physical measurements and microphotography [1]. When still being a student, Urazov commenced experimental studies of metal alloys under supervision of S.F. Zhemchuzhnyi (1873–1929). In 1906–1908, the results obtained in studying alloys of manganese with copper and nickel, and of magnesium with copper and gold, were published in *Zhurnal Russkogo fiziki-khimicheskogo obshchestva (chast' khimicheskaya)* [Journal of Russian Physicochemical Society (Chemistry)] and *Izvestiya Sankt-Peterburgskogo politekhnicheskogo instituta* (Bulletin of St. Petersburg Polytechnic Institute). Studies of the last two systems were presented is Urazov's graduation thesis, which he defended in 1909 to become engineer metallurgist. Already the very first Urazov's studies, which were

thoroughly carried out and produced reliable results and rigorous conclusions, attracted the attention of specialists. The young scientist was left to work at the chair of general chemistry of the Polytechnic Institute and became Kurnakov's lecture assistant in 1912. In June 1921, the Council of Petrograd Polytechnic Institute elected Urazov a professor of the chair of nonferrous metallurgy. In 1914, the Department of chemistry of the Russian Physicochemical Society awarded the Mendeleev Prize to Urazov for his investigations of metal alloys.

Simultaneously with teaching, Urazov conducted research at quite a number of institutions: in 1918–1920, he was a research worker at the Committee for Analysis of Productive Forces in Russia of the Academy of Sciences; in 1919–1924, head of laboratory at the Department of Industrial Surveys of the Northern Region; in 1924–1940, head of physicochemical laboratory, and later a consultant, at the Geological Committee; in 1931–1940, a consultant and head of

1070-4272/04/7701-0165 © 2004 MAIK "Nauka/Interperiodica"

a research group for chlorination of ores of nonferrous and rare metals at the State Institute of Applied Chemistry. In 1918, Kurnakov initiated foundation in Petrograd of the Institute for Physicochemical Analysis, which united organizationally his disciples and coworkers who had worked at the Polytechnic and Mining institutes and at the chemical laboratory of the Academy of Sciences [2]. Urazov occupied at the new institute the position of research worker. Later, after the Institute of General and Inorganic Chemistry, USSR Academy of Sciences, was organized and Urazov moved to Moscow, he became head of the Department of Chemical Equilibria in 1934 and head of the Department of Physicochemical Analysis at this institute. In June 1934, a scientific degree of doctor of engineering was conferred on Urazov by decision of the Higher Qualification Committee without defense of a dissertation, and in June 1935, the Presidium of the USSR Academy of Sciences conferred on him the degree of doctor of chemistry. Urazov was elected a corresponding member of the USSR Academy of Sciences by its general meeting in January 1939, and academician, in 1946.

From 1938 till 1957, Urazov headed the Chair of Technology of Fine Inorganic Products at the Lomonosov Institute of Fine Chemical Technology in Moscow and organized there the training of specialists in processing of mineral salts. During the period of time from 1943 till 1955, Urazov also headed the Chair of Metallurgy of Heavy Nonferrous Metals at the Kalinin Institute of Nonferrous Metals and Gold in Moscow.

Urazov's scientific activities during more than 50 years were diverse and fruitful. The main areas of his research were analyzed in [3–5]. The scientist's autobiography, published in a historical sketch by Yu.I. Solov'ev [6], read: "All my research activities aimed at diverse objects of study are unified and governed by a common scientific method developed by my teacher Kurnakov, physicochemical analysis."

Immediately after having graduated from the Polytechnic Institute, Urazov continued investigations of metallic systems by studying the magnesium–cadmium system. In view of the division of intermetallic compounds into daltonides and berthollides, suggested by Kurnakov, Urazov studied silicides, antimonides, and sulfides of a number of metals and alloys of iron with silicon. Kurnakov also enlisted the services of his disciple to solution of a number of problems of primary economic importance. As far back as 1914, Kurnakov and Urazov published a study "Toxic Properties of Commercial Brands of Ferrosilicon," in which they established, using methods of physicochemical analysis, the causes of accidents in storage and transportation of ferrosilicon of certain composition. On Kurnakov's initiative, Urazov took part in a survey of salt lakes of the Apsheron Peninsula (Azerbaijan) to determine the possibility of obtaining iodine from brines of these lakes. The results obtained were reported in the article "Baku Iodine Lakes" (1919). A number of lakes were recommended for industrial use. Later, Urazov developed, together with V.P. Il'inskii (1885–1964), an electrochemical technique for recovery of iodine from natural water (1919).

Urazov took an active part in chemical studies of brines from boreholes of the Upper-Kama region, carried out in 1916–1919 under Kurnakov's supervision. After the discovery of a deposit of potassium and magnesium salts by P.I. Preobrazhenskii (1874–1944) in 1925 [7], Urazov continued research in this area. Based on a study of crystallization processes in the quaternary system KCl–NaCl–$MgCl_2$–H_2O, the scientist made suggestions about the conditions of formation of salt seams in deposits of this kind (1930). Urazov was directly involved in studies of salt resources in other regions of the country. He permanently paid much attention to integrated use of the Inderskoe deposit of borate and other salts (western Kazakhstan) and the unique salt basin Kara-Bogaz-Gol (Turkmenistan).

In 1920–1921, at the laboratory of general chemistry of Petrograd Polytechnic Institute, Urazov studied in detail bauxites from the Tikhvin deposit and suggested a method of proximate analysis on the basis of heating curves. The results obtained in these studies were summarized by Kurnakov and Urazov in a paper "Chemical and Thermal Analysis of Tikhvin Bauxite Rock" (1924). Later, Urazov and coworkers developed procedures for recovery of alumina from high-silica bauxites. Systematic studies carried out by the scientist in this area favored the development of an industrial technology for processing of low-grade bauxites.

A large series of investigations by Urazov and coworkers were concerned with quite a number of aluminum-based alloys. Of scientific and practical importance were studies of the physicochemical properties of the ternary systems aluminum–silicon–copper, aluminum–magnesium–copper, and aluminum–silicon–magnesium. Of particular importance for the development of the theory and practice of pyrometallurgical processes were investigations concerned with reactions of metals with sulfur, systems comprising a metal and its halide, equilibria in chloride–sulfate

systems, chlorination of ores of nonferrous and rare metals and mattes, and studies of oxide systems, carried out by Urazov and coworkers.

Urazov's investigations of binary systems formed by silver and copper with sulfur, and also of antimony, initiated studies of physicochemical properties of semiconductor compounds in our country. In communications published in 1919–1921, specific features of the electrical conductivity in the compounds Ag_2S and Cu_2S were noted. The scientist analyzed in detail the publications devoted to unipolar conduction in compounds since M. Faraday (1791–1867) till 1918 and outlined ways to study the nature of conduction in semiconductor compounds.

Urazov's monograph *Metallurgiya nikelya* (Metallurgy of Nickel) ran into two editions (1931 and 1935); he wrote quite a number of articles for *Tekhnicheskaya entsiklopediya* (Technical Encyclopedia) and *Bol'shaya Sovetskaya entsiklopediya* (Great Soviet Encyclopedia), spacious reviews, recollections about his teachers, Zhemchuzhnyi and Kurnakov. The range of Urazov's scientific interests was exceedingly wide, it covered numerous problems of inorganic chemistry, halurgy, and metal science. The scientific and pedagogical activities of Academician Urazov were distinguished by a number of highest State awards.

An outstanding chemist and metallurgist, scientist and pedagogue, Grigorii Grigor'evich Urazov died on April 27, 1957, at the age of 73.

ANNIVERSARIES

Petr Grigor'evich Romankov (to Centennial Anniversary of His Birthday)

A hundred years has elapsed since the birthday of Petr Grigor'evich Romankov, a corresponding member of the USSR Academy of Sciences, professor, a remarkable person, excellent pedagogue and prominent scientist, whose talent and most valuable experience had served for more than half a century the cause of training of high-skilled specialists for domestic science and industry. In the most important field of the science of processes and apparatus of chemical technology, he created the Leningrad scientific school of chemical technologists, which successfully combined in-depth theoretical investigations with their practical implementation and became widely known both in our country and abroad.

P.G. Romankov was born on January 17, 1904, in the town of Eisk, into the family of an office worker. In 1923, he finished rabfak (educational establishment set up to prepare workers and peasants for higher education) at Petrograd State University and entered the chemical faculty of the Technological Institute. In 1929, Petr Grigor'evich graduated from the Leningrad Technological Institute with diploma of engineer chemist-technologist, rejected a tempting offer of post-graduate studentship by Academician A.E. Porai-Koshits, moved to Moscow, and, during the following six years, worked at Dorogomilovskii plant first as a shift chemist and then as a head of a designing shop, which later became a part of Aniloob"edinenie. Simultaneously, Romankov commenced his pedagogical activities at the Chemical Faculty of the Moscow Higher Technical School (1929–1933), chair of processes and apparatus of the Mendeleev Institute of Chemical Technology in Moscow (1929–1934), and at the chair of aniline-dye industry of the Moscow Institute of Chemical Machine-Building (1932–1934).

Beginning in 1934 and till the end of Romankov's life (1990), his active creative, scientific, and educational activities had been associated with the Lensovet Technological Institute (now St. Petersburg State Technological Institute—Technical University).

In 1934, Petr Grigor'evich became a postgraduate student at the chair of processes and apparatus of chemical technology; in 1938, he defended his candidate dissertation devoted to development of methods

for calculation of process modes of drying of milled peat and continued scientific and pedagogical work at the chair.

During the years of the Leningrad siege (1941–1944), Romankov remained in the besieged city; a method for vacuum drying of blood plasma was developed and manufacture of a number of preparations necessary for those at the front line and in the city was set up under his supervision. In 1943, teaching at the chair was resumed and reconstruction of the first country's laboratory of chemical apparatus, organized in 1936, was commenced.

In 1943, Romankov replaced professor K.F. Pavlov, whose investigations in the field of linearity of chemical-technological functions became classical, as head of the Chair of Processes and Apparatus of Chemical Technology, one of the leading chairs for higher education in chemical technology at the Technological Institute. He headed this chair for nearly 50 years.

In 1947, Romankov defended his doctoral dissertation, in which he formulated the concept of unified kinetic patterns of chemical technology as the basis of the modern science of processes and apparatus and

1070-4272/04/7701-0168 © 2004 MAIK "Nauka/Interperiodica"

thereby continued and developed fruitful ideas of such his predecessors as D.I. Mendeleev, A.K. Krupskii, D.P. Konovalov, L.F. Fokin, and K.F. Pavlov.

Since 1950, Romankov had been deputy rector for scientific work of the Technological Institute for 30 years (1950–1980). He desired to combine the achievements of science and technology on the basis of modern foundations of chemical technology, following D.I. Mendeleev's statement: "Education, science, and industry make our state economically strong."

In 1964, Romankov was elected a corresponding member of the USSR Academy of Sciences, and an honorary title of Honored Scientist and Technologist of the Russian Soviet Federative Socialist Republic was conferred on him.

Romankov understood as the main purport of his life to work so as to be of maximum possible benefit to the Motherland and to enhance the prestige of the science of processes and apparatus. Under his supervision, more than 25 doctors and 200 candidates of science, whose investigations made an essential contribution to the development of engineering chemistry and theoretical foundations of chemical technology, were trained. Original methods for carrying out and calculating a number of hydromechanical, thermal, and mass-exchange processes of drying, gas purification, adsorption, extraction, distillation, and agitation were developed. To problems associated with design of high-intensity continuous apparatus for drying of finely dispersed and paste-like materials, adsorption in fluidized bed, separation of heterogeneous systems, etc. were devoted more than 300 scientific publications and inventions and a number of monographs by Romankov and coworkers: *Gidromekhanicheskie protsessy khimicheskoi tekhnologii* (Hydromechanical Processes of Chemical Technology) (1982), *Massoobmennye protsessy khimicheskoi tekhnologii* (Mass-Exchange Processes of Chemical Technology) (1990), and *Metody rascheta protsessov i apparatov khimicheskoi tekhnologii* (Methods for Calculation of Processes and Apparatus of Chemical Technology) (1994).

Much attention was given by Romankov to the development of the students' laboratory and to writing of educational literature. In the 1950s, the students' laboratory at the Chair of Processes and Apparatus of the Technological Institute became a model laboratory in the country. In 1947, the first edition of the textbook *Primery i zadachi po kursu protsessov i apparatov khimicheskoi tekhnologii* (Examples and Problems for the Course of Processes and Apparatus of Chemical Technology) by Pavlov, Romankov, and L.A. Noskov was published. In the following 40 years, this textbook was translated into 12 foreign languages and ran into 10 editions of more than 300 thousand copies. *Rukovodstvo po laboratornomu praktikumu* (Manual of Laboratory Work) written by the staff members of the chair was republished six times.

Romankov's services in the development of international relationships of the domestic higher school were distinguished by honorary titles and State awards of not only our country, but also other European countries (Bulgaria, Hungary, Poland, Czechoslovakia, Yugoslavia).

Romankov liked literary work despite its labor-intensiveness and psychological tension. He worked actively at a journal *Teoreticheskie osnovy khimicheskoi tekhnologii* (Theoretical Foundations of Chemical Technology), published by the Academy of Sciences of the USSR, as deputy editor-in-chief and was a member of the editorial board of *Zhurnal prikladnoi khimii* (Russian Journal of Applied Chemistry). Beginning in 1976, Petr Grigor'evich headed for more than 12 years the editorial board of *Zhurnal prikladnoi khimii*, published by the Academy of Sciences of the USSR, regularly conducted meetings of the Editorial Board in a business-like, friendly climate of confidence and mutual respect, which resulted in that any, even conflicting situations were easily resolved.

As many talented persons, Romankov was an idea man for his colleagues, whose opinion was highly estimated and respected by him, and an exceedingly obliging and good-wishing person. He belonged to the cohort of those Russian scientists whose scientific longevity became legendary and the scope of whose interests seemed to be unbounded.

ANNIVERSARIES

Vladimir Stepanovich Shpak (To His 95th Birthday)

On February 20, 2004, Vladimir Stepanovich Shpak, full member of the Russian Academy of Sciences, councilor of the Director general of Prikladnaya Khimiya Russian Scientific Center, and Editor-in-chief of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry), Russian Academy of Sciences, is 95.

V.S. Shpak is a prominent scientist specializing in technical chemistry. He has initiated, organized, and supervised large-scale investigations into new classes of chemical compounds and fields of their application, and the work on development of new types of technological processes for synthesizing most important special purpose substances.

Under Shpak's supervision, and with his direct participation, fundamental studies have been performed and numerous processes of basic organic synthesis have been developed and put in practice at plants of chemical and petrochemical industries. In particular, manufacture of high-molecular-weight amines from nitroparaffins has been organized, a new method for synthesis of esters has been developed, and investigations of hydrazine derivatives and other classes of chemical compounds, such as oxidizing agents, surfactants, and catalysts for various processes, have been performed. Shpak was among originators of a new, most important branch of chemical industry, specifically, the manufacture of organofluorine compounds. His investigations of transformations in various chemical compounds under the impact of high energy yielded initial data for the development of novel kinds of defense equipment.

Vladimir Stepanovich Shpak commenced his working activities in 1931, after having graduated from the Leningrad Technological Institute as a specialist in explosives. Till 1977, he was engaged in pedagogical activities at this institute, occupying successively the positions of an assistant, docent, and professor. Among Shpak's teachers was professor S.P. Vukolov (1863–1940), one of the most prominent Russian specialists in explosives and powders, D.I. Mendeleev's pupil and coworker, originator and the first head of the chair of explosives at the Leningrad Technological

Institute. During several years, Shpak was his deputy. In 1941–1944, Shpak was evacuated, together with the Institute, to Kazan, where he was engaged in teaching and production activities. Shpak was deputy director of the State Institute of Applied Chemistry (GIPKh) for science and technology in 1948–1953 and director of this Institute in 1953–1977. Under his supervision GIPKh became the largest country's chemical institute with unique technological base and a number of branches. Shpak, together with the staff members of the Institute headed by him, could create a new, modern type of a research organization that comprises a research institute, a designing office, and a plant.

1070-4272/04/7702-0171 © 2004 MAIK "Nauka/Interperiodica"

From 1977 till 1992, Shpak was Chief chemist for heavy organic synthesis at the Ministry of Chemical Industry and, simultaneously, headed the Leningrad research center for interbranch activities. He paid much attention to preparation of suggestions, as well as to planning and coordination of joint research works by organizations of the Ministry of Chemical Industry, Ministry of Fertilizers, institutes of the Russian Academy of Sciences, and higher-school institutions of Leningrad. From 1992 till the present time, Shpak has been councilor of the Director general of Prikladnaya Khimiya Russian Scientific Center.

Shpak has always given much of his time to public and scientific-organizational activities. From 1977 till 1992, he was vice-president of the Mendeleev All-Union Chemical Society. At present Shpak is chairman of the Northwestern division of the Scientific Council for combustion, Russian Academy of Sciences. With the strong sense of responsibility, so characteristic of him, Shpak pays much attention to coordination of R&D works in the field of combustion, which are carried out at research organizations, higher-school institutions, and industrial plants of Northwestern Russia. The following areas of research are distinguished as priority issues: "Chemistry for Engine-making and Transportation in Russia," "Chemistry for the Fuel-and-Energy Complex," "Problem of Hydrogen as a Fuel of the Future," etc. Shpak continues to be most actively engaged in the activities of the Prikladnaya Khimiya Russian Scientific Center, being a member of its scientific and thesis councils.

For many years Shpak was a member of the Editorial board of *Zhurnal Prikladnoi Khimii*, Russian Academy of Sciences; from 1998 to the present day, he has been the Editor-in-chief of the Journal.

Shpak's scientific activities are reflected in more than 500 papers and scientific project reports, their scientific novelty has been confirmed by 57 Inventor's certificates and patents. Shpak's pupils include more than 30 doctors and candidates of science. In 1955, a scientific degree of a doctor of science was conferred on Shpak, and in 1956, he became a professor. He was elected a corresponding member of the Academy of Sciences of the USSR in 1968, and a full member of the Academy, in 1981. Shpak became Honored worker of science and technology of the Russian Soviet Federative Socialist Republic (RSFSR) in 1968, and Honorary chemist of the RSFSR in 1974.

For outstanding achievements in the development of rocket engineering, making possible the human flight to the outer space, Vladimir Stepanovich Shpak was given a title of the Hero of Socialist Labor in 1961. His many years' scientific, organizational, and pedagogic activities have been honored with quite a number of highest State awards.

The staff members of the of Prikladnaya Khimiya Russian Scientific Center, St. Petersburg State Technological Institute, and St. Petersburg department of Nauka Publishing House, as well as the Editorial Board and staff members of the Editorial office of Zhurnal Prikladnoi Khimii, congratulate Vladimir Stepanovich on his glorious jubilee and wish him sound health, many happy returns of the day, and success in implementation of his always numerous new scientific ideas.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Granulation of Calcium Sulfate Hemihydrate and Its Topochemical Transition to Dihydrate in Grains in the Presence of Copper, Cobalt, and Molybdenum Salts

L. P. Firsova

Lomonosov State University, Moscow, Russia

Received July 21, 2003

Abstract—The influence exerted by admixtures of ammonium molybdate and copper or cobalt sulfate in humidifying solutions on the granulation of calcium sulfate hemihydrate and its topochemical transformation to calcium sulfate dihydrate in granules was studied experimentally.

Phosphogypsum is a waste formed in industrial processing of phosphate raw materials and production of phosphoric acid. Annually its dumps grow in the world by millions of tons, polluting the environment. Therefore, it is still important to develop new methods for utilization of phosphogypsum, including that formed in manufacture of phosphoric acid by the sulfuric acid hemihydrate method. In particular, it has been suggested to use granulated phosphogypsum as a land-improving agent and carrier of nutritious substances, trace elements, and biologically active materials useful for plant cultivation [1–4].

This study is concerned with the physicochemical effects associated with introduction of biologically active microelements [copper(II), cobalt(II), and molybdenum(VI)] into calcium sulfate hemihydrate, which is a waste formed in manufacture of phosphoric acid. The deficit of these microelements in soil adversely affects agricultural plants. To effects of this kind belongs the influence exerted by admixtures on the formation of granules from a wet powder of the hemihydrate and on the topochemical transition of the hemihydrate to $CaSO_4 \cdot 2H_2O$, both directly in hemihydrate granulation and in the subsequent ripening and hardening of the grains.

By now, a certain amount of data on the mechanisms and kinetics of calcium sulfate hemihydrate–dihydarate transitions has been accumulated [5–7]. These transitions underlie such practically significant processes as, e.g., production and application of cementing materials based on gypsum. However, insufficient attention has been given in the literature [8, 9] to the dependence of the phase transition and granulation parameters on the presence of admixtures. At the same time, topical problems associated with utilization of large-tonnage industrial phosphogypsum wastes require a more detailed study of the effect of admixtures on the phase transitions and granulation and on the properties of the resulting grains, including their strength. It also seems expedient to supplement the list of admixtures to be studied, e.g., by including biologically active microelements (copper-, cobalt-, and molybdenum-containing compounds).

EXPERIMENTAL

The pretreatment of commercial calcium sulfate hemihydrate (manufactured by Voskresensk plant of mineral fertilizers) in order to produce grains containing the necessary admixtures, consisted in that hygroscopic water and, simultaneously, the residual amount of phosphoric acid were removed from the initial phosphogypsum powder by its successive treatment with several portions of a hot solution of calcium sulfate and with acetone. After that, acetone was removed when drying a washed powder in air. This precluded the transition of calcium sulfate hemihydrate to the dihydrate before granulation.

The $CaSO_4 \cdot 0.5H_2O$ powder obtained by this technique consisted of hexagonal prisms 1 to 30 μm long, aggregated into druses 10 to 300 μm in size. The $CaSO_4 \cdot 0.5H_2O$ powder contained (wt %): H_2O 6.5–7.0, CaO 39–40, SO_3 56–57, P_2O_5 0.9–1.1, F 0.3–0.4, SiO_2 0.7–0.8, and R_2O_3 0.5–0.6. The porosity of the powder was $65.1 \pm 2.1\%$, and that of druses,

1070-4272/04/7702-0173 © 2004 MAIK "Nauka/Interperiodica"

43.5 ± 1.3%; the bulk weight of the powder was 0.95–1.0 g cm^{-3}. The content of copper(II) and molybdenum(VI) in the initial hemihydrate was below the limit of their detection by photometry (based on the intensity of yellow coloration of phosphomolybdenum-vanadium heteropolyacid and the blue-violet coloration of copper ammonium complex, respectively).

Immediately before granulation, the washed air-dry powder of calcium sulfate hemihydrate was wetted with specially prepared aqueous solutions containing admixtures of nitric and sulfuric acids (0.5–7.0%) or copper(II) and cobalt(II) sulfates and also that of ammonium molybdate (up to 1–5%). The amount of solution used for humidifying the hemihydrate was varied within the range 20–40%.

The powder and the solution were mixed in the course of 30–60 s and then the wet stock was directly transferred to a plate-type granulator. The stainless steel granulator plate 250 mm in diameter had side walls of height 75 mm. To control the growth and abrasion of grains, the tilt angle of the plate was varied from 20 to 40°; the rotation rate, from 50 to 80 rpm; and the granulation time, from 2 to 30 min.

After the process was complete, the resulting deformable grains were carefully transferred for strengthening (ripening in the course of formation of dihydrate crystals) to a wet atmosphere of a desiccator filled with water-wetted calcium sulfate dihydrate. Within 60–120 min after the beginning of the exposure in the desiccator, grains with a strength higher than 2 kg cm^{-2} were transferred to vessels with aqueous solutions identical to the humidifying solutions. The time of full ripening of the grains was 8 to 30 h.

During the granulation and ripening, portions of grains were taken for analysis. The amount of hygroscopic and crystallization water in the grains was determined. The grain strength determined both by dynamic compacting loads in the rotating plate in the course of stock granulation and by the topochemical transition in the substance of the granules. For a portion of grains with strength more than 2–3 kg cm^{-2}, the size distribution of grains and the average grain diameter were determined.

The content of hygroscopic water in grains and powders was determined from the difference of weights of the initial samples and those washed with acetone and then dried to constant weight. The content of crystallization water in air-dry powders and grains was determined by thermogravimetry. The relative amounts of hygroscopic and crystallization water in the samples made it possible to examine the kinetics of the topochemical transformation and to estimate the degree of conversion of calcium sulfate hemihydrate to the dihydrate.

The grain strength was determined in relation to the presence of admixtures in calcium sulfate from the force required for their crushing under a uniaxial compression. Prior to the tensometric measurements, the surface of wet grains was dried with a filter paper. For grains of specified size and composition, 15–20 parallel measurements were carried out.

A screen analysis was carried out for powders (initial and produced by abrasion of grains in granulation), as well as for dried granules with a strength greater than 2 kg cm^{-2}, in order to determine the average size and particle size distribution in relation to the presence of admixtures in calcium sulfate, humidity, and nodulization conditions. Standard sets of metallic soil sieves (0.25 to 7 mm mesh) and nylon sieves (14 to 300 μm) were used in the screen analysis. The powders and grains were also analyzed with an MBI-14 microscope.

The experiments on granulation of wet hemihydrate powder have shown that the optimal stock humidity W, at which granulation is possible, lies within the range 27–35%. Changing the composition by introduction of various admixtures into the humidifying liquid virtually did not change the optimal humidity limits. At a humidity less than 27–28% (W_{min}), no grains greater than 1 mm in diameter were formed. At the humidity exceeding 35%, large lumps of irregular shape were formed instead of spherical grains. This is in agreement with published data on the influence exerted by the weight ratio of liquid and solid phases on the formation and growth of grains. For example, it was shown in [10] that there exists a rather narrow range of optimal l/s values for granulation, at which formation of spherical grains is possible. However, the influence exerted by the composition of the liquid phase on the range of l/s values at which spherical grains can be formed, and on the value of W_{min}, was not analyzed. The experimental results obtained in the present study show that the presence of admixtures in amounts of several percent in the aqueous solutions used to humidify phosphogypsum affects the value of W_{min} only slightly. For example, the lower humidity limit for the granulation was 28.0 ± 0.7% at 1–5% $(NH_4)_2MoO_4$ in a humidifier, W_{min} = 27.0 ± 0.8% at 1–5% $CuSO_4$, and W_{min} = 27.0 ± 0.5% in the presence of 2.5% H_2SO_4.

The value of W or the l/s ratio determines the mechanism by which grains are formed and the time de-

pendence of the grain size [10]. When the stock contains the minimum amount of a humidifier, which is present only on the surface of solid particles at places of their contact, a rather slow growth of the diameter of granules is observed. This results from the agglomeration of powder particles to give protograins and from the deposition of the powder onto the protograins under the action of surface tension forces at the phase boundary. If the amount of moisture is sufficient for filling of pores in the solid phase, the agglomeration of the initial small-sized powder particles to give protograins and the deposition of powder particles onto the surface of protograins mainly occur via formation of a binding liquid network and under the action of capillary forces. When the amount of the liquids is so large that it completely covers solid particles, adhesive fusion of small-sized grains into larger ones becomes the main mechanism of fast grain growth.

The influence exerted by the content of the liquid phase in a stock on the variation of the grain size with time and on the particle size distribution in granulation within the optimal humidity range is described by the equation [10]:

$$d_t = d_0 \exp(\nu t). \quad (1)$$

Here d_t is the mean size of grains at stock humidity $W > W_{min}$ for granulation time t; d_0, the mean size of the initial druses in the phosphogypsum powder; and ν, the frequency of adhesive sticking of protograins or particles of a powder being granulated, which is dependent on the stock humidity.

Taking into account the experimental dependence of the sticking frequency on the stock humidity and the existence of the lower humidity limit at which grain formation becomes possible and assuming that $\nu = m(W - W_{min})^n$, Eq. (1) can be written as

$$d_t = d_0 \exp[m(W - W_{min})^n t]. \quad (2)$$

Here m and n are empirical constants, which are independent of the stock humidity and account for the properties of solid and liquid phases, e.g., surface tension parameters.

Equations (1) and (2) suggest that $\ln(d_t/d_0)$ depends linearly on t. This assumption is confirmed by the experimental data (Fig. 1). Indeed, the expected linear behavior of the dependence of $\ln(d_t/d_0)$ on t is observed at a short granulation time (1–8 min). Introduction of nitric acid into a humidifying solution, instead of $CuSO_4$, at the same stock humidity leads

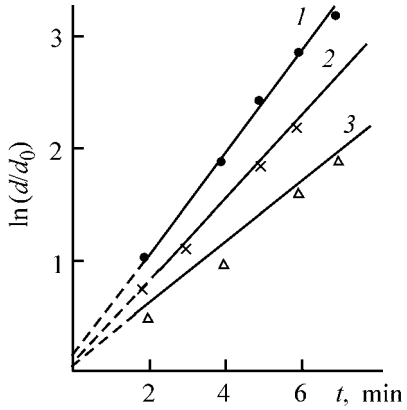

Fig. 1. Dependence of $\ln(d_t/d_0)$ on time t at various compositions of the humidifying solution. Humidifying solution (%): (*1*) 0.5 H_2SO_4, (*2*) 1.0 HNO_3, and (*3*) 2.0 $CuSO_4$. Stock humidity (%): (*1*) 33; (*2*) and (*3*) 30.

to a change in the slopes (or tan α) of straight lines in the coordinates $\ln(d_t/d_0)$–t and in the values of ν. A change in the slope is also characteristic of the case when the humidity of the stock is raised by adding H_2SO_4 solution.

The slope ratio of the straight lines can be represented as

$$\tan\alpha_1/\tan\alpha_2 = \nu_1/\nu_2 = \ln(d_t/d_0)_1/\ln(d_t/d_0)_2 = (m_1/m_2)\,[(W_1 - W_{min})^n/(W_2 - W_{min})^n]. \quad (3)$$

It is essential that, according to (3), the quantities ν and tan α should depend on the properties of solid and liquid phases and on the stock humidity. It is also not improbable that they may depend on the content of impurities in the humidifier, which modify the properties of a material being granulated, as is confirmed by the experimental data presented in Fig. 1 and in the table.

On the assumption that the properties of the solid and liquid phases are predominantly reflected by the coefficients m and n, respectively, several particular cases follow from Eq. (1). For example, if the nodulization of one and the same solid phase, phosphogypsum, is performed with two humidifiers of different

Values of $\ln(d_t/d_0)$ and ν at different humidities W of a stock wetted with 2.5% $CoSO_4$ solution

compositions, i.e. at $m_1 = m_2$ and $W_2 = W_1 = W$ and $W_{min1} = W_{min2} = W_{min}$, then

$$\log(\tan\alpha_1/\tan\alpha_2) = (n_1 - n_2)\log(W - W_{min}). \quad (4)$$

Here $\tan\alpha_1$ and $\tan\alpha_2$ are the slopes of the straight lines in the coordinates $\ln(d_t/d_0)$–t.

In the case when the compositions of humidifiers and the l/s ratios are the same ($W_2 = W_1$), but the solid phases are different, with $m_1 \neq m_2$, but $n_1 = n_2$, it follows that

$$\tan\alpha_1/\tan\alpha_2 = m_1/m_2. \quad (5)$$

If the compositions of the humidifiers are identical, but the l/s ratios are different, i.e., $n_1 = n_2$ (nature of admixtures in liquid phases and their concentration are the same), and also $m_1 = m_2$ and $W_{min1} = W_{min2}$, but W_1 and W_2 are different ($W_2 \neq W_1$), then

$$\log(\tan\alpha_1/\tan\alpha_2) = n\log[(W_1 - W_{min})/(W_2 - W_{min})]. \quad (6)$$

Expressions (3)–(6) can be used to estimate n or m and to verify various hypotheses concerning the mechanisms of grain formation and the particle size distribution. The experimental data in the table correspond to Eq. (6) as regards the granulation conditions and the stock composition. Consequently,

$$n = \log(\tan\alpha_1/\tan\alpha_2)/\log[(W_1 - W_{min})/(W_2 - W_{min})]. \quad (7)$$

A calculation based on the data in the table and expression (7), in which each pair from the experimental series with different degrees of humidification, yielded the coefficients n for the 2.5% solution of cobalt sulfate. For example, $n = 0.68$ at $W_1 = 34$ and $W_2 = 30\%$; $n = 0.71$ at $W_1 = 34$ and $W_2 = 28\%$; $n = 0.73$ at $W_1 = 30$ and $W_2 = 28\%$. The average value of n is 0.71. These data point to a weak dependence of n on the stock humidity. However, this conclusion was not confirmed by estimation of coefficients n for the case of an $(NH_4)_2MoO_4$ solution introduced into the stock. It is necessary to note that the estimates aimed, among other things, to determine the reliability of the technique suggested for analysis of granulation processes and to verify the assumptions made are tentative and require a refinement with other examples.

The effect of $CuSO_4$ and $CoSO_4$ admixtures contained in the humidifying solution also manifests itself in the kinetics of the solid-phase transition of calcium sulfate hemihydrate to the dihydrate, which is accompanied by an increase in the fraction of crystallization water and a decrease in the rate at which this parameter changes within grains. (Fig. 2).

As follows from the experimental data obtained, the nature of an admixture virtually does not affect the rate of grain strengthening in the initial stage, in the course of granulation, when a strength of less than 1.5–2.0 kg cm^{-2} is reached mainly under the action of compacting loads in the rotating plate of the granulator plate. However, admixtures of $(NH_4)_2MoO_4$ notably decelerate the subsequent stage of grain strengthening, which results from a topochemical transition of calcium sulfate hemihydrate to dihydrate in grains in a moist air (Fig. 3). A similar effect has been observed previously in the case of admixtures of salts of manganese and zinc and also boron in the form of a boric acid [11]. By contrast, the introduction of nitric and sulfuric acids into solutions used to humidify phosphogypsum accelerated the grain strengthening.

It was shown in [5–9] that the dihydrate crystals originate on the surface of single crystals of calcium sulfate hemihydrate, which have the form of elongated hexagonal or pseudo-hexagonal prisms (up to 30 μm long) with H_2O molecules contained in channels parallel to the hexagonal axis *c*. Dihydrate crystals can further grow, with the initial monoclinic crystal system retained and a phase transition zone formed on the periphery of the initial hemihydrate single crystal. This zone migrates from the surface to the center. In the process, the dihydrate crystals in grains penetrate through one another to form a rather strong structure. If impurity ions are sorbed on the surface of the crystals, defects originate in the block dihydrate layer that grows on the hemihydrate. Subsequently, these defects are not overgrown as the phase transition boundaries go deeper. Therefore, the dihydrate crystals may be more defective and shorter in the presence of impurity cations, compared with the case of their absence. Accordingly, the grain strength decreases. Impurities can also change the stability limits of the phases of calcium sulfate hemihydrate and dihydrate. For example, according to [8, 9], calcium sulfate dihydrate appears in the presence of an admixture of a rare earth under conditions of hemihydrate stability. The change in stability limits of calcium sulfate hemihydrate and dihydrate can also affect the rate and degree of the phase transition.

CONCLUSION

It was found that admixtures of molybdenum(VI), copper(II), and cobalt(II) compounds exert influence on the mean size of granules obtained by granulation of humidified calcium sulfate hemihydrate, on the kinetics of the topochemical transition of the hemihydrate to the dihydrate in grains, and, accordingly, on the kinetics of grain strengthening in the the phase transition or on the maximum achievable strength of the grains upon ripening.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Heat Conductivity of Zirconium and Alkali Metal (Na, Cs) Phosphates of the $NaZr_2(PO_4)_3$ Family

V. I. Pet'kov, V. N. Loshkarev, and E. A. Asabina

Lobachevskii State University, Nizhnii Novgorod, Russia

Received August 6, 2003

Abstract—The heat conductivity of porous $Zr_3(PO_4)_4$, $NaZr_2(PO_4)_3$, $CsZr_2(PO_4)_3$, and $Na_5Zr(PO_4)_3$ samples was studied in the range 298–673 K. The heat conductivity coefficients of the zero-porosity phosphates under study were calculated and prospects for their application were considered.

A great number of structural analogues of $NaZr_2(PO_4)_3$ (NZP) are known among inorganic orthophosphates [1–3]. The extensive crystallization field of compounds and solid solutions of the NZP structural type is determined by the broad isomorphism in positions of cations located in voids of the 3*D* skeleton of the structure and also by the possibility of isomorphous substitutions in the octahedra and tetrahedra forming the skeleton [4, 5].

It is known [6, 7] that NZP phosphates have high melting points, chemical stability, radiation hardness, and resistance to thermal shocks of any practically achievable intensity.

Thermal properties (heat expansion, specific heat, and heat conductivity) largely determine the high value of ceramic materials. A great number of publications [8–11] have been devoted to experimental determination of the heat expansion of NZP materials, which characterizes the relative change in the volume or linear dimensions of a body upon a certain change in its temperature. Analysis of the thermal coefficients of linear expansion of these materials suggests that the behavior of an NZP structure under thermal impact is determined by the nature, relative size, and number of cations occupying various crystallographic positions, by the number of vacant positions, and also by the unit cell symmetry. A set of empirical relationships governing the heat expansion of NZP phosphates was suggested in [4] on the basis of a crystal-chemical approach. These relationships make it possible to predict existence of new materials with controllable, including ultralow, heat expansion at an almost zero expansion anisotropy.

A precise determination of the specific heat (amount of thermal energy necessary for a certain change in the temperature of a substance) and heat conductivity (amount of heat passing through a material at a specified temperature gradient) is a rather labor-consuming operation. For this reason, the data on the specific heat and heat conductivity of representatives of the NZP family are limited to publications [7, 12–20], and the compounds studied are few in number. Data on the heat conductivity of ceramic materials are available for the following ceramic materials: $(Ca_{1-x}Mg_x)Zr_4(PO_4)_6$ [18, 19], $Ca_{0.9}Li_{0.2}Zr_4(PO_4)_6$ [19], $Ca_{0.9}Zr_{4.05}(PO_4)_6$ [19], and $(Sr_{1-x}K_{2x})Zr_4(PO_4)_6$ [20].

There is an imbalance between the fast accumulation of the information on the structure and heat expansion of NZP materials and the much slower study of their heat conductivity and specific heat. It is evident that the rate at which the temperature of an article varies during its heat treatment in the course of its fabrication or use depends on the heat conductivity and specific heat of the material used. It is the heat conductivity coefficient, alongside with the thermal coefficients of linear and volume expansion, that determines the heat resistance of a material. Therefore studying the heat conductivity of NZP materials in a wide temperature range is an topical scientific and practical task.

The aim of this study was to examine experimentally the temperature dependence of the heat conductivity of porous samples of crystalline NZP phosphates $Zr_3(PO_4)_4$, $NaZr_2(PO_4)_3$, $CsZr_2(PO_4)_3$, and $Na_5Zr(PO_4)_3$ in the temperature range 298–673 K, to

estimate the heat conductivity coefficients of such zero-porosity materials, to compare the data obtained with published experimental data on high-density NZP ceramics, and also to consider prospects for their application on the basis of their thermal properties. The objects of study were chosen taking into account the availability of experimental data on the temperature dependence of their specific heat in the above-mentioned temperature range.

EXPERIMENTAL

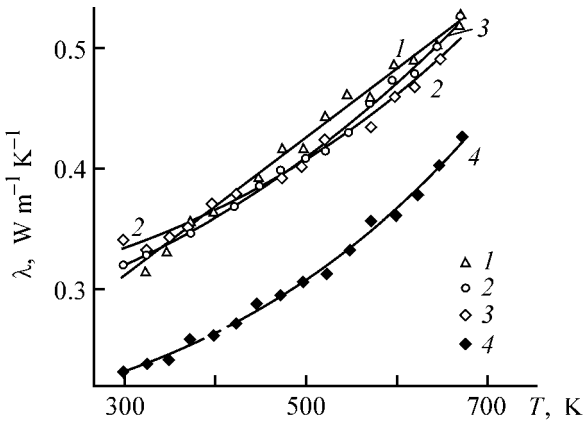
The compounds $Zr_3(PO_4)_4$ [$Zr_{0.25}Zr_2(PO_4)_3$], $NaZr_2(PO_4)_3$, $CsZr_2(PO_4)_3$, and $Na_5Zr(PO_4)_3$ were synthesized by the sol–gel method [7, 15]. For this purpose, stoichiometric amounts of aqueous solutions of zirconium oxychloride salts and a chloride of an alkali metal were poured together with permanent stirring at a temperature of about 295 K, and then a stoichiometric amount of a solution of orthophosphoric acid was added slowly with stirring. The resulting gel was dried at 353 K, heat treated at 873 and 1073 K with a free access of air for no less than 24 h at each stage. The stepwise heating alternated with dispersion. The maximum calcination temperature of the phosphate $CsZr_2(PO_4)_3$ was 1273 K.

The composition and structure of the resulting phosphates were confirmed by X-ray phase and X-ray fluorescence microprobe analyses and by IR spectroscopy. The X-ray phase analysis (DRON-3M, Cu_{K_α} radiation, 2θ = 10–50°) and the X-ray fluorescence microprobe analysis (Camebax analyzer with a Link AN-10000 energy-dispersion detector) of the samples demonstrated that they are homogenous, have nearly theoretical compositions, and their structure is NZP-like. The sets of interplanar spacings and unit cell parameters of the phosphates (see table) agree with the data in the PDF2 file. The positions and shapes of bands in the IR spectra of the samples are similar to those in [21] and are typical of orthophosphates.

To make samples suitable for heat conductivity measurements, the powders synthesized were compacted into cylinders. The porosity P (%) was estimated using the formula $P = (1 - \rho_a/\rho_X) \times 100$, where ρ_a and ρ_X are the apparent and X-ray densities of a sample, respectively. These densities and the porosity of the samples under study are listed in the table.

The heat conductivity of the phosphates was measured according to the technique [22] on cylindrical samples of diameter 15.0–16.1 mm and height 2.25–2.34 mm, using an IT-λ-400 device. The inaccuracy of the heat conductivity measurements was 8%.

The heat conductivity of the crystalline phosphates $Zr_{2.25}(PO_4)_3$, $NaZr_2(PO_4)_3$, $CsZr_2(PO_4)_3$, and $Na_5Zr(PO_4)_3$ was determined in air in the temperature range 298–673 K at 16 experimental points for each sample, with a temperature step of 25 K. The temperature dependences of the heat conductivity coefficient λ of the samples are shown in the figure. It is seen that, within the entire temperature range under study, the dependences show no features and the heat conductivity coefficient smoothly increases with temperature. The heat conductivities of $Zr_{2.25}(PO_4)_3$,



Heat conductivity coefficient λ of porous samples of NZP phosphates vs. temperature T. (*1*) $Zr_{2.25}(PO_4)_3$, (*2*) $NaZr_2(PO_4)_3$, (*3*) $CsZr_2(PO_4)_3$, and (*4*) $Na_5Zr(PO_4)_3$.

$NaZr_2(PO_4)_3$, and $CsZr_2(PO_4)_3$ are close to each other. Pentasodium-zirconium triphosphate has a somewhat lower heat conductivity, mainly owing to a different distribution of sodium ions in the crystal lattice as compared with other phosphates under study.

The temperature dependences of the heat conductivity coefficient λ–T of the samples studied can be described by the following semiempirical formulas:

$$\lambda_{Zr_{2.25}(PO_4)_3} = 0.14 + 0.00057T,$$

$$\lambda_{NaZr_2(PO_4)_3} = 0.23 + 2.58 \times 10^{-4}T + 3.88 \times 10^{-10}T^3,$$

$$\lambda_{CsZr_2(PO_4)_3} = 0.28 + 1.49 \times 10^{-4}T + 4.30 \times 10^{-10}T^3,$$

$$\lambda_{Na_5Zr(PO_4)_3} = 0.18 + 1.13 \times 10^{-4}T + 5.29 \times 10^{-10}T^3.$$

For each sample, the maximal deviation of experimental points from a smoothed λ–T curved did not exceed the inaccuracy of heat conductivity measurements.

The dashed line in the range 389–424 K in the curve describing the temperature dependence of the heat conductivity of $Na_5Zr(PO_4)_3$ corresponds to the region of a phase transition (T_{pt} = 406.9 K), which is associated with a change in the position ordering of sodium cations in voids of the structure skeleton under the action of temperature [23] and manifests itself in the temperature dependence of the specific heat [15, 17]. The transition was not seen in the curve for the heat conductivity of the sample under study, which seems to be due to a small change in energy in the phase transition ($\Delta_{pt}H^0$ = 4.32 kJ mol^{-1} [15, 17]) and to a 8% inaccuracy of the heat conductivity measurements.

The porosity of a system is an important factor, in addition to temperature, that determines its thermal characteristics. An increase in the porosity improves the heat-insulating properties of systems, and a decrease in this parameter enhances the corrosion resistance of the system. To make tentative conclusions concerning the value of high-density NZP ceramics for heat engineering, the heat conductivity of the samples under study at zero porosity was determined using the formula [24]

$$\lambda = \lambda_0 \frac{1 + 2V_a \dfrac{1 - \lambda_0/\lambda_a}{2\lambda_0/\lambda_a + 1}}{1 - V_a \dfrac{1 - \lambda_0/\lambda_a}{\lambda_0/\lambda_a + 1}}.$$

Here λ, λ_0, and λ_a are the heat conductivity coefficients of a porous body, solid phase, and gas (air) in pores, respectively; V_a is the volume fraction of pores in the porous body.

The calculated heat conductivity coefficients (W m^{-1} K^{-1}) at zero porosity in the range 298–673 K are as follows: 0.6–1.1 for $Zr_{2.25}(PO_4)_3$, 0.6–0.9 for $NaZr_2(PO_4)_3$, 0.7–1.1 for $CsZr_2(PO_4)_3$, and 0.4–0.7 for $Na_5Zr(PO_4)_3$.

In [18–20], densely sintered NZP ceramics (P < 5%) were used to measure the heat conductivity. For example, the heat conductivity of ceramics based on $Ca_{0.5}Zr_2(PO_4)_3$ was studied in [19]. It was found that, in the temperature range 298–873 K, the heat conductivity coefficient of $Ca_{0.9}Li_{0.2}Zr_4(PO_4)_6$, $Ca_{0.9}Mg_{0.1}Zr_4(PO_4)_6$, and $Ca_{0.9}Zr_{4.05}(PO_4)_6$ ceramic samples is 1.1–1.4 W m^{-1} K^{-1}. The heat conductivities of $Ca_{0.4}Mg_{0.1}Zr_2(PO_4)_3$ and $Ca_{0.25}Mg_{0.25}Zr_2(PO_4)_3$ ceramics, reported in [18] (λ = 0.6–0.7 W m^{-1} K^{-1} at 873 K), are much lower than those obtained in [19]. The heat conductivity coefficient of the dense ceramic $Sr_{0.5(1+x)}K_xZr_2(PO_4)_3$ at 298 K is 1.0 W m^{-1} K^{-1} [20]. The published values of the heat conductivity coefficients of NZP materials under study show a significant scatter, which is due to their chemical and phase composition, specific features of their crystal structure (valence state of ions, their distribution in a crystal lattice, kind and quantities of defects, and chemical bond nature) and microstructural organization (size, dispersity, and shape of grains; type of porosity), and methodological features of measurements. It is of interest that, despite this circumstance, NZP ceramics have a lower heat conductivity than the industrial stabilized zirconium dioxide (1.95–2.44 W m^{-1} K^{-1} in the range 373–1673 K [25]), which is the main ceramics-forming component of widely used refractories for heat-resistant elements of high-temperature furnaces.

The high melting points, low heat conductivity, ultralow heat expansion at almost zero expansion anisotropy, chemical stability, and radiation hardness allow NZP ceramics to be regardered as promising highly resistant refractories and heat insulators with a low heat conductivity, which outperform the known materials in their ability to withstand thermal shocks.

CONCLUSIONS

(1) The temperature dependences of the heat conductivity of porous phosphates $Zr_3(PO_4)_4$, $NaZr_2(PO_4)_3$, $CsZr_2(PO_4)_3$, and $Na_5Zr(PO_4)_3$, which crystallize in the structural type of sodium-dizirconium triphosphate (NZP), were studied in air in the temperature range 298–673. The temperature dependences of the heat

conductivity can be described with semiempirical linear and cubic equations.

(2) The calculated heat conductivity at zero porosity are equal to 0.6–1.1 W m^{-1} K^{-1} and are close to the heat conductivity of the known high-density NZP ceramics.

(3) Judging from their thermal properties, NZP ceramics are promising highly resistant refractory and heat-insulating materials, which are capable of working under conditions of abrupt temperature changes and high temperature gradients.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of Physicochemical Processes in Film-forming Ethanol Solutions of Zirconium and Cobalt Salts and Properties of Thin Films Obtained on Their Base

Abstract—The main physicochemical processes that occur in film-forming solutions based on zirconium oxochloride $ZrOCl_2 \cdot 8H_2O$, cobalt salts $CoCl_2 \cdot 6H_2O$ and $Co(NO_3)_2 \cdot 6H_2O$, and ethanol were studied. The intermolecular interaction in film-forming solutions was analyzed qualitatively and quantitatively.

Thin films find wide use as light-redistributing, protective, and decorative coatings [1]. Extensive studies intended to obtain new compositions of films, analyze their structure and properties, and extend application fields are being carried out in this country and abroad [2, 3]. Particular attention is paid to composite thin-film materials based on binary and ternary systems constituted by oxides of Group-IV elements [4, 5]. The properties of coatings of this kind are determined by the properties of the constituent oxides and their relative amounts. Films based on zirconium dioxide are promising because of their practically valuable properties: transparency and high refractive index, adhesion, thermal resistance, and chemical stability. However, the use of thin films based on zirconium dioxide is limited by the occurrence of polymorphic transformations, which affects the service characteristics and quality of films. Introduction of cobalt oxide into thin-film materials based on zirconium dioxide makes it possible to stabilize its structure and properties and vary widely the optical characteristics of the films.

This study is concerned with physicochemical processes that occur in film-forming solutions (FFS), qualitative and quantitative analysis of intermolecular interactions in solution, formation of thin films of the system ZrO_2–CoO, and examination of their properties.

EXPERIMENTAL

Thin films of double oxides of zirconium and cobalt were obtained by deposition from FFS based on 99% ethanol, zirconium oxochloride $ZrOCl_2 \cdot 8H_2O$, and cobalt salts $CoCl_2 \cdot 6H_2O$ or $Co(NO_3)_2 \cdot 6H_2O$. Ethanol was preliminarily dehydrated with calcium oxide, using the known procedure [6]. This is necessary for removing excess water, since the salts used contain crystallization water and its amount is sufficient to ensure a minor degree of hydrolysis in FFS. The excess amount of water, introduced with nondehydrated ethanol, enhances the hydrolysis, with the result that the working life of FFS becomes substantially shorter and a polymer is formed rapidly. The total concentration of the salts in the solutions was 0.4 M, the content of zirconium oxochloride was varied within the range 20–100 mol %.

The processes that occur in FFS were studied using viscometry (Ostwald viscometer), and the optical density of the solutions was measured with a KFK-2 photocolorimeter. The concentration dependence of reduced viscosity η_{sp}/c of an FFS based on zirconium oxochloride and cobalt nitrate was measured by diluting the initial FFS with ethanol, in the zirconium oxochloride concentration range 0.5–3.3 g dl^{-1}. The resulting concentration dependences of η_{sp}/c were processed using the method described in [7, 8].

Films were obtained on glass [GOST (State Standard) III-2001] and quartz substrates by centrifugation (rate of substrate rotation 1000–4000 rpm) and pulling from solution (pulling velocity 5 mm min^{-1}) at a temperature of 290–300 K. A thermal treatment of the films was done in two stages at 330 and 770–870 K. The optical characteristics of the films were studied on an LEF-3M laser ellipsometer and Specord-M40

1070-4272/04/7702-0182 © 2004 MAIK "Nauka/Interperiodica"

spectrophotometer; the adhesion was determined with a PMT-3 device.

The film-forming solutions based on $ZrOCl_2 \cdot 8H_2O$ are colorless; addition of cobalt chloride leads to appearance of a blue coloration, and that of cobalt nitrate makes the solution blue and violet. The composition of cobalt complexes in the FFS based on zirconium(IV) oxochloride and cobalt(II) nitrate was determined using data on the varied coloration of complex compounds of cobalt [9] and the Ostromyslenskii–Zhoba method [10]. Figure 1 shows how the optical density D of FFS at a wavelength of 670 nm varies with the content of cobalt nitrate. Probably, the existence of a varied coloration of FFS is associated with changes in the coordination of H_2O molecules and Cl^- ions around a Co^{2+} ion, with the blue color pointing to the presence of chloride complex anions $[CoCl_4]^{2-}$, and violet color, to that of a mixed complex $[Co(H_2O)_4Cl_2]$ [9]. It may be assumed that chloride complex species of composition $[CoCl_4]^{2-}$ predominate at a cobalt nitrate content in FFS lower than 33 mol %, and mixed-ligand complexes of composition $[Co(H_2O)_4Cl_2]$, at a higher content of cobalt nitrate (Fig. 1). The presence of cobalt(II)chloride complex species in FFS based on zirconium oxochloride and cobalt nitrate is accounted for by the high content of chloride ions formed in dissociation of zirconium oxochloride and also by the affinity of Co(II) for chloride ions.

The stability of the FFS viscosity with time is technologically important for obtaining films with reproducible properties. Therefore, the viscosity can serve as a criterion of suitability of a solution for film formation. The viscosity of FFS commonly varies with time in three stages, which correspond to ripening, region of stable properties, and aging through gelation and polymerization [11]. For the FFS based on zirconium oxochloride the three stages are preserved; the variation of the specific viscosity of this solution is shown in Fig. 2, curve *1*. The solution ripening takes 4 days, during which alcoholysis and hydrolysis occur, and oxozirconium(IV) ions, which exhibit high affinity for oxygen, are bound together by the alcohol molecules by ol (–OH) and oxol (–O–) bonds. The film-forming capacity of alcoholic solutions based on zirconium oxochloride is due to the presence of hydroxo complex of zirconium of the composition $[Zr(OH)_2(C_2H_5OH)_x(H_2O)_{4-x}]Cl_2$ [11]. Since Zr(IV) shows strong tendency toward formation of polynuclear compounds, particle condensation occurs in FFS to give more complex macromolecules, and, consequently, the viscosity changes.

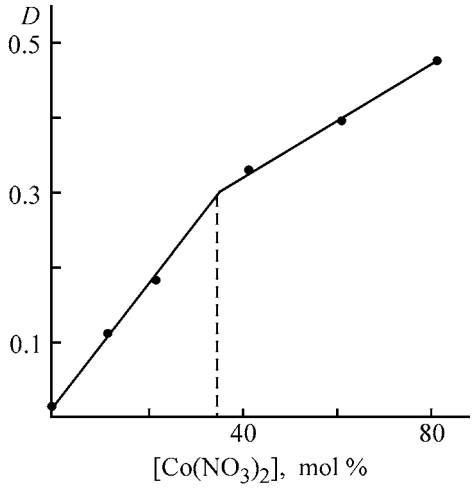

Fig. 1. Optical density D of an FFS based on zirconium oxochloride vs. the content of cobalt nitrate, $[Co(NO_3)_2]$.

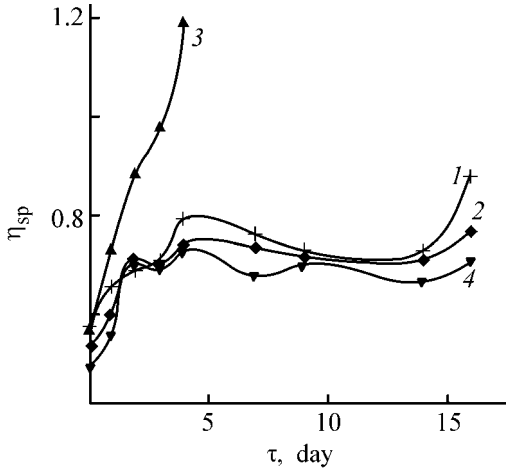

Fig. 2. Specific viscosity η_{sp} of an FFS based on zirconium oxochloride and cobalt chloride vs. the storage time τ. $CoCl_2$ content (mol %): (*1*) 0, (*2*) 50, (*3*) 80, and (*4*) 100.

Introduction of cobalt(II) chloride into an FFS based on zirconium oxochloride in amount of up to 70 mol % has no pronounced effect on the variation of viscosity with time (Fig. 2, curve *2*). At $CoCl_2$ content in FFS of 80 or 90%, the specific viscosity is anomalously high, and these solutions turn into gels already after 1.5 months (Fig. 2, curve *3*). In an FFS with 80 mol % $CoCl_2$, there are four cobalt atoms per zirconium atom, and, therefore, a complex tetrameric particle, in which each zirconium atom is bound to four cobalt atoms, can serve as a polymerization center [12]. The alcoholysis processes that occur in parallel lead to formation of larger macromolecules.

The affinity of cobalt for oxygen is low, and the probability of formation of ol and oxol bonds is considerably lower as compared with zirconium. There-

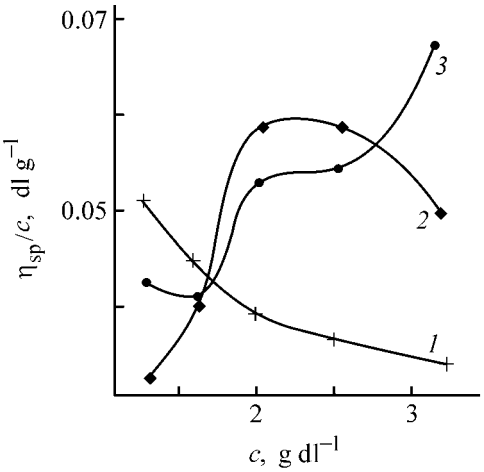

Fig. 3. Reduced viscosity of FFS, η_{sp}/c, vs. its concentration c. $Co(NO_3)_2$ concentration (g dl^{-1}): (*1*) 0, (*2*) 10, and (*3*) 20.

fore, the specific viscosity is lower, too (Fig. 2, curve *4*). The aging of a solution of this kind begins after 14 months.

It should be noted that processes in FFS with zirconium(IV) oxochloride and cobalt(II) nitrate are similar to those in film-forming solutions with zirconium(IV) oxochloride and cobalt(IV) chloride salts.

Taking into account the fact that the FFS based on zirconium oxochloride are polymer solutions, the approach described in [7] can be used to obtain quantitative characteristics of the interaction of macromolecules in solution. To describe the concentration dependence of the reduced viscosity η_{sp}/c, the authors of [7] employed a linear extrapolation equation (Huggins equation)

$$\eta_{sp}/c = [\eta]a + k'[\eta]^2c \quad (1)$$

and nonlinear extrapolation equations

$$\eta_{sp}/c = a + b\exp(-dc), \quad (2)$$

$$\eta_{sp}/c = a + b_1\exp(-d_1c) + b_2\exp(-d_2c), \quad (3)$$

where a, b_i, and d_i are empirical solvation coefficients, which depend on the dipole momentum and donor and acceptor numbers of a solvent and have a dimensionality of molar volume.

Various functions applicable to description of empirical concentration dependences of viscosity make it possible to determine the numerical values of the characteristic viscosity $[\eta]$.

The variation of the reduced viscosity of an FFS based on zirconium(IV) oxochloride (Fig. 3, curve *1*) can be described using Eqs. (1)–(3). The Huggins constants k' and the characteristic viscosities, calculated for this solution by three equations, are listed in Table 1. The Huggins constant has an unrealistic value ($k' = -2.41$), which is probably due to the presence of hydrogen bonds in solution. As indicated by variances and correlation coefficients, Eq. (3) describes the given experimental dependence the most precisely, and, consequently, the significant value of the characteristic viscosity is 0.102 dl g^{-1}. The variation of the reduced viscosity of an FFS based on zirconium oxochloride with addition of cobalt nitrate (Fig. 3, curves *2* and *3*) is also described more precisely by Eq. (3). The Gibbs energies of solvation (kJ mol^{-1}), calculated using the values of $[\eta_{sp}]$ for the FFS under study, are listed in Table 2. The interaction of the forming hydroxo complex of zirconi-

				kJ mol^{-1}					
0	0.145	–0.150	0.107	3.5	–3.64	2.60	0.063	0.686	0.102
10	0.310	–0.301	0.018	28.4	–27.60	1.65	0.050	0.046	0.027
20	0.114	–0.222	0.129	13.4	–26.18	15.21	0.160	0.050	0.021

um(IV) with the solvent occurs by both the donor–acceptor and ionic mechanisms. In an FFS that contains only zirconium(IV) oxochloride, there are insignificant electrostatic (ΔG_a = 3.5 kJ mol^{-1}) and specific donor–acceptor interactions (ΔG_{b_1} = 3.61, ΔG_{b_2} = 2.60 kJ mol^{-1}). This circumstance is accounted for by the fact that zirconium(IV) tends to form complex 3*D* polymeric structures to a greater extent and has high characteristic viscosity. Introduction of cobalt(II) nitrate strongly affects the Gibbs energies (Table 2): ΔG_a, ΔG_{b_1}, and ΔG_{b_2} increase and the characteristic viscosity decreases, which is due to the lower ability of cobalt(II) to form polymeric structures and to the enhancement of intermolecular interaction forces in solution. Thus, the film-forming capacity is characterized by formation of a microheterogeneous system in the FFS, and this may affect the thickness of the films obtained and their adhesion to a substrate.

Applying an FFS to a substrate and carrying out a thermal treatment yields thin films of zirconium(IV) and cobalt(II) oxides [12]. It has been established in previous studies (X-ray phase analysis) that films with cobalt(II) oxide content below 10 mol % are solid solutions based on the cubic modification of zirconium dioxide, and those with >10 mol % cobalt(II) oxide, a mixture of zirconium(IV) and cobalt(II) oxides [5]. The physicochemical properties of the films obtained are listed in Table 3. The tendency for zirconium to produce 3*D* polymeric structures leads to formation of thicker films. Raising the content of Co(II) oxide yields thinner films and makes lower their adhesion to a substrate, in agreement with the change in the structure of the hydroxo complex and the decrease in viscosity. The less pronounced affinity of cobalt for oxygen and the high extent of intermolecular interactions in solution lead to a poor adhesion of cobalt oxide films to glass substrates.

Table 3. Physical properties of films obtained from FFS based on zirconium(IV) oxochloride and cobalt(II) nitrate (substrate, glass)

CoO, mol %	Refractive index *n*	Film thickness *d*, nm	Adhesion, kg mm^2
0	2.1600	105.0	69.3
10	2.0875	102.5	56.5
20	2.0211	100.2	56.5
60	1.9907	80.9	31.0
80	1.8916	63.1	28.2

The absorption edge of zirconium oxide films lies at 220 nm, which allows their use as cutoff filters that eliminate the hard UV radiation. By changing the relative amounts of zirconium and cobalt oxides, the transmission coefficient of the films in the UV and in the visible can be varied widely (Fig. 4). Introduction of cobalt(II) oxide makes stronger the absorption not only in the UV range, but also in the visible, with the films remaining uniform and homogeneous. In this case, the color of a glass substrate with a deposited film of zirconium(IV) and cobalt(II) oxides changes from transparent to dark brown, which makes it possible to control the intensity of sunlight, obtain coatings with sun-protective effect, and adjust the spectral composition of light sources in the UV range and in the visible [13. 14].

Figure 5 shows how the refractive index of the films depends on their thickness. Films of thickness 50–100 nm have a higher refractive index. Probably, this

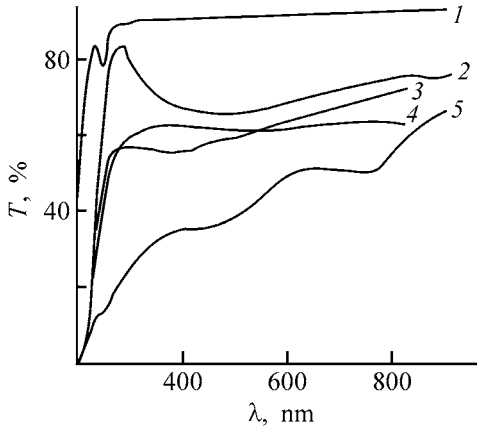

Fig. 4. Transmission spectra of films on quartz substrates. (λ) Wavelength. (*1*) Quartz substrate; films obtained from FFS with varied content of cobalt(II) nitrate (mol %): (*2*) 0, (*3*) 20, (*4*) 30, and (*5*) 50.

Table 4. Influence exerted by the content of cobalt(II) chloride and nitrate on the refractive index of films obtained from FFS based on zirconium(IV) oxochloride (substrate, glass)

CoO, mol %	Refractive index *n* obtained with a salt indicated		CoO, mol %	Refractive index *n* obtained with a salt indicated	
	$CoCl_2 \cdot 6H_2O$	$Co(NO_3)_2 \cdot 6H_2O$		$CoCl_2 \cdot 6H_2O$	$Co(NO_3)_2 \cdot 6H_2O$
20	2.075	2.021	40	2.025	1.881
30	2.089	1.950	50	1.959	1.930

occurs because of the formation of a metastable cubic modification of zirconium dioxide, which may be due to a manifestation of a confinement effect, which leads to stabilization of high-temperature phases in nanosystems [15].

The choice of the starting cobalt(II) salt (chloride, nitrate) has no effect on the chemical stability and color of a film. However, use of cobalt(II) chloride makes the refractive index of the films approximately 4.5% higher (Table 4), which indicates that the films obtained have higher density. This may be due to different compositions of cobalt complexes in the FFS (chloride, mixed-ligand), whose decomposition under thermal treatment affects the structure of a forming oxide film.

CONCLUSIONS

(1) Thin films of the system ZrO_2–CoO were obtained by deposition from film-forming solutions and their physicochemical properties (refractive index, thickness, transmission spectra, adhesion to substrate) were determined.

(2) It was shown that the composition of the starting cobalt salt (chloride, nitrate) and the film thickness affect the refractive index. Films of the system ZrO_2–CoO are promising as coatings protecting biological objects from the UV radiation and as decorative and sunlight-protecting coatings.

Received July 1, 2003

Abstract—A continuous laboratory installation with a horizontal reactor for obtaining carbon nanofibers by catalytic pyrolysis of methane was developed and tested. The conversion of methane at 600°C was studied and the nanofiber output capacity of the continuous installation under the optimal conditions on a Ni–La_2O_3 catalyst was determined.

Carbon nanofibers and nanotubes exhibit a number of properties which have attracted close attention of scientists and technologists in recent years. These materials have a developed surface and possess good mechanical and emission characteristics, are electrically conducting, and can be used as catalyst supports, sorbents, and components of supercapacitors and composites [1, 2]. However, the application of these materials is hindered by their high cost, which is due to the expensiveness of some preparation techniques (e.g., spark procedure [3]) and poor development of simpler methods. Moreover, the overwhelming majority of articles, reports, and patents devoted to synthesis of carbon nanofibers and nanotubes describe batch methods of synthesis, despite that use of continuous techniques makes it possible to diminish dramatically the production cost [4].

The most promising in this regard are pyrolytic methods, which can use low-cost hydrocarbons as starting compounds and do not require high temperature [1, 2, 5]. Fluidized-bed reactors can be used for performing the process. The fluidized-bed reactors for catalytic pyrolysis have been created in China [6–9]; laboratory installations have been tested in the Netherlands [10] and in France [11, 12]. The daily output capacity of the Chinese reactors has been brought to 50 kg of a carbon material containing 70–80% nanotubes.

However, the continuous process in a fluidized bed involves hydrodynamic limitations, since the initial particles of the catalyst are "overgrown" with the product, markedly increase in volume, and their density changes. In the process, the bed volume increases manyfold. The authors of designs mentioned above partly eliminated these limitations by the "nanoagglomeration" method [6–9]. It remains unclear whether or not this could ensure a truly continuous operation. The author of [10] mentioned the difficulties encountered in developing a stable pseudo-fluidized bed in the stage of catalyst reduction by hydrogen and carried out the reduction in a fixed filter bed. Chinese researchers also separated the process into two stages: catalyst reduction and pyrolysis proper, which made the procedure batch-like.

A simpler way to perform continuous pyrolytic synthesis with considerably less pronounced hydrodynamic limitations (or without any limitations at all) consists in use of horizontal tubular reactors with a continuous motion of a bed of a solid material. Preliminary calculations demonstrated that reactors of this kind may have a relatively high output capacity at comparatively small dimensions [13, 14].

The aim of the present study was to test a continuous installation with a horizontal tubular reactor for obtaining carbon nanofibers.

EXPERIMENTAL

Carbon fibers were synthesized by deposition of carbon from the gas phase on a Ni–La_2O_3 catalyst with Ni content of 23 wt %. The catalyst was prepared from $Ni(NO_3)_2 \cdot 6H_2O$ (analytically pure), $La(NO_3)_3 \cdot 6H_2O$, and citric acid (both chemically pure). As starting carbon-containing raw material was

1070-4272/04/7702-0187 © 2004 MAIK "Nauka/Interperiodica"

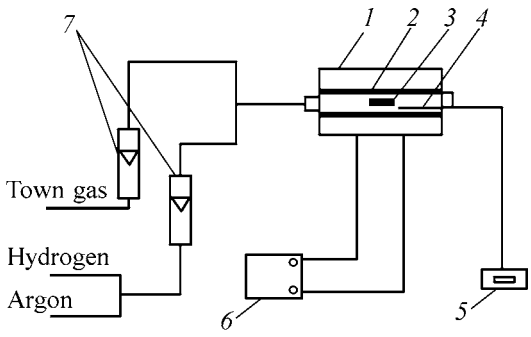

Fig. 1. Schematic of a batch installation for carbon deposition from the gas phase. (*1*) Electric furnace, (*2*) reactor, (*3*) boat with catalyst, (*4*) thermocouple, (*5*) millivoltmeter, (*6*) transformer, and (*7*) rotameters.

used town gas containing 98–99% methane and admixtures of water vapor and mercaptans. Distilled water was used to prepare solutions and wash the product to remove the acid.

The composition of the catalyst and methods of its synthesis were closely similar to those described in [15], with the only exception that the Ni : La atomic ratio was taken to be 5 : 6, against 1 : 2 in [15]. The catalyst was prepared by two procedures. In the first variant, 1.94 g of $Ni(NO_3)_2 \cdot 6H_2O$, 3.45 g of $La(NO_3)_3 \times 6H_2O$, and 2.00 g of citric acid were mixed, and the mixture was dissolved in 20 ml of water. Water was evaporated from the solution, and the residue was dried at 80°C. The resulting powder was calcined in air at 700°C for 5 h to give catalyst no. 1. The second variant of catalyst preparation consisted in burning of the initial mixture. A mixture of nitrates and citric acid was dissolved in water, with 1 ml of water taken per 1.2 g of the mixture, to give a transparent solution. The solution was placed in a furnace heated to 600°C. The product was extracted 15 min after the combustion was complete (catalyst no. 2). To test the continuous reactor, 100 g of the catalyst was synthesized by the second procedure, with the above-mentioned reagent proportions and modes preserved.

An installation comprising a feeding and gas-flow controlling unit, a temperature controlling unit, and a stainless steel reactor was used in the study (Fig. 1). The experiment was performed by passing successively from a small batch reactor (inner diameter 28 mm, length 200 mm) to a larger batch reactor (54 and 400 mm, respectively), and then to a continuous reactor (54 and 1000 mm). A Kipp generator or a cylinder with a nitrogen–hydrogen mixture served as sources of hydrogen. The gas flow rate was monitored with flow meters or rotameters. The temperature in the reactors was monitored with a Chromel–Alumel thermocouple connected to an MPShchPr-54 millivoltmeter with scale-division value of 20°C.

A quartz or ceramic boat with a weighed portion of a catalyst prepared by the first method was placed in batch reactors. The catalyst was reduced in a flow of hydrogen or a nitrogen–hydrogen mixture, with a reactor heated from 20°C to a required temperature and kept for varied time. Then methane was fed into the reactor and, after a prescribed time elapsed, the reactor was cooled in a flow of methane.

The resulting product was weighed and washed with 10% nitric acid at 60°C for 4 h, to remove the catalyst. The purified product was washed with distilled water to remove nitric acid. The amount of the product formed was determined by weighing the samples before and after an experiment.

An X-ray phase analysis was carried out on a DRON-3M diffractometer (Cu_{K_α} radiation, nickel filter, accelerating voltage 20 kV). The morphology and structure of the product were studied with a JEM-100C transmission electron microscope and Tesla BS-340 scanning electron microscope. A derivatographic analysis was performed on an MOM derivatograph (Hungary) at a rate of temperature rise in the range from 1 to 10 deg min^{-1}. The specific surface area of the samples was determined by the method of thermal desorption of nitrogen.

Catalyst samples prepared using different methods were subjected to an X-ray phase analysis. An analysis of the diffraction patterns obtained demonstrated that sample no. 1 is composed of a phase to which a formula $LaNiO_3$ corresponds, with rhombohedral crystal lattice [16]. Catalyst no. 2 contains, in addition to the $LaNiO_3$ phase, trace amounts of other phases. The specific surface area of catalyst nos. 1 and 2 was 36 and 25 $m^2 g^{-1}$, respectively.

Experiments in the small batch reactor at a temperature of 600°C and conditional linear flow velocity of methane of 70 cm min^{-1} (calculated without taking into account the thermal expansion of the gases) with sample no. 1 of mass 0.4 g demonstrated that making longer the process duration leads to a rise in the specific output of the solid product, with this rise terminating in 20–30 min. The catalyst was preliminarily reduced in a flow of the nitrogen–hydrogen mixture, with the reactor heated to 600°C and kept at this temperature for 15 min. The resulting solid product was in the form of bent nanofibers 15–60 nm in di-

ameter (prevalent diameter 25–35 nm), with ~96% purity. Catalyst particles were present at the ends of nearly all the fibers. The final specific output of the fibers was 4.6 g g_{cat}^{-1}.

To determine the dependence of the specific output of fibers on the catalyst bed thickness, different weighed portions of catalyst no. 1 were distributed uniformly over the same area and placed in the reactor (five different samples at a time), with the sample weight increasing or decreasing along the direction of gas flow in the reactor. The experiment was performed at a temperature of 600°C and a conditional linear flow velocity of methane equal to 70 cm min^{-1} in the course of 30 min, with the catalyst preliminarily reduced in a flow of the nitrogen–hydrogen mixture. It was found that this dependence shows an extremum (Fig. 2), with the run of the curve independent of the order in which the samples studied are arranged along the gas flow direction and the maximum reached at a bed thickness of about 1 mm). The rise in the specific output with increasing bed thickness is presumably due to the influence of intermediates formed in methane pyrolysis, and the decrease after reaching the maximum value, to hindered delivery of methane to lower layers of the catalyst bed.

Raising the conditional linear flow velocity of methane within the range 10–30 cm min^{-1} at a catalyst bed thickness of about 1 mm, temperature of 600°C, and preliminary reduction of the catalyst in a flow of H_2 at 600°C for 20 min led to an increase in the specific output, which was as high as 8.8 g g_{cat}^{-1} at a flow velocity of 30 cm min^{-1}. At the same time, raising the flow rate entails a decrease in methane conversion (Fig. 3). The optimal conditional linear flow velocity of methane is 20 cm min^{-1}, at which the specific output is 7.0–8.4 g g_{cat}^{-1}. In this case, the methane conversion is close to 65%.

It is noteworthy that experiments without preliminary reduction of the catalyst yielded the same results. The method used to synthesize the catalyst also affects the specific output and the characteristics of the carbon product only slightly.

The results obtained for the batch reactors were used in testing a continuous reactor (Fig. 4), in which a counterflow motion of gaseous and solid products was organized. The latter were moved by means of vibration.

An output capacity of 5 g h^{-1} or 3.2 g g_{cat}^{-1} h^{-1} was achieved at a temperature of 600°C, conditional linear flow velocity of methane equal to 20 cm min^{-1},

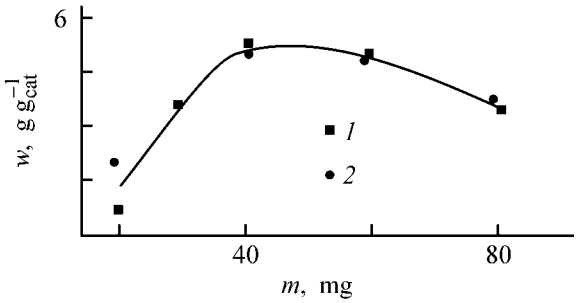

Fig. 2. Specific output *w* of the solid product vs. catalyst mass *m*. Fixed distribution area 220 mm^2, *T* = 600°C, linear flow velocity of methane 70 cm min^{-1}, τ = 30 min. Sample arrangement along the direction of methane flow in the reactor: (*1*) in order of increasing catalyst bed thickness and (*2*) in decreasing order.

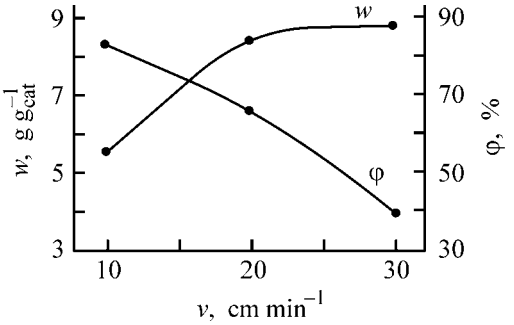

Fig. 3. Effect of the conditional flow velocity *v* of methane on pyrolysis characteristics: specific output *w* and methane conversion φ. τ = 30 min, *T* = 600°C.

catalyst bed thickness of about 1 mm, and a duration of residence of the solid material in the working zone of the reactor equal to 30 min. This value was 10 times that for the batch installations.

The particles of the product obtained in the continuous reactor are rounded and have sizes ranging from 1 to 10 mm. An analysis of their micrographs demonstrated that the particles are constituted by in-

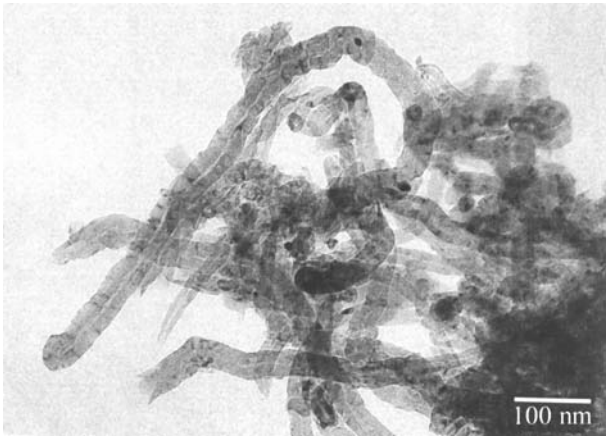

Fig. 5. Micrograph of nanofibers obtained on the continuous installation by pyrolysis of methane on the catalyst Ni–La_2O_3.

terwoven fibers with conical walls (Fig. 5). The fibers show wide scatter in diameter, from 15 to 60 nm, and, occasionally, even 100 nm and more. Catalyst particles not dissolved in washing are contained within some of the fibers.

The specific surface area of the fibers obtained was 105 $m^2 g^{-1}$. The X-ray diffraction patterns of the fibers show a signal corresponding to an angle of 26.25°, which is characteristic of the interplanar spacing d_{002} of multilayer carbon nanotubes and nanofibers, and exceeds somewhat that of graphite.

As follows from the derivatograms obtained, active oxidation of the samples in air begins at a temperature of about 450°C. The content of amorphous carbon and sorbed gases, which are removed at temperatures that are considerably lower than the combustion onset temperature of the product, does not exceed 2% of the original mass of a sample. The incombustible residue, whose content is about 0.5–1.0%, is composed of the catalyst undissolved in washing (nickel particles).

CONCLUSIONS

(1) Pyrolysis of methane was studied in laboratory horizontal tubular batch reactors at a temperature of 600°C and a conditional linear flow velocity of methane equal to 70 cm min^{-1} on a fixed bed of a Ni–La_2O_3-based catalyst preliminarily reduced in a flow of a nitrogen–hydrogen mixture. It was found that the specific output of a solid product reaches its maximum value of 4.6 g g_{cat}^{-1} in 30 min.

(2) It was established, using scanning and transmission electron microscopy, that carbon is deposited onto the catalyst in the form of nanofibers 15 to 60 nm in diameter, with conical walls. Catalyst particles are situated at fiber ends.

(3) It was found that the dependence of the specific output on the catalyst bed thickness shows an extremum, with the highest output capacity at a bed thickness of 1 mm.

(4) It was established that raising the conditional linear flow velocity of methane at a temperature of 600°C and catalyst bed thickness of about 1 mm leads to an increase in the specific output of fibers, which reaches its maximum value at a velocity of 30 cm min^{-1}. In this case, the conversion of methane is 40%. The optimal combination of the output capacity of the catalyst and of the conversion of methane is achieved at methane flow velocity of 20 cm min^{-1}.

(5) The process of pyrolysis in a continuous reactor was tested. The maximum output capacity was 5 g h^{-1} or 3.2 g g_{cat}^{-1} h^{-1}.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Influence Exerted by Pyrite Impurity in the Initial Graphite on Properties of Residual Graphite Hydrosulfates

Abstract—The influence exerted by the particle size and the distribution of sol impurities in the initial graphite, and also by pyrite additives, on the properties of residual graphite hydrosulfates synthesized by oxidation in the CrO_3–H_2SO_4 system was studied.

Graphite hydrosulfate compounds, which expand under heating, are widely used in diverse areas [1–3]. Commonly, compounds of this kind are obtained by liquid-phase chemical oxidation of natural flaked graphite with a strong inorganic oxidant [e.g., HNO_3, CrO_3, $K_2Cr_2O_7$, $(NH_4)_2S_2O_8$, H_2O_2, and O_3] in a concentrated sulfuric acid to give a graphite hydrosulfate $C_{24n}^{+} \cdot HSO_4^{-} \cdot mH_2SO_4$, where n is the stage of the graphite intercalation compound (number of graphene layers between two adjacent intercalate layers). Further, the resulting graphite hydrosulfate is commonly treated with water and dried [4]. The final product is residual graphite hydrosulfate (RGH), a compound in which the sulfuric acid molecules solvating a hydrosulfate anion in the interlayer space of the graphite matrix are replaced with water molecules.

Data on the influence exerted by sol impurities in the initial natural flaked graphite on the expansion coefficient K_{sw} of RGH obtained from it are scarce. In all probability, this is due to the fact that the RGH produced is mostly intended for fabrication of flexible sheet graphite, with thermally or chemically decalcified natural flaked graphite commonly used as raw material. Another possible reason is that a large excess of oxidant and sulfuric acid with respect to graphite has been used previously to perform oxidation of the initial graphite in RGH production. In these conditions, the presence of sol impurities has virtually no effect on the K_{sw} of the final product.

Recently, a number of economical high-tech methods for manufacture of RGH have been developed, in which the consumption of reagents in production of graphite hydrosulfate (GH) is extremely low, i.e., less than 100 parts (by weight) of oxidant and concentrated sulfuric acid per 100 parts by weight of initial graphite. Such low-consumption methods have been developed, in particular, for the intercalating systems HNO_3–H_2SO_4 [5] and CrO_3–H_2SO_4 [4, 6, 7]. For the latter system, it was of interest to study the influence exerted by the particle size and ash content of the initial natural graphites on the course of oxidation and on the characteristics of the resulting product.

As raw material for synthesis of RGH were used samples of GT-1 [GOST (State Standard) 4596–75], GL-1 (GOST 5279–74), and GE-1 (GOST 7478–75) natural flaked graphites from the Zaval'evskoe deposit, differing in the sieve analyses and contents of sol impurities. The granulometric composition and ash content of the natural graphite samples conformed to GOST 17818.2–90 and GOST 17818.4–90, respectively. A FRITSCH GMBH Analysette 3 vibration sizing screen was used. A chemical analysis of sol residues obtained by heating of the initial graphite samples in air at 900°C to constant mass was done according to GOST 2642.0-14–86. Graphite hydrosulfates were synthesized using a 50% aqueous solution of chromium(IV) oxide (ρ = 1.501 g cm^{-3}) and chemically pure sulfuric acid with 95.8 wt % pure substance (ρ = 1.835 g cm^{-3}).

The initial graphite and its fractions were oxidized under the standard conditions in a cylindrical glass reactor equipped with a T-shaped stainless steel stirrer. The process was performed at room temperature without forced heating or cooling. The reactor was charged with 25 g of graphite powder, the stirrer was switched on, and 2.5 cm^3 of chromium(VI) oxide aqueous solu-

Initial graphite		5.68		9.68		10.43

tion was added. After the graphite was stirred with an aqueous solution of oxidant for 10 min, 12 cm^3 of sulfuric acid was added, and the mixture was continuously stirred for 10 min more. Then, 1.5 dm^3 of water was added to the oxidized graphite, and the resulting mixture was allowed to stay for 24 h, for hydrolysis to occur. The solid phase was filtered in a vacuum of a water-jet pump and washed with water to pH 5–6. The washed product was dried at 100–110°C to moisture content not exceeding 1.0 wt %.

The influence exerted by pyrite additives in the initial graphite on the properties of the RGH obtained were studied with natural pyrite from the Uchaly deposit (Ural, Russia). The pyrite fraction with 97 wt % pure substance and 0.074 + 0.043-mm particles was used. A weighed portion of pyrite was added to the initial graphite, the mixture obtained was stirred for 10 min, and RGH was synthesized under the standard conditions.

For the RGH samples synthesized, the yield and the expansion coefficient at 500°C, K_{sw}^{500} ($cm^3\ g^{-1}$), were determined. The intercalate content of the product, m_i (wt %), was calculated from the product yield on the assumption that phase oxidation of graphite does not occur under the synthesis conditions [8], i.e., the whole amount of carbon passes from the graphite matrix into the final product.

The expansion coefficient was calculated by the following procedure. A weighed portion (m = 0.2–0,3 g) of the product was introduced into a stainless steel container, which was preliminarily installed in a muffle furnace preheated to 500°C, and was kept there for 5 min till complete expansion. The container with the thus expanded graphite was withdrawn from the furnace, its contents were carefully transferred to a volumetric glass cylinder, and the volume V (cm^3) occupied by the expanded graphite was measured. The expansion coefficient was calculated from the expression $K_{sw}^{500} = V/m$ as the arithmetic mean of three parallel measurements.

The granulometric composition, content of sol impurities, and their fractional distribution for natural flaked graphite of the brands studied are listed in Table 1, and the chemical composition of the ash residues in GT-1, GE-1 and GL-1 graphites, in Table 2.

The dependence of the expansion coefficient of RGH on the average size of the initial graphite particles used for RGH synthesis is shown in Fig. 1. If the particles of the initial graphite have the same size, the expansion coefficients of the RGH samples synthesized from different brands of natural graphites virtually coincide. To a first approximation, two linear portions, 0–0.2 and 0.2–0.5, can be distinguished in

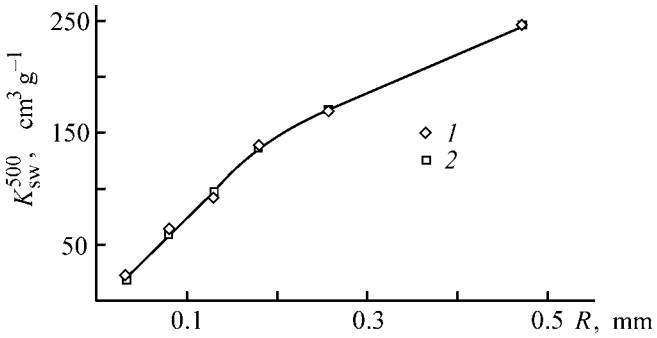

Fig. 1. Expansion coefficient K_{sw}^{500} of residual graphite hydrosulfates vs. the average particle size R of the initial graphite used for its synthesis. Initial graphite: (*1*) GL-1 and (*2*) GE-1.

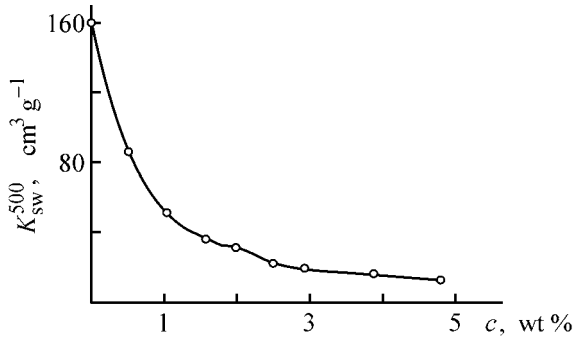

Fig. 2. Expansion coefficient K_{sw}^{500} of residual graphite hydrosulfates vs. the pyrite content c in its mixture with GT-1 initial graphite.

the dependence in question, with the slope of the first portion exceeding that of the second.

It may be assumed *a priori*, that, in the course of graphite intercalation, particles of different sizes interact with the intercalating solution independently. In this case, the expansion coefficient should be an additive quantity, i.e., the relation $K_{sw} = \Sigma(K_{swi}\alpha_i)$ should be valid for the overall expansion coefficient of RGH. In this relation, K_{swi} is the expansion coefficient of the RGH sample obtained from *i*th graphite fraction, and α_i is its share in the graphite. Unexpectedly, the additivity law is not obeyed for the GL-1 and GE-1 initial graphites. The experimental expansion coefficients were found to be substantially lower than the calculated additive values (Table 3). Successive removal of fractions from the initial graphite showed that, when the finest fraction (particle size less than 0.063 mm) is removed, the additivity law is fulfilled completely, i.e., the calculated values well coincide with the experimental data (Table 3). This indicates that all the graphite fractions, except that with particle size less than 0.063 mm, exhibit independent behavior in the course of intercalation. However, the presence of this fine fraction makes smaller the expansion coefficient of RGH obtained from coarser fractions. Such a behavior of the fine fraction may be due to the fact that its ash content exceeds by a factor of 2–4 that in other fractions (Table 1).

Table 3. Experimental and calculated expansion coefficients of RGH samples synthesized from Gl-1, GE-1, and GL-1 initial graphites and from those with the <0.063-mm fraction removed

Graphite	K_{sw}^{500}, cm^3 g^{-1}	
	Experimental	Calculated
Initial:		
GL-1	62	92
GE-1	45	88
Without <0.063-mm fraction		
GL-1	103	104
GE-1	105	107

Analysis of the mineral composition of sol residues of the graphite samples studied (Table 2) suggests that such a behavior of the fine fraction is associated with the increased content of pyrite in it. This assumption is confirmed by the high content of iron oxide (11–16 wt % Fe_2O_3) in the sol residue. Pyrite is a strong reducing agent: oxidation of 1 mol of pyrite requires up to 6 mol of chromium(VI) oxide. This means that, under the synthesis conditions used in this study, virtually the whole amount of the oxidant may be spent for oxidation of pyrite present in the finest graphite fraction. As a result, a considerable amount of oxidant introduced into the reaction zone is spent for side processes, rather than for the main reaction of graphite intercalation. Removal of the finest fraction from the initial graphite decreases the ash content in it by 30–50 wt %. This leads to a virtually twofold increase in the expansion coefficient (Table 3) [9] and to fulfillment of the additive law mentioned above.

To confirm the above argumentation concerning the negative influence exerted by pyrite present in the initial graphite on the formation of graphite hydrosulfate, a number of artificial mixtures of GT-1 graphite with a fine-grained natural pyrite were oxidized. GT-1 graphite was chosen because it is virtually free of the fine fraction (Table 1).

As can be seen from the data obtained (Fig. 2), the intercalate content in the final product and the expansion coefficient steeply decrease as the content of pyrite in the mixture with initial graphite grows. On adding even about 0.5 wt % pyrite to graphite,

the expansion coefficient of RGH decreases by approximately a factor of 2.

CONCLUSIONS

(1) In synthesis of residual graphite hydrosulfate in the CrO_3–H_2SO_4 system, the expansion coefficient grows with increasing particle size of the initial graphite.

(2) The sol impurities are distributed in natural flotation graphites nonuniformly. Approximately half of sol impurities is concentrated in particles less than 0.063 mm in size.

(3) Owing to the increased content of sol impurities, the fine graphite fraction (≤0.063 mm) suppresses the intercalation of coarser particles.

(4) Removal of particles less than 0.063 mm in size from the initial graphite leads to an increase in the expansion coefficient of the final product.

(5) The main mineral component of graphite, which is responsible for the consumption of an oxidant in the side reactions and for suppression of the graphite intercalation, is pyrite. The presence of even a minor amount of pyrite in the reaction mass results in a sharp decrease in the expansion coefficient of the residual graphite hydrosulfate.

ACKNOWLEDGMENTS

The authors are grateful to V.A. Sapunov for the provision of a sample of natural pyrite.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Phase Composition on Sulfuric Acid Leaching of Tantalum-containing Alloys

S. A. Krasikov, V. M. Chumarev, M. N. Sviridova, L. Yu. Udoeva, M. V. Timofeev, A. V. Safonov, V. D. Fedorov, and O. A. Arzhatkina

Received July 3, 2002; in final form, September 2003

Abstract—Phase composition of iron-based tantalum–niobium alloys (Ta 2–5, Nb 3–6, Si up to 12, C 1.4–2.4%) was studied. The kinetics of leaching of ferroalloys with H_2SO_4 aqueous solutions and with mixtures of sulfuric and hydrofluoric acids was considered. The conditions of hydrochemical treatment of the alloys, which make it possible to concentrate niobium and tantalum in the solid residue through dissolution of up to 94% of Fe, 90% of Mn, and 70% of Si, were found.

In pyrometallurgical dressing of low-grade tantalum–niobium raw materials of complex composition, rare metals are isolated into an iron-based alloy [1, 2]. Such alloys can be converted to chemical tantalum-niobium concentrates by their direct leaching with mineral acid solutions [1]. However, the processes of acid dissolution of such alloys have been insufficiently studied.

Among the known studies are those devoted to a formal-kinetic description of leaching of a carbidized tantalum–niobium ferroalloy with a mixture of hydrochloric and nitric acids [3] and to analysis of the phase composition of the products formed in decomposition of niobium-containing ferrophosphorus with oleum [4]. According to published data, the intensity and the order of dissolution of alloy components strongly depend on the composition of the metal phase, temperature, and reagent expenditure.

The aim of this study was to analyze the phase composition of silicon-containing iron-based tantalum–niobium alloys and to determine the optimal conditions of their leaching with solutions of H_2SO_4 and mixtures of H_2SO_4 and HF.

EXPERIMENTAL

The chemical composition of the alloys under study is illustrated in Table 1. The alloys were powdered by spraying a liquid metal with compressed air [5]. This technique is effective in alloy preparation for hydrochemical treatment, because it is insensitive to mechanical properties of a metal (hardness and ductility) and yields powders with grain size of 80 to 150 μm.

An examination of alloy particles on a Cameca X-ray fluorescence microanalyzer demonstrated that the constituent elements are selectively distributed between two phases (Table 2). The first phase ("base") contains mainly iron, manganese, and silicon. In the second phase (carbide), which forms irregularly shaped inclusions 3–25 μm in size, the total tantalum, niobium, and tungsten constitute more than 99%.

The results of an X-ray diffraction analysis were in agreement with the data of the X-ray fluorescence microanalysis. According to the X-ray diffraction patterns obtained on a DRON-2.0 diffractometer, iron and manganese are contained in the samples as metals and silicides, and niobium and tantalum, as carbides. The revealed phase distribution of elements and the known resistance of tantalum and niobium carbides to mineral acids [6] confirmed that tantalum and niobium can be concentrated by a hydrochemical technique in a solid residue, a carbide cake.

Alloys were leached in a fluoroplastic temperature-controlled reactor with a mechanical stirrer and a reflux condenser. The stirring rate was 95 rpm. The pulp formed in leaching was filtered, and the solid residue was washed with water and dried. The resulting cakes were analyzed for the content of iron, silicon, tantalum, niobium, and other elements contained in the alloys under study.

It was found in leaching of alloy no. 1 with sulfuric acid solutions that, at a solid-to-liquid ratio s : l = 1 : 5, varying the H_2SO_4 concentration in the range from 50 to 300 g l^{-1}, leaching duration from 2 to 6 h, and temperature from 60 to 100°C affects the dissolution process only slightly. The degree of leaching, α (%), expressed as a relative change in the weight of a solid, $\alpha = 100(G_0 - G)/G_0$, does not exceed 10%, with mainly iron dissolved. The pulps formed are poorly filterable owing to the gelation of the silicic acid. Addition of oxidizing agents, H_2O_2 or HNO_3, to the solution scarcely affects the value of α. Moreover, addition of nitric acid results in an appreciable decrease in the concentration of iron in the solution.

Additional grinding of alloy nos. 1 and 2 in a vibratory mill to a grain size of 20–40 μm made it possible to increase the degree of their leaching (concentration of H_2SO_4 300 g l^{-1}, s : l = 1 : 10, T = 100°C, τ = 6 h) to 20 and 50%, respectively (Fig. 1, curves *1* and *2*). Under these conditions, but without additional grinding, the degree of leaching of alloy nos. 3 and 4 was 70–80%. It should be noted that the reaction of the alloy with the H_2SO_4 solution is the most intensive during the first 60 min. By the end of this period, the degree of leaching at 100°C was 9% for alloy no. 1, 43% for alloy no. 2, and 60–70% for alloy nos. 3 and 4.

The temperature dependences of the leaching rate $\Delta\alpha/\Delta\tau$ during the first 60 min of the process at

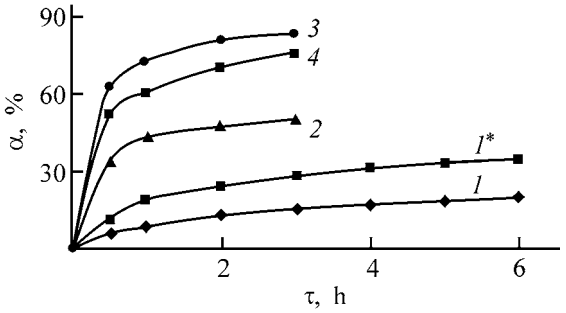

Fig. 1. Kinetics of leaching of tantalum–niobium ferroalloys in sulfuric acid solutions at 100°C. (α) Degree of leaching and (τ) time. Grain size (μm): (*1*, *2*) 20–40, (*1**) less than 20, and (*3*, *4*) 80–100. *Digits at the curves* correspond to alloy numbers in Table 1; the same for Fig. 2.

Table 3. Leaching of alloy no. 4 with H_2SO_4 solutions (T = 100°C, s : l = 1 : 10, τ = 1 h)

Experiment no.	Grain size, μm	H_2SO_4, g l^{-1}	α, %	Content in solid residue, wt %		Degree of recovery into solution, %	
				Fe	Mn	Fe	Mn
1	<30	50	15	43.2	16.3	39.4	32.0
2	<30	150	60	27.9	5.3	81.6	89.6
3	<30	300	74	13.3	–	94.3	–
4	80–150	150	41	28.5	–	72.3	–
5	80–150	300	60	13.9	5.7	90.8	88.8

80–100°C were described using the Arrhenius equation (Fig. 2).

The apparent activation energies E^* of leaching were found to be 32.1 and 29.9 kJ mol^{-1} for alloy nos. 1 and 2, respectively; and less than 15 kJ mol^{-1} for alloy nos. 3 and 4. These values indicate that the process occurs in the intermediate region, which is typical of complex heterogeneous systems. The diffusion hindrance is predominant in the case of alloy nos. 3 and 4, and chemical resistance, which grows with increasing silicide content [7], dominates for alloy nos. 1 and 2.

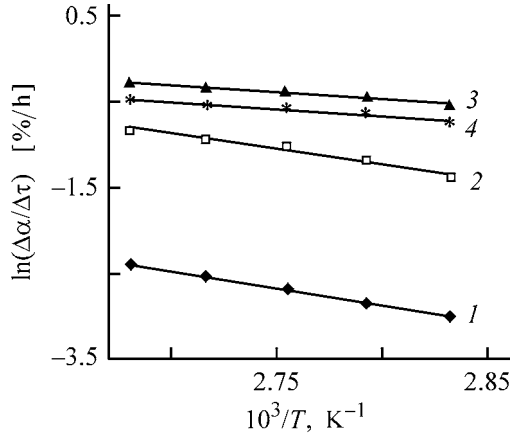

Fig. 2. Effect of temperature T on the rate of alloy leaching, $\Delta\alpha/\Delta\tau$.

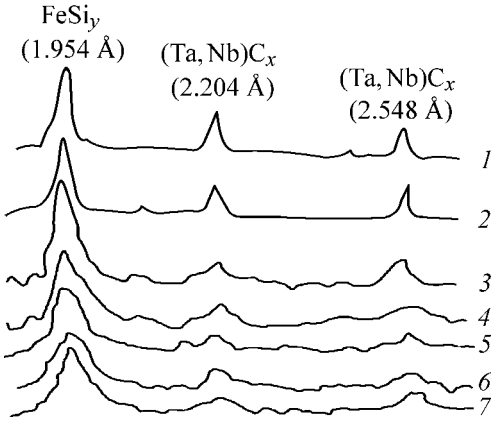

Fig. 3. X-ray diffraction patterns of alloy no. 1 ground to varied extent. Grain size (μm): (*1*) 150 (liquid-phase dispersion), (*2*) 20–40 (vibratory mill) and (*3–7*) <20 (planetary mill). Duration of treatment in a planetary mill (min): (*3*) 1, (*4*) 3, (*5*) 5, (*6*) 6, and (*7*) 9.

To raise the process rate, alloy no. 4 was ground in a vibratory mill to a particle size ≤30 μm, which resulted in an increase in the degree of leaching by 14–19%. The recovery of iron and manganese into solution was 90–94%, whereas rare metals and silicon were concentrated in the solid residue (Table 3).

The influence exerted by the duration of mechanical activation on the process of leaching with sulfuric acid solutions was studied using samples of the most acid-resistant alloy no. 1. A significant disruption of intercrystallite bonds in an alloy treated in a planetary mill, compared with the initial state, were revealed by X-ray phase analysis (Fig. 3). The number of active centers on the particle surface increases as the duration of activation in a planetary mill is made longer, which is manifested in the X-ray patterns as "smoothening-out" of the peaks related to iron silicides. The most pronounced changes were observed when the particle size was reduced to 20 μm and less. As can be seen from Fig. 1 (curve *1**) acid treatment of samples ground in a planetary mill for 8–12 min results that the degree of leaching increases to 35%.

Thus, the study of sulfuric-acid leaching demonstrated that the presence of silicon in an amount exceeding 10% prevents satisfactory dissolution of the components of the alloy even when it is finely ground. This hinders practical use of sulfuric leaching of alloys with high content of silicon.

In this context, it was of interest to study the leaching of alloy nos. 1 and 2 with a mixture of H_2SO_4 and HF. It was found that raising the concentration of hydrofluoric acid in the mixture H_2SO_4 + HF does not

Table 5. Leaching conditions of tantalum–niobium ferroalloys (T = 80–100°C)

Silicon content in alloy, wt %	Treatment procedure
10–15	Grinding in a planetary mill to <20 μm grain size; concentration, g l^{-1}: 150–300 H_2SO_4, 20–40 HF
5–10	Vibratory grinding to a <70 μm grain size; concentration, g l^{-1}: 150–300 H_2SO_4, 5–10 HF
<5	Dispersion of liquid alloys or crushing to <200 μm; concentration of H_2SO_4 150–300 g l^{-1}

intensify appreciably the leaching of ground alloys with particle size of 20–40 μm (Fig. 4). The effect is enhanced as the concentration of H_2SO_4 is raised from 50 to 300 g l^{-1} (Table. 4).

Silicon passes into the liquid phase in considerable amounts at HF concentrations of 20 g l^{-1} or more. The maximum recovery of silicon into solution in leaching of alloy no. 1 is about 70%.

As expected, the recovery of rare elements into solution in all the experiments was not greater than 0.4%, and their content in solid residues increased as the duration of alloy treatment was prolonged and the concentration of acid solutions was made higher. For example, a 6-h leaching of alloy no. 2 with a mixture of H_2SO_4 and HF resulted in that the content of Ta and Nb in the cakes formed was 27.4 and 23.8%, respectively.

The conditions under which a carbide cake 3–5-fold enriched with tantalum and niobium is obtained are listed in Table 5.

The experimental data on leaching of alloy nos. 1, 2 in mixtures of sulfuric and hydrofluoric acids indicate that the components interact in a certain order: fluoride ions react with iron and manganese silicides to form readily soluble compounds [8] only after removal of metal iron and manganese from the alloys. Hence, the treatment of the alloys should be started with a H_2SO_4 solution only, and continued with a

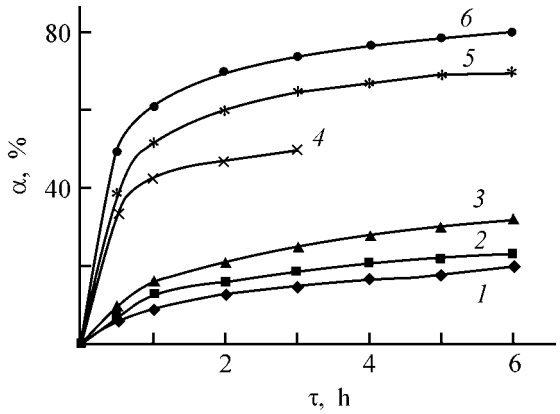

Fig. 4. Degree α of leaching of alloy nos. 1 and 2 with a mixture of H_2SO_4 and HF at various HF concentrations vs. time τ. H_2SO_4 concentration 300 g l^{-1}. HF concentration (g l^{-1}): (*1*, *4*) 0, (*2*, *5*) 5, and (*3*, *6*) 10. Alloy: (*1*–*3*) no. 1, and (*4*–*6*) no. 2.

mixture of H_2SO_4 and HF, which should appreciably decrease the consumption of hydrofluoric acid for leaching of high-silica alloys.

The expenditure for leaching can be diminished by a partial replacement of hydrofluoric acid with fluorine-containing compounds that form complex ions $[MF_x]^{n-}$ (M = Si, Fe, etc., $x > 1$). The experiments performed in this study demonstrated that, when H_2SiF_6 (10% relative to the alloy mass) is employed as a fluorine-containing reagent, the degree of leaching is virtually the same as in the case when an equivalent (in terms of fluorine ions) amount of hydrofluoric acid is used.

CONCLUSIONS

(1) The main phases of tantalum–niobium ferroalloys are carbides of rare metals, metallic iron and manganese, and their silicides. Tantalum, niobium, and tungsten constitute more than 99% in the carbide phases, whereas the total content of other elements is not greater than 1%.

(2) Leaching of tantalum-niobium-silicon-containing ferroalloys with sulfuric acid solutions occurs in the outer-diffusion region. As the silicon content in an alloy increases, its chemical resistance grows, which is due to the higher strength of chemical bonding in silicides.

(3) Extra grinding and addition of hydrofluoric acid and(or) fluorine-containing reagents to a sulfuric acid solution intensify the leaching of alloys that contain more than 5% Si.

(4) Leaching with a mixture of sulfuric and hydrofluoric acids makes it possible to transfer into solution up to 94% of iron, 90% of manganese, and 70% of silicon and to obtain a product 3–5-fold enriched with Ta and Nb, depending on the initial content of silicon in the alloys.

Received September 11, 2003

Abstract—Elemental, chemical, phase, and radionuclide composition of magnesium-containing slimes formed in the electrolytic production of metallic magnesium was studied. The binding properties of the slime were analyzed and the possibility of its use as a chloromagnesian binder was demonstrated.

One of ecological problems of large Russian industrial centers is the increasing amount of nonutilizable solid waste. Its storage and disposal have negative ecological, economical, and social impacts on both the environment and the human health.

Among industrial wastes of plants of nonferrous metallurgy, magnesium-containing slimes formed in the production of metallic magnesium are of special interest from the viewpoint of their being involved into further technological processing to give technical-grade products [1, 2]. The electrolytic production of magnesium involves a two-stage dehydration of carnallite:

$$KCl \cdot MgCl_2 \cdot 6H_2O = KCl \cdot MgCl_2 \cdot 2H_2O + 4H_2O$$

(first stage, 90°C),

$$KCl \cdot MgCl_2 \cdot 2H_2O = KCl \cdot MgCl_2 + 2H_2O$$

(second stage, 240°C).

When carnallite is fused and the melt is heated in chlorinators to 750–800°C, the remaining water is removed. In this case, $MgCl_2$ is partly hydrolyzed to give MgO, which is separated from the melt by settling. The slime formed in the process is poured into an ingot mold and, after cooling, stored in the form of a monolithic stock in slime pits.

One of possible ways to utilize slime consists in its reprocessing into a chloromagnesian binder. Inorganic binders with magnesian type of hardening are known [3, 4] to have good physicotechnical characteristics. They have found wide application in the metallurgical, chemical, and refractory branches of industry. Recently, magnesian binders have also been used to prepare wood-mineral composite construction materials [5, 6]. However, the increased sensitivity of the technology of magnesian binders to the activity of magnesium oxide and also the insufficient knowledge of the mechanisms by which basic processes of magnesian stone formation occur require special investigations of magnesium-containing waste as a raw material of technological origin.

This communication reports the results obtained in chemical, X-ray, and gamma-spectrometric studies, which make it possible to assess the prospects for processing of slimes into powders of magnesian binders that can be used in production of composite building materials, along with caustic magnesites.

EXPERIMENTAL

The study was performed with slime samples from a magnesium production shop (AVISMA Closed Joint-Stock Company, Berezniki). The content of Mg, Ca, K, Na, Cl, Fe, Si, Al, and Ba in the slime was determined quantitatively by atomic-absorption photometry, spectrophotometry, and plasma photometry. The content of magnesium-containing compounds (MgO, $MgCl_2$) and alkali metal chlorides (NaCl and KCl)

Table 1. Mass fraction of chemical compounds in slime samples under study

Sample no.	Chemical analysis				X-ray phase analysis		
	content, wt %						
	MgO	$MgCl_2$	KCl	NaCl	MgO	$KMgCl_3 \cdot 6H_2O$	NaCl
1	1.72	47.36	18.13	2.73	0.0	78.2	5.9
2	35.05	27.28	10.00	1.72	31.4	64.7	3.8
3	56.65	18.10	6.28	1.08	72.6	26.1	1.3
4	42.60	22.46	16.58	2.05	63.3	34.6	2.2

was found quantitatively by chemical and X-ray analyses. The phase composition of the slime was determined by X-ray phase analysis. The samples were tested for radioactivity by gamma spectrometry on an SEG-1P γ-spectrometer. The specific effective activity A_{eff} of natural radionuclides was calculated by the formula

$$A_{eff} = A_{Ra} + 1.31A_{Th} + 0.085A_K,$$

where A_{Ra}, A_{Th}, A_K are the specific effective activities of radium, thorium, and potassium, respectively.

The binding properties of the slime were studied by the procedure recommended by GOST (State Standard) 310.3–76, and the compression strength of the magnesian cement obtained from the slime, in accordance with GOST 310.4–81. A slime with a particle size of 100–150 μm was used in the experiments. To prepare a magnesian paste, the slime was mixed with water, since carnallite was contained in the slime. The thickness of the magnesian paste was determined with a Vicat device.

Preliminary elemental analysis demonstrated that the slime is mainly composed of Mg, O, Cl, K, and Na.

The main chemical compounds contained in the slime are MgO, $MgCl_2$, KCl, and NaCl; their total content is 98.4 wt %. The accompanying admixtures of Si, Fe, and Al oxides, and Ca and Ba chlorides, constitute 4×10^{-1}, 2.7×10^{-1}, 9×10^{-2}, 2×10^{-3}, and 4.3×10^{-4} wt %, respectively. Up to 80 wt % falls on main magnesium-containing components (MgO, $MgCl_2$), which are involved in the reactions of magnesian stone formation and hardening.

With account of the existing industrial technology for casting of the slime melt, it would be expected that the distribution of chemical compounds along the height of an ingot being formed in the mold is nonuniform. To verify this assumption, slime was sampled along a vertical cross-section of its ingot, approximately from each third of its height. Representative samples were taken from each part of the slime ingot in equal amounts (by mass) and carefully averaged. The content of magnesium oxide and magnesium, potassium, and sodium chlorides was determined quantitatively by chemical and X-ray phase analyses (Table 1).

The results of chemical analysis (Table 1) point to a nonuniform distribution of the active components MgO and $MgCl_2$ (main components involved in the formation of Sorel cement) along the height of the slime ingot formed. As the temperature of the melt decreases, the water-soluble components ($MgCl_2$, KCl, and NaCl) are "salted out" in the upper part of the slime ingot (sample no. 1). In the bottom part of the ingot (sample no. 3), the mass fraction of MgO is the largest. In the middle part (sample no. 2), the chemical composition is represented by magnesium oxide and magnesium chloride, their content being 35.05 and 27.28 wt %, respectively. The mass ratio MgO : $MgCl_2$ in this sample is 1 : 0.7, which is close to the optimal ratio of these components in mixing of caustic magnesite with an aqueous solution of $MgCl_2$ to obtain magnesian cement [7].

The use of the slime as a chloromagnesian binder requires its crushing and subsequent grinding to an apprpriate degree of dispersion. In the process, the chemical composition will also be averaged over the whole volume. A chemical analysis demonstrated that the averaged slime sample (sample no. 4) contains MgO and $MgCl_2$ in a mass ratio that allows its use as a magnesian binder and a mixing agent simultaneously.

An X-ray phase analysis of the slime samples not only confirmed the nonuniform distribution of chemical components along the height of a slime ingot (Table 1), but also made it possible to determine

Table 2. Specific activity of natural radionuclides in the slime

Sample	Specific activity, Bq kg^{-1}			A_{eff}, Bq kg^{-1}	Sample	Specific activity, Bq kg^{-1}			A_{eff}, Bq kg^{-1}
	A_{Ra}	A_{Th}	A_K			A_{Ra}	A_{Th}	A_K	
1	<10	<15	4800 ± 500	430	2	<10	<15	3000 ± 500	290

their phase state in the slime (Fig. 1). The samples under study contain chemical components as three individual phases: magnesium oxide MgO, carnallite $KMgCl_3 \cdot 6H_2O$, and sodium chloride NaCl. Sample no. 1 contains carnallite hexahydrate $KMgCl_3 \cdot 6H_2O$ (*d* 0.478, 0.386, 0.360, 0.332, 0.303, 0.297, 0.293, 0.239, 0.234, and 0.201 nm), anhydrous $KMgCl_3$ (*d* 0.349, 0.285, 0.248, and 0.174 nm), and NaCl (*d* 0.282, 0.199, and 0.163 nm) (Fig. 1, curve *1*). Sample nos. 2–4 also contain the MgO phase, as evidenced by the diffraction lines with *d* 0.242, 0.211, and 0.148 nm (Fig. 1, curves *2–4*).

The contents of individual phases in the slime samples under study are different, in good agreement with the data of chemical analysis.

The slime was found to be nontoxic, and ecologically and radiation safe as regards its chemical and radionuclide composition.

According to the specific effective activity of natural radionuclides (A_{eff} = 430 Bq kg^{-1}) contained in the slime, it belongs to class-II materials (Table 2, sample 1) and can be used for manufacture of construction materials suitable for industrial use and for construction of roads in residential areas and zones of future building.

A mixture of the slime with dispersed organic fillers of vegetable origin and, in particular, with shredded wood wastes (sawdust and shavings) in a mass ratio of 1 : (1–0.8) (Table 2, sample 2) belongs to class-I materials as regards the value A_{eff} = 290 Bq kg^{-1}. According to GOST 30 108–94, such a mixture can be used as a wood-mineral composite in manufacture of materials suitable for construction of residential and public buildings.

A study of hardening of magnesian cement showed that the setting time of the cements depends on the amount of water added: as the solid : liquid ratio decreases, the setting time becomes shorter. At the commonly accepted optimal ratio s : l = 1 : (0.42–0.43) (42–43 ml of water are added per 100 g of the slime) the initial and the final time of setting of magnesian cement was 20 and 40 min, respectively.

The dependence of the compressive strength of the samples under study on the amount of mixing water is shown in Fig. 2.

The highest compressive strength after 3 and 7 days of hardening was exhibited by samples formed from a magnesian paste with s : l = 1 : 0.37. In this case, the compression strength was 72.3 and 89.1 MPa,

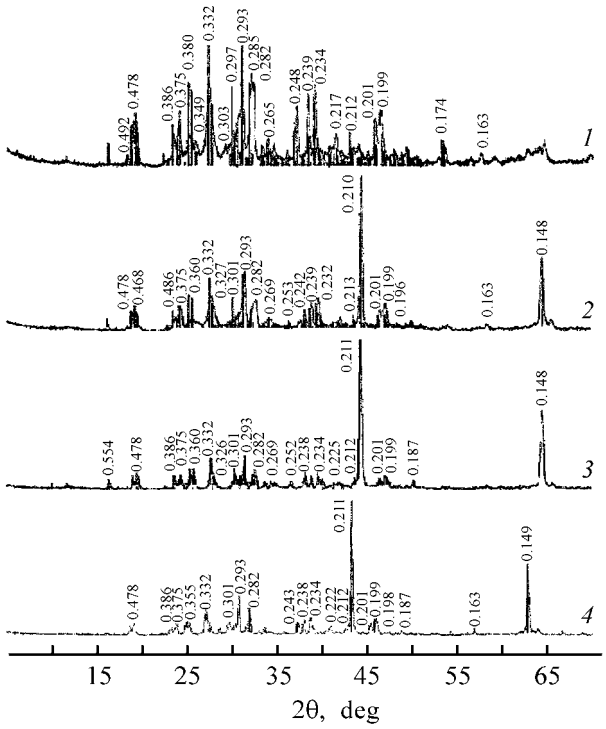

Fig. 1. X-ray diffraction patterns of slime samples taken at different heights of the vertical cut of an ingot. (2θ) Bragg angle. (*1*) Upper part, (*2*) middle part, (*3*) bottom part, and (*4*) thoroughly averaged sample.

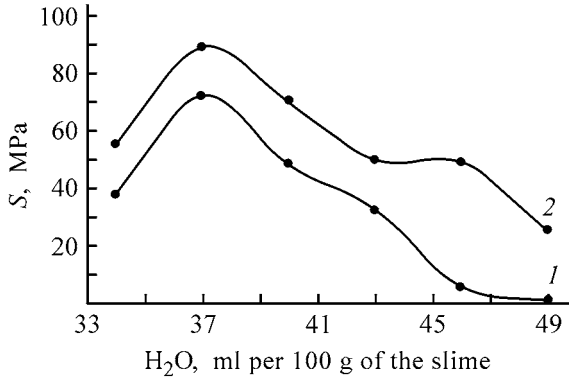

Fig. 2. Compressive strength *S* of the magnesian stone formed in the slime–H_2O system vs. the amount of water added. Time of hardening (days): (*1*) 3 and (*2*) 7.

respectively; however, the setting time of these mixtures was short (<5 min). At s : l = 1 : 0.43, the compressive strength of the samples after 3 and 7 days of hardening was 32.4 and 50 MPa, which is somewhat lower than the compressive strength of the samples formed from caustic magnesite.

The strength characteristics of the magnesian stone obtained from the slime can be improved by adding caustic magnesite to the chloromagnesian mixture. Adding even minor amounts (8–10%) of a PMK-75 caustic magnesite to the slime accelerated the formation of the oxochloride phase and increased the mechanic strength of the magnesian stone. For example, adding 8 and 10% caustic magnesite with s : l = 1 : 0.43 raised the strength of the magnesian stone formed after 28 days of hardening to 59.4 and 70.9 MPa, respectively, in good agreement with the strength characteristics of samples of caustic magnesite mixed with a $MgCl_2$ solution [8].

The microstructure of the solidified magnesian stone formed from the slime is that of a dense conglomerate with reduced porosity.

CONCLUSIONS

(1) Magnesium-containing metallurgical wastes formed in manufacture of metallic magnesium are a valuable raw material of technological origin for production of a magnesian binder.

(2) In mixing of the slime with water, hardening occurs rather actively by the reaction of magnesium oxide and chloride contained in the slime. However, the resulting magnesian stone has a reduced compressive strength, which can be substantially raised by addition of caustic magnesite. Adding caustic magnesite in an amount of 10% makes it possible to obtain samples of a construction material with a compressive strength of up to 70.9 MPa at a high hardening rate.

Abstract—The possibility of synthesizing composite sorbing materials on the basis of porous carbon powders was studied. The sorption and porosimetric characteristics of the composites were examined.

The rapid development of sorption technologies imposes increasingly stringent requirements upon the properties of sorbents: adsorption selectivity, physicochemical and physicomechanical characteristics. The acute need for widely diverse and highly efficient adsorbents becomes particularly pressing in connection with the problems of purification, concentration, separation, and accumulation of technological gases in modern high-output processes. The possibilities of varying widely the required sorbent properties are opened up by the creation of the so-called composite sorbing materials (CSM) on the basis of highly porous carbon powders with addition of a binder [1–3].

By distributing and binding monodisperse powders in a certain way, in conformity with the closest-packing law, one can obtain sorbing carbon materials with high specific pore volume of ~0.5 $cm^3\ cm^{-3}$ and narrow distribution of this volume over equivalent radii [3–6].

Creating mixed sorbents on the basis of finely ground porous powders, formed as by-products at plants that manufacture activated carbon, and ultradispersed additives makes it possible to obtain novel CSM, which contain particles with narrow size distribution, a kind of "binder," in spaces between packed particles of activated carbon (see scheme).

Depending on the CSM preparation conditions, the pores of the carbon powder are 30–70%-filled with this ultradispersed component, which determines the volume and radius of mesopores [7].

In order to develop this concept further, the possibility of obtaining carbon sorbents with high porosimetric characteristics and strength from half-products to be utilized and wastes formed in manufacture of activated carbon was studied. An attempt was made to develop technological foundations for synthesis of microporous CSM from porous carbon (activated and oxidized anthracite, activated salted carbon) and ultradispersed powders (technical-grade carbon–carbon black, activated carbon fiber). The choice of just these combinations is based on the authors' opinion that coal must improve the strength characteristics of the resulting formed material, and the ultradispersed powder additives introduced must contribute significantly to the development of porosity.

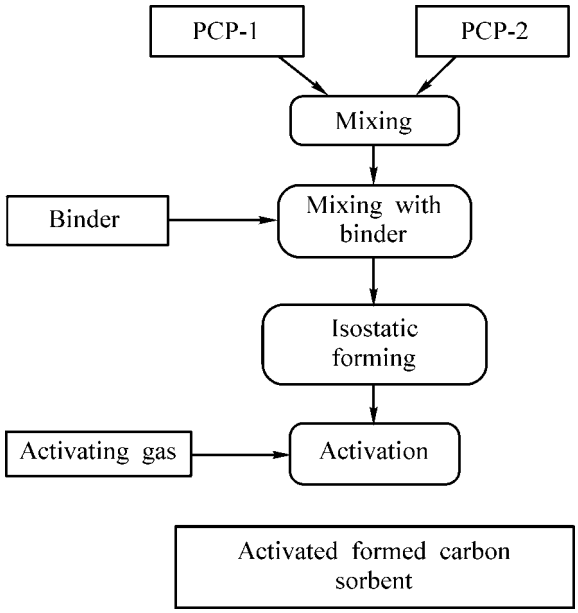

Table 1 lists characteristics of the starting components used to obtain formulations. The stock for synthesizing composite sorbing materials was prepared by mixing the main components with a binder in certain mass ratios and then subjected to forming.

Table 1. Characteristics of starting components used to prepare the stock

Starting component	Dispersity, μm	Pore volume for benzene, W_s, $cm^3\ g^{-1}$
Anthracite:		
activated	63–100	0.41
oxidized	63–100	0.39
Technical-grade carbon (carbon black)	≤50	0.44
Dispersed activated fiber	≤50	0.45
Activated salted carbon	63–100	0.56
Binder	≤50	0.016

It is known [8] that the conventional forming techniques fail to satisfy the requirements to the structural homogeneity of these materials. The development of new binders (polymeric resins) and forming techniques open up wider opportunities for synthesis of high-porosity materials.

High-porosity materials with uniformly distributed pore structure were synthesized by the isostatic forming method [9, 10]. This was done using a phenol-formaldehyde resin binder whose amount in the molding powder ensured a sufficient mechanical strength of the resulting half-finished articles.

The material formed was activated with water vapor and/or carbon dioxide. When activating the CSM, the method with temperature gradually raised at a rate of 10 deg min^{-1} was used in order to preserve their strength characteristics. The temperature was raised within the range 150–850°C.

In activating the formed material, the combustion loss during certain intervals of time was recorded, and the sorption pore volume for benzene and methanol was measured [11]. In some cases, the sorption activity toward iodine and Methylene Blue was studied; isotherms of nitrogen adsorption were measured, with the corresponding specific surface area evaluated on a Quantochrome Autosorb Automated Gas Adsorption System instrument (USA); adsorption of methane under elevated pressure and its subsequent desorption on relieving the pressure to its atmospheric value were carried out on a volumetric installation.

The variation of the texture characteristics and sorption properties of the composites in the course of their activation is illustrated by Table 2.

Table 2. Variation of texture characteristics and sorption properties of composites in the course of activation

Composite	Activating gas	τ, h	Combustion loss, %	Sorption pore volume W_s, $cm^3\ g^{-1}$		Sorption activity		Specific surface area S_{sp} for N_2, $m^2\ g^{-1}$
				for C_6H_6	for CH_3OH	for MB mg g^{-1}	for I_2, %	
KSM-1	H_2O	0.5	37	0.49	0.48			
	H_2O	1.0	53	0.56	0.61	68	66	854
KSM-2	H_2O	0.5	27.5	0.38	0.37			
	H_2O	1.0	42	0.47	0.45	60	62	756
KSM-3	H_2O	0.5	14.7	0.57	0.53			
	H_2O	0.85	25.2	0.59	0.59			
	H_2O	1.0	35.4	0.60	0.61	118	68	942
	CO_2	0.5	50.1	0.68	0.7	78	76	874
KSM-4	H_2O	0.66	54.5	0.67	0.60	124	78	936
KSM-5	CO_2	0.5	37	0.54	0.51			
	CO_2	0.75	45.7	0.51	0.48	56	66	831
KSM-6	H_2O	0.66	67.2	0.39	0.41	196	62	803
	CO_2	0.5	38.2	0.47	0.47	133	52	650
KSM-7	CO_2	0.5	50.8	0.60	0.56	47	69	800
	H_2O	0.66	18.2	0.42	0.40			
	H_2O	1.0	31	0.455	0.48			
	H_2O	1.4	44.5	0.56	0.50	120	70	944
KSM-8	H_2O	0.66	54.3	0.54	0.50	114	74	952
	CO_2	0.5	37.3	0.49	0.58			
	C_2O	0.75	39.2	0.44	0.46	46	64	798
KSM-9	H_2O	0.66	56.2	0.60	0.57	74	78	923

The chosen forming method yields CSM with good sorption characteristics (W_s = 0.5–0.7 $cm^3\ g^{-1}$, S_{sp} = 790–950 $m^2\ g^{-1}$) and sufficiently high mechanical strength.

It should be noted that, when composites are activated with water vapor, higher sorption of nitrogen is achieved, compared with the case of activation with CO_2, and the accordingly larger specific surface area is developed. The best sorption characteristics are observed for composites that contain activated anthracite and carbon black, as well as activated anthracite and carbon fiber. Introduction of a dispersed powder of activated salted carbon into a composite does not make such a significant contribution as the components mentioned above do.

Figure 1 shows isotherms of low-temperature adsorption of nitrogen, typical of the composites obtained, and Fig. 2 presents the differential distribution of pore volumes over equivalent pore radii. Analysis of the isotherms shows that the CSM obtained exhibit developed microporosity and small-size mesoporosity, and the adsorption and capillary condensation in these pores determines the run of the curves. Analysis of the differential sorption isotherms shows that the range of effective radii is 8–60 Å.

Table 3 lists comparative porosimetric characteristics of the best of the formed CSM samples obtained and commercial granulated carbon of SKT brands, prepared from a mixture of peat and coal dust by chemical activation with K_2S. It can be seen that the CSM obtained are distinguished by higher micropore volumes.

The ability of the samples with high sorption characteristics to absorb gaseous methane was studied. Typical amounts of adsorbed gas as a function of the number of adsorption–desorption cycles are shown in Fig. 3. It can be seen that the adsorption of methane on a composite that contains carbon fiber differs significantly from that for samples that contain carbon black as an additive. Adsorption of natural gas on porous carbon materials is accompanied by condensation of higher hydrocarbons (homologues of methane, propane, and butane) in the micropores of a sample, which leads to lower sorption capacity of the sorbents for methane in subsequent cycles of gas adsorption. The same behavior is observed in Fig. 3. For a composite that contains carbon fiber as an ultradispersed additive, the activity falls dramatically (by a factor of 2) in going from the first cycle to the second and sorption of methane is virtually constant in the subsequent cycles. For all other samples, a gradual filling of micropores with the condensate is observed, and only after the fourth cycle the adsorption of methane becomes virtually constant. Such a dependence indicates, in the authors' opinion, that the porous structure of the additive introduced affects the sorption properties of the composite as a whole.

CONCLUSIONS

(1) The method of isostatic forming was applied to demonstrate the possibility of obtaining highly porous (with predominance of a microporous structure) composite sorbing materials, which have good sorption characteristics (W_s = 0.5–0.7 $cm^3\ g^{-1}$, S_{sp} = 790–950 $m^2\ g^{-1}$) and retain sufficiently high mechanical strength, from porous dispersed carbon materials. The sorption and porosimetric characteristics of the materials obtained are comparable with, and in some case even surpass those of commercial industrial carbon of the SKT brand.

(2) The resulting formed adsorbents can be effectively used to accumulate methane in cylinders, which makes it possible to raise the adsorption capacity of a unit volume and to diminish the pressure without lowering the cylinder capacity.

SORPTION AND ION-EXCHANGE PROCESSES

Influence of Humus Acids on Physicochemical Features of KU-2 × 8 Cation Exchangers

G. V. Slavinskaya

Voronezh State University, Voronezh, Russia

Received March 12, 2003

Abstract—In prolonged industrial desalination of natural water with KU-2 × 8 cation exchanger, humic and fulvic acids are accumulated on the resin, which deteriorates its sorption characteristics and desalination efficiency.

In the late 1950s, the Dutch production engineers reported for the first time that the dynamic sorption capacity of strongly ionized anion exchangers used for industrial water desalination is deteriorated because of the sorption of natural organic substances [1]. As for cation exchangers, it was believed for a long time that organic matter does not affect their sorption capacity. However, several experimental facts show that this is not the case. For example, in water treatment with a cation exchanger, approximately 10% of organic impurities oxidizable with potassium permanganate is accumulated on the resin [2]. Accumulation of colored substances (most likely humus substances) on a cation exchanger was observed in [3]. In regeneration of spent cation exchangers with aqueous acid, the filtrates have high oxidizability, which is caused by removal of organic substances accumulated on the resin [4].

In this study, we examined how humic (HA) and fulvic (FA) acids accumulated on KU-2 × 8 cation exchanger in the course of prolonged desalination of natural water affect the physicochemical characteristics of resin and its desalination efficiency.

EXPERIMENTAL

The dimeneralization of natural water was carried out in two stages by passing it through different ion-exchange filters of an industrial desalination installation: cation exchanger I → anion exchanger I → cation exchanger II → anion exchanger II or cation exchanger I → anion exchanger I → MF (mixed cation exchange–anion exchange filter). The samples of cation exchanger were taken from filters I and II and also from MF filter used for exhaustive desalination of

Table 1. Content of organic substances in natural water*

Characteristic	Water		
	Artesian	Bystritsa river	Neva river

water. The content of main organic impurities in natural water desalinated using the above ion-exchange technique is given in Table 1. All the analyses were carried out by the methods reported in [5–7].

Table 1 shows that the main organic matter present in the natural water is composed of HA and FA, and their content varies in parallel with the color index. We found that, irrespective of the concentration of organic matter in natural water, the color of the cation-exchange filters changes from yellow to brown in the course of prolonged desalination. We believe that this color change is caused by accumulation of humus substances on the resin. The accumulation of humus substances on KU-2 × 8 was confirmed by the following experimental data.

(1) After desalination of natural water with KU-2 × 8 during five years (Fig. 1), a noticeable band of the C=O stretching vibrations at 1700 cm^{-1} appears in its IR spectra, along with the absorption bands at 1458, 1420, 1510, and 1605 cm^{-1} typical of sulfonic cation exchangers [8]. The enhancement of intensity of the absorption bands at 1665 and 1635 cm^{-1} can be attributed to amino groups [9, 10]. We believe that these carboxy and amino groups enter the composition of the peripheral amino acid groups of HA and FA macromolecules accumulated on the spent resin [11, 12].

(2) Accumulation of humus substances on the cation-exchange resin was confirmed by their recovery with chemical reagents. In these experiments, a KU-2 × 8 sample preliminarily used for desalination of an artesian water for eight years was treated for 15 and 30 days with solutions of the following composition (wt %): NaCl (10), NaOH (2) + NaCl (10), $Na_4P_2O_7$ (5), HCl (7), NaOH (2) + NH_4OH (2), water–acetone (1 : 1), water–dimethyl sulfoxide (1 : 4), and water–ethanol (1 : 5). It was found that treatment of the resin with alkali ensures the maximum recovery of humic substances. In order to separate humic acids from fulvic acids, the alkaline eluates were acidified with 1 M HCl to pH ~2.

In studies of molecular structure of HA and FA, these substances are subjected to acid hydrolysis to recover separate chemical constituents of these macromolecules. From the molecular species determined in the hydrolyzate, the initial humus substance structure can be reconstructed [13]. In our experiments, the colored organic substances recovered from the cation exchanger were hydrolyzed with 6 M HCl on heating in a sealed tube at 120 °C for 24 h.

The hydrolyzate was analyzed by descending paper partition chromatography using butanol-acetic acid-water mixture (4 : 1 : 5) as eluent and ninhydrin (0.05% aqueous solution) as developer. The particular amino acids were identified by comparison of the chromatograms of the hydrolyzate with those of model reference system containing twenty amino acids. The chromatograms of the hydrolyzates contain six bands with R_f from 0.05 to 0.88, related to the amino acid groups of natural HA and FA [12] (Table 2).

(3) After partial removal of HA and FA from spent KU-2 × 8, the resin becomes lighter. After removal of humus substances from the resin with a salt-alkali solution, the intensity of the absorption bands of humic acids at 1690, 1560, 1533, 1470, 1400, and 1300 cm^{-1} decreases (relative to the intensity of the most stable absorption band at 826 cm^{-1}) (Table 3). These spectroscopic data show that, in extraction with alkali, the structural fragments of HA and FA containing the aliphatic and aromatic amino acid groups,

Table 2. Amino acids recovered from humus substances accumulated on KU-2 × 8 cation exchanger

1800	910	1030	120	50	75	25

benzene rings with different substituents, aldehide groups, etc, are removed from the resin. On removing HA and FA, the content of the methyl and methylene groups in the side aliphatic chains (1346 cm^{-1}) decreases.

(4) To elucidate how treatment of natural water with KU-2 × 8 cation exchanger affects the chemical composition of organic impurities, we recorded the IR spectra of dry residues of the initial river water (sample 1) and of the water treated with the cation exchanger (sample 2). The IR spectrum of the initial natural water contains absorption bands of the amino (3400–3300, 1650–1630 cm^{-1}) and carboxy (2800, 1720, 1700, 1460 cm^{-1}) groups [9, 10]. After contact with the cation exchanger, all these absoprtion bands virtually completely disappear, and new absorption bands at 3030, 1600, 1550, 1450 and 690 cm^{-1} appear, which can be assigned to the stretching vibrations of the C–H, C=C, =C, and =C–H bonds in the aromatic ring. This spectrum also contains absorption bands of stretching vibrations of sulfonic groups (1200–1100 cm^{-1}). These data show that, in water treatment with cation exchanger, the resin not only accumulates the ionic groups of organic impurities, but simultaneously enriches water with products formed in destruction of the resin itself.

We found that, in treatment of water of the Bystritsa river with KU-2 × 8 resin, desalinated water is additionally contaminated with organic matter. In these experiments, natural water was passed through KU-2 × 8 cation exchanger preliminarily regenerated with aqueous acid. In the course of this experiment, 1-l water samples were taken at regular intervals at the inlet and outlet of the filter throughout the operation period. The filtered water was neutralized with 0.1 M KOH and dried, and the content of HA and FA in the dry residue was determined. The results of these analyses are listed in Table 4.

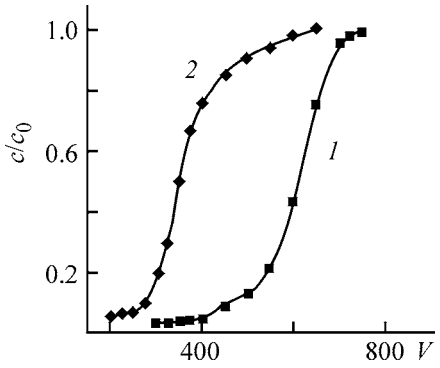

Fig. 2. Output curves of sorption of calcium cations on (*1*) fresh commercial KU-2×8 cation exchanger and (*2*) KU-2×8 after prolonged water desalination. Fig. 3. Kinetic curves of sorption of sodium cations on (*1*) fresh commercial KU-2×8 cation exchanger, (*2*) KU-2×8 from spent industrial filter after treatment with salt-alkali solution and (*3*) KU-2×8 from spent industrial filter. (F) Degree of saturation of the resin and (τ) time.

Table 4 shows that the content of HA and FA in the desalinated water exceeds that in the initial river water. We believe that this excess of humus acids was accumulated on the resin in the stage of its regeneration with aqueous acid and was then gradually released in the course of desalination of the river water. Thus, the natural organic impurities are accumulated in ion-exchange water desalination, not only on anion, but also on cation-exchange resins.

Our experimental results show that HA and FA accumulated on the sulfonic cation-exchange resin in the course of water desalination deteriorate its physicochemical properties and performance.

We found that, after service in desalination for 2–5 years, the operative exchange capacity (OEC) of the cation exchanger to breakthrough of cations $c/c_0 = 0.03$ (c and c_0 are the contents of cations in the desalinated and initial water, respectively) decreased by 10–30%. The same decrease was observed for the total exchange capacity. In sorption of calcium on fresh commercial KU-2×8 cation exchanger, the shape of the output curve of sorption (Fig. 2, curve *1*) shows that the mass transfer is controlled by external diffusion [14] (extended initial part and shortened late stage of sorption). In sorption of calcium on the spent cation exchanger, the shape of the output curve of sorption (Fig. 2, curve *1*) shows that the mass transfer is largely controlled by the internal diffusion (reduced initial part of the sorption curve and its extension in the final stage of sorption when the eluate contains a rather large amount of calcium).

We believe that the appearance of a certain contribution of the internal diffusion control to the total mass transfer of calcium, along with the common external diffusion mechanism typical of ion-exchange sorption under dynamic conditions, is caused by accumulation of HA and FA on the cation exchanger. These humus acids produce the diffusion resistance to transfer of mineral cations to cation-exchange sites, which deteriorates the kinetic characteristics of the resin. As a result, the OEC of the spent resin decreases under dynamic conditions. The humus substances accumulated on the resin fill its porous space and decrease the moisture content (from 1.020 to 0.885 g H_2O/g).

To elucidate how prolonged desalination affects the kinetic characteristics of KU-2×8 cation exchanger, we studied the sorption of Na^+ from aqueous 0.003 M NaCl on a fresh commercial resin and on a resin used for desalination of Neva water in the first stage of the desalination installation for five years. Figure 3 shows that prolonged industrial use of the resin noticeably deteriorates its kinetic characteristics: the half-sorption time increases from 10 to 60 min. In a separate experiment, an aliquot of the cation exchanger used for five years for desalination of Neva water was treated with a salt-alkali aqueous solution for 35 days to remove humus substances. The content of HA and FA in this resin was found to be 68.4 mg and 12.0 mg FA per gram of air-dry resin, respectively. Our experiments showed that, after removal of humus substances, the half-sorption time of Na^+ decreased to 26 min (Fig. 3, curve *2*) , i.e. the sorption rate somewhat increased.

In separate model experiments, we found that contamination of commercial cation exchanger with FA

of Neva water increases the time to half-cation exchange from 10 to 16 min. This negative effect of humus substances on the kinetic characteristics of the ion exchanger is consistent with the pattern of deterioration of the kinetic characteristics observed in functioning of the industrial desalination filter.

We found also that humus substances accumulated on the resin hinder the removal of HCl from regenerated KU-2 × 8. Figure 4 shows that, in the case of fresh commercial KU-2 × 8 treated with HCl, HCl is removed with five column volumes of distilled water. At the same time, HCl was not removed even with 200 column volumes of water from spent KU-2 × 8 cation exchanger. If humus acids were preliminarily partially removed from the spent industrial filter with a salt-alkali solution, HCl was removed with 140 column volumes of water (i.e., the wash water volume decreased by 30%) (Fig. 4, curve *2*).

The presence of the amino groups in HA and FA imparts to them anion-exchange features. The anion-exchange capacity of resins from different ion-exchange filters varies from 0.15 to 0.70 mg-equiv cm^{-3} swollen resin. In regeneration of cation-exchange filters with HCl, the amino acids are protonated to form salts $Cl^-[N^+H_3–CHR–COOH]$. In washing with water, these salts are hydrolyzed by the reaction

$$Cl^-[N^+H_3–R–COOH] + H_2O \rightleftarrows OH^-[N^+H_3–R–COOH] + HCl,$$

to give the zwitterion, which is the most stable amino acid species in neutral solutions [15]. Because of this reaction, the wash water is acidified and, therefore, the larger water volume is required for complete removal of the mineral acid. Since the cation-exchange filters are washed to remove the mineral acid under industrial conditions with natural mineralized water, this procedure decreases the exchange capacity of the resin. This decrease is the larger, the higher the mineralization of natural water.

CONCLUSIONS

(1) In desalination of natural water with a sulfonic cation exchanger in the H form, the resin is contaminated with humic and fulvic acids, irrespective of their content in natural water and position of the cation-exchange filter in the process chain.

(2) The humus acids accumulated on the spent cation exchanger fill its pores and decrease the moisture content. These factors increase the diffusion resistance to transfer of mineral cations from the bulk to the cation-exchange sites and, as a result, decrease the sorption capacity of the resin and deteriorate its kinetic characteristics.

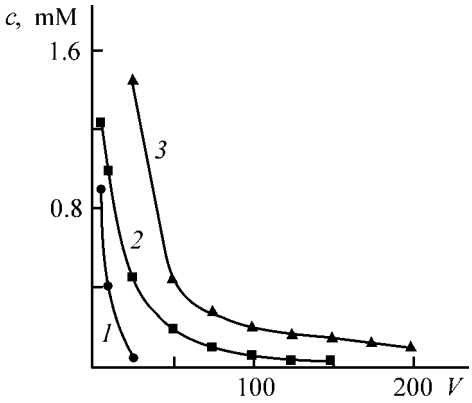

Fig. 4. Washing of KU-2 × 8 with water to remove HCl after regeneration: (*1*) fresh commercial KU-2 × 8 cation exchanger, (*2*) KU-2 × 8 from spent industrial filter treated with a salt-alkali solution, and (*3*) KU-2 × 8 from spent industrial filter without treatment. (*c*) HCl concentration and (*V*) number of column volumes of distilled water passed through the column.

(3) In regeneration of spent cation-exchange filters with hydrochloric acid, hydrogen chloride form salts with the amino groups of HA and FA. In washing the resin with water to remove HCl, these salts are hydrolyzed and, therefore, a larger water volume is required to remove the acid.

(4) To prevent poisoning of ion-exchange filters in desalination of mineralized natural water, humus acids should be preliminarily removed.

SORPTION AND ION-EXCHANGE PROCESSES

Determination of Metal Traces in Polypropylene by Gas Chromatography

Yu. G. Slizhov and M. A. Gavrilenko

Tomsk State University, Tomsk, Russia

Received May 10, 2001; in final form, December 2003

Abstract—A procedure was developed for determination of metal traces in polypropylene on chromatographic sorbents and phases of various polarities. The thermal stability of volatile aluminum, chromium, and gallium acetylacetonates under the conditions of gas chromatography was studied. The influence exerted on the determination process by the column material, temperature, and polarity of phases was examined.

Polyolefins, and polypropylene in particular, are produced on catalysts containing complexes of Al, Ti, Cr, and other metals [1–3]. Evaluation of the quality of the finished product involves determination of the residual catalyst, which is commonly done photometrically. The capability of many metals to form thermally stable volatile β-diketonates [4] offers an opportunity to use gas chromatography for determining metals in polyolefins [5, 6]. Therefore, study of chromatographic properties of metal β-diketonates and assessment of the possibility of using them to determine impurities in polyolefins is topical problem.

In this study, we examined the possibility of determining metals at their content of 10^{-3}–10^{-4} wt % by gas chromatography with a simplified sample preparation procedure.

EXPERIMENTAL

The metal acetylacetonates $Al(acac)_3$, $Ga(acac)_3$, and $Cr(acac)_3$ were prepared as described in [7]. The sample purity was checked by IR spectroscopy (400–4000 cm^{-1}, Specord M80 spectrophotometer). The thermal analysis was performed with a Q-1500 derivatograph in the temperature range 20–500°C at a heating rate of 10 deg min^{-1}, using Al_2O_3 as reference. The sample weight was 50 mg. Chromatographic experiments were performed with a Chrom 5 chromatograph equipped with a flame ionization detector. Glass and Teflon columns were packed with Tsvetosil M-SKT and Tsvetosil SKTFT diatomite supports modified with chemically grafted silicone rubbers, or with Chromosorb G AW DMDS impregnated with SE-30, OV-1, or SKTFV-803 (phenylvinylsilicone phase) liquid phases.

The metal impurities in polypropylene were determined as follows. A weighed portion of the polyolefin powder (4 g) was placed in a 100 cm^3 three-necked round-bottomed flask, 12 cm^3 of acetylacetone was added, and the mixture was heated at 60°C for 60 min. After cooling, the solution was filtered through a finely porous glass frit and vacuum-evaporated to dryness. The dry residue was dissolved in 6 cm^3 of CCl_4. The sample volume was 0.4 μl. The chromatographing conditions were as follows: column, vaporizer, and detector temperatures 140, 190, and 180°C, respectively; carrier gas flow rate 35 $cm^3\,min^{-1}$. The total analysis time was 1.5 h.

The possibility of direct reaction of β-diketones, including acetylacetone, with metals embedded in a polymeric matrix was demonstrated in [8, 9]. The metal transforms into the corresponding acetylacetonate on treatment of the polymer powder with the hot β-diketone. The IR spectra of the compounds thus prepared agreed with published data [10]. The strong bands at 1545 and 1590 cm^{-1}, characteristic of metal acetylacetonates, are indicative of the presence of a conjugated system of C=O and C=C bonds. The CH_3 bending vibration band is observed at 1390 cm^{-1}. The IR data allow the compounds obtained to be identified as acetylacetonates of the corresponding metals.

According to thermal gravimetric analysis, aluminum, gallium, and chromium acetylacetonates are stable up to temperatures exceeding 170°C (Table 1).

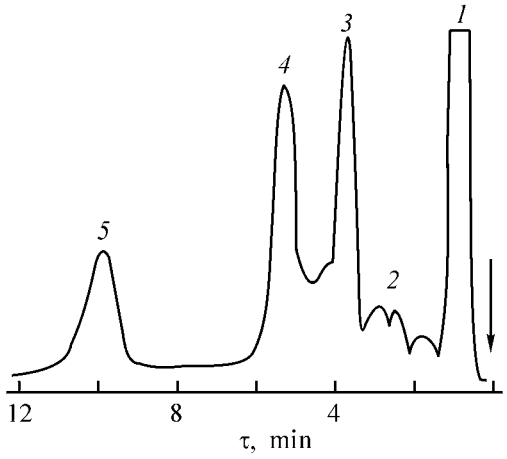
Table 1. Thermal stability of metal acetylacetonates

Chelate	Temperature, °C		Degree of evaporation at 500°C, %
	onset of weight loss	weight loss maximum	
$Al(acac)_3$	185	290	94
$Ga(acac)_3$	175	275	75
$Cr(acac)_3$	200	335	93

Table 2. Kovats retention indices *I* at 150°C on various stationary phases

Chelate	SE-30	OV-1	SKT	SKTFT	SFTFV-803
$Al(acac)_3$	1647	1678	1480	1730	1658
$Cr(acac)_3$	1844	2429	2134	1871	1995
$Ga(acac)_3$	1695	1579	1642	1770	1720

The thermal stability of acetylacetonates correlates with their electronic structure. Chromium acetylacetonate stabilized owing to the involvement of vacant *d* orbitals in coordination sublimes at a higher temperature than aluminum and gallium acetylacetonates; gallium acetylacetonate, characterized by the filled 3*d*-electron shell of Ga, shows the lowest sublimation temperature and the strongest tendency to decompose. Aluminum acetylacetonate, in which vacant 3*d* orbitals may take part in donor–acceptor interaction [10], occupies an intermediate position. The gas-chromatographic determination of Al, Ga, and Cr in the form of acetylacetonates is possible at temperatures of up to 170°C.



Chromatogram of a mixture of acetylacetonates on a 60 × 0.4-cm Teflon column. Stationary phase 5% SE-30 on Chromosorb G AW DMDS. Temperatures, °C: column 150, vaporizer 250, and detector 200; carrier gas He, flow rate 60 $cm^3\,min^{-1}$. (τ) Retention time. (*1*) CCl_4, (*2*) products of $Al(acac)_3$ decomposition, (*3*) $Al(acac)_3$, (*4*) $Ga(acac)_3$, and (*5*) $Cr(acac)_3$.

The Teflon columns are advantageous over the glass columns because of the more inert column material. On Teflon columns, $Al(acac)_3$ and $Cr(acac)_3$ gave reproducible peaks even in the first injections, whereas on glass columns the first peaks appear after repeated injections. Steel columns are wholly unsuitable for this purpose because of the catalytic degradation of the complexes on the column walls, to give large amounts of degradation products.

We found that the chromatographic separation of the β-diketonates under consideration is largely influenced by the solvent. With chloroform, resolution of the chelate and solvent peaks is unsatisfactory, and with acetone, the chromatographic peaks are resolved incompletely, probably because of the coordination interaction with possible outer-sphere ligand exchange. The best results were obtained with CCl_4.

For $Al(acac)_3$, $Ga(acac)_3$, and $Cr(acac)_3$, we calculated the Kovats retention indices. The results are listed in Table 2.

The retention index depends on the sorbate structure and strength of metal coordination in the chelate ring. The retention indices of $Al(acac)_3$ and $Ga(acac)_3$ are similar, which is consistent with the fact that the ionic radii of Al^{3+} and Ga^{3+} are approximately equal. The specific features of the electronic structure of chromium (presence of 3*d* electrons) are apparently responsible for the appreciably longer retention time of the acetylacetonate and increased logarithmic retention index. The minimal values of the Kovats index are observed on the SE-30 nonpolar phase. With this phase, the metal acetylacetonates can be determined most quickly, without loss in the accuracy of analysis. Acetylacetonates can also be separated on SKTFT and SKTFV-803 phases. In the case of SKT and OV-1, the high polarity of the phases results in a significant increase in the retention time of $Cr(acac)_3$ and in broadening of its chromatographic peak. The chromatogram of $Ga(acac)_3$, $Al(acac)_3$, and $Ga(acac)_3$, obtained on a Teflon column with the SE-30 phase, is shown in the figure.

The chromatogram reveals broadening of the peaks due to decomposition of gallium and aluminum acetylacetonates. As the vaporizer temperature is decreased, the peaks of decomposition products decrease in intensity and finally disappear. With chromium acetylacetonate, which is more stable thermally, we detected no decomposition products. Thus, the tem-

Table 3. Comparison of the suggested gas-chromatographic procedure for Al determination in polyolefins with the results obtained by independent methods (n = 4–5, P = 0.95)

Method	Sr	Detection limit, wt %	Analysis time, h
Spectrophotometry	0.06	>0.005	>4
Atomic emission spectroscopy	0.11	10^{-6}	>4
Gas chromatography	0.05	to 0.001	~1.5

perature conditions of the analysis should be chosen so as to minimize the degree of the chelate decomposition, but, at the same time, ensure short time of analysis (10 min retention time of the last component).

Using the introduced–found method, we compared our procedure with the most frequently used procedure for photometric determination of residual Al in polyolefins with Xylenol orange [11] and with atomic emission analysis. The results of chromatographic determination of the Al content (Table 3) coincide, within a random error, with the results of independent determinations, with the analysis time being appreciably curtailed.

CONCLUSIONS

(1) The study of the gas-chromatographic behavior of volatile aluminum, chromium, and gallium acetylacetonates in packed columns showed that these complexes can be determined quantitatively without appreciable degradation when the temperatures are relatively low and the columns are sufficiently short. The retention parameters of the compounds on various phases were measured experimentally.

(2) A procedure, based on the data obtained, was developed for determination of metal traces in polypropylene. The metrological characteristics of this procedure were compared with those of commonly used procedures.

Received April 10, 2003

Abstract—The catalytic activity of manganese oxide–containing anodic layers formed on titanium at room temperature in CO oxidation to CO_2 was studied.

Systems that contain MnO_2, Mn_2O_3, and Mn_3O_4 catalyze numerous gas- and liquid-phase reactions [1–4]. In particular, they are used as catalysts for CO oxidation to CO_2 [3, 5]. Manganese oxides are commonly obtained by various chemical methods; for example, Mn_2O_3 and Mn_3O_4 are prepared by heating salts, oxides, or hydroxides of manganese to 700 and 1000°C, respectively [2].

Previously, surface structures with thickness of up to 60 μm, which contained, together with TiO_2, oxides Mn_2O_3 and Mn_3O_4, have been obtained on titanium by anodic-spark deposition at room temperature from an electrolyte containing sodium tetraborate and salts of manganese [6]. In the process, both the phase composition and the content of manganese in the coatings (0–40 at.%) could be purposefully altered by varying the concentration of manganese salts and the forming modes.

This communication reports the results obtained in evaluating the catalytic activity in CO oxidation of manganese-containing structures formed on titanium.

EXPERIMENTAL

Electrolytes were prepared using distilled water and commercial reagents $Na_2B_4O_7 \cdot 10H_2O$ and $Mn(CH_3COO)_2 \cdot 4H_2O$ of chemically pure grade. Anodic films were formed by means of electric breakdowns on VT1-0 titanium samples in the galvanostatic mode (i = 0.2 A cm^{-2}) in the course of 4 or 10 min. As current source served a thyristor converter with unipolar current pulses. The process was performed in the temperature range 13–40°C. The specific features of electrolyte preparation, the design of the electrochemical cell and units for solution cooling and agitation, and the method for electrode pretreatment were described in [6].

The phase composition of the coatings was determined on a DRON-2.0 diffractometer (Cu_{K_α} radiation), and the elemental composition, on a JXA-5A X-ray fluorescence microanalyzer, with measurement error of about 10%.

The molar ratio of the gaseous components changes when the reaction $2CO + O_2 \rightarrow 2CO_2$ occurs. Therefore, a setup that comprised a 400-cm^3 quartz reactor and a pressure gage connected to it was used for evaluating the catalytic activity of the structures synthesized, in the reaction of CO oxidation to CO_2. The pressure gage provided measurements in the range –0.1–0 MPa with an accuracy of 5×10^{-3} MPa. Samples with a total area of 40 cm^2 were placed in the reactor. Preliminarily, a 2 : 1 gas mixture of oxygen and carbon(II) oxide with a total volume of 300 cm^3 was prepared volumetrically in a separate vessel. A rarefaction was created in the reactor with a fore pump. Then, the gas mixture prepared was admitted into the reactor at room temperature and heated at a rate of 20 deg min^{-1}. Simultaneously, the variation of pressure within the reactor was recorded.

The composition of the gas mixture at the reactor outlet was determined with an LKhM-8MD chromatograph.

Figure 1a shows how the pressure in the reactor varies with temperature in the presence (curves *1*, *2*) and in the absence (curve *3*) of titanium with manganese oxides in its surface layer. It can be seen that, in the presence of manganese-containing layers,

1070-4272/04/7702-0218 © 2004 MAIK "Nauka/Interperiodica"

the pressure in the reactor decreases in the range 250–350°C despite the rise in temperature. This indicates that the molar ratio of the gaseous components in the reactor changes because of the occurrence of the reaction $2CO + O_2 \rightarrow 2CO_2$. This conclusion is confirmed by the results presented below and by an analysis of these.

Figure 2 shows chromatograms of a gas mixture kept at 340°C in the absence (a) and in the presence (b) in the reactor of titanium with manganese oxides in its surface layer, c_{Mn} = 35.7 at.%. The decrease in the area of the peaks related to CO directly indicates that the reaction of CO oxidation to CO_2 occurs in the temperature range under study on manganese-containing layers formed by the anodic-spark deposition method.

Similar $P = f(T)$ dependences were obtained with a platinum grid with an area of 8 cm^2 charged into the reactor with the gas mixture (Fig. 1b). In this case, the conversion temperature was in the range 180–250°C.

When titanium or titanium that contains only TiO_2 in its surface layer is placed in the reactor, the temperature dependence of the pressure in the reactor is similar to that obtained in the absence of manganese-containing layers (Fig. 1a, curve *3*). This result, on the one hand, means that titanium and anodic-spark layers that contain only TiO_2 do not catalyze the reaction of CO oxidation in the absence of manganese oxides, and on the other, indicates that the influence exerted by the oxidation of the titanium base on the variation of the pressure in the reactor is insignificant at the given temperatures.

The results obtained in measuring the catalytic activity in five successive cycles of measurements on one and the same sample demonstrate that the dependences $P = f(T)$ are identical to those shown in Fig. 1a (curves *1*, *2*) as regards both the temperature range and the magnitude of changes in pressure. In this case, the phase (Fig. 3) and elemental (Table 1) composition of the coatings changed only slightly. The crystallinity of the coatings increased somewhat, and no new crystalline phases appeared. The minor decrease in the content of manganese, the increase in the content of titanium, and the corresponding change in the calculated amount of oxygen in the surface layer being analyzed (analysis to a depth of 3–5 μm) may be due both to the possible measurement errors and to processes of thermal diffusion of elements across the layer thickness and influence of crystallization processes, which lead to cracking. Undoubtedly, the problems of stability and working life of the systems in question under the conditions mentioned invite further investigation.

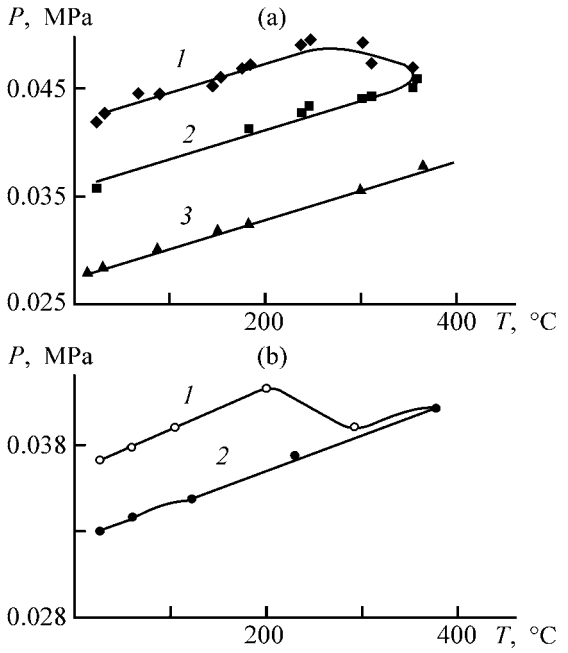

Fig. 1. Pressure *P* of the gas mixture vs. *T*, (*1*, *2*) in the presence and (*3*) in the absence of (a) titanium with manganese oxides in its surface layer and (b) platinum grid. (*1*) Heating, (*2*) cooling, and (*3*) heating–cooling.

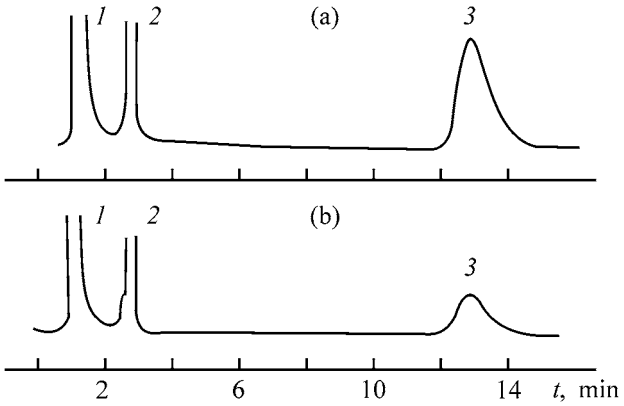

Fig. 2. Chromatograms of a gas mixture kept in the reactor at 340°C for 30 min (a) in the absence and (b) in the presence of titanium with manganese oxides in its surface layer. c_{Mn} = 35.7 at.%. (*t*) Time. (*1*) O_2, (*2*) N_2, and (*3*) CO.

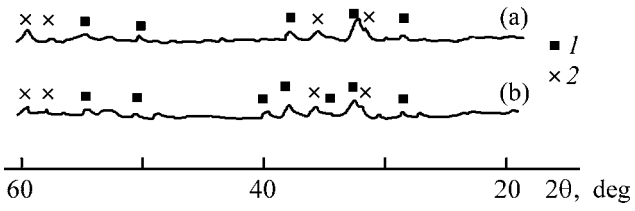

Fig. 3. X-ray diffraction patterns of anodic-spark layers formed on titanium: (a) initial layers and (b) those after catalysis. (2θ) Bragg angle. (*1*) Mn_2O_3 and (*2*) Mn_3O_4.

Table 1. Elemental composition of coatings

Composition	Content, at.%			
	Mn	Ti	Na	O*
Initial	39.7	1.9	0.3	58.2
After five measurement cycles	33.0	3.0	0.3	63.3

* Calculated from the difference.

Table 2. Rate constant of CO oxidation on various manganese-containing systems

System	$k \times 10^4$ (s^{-1}) at indicated T, °C	
	260	290
$Mn_2O_3 + Mn_3O_4$, c_{Mn}, at.%:		
22.9	0.15	0.16
31.4	0.19	0.23
35.7	1.75	1.90
39.6	0.24	0.34
β-MnO_2	0.88	0.90

It may be assumed that the change in the pressure in the reactor in the first measurement cycle may be due to oxidation of amorphous oxide MnO contained in the coatings to amorphous MnO_2 in the temperature range 250–350°C. In this case, the content of oxygen in the coatings must substantially increase, and the atomic ratio Mn/O must markedly decrease, after a cycle of heating–cooling in an oxygen-containing gas mixture. At the same time, as follows from the experimental data presented here, no decrease in this ratio was observed. Calculations show that the experimental data on the elemental composition of the coatings correspond to presence of the compounds TiO_2, Mn_2O_3, and Mn_3O_4 both in the initial state and after five cycles of catalytic activity measurements.

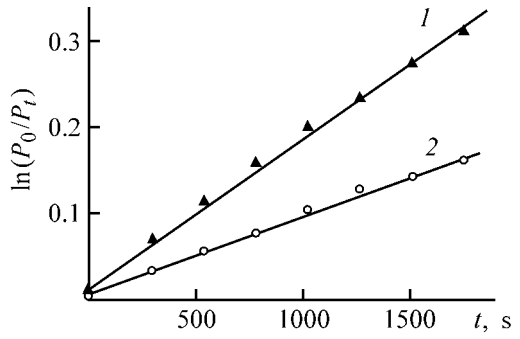

Fig. 4. $\ln(P_0/P_t)$ vs. time t of the process of CO oxidation on anodic layers that contain manganese oxides of various compositions, at 290°C. (P_0, P_t) Partial pressure of CO at the initial instant of time and at the instant of time t, respectively. (*1*) Mn_2O_3, Mn_3O_4 and (*2*) β-MnO_2.

Thus, the experimental data obtained show that, under the experimental conditions, the catalysts formed on titanium by anodic-spark deposition, which contain oxides Mn_2O_3 and Mn_3O_4, catalyze the reaction of CO oxidation to CO_2 in the temperature range 250–350°C.

Figure 4 shows kinetic curves that describe the reaction of CO oxidation at 290°C, plotted in the semilogarithmic coordinates $\ln(P_0/P_t)$–t. The partial pressures of CO, P_0 and P_t, were calculated from the known total pressure and molar ratio of the components. It can be seen that a linear dependence is observed in the presence in the reactor of titanium with a layer of oxides Mn_2O_3 and Mn_3O_4, with a manganese content c_{Mn} = 35.7 at.% (curve *1*), and titanium with a β-MnO_2 layer deposited by the conventional pyrolytic method (curve *2*) [7]. This dependence indicates that, in both cases, the CO oxidation formally proceeds by a first-order reaction and is due to the presence of an excess amount of oxygen in the reaction mixture. The rate constants of the reaction of CO_2 formation at 260 and 290°C, calculated using the equation $\ln(P_0/P_t) = kt$ for titanium with varied content of manganese in the surface layer, are listed in Table 2.

It can be seen that the rate of CO conversion to CO_2 depends on the content of manganese in the anodic layers. Samples that differed in the content of manganese were obtained both by using electrolytes with different concentrations of the components and by varying the forming modes. The optimal content of manganese at the chosen temperatures is 35.7 at.%. This is presumably due to a change in the ratio of the oxides, in their distribution in the surface layer, and in the surface morphology and also to specific features of coating formation by anodic-spark deposition.

CONCLUSIONS

(1) Manganese-containing anodic films on titanium, formed by the anodic-spark method, catalyze the reaction of CO oxidation in the temperature range 250–350°C. The catalytic activity of structures of this kind compares well with that of coatings obtained by the conventional pyrolytic technique.

(2) The rate of CO conversion on the anodic structures formed depends on the content of manganese in these structures.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Cathodic Deposition of Zinc from Dilute Solutions onto a Rotating Disc Electrode

V. S. Kolosnitsyn and O. A. Yapryntseva

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received May 22, 2003

Abstract—The cathodic deposition of zinc onto a rotating disc electrode was studied. The influence exerted by various parameters on the process was examined. The observed phenomena were explained in terms of corrosion and the positive difference-effect.

Purification of sewage to remove heavy-metal ions is a problem of current importance for many industries. Various methods can be used for sewage purification, but electrochemical methods, such as electrocoagulation, electroflotation, electrodestruction, and electrodeposition of metals, are of particular interest. The electric treatment makes it possible to purify wastewater of varied composition and dispersity without raising the content of salts in a water being purified and, rather frequently, with precipitates not formed at all or formed in a considerably decreased amount [1]. Among the electrochemical methods mentioned above, the electrolysis is of special interest, since it can be performed without use of chemicals in the course of purification and yields a metal in the form of a target product, which simplifies its further processing.

The electrodeposition of metals from dilute solutions has its own specific features, which consist in that the process rate is limited by delivery of a reagent to the electrode surface. This problem can be solved by using a rotating disc electrode instead of an immobile electrode. As shown previously [2], using a rotating disc cathode allows the rate of copper electrodeposition from dilute solutions to be increased by a factor of 5–10, with a high current efficiency (CE) retained.

In this study, we continue to examine the electrodeposition of metals onto a rotating disc electrode and the cathodic deposition of zinc from solutions with concentrations of up to 1 g l^{-1}.

EXPERIMENTAL

Zinc was electrodeposited in a glass cell with a rotating cathode. The cell volume was 0.5 l. As cathodes were used discs made of stainless steel, sheet copper, and aluminum. The cathode area was 160 cm^2. Semi-discs made of titanium gauze coated with ruthenium(IV) oxide served as anodes. Prior to the experiments, the cathodes were trimmed with an emery paper and washed in the electrolyte solution.

The electrodes were polarized in the galvanostatic mode with a B5-49 source of stabilized current and voltage. The voltage was monitored with a V7-27 A/1 voltmeter.

The rate of rotation of the disc electrode was determined and controlled using a tachometer.

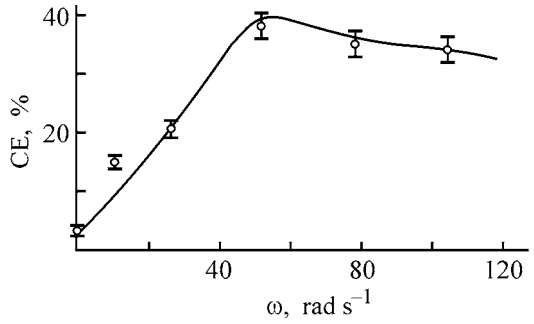

Fig. 1. Effect of the rotation rate ω on the current efficiency CE by zinc in cathodic deposition from dilute solutions. Supporting electrolyte 0.5 M Na_2SO_4, $c_{Zn^{2+}}$ = 100 mg l^{-1}, pH 6, copper cathode.

The electrolyte solutions were prepared by the gravimetric method by dissolving the appropriate dry salts in distilled water. The current efficiency was determined from the difference of the zinc concentrations before and after the electrolysis. The content of zinc(II) was determined by direct complexometric titration.

The duration of electrolysis was calculated on the basis of the initial concentration of zinc ions in the solution, so that the amount of electricity passed through the cell corresponded to the complete recovery of metal.

The dependence of CE on the rate of cathode rotation is shown in Fig. 1. It can be seen that CE is 5% for the immobile electrode. As the rotation rate is raised to 52.3 rad d^{-1}, CE increases to 35–40%. With the rotation rate raised further, CE somewhat decreases.

The pH value of the electrolyte solutions also affects the current efficiency. The dependence of CE on the solution pH passes through a maximum at pH 7 (Fig. 2).

Irrespective of the initial concentration of zinc ions, the dependences of CE on current density also pass through a maximum (Fig. 3), whose position shifts to higher current densities as the concentration of zinc ions in the electrolyte increases.

With a stainless steel electrode, no zinc is deposited onto the cathode, whereas with copper and aluminum electrodes, the cathodic deposition of zinc is rather effective (Fig. 4).

To account for the dependences obtained, it is necessary to note that the electrodeposition of metals, which stand to the left of hydrogen in the electrochemical series, is almost always complicated by a concurrent reaction of hydrogen evolution. In addition, electronegative metals can displace hydrogen from water, i.e., they may be subject to corrosion with a hydrogen and oxygen depolarization. Therefore, the CE by zinc in cathodic deposition will be determined by the relative rates of three processes: zinc recovery, hydrogen evolution, and corrosion of zinc from the electrode surface. It is also necessary to note that amphoteric metals, such as zinc, exhibit a positive difference-effect in cathodic polarization, which originates from destruction of a protective zinc oxide film upon alkalization of the near-cathode layer of the solution through cathodic evolution of hydrogen.

The flux N of a solution across the boundary diffusion layer, which appears on a rotating cathode and

is at rest with respect to it, is directly proportional to the diffusion coefficient D of the solution and to the gradient of the solution concentration Δc and inversely proportional to the thickness δ of the boundary diffusion layer δ: [3]:

$$N = D\Delta c/\delta. \quad (1)$$

In turn, δ can be calculated as follows [4]:

$$\delta = 1.61 D^{1/3} \nu^{1/6} \omega^{-1/2}, \quad (2)$$

where ν is the kinematic viscosity of the electrolyte solution (cm^2 s^{-1}), and ω is the angular velocity of rotation of the electrode (s^{-1}).

The concentration difference is given by

$$\Delta c = c_0 - c_c, \quad (3)$$

where c_0 is the concentration of ions in the solution bulk, and c_c is the concentration of ions at the electrode surface.

The latter concentration can be calculated as follows:

$$c_c = c_0 - i_c\delta/(DFz_i), \quad (4)$$

where i_c is the current flowing to the cathode, and z_i is the ion charge.

Substituting the expression for the boundary layer thickness into Eq. (4), we obtain

$$c_c = c_0 - 1.62 i_c \nu^{1/6}/(D^{1/3} F z_i \omega^{1/2}). \quad (5)$$

According to (5), the concentration of ions at the cathode surface increases with the rotation rate. This allows electrolysis to be performed at higher current densities.

At the same time, at high flow velocities of the electrolyte, the cathodically formed alkali is removed from, and the oxidant (e.g., oxygen) delivered to the cathode surface. As a result, the surface of freshly deposited zinc has enough time to be covered with a protective oxide film. This explains why CE increases when the rate of cathode rotation is raised to 52.3 rad s^{-1} (Fig. 1). However, as the rotation rate increases further, CE decreases somewhat, which is probably due to the fact that, at higher flow velocities of the electrolyte, the corrosion becomes the so-called impingement corrosion. In this case, the passivating films, which were formed and existed before the onset of corrosion, are torn off the metal surface by a liquid jet, so that the metal without a protective film undergoes intense corrosion [5].

The shape of the obtained CE-vs.-pH curve (Fig. 2) can be accounted for by the influence of acidity on processes of hydrogen evolution and zinc corrosion, which occur simultaneously at the cathode.

It is known that the dependence of the hydrogen overvoltage on the solution pH passes through a maximum at pH 7 [6]. Because zinc is an amphoteric metal, the rate of its corrosion also depends on the solution pH. The corrosion rate is the lowest in neutral solutions and increases dramatically in acid and alkaline solutions [5, 7].

Thus, the appearance of a peak in the CE-vs.-pH curve (Fig. 2) is due to the fact that, in acid and alkaline solutions, the processes of zinc corrosion and hydrogen evolution prevail over the cathodic deposition of zinc.

The effect of current density on the CE by zinc in cathodic deposition was studied in solutions with initial pH 6. The appearance of extrema in the CE–i dependences is probably due to the fact that, at low rates of the cathodic process, the pH of the near-electrode layer increases, but does not exceed 7. Under these conditions, the rates of hydrogen evolution and zinc corrosion are the lowest. Therefore, the CE by zinc in its cathodic recovery increases with current density at low polarizing currents. After the current densities at which pH 7 is established in the near-electrode layer are attained, the rates of cathodic hydrogen evolution and zinc corrosion start to increase. Therefore, CE by zinc starts to decrease after a certain polarizing current density is reached.

Presumably, the shift of the peak positions to higher current densities, observed in the CE–i dependences as the concentration of zinc(II) increases, is due to acceleration of the cathodic recovery of zinc

owing to a decrease in the overvoltage. In this case, the rates of other concurrent processes remain virtually unchanged.

When zinc is deposited onto the surface of metals that have a more positive standard potential than zinc, it forms with them short-circuited galvanic microcells [8], in which the more electropositive metal is a cathode, on which hydrogen evolution occurs, and zinc is a soluble anode. The dissolution of zinc is limited by the cathodic evolution of hydrogen, which, in turn, is dependent on the overvoltage of hydrogen evolution on a given metal.

As is known, the overvoltage of hydrogen evolution on metals that constitute stainless steel (such as iron and nickel) is lower than that on copper and aluminum. Therefore, the rate of electrochemical corrosion of zinc on the surface of a stainless steel electrode is such that we do not observe its deposition. At the same time, the deposition of zinc onto copper and aluminum is rather effective, with the CE by zinc in cathodic deposition being as high as 30–40%.

CONCLUSION

The study performed demonstrated that the deposition of zinc from dilute aqueous solutions onto a rotating disc electrode is complicated by intense corrosion. On an immobile cathode, the current efficiency does not exceed 5%. On a rotating electrode, the current efficiency by zinc grows with the rotation rate, to reach its maximum value (35–40%) at a rate of 52.3 rad s^{-1}. Irrespective of the initial concentration of zinc(II) in a solution, the current efficiency first increases and then decreases as the current density becomes higher. The pH value of the electrolyte solutions, at which the CE by zinc is at a maximum in electrodeposition from dilute solutions with concentration of up to 1 g l^{-1}, is 6–7.

Received August 4, 2003

Abstract—Voltammetry was applied to a study of joint electroreduction of Cd(II) and Te(IV) on a glassy carbon electrode from an ammonia-chloride buffer electrolyte with pH 8.4. The optimal conditions of electrodeposition of CdTe films were determined and their structure was examined by means of X-ray phase analysis.

The optimal band gap width (E_g = 1.44 eV) and the possibility of obtaining deposits with *p*- and *n*-type conduction allow wide use of electrodeposited CdTe films in photoelectric devices. CdTe films are commonly deposited electrochemically from acid electrolytes at pH 1–3 [1–7]. One of the principal disadvantages of acid electrolytes is that corrosion processes occur and elementary tellurium is codeposited together with the CdTe deposit. This is so because, as it follows from the potential–pH diagram of the CdTe compound in aqueous solutions [8], the stability region of elementary tellurium in acid solutions is wide and becomes narrower as pH increases. To prevent accumulation of elementary tellurium in CdTe films, the concentration of Te(IV) ions in acid solutions is chosen to be much lower than that of Cd(II) ions. The Cd(II)/Te(IV) concentration ratio should be about 10^4. In this case, the rate of CdTe formation in the process of deposition is controlled by transport of $HTeO_2^+$ ions to the electrode surface. The deposition is performed at 363 K. Under these conditions, uniform CdTe films with good adhesion cannot be always obtained. The difficulties encountered can be eliminated by using a complex electrolyte with high pH values.

The processes of CdTe formation affect the reaction kinetics in two ways. First, the equilibrium potential of the system $HTeO_2^+$/Te depends on the pH value, whereas that of the system (Cd^{2+} + Te)/CdTe is independent of this parameter. Second, the rate of electron transfer at the potential of $HTeO_2^+$ reduction decreases as pH increases. If the stage that governs the stoichiometry is potential-independent (e.g., if this is the subsequent chemical reaction), then the deposit quality will improve with decreasing rate of the electrochemical reaction.

The electrochemical deposition of CdTe films on a glassy carbon was carried out using an ammonia-chloride buffer electrolyte with pH 8.4, buffer capacity π = 0.4, and ionic strength μ = 2. This electrolyte enhances the proton-donor capacity of aqueous solutions and hinders hydrolysis of Cd(II) ions because of the formation of $Cd(NH_3)_n^{2+}$ ammonia complexes. The electrochemical processes that occur at the electrode in electrodeposition of CdTe were studied by means of voltammetry and X-ray phase analysis (XPA).

EXPERIMENTAL

The voltammetric studies were performed using a PI-50.1.1 potentiostat, with *I*–*E* curves recorded with a PDA-1 XY recorder. The potential sweep rate was 20 mV s^{-1}. A three-electrode electrochemical cell was in the form of a hermetically sealed thermostated Pyrex glass vessel with separated anode and cathode spaces. As working electrode served a glassy carbon disc electrode with an apparent surface area of 0.07 cm^2. As auxiliary electrode was used a platinum wire with an apparent surface area of 1.5 cm^2. All the potentials are given in this paper relative to a saturated silver chloride reference electrode.

The working solution was agitated with a magnetic stirrer. Measurements on the disc electrode were performed at a temperature of 30°C, CdTe films on

1070-4272/04/7702-0226 © 2004 MAIK "Nauka/Interperiodica"

glassy carbon electrodes with an apparent surface area of 1 cm^2 were obtained at 80°C. Prior to experiments, the glassy carbon was cleaned with a finely dispersed Al_2O_3 powder and then washed with ethanol and distilled water. X-ray analysis of the films was made on a DRON-3 instrument with Co radiation. Reagents of special-purity and chemically pure grades were used in the study. The solutions used were prepared with twice-distilled water.

Figure 1 compares potentiodynamic voltammetric curves of cathodic reduction of Te(IV) and Cd(II) ions and their reverse runs (curves *1*) in an ammonia-chloride buffer solution at pH 8.4 with voltammetric curves of their codeposition (curves *2*). The cathodic voltammetric curve obtained in a solution containing 3.8×10^{-4} M of Te(IV) (Fig. 1a, curve *1*) shows a region of limiting current, which is due to Te(IV) reduction to Te(0), with peak current at a potential $E_m = -0.6$ V [Eq. (1)], and a peak of cathodic current at a potential $E_p = -0.9$ V, which is associated with further reduction of elementary tellurium to a telluride [Eq. (2)]. When the direction of potential sweep is changed in the anodic region, elementary tellurium is oxidized to Te(IV) ($E_p = 0.09$ V) in accordance with Eq. (3):

$$TeO_3^{2-} + 6H^+ + 4e \rightarrow Te^0 + 3H_2O, \quad (1)$$

$$Te^0 + 2e + H^+ \rightarrow Te^{2-}, \quad (2)$$

$$Te^0 - 4e + 3H_2O \rightarrow TeO_3^{2-} + 6H^+. \quad (3)$$

As the concentration of Te(IV) ions in the solution bulk increases, the limiting current associated with electroreduction of Te(IV) to Te(0) and the current in the anodic peak at $E_p = 0.09$ V become higher.

Figure 1b shows the voltammetric curves of discharge–ionization of Cd(II) ions on a glassy carbon electrode in an ammonia-chloride buffer solution with pH 8.4. The voltammetric curve shows a wave associated with reduction of Cd(II) ($E_p = -0.9$ V) and a current peak related to oxidation of metallic cadmium ($E_p = -0.87$ V) in reverse sweep of the potential. The process of Cd(II) discharge–ionization in an ammonia-chloride buffer solution is reversible. This is indicated by the potential difference of the current peaks of reduction and oxidation, $\Delta E = 0.03$ V. With increasing Cd(II) concentration, the heights of the current peaks related to reduction of Cd^{2+} ions and oxidation of metallic cadmium grow linearly.

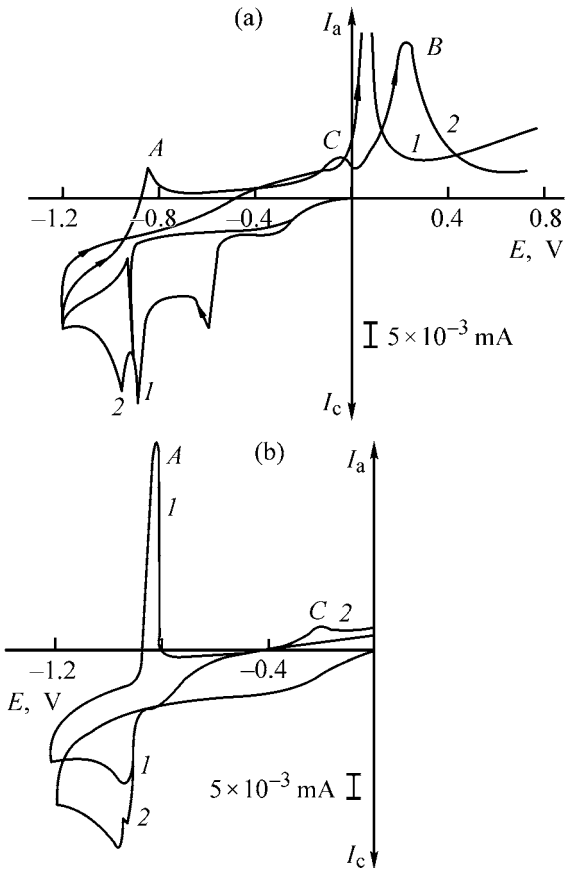

Fig. 1. Voltammetric curves of joint discharge–ionization of Te(IV) and Cd(II) ions on a glassy carbon electrode in an ammonia-chloride buffer electrolyte of varied composition at pH 8.4. (*I*) Current and (*E*) potential; the same for Figs. 2–4. (a) $c_{Te(IV)} = 3.8 \times 10^{-4}$ M. $c_{Cd(II)}$ (M): (*1*) 0 and (*2*) 4.58×10^{-4}. (b) $c_{Cd(II)} = 3.8 \times 10^{-4}$ M. $c_{Te(IV)}$ (M): (*1*) 0 and (*2*) 6.3×10^{-4}.

On addition of 4.58×10^{-4} M of Cd(II) to a solution that contains 3.8×10^{-4} M of Te(IV) (Fig. 1a, curve *2*), the wave of Cd(II) reduction is strongly shifted to negative potentials, to $E = -0.9$ V, and a new peak of cathodic current appears at $E = -0.94$ V. In this case, the wave of Te(IV) reduction coincides with that of Cd(II) reduction. The strong shift of the wave of tellurium reduction to negative potentials may be due to adsorption on the electrode surface of outersphere complexes $Cd(NH_3)_4^{2+} \cdot TeO_3^{2-}$, which hinder tellurium reduction.

At the reverse run of the voltammetric curve of codeposition of Te(IV) and Cd(II), there appear a current peak (peak *A*) related to oxidation of metallic cadmium that is unbound into the compound CdTe [Eq. (4)], a minor peak (peak *C*) associated with oxidation of the compound CdTe to elementary tellurium by Eq. (5), and a peak (peak *B*) related to oxidation of

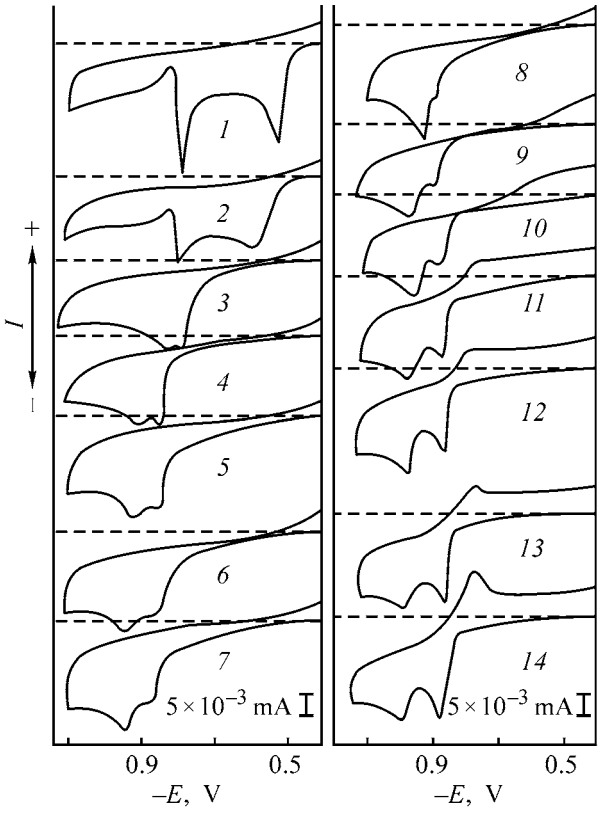

Fig. 2. Effect of Cd(II) concentration on the voltammetric curves of joint discharge–ionization of Te(IV) and Cd(II) ions on a glassy carbon electrode in an ammonia-chloride buffer electrolyte. pH 8.4, $c_{Te(IV)} = 3.8 \times 10^{-4}$ M; the same for Fig. 3. $c_{Cd(II)}$ (M): (*1*) 0, (*2*) 1.9×10^{-5}, (*3*) 3.8×10^{-5}, (*4*) 5.7×10^{-5}, (*5*) 7.6×10^{-5}, (*6*) 9.5×10^{-5}, (*7*) 1.1×10^{-4}, (*8*) 1.3×10^{-4}, (*9*) 1.7×10^{-4}, (*10*) 2.2×10^{-4}, (*11*) 2.9×10^{-4}, (*12*) 3.3×10^{-4}, (*13*) 3.7×10^{-4}, and (*14*) 4.6×10^{-4}.

tellurium contained in the compound CdTe to TeO_3^{2-} at $E = 0.22$ V [Eq. (6)]:

$$Cd^0 - 2e \rightarrow Cd^{2+}, \quad (4)$$

$$CdTe + 4NH_3^{2-} - 2e \rightarrow Cd(NH_3)_4^{2+} + Te^0, \quad (5)$$

$$CdTe + 4NH_3 + 3H_2O - 6e \rightarrow TeO_3^{2+} + Cd(NH_3)_4^{2+} + 6H^+. \quad (6)$$

The potential of the current peak *B* depends on the Cd(II) concentration in the electrolyte solution and varies within the range 0.1–0.22 V. As the concentration of Cd(II) increases, the potential of the current peak related to oxidation of the compound CdTe is shifted to more positive potentials.

On addition of a solution of 6.3×10^{-4} M of Te(IV) to a solution that contains 3.8×10^{-4} M of Cd(II), the current of the joint wave of reduction of Cd(II) and Te(IV) ions grows (Fig. 1b, curve *2*), with the current of this wave lower than the total current of Te(IV) and Cd(II) reduction at their corresponding concentrations in the electrolyte. In the cathodic voltammetric curve, as also in the voltammetric curve shown in Fig. 1a (curve *2*), there appears a current peak at $E = -0.94$ V, which is associated with the reduction of the CdTe compound formed by the equation

$$CdTe + 2H^+ + 2e \rightarrow Cd + H_2Te. \quad (7)$$

In the reverse run of the voltammetric curve (Fig. 1b, curve *2*), no current peak related to oxidation of elementary cadmium is observed, since the concentration of Te(IV) exceeds that of Cd(II) as compared with the 1 : 1 stoichiometric composition.

In order to consider in more detail the influence of Cd(II) ions on the electrochemical reduction of Te(IV) in an ammonia-chloride buffer solution, voltammetric curves were measured at a constant Te(IV) concentration of 3.8×10^{-4} M and various concentrations Cd(II) ions. On adding to the electrolyte solution even a minor amount of Cd(II) (1.9×10^{-5} M), the wave of Te(IV) reduction is shifted to more negative potentials, the current of Te(IV) reduction decreases, and the current peak related to further reduction of Te(0) to Te(–2) by reaction (2) becomes lower (Fig. 2, curve *2*). Raising the concentration of Cd(II) to 3.8×10^{-5} M leads to further shift of the wave of Te(IV) reduction to the region of negative potentials (Fig. 2, curve *3*).

At a Cd(II) concentration of 5.7×10^{-5} M, the wave of Te(IV) reduction reaches a potential of –0.9 V and coincides with the wave of Cd(II) reduction (Fig. 2, curve *4*). Under these conditions, Te(IV) is reduced directly to Te(–2), with addition of six electrons, and enters into chemical reaction with Cd^{2+} situated in the near-electrode layer to give the compound CdTe.

$$TeO_3^{2-} + Cd(NH_3)_4^{2+} + 6H^+ + 6e \rightarrow CdTe + 4NH_3 + 3H_2O. \quad (8)$$

At potentials more negative than that of the joint wave of Te(IV) and Cd(II) reduction, there appears a minor peak related to formation of the CdTe compound by Eq. (7). As the concentration of cadmium in the electrolyte solution becomes higher, the potential of this peak is shifted to more negative potentials and the current grows.

As the Cd(II) concentration increases, the potential at which the wave of joint reduction of Te(IV) and Cd(II) remains constant, but the shape of this wave changes: the current peak of reduction disappears and

a limiting current appears at a Cd(II) concentration of 9.5×10^{-5} M (Fig. 2, curve *6*). The current of this wave decreases gradually as the concentration of Cd(II) ions is raised to 1.3×10^{-4} (Fig. 2, curve *8*). With the Cd(II) concentration increasing further, to 1.7×10^{-4}, a minor peak reappears in the wave at a potential of –0.9 V (Fig. 2, curve *9*), and the current of the joint wave increases with Cd(II) concentration. At $c_{Cd(II)} = 2.9 \times 10^{-4}$ M, a minor peak associated with oxidation of metallic cadmium to Cd(+2) by reaction (4) appears in the reverse run of the voltammetric curve (Fig. 2, curve *11*), which indicates that free, elementary cadmium, unbound to tellurium, appears on the electrode surface. In this case, the peak of CdTe reduction reaches its maximum magnitude.

Consequently, as the concentration of cadmium grows, the total current of the reduction wave decreases, passes through a minimum, and again starts to increase, with the total current not additive to the currents of Te(IV) and Cd(II) reduction. The phenomenon observed is due to the reaction of the product formed in Te(IV) reduction with cadmium ions present in solution, to give a poorly soluble compound CdTe, which diminishes the flow of cadmium ions toward the electrode. A similar phenomenon has been observed in reduction of As(3+) and ions of bi- and trivalent metals (Cd^{2+}, Zn^{2+}, In^{3+}) on a mercury electrode in neutral solutions [9].

Raising the Cd(II) concentration to 2.98×10^{-4} M (Fig. 2, curve *11*) and more leads to an increase in the current of the joint reduction wave of Cd(II) and Te(IV) ions at $E = -0.9$ V, and the current of reduction of the CdTe formed decreases. Consequently, it may be assumed that the concentration ratio Cd(II) : Te(IV) = 1 : 1–0.8 : 1 in the electrolyte solution is the optimal for formation of the CdTe compound. The results obtained are confirmed by the dependence of the magnitudes of the anodic peaks related to CdTe electrooxidation on the concentration ratio of Cd(II) and Te(IV) ions in solution (Fig. 3). The current peak observed in the anodic portion of the voltammetric curves at potentials of 0.1–0.22 V, which correspond to oxidation of tellurium contained in the compound CdTe, reaches its maximum magnitude at a concentration ratio Cd(II) : Te(IV) = 0.8 : 1. With increasing content of Cd(II) ions in the electrolyte, the maximum current decreases.

The dependence of the current of the anodic peak of CdTe oxidation, observed at potentials of 0.15–0.3 V, on the potential of electrodeposition of this compound on a glassy carbon electrode in an ammonia-chloride buffer electrolyte with pH 8.4 was

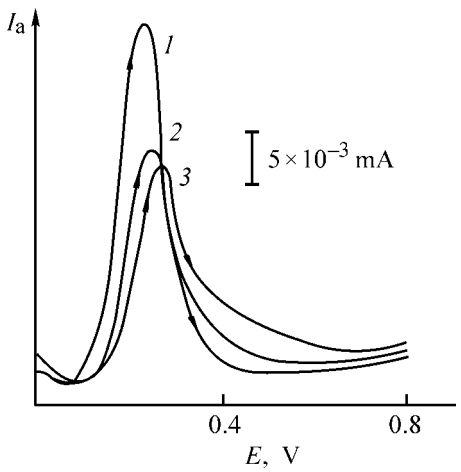

Fig. 3. Anodic voltammetric curves of CdTe ionization in an ammonia-chloride buffer electrolyte of varied composition. $c_{Cd(II)} \times 10^4$ (M): (*1*) 2.8, (*2*) 3.7, (*3*) 4.5.

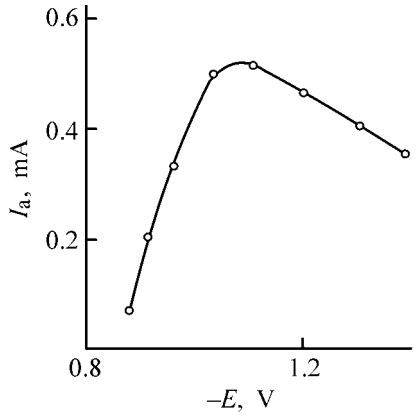

Fig. 4. Effect of the potential of CdTe deposition in an ammonia-chloride buffer electrolyte on the current of the anodic peak observed at potentials of 0.15–0.3 V at pH 8.4.

determined (Fig. 4). The electrodeposition was carried out at different cathode potentials (plotted in the figure along the abscissa axis), in the course of 30 s, with stirring. It was found that the maximum oxidation current of the compound formed is observed when CdTe is deposited onto the electrode surface at a potential of –1.1 V.

The data obtained are confirmed by the results of XPA. The X-ray phase analysis was carried out for CdTe films electrodeposited in the potentiostatic mode onto glassy carbon substrates with an apparent surface area of 1 cm^2. The electrodeposition of CdTe was performed from an ammonia-chloride buffer electrolyte with pH 8.4 at 80°C in the course of 20 min, with agitation of the electrolyte. The resulting films were annealed at 400°C for 10 min.

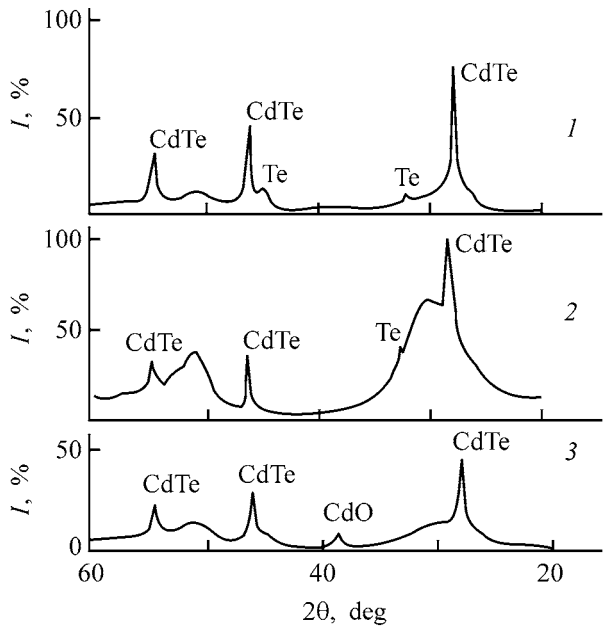

Fig. 5. X-ray diffraction patterns of CdTe films on a glassy carbon electrode. (*I*) Intensity and (2θ) Bragg angle. Concentration (M): (*1*) 1.2×10^{-3} Cd(II) and 1.2×10^{-3} Te(IV); (*2*) 1.17×10^{-3} Cd(II) and 1.47×10^{-3} Te(IV); and (*3*) 3.7×10^{-4} Cd(II) and 3.7×10^{-4} Te(IV). Deposition time (min): (*1, 2*) 20 and (*3*) 60.

Figure 5 (curves *1*, *2*) shows X-ray diffraction patterns of CdTe films electrodeposited at a potential of –1.1 V from an ammonia-chloride buffer electrolyte at a concentration ratio of Cd(II) and Te(II) in the electrolyte equal to 1 : 1 (diffraction pattern *1*) or 0.8 : 1 (diffraction pattern *2*). The clearly pronounced reflections of the compound CdTe can be seen in the figure. The three main reflections, which correspond to the interplanar spacings of 3.74, 2.29, and 1.95 Å, are in agreement with the ASTM file data for CdTe. Using an ammonia-chloride buffer electrolyte with pH 8.4 makes it possible to diminish the content of elementary tellurium in the CdTe deposit to CdTe : Te = 1 : 0.079–1 : 0.08, as indicated by the relative intensities of the main peaks of CdTe and Te in the X-ray diffraction patterns. In the widely used sulfate electrolytes, the CdTe : Te ratio is 1 : 0.30–1 : 0.31 [10]. Lowering the content of tellurium in the deposit of the compound obtained improves its semiconducting properties. It was shown, based on the relative intensities of the main reflections in the X-ray diffraction patterns, that CdTe films obtained from the ammonia-chloride buffer electrolyte have a regular cubic structure.

The effect of making longer (60 min) the time of CdTe electrodeposition was studied (Fig. 5, diffraction pattern *3*). The content of cadmium and tellurium in the ammonia-chloride solution was $c_{Cd(II)} = c_{Te(IV)} = 3.7 \times 10^{-4}$ M. It was found that sufficiently thick semiconducting CdTe films, which contain no elementary tellurium, are obtained at longer electrodeposition times. The reflections from the substrate are weakly pronounced, but there appear minor reflections corresponding to the CdO compound.

Thus, the use of an ammonia-chloride buffer electrolyte with pH 8.4 made it possible to obtain pure films of the semiconducting CdTe, which contain no elementary tellurium, and thereby to improve the semiconducting properties of the films obtained.

CONCLUSIONS

(1) In codeposition of cadmium(II) and tellurium(IV) from an ammonia-chloride buffer electrolyte with pH 8.4 onto a glassy carbon electrode, the potential of Te(IV) reduction is substantially shifted to more negative potentials, so that the reduction potentials of Cd(II) and Te(IV) coincide.

(2) The optimal conditions of CdTe electrodeposition from an ammonia-chloride electrolyte with pH 8.4 are as follows: deposition potential –1.1 V, temperature 80°C, concentration ratio Cd(II) : Te(IV) = 1 : 1–0.8 : 1.

(3) Using the ammonia-chloride electrolyte with pH 8.4 makes it possible to eliminate virtually totally the codeposition of elementary tellurium together with the CdTe deposit.

Received October 21, 2003

Abstract—The optimal composition of a cathode material based on films of an oxide chromium compound for a pulsed lithium chemical power cell that provides current densities of 80–140 mA cm^{-2} was determined.

Development of lithium chemical power cells that operate in pulsed mode is one of the most important tasks in view of the expanding range of their application in electronics. The operation of electronic devices (especially in its initial stage) frequently requires a very short high-current pulse. With account of this circumstance, the main requirement to chemical power cells is that they should provide high current densities (>50 mA cm^{-2}) in discharge through low external loads of the order of tens of ohms.

Commonly, lithium-based chemical power cells of pulsed type are fabricated using a thin-film technology for obtaining a cathode material on the basis of oxide systems of molybdenum, aluminum, and vanadium. The specific power of a power cell of this kind may be as high as 100 W g^{-1} [1]. The use of oxides is preferable, compared with compounds of other classes, since oxides are more stable in aprotic electrolytes, less toxic, and undergo only slight structural changes during operation of a chemical power cell.

At present, chemical power cells with a lithium anode and a manganese dioxide cathode are being commercially produced on a large scale. To their advantages belong the possibility of obtaining a rather high specific power (up to 200 W h kg^{-1}), stability of the discharge characteristic, and capacity for operation at low temperatures (below –20°C). A disadvantage of such a cell is the low discharge current (<1 mA cm^{-2}) [2].

The operation of lithium-based chemical power cells is based on solid-phase reduction of oxide materials, whose rate-determining stage is lithium diffusion in the solid phase. The diffusion coefficients are low (10^{-9}–10^{-13} cm^2 s^{-1} [3], and, as a result, the maximum current densities are low, too (commonly, ≤2 mA cm^{-2}).

To make higher the discharge current of lithium cells, a number of technological procedures have been advanced. It particular, it was suggested to assemble cells based on manganese dioxide into batteries, e.g., thin batteries with a voltage of 6 V. The discharge current of batteries of this kind may vary within the range 0.03–150 mA in their operation in the continuous mode (with the battery capacity being, in this case, 13 A h) and be as high as 1 A in the pulsed mode (with the battery capacity not exceeding 0.85 A h) [4].

In the recent 10–15 years, a close attention has been given to oxide compounds of nonstoichiometric composition as possible electrode materials. It has been established that the rate of electrochemical reactions and, consequently, the achievable current density are the higher, the stronger the deviation of the composition of a compound from the stoichiometry, which determines the type of conduction, the defectiveness of the structure, and the catalytic activity of a compound [5–7].

Using the nonstoichiometric oxides makes it possible to raise the specific capacity of the electrode, and varying the deviation of composition from the stoichiometry allows control over the rate of introduction of the lithium cation into the cathode material [8]. An important additional advantage of such oxides is their mixed conductivity with a considerable share of the electronic component [9]. In some cases, this obviates the necessity for introduction of electrically conducting additives (carbon black, graphite) into the cathode material, which not only simplifies the fabri-

1070-4272/04/7702-0231 © 2004 MAIK "Nauka/Interperiodica"

cation technology of chemical power cells and, accordingly, lowers its cost, but also makes it possible to raise the utilization factor of the cathode material.

Of particular interest among representatives of this class of compounds are nonstoichiometric oxide compounds of chromium [10–13]. For example, lithium cells with a cathode material based on $CrO_{2.66}$, which have a specific power of 300–1000 W h l^{-1} and a specific capacity of 370–410 A h kg^{-1}, have been suggested [13]. However, the technology for synthesis of this compound is rather complicated [14]: it is commonly obtained by removing a required amount of oxygen from a stoichiometric chromium(VI) oxide.

It is known that chemical methods for obtaining compounds of nonstoichiometric composition fail to ensure its due reproducibility, require long time, and are labor-consuming. Electrochemical synthesis yields virtually compositionally reproducible compounds and can be readily controlled with electrolysis parameters.

The aim of this study was to select a cathode material for pulsed lithium-based chemical power cells and to optimize its composition.

EXPERIMENTAL

The method of electrochemical synthesis from fluorine-containing electrolytes has been used to obtain a number of oxide compounds of copper, molybdenum, nickel, and chromium of nonstoichiometric composition [9]. Preliminary studies of these compounds as cathode materials for chemical power cells with a lithium anode demonstrated that oxide compounds of chromium and molybdenum are of particular interest. The peak currents in a pulse at discharge time of 10 s and load of 1 kΩ are given below for lithium power cells with cathodes made of the compounds under study:

Oxide	Cu(I)	Cr	Mo	Ni	Mn
Peak current in a pulse, mA	15	70	35	30	22

The highest discharge currents in the pulsed mode were obtained for a cathode material based on chromium compounds, and this material was chosen for the further study. An additional advantage is that oxide compounds of chromium can be deposited in the form of thin films that firmly adhere to the base, which obviates the necessity for introduction of a binder and electrically conducting additives into the cathode material. As a result, the fabrication technology of the lithium-based chemical power cell is strongly simplified because of the elimination of a number of technological procedures.

The oxide compounds of chromium were obtained from an electrolyte containing 250 g l^{-1} of chromium(VI) oxide and 0.1 to 0.8 g l^{-1} of hydrofluoric acid [9]. The thickness of a film of an oxide chromium compound, deposited onto the base, was 12–15 μm. The composition of the oxide compounds obtained was determined using the atomic-absorption and neutron activation methods of analysis. The latter technique was used to determine the total oxygen, including that contained in H_2O and in OH^- groups, in oxide compounds of chromium [15]. Taking into account the fact that the compounds under study are not stoichiometric and, consequently, their density differs from the tabulated values, the apparent and true densities of the oxide compounds synthesized were determined. The specific surface area of this compounds was found using the BET method.

The conductivity (ionic and electronic) is a structure-sensitive parameter that governs the electrical characteristics of a material. The total conductivity and its constituents were found using the procedure described in [16]. Also, the effect of the duration and the mode of thermal treatment on these quantities and on the peak current in a pulse of a lithium power cell was studied.

The electrical characteristics of prototype lithium power cells were determined with an S8-13 oscilloscope in the form of a 100-ms pulse on a load of 10 Ω. The prototype samples of lithium-based chemical power cells of standard size 23 × 25 were assembled in a box in the atmosphere of argon; as electrolyte served a 1 M solution of lithium fluoroborate in γ-butyrolactone.

The data on the composition of oxide compounds of chromium and the peak current in a pulse are listed in Table 1 in relation to the concentration of the ligand in the electrolyte. For example, raising the concentration of the F^- ion in the electrolyte leads to an increase in both the total and metallic chromium in the samples. In the same order decreases the amount of oxygen and OH groups, which stabilize the redox systems $M^{n+}/M^{(n-1)}$ in oxide compounds of this type [4].

The peak current in a pulse of a lithium power cell and the composition of an oxide compound used to fabricate the cathode are determined by the concentration of the ligand in the electrolyte: the maximum current is observed for sample no. 1 and decreases on passing to sample nos. 2–4, i.e., with increasing concentration of the ligand in the electrolyte. In the same way decreases the share of ionic conductivity in the

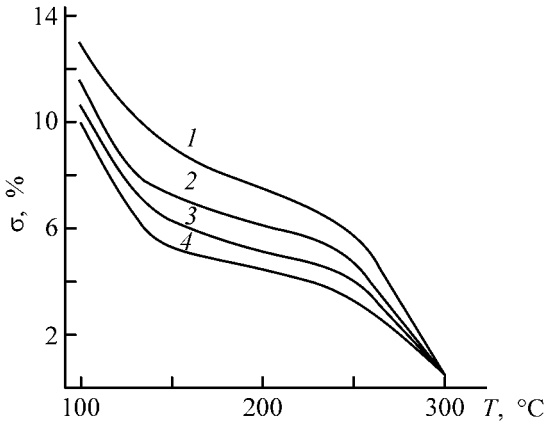
	true	apparent		true	apparent
0.2	2.1	1.41	0.6	2.27	1.65
0.4	2.25	1.58	0.8	2.29	1.78

compounds studied. The data in Table 1 were used to determine the optimal electrolyte composition for obtaining a cathode material for a pulsed lithium-based chemical power cell. In the same order grow the true and apparent densities of oxide compounds of chromium (Table 2), which is due to an increase in the content of metallic chromium in the samples studied. The specific surface area of the compounds obtained varies from 0.5 $m^2 g^{-1}$ for pelletized samples to 1.9 $m^2 g^{-1}$ for powdered samples.

To create lithium power cells that allow high discharge rate, it seems necessary to study the conductivity of the cathode materials used, since it is this parameter that largely determines the rate of the electrochemical process that occurs in operation of a chemical power cell. It is known that the conductivity of a substance is strongly temperature-dependent. To optimize the thermal treatment mode, temperature dependences of conductivity were studied. The peak currents in a pulse (current–time dependences) were examined for a lithium power cell with a cathode material based on an oxide chromium compound of the optimal composition no. 1 (Table 1).

The figure shows how the share of ionic conductivity of the oxide compounds of chromium, synthesized in this study, depends on the temperature of thermal treatment and on the electrolyte composition. It follows from an analysis of these data that, as the concentration of the F^- ion in the electrolyte increases in electrosynthesis of oxide compounds of chromium, the share of the ionic constituent of the conductivity decreases. A similar influence is exerted by the temperature of their subsequent thermal treatment. Moreover, after thermal treatment at 300°C the share of the ionic constituent of conductivity is virtually zero.

The results obtained suggest that the ionic conduction is due to the presence of hydroxy groups, which, in turn, predetermines the difference between the ionic components of samples with different compositions. This conclusion is confirmed by results of a thermogravimetric analysis and IR spectroscopy, according



Share of ionic constituent of the conductivity σ of oxide compounds of chromium vs. temperature T of their thermal treatment at different concentrations of the ligand in the electrolyte in synthesis of these compounds. Concentration (g l^{-1}): (*1*) 0.1, (*2*) 0.2, (*3*) 0.4, and (*4*) 0.8.

100	230	220	200	230	200	190	180	175	165	150	140	110

to which the crystallization water and OH^- groups are completely removed at 300–320°C. It should be noted that a correlation is observed between the modes of thermal treatment and the peak currents in the I–T dependences for the prototype samples of lithium power cells. The variation of the peak current in a pulse with the temperature of thermal treatment of oxide compounds of chromium are is illustrated in Table 3 for different pulse durations. According to these data, the optimal temperature of thermal treatment of oxide compounds of chromium is 250–260°C. The share of the ionic conductivity for the given cathode material should not exceed 4–5%.

A lithium-based chemical power cell of this kind allows multiple switch-ons (Table 4). Up to 20 successive switch-ons of a power cell were carried out, with the current pulse recorded. The peak current in a pulse decreases only slightly during the first ten successive switch-ons, but starts to fall more steeply after 20th switch-on of the chemical power cell. However, the discharge current density of the lithium-based power cell under study remains, even under these conditions, 20–30 times the discharge current density of the known lithium power cells.

Thus, there appears an opportunity to test preliminarily both the potential electrode materials and the systems as a whole for possible use in power cells providing high (up to 140 mA cm^{-2} for a short interval of time) discharge current densities at low external loads.

CONCLUSION

The data obtained indicate that oxide compounds of chromium can be used as cathode materials in lithium-based chemical power cells that provide high current densities (80–110 mA cm^{-2}) in discharge through low external loads during a short period of time.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electroless Nickel and Copper Plating of Carbon Fibers with the Use of Sulfur-containing Reducing Agents

I. N. Terskaya, V. V. Budanov, S. V. Makarov, and L. V. Ermolina

Ivanovo State University of Chemical Engineering, Ivanovo, Russia

Received April 3, 2003

Abstract—The fundamental aspects of electroless nickel and copper plating of carbon fibers with the use of sodium hydroxymethane-sulfinate and thiourea dioxide as reducing agents were studied.

The development of modern technology requires that new materials with special properties, including electrically conducting metallized fibers, should be created [1]. The efficiency of metallization depends on the state of the fiber surface. Surface pretreatment includes stages of cleaning, degreasing, etching, sensitization, and activation. Tin compounds are commonly used as sensitizing agents; the activation is done by treatment of a sensitized surface with solutions of compounds of platinum-group metals, most frequently with palladium salts [1, 2]. Of economic interest are activation methods that use no palladium. A disadvantage of the known techniques of this kind is that the composition of the activating solution is rather complex and the process is labor-consuming because of the great number of successive technological procedures involved [3, 4].

Of interest for further improvement of the existing methods and development of new techniques for electroless metallization is expansion of the number of the reducing agents used. The conventionally employed sodium borohydride and hypophosphite give no way of obtaining impurity-free metal coatings, and their solutions are insufficiently stable, especially in acid media [5]. In [6], it was suggested to use thiourea dioxide (TDO) and sodium hydroxymethane-sulfinate (SHMS) for electroless nickel plating of polyacrylonitrile (PAN) fibers. In this case, coatings with high adhesion can be obtained without activation with palladium salts.

The aim of the present study was to examine the possibility of using TDO and SHMS (technical name rongalite) for metallization of carbon fibers and to analyze the physicomechanical aspects of formation of metal coatings.

EXPERIMENTAL

Samples of black-reinforced epoxy plastic were prepared from UUT-2 fabric with carbon fiber content of 60% by the standard procedure [7, 8]. Thiourea dioxide $(NH_2)_2CSO_2$ was synthesized from thiourea of chemically pure grade by oxidation with hydrogen peroxide by the known technique [9], or a technical-grade product was used after double recrystallization. Sodium hydroxymethane-sulfinate $HOCH_2SO_2Na \cdot 2H_2O$ was obtained by double recrystallization of a technical-grade product from water. The content of the main substance in the reducing agents prepared, monitored iodometrically [10], was no less than 99.8%. Etching, activation, and metallization solutions were prepared from Ni, Cu, and Cd salts, potassium dichromate of chemically pure grade, and H_2SO_4 acid of analytically pure grade. Carbon fiber samples were preliminarily treated with concentrated sulfuric acid (d = 1.83 g ml^{-1}) with various additives for 3–10 min, with subsequent washing with water as described in [11]. The reaction of Ni^{2+}, Cu^{2+}, and $Cr_2O_7^{2-}$ with SHMS or TDO was performed in air. The content of Ni^{2+} ions in solution was monitored by trilonometry, and that of Cu^{2+} ions, by spectrophotometry (SF-46 spectrophotometer, λ_{max} = 740 nm), using the known procedures [12]. The amount of metal deposited was determined gravimetrically, with correction made for the content of sulfides and sulfites [12].[1] Additionally,

[1] Admixtures of sulfides and sulfites may appear through decomposition of sulfur-containing reducing agents.

1070-4272/04/7702-0236 © 2004 MAIK "Nauka/Interperiodica"

the metal deposit was analyzed for the content of Ni and Cu by atomic-adsorption spectrometry (Saturn spectrometer); the size of metal powder particles was determined with a Tesla BS-300 electron microscope. The adhesion strength of metal coatings with a black-reinforced plastic substrate was evaluated by the "thermal shock" and ultrasonic methods. The metal coatings were subjected to the action of high-frequency sound vibrations in a liquid medium, using a UD-20 ultrasonic integrator.[2]

In the experiments, the instant of time at which disintegration of a metal film started and the time of its complete disintegration (disintegration spot diameter 5 mm) were recorded.

A study of reduction of Ni^{2+}, Cu^{2+}, and $Cr_2O_7^{2-}$ with SHMS and TDO demonstrated that, in the absence of a substrate, the decrease in the concentration of the ions of the oxidizing agents at fixed concentration of a reducing agent, taken in excess, is described by the kinetic equation of a pseudo-monomolecular reaction. The effective rate constants of the reaction are listed in Table 1. The data in the table were used to calculate the activation energies and logarithms of the pre-exponentials in the Arrhenius equation; the dependences obtained are shown in Fig. 1. The strong influence of temperature on the reaction rate and the accordingly high activation energies of the process (84–187 kJ mol^{-1}) can be accounted for as follows.

It has been established previously [10, 13–15] that the reactions of reduction of organic and inorganic oxidizing agents with hydroxy and amine derivatives of sulfinic acids proceed by two parallel pathways: via direct interaction of reactant molecules (associative pathway) and via cleavage of the reducing agents at the C–S bond (dissociative pathway):

$$HOCH_2SO_2^- + H_2O = HSO_2^- + CH_2(OH)_2, \quad (1)$$

$$NH_2(NH)CSO_2H + OH^- = HSO_2^- + (NH_2)_2CO. \quad (2)$$

In the latter case, the role of reducing agents is played by sulfoxylate ions HSO_2^{2-} or secondary products of reactions (1) and (2), dithionite ions $S_2O_2^{2-}$. The occurrence of these pathways and their contribution to the overall rate of reduction processes were determined experimentally from the decrease in the reaction rate in the presence of an admixture of formaldehyde, which binds sulfoxylate to $HOCH_2SO_2^-$

[2] A sample was placed in a vessel with distilled water and the focusing attachment of the vibrator was mounted at a distance of 10 mm from the sample surface.

by a reverse reaction (1). It was established in [14] that an activation energy of more than 100 kJ mol^{-1} corresponds to the dissociative pathway, whereas in the case of an associative pathway, this quantity is about 20 kJ mol^{-1}, on average. The results obtained in a study of the influence exerted by formaldehyde additives [15] and a comparison of the activation energies indicate that the concepts developed are also applicable to reactions in which salts of transition

metals, nickel and copper, are reduced, with the dominant role played in this case by the dissociative pathway. It follows from Fig. 1 that, with allowance made for the rather high errors in measuring these quantities ($\Delta E_a = \pm 20$ kJ mol^{-1}, $\ln P = \pm 10$), the activation parameters $\ln P$ and E_a are correlated in terms of the compensation effect. This indicates that the rate-determining stages (1) or (2) proceed via intermediate states with configurations of the same type [16].

Table 2. Influence exerted by the mode of carbon fiber activation on the amount m of metal being deposited (metallization conditions: $[Ni^{2+}] = [Cu^{2+}] = 0.2$ M, T = 343 K, t = 10 min, [SHMS] = [TDO] = 0.4 M)

An important specific feature of the process of reduction with thiourea dioxide in a weakly acidic medium at temperatures lower than 333 K, in contrast to the process with SHMS, is that products of decomposition of the reducing agent, sulfite and sulfide ions, are virtually totally absent in the reaction system. This circumstance leads to a significant advantage of TDO over SHMS, since it furnishes an opportunity to obtain high-purity metal powders and coatings [17]. It can be seen from Table 1 that the rate constants of $Cr_2O_7^{2-}$ reduction are, on average, an order of magnitude higher than those of Ni^{2+} and Cu^{2+} reduction. Hence follows that, in the case of joint presence of Ni^{2+}, Cu^{2+}, and $Cr_2O_7^{2-}$ ions, the last type of ions will be more rapidly reduced to Cr^{3+} and Cr_2O_3. Being adsorbed on the surface of carbon fibers, these species may act as active centers in chemical deposition of metals [18].

In order to elucidate the mechanism by which carbon fibers affect the rate of redox reactions, decomposition of the reducing agents was studied in the presence of carbon fibers and Cu and Ni powder additives or without these (Figs. 2a, 2b). It can be seen that, in the presence of carbon fibers, the decomposition rate of SHMS (Fig. 2a) and TDO (Fig. 2b) increases. This is particularly pronounced in the case of a carbon fiber etched in conc. H_2SO_4 with addition of Cd^{2+} and $Cr_2O_7^{2-}$ (Figs. 2a, 2b; curves *4*, *5*). In the presence of Ni and Cu powders (Figs. 2a, 2b; curves *6*, *7*), the decomposition rate also increases, even though to a lesser extent than in the presence of an activated carbon fiber. It is known that Cu and Ni metals catalyze the decomposition of SHMS [6].

The data in Fig. 2 are in good agreement with the results obtained in determining the rates of redox reactions in the presence of carbon fibers. It has been found [11, 15] that, in reduction of Cu^{2+}, the highest rate is observed in the presence of a carbon fiber etched in conc. H_2SO_4 with addition of Cd^{2+} ($K_{eff} = 3.6 \times 10^{-3}$ min^{-1}), whereas in reduction of Ni^{2+}, the most efficient treatment is that with conc. H_2SO_4 with addition of $Cr_2O_7^{2-}$ ($K_{eff} = 9.3 \times 10^{-3}$ min^{-1}). At the same time, the effective rate constants of reduction of Cu^{2+} and Ni^{2+} ions in the absence of carbon fibers are 1.4×10^{-3} and 3.4×10^{-3} min^{-1}, respectively.[3] It is known that etching of carbon fibers leads to a certain surface roughness, with simultaneous appearance of –C=O and –C–O– groups involved in redox processes of formation of primary metal crystallization centers [7]. The data in Table 2 indicate that a sufficiently high content of copper and nickel in car-

[3] All values of K_{eff} are related to a temperature of 298 K.

bon fiber samples (up to 3.8–5.8 mg g^{-1}) is achieved in etching the substrate in conc. H_2SO_4 with addition of Cd^{2+} (in Cu deposition) or $Cr_2O_7^{2-}$ (in Ni deposition) for 6 min. It can be seen from Table 3 that the optimal concentration of the additives in the etching bath should be 0.3 g l^{-1} at the etching time of 6 min.

Thus, comparison of the data on the decomposition rates of the reducing agents and the rates of redox reactions in the presence and in the absence of a carbon fiber substrate gives reason to believe that the influence of the substrate on the rate of metal deposition is determined by the following two factors. On the one hand, there is a growing contribution from the dissociative pathway and increasing quasi-stationary concentration of intermediates, sulfoxylate ions. On the other hand, the Cd(0) and Cr(III) species formed on the substrate surface upon its activation exert an accelerating action.

Figure 3 compares the adhesion strengths of nickel coatings formed upon different kinds of pretreatment of carbon fiber substrates. The data obtained indicate that the adhesion strength of the nickel coating formed using the suggested procedure is high. A sample treated with conc. H_2SO_4 with addition of $Cr_2O_7^{2-}$ significantly surpasses the samples treated with salts of tin and palladium in the time of beginning and completion of coating disintegration. Thus, the method of simultaneous etching and activation of carbon fibers, suggested here, leads to enhanced localization of the redox process on the surface and to improved adhesion strength of the coating.

Analysis of the experimental data obtained makes it possible to recommend a rather simple method for electroless nickel plating of carbon fibers, protected by a patent [19]. The procedure is as follows. The surface of an article made of carbon fibers is etched for 6 min at a temperature of 353 K with a 0.3 M solution of potassium dichromate in concentrated sulfuric acid (d = 1.83 g cm^{-1}). After that the article is placed, without washing or removal of the etching mixture remaining on its surface, in a metallization bath with an aqueous solution of nickel chloride and SHMS or TDO. The duration of this stage is 3–5 min, after which the article is washed and dried. The method can produce nickel coatings with a layer thickness of 4.5–5.2 μm at an average metallization rate of 24 μm h^{-1}. The technique suggested makes the process less labor-consuming. This is achieved by combining the stages of activation and chemical metallization into a single stage, eliminating the stages of washing and preparation of a special activating formulation, and excluding the use of highly expensive components (Sn and Pd). Moreover, if sodium borohydrate is used, the coating contains, in addition to the main substance, a boron impurity. However, a keen interest in obtaining pure metal coatings has aroused recently [2, 3, 5]. In this context, more promising reducing agents are SHMS and TDO, which provide a 99.0–99.9% content of the main metal in a coating.

Table 3. Influence exerted by the concentration of Cd(II) and Cr(IV) additives in the etching solution on the mass of the metal being deposited (metallization conditions: $[Cu^{2+}] = [Ni^{2+}] = 1.0$ M, t = 6 min, [SHMS] = [TDO] = 0.2 M)

CONCLUSION

A study of the influence exerted by a carbon fiber substrate and methods of its activation on the rate of chemical deposition of nickel and copper demonstrated that use of sulfur-and-oxygen-containing reducing agents, rongalite and thiourea dioxide, yields coatings with high adhesion to the substrate and makes the metallization process simpler and less expensive.

Abstract—Biosensors based on a carbon paste electrode with immobilized cholinesterase and cobalt(II) phthalocyanine as a mediator are studied. Electrochemical characteristics of the biosensors are investigated in relation to the carbon paste composition, the enzyme and mediator immobilization procedures, nature of the protective film and procedure of its application, and also storage conditions of the electrodes. A method is suggested for fabricating a cholinesterase biosensor with cobalt(II) phthalocyanine mediator, providing the maximum electrocatalytic response in electrooxidation of butyrylthiocholine iodide (substrate for cholinesterase).

The development of various biosensors has attracted much attention [1–4]. Biosensors differ from each other in the composition and design of their biosensing elements, and also in the design of the detection system [5]. Among diverse existing biosensors, those with electrochemical detection systems have found wide application [6–8]. The use of biocatalytic and electrochemical reactions in combination allows development of highly sensitive and fast methods for determining various bioactive compounds [2–8]. One of the lines in this area is the development of electrochemical biosensors with immobilized mediators [9, 10]. Mediators serve to provide facilitated electron transfer between active centers of the enzyme and a transducer. The use of mediators in biosensors allows an increase in the electrochemical response and selectivity by virtue of a decrease in the electrode potential.

Biosensors with electron-transfer mediators can be improved in different ways: development of novel mediating systems and elaboration of advanced methods for immobilizing a mediator and an enzyme and new techniques for fabricating a sensing element of the electrode. The development of biosensors with carbon paste electrodes is regarded as a promising way for improving analytical characteristics of amperometric enzyme sensors [11]. The sensitivity of amperometric determinations with carbon paste electrodes (CPE) is limited by the background interference and also by noises generated in electrochemical transducers. The signal-to-noise ratio can be improved by lowering the residual current in such ways as development of new sensing materials, modification of the electrode surface, and immobilization of a redox mediator.

Metals, metal oxides, complexes of metals, and polymers can be used as mediators [5]. Ferrocene-like compounds are frequently used for this purpose [10]. For example, ferrocenes have been successfully used in glucose oxidase biosensors [12]. The same mediator has been employed for amperometric determinations with the cholinesterase enzyme system [13]. Quinone has been used as a mediator in glucose oxidase biosensors for determination of, e.g., glucose [10]. Amperometric biosensors based on inorganic polycrystalline materials show interesting properties too [14, 15]. The use of electrodes modified with Prussian Blue in biosensors [14] allowed an increase in the current density of hydrogen peroxide reduction and a decrease in the potential of the working electrode, thus reducing the sensitivity of the biosensor to oxygen, ascorbic acid, and other reducing agents. However, iron(II) ferrocyanide films obtained by electrochemical deposition are insufficiently stable, especially, in alkaline solutions. The stability of a glucose oxidase biosensor can be improved by making use of, e.g., synthetic copper(II) ferrocyanide incorporated into the carbon paste in addition to glucose oxidase [15]. Such an electrode may operate at the physiological pH ~7.4. In contrast to the above-indicated mediators, metallophthalocyanines (MPc) are charac-

terized by both high catalytic activity in various electrochemical reactions and sufficient chemical stability [16, 17]. Therefore, metallophthalocyanines have been used as mediators for biosensors too [18, 19]. The catalytic activity of metallophthalocyanines depends on the ligand structure and the nature of a metal. Among 3*d* metal complexes, Co(II) and Fe(II) phthalocyanines demonstrate the highest catalytic effect in oxidation of organic hydrosulfides [20]. In studying the electrocatalytic properties of metallophthalocyanines-modified electrodes in the system constituted by cholinesterase (CHE) and thiocholine ester, we also demonstrated that the highest catalytic effects are observed on CoPc- and FePc-modified electrodes [21].

In this study, we examined how the composition of the sensing element of the electrode and the procedure of its formation affect the performance of CPE-based biosensor with immobilized CHE and CoPc as a mediator.

In developing an amperometric CHE biosensor with CoPc, we compared various methods for immobilization of the enzyme and mediator, such as incorporation of all or some of components into carbon paste or their application as films on the CPE surface.

It is known [22] that butyrylthiocholine (BTCH) iodide is a specific substrate for CHE. Enzymatic hydrolysis of BTCH produces butyric acid and thiocholine (TCH) iodide:

$$C_3H_7C(O)SCH_2CH_2N^+(CH_3)_3I^- + H_2O \xrightarrow{CHE} C_3H_7COOH + HSCH_2CH_2N^+(CH_3)_3I^-.$$

The CHE activity was determined by amperometric measurement of TCH iodide as a product of enzymatic hydrolysis of BTCH. Anodic voltammograms were recorded in 2×10^{-3} M BTH in borate buffer solution (pH 9.0) over the potential range 0.0–1.0 V. We observed two steps in the anodic oxidation curve of BTCH, measured with CPE after spontaneous hydrolysis (Fig. 1, curve *1*). The first peak (E_p = 0.60 V), corresponding to oxidation of TCH, was used as the analytical response. Previously, we demonstrated [21] that, in this potential range, TCH is oxidized and iodide acts as a mediator:

$$I^- - e \rightleftarrows I, \quad I + RSH \rightarrow I^- + \tfrac{1}{2}RSSR + H^+,$$

where $R = -CH_2CH_2N^+(CH_3)_3$.

In the presence of both native CHE [21] and that immobilized on carbon paste (Fig. 1, curve *2*), the intensity of the peak at E_p ~0.60 V increased because of the enzymatic hydrolysis of BTCH. Figure 1 (curve *3*) shows the curve of anodic oxidation of BTCH, obtained with a biosensor fabricated using simultaneous immobilization of CHE and CoPc, as a mediator, on CPE. In this case, the anodic peak is observed within the same potential range as that without mediator, but it has higher intensity. In the presence of CoPc, heterogeneous electrocatalytic oxidation of TCH occurs in addition to the above-described electrochemical reaction. In this case, the electrochemically generated Co(III)Pc acts as a catalyst [21]:

$$M(II)Pc \rightleftarrows M(III)Pc + e, \quad M(III)Pc + RSH \rightarrow M(II)Pc + \tfrac{1}{2}RSSR + H^+.$$

The structure of the CHE biosensor and the procedure of its fabrication also affect the peak potential and TCH oxidation current.

The CPE performance, including the residual current, depends on a conducting carbon-based material and a binder used. We used various types of carbon materials such as spectroscopy-grade graphite powder, activated carbon, and flake graphite. The current–voltage characteristics of the electrodes were compared using the TCH oxidation data (Table 1). Globular graphite powders (spectroscopy-grade graphite and activated carbon) demonstrated better electrochemical performance: lower peak potentials and higher anodic peak currents. Carbon-paste electrodes fabricated from

flake graphite show a lower conductivity and, as a result, higher peak potentials, lower peak currents, and worse reproducibility of the electrochemical response. The nature of a binder influences the ohmic resistance of the electrode and, therefore, the detection sensitivity. The finer a powder, the larger amount of a binder is needed. But an increase in the amount of a binder results in that the ohmic resistance of the electrode becomes higher. The TCH oxidation current decreases in the order Nujol > paraffin > polyethylene. The ohmic resistance of the electrode and the residual current are at a minimum for the electrode fabricated from spectroscopy-grade graphite with Nujol as a binder (Table 1).

The CPE characteristics are strongly affected by pretreatment of the initial carbon material with an organic solvent. Such a pretreatment, followed by removal of a solvent, occasionally leads to a considerable decrease in the electrode polarization. We compared properties of CPEs treated with various solvents, such as butyl acetate, ethanol, toluene, acetonitrile, acetone, and methylene chloride (Table 1). As can be seen, the best characteristics (lower resistance and higher peak current) were provided by pretreatment with butyl acetate. Furthermore, pretreatment of activated carbon with butyl acetate shifts the peak potential by 150 mV (Fig. 1, curve *4*).

The crucial point in development of biosensors is to properly arrange an enzyme molecule on the electrode surface. We tested various methods of CHE immobilization such as adsorption on the electrode surface, incorporation into carbon paste, chemical (covalent) binding, and incorporation into a polymeric film (Table 2).

Immobilization of CHE by adsorption on the electrode surface (Table 2, experiment no. 1) or by in-

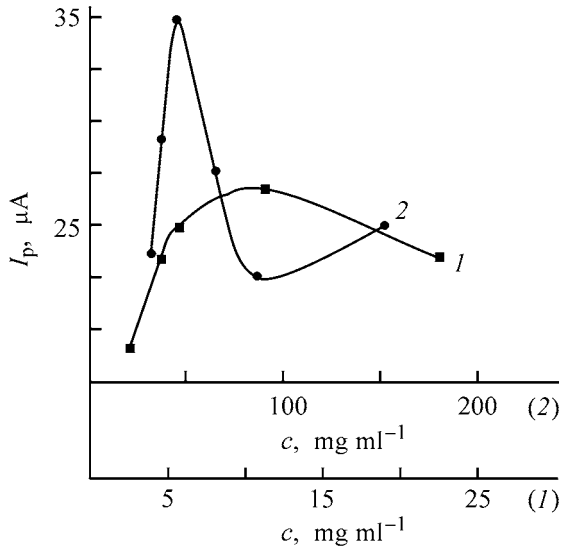

Fig. 2. Peak current I_p of BTCH oxidation on CHE biosensor vs. (*1*) CHE and (*2*) glycerol concentration c in the film.

corporation into the carbon paste (Table 2, experiment no. 2) resulted in a low and poorly reproducible (S_r > 10%) TCH oxidation current, because of the rapid washout of the enzyme from the electrode surface.

To more tightly fix CHE in the electrode matrix, we employed covalent binding with a bifunctional agent, glutaraldehyde (GA) (Table 2, experiment no. 3). The carbon powder was impregnated with butyl acetate and then with a mixture of CHE and GA, followed by removal of the solvent. The optimal CHE to GA ratio has been established previously [23]. The resulting biosensor demonstrated better metrological characteristics (S_r < 5%) and a satisfactorily low E_p = 0.50 V (Table 2, experiment no. 3a). In fabricating a biosensing element in the form of a layer on CPE (Table 2, experiment no. 3b), a drop of an aqueous solution containing CHE and GA was deposited onto the electrode surface. We also varied the order of CHE and GA deposition: the CHE layer was deposited first, and the GA layer, second, and vice versa. One more variant of immobilization was deposition of the GA layer, followed by adsorption of CHE from its aqueous solution. In this case, the optimal CHE concentration on the electrode surface was created by adsorption from a 5 mg ml^{-1} solution (Fig. 2, curve *1*). The best electrochemical (E_p and I_p) and metrological (S_r < 5%) characteristics were obtained with a sensor fabricated by deposition of a mixture of CHE and GA on the electrode surface.

Another procedure used for CHE immobilization was exposure of the electrode, modified with adsorbed CHE, to a GA vapor [24]. Varying the temperature, we established that the highest response is observed with CHE covalently bound to GA at 4–7°C (Table 2, experiment no. 3c). However, we observed an increase in E_p in this case.

To stabilize the electrochemical response and catalytic activity of immobilized CHE, the electrode surface was coated with a film of various polymeric materials, such as nitrocellulose, gelatin, agar-agar, and chitosan (Table 2, experiment no. 4). The films were obtained by deposition of 0.1 ml of a solution with various polymer concentrations on the electrode surface with subsequent removal of the solvent. A mixture of butyl acetate and toluene was used as a solvent for NC, and water, for the other polymers. The optimal NC concentration in the solution used for the film preparation was established from the dependence of the TCH oxidation current on the polymer concentration to be 1 mg ml^{-1} (Fig. 3). The optimal concentrations of gelatin, agar-agar, and chitosan were found to be 6–15, 20, and 25 mg ml^{-1}, respectively (Fig. 3).

In a series of experiments (Table 2, experiment no. 4) we varied the sequence of reagent deposition on the electrode surface. Adsorption of CHE over the NC layer did not increase the TCH oxidation peak; in addition, in this case, CHE is rapidly washed out from the electrode surface. The immobilization of CHE bound to GA in an NC film improved the reproducibility of the peak current, but strongly decreased the enzyme activity, which was reflected in a decreased

analytical response. The deposition of an NC film over the layer of CHE, covalently bound to GA, totally inactivated CHE, i.e., the peak current was equal in this case to that in the absence of CHE, which is probably due to the inhibiting effect of the organic solvent used for NC dissolution.

In a similar experiment, but with gelatin instead of NC, we also observed a decrease in the enzyme activity, but it was considerably less pronounced. A higher response was obtained on an electrode successively coated with a layer of CHE + GA and a layer of gelatin. With the use of agar-agar and chitosan, better results were also obtained when polymeric films were applied over the enzyme-containing layer (Table 2, experiment no. 4).

Thus, application of a polymeric film improved the reproducibility of the electrochemical response of the biosensors, but decreased the catalytic activity of the enzyme. The use of films of natural polymers favored tight binding of CHE to the electrode matrix, and, unlike NC, had no inhibiting effect on the catalytic activity of immobilized CHE.

It should be pointed out that the storage conditions also influence the electrochemical characteristics of the biosensors. The activity of biosensors decays with time. However, if stored under conditions of increased humidity, the biosensors demonstrated even better metrological characteristics, and their lifetime increased to a week.

Introduction of some "water-like" compounds into the enzyme-containing layer of a biosensor increases the activity of immobilized CHE, including that upon in storage. For example, introduction of glycerol considerably increases the CHE activity. In [25, 26], it was demonstrated for the example of proteins other than CHE that raising the sorbitol content in a chymotrypsin preparation leads to a higher enzyme activity, and the absence of glycerol in the immobilized enzyme results in a total loss of activity [26]. Most likely, such compounds as sorbitol [25] and glycerol [26] provide a favorable environment for an enzyme in dehydration compensating hydrogen bonds. Evidently, that is why the introduction of glycerol into the film considerably increases the CHE activity. In special experiments, we established the optimal glycerol to CHE ratio in the sensing element (Fig. 2).

In development of biosensors with mediators, it is important to provide conditions for facilitated electron transfer between an enzyme and a transducer. This can be done through optimal orientation of enzymes and mediators on the electrode surface. Therefore, we studied various immobilization modes of the enzyme (CHE) and mediator (CoPc) on CPE.

In fabricating biosensors, we used various electrode modification procedures, such as successive deposition of layers of the mediator, enzyme, and other components or formation of a biosensing membrane containing all these components (Table 3, experiment no. 1).

Table 4. Parameters of flow-injection analysis for heavy metals with CHE biosensor with CoPc mediator (regression equation: $\log I = a + b \log c$; I, μA; c, M)

Cation	Concentration, M	a	b	R	c_{min}, μg l^{-1}	MPC, μg l^{-1} [29]
Zn^{2+}	1×10^{-6}–1×10^{-3}	0.94 ± 0.02	–0.180 ± 0.005	0.9991	8×10^{-7} (52)	1000
Cd^{2+}	1×10^{-8}–1×10^{-5}	1.05 ± 0.02	–0.048 ± 0.002	0.9995	5×10^{-9} (0.56)	100
Cu^{2+}	5×10^{-10}–1×10^{-6}	2.20 ± 0.04	–0.150 ± 0.006	0.9997	1×10^{-10} (0.01)	500

In this case, higher currents were observed for electrodes manufactured by successive application of the layers of CoPc, CHE covalently bound to GA, and gelatin, or of CoPc, CHE, and gelatin. The decrease in the TCH oxidation current observed with CPE modified with CoPc and CHE + GA can be attributed to decreasing number of enzyme active sites or lesser accessibility of the substrate for the enzyme. To fix the mediator on the electrode surface, we used a nonconducting film of NC and polyvinylpyridine (PVP), which were obtained electrochemically or by deposition of a drop of an organic solution on the CPE surface followed by solvent removal. However, incorporation of CoPc into the film did not increase the TCH oxidation current (Table 3, experiment nos. 2, 3).

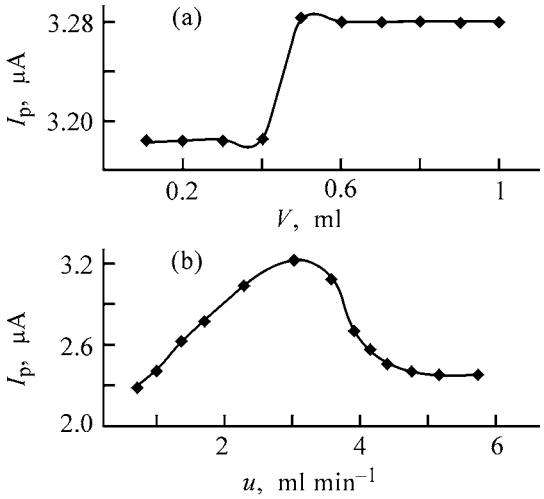

Fig. 4. FIA response to BTCH oxidation on CHE biosensor vs. (a) injected sample volume V and (b) flow rate u. (I_p) Current.

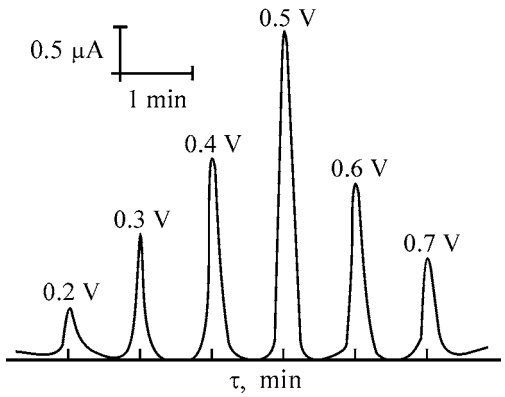

Fig. 5. FIA response to BTCH oxidation on CHE biosensor with CoPc mediator vs. the applied potential E. Initial BTCH concentration 2×10^{-3} M; injected sample volume V = 0.5 ml; and flow rate u = 3.0 ml min^{-1}. (τ) Time.

In developing carbon paste electrodes, special efforts are made to provide high stability and reproducibility of the analytical response and easy renewability of the electrode surface. For this purpose, we incorporated in this study CoPc, taken in various combinations with other components, into the carbon paste (Table 3, experiment nos. 4–6). Deposition of the CHE + GA layer over the CoPc-modified CPE provided high and reproducible response (Table 3, experiment no. 4). A lower response was obtained with the biosensor fabricated by successive incorporation of CoPc and CHE + GA into the carbon paste (Table 3, experiment no. 5). However, this procedure allowed a decrease in E_p to 0.50 V. Furthermore, is becomes possible in this case to mechanically renew the electrode surface. Incorporation of NC into the paste improved the reproducibility of the response, but impaired the sensitivity of the biosensor (Table 3, experiment no. 6).

Finally, the best characteristics were obtained with biosensors fabricated using immobilization of CHE bound to GA on the surface of a CoPc-modified CPE or over a CoPc layer deposited on the CPE surface. Evidently, the optimal coupling of the enzymatic and electrocatalytic reactions is achieved in these cases. Application of a protective gelatin film in all cases improved the stability of the electrochemical response.

The biosensor in its optimal version was tested under conditions of flow-injection analysis (FIA). The maximum FIA response was obtained at a flow rate u = 3.0 ml min^{-1} and injected sample volume V = 0.5 ml (Fig. 4). Since the FIA response was recorded in the controlled potential mode, we studied the effect of the applied potential on the BTCH oxidation current. Figure 5 shows that the maximum response is observed at E = 0.50 V.

The FIA response is a linear function of the BTCH concentration over the concentration range 1×10^{-5}–2×10^{-3} M, and it can be fitted with the equation $I = a + bc$ (I, μA; c, M) with $a = (7.78 \pm 0.09) \times 10^{-3}$ and $b = (1.65 \pm 0.08) \times 10^{3}$ (r 0.9992). The detection limit was found to be 4×10^{-6} M. Within the working concentration range, the standard deviation was within 5% at $n = 10$.

It is known that many metal ions inhibit the activity of both native and immobilized CHE [27]. In this study we used a CHE biosensor with a CoPc mediator, to assess the inhibiting effect of such heavy metal cations as Cu(II), Cd(II), and Zn(II) on immobilized CHE. The reversible inhibiting effect of the metal cations was evaluated by the decrease in the FIA response initiated by injection of a metal-containing sample in the presence of BTCH, compared to the blank experiment without a metal. The results of determinations of metal cations are listed in Table 4. Like other CHE biosensors [28], the biosensor with CoPc mediator is the most susceptible to the effect of copper(II). The concentration ranges in which the FIA response is a linear function of the concentration of the metals studied coincide with those obtained previously in determining the inhibiting ranges for of the CHE activity by these ions [28]. Incorporation of the mediator into the biosensing element has more a pronounced effect on the inhibitors detection sensitivity. The detection limits of the metal ions on the CHE biosensor with CoPc mediator are lower by several orders of magnitude as compared to the corresponding maximum permissible concentrations.

EXPERIMENTAL

DC votammograms were recorded on a PU-1 polarograph with a three-electrode cell. The working electrodes were CPE, chemically modified electrode (CME), and biosensor with a mediator. The reference electrode was Ag/AgCl, and the anode, Pt wire. The CPE fabrication procedure was described elsewhere [20]. The surface was renewed by mechanical polishing of the electrode surface with filter paper and tracing paper. In constructing CME, we used CoPc (2 wt %) in addition to the common CPE components (carbon powder and Nujol). The modifier was either incorporated into the carbon paste or deposited onto CPE. In manufacturing the biosensor, the enzyme (CHE) was also incorporated either into CPE or into the films applied onto the CPE surface.

The flow-injection analysis system included a DLV-1 peristaltic pump, an injector, a mixer, a flow-through electrochemical cell (V = 0.2 ml), and a polarograph as a recording device.

In manufacturing a biosensing element of the sensor, we used a cholinesterase preparation (EC 3.1.1.8) with an activity of 110 units per mg protein (Biomed Research and Production Association, Perm, Russia). As a specific substrate for CHE, we used recrystallized BTCH. Other chemicals used were CoPc (Fluka, Switzerland), GA (Reanal, Hungary), glycerol (chemically pure grade), NC $[C_6H_7O_2(OH)_{3-x}(ONO_2)_x]_n$ of the colloxylin type with a nitrogen content from 10.7 to 12.2%, gelatin, agar-agar, and chitosan (chemically pure grade). As analytes, we used Cd(II), Cu(II), and Zn(II) as chlorides.

Solutions were prepared gravimetrically using double-distilled water or organic solvents (butyl acetate, ethanol, toluene, acetonitrile, acetone, and methylene chloride). Nitrocellulose was dissolved in a mixture of butyl acetate and toluene. Gelatin and agar-agar were dissolved on heating on a water bath until complete dissolution. Chitosan was dissolved in 1% acetic acid, then 1% KOH was added, and the resulting gel was filtered off, washed with water, dried a little, and repeatedly dissolved in 1% acetic acid. An electrode with a poly(2-vinylpyridine) membrane modified with CoPc was fabricated by the procedure described in [30].

Amperometric determinations were carried out in a borate buffer solution (pH 9.0). The solution pH was measured with a pH-150 pH-meter.

CONCLUSIONS

(1) The composition of cholinesterase biosensor with CoPc mediator has been optimized. The biosensor was constructed by immobilization of cholinesterase chemically bound to glutaraldehyde on the carbon-paste electrode surface modified with CoPc, followed by application of a gelatin layer. Another fabrication procedure involved successive deposition of the layers of CoPc mediator, a mixture of cholinesterase with glutaraldehyde, and gelatin.

(2) The cholinesterase biosensor with Co(II) phthalocyanine mediator was used for flow-injection determination of butyrylthiocholine iodide (substrate for cholinesterase) and Zn(II), Cd(II), and Cu(II) (cholinesterase inhibitors).

(3) The flow-injection analysis response was recorded at the applied potential E = 0.50 V, flow rate u = 3.0 ml min^{-1}, and injected sample volume V = 0.5 ml. The response is a linear function of the buty-

rylthiocholine iodide concentration over the concentration range 1×10^{-5}–2×10^{-3} M. In metal determinations, linear logarithmic dependences of the response on the metal concentrations were observed over the concentration ranges 1×10^{-6}–1×10^{-3}, 1×10^{-8}–1×10^{-5}, and 5×10^{-10}–1×10^{-6} M for Zn(II), Cd(II), and Cu(II), respectively ($S_r < 0.07$).

(4) High analytical and metrological performance of the cholinesterase biosensor with CoPc mediator makes it suitable for determination of cholinesterase substrates and inhibitors.

Received March 4, 2003

Abstract—Treatment of drinking water to remove heavy metal ions Pb^{2+}, Cu^{2+}, Cd^{2+}, Co^{2+}, Ni^{2+}, and Zn^{2+} with commercial fibrous carboxylic ion exchangers FIBAN Kh-1, K-3, K-4, and K-5 was studied. Features of metal ion sorption from two-component solutions were determined. A comparative evaluation of the sorption selectivity of FIBAN fibrous ion exchangers with respect to heavy metal ions was made.

Fibrous carboxylic ion exchangers are of interest in treatment of natural water and wastewater to remove heavy metal ions [1–4]. However, methods usually used in studying metal sorption with both fibrous and granulated ion exchangers do not allow assessment of their practical efficiency in water purification. These methods give too optimistic estimations and reveal no significant differences between various carboxylic ion exchangers. The capacity with respect to an ion being recovered, which is the criterion of the sorptive power, is determined by a static method at a preset volume ratio of the sorbent to the solution containing a metal in a too high concentration [5, 6]. The model solution containing 1–5 g l^{-1} heavy metal ions is prepared with distilled water with addition of 0.5 M supporting ions, usually Na^+. Carboxylic ion exchangers are very weakly selective with respect to these ions as compared to double-charged ions. Thus, the data obtained are related to the systems far from the real water for which the sorbents are intended. In such experiments, the amount of sorbed ions is actually determined by the total ion-exchange capacity and pH of the initial and equilibrium solutions.

In natural water, the concentration of heavy metal ions is usually substantially lower than that used in the model solution, and the content of these ions should be monitored at the maximum permissible concentration (MPC) limit. As a rule, water to be purified contains a background of metal ions (Na^+, Ca^{2+}, Mg^{2+}, Fe^{2+}/Fe^{3+}) with the concentrations exceeding the concentration of toxic ions by 2–5 orders of magnitude. The problem of water treatment to remove iron is solved separately, and then water containing Na^+, Ca^{2+}, and Mg^{2+} is usually subjected to purification. Water with moderate hardness contains 1.5–3 mM (Ca^{2+} + Mg^{2+}) ions, which are also selectively sorbed by carboxylic ion exchangers and compete with heavy metal ions for ion-exchange centers. In the static method of sorption, pH and concentrations of supporting and target ions change simultaneously in the equilibrium solutions, and hence each point of the sorption curve is related to different conditions. Therefore, the static method of determination of the ion exchanger sorption power in a multicomponent solution inadequately characterizes the sorbent behavior in purification of real drinking water.

In this study, real possibilities of commercial FIBAN carboxylic ion exchangers in treatment of drinking water to remove heavy metal ions Pb^{2+}, Cu^{2+}, Cd^{2+}, Co^{2+}, Ni^{2+}, and Zn^{2+} were assessed under the dynamic conditions.

EXPERIMENTAL

FIBAN Kh-1, K-4, and K-3 ion exchangers produced by the Institute of Physical Organic Chemistry and FIBAN K-5 ion exchanger produced by Ekofil-Deko Research and Production Association in the form of a staple with single fibers about 30 μm in diameter and 66 mm long were used in the experiments. FIBAN Kh-1, K-3, and K-5 ion exchangers are products of chemical modification of Nitron polyacrylonitrile (PAN) fiber. They contain several kinds of carboxy groups and a certain amount of various basic groups.

Table 1. Properties of FIBAN fibrous ion exchangers

Ion exchanger	Functional groups of an ion exchanger	SEC,* mmol g^{-1}		Swelling in H^+ form, g H_2O per g of ion exchanger
		–COOH	$-NR_2$	
Kh-1	–COOH, $-N(CH_2COOH)_2$	3.76	0.6	0.60
K-4	–COOH	4.25	–	0.85
K-3	–COOH, =NH, ≡N	5.3	1.8	0.46
K-5	–COOH, $-NH_2$, =NH, ≡N	5.6	1.3	0.44

* SEC is the static exchange capacity of an ion exchanger.

FIBAN K-4 is the product of radiation grafting of acrylic acid to polypropylene (PP) fiber and contains carboxy groups only. The main characteristics of the ion exchangers studied are listed in Table 1.

The acid–base properties of the ion exchangers were studied by a potentiometric titration procedure described in [7, 8], and titration curves were interpreted in terms of acidity parameters by computer analysis [9]. Staple fibers were additionally cut to 1–3 mm length. Titration was performed by the method of a single sample with 1.0 M KOH + 1.0 M KCl titrant. Initially, the ion exchanger sample based on Nitron fiber was introduced into a cell containing HCl solution to completely convert the carboxy groups into the H^+ form, and amino groups, into the Cl^- form, with the same supporting electrolyte. The cell was isolated from ambient air to prevent penetration of CO_2 into the solution during titration. A FIBAN K-4 fiber sample was used in the H^+ form. The titrant was added to the solution in weighed portions at 20-min intervals (time sufficient for the equilibrium to be attained in the system). After reaching pH 12, the back-titration of certain ion exchangers with 1 M HCl in 1 M KCl supporting electrolyte was performed. pH was measured with an OP 211/1 digital laboratory pH-meter equipped with an OP-0808P combination pH electrode.

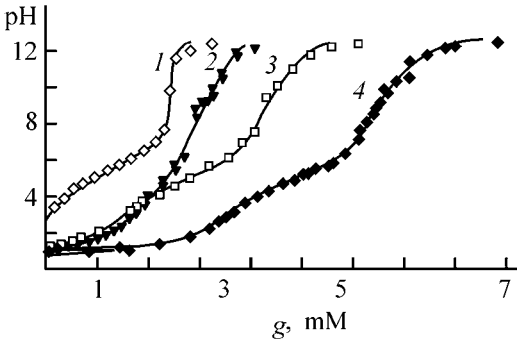

Fig. 1. Experimental points and calculated curves of potentiometric titration of FIBAN fibrous sorbents. Supporting electrolyte 1.0 M KCl. (*g*) Titrant amount. Sorbent: (*1*) K-4, (*2*) Kh-1, (*3*) K-5, and (*4*) K-3. Sample weight, g: (*1*) 0.6169, (*2*) 0.6067, (*3*) 0.5285, and (*4*) 0.535. Initial HCl excess, mM: (*2*) 2.74, (*3*) 2.54, and (*4*) 6.6. Initial solution volume V_0, ml: (*1*) 19.4, (*2*) 20.5, (*3*) 22.0, and (*4*) 20.

To study the sorption of heavy metal ions, two kinds of salt solutions were prepared. The first was a binary solution containing 2 mM of any heavy metal ion (Cu^{2+}, Pb^{2+}, or Ni^{2+}) and 2 mM of Ca^{2+} background. Sorption was performed at optimal pH 4–7 adjusted by adding small amounts of NaOH or HNO_3 solutions. The second is a multicomponent solution containing Pb^{2+}, Cu^{2+}, Cd^{2+}, Co^{2+}, Ni^{2+}, and Zn^{2+} ions (each in a concentration of 2×10^{-2} mM) and 2 mM of Ca^{2+}. Sorption of each heavy metal ion was determined at pH 6.

The metal ion sorption was studied under dynamic conditions. In the first series of experiments, a 0.2-g ion exchanger sample in the H^+ form was placed in a glass column, and a binary solution containing 2 mM of one of heavy metal ions (Cu^{2+}, Pb^{2+}, or Ni^{2+}) and 2 mM of Ca^{2+} was passed through it at optimum pH at a flow velocity of about 1.5 cm min^{-1}. The salt solution was passed in an amount of 4 l through each sample to attain equilibrium, when the ion concentrations and pH in the initial solution and in the solution outflowing from the column become equal. Heavy metal and calcium ions sorbed were eluted with 1 M HNO_3.

In the second series, a dilute solution containing heavy metal ions and 2 mM calcium background was pumped through a column 12.5 mm in diameter and 30 mm high, packed with an ion exchanger (packing density 0.13–0.23 g cm^{-3}). The solution flow velocity was 9.5 cm min^{-1}. The ion exchanger was preliminarily treated with acetate buffer solution with pH 6 to convert it into a mixed $H^+ + Na^+$ form. After sorption, the excess solution was removed by blowing air through the sorbent bed, and then metal ions were desorbed with 1 M HCl or 1 M HNO_3 with the linear flow velocity of 0.8 cm s^{-1}. The metal ion contents were determined on a Vista PRO atomic-emission spectrometer with inductively coupled plasma (Varian) under the following conditions: RF plasma 1.1 kW, plasma-forming argon flow 15, axial argon flow 1.5, and argon flow to the sprayer 1.2 l min^{-1}.

The curves of potentiometric titration of FIBAN Kh-1 chelate ion exchanger and weakly acidic FIBAN K-4, K-3, and K-5 ion exchangers are shown in Fig. 1.

Table 2. Acidity parameters of FIBAN ion exchangers

Ion exchanger	E_1	pK_1	Δpk_1	E_2	pK_2	Δpk_2	E_3	pK_3	Δpk_3	E_4	pK_4	Δpk_4
Kh-1	1.5	3.2	0.8	1.1	5.0	0.4	1.5	9.0	0.6	0.7	11.5	0.3
K-4	–	–	–	4.85	5.3	2.0	–	–	–	–	–	–
K-3	0.7	4.0	0.35	5.2	5.0	2.0	0.5	8.7	0.25	1.7	10.5	0.85
K-5	0.6	3.0	0	5.6	5.0	2.0	0.7	9.0	0.3	1.1	10.5	0.4

To calculate the potentiometric titration curves (CPT), computer simulation described in [9] was used. The software developed allows determination from the experimental titration curve of exchange capacities with respect to each type of E_i groups and of the ion exchanger acidity parameters pK_i and Δpk_i, where K_i is the H^+–Me^+ exchange constant and k_i, equilibrium constant:

$$\Delta\text{p}k_i = \text{p}k_{i(x=1)} - \text{p}k_{i(x=0)}.$$

The titration curve was reconstructed by the inverse calculation; its coincidence with the experimental curve indicates reliability of the parameters found. In all calculations of the kind, the parameters E_i, pK_i, and Δpk_i cannot be determined unambiguously. Therefore, to interpret the results, independent data on properties, chemical composition, and synthesis method of ion exchangers should be invoked. However, in simple cases, the acidity parameters are determined with a high degree of reliability. This is confirmed by practical coincidence in all the details between the experimental and calculated titration curves shown in Fig. 1.

Among the ion exchangers considered, FIBAN K-4 ion exchanger has the simplest structure. It is a monofunctional ion exchanger containing carboxy groups only (this follows from the synthesis method) and is well described by a single set of acidity parameters (Table 2). In contrast to it, all the other ion exchangers studied, which were synthesized on the basis of PAN fibers, are inevitably polyfunctional and contain not only carboxy groups but also anion-exchange (various nitrogen-containing) groups protonated in the acid medium. Carboxy groups are formed by hydrolysis of the nitrile groups, and amino groups, during treatment of PAN fibers with hydrazine or polyamines [10], which are used to cross-link the polymer chains to prevent the polymer dissolution after hydrolysis. Thus, ion exchangers based on PAN fibers are polyampholytes. At definite pH, they form intramolecular salts or strong associates of $RCOO^- + R_3HN^+ = RCOOH \cdot R_3N$ type, which substantially complicates the shape of the titration curve.

To obtain the total curves of polyampholyte titration, it is necessary to start from one pure ionic form of the ion exchanger: completely protonated or completely deprotonated. This means that, in the first case, the ion exchanger should contact with a solution containing excess acid, and in the second, with a solution with excess alkali. The excess amount of these reagents can be arbitrary and can be determined by a computer analysis of the titration curve described above [9]. We titrated ion exchangers based on PAN fibers in the presence of excess hydrochloric acid. Under these conditions, the ion exchanger contains undissociated carboxy groups –COOH and protonated basic groups $\equiv N \cdot HCl$, or, at higher HCl concentrations, associates of the $\equiv N \cdot (HCl)_n$ type [11]. Titration of this system includes the following reactions:

$$HCl + KOH \rightarrow KCl + H_2O, \quad (1)$$

$$R{\equiv}N \cdot HCl + KOH \rightleftarrows R{\equiv}N + KCl + H_2O, \quad (2)$$

$$R{\equiv}N + R\text{–}COOH \rightleftarrows R{\equiv}N \cdot HOOC\text{–}R, \quad (3)$$

$$R\text{–}COOH + KOH \rightleftarrows RCOOK + H_2O, \quad (4)$$

$$R{\equiv}N \cdot HOOC\text{–}R + KOH \rightleftarrows R{\equiv}N + R\text{–}COOK + H_2O. \quad (5)$$

Reaction (1) corresponds to titration of excess HCl. Reaction (2) is the reaction of an alkali with HCl bound with weakly protonated basic groups, which then form an intramolecular bond with carboxy groups [reaction (3)]. In the case of excess carboxy groups with respect to basic groups, their neutralization is the next stage [reaction (4)]. Finally, carboxy groups incorporated in intramolecular complexes and showing the weakest acidity are neutralized [reaction (5)].

In real systems, as in our case, the pattern is further complicated by the presence in the ion exchanger phase of different kinds of carboxy and weakly basic groups. The results of the computer analysis of ion exchangers studied are listed in Table 2. It follows from Tables 1 and 2 that the ion exchangers strongly differ in the acidity parameters, although having com-

Table 3. Total dynamic capacity of FIBAN ion exchangers with respect to metal ions in sorption from binary M^{2+}–Ca^{2+} solutions as a function of pH (metal ion concentration in the solution 2 mM)

Ion exchanger	Total dynamic capacity (mmol g^{-1}) at indicated pH							
	4.5*		5.0*		5.0		7.0	
	Cu^{2+}	Pb^{2+}	Cu^{2+}	Pb^{2+}	Ni^{2+}	Ca^{2+}	Ni^{2+}	Ca^{2+}
Kh-1	1.3	1.4	1.8	1.6	1.15	0.3	1.35	0.2
K-4	1.5	1.7	1.75	2.1	1.0	0.45	1.25	0.3
K-3	–	1.35	–	1.45	0.9	0.4	1.2	0.25
K-5	1.45	1.8	1.9	1.7	1.3	0.5	1.6	0.35

* Sorption of Ca^{2+} with the ion exchanger is less than 0.05 mmol g^{-1}.

parable static exchange capacities with respect to carboxy groups. FIBAN K-3 and K-5 ion exchangers are the most similar in the acid-base properties. They contain about 5 mmol g^{-1} carboxy groups with pK 5 and ΔpK 2.0. Among the ion exchangers studied, a special place is occupied by FIBAN Kh-1, which contains more acidic groups with pK 3.2 and ΔpK 0.8, since the existence of functional groups with such acidity parameters cannot be caused by reaction (2) as in the case of FIBAN K-3 and K-5 because of the small capacity of FIBAN Kh-1 with respect to amino groups.

It follows from the above data that all the carboxylic ion exchangers studied strongly differ in the chemical composition, acidity, and set of functional groups. However, in sorption from binary solution with equal concentrations of heavy metal ions and Ca^{2+}, there is no substantial difference in sorption properties of ion exchangers (Table 3). In all the cases, different ion exchangers sorb only heavy metal ions, while Ca^{2+} ions are not appreciably sorbed. This produces an illusion of equal sorption efficiency of any carboxylic ion exchanger in water purification. However, the results substantially changed when the solutions used more closely simulated the real water to be purified.

The outlet curves of sorption are shown in Fig. 2, and the working capacities with respect to heavy metal ions at their concentrations of 2×10^{-2} mM

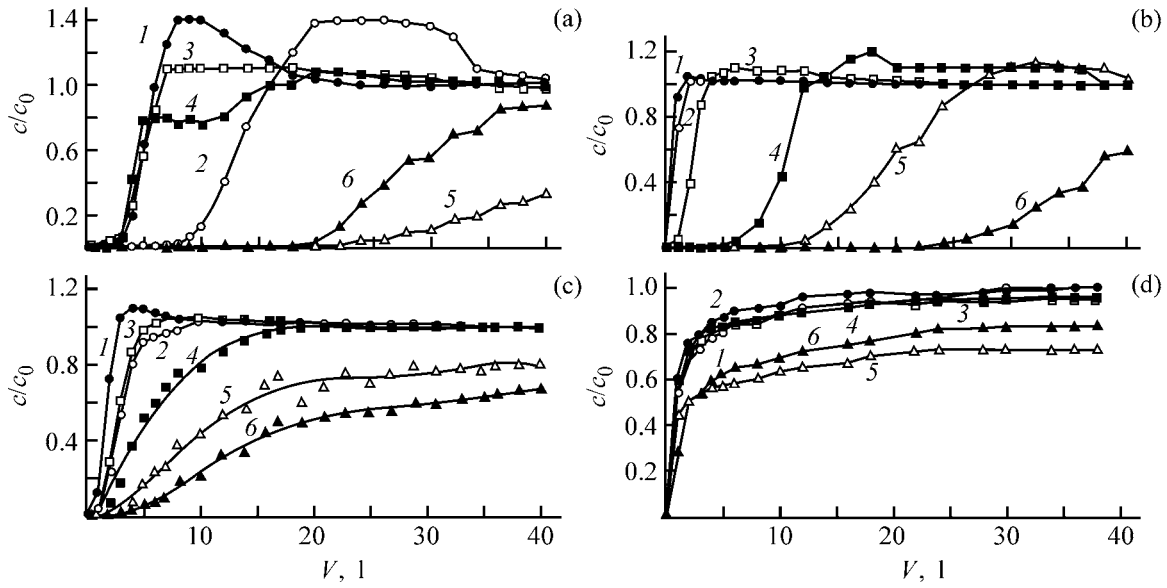

Fig. 2. Outlet curves of sorption of heavy metal ions by fibrous ion exchangers (a) FIBAN Kh-1, (b) FIBAN K-4, and (c) FIBAN K-5 and with (d) ANKB-35 granulated ion exchanger. (c/c_0) Ratio of metal ion concentration in the solution outflowing from the column to the concentration in the initial solution and (V) volume of the solution passed through the column with the ion exchanger. Cation sorbed: (*1*) Co^{2+}, (*2*) Ni^{2+}, (*3*) Zn^{2+}, (*4*) Cd^{2+}, (*5*) Cu^{2+}, and (*6*) Pb^{2+}.

with a higher Ca^{2+} background concentration (2 mM) are listed in Table 4. As can be seen from these data, the ion exchangers show quite specific individual properties. Among fibrous ion exchangers, FIBAN K-3 and K-5 prepared by saponification of cross-linked PAN fibers are the least effective. FIBAN Kh-1 ion exchanger containing chelate groups is the most universal. It showed the best results in water treatment to remove all the heavy metal ions studied. Granulated chelate ion exchanger ANKB35 which is based on styrene and divinylbenzene copolymer and contains functional groups similar to those in FIBAN Kh-1 is ineffective in heavy metal ion sorption from water by the dynamic method. All heavy metal ions studied appear already in the first portions of the eluate in concentrations exceeding 0.05 mg l^{-1}. At the same time, FIBAN K-4 monofunctional fibrous ion exchanger proved to be almost as effective as FIBAN Kh-1 with respect to Cu^{2+} and substantially exceeded the latter in the efficiency of removal of Cd^{2+} and Pb^{2+}. However, FIBAN K-4 is inefficient in water treatment to remove Ni^{2+}, Co^{2+}, and Zn^{2+}. It should be noted that FIBAN Kh-1 has a substantial advantage over the other ion exchangers studied in water treatment to remove Fe^{2+}, which makes it the most suitable ion exchanger for natural water purification to obtain technical and drinking water.

Thus, the study of heavy metal ion sorption from dilute solutions against a background of high Ca^{2+} concentration revealed features of selective sorption of these ions by FIBAN fibrous ion exchangers from multicomponent aqueous solutions. Among the ion exchangers based on PAN fibers, the best results in water treatment to remove heavy metal ions were obtained with FIBAN Kh-1 chelate ion exchanger, which substantially suprasses FIBAN K-3 and K-5 cation exchangers in the dynamic capacity. Good results were also obtained with FIBAN K-4 monofunctional carboxylic cation exchanger based on PP fibers.

CONCLUSIONS

(1) A dynamic study of sorption properties of FIBAN Kh-1, K-3, K-4, and K-5 with respect to heavy metal ions showed that, in sorption from binary M^{2+}–Ca^{2+} solutions containing 2 mM of each cation, all the ion exchangers studied almost equally sorb Pb^{2+}, Cu^{2+}, or Ni^{2+} and do not noticeably sorb Ca^{2+}.

(2) In sorption from a multicomponent system containing heavy metal ions in concentrations close to their maximum permissible concentration (2×10^{-2} mM), with the background of 2.0 mM Ca^{2+}, FIBAN Kh-1 chelate ion exchanger based on polyacrylonitrile fibers is the most universal ion exchanger for water treatment to remove heavy metal ions, while FIBAN K-4 monofunctional carboxylic cation exchanger based on polypropylene fibers is the best for water purification to remove Pb^{2+} and Cd^{2+}.

Table 4. Dynamic capacity (to metal ion breakthrough) of FIBAN fibrous ion exchangers (metal ion concentration in the solution 2×10^{-2} mM)

Ion exchanger	Dynamic capacity (mmol g^{-1}) to breakthrough of 0.05 mg l^{-1}					
	Cu^{2+}	Pb^{2+}	Ni^{2+}	Co^{2+}	Cd^{2+}	Zn^{2+}
Kh-1	0.46	0.35	0.18	0.07	0.05	0.05
K-4	0.45	0.75	0	0	0.15	0
K-3	0.11	0.10	0	0	0.04	0
K-5	0.12	0.12	0.005	0.04	0.05	0

Received July 10, 2003

Abstract—Binding of lipids from aqueous protein-lipid suspensions with a natural polysaccharide, chitosan, was studied in order to develop a procedure for removal of impurities from water. The physicochemical nature of this process was analyzed. The mechanism involving formation of structurally ordered chitosan precipitates, and adsorption and solubilization of lipids with chitosan macromolecules was discussed. The best conditions for defatting of aqueous protein-lipid dispersions with the aid of chitosan were determined.

Removal of proteins and lipids from industrial wastewater is being studied extensively. The conventional physicochemical procedures used to remove proteins and lipids from aqueous dispersions with high content of these impurities (e.g., wasterwater of fish industry and hydrobiont reprocessing) are sorption on various sorbents and flotation with preliminary coagulation of proteins and lipids with inorganic electrolytes and macromolecular flocculants. Inorganic coagulants, such as aluminum and iron salts, calcium compounds, and dry lime, are ineffective for purification of aqueous dispersions with low lipid content (e.g. protein hydrolyzates). Moreover, some of these compounds are toxic. Proteins and lipids recovered with the aid of synthetic flocculants (e.g., polyacrylamides and polymeric quarternary ammonium salts) cannot be used as forage additives without additional purification [1, 2].

Hence, a search for new nontoxic biodegradable reagents suitable for exhaustive removal of peptides and lipids from aqueous dispersions is a topical problem. Natural macromolecular polysacharides including a cationic polysacharide, chitosan, can be used for this purpose. Chitosan is produced by deacetylation of the natural biopolymer, chitin [3]; it consists of residues of 2-deoxy-2-amino-*D*-glycose bound via β-1,4-bonds. Chitosan contains reactive free amino groups. This polysacharide coagulates peptide-lipid colloids [4–6] and can be used for efficient recovery of lipids from aqueous dispersions [7], e.g., from peptide hydrolyzates. Peptide hydrolyzate is a dispersion containing low-molecular-weight peptides, suspended substances, free amino acids, and lipids. Peptide hydrolyzates are mainly used for preparing microbiological culture media [8, 9]. Lipids and, in particular, fatty acids are toxic for most of bacterial cultures [10].

The interaction mechanism in the systems containing peptides and lipids and macromolecular compounds has been recently studied [11–13]. It is known [11] that macromolecular compounds can solubilize small amounts of oleophilic compounds to form colloids. Probably, the solubilization of lipids can affect the quality of purification of peptide hydrolyzates with chitosan.

The aim of this study was to examine sorption of lipids from aqueous peptide-lipid dispersions on chitosan and to determine the physicochemical mechanism of this process.

EXPERIMENTAL

Protein hydrolyzates of wastes from processing of northern shrimp fishery (SFW), king crab (KCW), Icelandic comb (ICW), and sea cucumber (cucumaria) (CW) were prepared and characterized by the conventional procedures [14, 15]. The wastes were treated with a Model 1094 (Tecator) homogenizer. The proteins were hydrolyzed for 6 h in the presence of proteinases at 50°C and a protein : water weight ratio of 1 : 1. Proteinases were synthesized from hepatopancrease of king crab [16, 17].

Protein hydrolyzates were treated with chitosan solutions in the ratio of 0.125–1.000 g of the polymer

Table 1. Influence of chitosan concentration c on the quality of protein hydrolyzate prepared from ICW

c, g l^{-1}	Effect observed	
	before centrifuging	after centrifuging
0.125	No changes in the solution	Turbid solution, lipid film on its surface
0.250	Slight turbidity of the solution	The same
0.375	Flocculation in the whole solution volume, formation of fat drops on the surface	Transparent solution, thinner lipid film
0.500	Flocculation in the whole solution volume, fat in completely bound with chitosan	Transparent solution, traces of lipid film
0.750	Large readily precipitated flakes	Transparent solution, no lipid film
1.000	The same	The same

per 1 l of the hydrolyzate solution. The degree of deacetylation of the chitosan samples with average molecular weight of 285, 265, and 255 kDa was 75.1, 91.2, and 99.8%, respectively. Chitosan was dissolved in 1% acetic acid or 0.1 N hydrochloric acid. A chitosan solution was added to protein hydrolyzate acidified to pH 6.5 and the mixture was stirred. Chitosan was precipitated by addition of a 1% NaOH solution to pH 7–9.5. The resulting dispersion was left to coagulate for a time of 10 min to 3 h. The precipitate was separated by centrifuging. To determine the protein concentration in the hydrolyzate, the optical density of the solution at 280 nm was measured on a UV 3101 PC Shimadzu spectrophotometer by the conventional procedure [18].

Lipids were extracted from hydrolyzates with hexane. The optical density of the extract in the UV–Vis range was measured relative to pure hexane.

The degree of defatting of the hydrolyzate was estimated from the relative optical density D_{rel} (%) at 195 nm.

$$D_{rel} = D/D_0 \times 100,$$

where D is the optical density of the extract of the hydrolyzate treated with a chitosan solution; D_0 is the optical density of the extract of hydrolyzate without chitosan addition.

To study the solubilizing power of chitosan, we used oleophilic lipid, cod-liver oil, prepared from cod liver [GOST (State Standard) 3714–72].

The solubilzation of cod-liver oil with chitosan solutions was determined by the degree of solution turbidity [19], which, in turn, was measured on a KFK-3 photocolorimeter in 5-cm cells at the wavelength of 540 nm. This method is based on the following phenomenon. When a saturated solution of an oleophilic compound in an aqueous solution of a macromolecular compound (MMC) is formed, excess MMC is emulsified and the turbidity of the system increases. The saturation point of the system with the oleophilic component, taken as the measure of the solubilizing power of the solution at a definite polysaccharide concentration, was determined from the inflection point in the dependence of the optical density on the concentration of the oleophilic component.

The Gibbs energy $\Delta G^0_{T,P}$, enthalpy $\Delta H_{T,P}$, and entropy $\Delta S_{T,P}$ of binding of the solubilizate were calculated by the equations given in [11].

In preliminary experiments, we studied the influence of chitosan additives on the concentration of low-molecular-weight proteins contained in the hydrolyzate and not precipitated with 10% trichloroacetic acid. We found that chitosan did not precipitate these compounds under the experimental conditions and hence did not decrease the yield of the target hydrolyzate.

Chitosan is completely coprecipitated with lipids and insoluble proteins (Table 1) after its addition in amount of 0.75 g l^{-1} of the incubation solution (1.5 g kg^{-1} of the initial hydrolyzate).

The efficiency of defatting of protein hydrolyzates was studied at different pH values. The relative optical density D/D_0 of the hydrolyzate containing 1 g of chitosan per 1 kg of the solution was constant (65%) at pH from 5.5 to 9.5. Hence defatting of the hydrolyzate is independent of pH in this range. However, at higher pH, the transparency of the solution increased and the lipid film formed on the solution surface after centrifuging decreased and then disappeared at all.

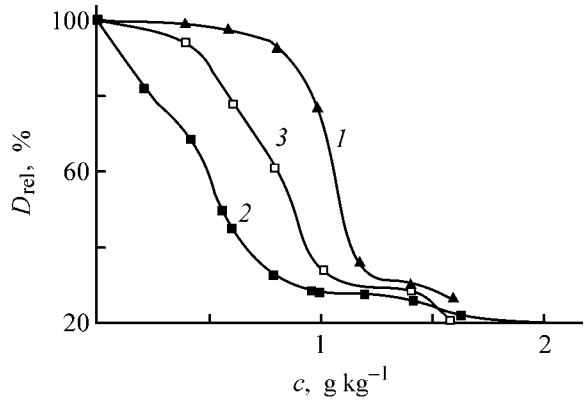

Fig. 1. Efficiency of defatting of ICW hydrolyzates with chitosan deacetylated to (*1*) 75.1, (*2*) 90.1, and (*3*) 99.8% vs. chitosan concentration *c*. Precipitated at pH 8.3. (D_{rel}) Relative optical density; the same for Fig. 2.

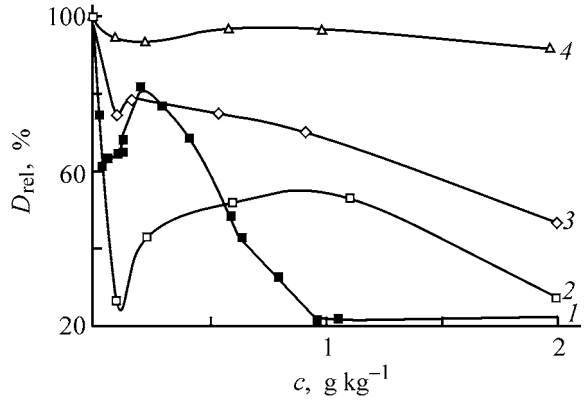

Fig. 2. Efficiency of defatting of (*1*) ICW, (*2*) NSW, (*3*) KCW, and (*4*) CW hydrolyzates vs. the concentration *c* of chitosan with 90.1% degree of deacetylation. pH of precipitation 8.3.

The influence of the degree of chitosan deacetylation on the efficiency of defatting of the hydrolyzates is shown in Fig. 1. Chitosan deacetylated to 90% provides the maximum defatting. At lower or higher degree of deacetylation, the degree of defatting decreases.

Probably, the sorption capacity of chitosan for lipids is determined by its degree of deacetylation and the presence of inter- and intramolecular chemical bonds.

As the degree of deacetylation increases, the number of active sorption centers grows. However, in the samples with a high degree of deacetylation, intra and intermolecular interaction of chitosan molecules is observed. As a result, the number of sorption centers decreases owing to both globulation of the macromolecules and formation of strong intermolecular bonds to give ordered structures. The sorption properties of chitin and chitosan depends on their crystallinity. It is known [20, 21] that the sorption capacity of chitosan increases with a decrease in the degree of its crystallinity, i.e., with an increase in the content of the amorphous phase of the polymer. At a high degree of deacetylation (from 91 to 96%), the mechanical and spectral properties of chitosan appreciably change owing to an increase in its crystallinity [22].

In the initial stages, lipids are probably bound with dissolved chitosan molecules. In the course of precipitation, the chitosan structure is ordered owing to the formation of intermolecular bonds. As the degree of chitosan deacetylation increases, the intramolecular bonds between amino and hydroxy groups are strengthened, and foreign molecules (in our case lipids) are "forced out" from the internal structure and are sorbed on the free surface of the precipitate. As a result, the concentration of centers capable of sorbing lipids decreases.

The chitosan concentration optimal for defatting of ICW hydrolyzates is 1 g kg^{-1} of the solution. Defatting of hydrolyzates of king crab and cucumaria production wastes by chitosan treatment is less efficient.

The dependence of the relative optical density of the NSW hydrolyzates on the chitosan concentration passes through a sharp minimum at low chitosan concentration and has a maximum at the higher concentration (Fig. 2).

The abnormal decrease in the optical density at low chitosan concentration (about 0.1 g kg^{-1} solution) is of interest. In this case, the hydrolyzate remains turbid, as also does the reference sample without chitosan additive. The dependences observed with the other hydrolyzates examined are similar to some extent (Fig. 2).

At a low chitosan concentration, the dissolved macromolecules partially bind lipids. However, this concentration is insufficient for complete precipitation. Probably, only free lipids are extracted in hexane. The growth of D_{rel} with increasing chitosan concentration is caused by two factors. On the one hand, at a high concentration of chitosan, it is precipitated from the solution and hence the concentration of dissolved chitosan capable of binding the lipids decreases. On the other hand, lipids and proteins probably compete for the sorption centers of chitosan macromolecules.

The increase in the relative optical density is most likely due to the formation of a dense precipitate with an ordered structure at high chitosan concentration, which results in lipid desorption. This is confirmed

by a gradual increase in D/D_0 during aging of the precipitate, probably accompanied by its ordering.

As the chitosan concentration growths further, D/D_0 increases owing to a rise in the adsorption surface area of the chitosan precipitate.

Thus, the mechanism of interaction of lipids with chitosan is complex. Probably, sorption of lipids on chitosan macromolecules is caused by electrostatic interaction of positively charged functional groups of chitosan and deprotonated carboxy groups of lipids, which is indicated by a rise in the lipid sorption with increasing degree of chitosan deacetylation (Fig. 1). In addition, the shape of $D_{rel} = f(c)$ curve depends not only on the sorption but also on solubilization of lipids with chitosan macromolecules. Probably, extraction of solubilized lipids in hexane is more difficult.

One of the processes responsible for binding of lipids with chitosan is the solubilization of lipids. To study the solubilizing effect of chitosan, we used a model system containing cod-liver oil as the lipid component. The chitosan concentration varied from 0 to 0.5 g l^{-1}. At this concentration, chitosan macromolecules do not precipitate in the pH range examined (1.2–9.5). Chitosan solutions were prepared in 1% acetic acid.

The solubilization of cod-liver oil grows with increasing chitosan concentration. Clearly, the total capacity of the hydrophobic regions grows with increasing chitosan concentration.

The solubilization of oleophilic compounds with the polymer is due to the formation of hydrophobic "intramolecular micelles" of the macromolecules bound by the hydrophobic bonds [11]. Probably, binding of lipids with chitosan is caused by this phenomenon.

Solubilization can be regarded as distribution of a third component among two immiscible phases. This approach makes it possible to calculate of the thermodynamic parameters of solubilization, estimate the free energy of solubilizate binding, and determine the solubilization mechanism. We calculated the thermodynamic parameters of solubilization of the examined systems by the procedure used in [11] for calculations system constituted by a protein and low-molecular-weight hydrocarbons. The results are presented in Figs. 3 and 4.

A calculation of ΔS and ΔG in solubilization of cod-liver oil with chitosan solution demonstrated that $\Delta G < 0$ and $\Delta S > 0$ in the whole range of pH. The Gibbs energy is at a minimum in acidic and neutral solutions. In alkaline solutions (pH > 10), ΔG increases owing to a decrease in the solubilizing power of chitosan and deterioration of the solubilization conditions.

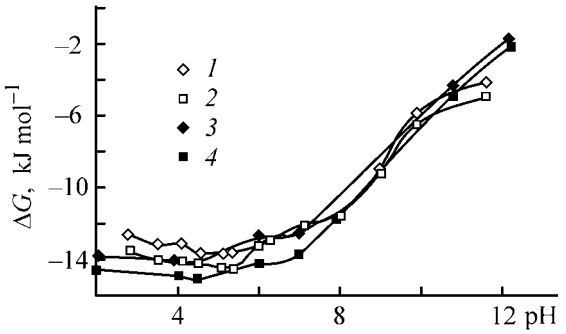

Fig. 3. Gibbs energy ΔG of solubilization of cod-liver oil with chitosan solutions at (*1*, *3*) 20 and (*2*, *4*) 40°C vs. pH. Chitosan concentration (mg l^{-1}): (*1*, *2*) 25 and (*3*, *4*) 250.

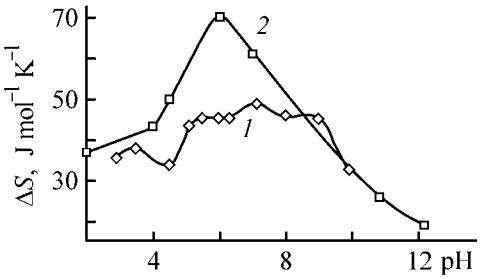

Fig. 4. Entropy ΔS of solubilization of cod-liver oil in chitosan solution with chitosan concentration of (*1*) 25 and (*2*) 250 mg l^{-1} vs. the solution pH.

The sign of the thermodynamic parameters ($\Delta G < 0$; $\Delta S > 0$) is in agreement with the statistic thermodynamic model of hydrophobic bonding. These parameters are close to those of transfer of nonpolar substances from polar to nonpolar medium [23]. Thus, these calculations and analysis of the published data show that the solubilization of cod-liver oil in chitosan solutions, as well as that of other oleophilic compounds, is a spontaneous thermodynamically favorable process. In this case, cod-liver oil penetrates into internal hydrophobic regions formed by chitosan macromolecules.

The dependence of the degree of defatting of protein hydrolyzates on the chitosan concentration and on the precipitation time can also be understood in terms of the solubilization mechanism. We found that lipids are desorbed from the precipitate formed in more than 1 h. Freshly prepared amorphous chitosan gradually crystallizes with time. As a result, the number of amorphous hydrophobic regions in the chitosan precipitate decreases and lipids are desorbed into the solution.

Table 2. Chemical composition of the hydrolyzates before and after treatment with chitosan solutions

Component content, wt %	NSW hydrolyzates		ICW hydrolyzate		Component content, wt %	NSW hydrolyzates		ICW hydrolyzate	
	no chitosan	after precipitation	no chitosan	after precipitation		no chitosan	after precipitation	no chitosan	after precipitation
Moisture	3.00	3.67	1.7	0.43	Ash	4.60	4.28	12.80	12.60
Lipids	1.84	0.33	2.30	0.56	Proteins	90.56	91.72	83.20	86.40

Thus, small amounts of chitosan can be effectively used for clarification and defatting of protein hydrolyzates of NSW and ICW.

As can be seen from Fig. 2, the weight fraction of lipids in WSF and ICW hydrolyzates treated with chitosan under the optimal conditions decreases by a factor of 4–5.

The chemical composition of the hydrolyzates before and after treatment with chitosan is listed in Table 2.

CONCLUSIONS

(1) The degree of clarification and defatting of protein hydrolyzates depends on the degree of deacetylation of chitosan. The relative optical density D_{rel} of the extract of the hydrolyzates treated with chitosan deacetylated to 90% is at a minimum. At higher degree of deacetylation, D_{rel} increases again.

(2) The degree of defatting is determined as influenced by pH of the solution, chitosan concentration, and time of treatment of the hydrolyzate with a chitosan solution. The best conditions of the chitosan treatment are as follows: chitosan concentration from 1.0 to 1.5 g kg^{-1} of hydrolyzate, precipitation at pH 8.0–8.5, and time of incubation after addition of chitosan shorter than 1 h.

(3) The suggested mechanism of defatting of protein hydrolyzates involves crystallization of chitosan precipitate, adsorption, and solubilization of lipids with chitosan macromolecules.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Acylation of Amines with Carboxyethyl Dextran Azides

A. V. Krasnikova, Yu. L. Vasil'eva, and A. A. Iozep

St. Petersburg State Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

Received July 9, 2003

Abstract—The stability and reactivity of carboxyethyl dextran azides toward amines, and also the influence exerted by the pH of the reaction medium and pK_a of the amine on the number of amide groups in acylation products were studied.

The assortment of physiologically active polymers (PAPs) used in medicine steadily grows. Among the routes to PAPs, the "carboxyethyl" route is the least studied. At the same time, the use of longer spacers between the polymer and a biologically active substance (BAS) can make the active fragment more accessible and enhance the effect of the biopolymer. Therefore, development of procedures for preparing carboxyethyl polysaccharide derivatives and study of their reactivity is a topical problem from both theoretical and applied viewpoints.

The carboxyethyl route suggested in [1–3] for modification of polysaccharides with amines with the aim to develop new physiologically active polymers has a number of significant darwbacks: The H form and esters of carboxyethyl dextran (CED) react with amines at high temperature, which is unacceptable for binding to polysaccharides of such BASs as antibiotics and enzymes. At the same time, more reactive CED azides are poorly studied.

Therefore, our goal was to study the stability and reactivity of CED azides in reactions with amines.

EXPERIMENTAL

The chemical scheme for acylation of amines with CED azides is as follows:

$$[C_6H_7O_2(OH)_{3-m}(OCH_2CH_2COONa)_{m-k}(OCH_2CH_2CONHNH_2)_k]_m$$
A

$$\xrightarrow{NaNO_2,\ HCl}$$

$$[C_6H_7O_2(OH)_{3-m}(OCH_2CH_2COOH)_{m-k}(OCH_2CH_2CON_3)_k]_m$$
B

$$\xrightarrow{RNH_2}$$

$$[C_6H_7O_2(OH)_{3-m}(OCH_2CH_2C\overset{-}{O}O\overset{+}{N}H_3R)_{m-k}(OCH_2CH_2CONHNR)_k]_m$$
C

$$\xrightarrow{NaOH}$$

$$[C_6H_7O_2(OH)_{3-m}(OCH_2CH_2COONa)_{m-k}(OCH_2CH_2CONHR)_k]_m,$$
D

R = $PhCH_2$, Ph, *p*-$MeOC_6H_5$, *p*-MeC_6H_5, *p*-$NO_2C_6H_5$, *p*-BrC_6H_5.

CED hydrazides **A** containing 0.3–0.35 hydrazide group and 1.0–0.9 carboxyethyl group per monosaccharide unit of the polymer were prepared from CED amides and hydrazine hydrate at 10–15°C [3]. These products were dissolved in a 0.5 N solution of sodium nitrite; the mixture was acidified with HCl to pH 2 and stirred for 1.5 h at 0–5°C. To the resuilting solution of CED azide **B**, an appropriate amine was added, pH 2–10 was adjusted with an acid or alkali, and the reaction was performed for 1–18 h at 15–20°C; the molar ratio of the amine to the monosaccharide units was 5 : 1. The reaction product **C** was

1070-4272/04/7702-0260 © 2004 MAIK "Nauka/Interperiodica"

precipitated with ethanol and reprecipitated from 0.1 N NaOH solution to decompose the ammonium salt whose absence in the product **D** was checked by TLC. Amides **D** were vacuum-dried (20–25 mm Hg) at 61°C. The substituted amides **D** are colorless or yellow amorphous powders readily soluble in water but insoluble in ethanol, acetone, diethyl ether, and most of other organic solvents.

The IR spectra of CED azides **B** contain a $\nu(N_3)$ stretching band at 2150 cm^{-1}, disappearing on treatment of azides with amines. The IR spectra of amides **D** treated with an acid contain the absorption bands at 1540–1550, 1650–1670, and 1490–1610 cm^{-1}, characteristic of δ(N–H) (amide **II**), ν(C=O) (amide **I**), and ν(C⋯C) of the benzene ring, respectively, and absent in the spectra of the starting polysaccharides; the carboxy group band at 1720–1730 cm^{-1} is preserved. In the IR spectra of sodium salts **D**, the bands of amide groups are obscured by the strong absorption band of the carboxylate ion (1570 cm^{-1}).

The UV spectra of the synthesized amides **D** in 0.1 N NaOH contain absorption peaks characteristic of aromatic compounds. The position of the peaks in the UV spectra of CED *N*-benzylamide, benzylamine, and *N*-benzylacetamide is the same. The UV spectra of CED *N*-arylamides also coincide with those of the respective anilides, but the λ_{max} values for the free amines are different. CED azides **B** show no absorption in this range. Hence, UV spectroscopy is a convenient method for analysis and evaluation of the purity of the compounds. The calibration plots were constructed using benzylamine and the corresponding anilides.

Amides **D** were characterized by the degree of aminocarbonylethylation N_{ace} (number of amide groups per monosaccharide unit of the polysaccharide), which was calculated from the UV and elemental analysis data. The reactions of CED azides **B** with different amines were characterized by the degree of amidation, N_{am} (%), which was calculated by the formula $N_{am} = (N_{ace}/N_{hce}) \times 100$, where N_{hce} is the number of hydrazide groups per monomeric unit of hydrazide **A**.

To find the best conditions for the reactions of azides **B** with amines, we studied the stability of aqueous solutions of azide **B** in time, as influenced by the temperature and pH. The concentration of azides **B** in solutions was determined spectrophotometrically after addition of hydroxylamine and $FeCl_3$ [4] (Fig. 1).

Azides **B** are stable in strongly acidic aqueous solutions. At pH 2, the content of azide groups decreases with time only slightly (by 5–10%). The difference between the losses of azide groups observed at 0 and 20°C is insignificant, which allows the acylation to be performed at a higher temperature (and hence at a higher rate). However, as the solution pH is increased, the content of azide groups capable of acylating amines drastically decreases. At 0°C, it decreases within several minutes to 85% at pH 6 and to 40% at pH 10. Therefore, the order of adding the reactants in acylation of amines with CED azides is essential. When aniline is added first and then KOH is added to adjust the required pH, the degree of amidation is approximately 30% higher than when KOH is added first.

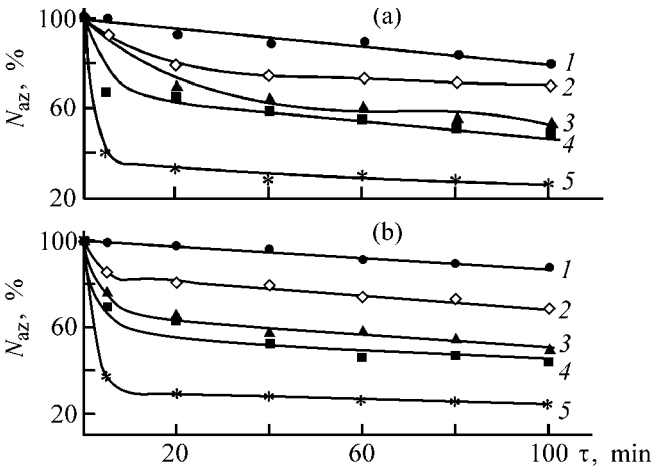

Fig. 1. Content of azide groups N_{az} (relative to the initial content of azide groups in CED azide) vs. time τ of keeping CED azide in solution at (a) 0 and (b) 20°C. pH: (*1*) 2, (*2*) 4, (*3*) 6, (*4*) 8, and (*5*) 10.

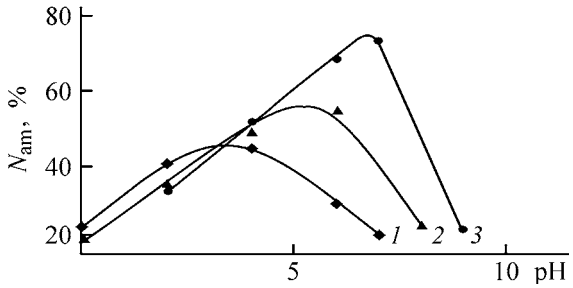

Fig. 2. Degree of amidation N_{am} of azides **B** with (*1*) *p*-bromoaniline, (*2*) aniline, and (*3*) *p*-phenetidine vs. pH. 17–20°C; 18 h; 5 mol of amine per mole of monosaccharide units; the same for Fig. 3.

When studying the acylating power of azides **B** toward amines, we expected that, similarly to carboxymethyl dextran azides [5], the solution acidity would exert a major influence on the degree of conversion of the azide groups into amide groups. The optimal pH is specific to each particular amine, in accordance with pK_a of the amine. Indeed, acid–base transforma-

Optimal pH values of solution (pH_{opt}) and degrees of conversion of azide groups into amide groups in reactions of azides **B** with amines (17–20°C; 18 h; 5 mol of amine per mole of monosaccharide units)

Amine	pK_a	σ_p	pH_{opt}	N_{am}	Amine	pK_a	σ_p	pH_{opt}	N_{am}
$PhCH_2NH_2$	9.37	–	10	70	$PhNH_2$	4.6	0	5.5	50.1
p-$EtOC_6H_4NH_2$	5.25	–0.24	7	72.0	*p*-$BrC_6H_4NH_2$	3.9	0.232	4	37.5
p-$MetC_6H_4NH_2$	5.12	–0.17	6	61.9	*p*-$NO_2C_6H_4NH_2$	1.02	0.778	0	10.0

tions of amines in the reaction medium exert a major effect on the reaction results (Fig. 2). When the pH deviates from the optimal value, N_{am} may decrease by a factor of 10. The lower the nucleophilicity of the amine, the lower the pH at which the degree of amidation of azides **B** is maximal. By contrast, strong bases better react with azides **B** in neutral and alkaline media. For example, the optimal pH is 10 for benzylamine and 5–6 for aniline. The optimal pH values at which the degrees of amidation of CED azides with aromatic amines are maximal linearly correlate with pK_a of the amines: pH = 1.5636 pK_a – 1.7201; n = 5, R^2 = 0.9833) (Fig. 3). With this correlation, it is possible to estimate the optimal acylation conditions from the known pK_a value of an amine without preliminary experiments.

As in the case of carboxymethyl dextran [5], the degree of conversion of azide groups into amide groups in reactions of azides **B** with aromatic amines also depends on the substituent in the benzene ring. Electron-donor substituents increase, and electron-acceptor substituents decrease N_{am} as compared to the reaction of azide **B** with aniline (see table). For example, the degree of amidation of azides **B** with aromatic amines increases from 10% with *p*-nitroaniline to 72% with *p*-phenetidine, which may be due to increasing nucleophilicity of the amines. The correlation of N_{am} with the Hammett constants of substituents σ_p is linear: $N_{am} = -58.05\sigma_p + 53.266$ (n = 5, R^2 = 0.9812).

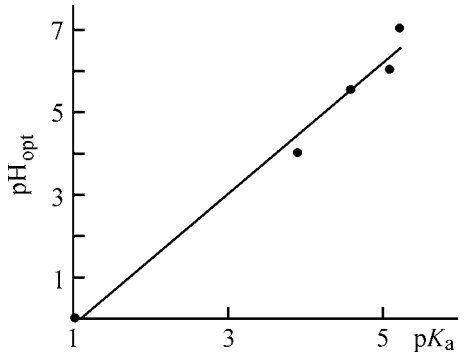

Fig. 3. Correlation between pK_a of aromatic amines and optimal pH (pH_{opt}) of their reaction with azides **B**.

CONCLUSIONS

(1) Aqueous solutions of carboxyethyl dextran azides can be used for acylation of aromatic and aliphatic amines in acidic and alkaline solutions at 0–20°C.

(2) The pH at which the degree of conversion of carboxyethyl dextran azide into amide passes through a maximum is specific to each particular amine and, in the case of aromatic amines, correlates with pK_a of the amine.

(3) The degree of amidation of azides with carboxyethyl dextran grows with increasing pK_a of the aromatic amine and linearly correlates with the Hammett σ_p constants of substituents.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Reactions of Carboxymethyl Polysaccharides and Their Ethyl Esters with Amines

O. V. Sibikina, A. A. Iozep, and B. V. Passet

St. Petersburg State Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

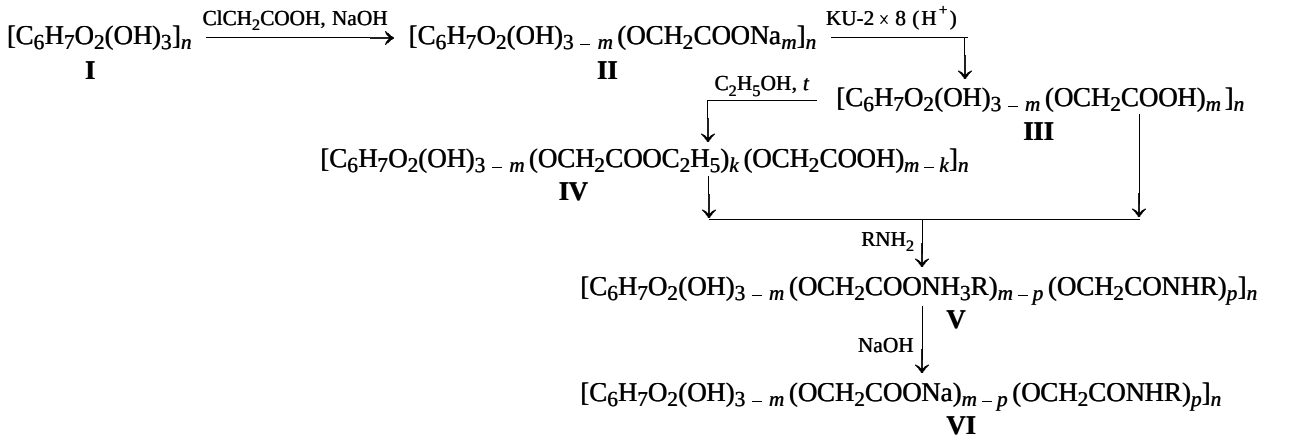
Received September 23, 2003

Abstract—The reaction of carboxymethyl polysaccharides and their ethyl esters with amines was studied with the aim to determine how the structure of the polymeric acylating agent affects the composition of the reaction products.

Previously, we heve studied the reactions of carboxymethyl dextran and its ethyl esters with aliphatic and aromatic amines [1, 2] and, based on these results, developed procedures for designing physiologically active polymers (PAPs) with the aim to prepare new biologically active substances and improve the existing drugs [3]. In view of the fact that PAPs are prepared with polysaccharides of different structures, we studied the reactions of amines with carboxymethyl polysaccharides (CMPs) and their ethyl esters, aiming to determine how the structure of the polymeric acylating agent affects the composition of the reaction products.

Our experiments were performed with aubasidan [branched β-1,3-β-1,6-α-1,4-*D*-glucan produced by *Aureobasidium pullulans*, molecular weight $(5–9) \times 10^6$]; corapulan (linear β-1,3-*D*-glucan prepared from aubasidan by Smith degradation); amylose (isolated from potato starch by the procedure described in [4], mean molecular weight 4×10^5); rhodexman (linear β-1,3-β-1,4-*D*-mannan produced by *Rhodotorula rubra*, molecular weight 6.5×10^4); cellulose [molecular weight $(1.5–2) \times 10^4$]; and also dextran commercially produced in Russia (used in production of Poliglyukin plasma-substituting antishock agent), with the average molecular weight of $(6 \pm 1) \times 10^4$.

Chemical modification of polysaccharides was performed by the scheme



Carboxymethyl polysaccharides and their ethyl esters (CMPEEs) were prepared as described in [4, 5]. Polysaccharide **I** was alkylated with monochloroacetic acid in isopropanol in the presence of alkali [4]. Poly acid **III** was prepared by treatment of aqueous solutions of CMP salt **II** with KU-2 × 8 cation exchanger.

Table 1. Ionization constants of carboxymethyl polysaccharides

Polysaccharide	C_{cm}	$K_a \times 10^5$	pK_a
Carboxymethyl dextran	0.94	9.772	4.01
Carboxymethyl rhodexman	1.07	7.079	4.15
Carboxymethyl amylose	1.61	4.57	4.32
Carboxymethyl cellulose	0.91	3.715	4.43
Carboxymethyl corapulan	1.73	2.512	4.60
Carboxymethyl aubasidan	1.11	1.259	4.90

Table 2. Degree of esterification C_e of carboxymethyl polysaccharide samples as influenced by pK_a of the poly acid

Polysaccharide	C_{cm}	pK_a	C_e, %
Carboxymethyl dextran	1.09	4.01	49
Carboxymethyl aubasidan	1.11	4.90	48
Carboxymethyl rhodexman	1.07	4.15	37
Carboxymethyl cellulose	0.91	4.43	37
Carboxymethyl amylose	1.61	4.32	34
Carboxymethyl corapulan	1.04	4.60	28

To prepare CMP ethyl ester **IV**, the poly acid was refluxed in excess ethanol under conditions of autocatalysis [5]. The resulting CMP and CMPEE samples were characterized by the degree of carboxymethylation, C_{cm}, and degree of alkoxycarbonylmethylation, C_{acm} (numbers of carboxymethyl and ester groups, respectively, per polysaccharide monomeric unit).

CMP sodium salts are white amorphous powders soluble in water (solubility: carboxymethyl aubasidan Na salt 10%; carboxymethyl rhodexman Na salt 15%; carboxymethyl dextran Na salt 20%) but insoluble in alcohol, acetone, ether, and most of other organic solvents.

For the CMP samples synthesized, we determined the acid ionization constants. Solutions of the poly acids were prepared by passing CMP sodium salts through a cation-exchange column, which was followed by potentiometric titration of the acid. The content of carboxy groups was determined by volumetric titration. The acid ionization constant was calculated as described in [6]. The relative error of the mean result did not exceed 4% (Table 1).

The apparent ionization constants of the carboxymethyl derivatives of dextran and cellulose coincided with the published values [7, 8].

One of the factors responsible for a decrease in the ionization constants in going from carboxymethyl dextran to carboxymethyl aubasidan (Table 1) may be different positions of substituents in the monomeric units of the polysaccharides. The effects of the monosaccharide unit on the carboxy group in positions C^2–O, C^3–O, C^4–O, and C^6–O are different. The ionization constant of the C^2–O-carboxymethyl group is higher, compared to the other positions. The electron-withdrawing effect of the carbonyl group of the monosaccharide unit is in this case the strongest. Hence, the higher the content of carboxymethyl group in the C^2–O position of the monosaccharide unit, the higher the ionization constant of the poly acid.

It should be noted that the capability of linear CMPs to form esters in reactions with ethanol correlates with pK_a of the poly acids (Table 2), except in the case of carboxymethyl amylose. Carboxymethyl dextran reacts with alcohol the most readily, and carboxymethyl corapulan, the least so. However, taking into account that, at $C_{cm} > 1$, C_e decreases, on the average, by 20–25% with increasing degree of substitution of CMP [5], carboxymethyl amylose, as expected, reacts with the alcohol more readily than carboxymethyl cellulose.

Acylation of amines with CMPs and their esters was performed in dioxane at 50–100°C for 4–16 h at a fivefold excess of the amine. The compounds were precipitated and reprecipitated with ethanol, acetone, or their mixtures with ether from aqueous solution of an alkali to remove low-molecular-weight impurities. The absence of low-molecular-weight impurities in the reaction products was checked by TLC. The CMP amides were examined by IR and UV spectroscopy, conductometric titration, and elemental analysis. The IR spectra of the reaction products in the H form contain absorption bands at 1535–1590 and 1640–1685 cm^{-1}, which are absent in the spectra of the starting substances and are characteristic of δ(N–H) (amide **II**) and ν(C=O) (amide **I**).

The content of amide groups in polysaccharide samples was determined by elemental analysis and UV spectroscopy. The acylation was characterized by the degree of amidation, C_{am} (percentage of acyl groups of the polysaccharide converted into amide groups).

Table 3. Results of reactions of carboxymethyl polysaccharides with aniline and benzylamine in dioxane (100°C, 6 h, molar ratio of amine to carboxy groups 5 : 1)

Polysaccharide	C_{cm}	C_e, %	C_{am} (%) in reaction with	
			benzylamine	aniline
Carboxymethyl dextran	0.9	49	26	43
Carboxymethyl aubasidan	1.11	48	18	39
Carboxymethyl rhodexman	0.91	37	14	27
Carboxymethyl cellulose	1.06	37	10	26
Carboxymethyl amylose	1.61	34	–	26
Carboxymethyl corapulan	1.04	28	10	11

Table 4. Degree of amidation of carboxymethyl polysaccharide ethyl esters in reactions with benzylamine (50°C, 4 h) and aniline (70°C, 16 h) in dioxane (fivefold excess of amine)

Ethyl ester of	C_{cm}	C_{acm}	C_{am} (%) in reaction with	
			benzylamine	aniline
Carboxymethyl dextran	0.36	0.56	38	82
Carboxymethyl aubasidan	0.58	0.53	45	72
Carboxymethyl cellulose	0.57	0.34	35	56
Carboxymethyl amylose	1.06	0.55	31	55
Carboxymethyl rhodexman	0.67	0.39	31	49
Carboxymethyl corapulan	0.75	0.29	31	45

The results of acylation of benzylamine and aniline with CMPs and their ethyl esters are given in Tables 3 and 4.

These results show that the reactivity of CMPs toward amines varies approximately similarly to the reactivity of the poly acids toward ethanol (Table 3). The dextran and aubasidan derivatives are modified with amines the most readily. The reactivities of the rhodexman, amylose, and cellulose derivatives toward amines are similar and somewhat lower than that of the dextran and aubasidan derivatives. Carboxymethyl corapulan reacts with amines the most difficultly. The same trend, with a minor exception (Table 4), is observed in acylation of benzylamine and aniline with ethyl esters of carboxymethyl polysaccharides under the conditions when only esters react with the amines. The influence of the polymer structure on the reactivity of CMPs and their ethyl esters is probably also associated with different arrangements of substituents in the monosaccharide unit and with structural features and properties of these polysaccharides.

Experiments on acylation of benzylamine and aniline with different CMPs showed that, in all the cases, aniline reacts under equal conditions with CMPs almost a factor of 2 faster than benzylamine. This is probably due to the higher stability of benzylammonium salts of polymeric carboxylic acids under acylation conditions and hence to lower concentrations of the acid (H form) and free amine in the reaction mixture (the carboxylate ion does not acylate amines). With CMP ethyl esters, benzylamine, being a stronger nucleophile, reacts considerably faster than aniline.

CONCLUSIONS

(1) Carboxymethyl derivatives of polysaccharides of different structures and their esters are simple and convenient acylating agents in reactions with amines.

(2) The apparent ionization constant of carboxymethyl polysaccharides depends on the position of the carboxymethyl groups in the monosaccharide unit of the polymer.

(3) The acylating activity of carboxymethylated linear polysaccharides and their ethyl esters grows with decreasing pK_a of the poly acid.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Theoretical Description of Physical Aging of Amorphous Polymers

G. V. Kozlov, I. V. Dolbin, and G. E. Zaikov

Kabardino-Balkarian State University, Nalchik, Kabardino-Balkaria, Russia

Emanuel Institute of Biochemical Physics, Russian Academy of Sciences, Moscow, Russia

Received August 20, 2002; in final form, December 2003

Abstract—Physical aging of amorphous polymers was studied, and a theoretical description of the process in terms of fractal analysis was attempted.

Physical aging of polymers involves modification of their structure and properties with time and reflects the thermodynamically nonequilibrium nature of these materials. Physical aging typically results in increased brittleness of polymeric materials, which makes it important to forecast how the structural characteristics vary with time, so as to estimate the safe service life of polymeric articles. For network polymers, Kozlov *et al.* [1, 2] quantitatively estimated the structural changes in terms of the fractal analysis [3] and of the cluster model of the structure of polymers in the amorphous state [4, 5]. In the present, these models were applied to description of physical aging of polycarbonate (PC) based on bisphenol A. Also, we examined in more detail the behavior of PC during physical aging by using the concept of the quasiequilibrium state of the polymer structure [6] and to the model of a thermal cluster [7], which is a variant of the percolation theory.

EXPERIMENTAL

We studied granulated commercial PC of the Lexan brand (USA). The reduced viscosity η_{red} of a 0.5% chloroform solution of PC, measured on an Ubbelohde viscometer at 298 K, was 0.12 $m^3\ kg^{-1}$. We prepared $4 \times 6 \times 50$-mm samples by pressing at ~7 MPa and 490 K. The physical aging of the PC samples was carried out at T_{ag} = 403 K, which is below the glass-transition point of 423 K for PC [8]. The aging continued for 1000 h, during which time mechanical tests were run at 200-h intervals. Also, the reduced viscosity η_{red} was measured at 200-h intervals for the same samples and proved to be constant, which suggests the lack of thermal-oxidative degradation. Impact tests were carried out at 293 K by the Charpy technique on a UT-1/4 pendulum impact machine equipped with a piezoelectric load sensor. This installation records the load–time, P–τ, diagrams suitable for calculating the elasticity modulus E [9] and the yield stress σ_y [10]. These parameters, in turn, allow calculation of the Poisson coefficient ν by the relationship [11]

$$\frac{\sigma_y}{E} = \frac{1 - 2\nu}{6(1 + \nu)}. \quad (1)$$

In terms of the model [4, 5], the PC structure can be characterized by the relative proportion of the domains exhibiting local ordering (clusters), φ_{cl}, which is an order parameter in the strict physical sense [12]. For the starting PC, φ_{cl} is calculated by the relationship [12]

$$\varphi_{cl} = 0.03(T_g - T)^{0.55}, \quad (2)$$

where T is the test temperature (K); and T_g, the glass-transition point (K).

In terms of fractal analysis [13], the polymer structure is characterized by the fractal (Hausdorfian) dimensionality d_f and by the dimensionality of the excess energy localization domains, D_f, which characterizes the degree of the energetic excitation of loosely packed areas of the polymer structure and the size distribution of microcavities of the fluctuation free volume [6]. The dimensionalities d_f and D_f can be calculated by the equations [13]

$$d_f = 2(1 + \nu), \quad (3)$$

$$D_f = \frac{2(1 - \nu)}{1 - 2\nu}. \quad (4)$$

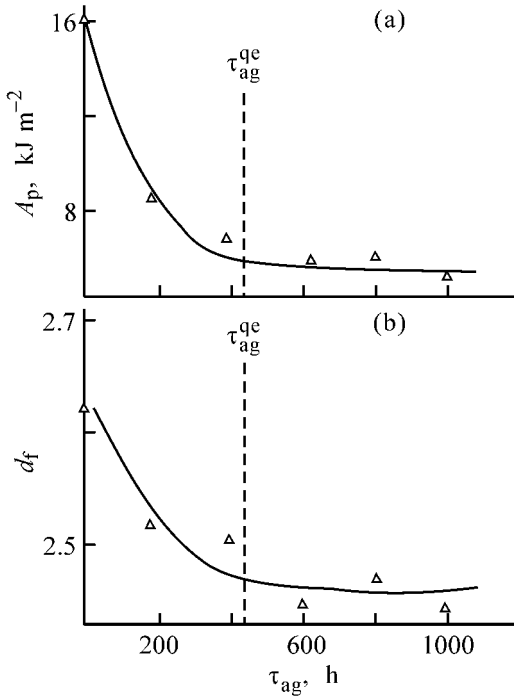

Fig. 1. (a) Resilience A_p and (b) fractal dimensionality of the structure d_f vs. the aging time τ_{ag} for PC. The vertical dashed line indicates the τ_{ag}^{qe} parameter calculated by Eq. (11).

Common knowledge [14] suggests that physical aging involves a decrease in the plasticity of PC, which is manifested in a decrease in the resilience A_p with the aging time τ_{ag} (Fig. 1). Figure 1a shows that A_p tends to decrease during the first 500 h of aging, whereupon the A_p-vs.-τ_{ag} plot flattens out with minor absolute values of A_p of ~4.5 kJ m^{-2}. Such a run of this plot may be due to the fact that the structure attains a certain limiting state which is defined as a quasiequilibrium state [6]. In terms of the model [4, 5], the tendency toward thermodynamic equilibrium, exhibited by the nonequilibrium structure of the polymer during physical aging, is expressed by an increase in the degree of local (short-range) order, φ_{cl} [1, 2]. In a certain stage of aging, however, the entropy-related chain tension counterbalances this tendency, and φ_{cl} ceases to increase [6], thus yielding the quasiequilibrium state. The dimensionality of the domains characterized by excess energy localization for this state, D_f^{qe}, is defined by the equation [6]

$$D_f^{qe} = \frac{4\pi T}{\ln(1/f_{ff})T_g}, \quad (5)$$

where f_{ff} is the relative fluctuation free volume, and T, test temperature.

Novikov and Kozlov [15] have found earlier that the polymer structure can be modeled as a thermal cluster whose formation is governed by both geometric and thermal interactions. The order parameter φ_{cl} for such a cluster is defined by the equation [7]

$$\varphi_{cl} = \left(\frac{T_g - T}{T_g}\right)^{\beta_t}, \quad (6)$$

where β_t is the critical index of the thermal cluster; T, test temperature (K); and T_g, the glass transition point (K).

Novikov and Kozlov [15] have shown earlier that β_t is generally a function of the degree of molecular mobility of the polymer and that $\beta_t \geq \beta$, where β is the corresponding critical index of the percolation cluster whose formation is controlled by geometric interactions only [16]. The $\beta_t = \beta$ equality is attained only when molecular mobility is totally suppressed, i.e., in the quasiequilibrium state.

Figure 1b shows the d_f–τ_{ag} plot calculated by Eqs. (1) and (3), which illustrates the evolution of the PC structure during physical aging. It is seen that, at $\tau_{ag} > 500$ h, the plot flattens out, with A_p attaining a value of ~2.46. The parameter f_{ff} for this case [$\nu = 0.23$ from Eq. (3)] can be calculated by the equation [11]:

$$f_{ff} \approx 0.017\frac{(1+\nu)}{(1-2\nu)}. \quad (7)$$

Next, we can calculate D_f^{qe} by Eq. (5) and then estimate the corresponding d_f^{qe} using the relationship [13]

$$D_f^{qe} = 1 + \frac{1}{3 - d_f^{qe}}. \quad (8)$$

Using Eqs. (5) and (8), we obtain $D_f^{qe} = 2.68$ and $d_f^{qe} = 2.41$. The latter value agrees well with the above-cited d_f value for the asymptotic branch of the d_f–τ_{ag} plot (Fig. 1b). Thus, the fact that the plot for resilience A_p (kJ m^{-2}) flattens out (Fig. 1a) is due to the attainment of a quasiequilibrium state by the PC structure in the course of physical aging.

Next, we estimate φ_{cl} in the quasiequilibrium state, using Eq. (6) and determining $\beta_t = \beta$ as [17]:

$$\beta_t = \beta = 1/d_f, \quad (9)$$

where β is the critical index of the percolation cluster.

Calculation by Eq. (6) yields $\varphi_{cl}^{qe} = 0.619$. Next, a_f^{qe} can be estimated from the expression [6]

$$d_f = 3 - 6\left(\frac{\varphi_{cl}}{SC_\infty}\right)^{1/2}, \quad (10)$$

where S is the cross-section area of the macromolecule (for PC, S = 30.7 Å^2 [18]), and C_∞, a characteristic ratio that reflects the statistical flexibility of the chain [19] (for PC, C_∞ = 2.4 [21]).

Calculation by Eq. (10) yields d_f^{qe} = 2.45, which agrees well with the above-cited values. Thus, the thermal cluster model adequately describes the polymer structure and, in particular, the conditions of realization of the quasiequilibrium state.

Using Eqs. (4), (5), and (8), we estimated D_f^{qe} to be 2.85, 2.68, and 2.82, respectively, which also shows that the techniques mentioned give well consistent results.

Let us estimate the time of physical aging, τ_{ag}^{qe}, required for attainment of the quasiequilibrium state. To this end, we use the equation derived by Aharoni [20]:

$$\varphi_{cl}^{qe} = k\varphi_{cl}\tau_{ag}^{(d_f - 2)(d_f - d_f^{qe})}, \quad (11)$$

where k is a constant equal to 0.14 [2], and φ_{cl}, the relative fraction of the clusters for the initial polymer; τ_{ag} is given in seconds.

The parameters in Eq. (11) can be estimated as follows. The parameter φ_{cl}^{qe} is calculated at T_{ag} by Eq. (6), and φ_{cl}, also at T_{ag} according to Eq. (2). Next, d_f and d_f^{qe} at T_{ag} can be calculated by Eq. (10) for the corresponding φ_{cl} and φ_{cl}^{qe}. The τ_{ag}^{qe} value of ca. 438 h, calculated in the given conditions by Eq. (11), is indicated in Figs. 1a and 1b with a vertical dashed line. It is seen that τ_{ag}^{qe} agrees well with τ_{ag} that corresponds to flattening out of the A_p–τ_{ag} and d_f–τ_{ag} plots. Thus, we can estimate the transient (nonstationary) period τ_{ag}^{tr} (h) during which the structure and properties of the polymer are modified by physical aging ($\tau_{ag}^{tr} \le \tau_{ag}^{qe}$).

It is known [14] that A_p grows with increasing molecular mobility associated with the mobility of the chains in loosely packed domains of the polymer structure [21]. The model discussed in [4, 5] treats such a domain as a loosely packed matrix in which the clusters are embedded. The relative proportion of such a domain φ_{lm} can be determined by the equation [11]

$$\varphi_{lm} = 1 - \varphi_{cl}. \quad (12)$$

Figure 2 presents the A_p–φ_{lm} plot, which has the expected shape. According to Aharoni [14], A_p tends to linearly grow with increasing φ_{lm}, and A_p = 0 corresponds to $\varphi_{lm} \approx 0.352$, rather than to the expected φ_{lm} = 0. According to Eq. (12), $\varphi_{lm} \approx 0.352$ corresponds to $\varphi_{cl} \approx 0.648$, which is fairly close to $\varphi_{cl} \sim 0.619$ at 293 K. This is consistent with the postulated total extension of the chains in the quasiequilibrium state, which restrict the growth of φ_{cl}, and with the resulting total suppression of the molecular mobility, which yields A_p = 0, i.e., totally brittle polymer.

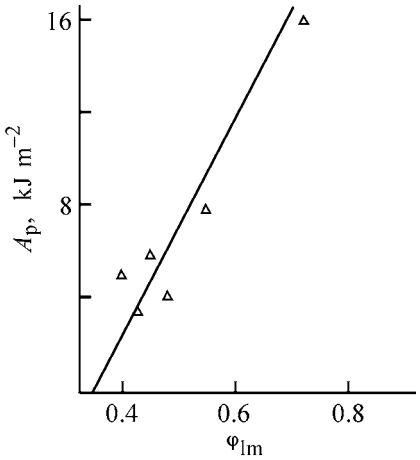

Fig. 2. Resilience A_p vs. the relative proportion of the loosely packed matrix φ_{lm} for PC.

CONCLUSION

Physical aging of amorphous polymers was theoretically described in terms of the fractal analysis and the thermal cluster model, taking polycarbonate as a typical example. It was shown that, during physical aging, the polymer structure attains a quasiequilibrium state. The evolution of the structure and properties of polymers during this process can be quantitatively described.

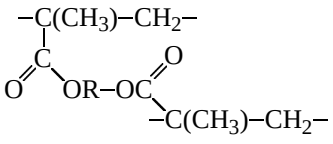
Received July 29, 2003

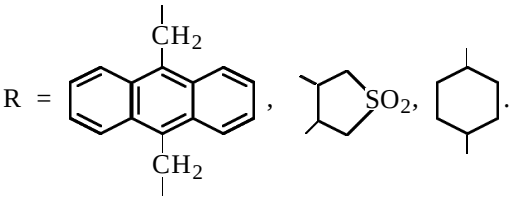
Abstract—Radiation aging of poly(methyl methacrylate) and copolymers of methyl methacrylate with *trans*-1,2-di(methacryloxy)cyclohexane, 3,4-di(methacryloxy)sulfolane, and 9,10-di(methacryloxymethyl)anthracene was studied.

The radiation resistance of polymers is influenced by the chemical structure of a polymer, its supramolecular structure, and chain mobility. Any of these factors can be decisive, depending on conditions. Studies of the radiation resistance of ionomers (copolymers of ethylene with acrylic acids, in which the carboxy groups are partially converted to Mn, Pb, and Cd salts) showed that, upon irradiation, these copolymers exhibit higher strength than polyethylene (PE) irradiated with the same doses (PE macromolecules cross-link under the action of high-energy radiation [1]).

The crystallinity decreases in going from PE to the ionomer [2], which should result in lower radiation resistance [3]. The higher, compared to PE, resistance of the ionomers to radiation (at doses of up to 70 Mrad [4]) cannot be accounted for by the presence of metal-containing fragments only (as these fragments protect the polymers only at irradiation doses not exceeding 0.1 Mrad [4]) but can be explained in terms of structural protection. In ionomers, the macromolecules (and also separate fragments of a macromolecule) form with each other not only common van der Waals and hydrogen bonds, but also ionic bonds [2] decreasing the molecular mobility. As a result, the probability of radiation-induced intermolecular cross-linking, impairing the PE properties, decreases.

It seems interesting to evaluate the effect of intermolecular cross-links on the radiation aging of a polymer degrading under high-energy radiation, poly(methyl methacrylate) (PMMA). To this end, we examined in this study the radiation resistance of copolymers of methyl methacrylate (MMA) with *trans*-1,2-di(methacryloxy)cyclohexane (DMCH), 3,4-di(methacryloxy)sulfolane (DMS), and 9,10-di(methacryloxymethyl)antracene (DMMA). The main macromolecular chains in these copolymers are cross-linked with cyclohexane, sulfolane, and dimethylanthracene bridges. The cross-links have the following structure:





EXPERIMENTAL

The radiation resistance of MMA copolymers was evaluated by comparing the accumulation curves and radiation-chemical yields of radicals and the thermomechanical properties of irradiated samples with the respective characteristics of the homopolymer.

Polymer samples were prepared by bulk polymerization, performed to full conversion, at 40°C in the presence of dicyclohexyl peroxydicarbonate initiator with various amounts of DMCH or DMMA, or at

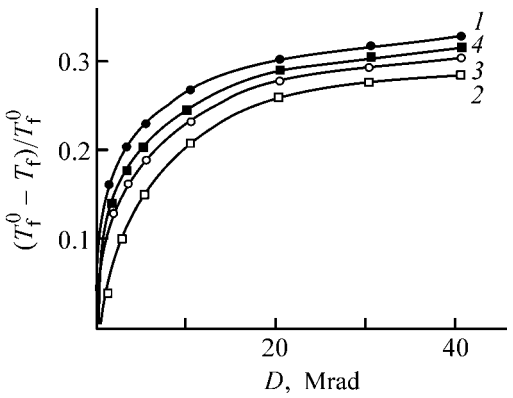

Fig. 1. Relative change in the flow point, $(T_f^0 - T_f)/T_f^0$, of (*1*) PMMA and copolymers of MMA with (*2*) DMMA, (*3*) DMS, and (*4*) DMCH vs. the absorbed dose *D*. Content of the second comonomer in the polymer 0.7 mol %; the same for Fig. 5. (T_f^0, T_f) Flow points (°C) of the unirradiated and irradiated samples, respectively.

50°C in the presence of azobis(isobutyronitrile) and DMS. DMCH, DMMA, and DMS were prepared according to [5–7] and were added to the polymerization mixture in amounts of 0–5.1, 0–1.3, and 0–4.5 mol %, respectively. The copolymers are insoluble in organic solvents. The molecular weight of PMMA is 9.11×10^5.

From the polymer blocks, we cut disks 3 mm in diameter and 4 mm high and irradiated them with ^{60}Co γ-rays at 25°C on an Issledovatel' installation (dose rate 0.15 Mrad h^{-1}, absorbed dose 0–60 Mrad).

The ESR spectra of the irradiated samples were recorded on an RE-1301 spectrometer at 77 K; the relative error in determination of the macroradical concentration was 5–10%.

The radiation-chemical yields of radicals (per 100 eV of absorbed energy) were determined from the slopes of the linear portions of the radical-accumulation curves.

Thermomechanical tests were performed on an installation providing progammed heating of the sample, by the method of constant loading. The load was 0.13 MPa, and the heating rate, 0.04 deg s^{-1}. The glass transition (T_g) and flow (T_f) points were determined by the method of interception of tangents to the initial portions of the thermomechanical curves.

Poly(methyl methacrylate) degrades under the action of ionizing radiation, with scission of the backbone at the quaternary carbon atom. These scissions are random, and the molecular weight of the polymer considerably decreases even in the initial step of irradiation. A similar pattern is observed with MMA copolymers: Their T_f (which directly correlates with the molecular weight, the parameter that is the most sensitive to irradiation) drastically decreases (Fig. 1). However, with MMA–DMCH and MMA–DMS copolymers this trend is appreciably less pronounced than with PMMA (cf. curves *1*, *3*, *4* in Fig. 1). Neither dissipation of the absorbed energy nor deactivation of the intermediate reactive states can be responsible for the observed protection effect. In the sulfolane groups of DMS–MMA copolymers, all the six valence electrons of the S atom involved in the formation of the S=O and C–S bonds. In contrast to bivalent sulfur compounds, sulfolane has no electrons capable of excitation to the *d* level. The cyclohexane fragment in the MMA–DMCH copolymer contains no conjugated double bonds and, similarly to the sulfolane group, cannot be involved in redistribution of the absorbed energy. In radiolysis, these groups do not generate species able to deactivate macroradicals. The stabilization of the polymer is apparently due to structural features of the macromolecules. The cross-links decrease the mobility of the macromolecules, and radicals arising in a macromolecule cannot cause degradation of another macromolecule, as it takes place, e.g., in PMMA [8].

The radicals decay by interaction with the radiation field (leading to the polymer degradation) and recombination (inhibiting degradation) [9]. Cross-links favor stabilization of radicals by complicating their decay both via thermal recombination and via direct interaction with the radiation (e.g., by dissociation to form stable molecules and hydrogen atoms recombining with the nearest radicals [9]). The rate constant of radical decay in irradiated MMA–DMS copolymer by direct interaction with the radiation is 0.23 $Mrad^{-1}$, whereas in PMMA it is 0.37 $Mrad^{-1}$ [10]. The activation energy of bimolecular radical decay in 110 kJ mol^{-1} in PMMA [10] and 146 kJ mol^{-1} in the copolymer. The inhibition of radical recombination in the copolymer is apparently due to a decrease in their "rotational" mobility in a cage and to the decreased probability of their escape from the cage.

The cross-linking of PMMA macromolecules of the sulfolane group causes a stronger radiation-protective effect than cross-linking with the cyclohexane fragment (curve *3* in Fig. 1 lies below curve *4*). This is apparently due to the lower concentration of free radicals accumulating in the MMA–DMS copolymer, compared to the copolymer with DMCH, in the exam-

ined ranges of the irradiation doses (Fig. 2) and comonomer concentrations in the copolymers (Fig. 3). As seen from the table, the radiation-chemical yield of free radicals G in the MMA–DMS copolymer is lower than in the MMA–DMCH copolymer.

The cross-links decrease the mobility of separate fragments of polymeric chains and give rise to mechanical stresses. Therefore, in the cross-linked polymers, compared to PMMA, the probability of macromolecule scission, the concentration of radicals, and their radiation-chemical yield increase. Furthermore, the comonomers can increase the concentration of defects of macromolecular packing owing to the steric effect, which may also be responsible for the experimentally observed growth of the radical concentration in proportion to the amount of the comonomer (Fig. 3).

Despite the higher, compared to PMMA, radiation-chemical yields and concentrations of radicals in the cross-linked samples, these samples appear to be more resistant to high-energy radiation. This means that, for the copolymers in hand, the macromolecular mobility is the major factor affecting the radiation aging, although the effect of the first two factors is also noticeable.

In real network polymer samples, not all the molecules are cross-linked, i.e., the sol fraction is present. The macromolecules that are not incorporated in the network exhibit not only hyperelastic but also viscous-flow properties. The contribution of the viscous-flow deformation depends on the content of such macromolecules. In copolymers of MMA with DMCH, DMS, and DMMA, the content of non-cross-linked PMMA macromolecules should be significant, since the concentrations of the comonomers are low (≤5.1 mol %). Furthermore, apparently, not all the comonomer molecules are involved in cross-linking of the macromolecules in the course of the synthesis. Some of them can be present as fragments of the linear copolymer chain and can participate in cross-linking by radiation-induced copolymerization of the pendant methacryloxysulfolane (or -cyclohexane, -methylanthracene) group with PMMA. This process may be responsible for the fact that T_g of the MMA–DMS copolymer, in contrast to T_g of PMMA, tends to increase upon γ-irradiation with small doses (Fig. 4).

Cross-linking with anthracene groups (in MMA–DMMA copolymer) enhances the radiation resistance of the polymer to a still greater extent. DMMA, compared to DMCH and DMS, inhibits to a greater extent the decrease in the flexibility of the whole macromolecule (factor responsible for the polymer flowability,

Fig. 1) and in the mobility of separate chain segments (factor responsible for the glass transition, Fig. 5), occurring upon γ-irradiation.

The curves of radical accumulation in MMA–DMMA copolymers upon irradiation at 25°C level off at $D > 30$ Mrad, whereas for PMMA and the other copolymers they pass through a maximum (Fig. 2). The descent of the curve after the accumulation of a certain concentration of radicals in PMMA and copolymers of MMA with DMS and DMCH is apparently due to the fact that the radiation-induced degradation of the polymers appreciably alters the macrochain mobility, making possible subsequent thermal transformations of the radicals since irradiation is performed at a relatively high temperature. When PMMA is irradiated at low temperatures, such transformations are impossible, and the plot of the radical concentration vs. irradiation dose levels off [9]. In MMA–DMMA copolymers, the transformations of radicals are hindered by the high rigidity of the anthracene core and of macromolecules containing it.

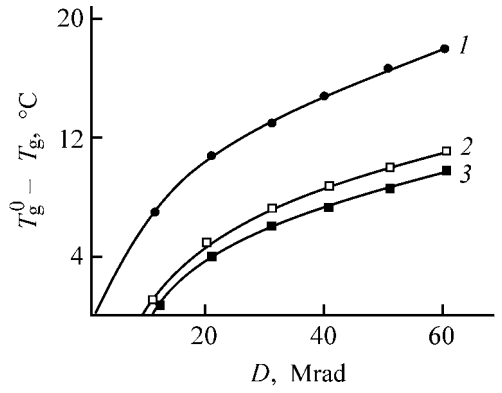

Fig. 5. Change in the glass transition point, $T_g^0 - T_g$, of (*1*) PMMA and copolymers of MMA with (*2*) DMS and (*3*) DMMA vs. the irradiation dose *D*.

The maximal concentration of free radicals, attained in irradiation of this copolymer, is lower than that attained in MMA–DMCH and MMA–DMS copolymers (Fig. 1). This relationship is preserved when the content of DMMA units in the copolymer is increased to 1.3 mol % (Fig. 3; the upper concentration limit corresponds to the limit of DMMA solubility in MMA).

The anthracene groups present in the MMA–DMMA copolymer are capable to absorb the incident energy by the system of conjugated double bonds and to dissipate it in the form of heat and light so rapidly that the polymer has no time to degrade. Apparently, owing to this protective effect ("radiation sponge"), the radiation-chemical yield of radicals in this copolymer appears to be lower, compared to MMA–DMS and MMA–DMCH copolymers and to PMMA (see table). The anthracene fragments, on the one hand, protect the polymer from radiation and, on the other hand, when present in certain concentration, alter its supramolecular structure, stabilizing the macroradicals: As the DMMA content in the copolymer is increased, the radiation-chemical yield of the radicals and their concentration grow.

Mechanical blending ot antracene with PMMA, compared to preparation of MMA–DMMA copolymers, provides the same radioprotective effect at 5–10 times higher content of anthracene. This fact is indicative of a complex protection mechanism in the copolymer, involving both the redistribution of the absorbed energy by aromatic cores and the structural protection due to cross-linking of the macromolecules.

Thus, in copolymers of MMA with monomers that act as cross-linking agents, radiation-induced degradation is inhibited.

CONCLUSIONS

(1) Cross-linking of poly(methyl methacrylate) macromolecules with cyclohexane and sulfolane bridging groups in copolymers of methyl methacrylate with *trans*-1,2-dimethacryloxycyclohexane and 3,4-dimethacryloxysulfolane enhances the radiation resistance of the polymer owing to a decreased mobility of macromolecules, despite the higher radiation-chemical yields and concentrations of the radicals, compared to the homopolymer.

(2) Introduction of anthracene fragments into poly(methyl methacrylate) enhances the radiation-protec-

tive effect of cross-linking owing to the capability of aromatic cores to participate in redistribution of the incident energy.

Abstract—Thermal stability of the electret state of polytetrafluoroethylene films with element oxide structures on the surface was studied. The frequency factor and the activation energies of the newly formed groups of deep centers that capture the electret charge were determined.

As is known [1], when irradiated with charged particle fluxes, polymer insulators accumulate a positive or a negative charge on their surface, yielding an electret state. Such materials are called electrets, and the charge on their surface can be preserved for a fairly long time, depending on the external conditions and properties of the polymer. This effect finds application in electroacoustic transformers and sensors, as well as in nonlinear-optics components [2]. Of great practical importance for such systems is the stability of the electret state. For nonpolar polymers, such a stability is afforded by creation on their surface of deep charge capture centers, using specially developed procedures [3]. For example, fluoropolymers are characterized by extremely low mobility of charge carriers [1–3]. Their equilibrium concentration is so small, compared to that of the injected charges, that the deciding role in relaxation of the electret state is played by the surface traps [3]. Therefore, it is not surprising that, the stability of the nonequilibrium charge injected into nonpolar polymers during charging in the corona discharge, is strongly dependent on the chemical structure of the surface [3–5]. Rychkov and Boitsov [3] showed that, with increasing degree of hydration of the surface of nonpolar fluoropolymer films, the curves of thermoinduced relaxation of the surface potential tend to regularly shift to higher temperatures. X-ray photoelectron spectroscopic (XPS) studies revealed major defluorination of the surface being modified [3]. Thus, chemical modification of the surface can efficiently control the electret characteristics of polymers.

Modification of the energy spectrum of the surface traps is the most pronounced in hydration of the polytetrafluoroethylene (PTFE) surface. Rychkov *et al.* [3, 6] revealed a correlation between the thermal stability of the surface potential and the concentration of the OH groups on the film surface. At the same time, it is known that the concentration of the active sites chemisorbing the OH groups on the film surface can be significantly increased by molecular layer deposition (MLD). This method is based on chemical reactions between the functional groups of the solid-phase matrix and volatile low-molecular-weight reagents [7, 8].

EXPERIMENTAL

In this study, we examined the nature of the centers that capture the electret charge in PTFE films with element oxide nanostructures on their surface and also determined the microscopic parameters of the forming surface traps of the positive homocharge.

We studied 10-μm-thick F4-EA grade PTFE films coated with aluminum on one side. The desired composition of the surface was achieved by using chemical nanotechnology based on the MLD principles.

The element oxide groups were synthesized in a flow reactor, by treating 50×20-mm film samples of the polymer material with a PCl_3 vapor. The choice of PCl_3 as the modifying agent was dictated by the high hydrolytic activity of polar phosphorus-containing groups. After synthesis, the physisorbed PCl_3 and HCl were removed by a dried air flow until they ceased to evolve at the reactor outlet. To replace the chloride ions with OH groups in the products of the reaction of

1070-4272/04/7702-0276 © 2004 MAIK "Nauka/Interperiodica"

PTFE with the modifier vapor, the samples were subjected to vapor-phase hydrolysis. The completion of this hydrolysis was ascertained by ceased evolution of HCl at the reactor outlet. The modification temperature was 180°C, the times of treatment of the samples with PCl_3 and H_2O vapor, 1 h and 30 min, respectively, and the flow rate of air dried to a dew point (from –50 to –55°C), 100 $cm^3\ min^{-1}$.

The electret state in the initial and modified films was created by charging in a positive corona discharge on a setup shown schematically in Fig. 1. The initial surface potential V_0 = +500 V was set by the voltage on grid *2*. The charging time was 1 s, and the charging temperature, 290 K.

The electret properties of the samples were studied by the method of thermoinduced relaxation of the surface potential (TIRSP) [3] in the linear heating mode at β_1 = 0.10 and β_2 = 0.17 deg s^{-1}. This method allows recording of the temperature dependences of the surface potential of electrets. Simmons *et al.* [9] suggest that, for nonpolar fluoropolymers, the TIRSP curves can be described by the expression [3]

$$\frac{V(T)}{V_0} = 1 - \frac{1}{\beta}\int_{T_0}^{T} D f_0^*(E_s)\, N^*(E_s)\, dT', \qquad (1)$$

$$E_s = T\left(\log\frac{\omega_s}{\beta} + a\right)b - c. \qquad (2)$$

Here, E_s is the activation energy of surface traps; $f_0^*(E_s)N(E_s)$, distribution function of the filled surface traps with respect to activation energies; $D = 1.2\beta E_s T^{-1}$, a weakly temperature-dependent coefficient [9]; and ω_s, frequency factor of surface traps.

The constants *a*, *b*, and *c* are determined by the system of units chosen. For E_s measured in eV, and *T*, ω_s, and β, in International System units, these constants take the following values: a = 1.66, $b = 1.92 \times 10^{-4}$, and c = 0.015 [9].

Equations (1) and (2) show that, in terms of the model accepted, TIRSP of the electret state is fully determined by the parameters of the energy spectrum of the surface traps. The d*V*/d*T* dependence on the temperature *T* reflects the distribution of the traps with respect to energies. Thus, to derive the distribution function of the filled surface traps with respect to activation energies from the experimental data, it is sufficient to transform the d*V*/d*T* scale to the $f_0^*(E_s)N(E_s)$ scale, and the temperature scale, to the energy scale. These transformations present no difficulties, since the required frequency factor ω_s can be determined experimentally from the shift of the maximum of

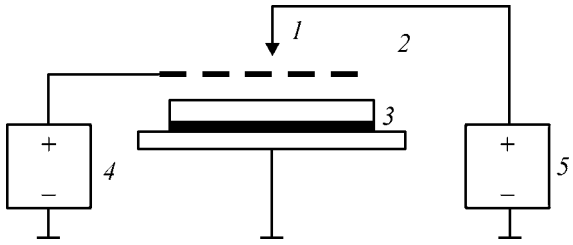

Fig. 1. Schematic of the setup for polarization in a corona discharge: (*1*) corona discharging electrode, (*2*) grid, (*3*) sample being charged, (*4*) stabilized power supply, and (*5*) high-voltage source.

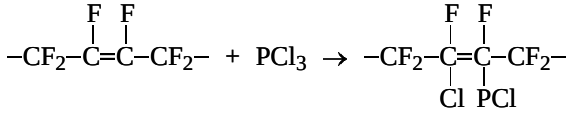
the derivative of the TIRSP signal with respect to temperature depending on the heating rate, using the formula [9]

$$\log\omega_s = \frac{T_2^*\log\beta_2 - T_1^*\log\beta_1}{T_2^* - T_1^*} - a, \qquad (3)$$

where T_1^* and T_2^* are the temperatures corresponding to the peaks of the d*V*/d*T*–*T* curves recorded at the heating rates β_1 and β_2, respectively.

Chemical modification, evidently, involves grafting of phosphorus-containing groups to the polymer matrix surface. According to the XPS data [3], the chemical structure of PTFE includes $–CF_2–CF{=}CF–CF_2–$ groups incorporating double bonds, which can be active in reactions with PCl_3:



A chemical analysis showed that the phosphorus concentration in the modified samples is insignificant (ca. 0.01 wt %).

In our earlier communication [10], we reported similar chemical transformations, namely, addition of phosphorus-containing groups to the surface of nonpolar low-density polyethylene via scission of the C=C bond, as revealed by various methods (chemical analysis, IR spectroscopy). The subsequent vapor-phase hydrolysis of the modified films results in replacement of the chloride ions and an increase in the concentration of OH groups.

Also, the surface of real polymers contains chemisorbed molecules strongly fixed to certain moieties of the polymer chains. These moieties include OH, CO, C–C, C=C, CH_2, CH_3, and other groups, among which oxygen-containing groups result from polymeric material the contact of an air [11]. These defects are, evidently, reactive and can exhibit activity during

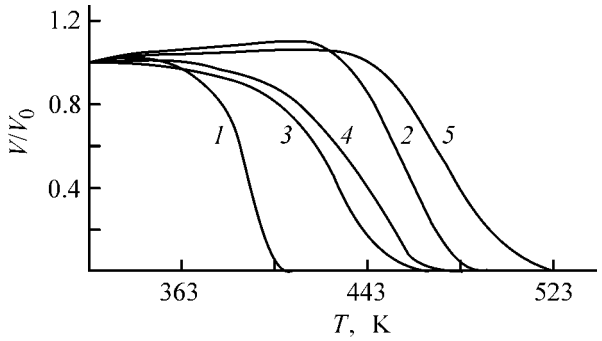


Fig. 2. Thermoinduced relaxation of the surface potential V/V_0 as influenced by the surface modification modes for the electret structures of PTFE-A1. (T) Temperature. (*1*) Initial sample; (*2*) treatment in water; (*3*) gas-phase modification with PCl_3 vapor; (*4*) gas-phase modification with PCl_3 vapor, followed by gas-phase hydration; and (*5*) sample no. 3 subjected to additional treatment with water; the same for Fig. 3.

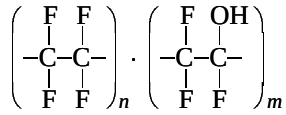
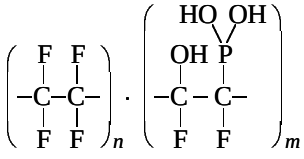
surface modification of the PTFE film with PCl_3 vapor. Thus, the chemical structure of the modified polymer can be represented schematically as follows:



(a)



(b)

Figure 2 shows the TIRSP of the samples depending on the surface treatment modes. Curve *1* corresponds to relaxation of the potential of the initial PTFE film. As already mentioned, the sample treated by the known hydration procedure (the time of contact between the film surface and water 10 s [3]) exhibits a much greater thermal stability of the surface potential (Fig. 2, curve *2*).

Chemical modification of the polymer with PCl_3 vapor is also responsible for the increased thermal stability of the potential of electret structures (Fig. 2, curve *3*) relative to untreated samples (curve *1*). However, the highest thermal stability is achieved in the case of a complex treatment, when the polymer films with element oxide surface nanostructures are additionally hydrated by 10-s contact with water (Fig. 2, curve *5*). Notably, the kinetics of the relaxation processes is less affected by the gas-phase treatment of phosphorus-containing PTFE-A1 with water vapor (Fig. 2, curve *4*).

Our results suggest that chemical modification of the surface of the PTFE films yields additional centers that of the electret charge. The deciding role in homocharge accumulation belongs to surface traps, by which are usually meant specific surface defects such as, e.g., chain breaks, adsorbed molecules, oxidation products, etc. Sessler [1] distinguished three types of such traps, namely, primary, secondary, and tertiary. Thermal activation of charge carriers from these traps occurs in different temperature ranges. The least thermally stable are primary traps which are represented by atoms incorporated in macromolecules. The release of charge from them is limited by small-scale motions of the macromolecular chain. The tertiary traps are activated at higher temperatures, when the crystal structure of the polymer is rearranged. Our experimental data suggest (Fig. 2) that treatment with water yields charge capture sites at the interface between a crystallite and a amorphous phase, which is specifically responsible for the high thermal stability of the potential of the electret structures (Fig. 2, curve *2*).

Thus, it can be assumed that the chemical modification of the PFTE film surface with PCl_3 vapor yields new charge capture centers in the near-surface layers of the polymer film, which can be treated as primary traps.

The theoretical concepts being developed in this study regard the thermal stability of the electret state in the PTFE films as being strongly dependent on the degree of surface hydration. The steady-state contact angles θ were estimated at 92° for the initial sample, at 88° and 79° for samples treated with PCl_3 vapor and water, respectively, and at 57° for the sample subjected to complex treatment (gas-phase modification with PCl_3 vapor, followed by treatment with water). The contact angles were determined by a standard technique [3] involving the contact of a microdrop (1–2 mg) of distilled water with the sample surface. The above-mentioned data are average values obtained for no less than seven points on the sample surface.

It is seen that, whatever the treatment procedure, the contact angle tends to decrease after treatment, most profoundly in the case of the complex treatment, which suggests a high surface energy of the modified film [11].

Thus, introduction of chemisorbed reactive phosphorus-containing groups into the polymer chain of PTFE increases the concentration of the OH groups on the surface being modified. The structures being

formed act as deep centers that capture the electret charge. Therefore, it is of interest to determine the microscopic parameters characterizing these capture sites.

To this end, we carried out the following experiments. We varied the heating rates for samples during TIRSP and, using formulas (1)–(3), determined the frequency factor and reconstructed the energy spectrum of the surface traps. Notably, in a number of cases, the TIRSP curves exhibit initial rise in the surface potential during heating. Rychkov and Boitsov found earlier [3] that the rise in the potential is due exclusively to a decrease in the electric capacitance of the fluoropolymers with rising temperature rather than to relaxation of the electret charges. Therefore, to determine the distribution functions, we normalized the experimental curves, taking into account the temperature dependence of the electric capacitance of the film.

Figure 3 demonstrates how the distribution of the electret charge capture centers with respect to energy varies with the modification mode. It is seen that modification of the PTFE film surface yields new groups of capture centers lying deep in energy. For example, for unmodified sample (Fig. 3, curve *1*) the frequency factor ω_s was estimated at 7×10^{13} s^{-1}, and the energy at the distribution maximum E_s^*, at 1.23 eV, and for the sample treated with water, at 1×10^{13} s^{-1} and 1.39 eV, respectively (Fig. 3, curve *2*). Upon chemical modification of the film surface with PCl_3 vapor, ω_s decreases to 8×10^{12} s^{-1}, E_s^* being 1.26 eV (Fig. 3, curve *3*). Additional gas-phase modification with H_2O vapor of the surface modified with PCl_2 groups favors formation of traps characterized by $\omega_s = 9 \times 10^{12}$ s^{-1} and $E_s^* = 1.34$ eV (Fig. 3, curve *4*). However, the spectrum of the surface capture centers is the most profoundly affected by the complex treatment of PFTE films (Fig. 3, curve *5*). In this case, $\omega_s = 6 \times 10^{12}$ s^{-1}, $E_s^* = 1.4$ eV, and also a new group of traps with $E_s^* = 1.48$ eV is formed.

The rise in the efficiency of capture of positive electret homocharge on the polymer surface is usually attributed to the structures having a higher affinity for holes. In the given case, the $P(OH)_2$ groups occurring in the polymer chain of PTFE can well act as such capture centers. At the same time, the resulting functional groups can indirectly affect the thermal stability of the electret charge. Specifically, the nonstoichiometric defects such as new surface functional groups introduced into the macromolecules can significantly decrease the molecular mobility via an increase in the chain packing density and growth of the

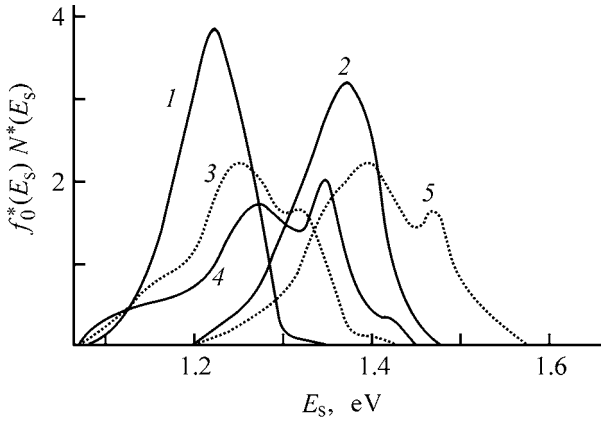


Fig. 3. distribution function $f_0^*(E_s)N^*(E_s)$ of the surface traps with respect to the activation energies E_s for PTFE films depending on the surface modification procedure.

effective length of the kinetic segments. The resulting capture centers can be treated as secondary traps responsible for a growth of the glass-transition temperature of the amorphous phase on the polymer surface [2]. From the viewpoint of charge accumulation and retention, this should be manifested in a decreased frequency factor of the capture centers owing to increased moment of inertia of the kinetic units [12]. This was actually revealed by our TIRSP experiments.

CONCLUSIONS

(1) Chemical modification of the polytetrafluoroethylene film surface is an efficient means for controlling its electret characteristics.

(2) Introduction of phosphorus-containing nanostructures into the surface layer of the polymer films presumably increases the concentration of the OH groups. These groups form new deep centers that capture positive electret charge; they are characterized by a quasicontinuous distribution with respect to the activation energies.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Morphological Features of the First Growth Steps of Polymeric Coatings from the Active Gas Phase on the Activated Surface

A. A. Rogachev

Belarussian State University of Transport, Gomel, Belarus

Received May 14, 2003

Abstract—Morphological features of the first growth stages of polytetrafluoroethylene films from the active gas phase on the silicon surface treated by various methods were studied. The influence of the surface energy of the support on the distribution of polymer microparticles in these stages and on the distribution kinetics was determined.

Thin films with unique properties can be grown from an active gas phase formed by electron-beam dispersion of initial polymer [1–3]. This method is used to solve complex technical problems, including dressing and coloration of fiber-fabric materials, growth of 0.1–5.0 μm polymeric films with a low constant of friction and high resistance to wear, and preparation of thin-film recording systems [1–4].

Growth of a polymeric coating on the support surface involves sorption of low-molecular-weight particles of the dispersion, their migration along the surface, and subsequent polymerization. The structure and physicochemical properties of these films are mainly determined by the features of the initial stages of formation of the polymer-support interface, density and orientation of polymeric particles, kinetics of their growth, intermolecular interactions, etc. Nucleation of the polymeric phase, unlike that of the solid phase, is a nonequilibrium process [5]. The parameters of the surface particle size distribution and the changes in the particle density in the course of deposition indicate that the density of polymerization nuclei depends on the presence of surface defects. Chemisorption of molecular fragments on the support surface is also possible and the interface shows strong structural nonuniformity.

In this context procedures that affect the state of the surface can be effectively used to control the structure and properties of the coatings.

The aim of this study was to examine the structural and morphological features of nucleation and the first growth stages of polytetrafluoroethylene (PTFE) coatings on the surface of single-crystalline silicon activated by various methods.

The morphology and adsorption properties of PTFE coating in the first deposition stages were studied as influenced by the pretreatment conditions of the support. The coatings were grown from the active gas phase obtained by electron-beam dispersion of the initial polymer in a vacuum [6]. The thickness of PTFE coating was controlled with the aid of a special device with a controllable shutter. The growth rate was measured with a quartz thickness gage (QTG) by the conventional procedure. Single-crystalline silicon wafers treated with an organic solvent and a beam of N^+ and Ar^+ ions (ion energy 3 keV and flux density 1.2 A m^{-2}) for 5 min was used as the supports.

To eliminate the influence of the nonuniformity of the flux density in the cross section of the ion beam on the treatment efficiency, the radial distribution of ions in the flux was preliminarily estimated with the aid of a Faraday cylinder. The experimental data were processed with account to this correction.

The adsorption activity of the support was determined from the surface energy and its Livshits–van der Waals, acid, and base constituents which, in turn, were calculated from the angle of contavt between the sample surface and twice-distilled water, glycerol, and dimethyl sulfoxide [7].

The morphology of the surface of the treated films was studied by atomic force microscopy (AFM) on

a NANOTOP-203 setup. The scanning was performed in the tapping mode. To determine the features of formation of three-dimensional supramolecular structures, thick films were etched with nitrogen ions. A fractal analysis on the surface structures was performed by Feder's procedure [8].

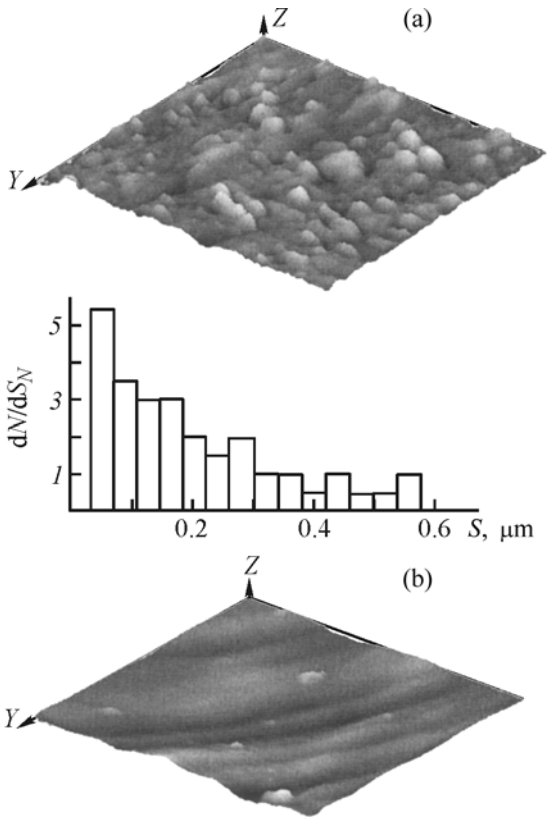

Fig. 1. AFM image of the surface of a PTFE coating on (a) active and (b) inactive regions of the silicon surface treated with the solvent and the distribution of microparticles with respect to the base surface area S, corresponding to section (a). Apparent thickness of the coating 3.8 nm. The image was scanned in a 12.6×12.6 μm area; the same for Figs. 2–4.

The total surface energy of single-crystalline silicon wafers and its components dramatically change after the treatment with nitrogen and argon ions (see table).

The maximum increase in the surface energy (by a factor of 1.5) and especially in its acid component was observed after the treatment of the silicon surface with nitrogen ions.

The morphology and properties of PTFE coatings depend on the conditions of the support activation. Adsorption and nucleation of polymeric microparticles on the silicon surface treated with the solvent are nonuniform. There are surface regions on which relatively large particles are formed even in the first deposition stages (Fig. 1a).

For example, at an apparent film thickness of 3.8 nm, particles growing on these regions are dome-shaped with a base area of 0.6 μm^2 and a height of up to 20 nm. The calculated fractal dimension of these structures ($D = 2.73 \pm 0.19$) is close to that of nonfractal surfaces ($D = 3$). There are also surface regions in which virtually no microparticles are observed in this deposition stage (Fig. 1a). These results agree with our previous data [5] and indicate that adsorbed molecular fragments can easily move along the surface and the growth of polymerization nuclei is mainly lateral. We also conclude that the aerosol mechanism fails to describe the formation of volatile dispersion products under these conditions [9].

In the course of further deposition of the polymeric coating, the particles grow and, what is the most important, they are nucleate on less active surface regions (Fig. 2).

At the apparent film thickness greater than 10 nm, the monotonic particle distribution with respect to the base area transforms into a curve with a sharp peak, suggesting a change in the deposition mechanism. The first non-steady-state stage of continuous nucleation of the particles gives way to the stage in which the bases of deposited stable particles predominantly grow. This is confirmed by the calculated fractal dimension. The fractal dimension calculated at the apparent thickness of PTFE layer d = 7.6, 11.5, and 15.3 nm is $D = 2.84 \pm 0.12$, 2.66 ± 0.14, and 2.38 ± 0.29, respectively.

The mechanism of deposition of volatile dispersion products on the silicon surface treated with nitrogen and argon atoms is different (Fig. 3, *I*, *II*).

Formation of morphologically discrete structures typical of a solvent-treated silicon surface was not

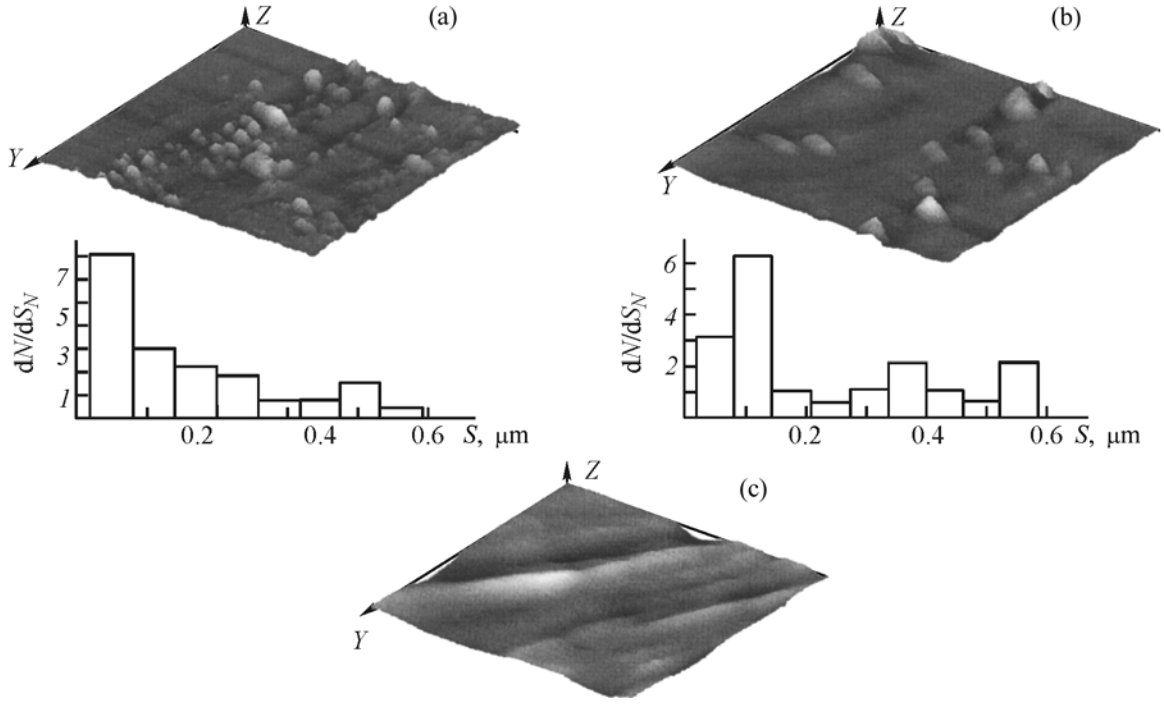

Fig. 2. AFM image of the surface of a PTFE coating with an apparent thickness of (a) 7.6 , (b) 11.5, and (c) 15.3 nm on the silicon surface treated with the solvent and the corresponding distributions of microparticles with respect to the base surface area *S*.

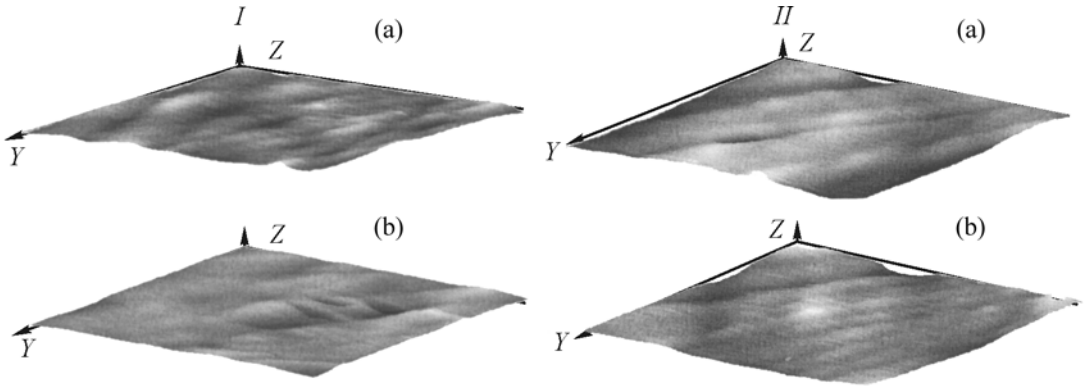

Fig. 3. AFM image of the surface of a PTFE coating with an apparent thickness of (a) 3.8 and (b) 19.1 nm on the silicon surface treated with (*I*) argon and (*II*) nitrogen ions.

detected in the first deposition stages on the ion-treated surface.

In this case, the energy of the silicon surface treated by different procedures (see table) correlates with the microrelief parameters of the deposits. The higher the surface energy, the denser the coatings, i.e., the adsorption growth mechanism prevails.

Thick PTFE coatings contain alternating relief structures formed by intermolecular interaction to give primary supramolecular structures. This is confirmed by the morphology of these coatings etched in a glow discharge plasma (Fig. 4).

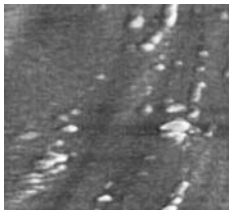

Fig. 4. AFM image (phase contrast mode) of the surface of a silicon-supported PTFE coating etched in a glow discharge plasma.

We found that supramolecular structures more than 20 nm in size and stable to ion etching are formed in the bulk of the polymeric coating. These structures can be regarded as macromolecular plates.

Thus, we have studied the morphological features of the growth of PTFE coatings on the silicon surface activated by different methods and the adsorption properties of these coating. On the solvent-treated silicon surface, the polymeric coating is deposited selectively. This is due to nonuniform adsorption properties of the silicon surface. The deposition on the silicon surface treated with nitrogen and argon ions is characterized by low activation energy and yields continuous polymeric layers even at a low apparent thickness.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermal and Thermal-Oxidation Stability of Permethylpolysilane-Siloxanes and Permethylpolyoxysilane

A. I. Chernyavskii, D. Yu. Larkin, M. I. Buzin, E. G. Kononova, and N. A. Chernyavskaya

Nesmeyanov Institute of Heteroorganic Compounds, Russian Academy of Sciences, Moscow, Russia

Received March 4, 2003

Abstract—Thermal and thermal-oxidation stability of organosilicon copolymers with linear or/and cyclic oligosilane fragments in the backbone was studied by thermal gravimetric analysis in an inert gas and in air. The dependence of the thermal characteristics of polysilane-siloxanes on the number of $SiMe_2$ units in the oligosilane fragment of copolymers was established.

The development of modern branches of industry (mechanical engineering, machine building, aircraft industry, etc.) requires production of new construction materials with high strength and high thermal characteristics. Of particular interest are silicon carbide and silicon carbide oxide construction ceramics having unique properties, untypical of the traditional structural materials [1, 2].

In this connection, development of new precursors of ceramic materials is an important scientific and practical problem. At present, polycarbosilanes are of the most practical importance as precursors of silicon carbide ceramics [1]. For production of silicon carbide oxide ceramics, polysilane-siloxanes of various structures may be of certain interest. New permethylpolysilane-siloxanes with linear and cyclolinear structure of the backbone and permethylpolyoxysilane have been synthesized previously [3–8] (see table). In this study, we examined the thermal and thermal oxidation stability of the synthesized copolymers with the aim to assess the prospects for their use as precursors of Si–O–C ceramic materials.

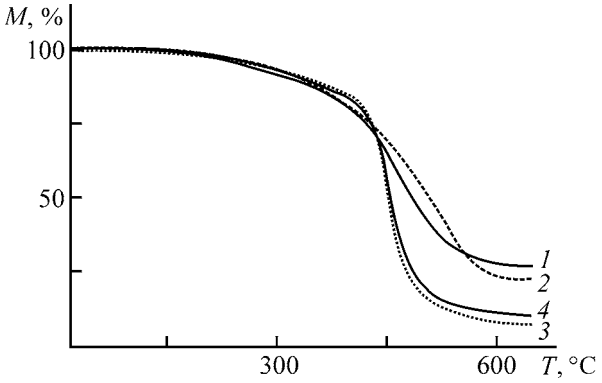

Fig. 2. (*1*–*4*) TGA curves of copolymers **Ia** and **Ic**–**Ie**, respectively, in argon.

ropermethyloligosilanes $Cl(Me_2Si)_mCl$ (m = 2–6) with 1,5-dihydroxyhexamethyltrisiloxane [5, 6, 8]. Cyclolinear polysilane-siloxane **IIa** and permethylpolyoxysilane **IIb** were synthesized by heterofunctional polycondensation of 1,3-dihydroxydecamethylcyclohexasilane with 1,7-dichlorododecamethylcyclohexasiloxane and 1,3-dichlorohexamethyltrisilane, respectively [3, 4, 6, 7]. Some characteristics of the resulting copolymers are listed in the table.

The thermal and thermal-oxidation stability of copolymers **Ia**–**Ie**, **IIa**, and **IIb** was studied by thermal gravimetric analysis (TGA) and differential thermal analysis (DTA) on a Q-1500D MOM derivatograph (Hungary). The 60–80-mg samples were heated in argon or air in the range 20–700°C at a heating rate of 10 deg min^{-1}.

The IR spectra were recorded on a Specord M-82 spectrophotometer in the range 400–3700 cm^{-1}, using thin films on a KBr support or compacted KBr pellets. The UV spectra were recorded on a Specord M-40 spectrophotometer from thin films on a quartz support.

Thermal oxidative degradation of copolymers **Ia**–**Ie** in air (Fig. 1) proceeds in two stages: the first at 200–300°C, and the second at 300–560°C. Comparison of the TGA curves (Fig. 1a) shows that, in the range 200–300°C, the weight loss of copolymers with an even number of $SiMe_2$ units in the oligosilane fragment (copolymers **Ia**, **Ic**, and **Ie** with m 2, 4, and 6; curves *1*, *3*, and *5*) is approximety 9 wt %, which is less than that for copolymers with an odd number of $SiMe_2$ units, copolymers **Ib** and **Id** with m 3 and 5 (curves *2* and *4*). These trends are retained in the second stage of degradation of copolymers in the range 300–560°C, i.e., the copolymers with an even number of $SiMe_2$ units give a larger amount of the coke residue, 50–60% against 40% (see table). At a higher temperature, the amount of coke residue for all the copolymers studied remains virtually the same. It should be noted that, in the series of the copolymers with both even and odd number of $SiMe_2$ units, the thermal stability of the copolymers decreases with increasing m. With respect to the thermal oxidation stability dependent on the number of $SiMe_2$ units in the oligosilane fragment, copolymers **Ia**–**Ie** can be ranked in the following order: $m = 2 > m = 4 > m = 6 > m = 3 > m = 5$.

The DTA curves of copolymers **Ia**–**Ie** are shown in Fig. 1b. The weight loss in copolymers is accompanied by exothermic effects, which suggests that of atmospheric oxygen is involved in chemical transformations that proceed in the copolymers at elevated temperatures. The shapes of exothermic peaks are similar for copolymers with m = 1, 2, and 3 (Fig. 1b, curves *1*–*3*). In the case of copolymers with m = 5 and 6 (Fig. 1b, curves *4* and *5*), the pattern is different: A strong exothermic peak is observed at about of 460°C, which may be due to a decreased thermal oxidation stability of copolymers with the length of dimethylsilane fragment increased to five or six units.

The TGA curves of copolymers **Ia** and **Ic**–**Ie** under argon are shown in Fig. 2. The main weight loss is observed in the range 350–550°C; at higher temperatures, the weight of the samples remains virtually

unchanged. The trends in thermolysis of the copolymers are the same as in the case of thermal oxidative degradation: the thermal stability of copolymers decreases with increasing number of $SiMe_2$ units in the copolymer chain and the thermal stability falls in passing from copolymers with even *m* to copolymers with odd *m*. Similar trends have been observed previously in thermolysis of permethylpolyoxysilanes $–[(SiMe_2)_mO]_n–$ [9].

The chemical transformations that occurr in the oligosilane fragment of linear copolymers **Ia**–**Ie** in thermolysis were studied by IR spectroscopy for the example of copolymer **Ic** (Fig. 3). The main weight loss of copolymer **Ic** in the range 350–550°C (Fig. 2) is accompanied by degradation, cross-linking, and transition to an insoluble form. This is apparently caused by the abstraction of methyl groups from the silicon atoms in the copolymer chain and rearrangement of the skeleton of the copolymer chain, which is suggested by the appearance of Si–H stretching bands in the spectrum of copolymer **Ic** in the region of 2110 cm^{-1} after heating at 450°C for 0.5 h (Fig. 3, spectrum *2*) and $Si–CH_2–Si$ bending bands in the region of 1360 cm^{-1}, and also by broadening of the absorption band in the range 1100–1000 cm^{-1}. The broadening is apparently caused by superposition of Si–O–Si stretching bands (1085 and 1034 cm^{-1}) and $Si–CH_2–Si$ bending bands (1050 cm^{-1}). The appearance of abnormal Si–H bonds and $–Si–CH_2–Si–$ units in the copolymer chain is apparently caused by Yajima rearrangement in the oligosilane fragment of the copolymer at 450°C [10–12]:

$$-\left(Me_2Si\right)_n- \xrightarrow{450°C,\ Ar} -\left(\begin{array}{c}H\\|\\Si\\|\\Me\end{array}-CH_2\right)_n-.$$

After heating at 1000°C for 0.5 h, copolymer **Ic** loses the majority of methyl groups and transforms into a silicon carbide oxide material: In the IR spectrum (Fig. 3, spectrum *3*), there are absorption bands of the residual CH_3 groups in the region of 2960 and 2900 cm^{-1}, a broad band corresponding to the $Si–CH_2–Si$ vibrations, and overlapping Si–O–Si vibrations, and also an absorption band of the Si–C bonds. At the same time, the Si–H absorption band is absent. As judged from the IR spectra, thermolysis of the other linear copolymers proceeds similarly.

Similar processes, the Yajima rearrangement and formation of silicon carbide oxide material, have been observed in thermolysis of linear permethylpolyoxysilanes, in which the oligosilane fragments of the macromolecule are linked by oxygen bridges [9].

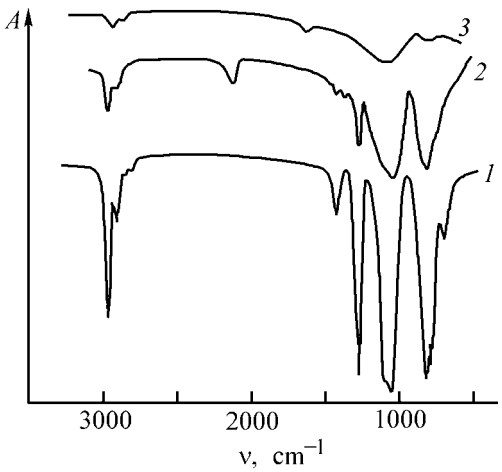

Fig. 3. IR spectra of copolymer **Ic** (*1*) before and after heating at (*2*) 450, and (*3*) 1000°C. (*A*) Transmission and (ν) wavenumber.

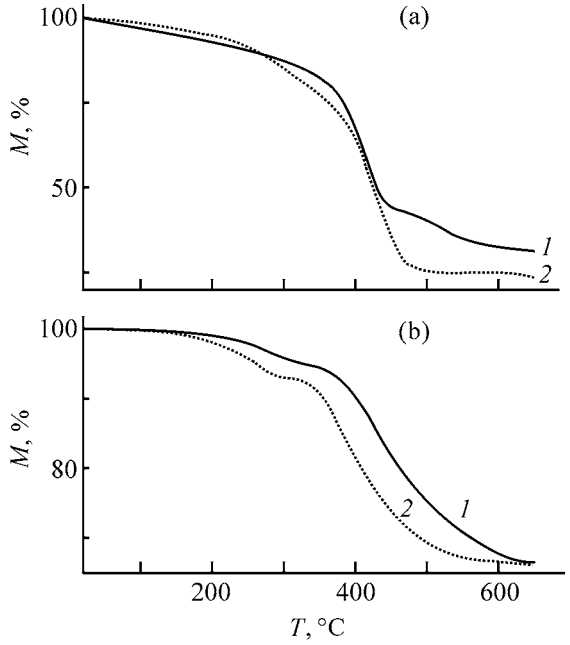

Fig. 4. DTA curves (a) in air and (b) in argon of copolymers (*1*) **IIa** and (*2*) **IIb**.

The spectra, similar to spectra *2* and *3* in Fig. 3, were recorded after heating of these polymers for 2 h at 500°C and 1000°C, respectively. The ^{29}Si MAS NMR spectra of the coke residue of copolymers contained the signals of the SiC, $SiCO_3$, SiC_2O_2, and SiC_3O fragments.

Similarly to linear copolymers **Ia**–**Ie**, thermal oxidative degradation of cyclolinear copolymers **IIa** and **IIb** proceeds in two stages: the first at 200–300°C and the second at 300–530°C, at which the main weight loss of the copolymers is observed (Fig. 4a). Further

heating of the copolymers does not result in a decrease in the amount of the coke residue. Cyclolinear copolymers **IIa** and **IIb**, whose backbone consists of a cyclohexasilane fragment linked by oxygen bridges to cyclohexasiloxane or to linear trisilane fragments, respectively, exceed linear copolymers **Ia**–**Ie** in the thermal oxidation stability, which is apparently due to the presence of the cyclohexasilane unit in the macromolecules of copolymers **IIa** and **IIb**.

The TGA curves of copolymers **IIa** and **IIb** in argon are shown in Fig. 4b. The main weight loss of the copolymers is observed in the range 300–500°C, and at higher temperatures the weight of the samples remains the same. The coke residue of copolymers **IIa** and **IIb** was approximately 30% and exceeded the similar characteristic of linear copolymers **Ia**–**Ie**.

Owing to the presence of oligosilane fragments in the polymer chain, copolymers **Ia**–**Ie**, **IIa**, and **IIb** retain the UV absorption characteristic of oligo- and polysilanes [13, 14]. The wavelength λ_{max} of the absorption peak in the spectra of linear copolymers **Ia**–**Ie** grows with increasing number of $SiMe_2$ groups in the oligosilane fragment of the copolymer (see table).

The UV absorption of copolymers **IIa** and **IIb** is caused by the presence of the cyclohexasilane fragment in the copolymer chain. In the UV spectrum of copolymer **IIb**, there is an absorption peak at 280 nm, characteristic of the cyclohexasilane unit of the copolymer, and the absorption peak corresponding to the linear trisilane fragment is absent. A similar pattern (the presence of the absorption peak of the cyclic fragment and the absence of the absorption peaks of linear fragments) has been observed previously in the UV spectra of cyclolinear compounds on the purely silane structure, α,ω-bis(cyclopentasilanyl)oligodimethylsilanes [15].

It has been shown previously [16] that oligodimethylsilanoxanes, oligomers in which $(Me_2Si)_n$ fragments alternate with $(Me_2SiO)_m$ groups, are effective vulcanizing agents in photolytic curing of silicone rubbers. The synthesized copolymers **Ia**–**Ie**, **IIa**, and **IIb** are transparent viscous liquids readily soluble in polydimethylsiloxanes. The trial experiments showed that, similar to oligosilanoxanes, copolymers **Ia**–**Ie**, **IIa**, and **IIb** can cause vulcanization of polymethylvinylsiloxanes: under UV radiation of a mixture of liquid siloxane rubber with polysilanesiloxane and polyoxysilane copolymers (3–5 wt %), silicone rubber was cured within a few minutes.

CONCLUSIONS

(1) The thermal and thermal oxidation stability of linear permethylpolysilane-siloxanes is governed by the number of dimethylsiloxane units in the oligosilane fragment of the copolymers. In passing from copolymers with an even number of $SiMe_2$ units to copolymers with an odd number of $SiMe_2$ units in the oligosilane fragment of copolymers, and also with increasing number of $SiMe_2$ units, the thermal and thermal oxidation stability of the copolymers decreases.

(2) A study of the thermal and thermal oxidation stability of permethylated linear and cyclolinear polysilane-siloxanes and polyoxysilanes showed that copolymers **IIa** and **IIb** with cyclolinear structure of the backbone have the best thermal characteristics: the amount of coke residue was approximately 65% in air and 30% in argon. These copolymers are of interest as precursors of Si–O–C ceramic materials.

(3) The linear and cyclolinear copolymers studied show promise as polymeric photoinitiators of cross-linking of organosilicon rubbers and as cross-linking agents for compounds based on these.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Acetic Acid in Sol–Gel Process of Hydrolytic Polycondensation of Tetramethoxysilane

N. N. Khimich, B. I. Venzel', L. A. Koptelova, and I. A. Drozdova

Grebenshchikov Institute of Silicate Chemistry, Russian Academy of Sciences, St. Petersburg, Russia

Received March 7, 2003

Abstract—The possibility of using acetic acid in the organic sol–gel synthesis of a monolithic SiO_2 gel both in the presence of water and in an anhydrous medium was studied.

The science of organic-inorganic nanohybrids is a new area of research that has appeared at the interface between organic chemistry, macromolecular chemistry, and colloid chemistry. The rapid development of this field, especially in the last ten years, has resulted in the synthesis of novel materials, whose distinctive feature is the nanosize of their structural elements.

One of the simplest and, consequently, promising, from the preparative standpoint, methods for obtaining hybrids of this kind is the sol–gel synthesis [1]. Unfortunately, the standard sol–gel technique for obtaining inorganic materials, which involves hydrolysis of silicon alkoxides and polycondensation of the forming compounds, requires that polar solvents, strong inorganic acids (in performing the sol–gel process in an acid medium), and water should be used as the necessary components of the sol–gel system [2]. This considerably restricts the possibility of varying the organic component of the hybrid. The reason is that the overwhelming majority of organic compounds (with both low and high molecular weight) are sparingly soluble in water-containing systems. Therefore, the variety of organic components introduced into the inorganic SiO_2 matrix in the sol–gel synthesis of nanocomposites is commonly limited to a number of strongly polar organic substances, such as polyalcohols [3], polyamines [4], and other organic compounds of varied molecular weight, soluble in water–alcohol systems.

At the same time, the possibility of obtaining polyorganosiloxanes by various methods of heterofunctional condensation of silicon alkoxydes in the absence of water has been studied previously [5–7]. The studies performed demonstrated that heating of a number of monocarboxylic acids (formic, acetic, chloroacetic, propanoic, and butyric) with diethyldiethoxysilane yields polydiethylsiloxanes in up to 98% yield [6]. With account of this fact, the possibility of synthesizing a monolithic inorganic SiO_2 matrix, with tetramethoxysilane (TMOS) solutions in the above organic acids without addition of water used as the sol–gel system, has been studied [8].

There also exist, however, a great number of practically promising compounds, which are soluble solely in strongly polar solvents (alcohol, water, organic amides, etc.). To these belong, e.g., complexes of transition metal ions (Cu^+, Cd^{2+}, Pt^{2+}, Ru^{2+}, Er^{3+}, etc.) with various ligands (2,2'-dipyridine, 1,10-phenanthroline, diacetyl, etc.), which are of great practical importance. Being stable in a neutral medium, some of them (e.g., Cu^+ complexes) are decomposed in the presence of strong mineral acids. But even when these organometallic complexes are stable at any acidity of the medium (e.g., Ru^{2+} complexes), the so-called drying control chemical additives (DCCA) should be introduced into a sol–gel system to obtain a monolithic organic-inorganic hybrid [9, 10].

Despite the fact that the total amount of these reagents can be considerably reduced, their use leads to formation of low-volatile organic impurities in gel pores [11], which impairs the mechanical and, especially, optical properties of the monoliths obtained. That is why a novel catalyst, trifluoroacetic acid, has been suggested for organic sol–gel process [8]. Its use instead of a strong inorganic acid enabled optimization of the processes of TMOS hydrolysis and polycondensation of the forming compounds without DCCA reagents [8]. This optimization is done by means of gradual removal of trifluoroacetic acid from

* t as obtained at 70°C.

the sol–gel system in the form of its volatile methyl ester. With acetic acid used as solvent, methylacetate is also present, in addition to methyl trifluoroacetate, in the dispersion medium, i.e., acetic acid itself reacts with methanol under the conditions of a sol–gel process. This reaction suppresses alcoholysis of the Si–O–Si bond, promotes condensation, ensures fast removal of residual amounts of the low-volatile acetic acid, and leads to the minimum content of carbon in the gel matrix. To make the sol–gel system even simpler, a decision was made to abandon use of trifluoroacetic acid as a catalyst and to study the possibility of synthesizing a monolithic SiO_2 gel in a two-component system constituted by TMOS and acetic acid (AcOH) or in a three-component system, TMOS–AcOH–H_2O.

EXPERIMENTAL

To study the gelation of TMOS in the presence of acetic acid, we prepared sample nos. 1–10, which contained (per 1 mol TMOS) 4 mol water (nos. 4–10) and different amounts of AcOH (mol):

Sample no.	1	2	3	4	5	6	7	8	9	10
AcOH	4	6	8	0.2	0.5	0.7	1	2	3	4

The resulting solutions were placed in hermetically sealed polypropylene test tubes and heated at 70°C for 4 days. Then the hermetic stoppers of the test tubes were replaced with stoppers with apertures (d ~1.5 mm), and humid gels were dried in the following temperature mode: heating from 70 to 100°C for 6 h, keeping at 100°C for 20 h, heating from 100 to 120°C for 4 h, and keeping at 120°C for 30 h. Samples of gel no. 11 were obtained by gelation of solution no. 7 in the presence of 0.1 mol CF_3COOH catalyst and were additionally dried at 150°C for 20 h.

For the resulting samples were determined the open and total porosity, W_{op} and W_{tot}, and the apparent and true, d_a and d_t, density (by the Archimedes method with toluene as saturating fluid and water as second working fluid). The gelation point t (h) was found as the time after which the gel lost its fluidity. The hardness T of the samples was measured on a PMT-3 microhardness meter. A thermal analysis was done on a Q-1500D derivatograph (Hungary) at temperatures of up to 1000°C at a heating rate of 20 deg min^{-1}. The content of SiO_2 (wt %) in the gels obtained was determined thermogravimetrically, and the carbon content was found from the change in the electrical conductivity of a $Ba(OH)_2$–CO_2 solution that served as absorber of CO_2 formed in burning of the samples in oxygen. The porous structure of the gels obtained was studied by analyzing the adsorption–desorption of ethanol on a McBain spring vacuum balance. The pore volumes V (cm^3 g^{-1}), specific surface area S (m^2 g^{-1}), and predominant pore radii r (Å) were calculated by the standard procedures [12] from the adsorption data. An electron-microscopic study of the gels was performed on an EM-125 microscope at an accelerating voltage of 75 kV, with cellulose replicas prepared on freshly cleaved surfaces of the gels studied.

All the gels synthesized were monolithic transparent cylinders; sample nos. 4–11, colorless, and sample nos. 1–3, yellow-pale. Table 1 lists the physicochemical characteristics of gel nos. 1–11.

The data presented show that raising the amount of AcOH in the sol–gel system makes lower the hardness

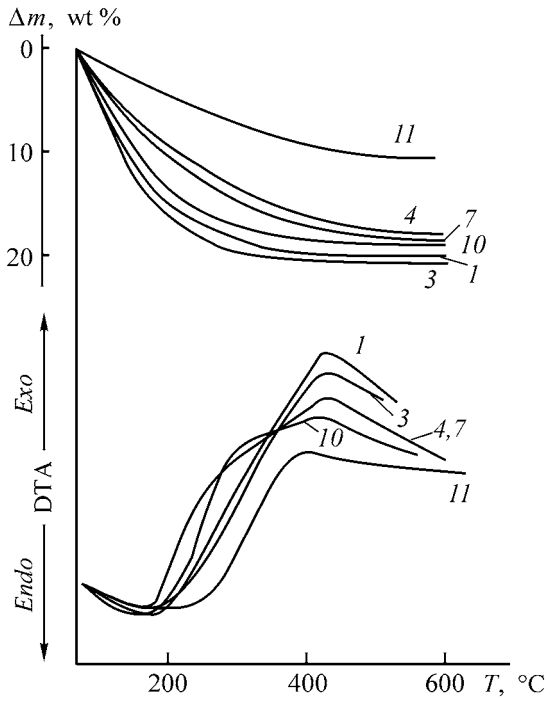

Fig. 1. TG and DTA curves of the gels.(Δm) Mass loss and (T) temperature. The *curve numbers* denote the gel numbers.

and density of the gels synthesized. It should be noted that this is true both for sol–gel processes that occur in the presence of water (gel nos. 4–11) and for those proceeding in an anhydrous medium (gel nos. 1–3), although the mechanisms of both the processes are fundamentally different.

The standard sol–gel system consists of four components: e.g., TMOS, water, alcohol (solvent), and acid (catalyst). As is known, the rate of tetramethoxysilane hydrolysis in an acidic medium is proportional to the concentration of protons. This predetermines the use of strong inorganic acids as catalysts [2]. Raising the amount of AcOH, which is a weak acid ($K = 1.75 \times 10^{-5}$), in the sol–gel system from 0.2 mol (sample no. 4) to 4 mol (sample no. 10) should not substantially affect the rate of TMOS hydrolysis. In this case, as indicated by kinetic studies, AcOH is an inefficient catalyst for TMOS hydrolysis, i.e., the content of the unhydrolyzed product and low-molecular-weight siloxanes is very high even in the vicinity of the gelation point. It appears that trifluoroacetic acid ($K = 0.23$) is a considerably more efficient catalyst for the sol–gel process [8]. Despite this circumstance, gel nos. 4–7 are only slightly inferior to sample no. 11 in hardness and density. The reason for such a high efficiency of acetic acid is that the following reaction occurs

$$CH_3COOH + CH_3OH \rightarrow CH_3COOCH_3 + H_2O.$$

Acetic acid reacts with the residual methanol (as confirmed by a study of the dispersion medium of the sol–gel process), with the volatile methyl acetate $CH_3COOOCH_3$ removed from the system in drying of the xerogel. The occurrence of this reaction suppresses alcoholysis of silanols formed in hydrolysis of TMOS and promotes their condensation.

In this study, AcOH served not only as a catalyst, but as a solvent, too. Water and TMOS, which are mutually insoluble, are soluble in AcOH. Moreover, raising the AcOH concentration, which leads to a slight acceleration of the hydrolysis, makes higher the concentration of methanol, the product of TMOS hydrolysis. Methanol is also a solvent for the sol–gel process. Therefore, the initial hydrolysis of TMOS and the homogenization of the system occur virtually instantaneously at an AcOH amount in the sol–gel system equal to 1 mol and more, whereas at an AcOH amount decreased to 0.2 mol, the heterogeneous system is to be vigorously stirred for a long time.

At the same time, AcOH is a low-volatile compound. Therefore, raising its concentration in the system to above 0.5–1.0 M leads to a drastic deterioration of the physicochemical properties (gel nos. 8–10 in Table 1). In this case, the content of SiO_2 in the gel matrix falls, despite a decrease in the total content of carbon and in the number of unhydrolyzed methoxy groups in it. This is confirmed by thermogravimetric data (Fig. 1) and by analysis of the silica gel for the content of carbon.

Taking into account the results obtained, we suggested a novel method for sol–gel synthesis, which does not require introduction of water into the initial sol–gel system. This method enables synthesis of a monolithic SiO_2 gel in the two-component system TMOS–AcOH in the absence of water. In this case, acetic acid serves not only as the catalyst and the solvent, but also as a reagent of the sol–gel process. Attempts to use other organic acids, such as monochloroacetic, propionic, butyric, and oxalic acid, failed. Use of formic acid was also unsuccessful: owing to the low thermal stability of this compound, the SiO_2 matrix obtained contained a too large amount of thermally decomposed organic impurities and did not possess the necessary strength, although the possibility of using this acid in the sol–gel process has been reported [13]. It should be emphasized that the sol–gel synthesis in the two-component system TMOS–AcOH differs fundamentally from that described in the literature [14, 15], in which water is

generated *in situ* and methanol is introduced into the sol–gel system, along with AcOH. In this case, gradual formation of water through the reaction of methanol with the acid ensures hydrolysis and polycondensation by the standard mechanism.

The mechanism of processes that occur when two-component system TMOS–AcOH is used in sol–gel synthesis is more complex. In any case, the first stage of the process is condensation of tetraalkoxysilane with acetic acid [6, 7]:

$$Si(OMe)_4 + AcOH \rightarrow (MeO)_3SiOAc + MeOH.$$

The forming methanol can either enter into a further reaction with acetoxysilane or esterify acetic acid, with water released in the process also leading to formation of silanols through hydrolysis. In this study, the occurrence of these chemical reactions was confirmed by addition to the initial sol–gel system of methanol in one case and acetic anhydride in another, as it was done in [14, 16]. The addition of methanol makes considerably shorter the gelation time, whereas acetic anhydride (which reacts with methanol in quantitative yield) inhibits the sol–gel process.

A study of the porosity of some of the gels synthesized (Table 2) demonstrated that the nanostructure of the samples obtained is about the same, although raising the AcOH concentration always leads to an increase in the average pore radius.

The drastic drop in the hardness and density of the samples, which occurs in this case, can be understood by comparing their electron micrographs, shown in Fig. 2. The dense and uniform structure of gel no. 11 (and the closely similar structure of gel no. 7), with the average size of visible pores of about 80–120 Å (Fig. 2a), becomes much looser, channel-like (with the size of visible pores of about 180–220 Å) on passing to gel no. 10 (Fig. 2b). A similar conclusion can be made when comparing gel nos. 1 (Fig. 2b) and 3 (Fig. 2c), which were obtained in an anhydrous medium.

CONCLUSIONS

(1) A novel method for sol–gel synthesis without addition of water or polar solvents (alcohol) to the system is suggested. The method employs acetic acid as solvent, catalyst, and reagent simultaneously, which makes a sol–gel system considerably simpler and allows synthesis of organic-inorganic hybrids from components insoluble in polar systems.

Table 2. Porosity characteristics of the gel samples

Sample no.	V, $cm^3\ g^{-1}$	S, $m^2\ g^{-1}$	r,* Å
1	0.316	530	12.0
3	0.595	660	18
7	0.29	490	12.0
10	0.51	620	16–17
11	0.061	–	–

* Isotherm for sample no. 11 has no adsorption hysteresis, and, therefore, the pore size cannot be determined ($r \geq 10$).

(2) It is demonstrated that the traditional sol–gel synthesis in the system TMOS–solvent–catalyst–water can be performed with acetic acid used as a solvent and a catalyst. In this case, the low efficiency of AcOH as a catalyst is compensated for by its reaction with methanol formed in the sol–gel system, which suppresses the alcoholysis of the Si–O–Si bond and promotes condensation processes.

(3) Monolithic gels formed in hydrolytic polycondensation do not crack in drying and have a high hardness and density, which are comparable with the analogous characteristics of gels synthesized in the presence of trifluoroacetic acid.

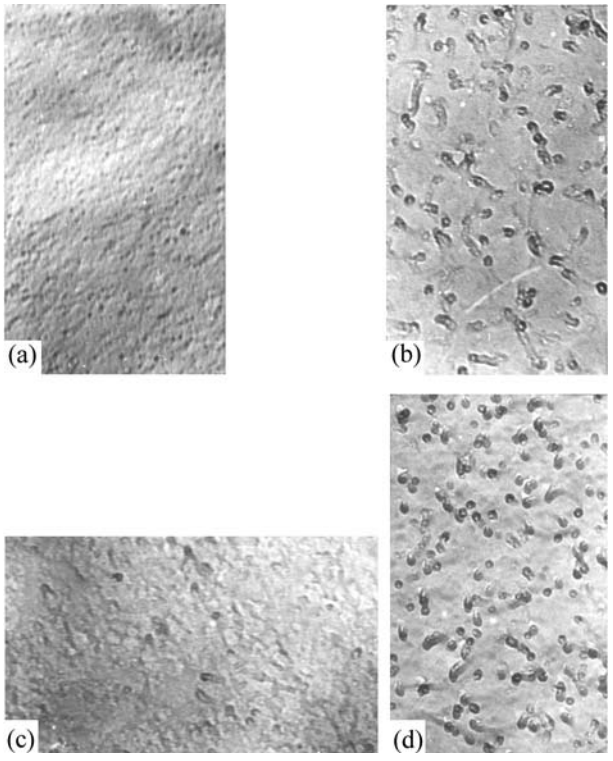

Fig. 2. Electron micrographs of gel nos. (a) 11, (b) 10, (c) 1, and (d) 3. Magnification: (a, b, d) 60 000 and (c) 80 000.

Abstract—Polymerization of 1-hexene on the catalytic system $TiCl_4$–$Al(C_6H_{13})_3 \cdot Mg(C_6H_{13})_2$ was studied.

Copolymerization of ethylene and propylene with a small amount of higher α-olefins yields polymeric materials with a wide range of consumer characteristics (density, melting point, crystallinity) [1–4]. Data on homopolymerization of higher α-olefins allow better understanding of their behavior in copolymerization. At the same time, homopolymers based on higher α-olefins with high molecular weight (MW) show promise as depressing agents, w3hich improve the rheological characteristic of crude oil. Among the catalysts tested, the most efficient catalysts for production of these materials are supported titanium–magnesium catalytic systems [5, 6]. By contrast, metallocene catalysts, which have rather high activity, favor formation of polymers with low MW [2, 7–10].

It has been shown previously [11] that the use of higher magnesium aluminum alkyls (MAA) as organometallic components of Ziegler catalysts significantly increases the yield, MW, and isotacticity of polystyrene in comparison with the classic systems. The catalytic systems based on MAA are also effective in synthesis of ultra-high-molecular-weight polyethylene and its copolymers with higher α-olefins [12]. In this context it was interest to study the polymerization of 1-hexene on the system $TiCl_4$–$Al(C_6H_{13})_3 \cdot Mg(C_6H_{13})_2$.

Data on the polymerization of 1-hexene on the catalytic system $TiCl_4$–$Al(C_6H_{13})_3 \cdot Mg(C_6H_{13})_2$ at various temperatures are presented in Figs. 1 and 2. Figure 1 shows that the process decelerates on heating, whereas in polymerization of styrene the reaction rate on this system decreases with as the temperature is lowered [11, 13]. The maximum rate of hexene-1 polymerization is reached at 25°C. At this same temperature, the catalytic system exhibits the highest activity,

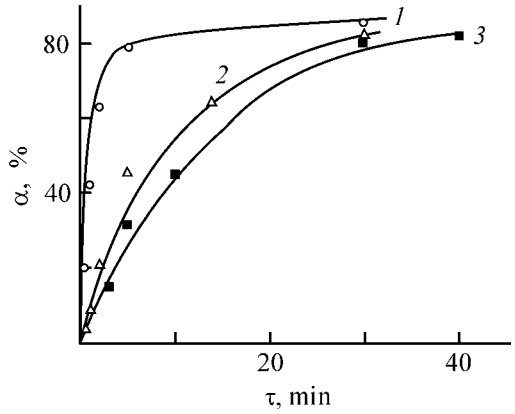

Fig. 1. Kinetic curves of polymerization of 1-hexene on the system $TiCl_4$–$AlMg(C_6H_{13})_5$ at (*1*) 25, (*2*) 15, and (*3*) 45°C. Polymerization conditions: $[TiCl_4]$ = 0.028 M, [1-hexene] = 2.24 M, $[TiCl_4] : [AlMgR_5]$ = 1 : 1, solvent hexane; the same for Figs. 2 and 3. (α) Degree of conversion and (τ) time.

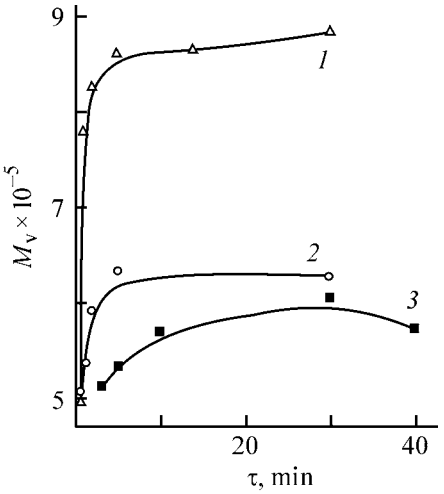

Fig. 3. Molecular weight of poly-1-hexene, M_w, vs. the polymerization time τ at (*1*) 15, (*2*) 25, and (*3*) 45°C.

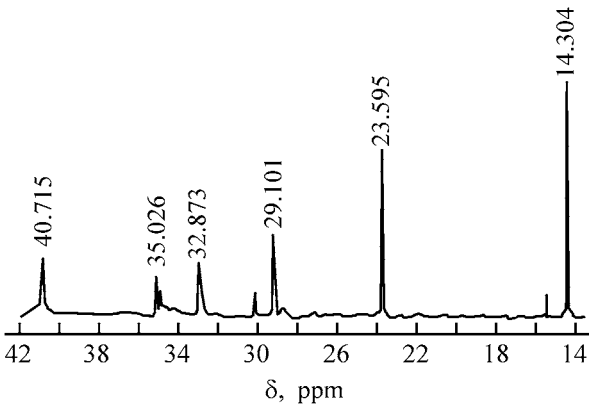

Fig. 4. ^{13}C NMR spectrum of poly-1-hexene prepared on the $TiCl_4$–al$Mg(C_6H_{13})_5$ system at 25°C. (δ) Chemical shift; the same for Fig. 5.

which abruptly decreases with time (Fig. 2). This abrupt decrease in the catalyst activity may be due to hindered diffusion of the monomer to the active centers, since within 10–15 s after the beginning of polymerization the reaction mixture becomes viscous. At other temperatures, the activity reaches a maximum within 2.5–5 min and then slightly decreases and tends to a constant value. The low activity of the catalyst is apparently caused at high temperatures by a high rate of deactivation of the active centers of polymerization, and at low temperatures, by slow activation of the catalyst. A similar temperature dependence of the catalyst activity was observed in polymerization of 1-hexene on post-metallocene catalyst (maximum activity of the catalyst was reached at 28°C) [14]. In polymerization of higher α-olefins on supported titanium-magnesium catalyst in the range 25–60°C, the polymerization rate and the catalyst activity increase steadily with temperature [5, 6].

It should be noted that, in polymerization of 1-hexene, the catalytic system $TiCl_4$–$Al(C_6H_{13})_3 \cdot Mg(C_6H_{13})_2$ is more active (30–100 kg mol^{-1} Ti h^{-1}) than the supported titanium-magnesium catalysts (15–35 kg mol^{-1} Ti h^{-1}) [5]. We showed that the maximum activity of the catalyst is reached at the $AlR_3 : MgR_2$ ratio in MAA equal to 1 : 1, and a decrease or increase in the content of magnesium dialkyl results in a decreased activity of the catalytic system [15]. This is apparently due, on the one hand, to higher alkylating power of MAA, compared to the equivalent amount of AlR_3, which result from involvement of two radicals from MgR_2 in this process, whereas in the case of AlR_3 only one alkyl radical participates in the process [16]. On the other hand, at a high content of magnesium dialkyl in the organometallic component, the low activity can be caused by overreduction of $TiCl_4$ with excess MgR_2 [17]. It should be noted that the molecular-weight distribution (MWD) of the polymer synthesized is rather wide (M_w/M_n = 28–29) and suggests the presence of several types of active centers, which can alter their activity in the course of polymerization [18]. This fact also confirms participation of both AlR_3 and MgR_2 in alkylation of $TiCl_4$.

Figure 3 shows that the molecular weight of poly-1-hexene is significantly higher at lower synthesis temperature. The MW of the polymer increases with polymerization time [19]. This is apparently caused by stabilization of the Ti–C bond owing to formation of triple Ti–Al–Mg complexes, which hinders the deactivation of active centers and hampers the chain termination and transfer. It was found that the weight-average molecular weight of the synthesized polymer M_w, similarly to M_w of poly-1-hexene prepared on supported titanium-magnesium catalyst, is 2×10^5–6×10^5, which is significantly higher than the molecular weight of the polymer synthesized on metallocene catalysts [7–10].

It has been shown previously that polymerization of styrene on the catalytic system $TiCl_4$–$Al(C_6H_{13})_3 \cdot Mg(C_6H_{13})_2$ yields the polymer with a high degree of isotacticity [11]. Here, we studied the structure of the forming polymers by ^{13}C NMR (Fig. 4). The ^{13}C NMR spectrum of poly-1-hexene prepared at 25°C consists of six resonance lines. The chemical shifts of six carbon atoms well correlate with published data [8, 14]. As a rule, the degree of isotacticity of higher α-olefins is evaluated as the ratio of the intensity of

the C-3 line at approximately 35.0 ppm (Fig. 5) to the total intensity of the signals at 34.0–35.0 ppm [8, 14]. The degree of isotacticity of the polymer, evaluated by this method, was 35%.

It should be noted in conclusion that the resulting polymers can be efficiently used as depressants for crude oils with a high solidification point.

EXPERIMENTAL

Polymerization of 1-hexene was carried out in hexane at 15–65°C. The catalyst was prepared by reduction of $TiCl_4$ with an $AlMg(C_6H_{13})_5$ solution for 10 min at 20°C. The components were added in the following order: $TiCl_4$, metallorganic component and solution of monomer in hexane. The reaction was terminated by adding a mixture of ethanol and HCl. The polymer was separated from the reaction mixture, washed with ethanol, and dried in a vacuum at 60–75°C to constant weight. The compounds $Al(C_6H_{13})_3$ and $Al(C_6H_{13})_3 \cdot Mg(C_6H_{13})_2$ were prepared by the procedure described in [20]. All manipulations in synthesis of the catalysts and polymerization were performed under argon. 1-Hexen and hexane were dried and twice distilled from CaH_2. The viscosity-average molecular weight M_v of poly-1-hexene was evaluated by the equation $[\eta] = 2.05 \times 10^{-4} M_v^{0.72}$ (cyclohexane, 25°C) [21]. The weight-average molecular weight and MWD of polymers were determined by gel-permeation chromatography on a Waters device equipped with three Styro-gel columns with the pore size of 1×10^3, 5×10^4, and 5×10^5 Å. THF was used as a solvent. The elution rate was 1.2 ml min^{-1}. The structure of the resulting polymers was studied by ^{13}C NMR on a Bruker AC-400 spectrometer operating at 100.6 MHz. The spectra were recorded in CD_2Cl_2 at 25°C.

CONCLUSIONS

(1) The catalytic system $TiCl_4 - Al(C_6H_{13})_3 \cdot Mg(C_6H_{13})_2$ is more active in polymerization of 1-hexene than supported titanium-magnesium catalysts and favors synthesis of the polymer with a high molecular weight ($M_w = 2 \times 10^5 - 6 \times 10^5$). The activity of the catalytic system and the molecular weight of the resulting polymers strongly depend on the polymerization temperature.

(2) The microstructure of the synthesized polymers was studied by ^{13}C NMR. It was found that this system yields polymers with degree of isotacticity of approximately 35%.

Abstract—The effect of a piperylene modification of Ziegler–Natta catalytic systems was studied by sedimentation analysis in the gravity field. The rate of isoprene polymerization was analyzed as influenced by additional crushing of catalyst particles and formation of uniform reaction mixture in mixing of the initial components in a tubular turbulent prereactor of the diffuser-confuser design.

The production cost of synthetic products is determined by the cost of raw materials and power consumption in separate stages of industrial production. In synthesis of polymers, in particular, the cost of treatment of the final product to remove the catalyst residues reaches 30–40% of the overall production cost. Thus, to improve the profitability of the polymer production by catalytic polymerization, the consumption of expensive catalysts should be decreased, which would simultaneously decrease the production coast due to simpler polymer treatment to remove the catalyst residues. It has been found [1] that, in stereospecific polymerization of isoprene using Ziegler–Natta catalytic systems, the reaction rate grows and, as a result, the catalyst consumption decreases with increasing stirring rate of the reaction mixture. However, intensive turbulent mixing of a high-viscosity reaction mixture directly in the reaction zone is difficult to ensure by mechanical stirring. In this case, the use of small tubular diffuser-confuser reactors with a high output capacity [2], which provide intensive turbulent mixing of the reaction mixture in catalytic (co)polymerization of olefins and dienes, seems promising [3, 4].

In this study we examined the disperse composition and activity of the catalyst as influenced by the turbulent mixing in the stage of formation of the reaction mixture and microheterogeneous $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ Ziegler–Natta catalytic systems in stereospecific polymerization of isoprene.

A schematic of the experimental setup for isoprene polymerization is shown in Fig. 1. The starting reagents were purified by standard procedures commonly used in stereospecific polymerization of dienes in the presence of Ziegler–Natta catalysts. Under similar polymerization conditions [Ti : Al : piperylene molar ratio 1 : 1.25 : 2], piperylene modifying agent (M) was added to a solution of the catalytic system in the course of its keeping prior to the process [keeping time τ_{ck} 30 min at 273 K , polymerization temperature

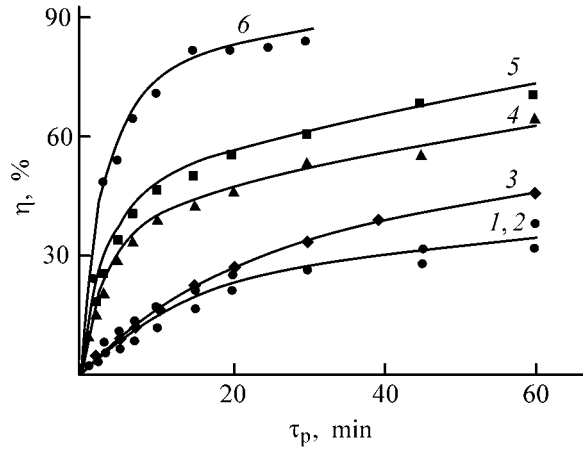

Fig. 2. Isoprene polymerization in the presence of catalytic systems: (*1–3*) $TiCl_4$–Al(*i*-$C_4H_9)_3$ and (*4–6*) $TiCl_4$–Al(*i*-$C_4H_9)_3$–piperylene. c_{Ti} = 6 mM, c_M = 1.5 M, Ti : Al : piperylene = 1 : 1.25 : 2, τ_{ck} = 30 min at 273 K, toluene solvent, 298 K. (η) Product yield and (τ_p) polymerization time. (*1, 4*) Blank tests; polymerization modes: (*2, 5*) 1, (*3*) 2, and (*6*) 3.

298 K, toluene solvent, c_{Ti} = 6 mM, c_M = 1.5 M]. Several process modes were tested.

Mode 1. Pretreated two- or three-component catalytic system [$TiCl_4$–Al(*i*-$C_4H_9)_3$ or $TiCl_4$–Al(*i*-$C_4H_9)_3$–piperylene] and solvent from vessels *1* and *2*, respectively, were mixed in the tubular turbulent unit *3* at a linear flow velocity in the wide section (diffuser) of no less than 0.5 m s^{-1} and a residence time of the reactants in the mixing zone of 2–3 s (hydrodynamic treatment the catalytic system in the turbulent mode). Then, the catalyst solution from unit *3* was fed into the 500-cm^3 vessel *4*, isoprene was added, and polymerization was carried out with slow agitation.

Mode 2. Solutions of $TiCl_4$ and Al(*i*-$C_4H_9)_3$ from vessels *1* and *2*, respectively, were fed through unit *3* into reactor *4*, in which the catalytic system was kept at 273 K for 30 min with subsequent monomer addition (formation of the catalytic system in the turbulent mode).

Mode 3. Solutions of the pretreated three-component catalytic system and monomer from vessels *1* and *2*, respectively, were mixed in unit *3* and then fed into unit *4* (formation of the reaction mixture in the turbulent mode). Polymerization of isoprene was carried out under slow agitation with a magnetic stirrer *5* (100 rpm) under the standard conditions; in this case, the tubular turbulent unit *3* worked as a prereactor (Fig. 1).

For each of the above experimental modes we performed blank tests, simulating the traditional process (the starting reagents without mixing in prereactor *3* are fed directly into reactor *4*). The conversion curves of isoprene polymerization were recorded by a gravimetric procedure. The quality of microheterogeneous catalytic systems after hydrodynamic treatment in the turbulent mode (mode 1) and blank test was determined by sedimentation using a torsion balance [5]. The sediment accumulation curves were graphically differentiated, and these results were used to evaluate the equivalent weight-average radius r_e (radius of the spherical particle settling at the same rate).

Hydrodynamic treatment of the separately prepared Ti–Al catalytic system in the turbulent mode (mode 1) does not noticeably affect the rate of isoprene polymerization as compared to the standard process modes (blank test; Fig. 2, curves *1*, *2*). In this case, the catalyst can be activated owing to formation of the catalytic system in mixing of the initial components directly in the tubular turbulent prereactor with subsequent keeping at 273 K (mode 2, Fig. 2, curve *3*). A somewhat different pattern is observed in modification of the Ti–Al catalytic system with diene (piperylene) additives. In the presence of the modified Ti–Al catalyst, the rate of isoprene polymerization significantly increases even in the blank tests (Fig. 2, curves *1*, *4*). This phenomenon is widely used in industry for activation of the Ziegler–Natta catalytic systems for diene polymerization.

Hydrodynamic treatment of the three-component catalytic system in its mixing with the solvent in the turbulent mode (mode 1) at maximum activity in the blank tests (Fig. 2, curves *1*, *4*) increases the yield of the final product by nearly 10% at a polymerization time of 1 h (Fig. 2, curve *5*). A more pronounced acceleration of isoprene polymerization is provided by a hydrodynamic treatment of the reaction mixture in the course of its formation, i.e., in mixing of the solution of the monomer and catalytic complex in the turbulent mode (mode 3). In this case, the yield of isoprene reaches ~80% at a polymerization time as short as 20 min (Fig. 2, curve *6*). The acceleration of isoprene polymerization, observed in the above tests, is obviously due to the fragmentation of the particles of microheterogeneous catalysts based on $TiCl_4$. To verify this assumption, we performed a dispersion analysis of particles of the catalytic systems prepared.

When the Ti–Al catalytic system is formed without diene modification, relatively coarse catalyst particles are formed (~3–4 μm average radius). As compared with the standard process, hydrodynamic treatment of the two-component Ti–Al catalytic system in the turbulent mode (mode 1) does not noticeable af-

fect the size of the catalyst particles and, hence, its specific surface area (Fig. 3, curves *1*, *2*). As a result, the rates of isoprene polymerization are similar (Fig. 2, curves *1*, *2*).

When the Ti–Al catalytic system is formed in the presence of piperylene (three-component system), the size of the catalyst particles decreases to $r_e \sim 1.5$ μm (Fig. 3, curve *3*). Since the active centers of stereospecific polymerization are located at the defects of the catalyst crystal structure (in our case, β-$TiCl_3$ [6]), the increase in the specific surface area of the catalyst should increase the polymerization rate, which is observed experimentally (Fig. 2, curve *4*). A hydrodynamic treatment of the modified Ti–Al catalytic system in the turbulent mode (mode 1) also decreases the catalyst particle size to $r_e \approx 1$ μm (Fig. 3, curve *4*), providing an increase in the polymerization rate as compared with the traditional process (Fig. 2, curves *4*, *5*). Apparently, when the catalyst is formed in the presence of dienes, macrochains of piperylene fragments start to form on the active particles, which decreases the strength of the solid phase structure and, thus, simplifies its fragmentation in the turbulent flow. The hydrodynamic treatment in the tubular turbulent prereactor (mode 1) is similar to fragmentation of heterogeneous Ziegler–Natta catalysts in the course of polymerization [6]. The increased polymerization rate in the case when the catalytic system is formed in the turbulent mode (mode 2; Fig. 2, curve *3*) and $TiCl_4$ and Al(*i*-$C_4H_9)_3$ solutions are mixed directly in the tubular turbulent prereactor; is also accounted for by a simultaneous increase in the specific surface area of the catalyst. In this case, at high rate of micromixing attained in the turbulent prereactor, the rate ratio of the crystal nucleus formation and crystal growth increases, so that the number of the crystal nuclei grows and r_e decreases.

Our experimental data show that the increase in the specific surface area of the catalyst in stereospecific polymerization of dienes is a necessary but insufficient factor to accelerate the polymerization. Significant activity of the catalyst system is achieved by premixing of the catalyst and monomer solutions in the turbulent mode (mode 3; Fig. 2, curve *6*). In this case, the catalyst particles are disintegrated (Fig. 3, curve *4*) and uniformly distributed in the reaction mixture. Moreover, the effect can be enhanced by elimination of the diffusion limits to linking of the first monomer molecule with the active center (initiation proceeding at a high rate [3]).

Thus, the process rate strongly depends on the mode of isoprene polymerization in the presence of the Ziegler–Natta catalytic systems. High reaction rate

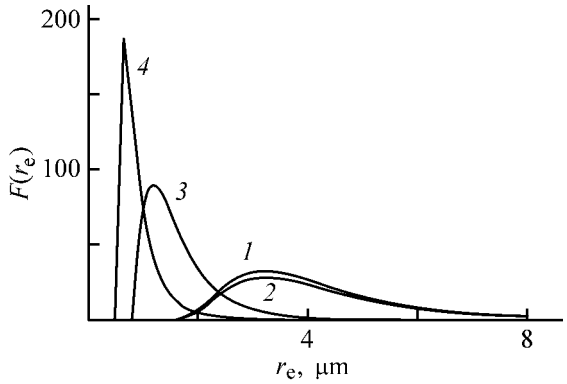

Fig. 3. Differential size distribution of particles in the catalytic systems (*1*, *2*) $TiCl_4$–Al(*i*-$C_4H_9)_3$ and (*3*, *4*) $TiCl_4$–Al(*i*-$C_4H_9)_3$–piperylene. (r_e) Particle size. c_{Ti} = 12 mM, Ti : Al : piperylene = 1 : 1.25 : 2, τ_{ck} = 30 min at 273 K, 298 K. (*1*, *3*) Blank tests and (*2*, *4*) polymerization mode 3.

is attained using a simple tubular turbulent prereactor, which provides a residence time of the reaction mixture of 2–3 s in the mixing zone. Modification of the Ti–Al catalytic systems with dienes increases the specific surface area in the case of catalyst and, in turn, the polymerization rate. This effect can be enhanced by additional fragmentation of the catalyst particles under hydrodynamic treatment in the turbulent mode. The polymerization rate in the case of premixing of the monomer and catalyst solutions in the turbulent mode is the highest, which is due to the increase in the specific surface area of the catalyst and its more uniform distribution in the reaction mixture. The modes of isoprene polymerization in the presence of microheterogeneous Ti–Al catalytic system given above allow the catalyst consumption and, thus, the production cost of the final product to be decreased.

CONCLUSIONS

(1) Turbulent premixing of the components of the reaction mixture and Ziegler–Natta catalytic system in isoprene polymerization using a tubular turbulent diffuser-confuser prereactor allows the process rate to be varied widely and the catalyst consumption to be decreased.

(2) The dispersion composition and the activity of microheterogeneous Ziegler–Natta catalysts can be improved by their modification with dienes, and the strongest effect is observed in the case of hydrodynamic pretreatment of the reaction mixture in the turbulent mode.

Abstract—Spontaneous polymerization of *N*-(3-dimethylaminopropyl)methacrylamide in concentrated aqueous solutions in the presence of inorganic and organic acids was studied. A common mechanism of initiation of spontaneous polymerization of amine-containing (meth)acrylamides and (meth)acrylic acid esters in water was suggested.

Much attention has been given recently to spontaneous polymerization of (meth)acrylic monomers in concentrated aqueous solutions. The process was studied for acrylamide [1], 2-acrylamido-2-methylpropanesulfonic acid [2], and *N*,*N*-dialkylaminoethyl methacrylate salts [3–5]. The reaction was shown to occur by the radical mechanism, with the monomer molecules being the sources of radical [1]; the initiation mechanism was suggested in [5].

In this study, we examined spontaneous polymerization of *N*-(3-dimethylaminopropyl)methacrylamide (**I**) salts in concentrated aqueous solutions.

Our preliminary experiments showed that spontaneous polymerization of amide **I** in water at 50–70°C occurs at a noticeable rate in weakly alkaline, neutral, and acidic solutions (pH ≤ 8) at the monomer concentration exceeding 20 wt %. The process is suppressed by adding inhibitors of radical polymerization (hydroquinone, phenothiazine).

Figure 1 shows the kinetic curves of consumption of C=C bonds in the course of spontaneous polymerization of **I** at various degrees of its neutralization with sulfuric acid. It is seen that, without acid additions or with insufficient amounts of the acid (curves *1*, *2*), no reaction occurs. The polymerization becomes noticeable only after 80% of the amino groups of the monomer are neutralized (pH 8). However, even under these conditions, the reaction is slower than that in an acidic solution (curves *5*–*7*). The influence of the ratio of the acid and amino components of the system on the initial rate is illustrated by Fig. 2. The curve

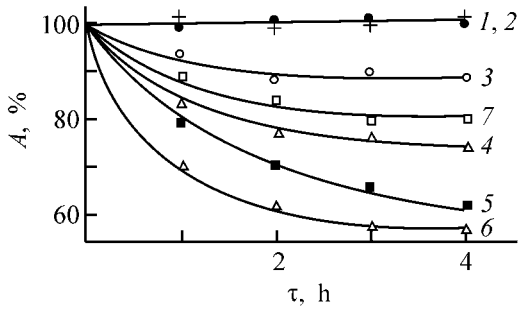

Fig. 1. Variation of the content of C=C bonds *A* (relative to the initial content) with time τ in the system amide **I**–H_2SO_4, as influenced by the amount of sulfuric acid. $[\mathbf{I}]_0$ = 50 wt %, 70°C; the same for Fig. 2. $[\mathbf{I}]_0 : [H^+]_0$ ratio: (*1*) 1 : 0, (*2*) 1 : 0.5, (*3*) 1 : 0.8, (*4*) 1 : 1, (*5*) 1 : 1.1, (*6*) 1 : 1.5, and (*7*) 1 : 2.

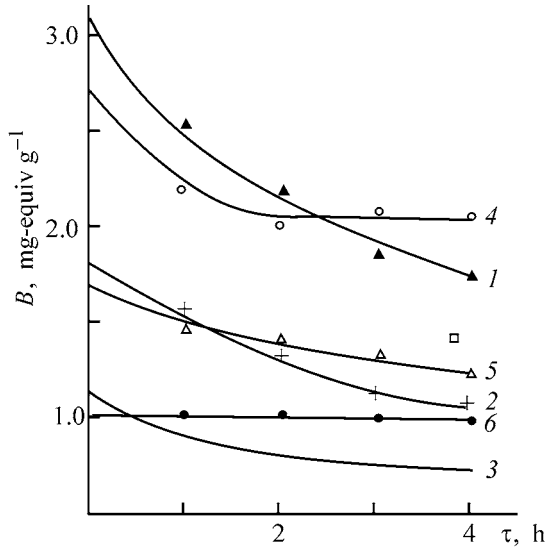

Fig. 4. Variation with time τ of the content of C=C bonds *B* in amides (*1–3*) **II** and (*4–6*) **III** in the course of spontaneous polymerization in the presence of H_2SO_4, as influenced by the amide concentration. $[H^+]$ = 0.4 mg-equiv g^{-1}, 70°C; (τ) time. $[Amide]_0$, wt %: (*1*) 70, (*2*) 41, (*3*) 25, (*4*) 80, (*5*) 50, and (*6*) 30.

passes through a maximum at approximately 50% excess of the acid groups relative to amino groups. It should be noted that a similar maximum in the pH dependence of the initial reaction rate was observed in spontaneous polymerization of 2-acrylamido-2-methylpropanesulfonic acid [2].

Figures 3 and 4 illustrate the influence of temperature and initial monomer concentration on the course of polymerization in solutions of *N*,*N*-dimethylammoniopropylmethacrylamide sulfate **II** and *N*,*N*,*N*-trimethylammoniopropylmethacrylamide methyl sulfate **III**. As the temperature and monomer concentration are increased, the reaction dramatically accelerates. From the temperature dependences, we determined the overall activation energy of spontaneous polymerization of **II**: 51 kJ mol^{-1}. This value is close to that obtained in [4] for spontaneous polymerization in water of a related ester, *N*,*N*,*N*-trimethylammonioethyl methacrylate methyl sulfate (63.5 kJ mol^{-1}). Figure 4 shows that tertiary salt **II** polymerizes more actively than quaternary salt **III**. In particular, a decrease in the concentration of **II** from 70 to 25 wt % causes only deceleration of the process, whereas in the case of **III**, spontaneous polymerization does not occur at all at a monomer concentration of 30 wt % (Fig. 4).

The influence exerted by the solution acidity and by the initial concentration and structure of the monomer on the spontaneous polymerization should be analyzed, in our opinion, taking into account the association of the compounds in water. The association has been detected previously in aqueous solutions of acrylamide [6] and *N*,*N*-dimethylaminoethyl methacrylate [7] on the basis of viscosity and surface tension data. Furthermore, we showed in [5] that the spontaneous polymerization of amino methacrylate salts is largely governed by association of the monomers. To evaluate the tendency of amino amide **I** and its salts to associate in water, we measured the concentration dependences of the viscosity (Fig. 5).

We found that, at a monomer concentration of 10–15 wt %, the linearity of the dependences is disturbed, and the viscosity sharply grows, suggesting an association of the monomeric molecules. It should be noted that both the amino amide salts and free monomer **I** tend to associate. Since spontaneous polymerization occurs only in concentrated solutions, it can be concluded that the necessary condition for the polymerization is the formation of monomeric associates of a definite structure. In dilute solutions, conditions for the association are unfavorable. Therefore, apparently, the polymerization does not occur if the monomer concentration is below a certain limit. However, the association of the amides does not necessarily lead to their polymerization. For example, amide **I** and *N*,*N*,*N*-dimethylbenzylammoniopropylmethacrylamide **IV** do not undergo spontaneous polymerization under the conditions indicated in the caption to Fig. 4, despite their strong tendency to associate in water. Such a difference in the behavior of the monomers may be due, e.g., to "favorable" or "unfavorable" molecular packing in the associate (following the terminology of [8]). Hence, the association of monomers is a necessary but insufficient condition for spontaneous polymerization.

The acid anion exerts a significant effect on the polymerization of **I** (Fig. 6). The reaction occurs in the presence of not only strong mineral acids, but also weaker organic acids. Furthermore, acetic and formic acids appeared to be more active than strong hydrochloric acid, and with hydrofluoric acid the reaction did not occur at all. Hence, the acid strength is not the major factor affecting the polymerization.

The experimental results, combined with published data, show that, in the absence of anions, there is no self-initiation of radical polymerization of acrylic monomers in aqueous solutions. For example, upon dissolution of free amide **I** in water, no spontaneous polymerization occurs, despite the association in concentrated solutions. Additions of inorganic salts do not induce polymerization of the amides either. For example, no changes in the concentration of **I** were observed in 4.1 M solution of **I** containing 0.5 M Na_2SO_4 upon keeping for 5 h at 70°C.

To sum up, we can state that the influence of the initial monomer concentration, solution acidity, and nature of the acid added, observed in our systems, is largely similar to the trends observed previously in spontaneous polymerization of amino methacrylate salts [5], for which a hypothesis was put forward that the polymerization is initiated in monomeric associates by a redox reaction of the anions present in the system with the C=C bonds. A similar mechanism of radical generation was suggested in [9] for polymerization of acrylamide in surfactant micelles in the presence of Na_2SO_3. Thus, presumably, the spontaneous polymerization of (meth)acrylic monomers occurs by a similar mechanism in all the cases.

EXPERIMENTAL

Amino amide **I** was twice distilled in a vacuum before use. Quaternary ammonium salts were prepared from amide **I** and the corresponding alkylating agents in toluene or acetone. Tertiary salts were prepared by mixing of equivalent amounts of the amine-containing monomer and protonic acid with cooling.

Spontaneous polymerization of the monomeric salts was studied at 50–90°C and initial reactant concentrations of 25–80 wt %.

The course of the polymerization was monitored by measuring the concentration of C=C bonds and by isolating the reaction products. The products were isolated by precipitation into acetone, followed by separation of the unchanged starting compounds by repeated washing. After washing, the polymers were dried in a vacuum (20°C, 2 mm Hg) to constant weight.

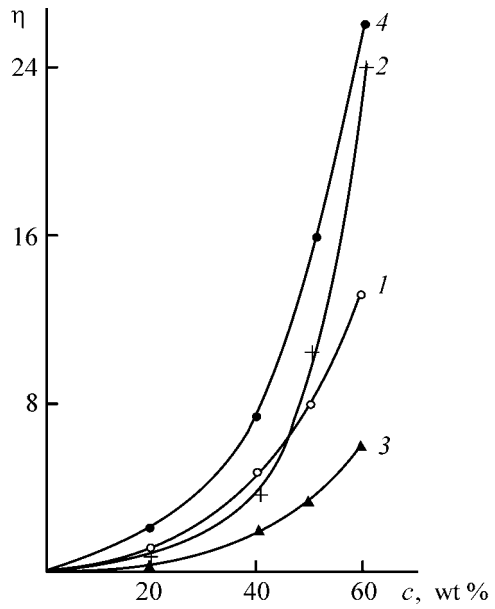

Fig. 5. Specific viscosity η of aqueous solutions of amides (*1*) **I**, (*2*) **II**, (*3*) **III**, and (*4*) **IV** at 25°C vs. the amide concentration.

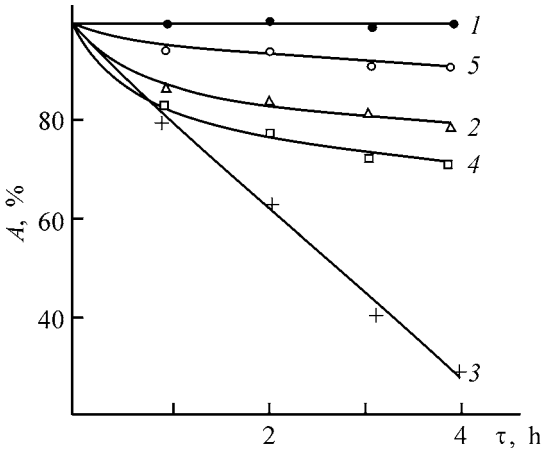

Fig. 6. Spontaneous polymerization of amide **I** in the presence of different acids. $[\mathbf{I}]_0 : [HAn]_0 = 1 : 1$, 70°C. (*A*) Amount of monomeric salt of **I** (relative to the initial amount) and (τ) time. Acid: (*1*) HF, (*2*) HCl, (*3*) HCOOH, (*4*) CH_3COOH, and (*5*) CH_3CH_2COOH.

The concentration of C=C bonds was determined by bromide–bromate titration. The intrinsic viscosity of the monomers was measured in an Ubbelohde viscometer with the capillary diameters of 0.56, 0.73, and 0.99 mm at 25°C. The ^{13}C NMR spectra were recorded on a Varian Gemini-300 Fourier spectrometer (75 MHz, solvent D_2O, reference DMSO).

Poly-*N*,*N*-dimethylammoniopropylmethacrylamide sulfate. To 7.12 g (0.0419 mol) of amide **I** in

1.4 ml of water, we added with stirring and cooling 4.62 g of 50% sulfuric acid. The solution was heated at 70°C for 4 h, and the resulting polymer was precipitated into acetone, washed twice with acetone, and vacuum-dried (20°C, 2 mm Hg). Yield 3.21 g (35%). The product contained no C=C bonds. The ^{13}C NMR spectrum contained the following signals, δ_C, ppm: 179.6–179.2 (–CONH–), 55.7 (–CH_2N–), 54.0–53.8 (–CH_2– in the chain), 45.6–45.3 (–C– in the chain), 43.1 (CH_3–N), 37.5 (–CH_2–NH–), 24.6 (–C–CH_2–C–), 18.5–17.2 (CH_3–C–).

CONCLUSIONS

(1) Spontaneous polymerization of tertiary and quaternary salts of *N*-(3-dimethylaminopropyl)methacrylamide occurs in concentrated aqueous solutions at pH $\leq$ 8.

(2) The initial reaction rate is the highest at a 50% excess of the acid relative to the amide and depends on the anions present in the system.

(3) The presence of anions and association of *N*-(3-dimethylaminopropyl)methacrylamide salts are necessary conditions for spontaneous polymerization.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Copolymerization of Sodium 2-Acrylamido-2-methylpropanesulfonate with *N*-Vinylpyrrolidone in Water and Dimethyl Sulfoxide

V. F. Kurenkov and T. A. Zhelonkina

Kazan State Technological University, Kazan, Tatarstan, Russia

Received July 21, 2003

Abstract—The kinetics of radical copolymerization of sodium 2-acrylamido-2-methylpropanesulfonate with *N*-vinylpyrrolidone in water and dimethyl sulfoxide at pH 9 and 50°C in the presence of potassium peroxodisulfate initiator were studied dilatometrically.

The interest in synthesis of copolymers of 2-acrylamido-2-methylpropanesulfonic acid (H-AMS) salts with *N*-vinylpyrrolidone (VP) is due to unusual and insufficiently studied features of radical copolymerization of ionic monomers [1, 2] and VP [3–5] in various media, and also to prospects for diverse applications of these copolymers in industry and medicine as flocculants [6], adhesives, antistatic agents [7], thickeners, and complexing agents [4, 8]. Previously we have studied some features of copolymerization of H-AMS sodium salt (Na-AMS) with VP in aqueous solutions [9–11] and evaluated the effect of the solution ionic strength and kind of single- [12, 13] and double-charged [13, 14] cations on the copolymerization. In this study, we revealed new features of radical copolymerization of Na-AMS with VP in water and dimethyl sulfoxide (DMSO).

EXPERIMENTAL

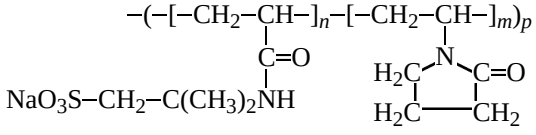
Na-AMS was prepared by neutralization of H-AMS [Lubrizol 2404 (Lubrizol, the United Kingdom), mp 185°C, main substance content 99%) solutions with NaOH to pH 9. VP (Merck, Germany) was used after double distillation in a vacuum from 0.1% KOH, n_D^{20} 1.5117, main substance content (GLC) >99%. Potassium peroxodisulfate (PP) was recrystallized twice from aqueous solutions; the main substance content, as determined by the redox method, was 97.8%. The other chemicals were of chemically pure or analytically pure grades.

The kinetics of copolymerization of Na-AMS (M_1) with VP (M_2) was studied in 10 and 15% solutions in water and DMSO at pH 9 and 50°C. The reaction was initiated by thermal decomposition of PP ([PP] 7.4×10^{-4} M). The pH was maintained with the aim to prevent hydrolysis of VP [15] and to ensure the effectiveness of PP as initiator [16] and a constant initiation rate under the conditions when the solution ionic strength varies in the course of copolymerization owing to variation of the Na-AMS concentration [17]. The copolymerization was performed under homogeneous conditions, and no spontaneous polymerization was observed. However, in concentrated solutions of the monomers in DMSO, partial microheterogeneity of the process was not excluded.

The kinetic information on the process was obtained dilatometrically. The initial copolymerization rates V_0 were determined at low conversions ($x < 3\%$) from the slope of the linear portions of the kinetic curves. The experimental procedures are similar to those described in [10].

After the synthesis, Na-AMS–VP copolymers were precipitated from reaction solutions with acetone, washed with acetone, and dried in a vacuum at 50°C to constant weight. The yields of the copolymers were determined gravimetrically. The molecular weights of the copolymers were judged from the intrinsic viscosities [η], which were determined in 0.5 M NaCl at 30°C with a VPZh-3 viscometer (capillary diameter 0.43 mm).

The content of ionic units in the VP–Na-AMS copolymer



1070-4272/04/7702-0307 © 2004 MAIK "Nauka/Interperiodica"

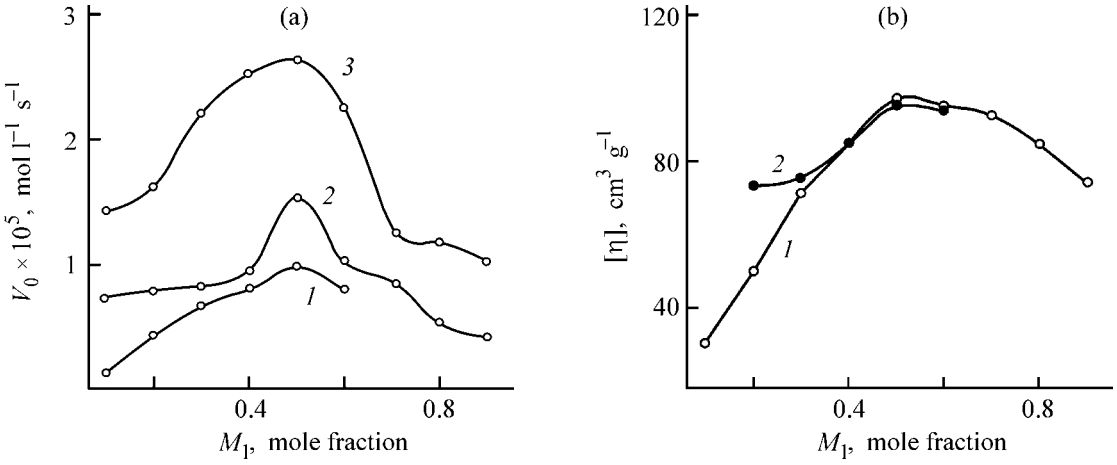


Fig. 1. (a) Initial rate V_0 of copolymerization of Na-AMS with VP and (b) intrinsic viscosity [η] of copolymers vs. Na-AMS mole fraction M_1 in the starting monomeric mixture. Solvent: (*1*) water and (*2*, *3*) DMSO. [M_1 + M_2], %: (*1*, *2*) 10 and (*3*) 15.

was determined by elemental analysis for sulfur, performed as described in [18].

The electrical conductivity of solutions of mixtures of the monomers and copolymer was measured at 25°C with an Anion-410A ionomer–conductometer equipped with a DKV-1 sensor.

The pH was determined at 25°C with a pH-121 pH-millivoltmeter using an ESL-63-07 glass indicator electrode and an EVL 1M3 silver chloride reference electrode.

To examine how the copolymerization of Na-AMS with VP is influenced by the composition of the starting monomeric mixture, we performed the reaction in concentrated solutions of the monomers ([M_1 + M_2] 10 and 15%) in water and in DMSO under equal other conditions. Figure 1 shows the dependences of V_0 and [η] of the resulting copolymers on the Na-AMS mole fraction in the starting monomeric mixture M_1. As seen, V_0 and [η] vary with M_1 similarly. Both the dependences, $V_0 = f(M_1)$ (Fig. 1a) and [η] = $f(M_1)$ (Fig. 1b) in water (curves *1*) and DMSO (curves *2*), pass through maxima at the equimolar ratio of the monomers in the starting mixture ([M_1] : [M_2] = 1 : 1). This is in good agreement with published data [9, 10] and confirms the donor–acceptor character of the reaction of Na-AMS with VP [19]; Na-AMS shows a medium electron-acceptor power, and VP, a medium electron-donor power. Figure 1a shows that the rate of copolymerization in DMSO grows with increasing total concentration of the comonomers (curves *2*, *3*), which is well consistent with the general relationships of radical copolymerization.

Table 1. Yield of Na-AMS–VP copolymer in copolymerization in water and DMSO as influenced by the Na-AMS mole fraction in the starting monomeric mixture M_1 ([M_1 + M_2] = 10%)

M_1	Yield, %	
	in H_2O	in DMSO
0.1	–	21
0.2	23	30
0.3	26	31
0.4	31	38
0.5	47	50
0.6	46	51
0.7	47	47
0.8	52	56
0.9	58	67

Comparison of data in Fig. 1a at [M_1] = const shows that, in a wide range of compositions of the starting monomeric mixture, V_0 increases in going from water to DMSO. At the same time, the intrinsic viscosities of the copolymers obtained in water and DMSO differ insignificantly (Fig. 1b) because of the negligible contribution of the chain transfer to DMSO molecules. Such a loss of the capability of compounds to participate in chain transfer has been noted previously for alternating copolymerization in other systems [20].

The yields of Na-AMS–VP copolymers in copolymerization are listed in Table 1. It is seen that, both in water and DMSO, the copolymer yield grows with increasing content of Na–AMS in the starting mixture;

it also grows somewhat in going from water to DMSO (at the same $[M_1]$).

To obtain an equation of the overall rate of copolymerization of Na-AMS with VP in DMSO, we performed experiments at various concentrations of Na-AMS, VP, and PP under equal other conditions. The influence exerted on the copolymerization by the Na-AMS concentration was examined in the range 0.110–0.661 M. The V_0 values found in this experimental series are plotted in Fig. 2, and the intrinsic viscosities and yields of the copolymers are listed in Table 2. As the Na-AMS concentration is increased, V_0 (the reaction order with respect to Na-AMS is 1.0, Fig. 2, straight line *1*), [η], and the yield of the copolymer grow (Table 2).

The influence of VP on the copolymerization was examined in two concentration ranges, 0.145–3.112 and 0.437–4.298 M, under equal other conditions. We found that V_0 grows with increasing VP concentration (Fig. 2, straight lines *2*, *3*); in both experimental series, the reaction order with respect to VP was 0.5. It should be noted that an unusual (lower than unity) reaction order with respect to the monomer has also been observed previously in radical polymerization of VP at $1 < [VP] < 6$ M [3, 21] and in graft polymerization of VP on chitosan [22].

As the initiator (PP) concentration was increased in the range $(1.57–7.4) \times 10^{-4}$ M, V_0 grew (Fig. 2, straight line *4*); the reaction order with respect to the initiator was 1. The intrinsic viscosity decreased with increasing PP concentration (Table 2), in agreement with the general relationships of radical polymerization.

From the above data, we obtained an empirical equation for the overall rate of copolymerization of Na-AMS with VP in DMSO:

$$V = k_c[M_1]^{1.0}[M_2]^{0.5}[PP]^{1.0}, \quad (1)$$

where k_c is the copolymerization rate.

Below is given for comparison the corresponding equation for the copolymerization in water, obtained in [10]:

$$V = k_c[M_1]^{0.9}[M_2]^{0.7}[PP]^{0.5}. \quad (2)$$

Comparison of Eqs. (1) and (2) shows that the kinetic orders of the reaction with respect to the comonomers change insignificantly in going from water to DMSO, whereas the order with respect to the initiator changes appreciably. Similar changes in the reaction orders with respect to $[M_1]$ and [PP] in going from water to DMSO have been observed previously in copolymerization of acrylamide with Na-AMS [23] and with another strong unsaturated electrolyte, sodium *p*-styrenesulfonate [2]. The reaction order of 0.5 with respect to the initiator in Eq. (2) suggests a bimolecular termination of the kinetic chains, and the first order with respect to the initiator in Eq. (1) suggests a monomolecular chain termination due to partial microheterogeneity of the process in concentrated solutions of the monomers in DMSO.

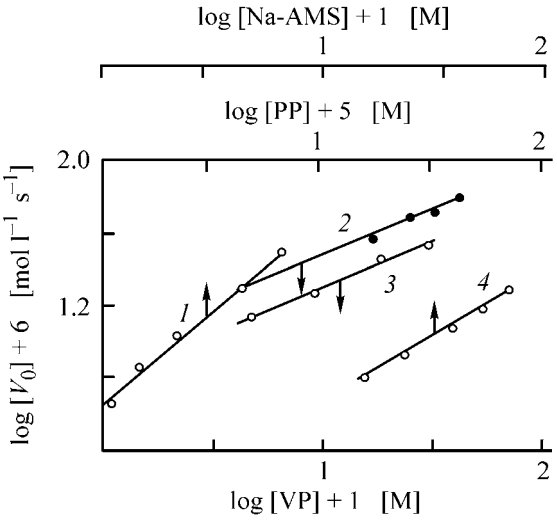

Fig. 2. log–log plot of the rate V_0 of copolymerization of Na-AMS with VP in DMSO vs. concentration of (*1*) Na-AMS, (*2*, *3*) VP, and (*4*) PP. Concentrations, M: VP (*1*, *4*) 0.44; PP (*1*–*3*) 7.4×10^{-4}; Na-AMS (*2*, *4*) 0.44 and (*3*) 0.53.

To explain the kinetic effects revealed in copolymerization of Na-AMS with VP in water and DMSO,

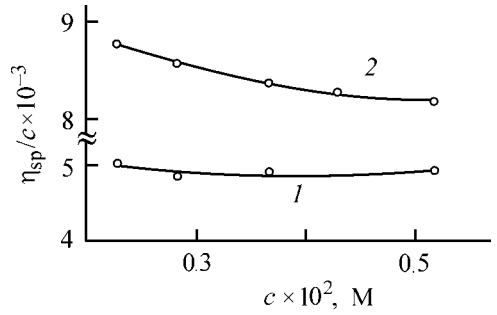

Fig. 3. Reduced viscosity η_{sp}/c of Na-AMS–VP copolymer vs. the copolymer concentration c in (*1*) water and (*2*) DMSO at 30°C. $[\eta] = 260$ cm^3 g^{-1}; content of Na-AMS units 34 mol %.

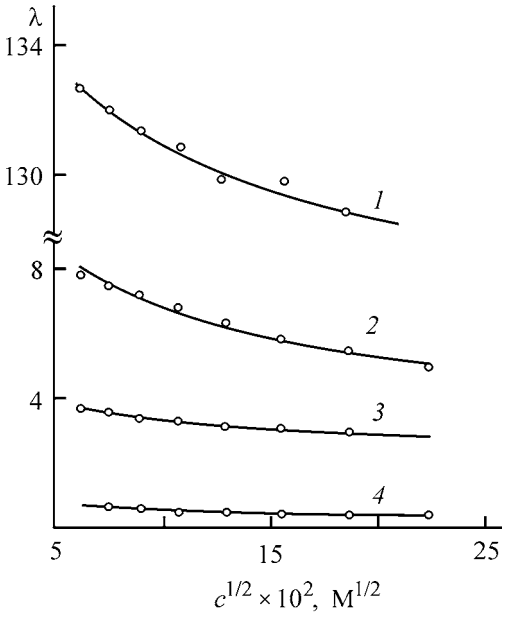

Fig. 4. Equivalent electrical conductivity λ of (*1, 2*) mixture of the monomers ($[M_1] : [M_2] = 20 : 80$) and (*3, 4*) Na-AMS–VP copolymer ($[m_1] : [m_2] = 20 : 80$, $[\eta] = 260$ cm^3 g^{-1}) (*1, 3*) in water and (*2, 4*) in DMSO vs. the square root of the concentration of the monomer mixture or copolymer $c^{1/2}$ at 20°C.

let us consider the ionization equilibrium of ionic groups of Na-AMS and their units in macromolecules:

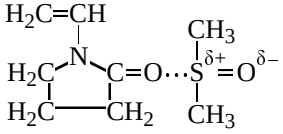
$$\underset{\textbf{I}}{A^-X^+} \rightleftarrows \underset{\textbf{II}}{A^- \,||\, X^+} \rightleftarrows \underset{\textbf{III}}{A^- + X^+}, \qquad (3)$$

where A^- is the monomer anion or macroanion and X^+ is the cation; **I**, **II**, and **III** are, respectively, the contact ion pairs, solvent-separated ion pairs, and free ions.

As the solvent polarity decreased in going from water to DMSO, the effective degree of ionization of the sulfonate groups of the monomer and macroradicals decreased, with equilibrium (3) shifted to the left. As a result, the ratio of different ionic species in the reaction mixture and the intensity of their electrostatic interactions changed, affecting the relative activities of the monomer (copolymerization constants r_1 and r_2). Along with the multicomponent composition of the system, the nonisoionic synthesis conditions (due to variations in the content of the ionic monomer in the starting mixture and with conversion) could also cause changes in r_1 and r_2. Thus, copolymerization involving an ionic monomer cannot be described by fixed values of r_1 and r_2 [2].

The change in the effective degree of ionization of sulfonate groups in Na-AMS and macromolecules of Na-AMS–VP copolymer on replacement of water with DMSO is confirmed by viscometric (Fig. 3) and conductometric (Fig. 4) data. The concentration dependences of η_{sp}/c (Fig. 3) and electrical conductivity λ (Fig. 4) are typical of polyelectrolytes and indicative of an appreciable electrostatic interaction of the sulfonate groups in Na-AMS and its copolymer with VP in water and DMSO. In going from water to DMSO, η_{sp}/c (at c = const) and the effective size of macromolecular globules of Na-AMS–VP copolymer decrease (Fig. 3). The electrical conductivities λ of the Na-AMS–VP copolymer (Fig. 4, curves *1*, *2*) and a mixture of the monomers of a similar composition (Fig. 4, curves *3*, *4*) decrease also. Figure 4 shows that, in the same solvent and at c = const, λ decreases in going from the monomeric mixture to the copolymer. This is due to the lower effective degree of ionization of the sulfonate groups in the copolymer, compared to Na-AMS monomer, owing to the specific binding of Na^+ ions with the copolymer macromolecules [24].

In view of these facts, it can be noted that the electrostatic repulsion between the similarly charged Na-AMS monomer and macroradical with the terminal Na-AMS unit in the chain propagation events should decrease in going from water to DMSO. Therefore, an increase in the rate constant of chain propagation k_{11} was the decisive factor responsible for the growth of V_0 of Na-AMS–VP copolymerization in going from water to DMSO. Another possible factor could be the complexation between VP as electron donor and DMSO as electron acceptor. The presumed structure of the complex is as follows:



(4)

We also studied how the composition of the Na-AMS–VP copolymer correlates with the composition of the starting monomeric mixture, for the process performed in water and DMSO (Fig. 5, curves *1* and *2*, respectively). From the experimental data, we calculated the effective relative activities of the monomers $r_1 = k_{11}/k_{12}$ (for Na-AMS) and $r_2 = k_{22}/k_{21}$ (for VP) using the Mayo–Lewis equation. The $m_1 = f(M_1)$ plot for copolymerization in water corresponds to $r_1 = 0.35 \pm 0.01$ and $r_2 = 0.15 \pm 0.08$, $r_1r_2 = 0.05$, and that for copolymerization in DMSO, to $r_1 = 0.11 \pm 0.07$ and $r_2 = 0.44 \pm 0.36$, $r_1r_2 = 0.05$. These values of the relative activities of the monomers r_1 and r_2 show that, both in water and in DMSO, both kinds of macroradicals react considerably faster with the monomer of the other kind than with the "own" monomer, owing to complexation between the monomers. This results in the formation of alternating copolymers of regular composition, which is confirmed by the r_1r_2 values. In both solvents, the system has an azeotropic point (Fig. 5). Figure 5 shows that, at $[M_1]$ = const, the content of the ionic units in the copolymer decreases in going from water to DMSO (going from curve *1* to curve *2*) in a wide range of compositions of the starting monomeric mixtures. Apparently, DMSO molecules compete with Na-AMS in complexation with VP [scheme (4)], enhancing the activity of VP in copolymerization and increasing the content of VP units in the copolymer.

The intrinsic viscosities and compositions of the Na-AMS–VP copolymers in the course of copolymerization in DMSO at Na-AMS mole fractions in the starting monomeric mixture of 0.5 and 0.7 are shown in Fig. 6. It is seen that [η] increases with conversion (curves *1*', *2*'). Similar dependences have also been observed in other systems with alternating copolymerization [20]. The composition of the copolymer at M_1 0.5 varies with conversion only slightly (curve *1*), whereas at M_1 0.7 the variation is significant (curve *2*). One of the possible factors responsible for the variation of the copolymer composition with conversion is that the synthesis conditions are not isoionic, which affects the activity of the ionic comonomer in copolymerization [2].

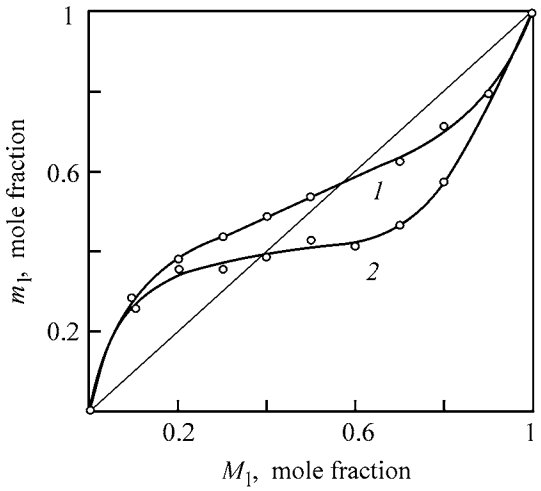


Fig. 5. Mole fraction m_1 of Na-AMS units in the copolymer with VP at <3% conversion vs. the mole fraction M_1 of Na-AMS in the starting monomeric mixture. Solvent: (*1*) water and (*2*) DMSO. $[M_1 + M_2]$ = 10%; the same for Fig. 6.

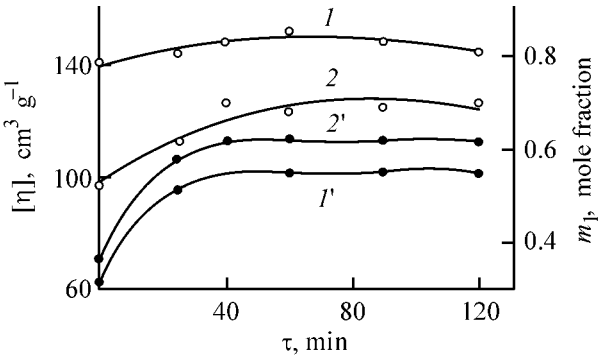

Fig. 6. (*1*', *2*') Intrinsic viscosity [η] and (*1*, *2*) mole fraction m_1 of Na-AMS units in the copolymer with VP vs. time τ of copolymerization in DMSO. Na-AMS mole fraction M_1 in the starting monomeric mixture: (*1*, *1*') 0.5 and (*2*, *2*') 0.7.

CONCLUSIONS

(1) In radical copolymerization of sodium 2-acrylamido-2-methylpropanesulfonate with *N*-vinylpyrrolidone in water and dimethyl sulfoxide, V_0 grows as the concentrations of M_1, M_2, their sum, and initiator increase and passes through a maximum (at equimolar ratio of the comonomers) with variation of $[M_1] : [M_2]$; V_0 also increases in going from water to dimethyl sulfoxide.

(2) The intrinsic viscosities of the copolymers pass through a maximum with variation of $[M_1] : [M_2]$ and grow as the $[M_1]$ and conversion increase and in the initiator concentration decreases.

(3) The content of ionic units in the copolymer decreases on replacement of water with dimethyl sulfoxide and as the conversion becomes lower.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Properties of Some Chitosan-containing Blends and Films Therefrom

Abstract—Mixed solutions of chitosan and polymers with different chain rigidities (polyvinyl alcohol and methyl cellulose) in 2% acetic acid, at various component ratios, were studied viscometrically. The compatibility of the components in solutions and in the solid phase was assessed, and the mechanical characteristics of films prepared from these blends were determined.

Chitosan is a nontoxic biocompatible and biodegradable polymer used in various fields of medicine and cosmetics as a drug carrier and as a material for separation membranes and sutures [1–5]. However, fibers and films prepared from pure chitosan are relatively brittle, and making them more elastic is an topical problem. One of the ways to improve the performance of polymers is their modification with other polymers. Blending allows preparation of systems with properties significantly differing from those of the starting components, without sophisticated chemical modification procedures or synthesis of new macromolecular compounds. Forming of articles from polymer blends in a common solvent is a relatively simple and accessible procedure.

Published data show that addition of some polymers to chitosan improves the mechanical characteristics of films therefrom. As modifying additives have been used oligomers [6], polyvinyl alcohol (PVA) [7–10], polyoxyethylene (POE) [10], polyethylene glycol [11], polygalacturonic acid [12], polyvinylpyrrolidone [13], and disperse cellulose [14]. Additions of chitosan considerably decrease the solubility and water absorption of PVA–chitosan films [7]. Mukhina *et al.* [8] revealed a certain enhancement of the mechanical characteristics of films prepared from chitosan–PVA blends: The strength and elongation at break increased by 10–30% at 20% content of PVA. However, strengthening of chitosan films with PVA was not observed in other studies [7, 9]. It has been shown previously that the strength of films prepared from chitosan–POE blends at a stoichiometric ratio of the components is two times higher, and the elongation at break, six times higher as compared to the films prepared from blends of other compositions or from pure components [15]. It was also shown [15] that this pair of polymers is only partially compatible, and it was suggested that the improvement of the deformation-strength characteristics of the polymers is due to a favorable steric arrangement and to ordering of polymeric chains in the films, rather than to formation of interpolymeric complexes, suggested in [10].

It seemed appropriate to continue systematic studies of blends of chitosan with macromolecular modifiers, with the aim to obtain promising chitosan-containing materials and reveal correlations between the properties of modifying polymeric additives and the deformation-strength characteristics of films prepared from these blends.

In this study, we used as polymeric additives two water-soluble polymers: a flexible-chain film- and fiber-forming polymer, PVA, and a semirigid-chain polymer, methyl cellulose (MC).

EXPERIMENTAL

We used the following polymers: chitosan (Aldrich, the United States), $M_w = 2.5 \times 10^5$, degree of deacylation 0.75–0.85; PVA (Plastpolimer, St. Petersburg, Russia), $[\eta] = 0.86$, $M_\eta = 1.2 \times 10^5$ (evaluated by the formula $[\eta] = 7.5 \times 10^{-4} M^{0.6}$ in water at 25°C [16]), 3% acetate groups; and MC (Aldrich), $M_n = 8.6 \times 10^4$, degree of substitution 1.6–1.8.

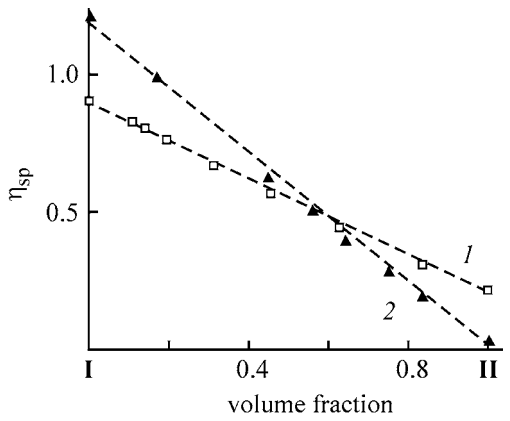

Fig. 1. Specific viscosity η_{sp} of mixed solutions of chitosan (component **I**) with (*1*) MC and (*2*) PVA (component **II**) in 2% acetic acid vs. the mixture composition. Total concentration of solutions, %: chitosan–MC 0.028 and chitosan–PVA 0.035. *Dashed lines* are calculated additive values.

In all the experiments, we used 2% acetic acid as common solvent (hereinafter, solvent).

Films were prepared from 1.5% solutions of the components. It should be particularly noted that, since PVA is soluble in 2% acetic acid only on heating, we initially dissolved it in distilled water with heating, to avoid changes in the solvent composition. The concentration of the aqueous solution was about 3%. Then the cooled solution was diluted with a more concentrated solution of acetic acid, so as to obtain a solution containing 2% acetic acid and 1.5% polymer. Then the solutions of the components were mixed in volume ratios of 0.9 : 0.1, 0.8 : 0.2, 0.6 : 0.4, 0.4 : 0.6, 0.2 : 0.8, and 0.1 : 0.9. The mixed solutions were stirred and kept until air bubbles fully disappeared. Films were prepared by casting onto silicone-coated glass support, followed by drying in air to constant weight. All the films were homogeneous and transparent; their thickness was 30–50 μm.

The occurrence of intermolecular interactions in dilute mixed solutions of the polymers was judged viscometrically. Measurements were performed in a capillary Ubbelohde viscometer at a solvent outflow time of about 125 s at 25 ± 0.1°C. The measurement error did not exceed 3%.

The intermolecular interactions in films were studied by sorption of solvent vapor with films of various compositions (chitosan–PVA and chitosan–MC), using an experimental installation with a quartz spring balance at a saturated vapor pressure of the solvent at room temperature. Our approach was based on studying the equilibrium sorption of vapor by a polymer blend, which furnishes information on the polymer–polymer interactions. The experimental error did not exceed 5%.

Mechanical tests of the films were performed with a UMIV-3 tensile-testing machine in the extension mode at a rate of 5 mm min^{-1} (sample length 25 mm, width 2 mm, interclamp distance 15 mm). The tensile strength, relative elongation at break, and Young's modulus of the films were determined from the experimental stress–strain curves with a ≤10% error.

Specific intermolecular interactions of polymeric components in solutions (e.g., formation of interpolymeric complexes) are usually studied viscometrically, as this method is relatively simple and furnishes rich information. If the measured specific (or relative) viscosity of a polymer blend in a common solvent, η_{exp}, differs from the calculated additive value η_{ad}, this is regarded as an evidence of complexation. The procedure is well known [17–19]. The additive values are calculated from the experimental concentration dependences of the specific viscosities η_{sp}, measured for each component in the course of dilution with a pure solvent (2% acetic acid in our case) [19]:

$$\eta_{sp,\,ad} = \eta_{sp,\,\mathbf{A}}(c_{\mathbf{A}}) + \eta_{sp,\,\mathbf{B}}(c_{\mathbf{B}}), \qquad (1)$$

where $\eta_{sp,\,\mathbf{A}}(c_{\mathbf{A}})$ and $\eta_{sp,\,\mathbf{B}}(c_{\mathbf{B}})$ are the specific viscosities of polymers **A** and **B** at their concentrations $c_{\mathbf{A}}$ and $c_{\mathbf{B}}$, respectively; $c_{\mathbf{A}} + c_{\mathbf{B}} = c$, where c is the total concentration of the polymers in the blend.

Deviation of the experimental dependence of η_{sp} from the calculated additive dependence suggests the formation of complexes. A coincidence of the experimental and additive dependences means that interactions between the components are not pronounced: either the complexes are not formed, or the hydrodynamic volume of the complex macromolecule is equal to the sum of the hydrodynamic volumes of the components (which is most often due to the low molecular weight of one of the components). The same criterion is used as the criterion of compatibility of the polymers in solutions.

The experimental specific viscosities of 0.028% chitosan–MC and 0.035% chitosan–PVA solutions are plotted in Fig. 1 vs. the component ratio. It is seen that the calculated additive values coincide with the experimental values for all the polymer blends studied. These results suggest that strong specific intermolecular interactions in the chitosan–MC system are absent, and complexation is insignificant. In chitosan–PVA blends, the specific viscosities of PVA solutions at this concentration are extremely low (in contrast to

MC having η_{sp} comparable with that of chitosan). Therefore, it is difficult to make any definite conclusions about the occurrence or absence of complexation between chitosan and PVA.

Similar results for chitosan–PVA blends have been obtained previously [9]. However, Mukhina *et al.* [8] and Mucha [10] did detect formation of interpolymeric complexes of chitosan with PVA. This discrepancies may be due to the fact that, firstly, the sources of chitosans were evolutionarily different (from crab shells, Russia [8]; from Antarctic crill, Poland [10]; from crab shells, Japan [9]; chitosan purchased from Aldrich, this study), and, secondly, different solvents were used (0.33 M CH_3COOH + 0.3 M NaCl [8]; 1% CH_3COOH for chitosan and water for PVA and POE [10]; and 2% CH_3COOH for all the polymers in this study). Since chitosan–PVA and chitosan–MC blends remain transparent at concentrations of up to 1.5% and any component ratios, and the experimental η_{sp} of the blends do not differ from the calculated additive values, we can conclude that there is no phase segregation of the components in the concentration range studied.

The compatibility of the polymeric components in the blends was judged from the polymer–polymer interaction parameter χ_{23} [20], calculated from the results of experiments on sorption of saturated vapor by films cast from mixed 1.5% chitosan–MC and chitosan–PVA solutions in 2% acetic acid. The curves of solvent vapor sorption by films formed from polymer blends with various component ratios were obtained, and the equilibrium values of the specific sorption A ($g\,g^{-1}$) were determined. The polymer–polymer interaction parameters for films of each composition were calculated as follows [20]:

$$\chi_{23} = \frac{[\ln\Phi_1 + (1 - \Phi_1) + (1 - \Phi_1)(\chi_{12}\Phi_2 + \chi_{13}\Phi_3)]}{\Phi_2\Phi_3}, \quad (2)$$

where subscript 1 refers to the solvent (2% acetic acid), 2, to chitosan, and 3, to the modifying polymer (PVA or MC); χ_{23} is the polymer–polymer (chitosan–MC or chitosan–PVA) interaction parameter characterizing interactions of segments of different polymers; Φ_1 is the volume fraction of the solvent absorbed by the film in the course of the experiment; Φ_2 and Φ_3 are the volume fractions of the respective polymers in the swollen film; and χ_{12} and χ_{13} are the Flory–Huggins polymer–solvent (e.g., chitosan–2% aqueous acetic acid) interaction parameters.

The parameters χ_{12} and χ_{13} were calculated from the results of separate sorption experiments with films cast from solutions of the respective polymers, taken separately, in 2% acetic acid:

$$\chi_{12} = -(\ln\Phi_1^* + \Phi_2^*)/(\Phi_2^*)^2,$$
$$\chi_{13} = -(\ln\Phi_1^* + \Phi_3^*)/(\Phi_3^*)^2, \quad (3)$$

where Φ_1^*, Φ_2^*, and Φ_3^* are, respectively, the volume fractions of the solvent, chitosan, and modifying polymer (PVA or MC) in the swollen film cast from the solution of the separately taken polymer.

The polymer volume fractions Φ_2^* and Φ_3^* (in the films cast from solutions of the separate components) and Φ_{pol} ($\Phi_{pol} = \Phi_2 + \Phi_3$ in the films cast from the polymer blend; Φ_2 and Φ_3 were calculated from the initial component ratio in the blend) were calculated from the specific sorption A for each film:

$$\Phi_2^* = (1 + A\rho_2/\rho_1)^{-1},$$
$$\Phi_3^* = (1 + A\rho_3/\rho_1)^{-1}, \quad (4)$$
$$\Phi_{pol} = (1 + A\rho_{pol}/\rho_1)^{-1},$$

where ρ_2, ρ_3, and ρ_{pol} are the polymer densities determined gravimetrically; ρ_1 is the solvent density determined with a densimeter; and A is the specific sorption for each film.

The dependence of the specific sorption A on the film composition is shown in Fig. 2a. It is seen that, in chitosan–MC films with the fraction of MC exceeding 0.8 (Fig. 2a, curve *1*), the specific sorption of acetic acid vapor is appreciably decreased. All the other values differ insignificantly. The χ_{23} values calculated by formula (2) (Fig. 2b, curve *1*) are close to zero at an MC fraction in the films of up to 0.4 and positive at larger MC additions. These data show that, in blends with the MC fraction of 0.1–0.4, all the polymer–polymer and polymer–solvent interactions are identical to those occurring in solutions of each component, taken separately, in 2% aqueous acetic acid. An increase in the MC fraction above 0.4 makes this polymer incompatible with chitosan. Taking into account the viscometric data, these polymers can be concluded to be partially compatible in the blend.

For chitosan : PVA = 0.9 : 0.1 blends, addition of PVA drastically (by a factor of 2.5) decreases the specific sorption (Fig. 2a, curve *2*). As the PVA content in the system is increased further, the specific sorption smoothly decreases. The calculated χ_{23} values for these films are negative at any compositions (Fig. 2b, curve *2*), unambiguously suggesting full compatibility of this pair of the polymers.

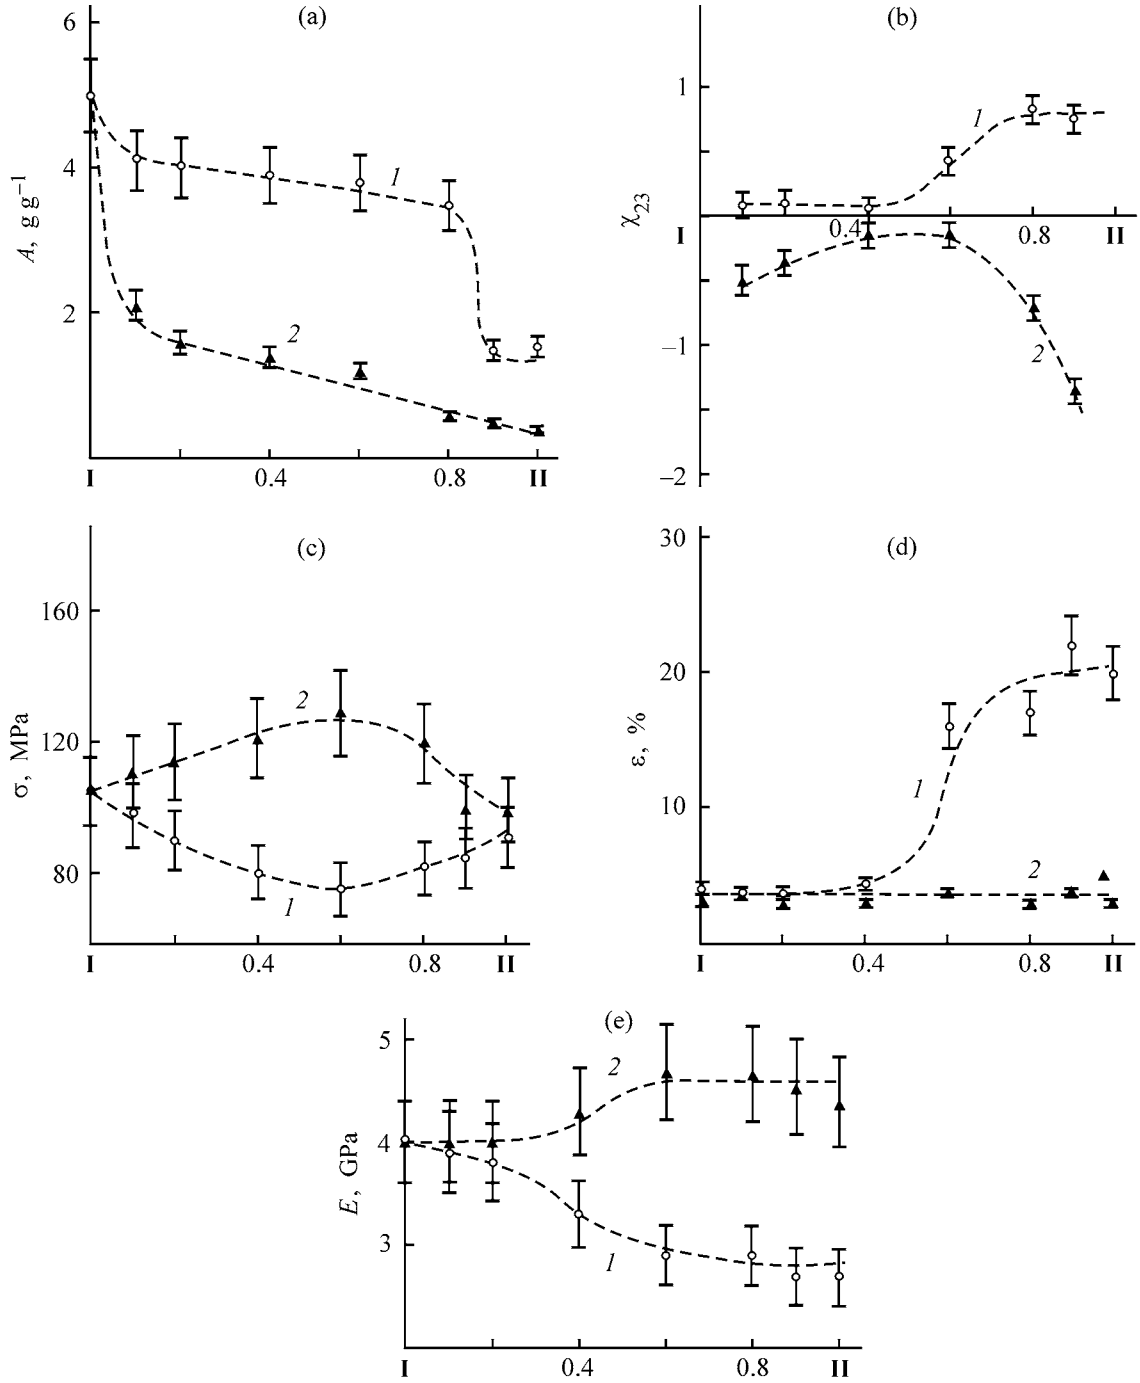

Fig. 2. (a) Specific sorption of the solvent (2% aqueous acetic acid), *A*; (b) polymer–polymer interaction parameter χ_{23}; (c) strength σ; (d) elongation at break, ε; and (e) Young's modulus *E* of (*1*) chitosan (**I**)–MC (**II**) and (*2*) chitosan (**I**)–PVA (**II**) films vs. their composition.

The results of mechanical tests of the films cast from blends of different compositions are shown in Figs. 2c–2e. The composition dependences of the elongation at break, strength, and Young's modulus deviate from the additivity. As the MC fraction in a chitosan–MC blend is increased to 0.5, the strength σ (Fig. 2c, curve *1*) and Young's modulus *E* (Fig. 2e, curve *1*) decrease to a similar extent (by approximately a factor of 1.4), compared to pure chitosan, whereas the elongation at break remains unchanged (Fig. 2d, curve *1*). At larger amounts of the MC added, the Young's modulus varies insignificantly (Fig. 2e,

curve *1*), but the strength (Fig. 2c, curve *1*) and especially elongation at break (Fig. 2d, curve *1*) grow: by approximately factors of 1.2 and 4.8, respectively. Thus, the MC fraction in chitosan–MC blends of 0.6 and higher is preferable.

In the chitosan–PVA system, no significant changes in the mechanical properties were revealed at any component ratios. As the PVA fraction in the blend was increased to 0.6, the strength (Fig. 2c, curve *2*) and Young's modulus (Fig. 2e, curve *2*) increased by a factor of approximately 1.2 compared to pure chitosan. Further increase in the PVA fraction in the blend caused a decrease in the strength and no changes in Young's modulus as compared to the above-indicated maximal values. The elongation at break varies insignificantly with the composition of chitosan–PVA films (Fig. 2d, curve *2*).

Comparison of the data obtained for the chitosan–MC and chitosan–PVA systems with those obtained previously for the chitosan–POE system [14] shows that the elastic properties of chitosan-containing films are improved at relatively high weight fraction of the second component: 0.6 MC in chitosan–MC films and 0.17 POE in chitosan–POE films. Actually we deal with polymer blends and films therefrom, rather than with modification of chitosan. Despite good fiber- and film-forming properties of PVA, the chitosan–PVA system is of no interest from the viewpoint of improving the elasticity of the films.

It should be noted that the weight fraction of the second component (MC or POE) that provides the best elastic properties of chitosan-containing films approximately corresponds to the stoichiometric ratio of the components in the blend. Furthermore, the components in the above systems are only partially compatible, and improvement of the elastic properties of the films is observed just in the composition range at which the components become incompatible (stoichiometric ratio; Fig. 2b, curve *1*). Thus, the improvement of the mechanical properties of films cast from solution and, in particular, the appreciable increase in their elongation at break, are due to combination of a favorable steric arrangement of macromolecules of different kinds and their partial compatibility, rather than to thermodynamic rigidity of the polymeric additive or specific interactions with chitosan (complexation with chitosan was not detected). Specifically the partial compatibility of the components, which does not result in their phase segregation, favors the ordering of the different macromolecules. Apparently, further search for chitosan-containing films and fibers with improved mechanical properties should be performed taking into account the polymer–polymer interaction parameter.

CONCLUSIONS

(1) In the systems chitosan–methyl cellulose and chitosan–polyvinyl alcohol, strong specific intermolecular interactions that would lead to formation of interpolymeric complexes do not occur.

(2) Experiments on sorption of solvent vapor show that chitosan and methyl cellulose are partially compatible, whereas chitosan and polyvinyl alcohol are compatible in the entire composition range.

(3) The strength of films cast from chitosan–methyl cellulose blends at any component ratio does not exceed that of the films cast from separate components.

(4) At a stoichiometric ratio of the components in the chitosan–polyvinyl alcohol system, the strength grows, but Young's modulus and elongation at break are close to those for films obtained from pure polyvinyl alcohol.

Abstract—Rheological properties of urethane-containing oligomers as influenced by intermolecular interactions in them were studied.

The great diversity of structures of urethane-containing oligomers and the complex nature of their synthesis reactions present a severe problem in studying the composition, final structure, and properties of these polymers [1].

The properties of urethane-containing oligomers are primarily governed by specific intermolecular interactions in them. Published data [1–4] suggest that intermolecular interactions and, in particular, hydrogen bonding, largely affect the physicochemical properties of oligomers containing reactive groups. A parameter highly sensitive to structural changes is viscosity of oligomers [5].

Romanovskii *et al.* [6, 7] have shown that the viscosity of oligomers whose molecules contain groups capable of hydrogen bonding significantly exceeds that of the oligomers of comparable molecular weights, but lacking such groups. It is believed that the major factor affecting the rheological properties of urethane-containing polymers, e.g., oligodienourethanoepoxide, are intermolecular interactions involving functional groups.

In this study, we examined the rheological properties of urethane-containing oligomers as influenced by intermolecular interactions. This seems to be a topical task in view of the development of studies of the structure and properties of polymers characterized by strong intermolecular interactions, as well as in view of the growing applications of such oligomers.

EXPERIMENTAL

Our experimental studies were performed with oligodienourethanoepoxide samples differing in the content of epoxy groups (see table).

The rheological properties were studied on a Rheotest 2.1 rotary viscometer at 25–60°C at shear rates of 0.024 to 70 s^{-1}.

Band intensities of the epoxy groups and bound and free carboxy groups, ratio of the band intensities of bound and free epoxy groups, and ratio of room-temperature viscosities at shear rates of 0.024 and 2.33 s^{-1}

Sample no.	Content of epoxy groups	I_{1223} (epoxy group)	I_{1735} (–C=O free)	I_{1710} (–C=O bound)	$\frac{I_{1735}}{I_{1710}}$	$\frac{\eta_{0.024}}{\eta_{2.33}}$
1	1.84	0.570	0.466	0.374	1.25	1.93
2	1.80	0.570	0.473	0.374	1.26	1.25
3	1.84	0.431	0.435	0.342	1.27	1.23
4	1.84	0.693	0.555	0.454	1.22	2.62
5	1.97	0.621	0.510	0.417	1.22	0.24
6	1.79	0.653	0.530	0.444	1.19	14.1
7	2.00	0.646	0.539	0.454	1.19	4.55
8	1.90	0.635	0.533	0.453	1.19	4.33

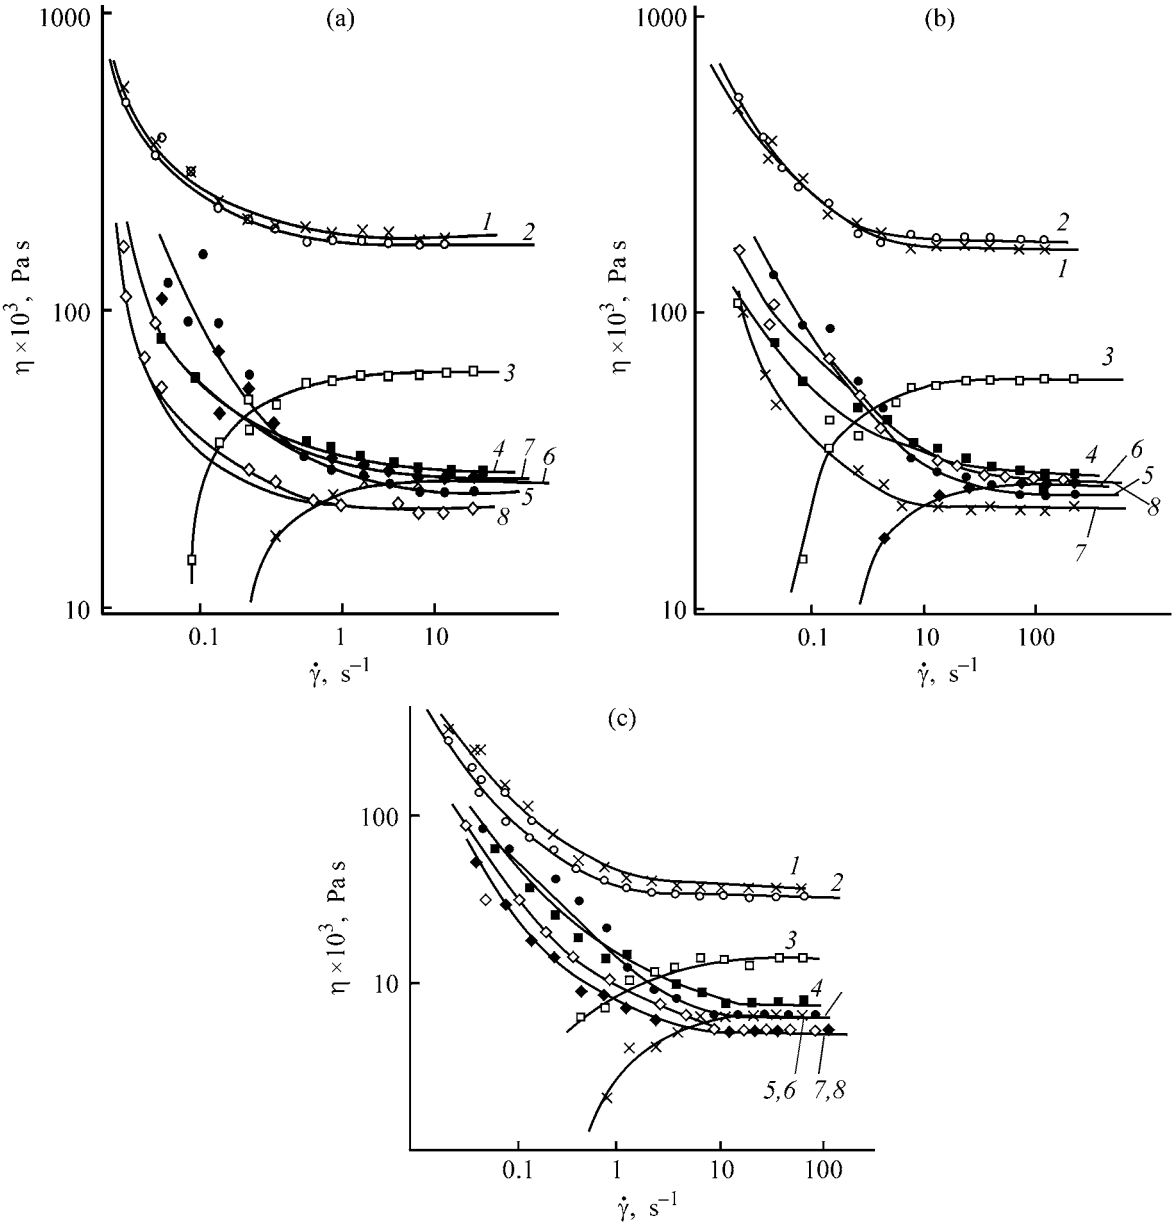

Fig. 1. Viscosity η of the oligodienourethanoepoxide samples vs. the shear rate $\dot{\gamma}$ at (a) 25, (b) 40, and (c) 60°C. *Figures at curves* correspond to sample nos. in the table; the same for Fig. 2.

The chemical structure of the samples was studied by infrared multiple attenuated total internal reflection (IR MATIR) spectroscopy on a Bruker IFS 66/S Fourier spectrometer using a KRS-5 crystal (α = 45°).

Figures 1a–1c show the results of the rheological studies. It is seen that the oligomer of interest is a non-Newtonian liquid. The maximum viscosity at high shear rates at all the temperatures was exhibited by sample nos. 1–3. Also, sample nos. 3 and 5 showed an abnormal rheological behavior: their viscosity tended to grow with increasing shear rate. This may be due to the branched structure of the molecules of these samples.

We determined the optical density ratio of the analytical to the reference band. As the reference served the band of the component whose concentration is known and invariable under the actual conditions [8, 9], in our case, the band at 2915 cm^{-1}, belonging to $-CH_2-$ groups.

For oligodienourethanoepoxide samples under study, the Amide I band lies 1760–1680 cm^{-1}. As

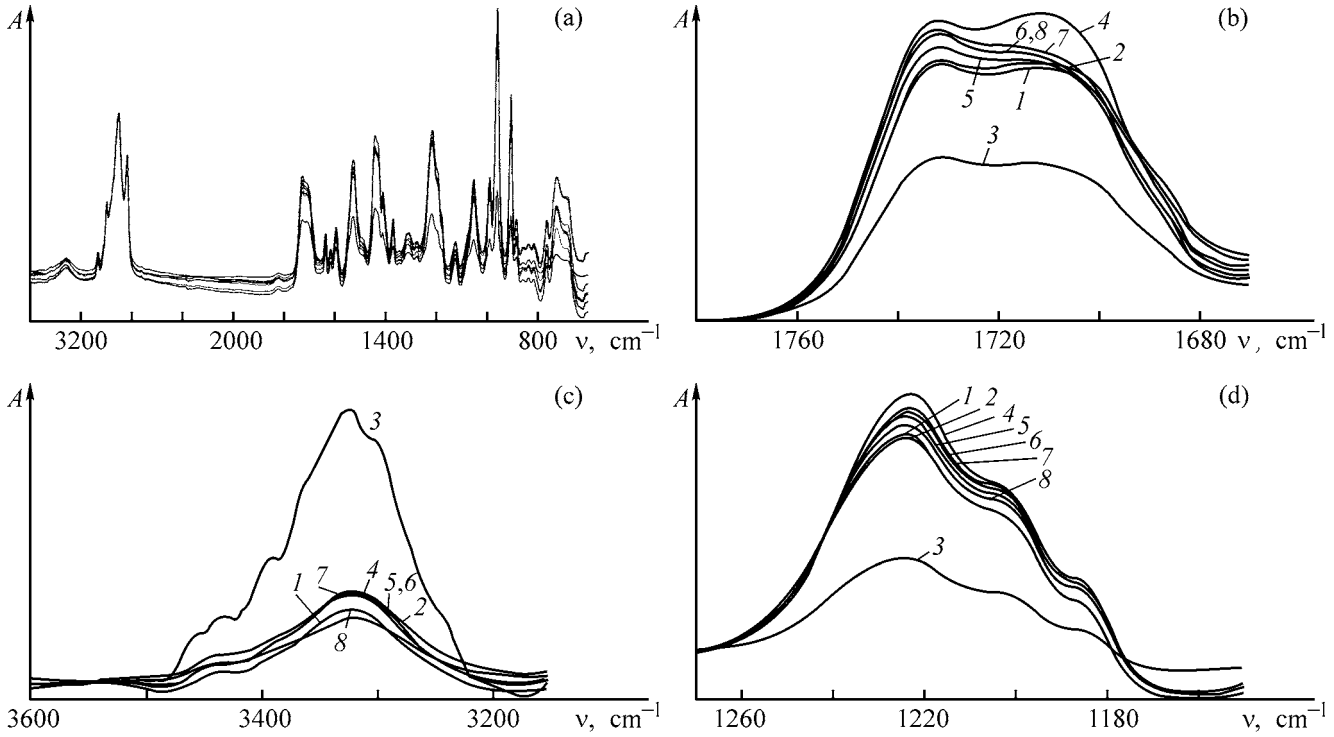

Fig. 2. (a) Total IR spectrum and (b, c, d) fragments corresponding to (b) Amide-I vibrations, (c) stretching vibrations of NH groups, and (d) vibrations of epoxy groups in different oligodienourethanoepoxide samples.(*A*) Absorption and (ν) wave number.

seen from the spectrum (Figs. 2a, 2b), this region contains a band at 1710 cm^{-1} (C=O). This band belongs to associates of urethane groups and can surpass in intensity the band at 1735 cm^{-1}, characteristic of the free C=O group. For the batch under study, the band at 1710 cm^{-1} is rather intense for all the samples, which suggests the presence of associates of urethane groups [10, 11].

The existence of three-dimensional associates in the oligomers under study is also evidenced by the IR data for the region corresponding to urethane groups, namely, bands at 3200–3500 cm^{-1} characteristic of stretching vibrations of the NH groups (Fig. 2c). It is seen from Fig. 2c that, in the spectra of sample nos. 1–5, the band corresponding to "free" NH groups (3440 cm^{-1}) is virtually lacking.

The tabulated data suggest that the relatively weak dependence of the viscosity of oligodienourethanoepoxides on the shear rate for sample nos. 1–3 is due to a lower concentration of hydrogen bonds (I_{1735}/I_{1710}) in these samples. At the same time, the high viscosities of these samples are, apparently, due to increased molecular weight of the product, as evidenced by the lower content of epoxy groups in these samples (see table; Figs. 2a, 2d).

CONCLUSIONS

(1) The rheological properties of oligodienourethanes that differ in the content of epoxy groups are strongly influenced by the chemical structure and intermolecular interactions. A decrease in the number of epoxy groups increases the molecular weight and, thus, the viscosity of the oligomer.

(2) A high content of hydrogen bonds is responsible for the increased viscosity and stronger influence of the shear rate on the non-Newtonian rheological behavior of the rubber.

Received June 3, 2003

Abstract—Relationship between the swellabilities of butyl rubber and polybutadiene in organic solvents and the physicochemical characteristics of solvents, including their capability for nonspecific and specific solvation, was studied.

The problem of quantitative evaluation of the solvent effect on the swellability of polymers in organic solvents is not yet satisfactorily solved. This is, evidently, due to the fact that the swelling process is attempted to be described using one-parameter equation. For example, the most commonly used relationships between the swellability and Hildebrand's solubility parameter δ, based on the regular solution theory and Flory–Huggins theory [1], yield fuzzy bell-shaped curves with strong deviations [2]. More or less acceptable correlation factors have been obtained only for homologous series of solvents [3]. This is true also for correlations with the molar volume of solvents [4]. It is well known, however, that the integral solvent effect is a resultant of a number of particular solvation effects. Therefore, in the chemistry of solutions, the solvent effect is treated in terms of the principle of linear free energies, using multiparametric equations that take into account the total change in the thermodynamic potential: $\Delta G = \Sigma \Delta g_i$ [5–8].

Such an approach appeared to be suitable for analysis of data on swellability of polyethylene [9] and natural carbonaceous polymers (coals) [10]. However, these polymers have relatively simple structures, and it was appropriate to check the applicability of multiparametric correlations to generalization of the swellability data for polymers of more complex structure.

Therefore, we applied in this study this approach to generalization of data on the swellability of vulcanized butyl rubber and polybutadiene in various organic solvents. Unlike other synthetic rubbers, these polymers contain no cycles or polar groups, so that their structures are, in principle, similar to the structure of polyethylene, which permits comparison of the swellability data. Rostler and White [11] studied the swellability of polyethylene in ten solvents. However, as they themselves noted, only qualitative conclusion like "the similar swells in the similar" could be drawn from their results (data were presented only graphically could not be used for quantitative processing). Reviewing this study, we only note that the maximum swelling to above 300 vol % was observed in cyclohexane. The increase in the volume in alkanes, dichloroethane, and CS_2 was determined to be above 200, and that in benzene, about 150 vol %. At the same time, in polar solvents, such as aniline, acetone, and hexanol, the swelling is less than 10 vol %, i.e., virtually no swelling is observed. Diethyl ether stands intermediately.

Bristow and Watson [2] the studied swelling of butyl rubber in more detail. They used Butyl-400 commercial polymer containing 5% ZnO, 2% S, 1% tetramethylthiuram disulfide, and 1% stearic acid, vulcanized at 150°C, and then extracted with acetone. The density of the sample was 0.91 g ml^{-1}. The 0.25-g samples were swollen for three days at 25°C, dried, and weighed. The results were represented as the polymer volume fraction V_2 in the swollen sample (Table 1). However, analysis of these data in terms of Flory's theory appeared to be unsuccessful: even in a series of *n*-alkanes C_5–C_{16}, the dependence of V_2 on the Hildebrand's solubility parameter δ was represented by a fuzzy broken-line function with a minimum for *n*-heptane.

Bristow and Watson [2] wrote that the cohesion energy density may be only an available indication of a certain mutuality in the system polymer–sol-

1,4-Dioxane	0.8719	0.0006	–2.7226	–1.4765	0.7556

vent, but only a rather approximate indication, as, generally, other significant factors exert influence too.

It is noteworthy here that the use of the polymer volume fraction in a swollen polymer as a correlating factor is incorrect: if swelling is considered a thermodynamically reversible process, it is necessary to use the mole fraction of a solvent as a parameter. Therefore, we recalculated V_2 to the solvent uptake in moles S_M (Table 1). Because of the high average molecular weight of the polymer, we did not recalculate the polymer volume to the moles.

We generalized data from [6] using Eq. (1).

$$\log S_M = a_0 + a_1\frac{n^2-1}{n^2+2} + a_2\frac{\varepsilon-1}{2\varepsilon+1} + a_3B + a_4E_T + a_5\delta^2 + a_6V_M, \quad (1)$$

where n is the refractive index; ε, the dielectric constant; B, Palm's basicity [5]; E_T, Reichardt's electrophilicity index [2]; δ, Hildebrand's solubility parameter; and V_M, molar volume of a solvent.

The first four terms of the equation reflect the effects of specific and nonspecific solvation. They are commonly used in the chemistry of solutions to reproduce the solvent effect on the chemical reaction rate, some spectroscopic characteristics, etc. The cohesion energy density characterizes self-association of a solvent and, correspondingly, the energy consumption for detachment of its molecule from the structure. High molar volume of a solvent, as a rule, hinders penetration of solvent molecules to the polymer structure, thereby decreasing the swellability. However, Aminabhavi *et al*. [4] have demonstrated that these are correlated, but not proportional parameters. Accordingly, for all the 18 solvents studied, calculation by Eq. (1) gives the multiple correlation factor $R = 0.876$, which is unacceptably low [1]. After excluding from consideration data for only two solvents, bromoform and dibromoethane, as the most outlying, R increased to 0.977. In this case, we obtain Eq. (2) reproducing the solvent effect on the swellability of butyl rubber with an acceptable accuracy.

$$\log S = -0.911 + (6.45 \pm 1.50)f(n^2) + (4.32 \pm 0.74)f(\varepsilon) - (3.47 \pm 0.25) \times 10^{-3}B - (0.07 \pm 0.03)E_T - (1.69 \pm 0.93) \times 10^{-3}\delta^2 - (3.62 \pm 0.54) \times 10^{-3}V_M; \quad (2)$$

$$R = 0.977, \; s \pm 0.09.$$

This equation, as well as all the equations presented below, is adequate, as demonstrated by comparison of the estimated Fisher test parameter F with the tabulated values for the corresponding number of degrees of freedom at a 95% confidence level [12]. Analysis of the signs at separate terms of the equation shows that the capacity of the solvents for specific interaction prevents their penetration into the nonpolar struc-

Table 2. Solvent volume fraction V_2 in swollen polybutadiene [14] and solvent uptake S_M (mol), determined experimentally and estimated by Eq. (5)

Solvent	V_2	$S_{M(exp)}$	log $S_{M(exp)}$	log $S_{M(calc)}$	Δlog S
Hexane	1.40	0.0110	–1.9731	–1.9325	0.0406
Heptane	1.48	0.0100	–1.9983	–1.9483	0.0499

Cyclohexane	3.05	0.0280	–1.5494	–1.5486	0.0886
Tetrachloromethane	4.35	0.0450	–1.3460	–1.3861	–0.0401
p-Xylene	3.84	0.0310	–1.5123	–1.4829	0.0294
Ethylbenzene	3.63	0.0300	–1.5280	1.4998	0.0281
Toluene	3.91	0.0370	–1.4366	–1.4175	0.0191
Benzene	3.51	0.0390	–1.4060	–1.4365	–0.0305
Choroform	4.50	0.0560	–1.2525	–1.2534	–0.0875
Nitrobenzene	0.98	0.0098	–2.0186	–0.4917	–0.0153
1,4-Dioxane	1.32	0.0150	–1.8099	–1.8167	–0.0068

ture of the polymer; as expected, an increase δ^2 and V_M has an antiswelling effect. At the same time, nonspecific solvent–rubber interactions favor swelling. However, low pair correlation factors (r_1 = 0.176, r_2 = 0.549, r_3 = 0.804, r_4 = 0.664, r_5 = 0.302, and r_6 = 0.08) do not permit evaluation of the separate contributions of the equation parameters, and high standard deviations of some regression coefficients suggest their nonsignificance.

The significance of contributions of particular factors to log S_M was examined by alternate exclusion of separate terms of the equation, with R determined in each case [12]. The calculation revealed nonsignificance of the cohesion energy: its exclusion has no considerable effect on R.

$$\log S_M = -0.07 + (4.84 \pm 1.34) f(n^2) + (4.59 \pm 0.80) f(\varepsilon) - (3.55 \pm 0.27) \times 10^{-3} B - (0.10 \pm 0.02) E_T - (3.48 \pm 0.59) \times 10^{-3} V_M; \quad (3)$$

$$R = 0.972, \; s \pm 0.10.$$

But exclusion of any other term, especially V_M or B, decreases R to below the acceptable value R 0.95.

As can be seen from Table 1, for all the solvents studied, except $CHBr_3$ and $C_2H_4Br_2$, the ΔS values ($\Delta\log S = \log S_{calc} - \log S_{exp}$) are within the determination error ($s \pm 0.10$) or only slightly exceed it.

Therefore, generalization of data on the swellability of butyl rubber in various solvents allows prediction of swelling of butyl rubber in other solvents. Also, multiparametric analysis of the solvent effect provides a better insight into the swelling mechanisms.

To validate our approach, we similarly generalized data on swelling of polybutadiene, reported by Scott and Magat [13]. They determined the solvent uptake in 5 days at 25°C. The density of the initial cross-linked sample was 0.976, and the average molecular weight of the polymer units between cross-links, 5600, i.e., the cross-links are arranged at average intervals of 400 carbon atoms.

The solvent uptake in volumes per unit volume of the polymer (V_2) and in moles (S_M), and also log S_M values are listed in Table 2.

The initial value R 0.909, obtained for the entire set of 13 solvents, is unsatisfactory. According to the IUPAC recommendations for generalization of correlation analysis data [8], we excluded from consideration the data for nitrobenzene as the most outlying, and obtained Eq. (4) characterized by an excellent R 0.996, s ±0.02, and the following pair correlation factors: r_1 = 0.707, r_2 = 0.702, r_3 = 0.064, r_4 = 0.570, r_5 = 0.598, and r_6 = 0.703.

$$\log S_M = -1.17 + (3.24 \pm 0.63) f(n^2) + (5.08 \pm 0.89) f(\varepsilon) - (1.85 \pm 0.43) \times 10^{-3} B - (0.10 \pm 0.02) E_T + (4.03 \pm 0.84) \times 10^{-3} \delta^2 - (1.56 \pm 0.77) \times 10^{-3} V_M. \quad (4)$$

As in the case of polyethylene [9], the higher the solvent molar volume V_M and its capacity for specific interaction, the lower the swellability of polybutadiene. At the same time, the strong tendency of a solvent toward nonspecific solvation promotes swelling.

The terms of the cohesion energy density $f(\delta^2)$ and basicity (B) in Eq. (4) are nonsignificant, and the solvent effect on swelling of polybutadiene can be sat-

isfactorily reproduced using a four-parameter equation (5).

$$\log S_M = -0.51 + (5.77 \pm 0.61) f(n^2) + (6.39 \pm 0.71) f(\varepsilon) - (0.11 \pm 0.01) E_T - (4.63 \pm 0.76) \times 10^{-3} V_M; \quad (5)$$

$$R = 0.988, \; s \pm 0.04.$$

Further decrease in the number of parameters is unacceptable, as resulting in an abrupt decrease in *R*.

The sign and significance of separate terms of Eqs. (2) and (4), and (3) and (5) only slightly differ from each other, suggesting that, despite the difference in the polymer structure (methyl branching in butyl rubber and double bonding in polybutadiene), the swelling mechanisms are quite similar, being controlled essentially by their backbone structure.

CONCLUSIONS

(1) The swellability of a polymer in organic solvents depends on the integral solvent effect, which can be estimated on the basis of the principe of linear free energies, using multiparametric equations.

(2) Swelling of butyl rubber and poly(isobutylene) is controlled essentially by the molar volume of a solvent. Both nonspecific and specific solvation effects also contribute significantly, but not the cohesion energy density of a solvent.

Received October 8, 2003

Abstract—Formation of a consolidated bed by carbon sorbent and oil in sorption removal of spilled oil was observed and substituted experimentally; the dynamics of this process was analyzed. A process for eliminating oil spills on the water surface using a carbon sorbent was developed.

Large-scale spills of oil and petroleum products upon mechanical or corrosion failure of pipelines and upon incidents on water, railway, and motor transport are important sources of environmental pollution, often causing real ecological catastrophes. The environmental damage on spilling of 1 ton of oil in water and soil can be estimated at 3 104 500 and 3 528 000 rubles, respectively (costs as of 1997) [1]. Removal of oil and petroleum products spilled over the soil and, especially, water surfaces is rather complex and laborious technical problem. Oil is removed from the water surface using barrier and pump systems, oil-spill boats, and various sorbents [2–6], including both special sorbents or industrial and agricultural wastes [7–10] (Table 1).

Finely dispersed sorbents, e.g., chopped straw and cane, peat, moss, buckwheat husk, rubber crumb, and special sorbents (Lessorb, Peat Sorb) allow relatively simple collection of spilled oil. This procedure includes two main stages: distribution of the sorbent over the oil–spill surface and collection of the sorbent with adsorbed oil from the surface using gauze frames, shovels, scoops, and other instruments, with the collected matter in special tanks. However, analysis of the physical interaction of various sorbents with oil layer revealed rather important dynamic changes in the sorbent–oil system upon their contact.

A fine sorbent added to an oil layer forms a specific three-dimensional structure between the upper surface of the oil layer and water surface (Fig. 1). Within several minutes, oil fills these free voids, and the resulting sorbent–oil system can be recovered using, e.g., gauze apparatus. However, the resulting sorbent–oil system is unstable, and in the course of removal not only water, but also certain fraction of sorbed oil escape through the gauze. In this case, the sorbent–oil system acts as a non-Newtonian liquid and spreads from the zone of treatment of the oil spill to the zone of removal of the spent sorbent (Fig. 2). As a result, the total area of the oil spill remains unchanged, with only result that the sorbent bed layer containing oil on the water surface becomes thinner. In this case, manual labor expenditures are very high, because multiple treatment to remove diffluent spent

from the same section of the oil spill is required. For the same reason, the efficiency of mechanical devices in removal of spent sorbent, e.g., bucket elevator with gauze ladles, is also low.

Quite a different pattern is observed in sorption of spilled oil using carbon sorbents. The carbon sorbent (CS), being a product of carbonization of the wastes of merchantable wood treatment, is produced on an industrial scale [11]. Finely dispersed macroporous carbon sorbent (technical carbon) produced in this process is characterized by 0.170 g cm^{-3} bulk density and free volume of 4.18 cm^3 per gram of sorbent. This sorbent, consisting predominantly of needle-like particles (3.5–6 mm long and 0.47–0.71 mm thick), exhibits high hydrophobic and lipophilic properties, and it can sorb up to 4 g oil per gram of sorbent (Table 2). Hence, it is rather competitive compared with the other sorbents studied (Table 1).

The data on the oil removal performed on the model systems with oil spill 0.5 m in diameter and in the course of pilot tests of the carbon sorbent at an accidental oil spill near Pyt'-Yakh town (Khanty-Mansi Autonomous District) showed that the system consisted by a carbon sorbent and oil is characterized by some specific features untypical of other sorbents. Removal of the CS–oil system in 1–5 min after treatment of the oil spill proceeds similarly to that with the other fine sorbents (Fig. 2), whereas keeping this system on the water surface for several hours causes formation of a rather strong sorbent–oil system, which prevents spill of oil from the recovered spent sorbent over the cleaned water surface; this is also the case when the spent sorbent is removed from the water surface using gauze frames (Fig. 3). We also observed no spreading of the layer remaining on the water surface toward the cleaned zone. Such a strong CS–oil layer was named consolidated bed. The strength of this bed is so high that it holds branches and boards on the surface, though its density is smaller that that of the load (wood).

Two concepts concerning the mechanism of formation of this consolidated bed were suggested. (1) Evaporation of the light oil fractions in the course of keeping of the CS–oil system provides strengthening of the system owing to increasing viscosity of the oil remaining in the consolidated bed. (2) Formation of the "carpet" CS–oil system is related to slow diffusion of oil in microchannels at the particle interface due to capillary forces, which "glues" sor-

Table 2. Sorption capacity of carbon sorbent in removal of petroleum products from the water surface, 5 min contact time

Petroleum product	Sorption capacity, g per gram of sorbent
Oil from Tyumen field	4.27–4.34
Oil from Shaim field	4.13–4.35
Oil from Arlan field	4.4–4.5
Diesel oil	4.04–4.13

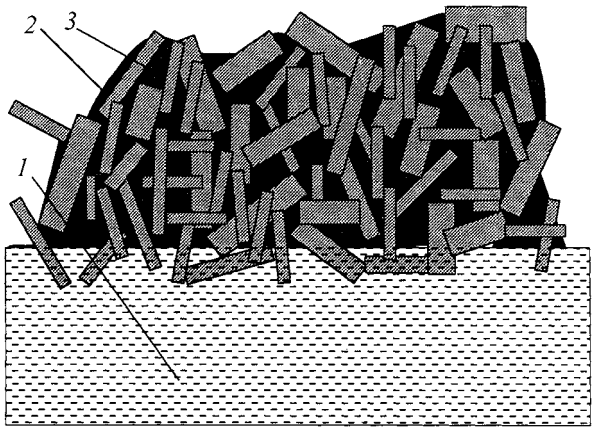

Fig. 4. Formation of a consolidated CS–oil bed on the water surface: (*1*) water, (*2*) oil, and (*3*) sorbent.

bent particles and improves the retention of oil in the free voids of the sorbent (Fig. 4).

The mechanism of the sorbent–oil consolidation on the water surface was studied on a laboratory setup equipped with a different-arm balance allowing registration of the forces appearing in removal of a fragment of the sorbent–oil system from the water surface with a gauze. In the course of the experiments, we determined the force of adhesion between the gauze and water, the force required to remove certain fragment of the sorbent–oil system from the whole layer of the spent sorbent, the weight of this removed fraction, the force acting at the perimeter and over the area of the boundary between the whole sorbent–oil system and its removed fragment. In our experiments, we used both fresh oil of the Arlan field (801 kg m^{-3} density, 30 mm^2 s^{-1} viscosity) and oil artificially aged by evaporation in air for 2 weeks in a hood, whose viscosity was greater than that of the fresh oil by a factor of 15 (920 kg m^{-3} density, 450 mm^2 s^{-1} viscosity).

It was found that, with increasing contact time in the CS–oil system, the degree of consolidation of the system increases to a certain level for both fresh and aged oil (Fig. 5). The reliability of experimental data in a series of replicate tests was confirmed by statistical analysis in accordance with Student's test [12].

In both cases, the stable consolidated CS–oil system is formed in 2 h. Our experimental data showed that the formation of this consolidated CS–oil bed is not due to partial evaporation of the oil and the related increase in its density and viscosity on keeping for 2–6 h, because the consolidation of the aged oil proceeds similarly to that of the fresh oil. If evaporation of the light oil fractions were responsible for the bed consolidation, then, for the aged oil, the dependence of the force acting at the perimeter and over the area of the boundary between the whole sorbentoil system and its removed fragment would be nearly constant in time. However, as can be seen from the experimental data, these dependences are similar for both aged and fresh oil.

The second concept of fuller impregnation of the sorbent bed with oil in the course of the system keeping as the reason for bed consolidation was not confirmed either, because our additional studies of the kinetics of oiling of a 60–70-mm sorbent bed on bringing its bottom in contact with an oil layer showed that, already after 10 min of contact, the height of the oil lift was 10–20 mm. The kinetics of sorption of the oil of Arlan field aged for 1 month (67 mm sorbent bed, 531.5 mm s^{-1} viscosity) on the carbon sorbent is illustrated below:

Height of the oil lift in the sorbent, mm	Contact time of oil and sorbent, min
2	2
5	5
10	10
20	15
30	17
40	19
50	21
60	23

In the studies of the consolidation of the CS–oil system, the layer thickness was 10 mm. A twofold increase in the layer thickness after the same contact time of the sorbent and oil did not change the specific disruptive force at the boundary between the whole sorbent–oil system and its fragment being removed.

Our experimental data suggest that an additional intermolecular interaction appears between the sorbent surface and oil in narrow slits between the fine sorbent particles. This concept is confirmed by computer simulation of nanostructures formed by spread-

ing of small drops over microheterogeneous supports [13]. These data show that four compact "legs" are formed in the microdrop, which support its upper section and provide strong and stable contact between the nanoobject and heterogeneous solid surface. At low- and high-energy sections of the surface the molecular clusters are formed, which round low-energy sections or link high-energy sections. This concept is confirmed by the fact that the cogesion energy (energy necessary for rupture of the oil layer) determined from the surface tension of the fresh and aged oil, respectively, constitutes 0.08–0.10 g cm^{-2}, which is smaller by a factor of 5–7 than the specific disruptive energy at the boundary between the whole sorbent–oil system and its fragment being removed (0.68–0.75 g cm^{-2}).

This phenomenon of consolidation of the CS–oil system allows the process of oil removal to be simplified by elimination of a multiple treatment of the oil spill with sorbent the consumption of the sorbent and labor and the cost of the process thereby lowered.

We suggest the following scheme for removing oil spill with the use of a dispersed carbon sorbent.

(a) Evaluation of the oil spill capacity by its area and oil layer thickness according to Table 3.

(b) Evaluation of the amount of carbon sorbent required, using Table 4.

(c) Uniform distribution of the dispersed carbon sorbent over the oil spill area with a pneumatic batcher to provide complete oiling of the sorbent.

(d) Keeping of the sorbent bed with sorbed oil for at least 2 h to form a consolidated sorbent–oil system.

(e) Removal of the consolidated sorbent–oil bed by scoops or mechanical elevators or drags and storage of the spent sorbent in special tanks.

(f) If necessary, secondary treatment of the water surface with a small amount of dispersed carbon sorbent to remove separate spots and films of oil.

(g) Transportation of the spent sorbent to special installation for oil recovery.

(h) Further regeneration of the spent sorbent, e.g., burning out of residual oil.

CONCLUSIONS

(1) At a contact time of no less than 2 h, a consolidated CS–oil bed is formed upon treatment with carbon sorbent of an oil spill on the water surface; this bed is easily removed from water without its secondary pollution.

(2) The specific disruptive energy at the boundary between the whole sorbent–oil system and its fragment being removed is greater by a factor of 5–7 than the cohesion energy (energy of the oil layer rupture).

(3) A scheme of the process for removal of spilled oil from the water surface using a carbon sorbent to form a consolidated sorbent–oil bed is suggested.

BRIEF COMMUNICATIONS

Partial Pressure of Saturated Sodium Nitrite Vapor over the System $NaNO_2$–$NaNO_3$

V. I. Glazov, G. P. Dukhanin, M. Kh. Dkhaibe, and V. A. Losev

Volgograd State Technical University, Volgograd, Russia

Received November 13, 2003

Abstract—The partial pressure of sodium nitrite was measured in the system $NaNO_2$–$NaNO_3$ at temperatures of 798, 823, and 848 K and the logarithm of the $NaNO_2$ pressure was obtained as a function of inverse temperature. The coefficients A and B of the Clausius–Clapeyron equation and the partial molar heats of evaporation were calculated. The activities and activity coefficients of sodium nitrite were determined for various compositions of the system $NaNO_2$–$NaNO_3$.

In continuation of studies of the physicochemical and thermodynamic properties of molten nitrite–nitrate systems [1–4], the partial pressure of saturated sodium nitrite vapor was measured over the system $NaNO_2$–$NaNO_3$.

The procedure of salt preparation, the experimental setup, and the method used for analyzing the condensate of the vapor phase have been described previously [1, 4]. The saturated vapor pressure of sodium nitrite over liquid $NaNO_2$–$NaNO_3$ mixtures was measured at 798, 823, and 848 K. The temperature dependence of the sodium nitrite vapor pressure is described by the Clausius–Clapeyron equation $\log P = B - A/T$.

The results obtained in measuring the vapor pressure of sodium nitrite over melts of various compositions, as well as the calculated coefficients of the Clausius–Clapeyron equation and partial molar heats of $NaNO_2$ evaporation, are listed in Table 1. The logarithm of the vapor pressure of sodium nitrite at its varied content in the melt is shown as a function of inverse temperature in Fig. 1.

The coefficient of linear correlation of $\log P$ as a function of $1/T$ is in the range from 0.78 (at low sodium nitrite concentrations) to unity.

As shown previously [4], the concentration behavior of the curves for partial pressures of sodium

nitrite and nitrate shows negative deviations from the Raoult law. Under isothermal conditions, the vapor pressure of sodium nitrite grows steadily with decreasing content of the second component.

As the content of sodium nitrite in the system decreases, the heat of its evaporation becomes higher, which points to increasingly enhanced interaction of particles in the melt.

The experimental values of the saturated vapor pressure over a pure component, P_i^0, and partial pressures of this component, P_i, in the system were used to calculate the activities a_i and activity coefficients γ_i of sodium nitrite in the system $NaNO_2$–$NaNO_3$. The results obtained are listed in Table 2.

The activities and activity coefficients of sodium nitrite in the system under study have been reported previously [4].

Figure 2 shows the temperature dependences of the activity and activity coefficient of sodium nitrite and nitrate vs. the content of $NaNO_3$ in the system at 798 and 848 K.

It can be seen from Fig. 2 that the activities of sodium nitrite and nitrate show negative deviations from the concentrations expressed in mole fractions, and, therefore, the calculated activity coefficients are less than unity. The isotherms of sodium nitrite activity show large negative deviations. The negative deviations point to a certain extent of complexing in

the system [4, 5]. With increasing temperature, the negative deviations become less pronounced.

CONCLUSIONS

(1) The partial pressure of sodium nitrite in the system $NaNO_2$–$NaNO_3$ was determined at 798, 823, and 848 K. The temperature dependence of the vapor pressure was found to be described by the Clausius–Clapeyron equation.

(2) The experimental values of the saturated vapor pressures over pure components and the partial pressures of these components over the system were used to calculate the activities and activity coefficients of sodium nitrite. It was established that the activities of both the components show negative deviations from the ideal behavior, and the activity coefficients are less than unity. This points to a certain extent of complexing in the system.

BRIEF COMMUNICATIONS

Catalytic Transformations of Bornyl Chloride under the Action of $AlCl_3$

E. V. Vishnyakova, V. A. Utsal', and D. A. Ponomarev

St. Petersburg State Forestry Academy, St. Petersburg, Russia

Received June 2, 2003

Abstract—The composition of products formed in catalytic transformations of bornyl chloride under the action of $AlCl_3$ was studied.

Turpentine, which is a mixture of monoterpenes $C_{10}H_{16}$, is one of the main products of the wood-chemical industry and serves as starting raw material for synthesis of various substances, e.g., those used in the perfumery-cosmetic industry [1]. In some cases, obtaining the target product involves a preliminary isomerization of the starting monoterpenes, which yields substances with various types of carbon skeletons. In the course of isomerization under the action of acid catalysts, the double bonds of monoterpenes are frequently involved in polymerization processes, which leads to a decrease in the output of the target product [2, 3]. Therefore, it seemed appropriate to study acid-catalytic transformations of mono halogen derivatives of monoterpenes. In this case, the polymerization processes mentioned above do not occur, which makes it possible to synthesize valuable products in good yield from the available vegetable raw materials.

EXPERIMENTAL

Bornyl chloride (BCh), *endo*-2-chloro-1,7,7-trimethyl[2.2.1]bicycloheptane, which can be easily synthesized from α- and β-pinenes [4, 5], was chosen as object of study. As catalysts were taken $AlCl_3$ (Aldrich) and $ZnCl_2$ (prepared by calcination of $ZnCl_2$ in the presence of several drops of concentrated HCl), which are a strong and a relatively weak Lewis acids, respectively. It was assumed that treatment of BCh with these acids leads to formation of a mixture of halogenocycloalkanes $C_{10}H_{17}Cl$ (isomeric to BCh), whose structure and relative amounts depend on the process conditions. Despite the fact that the isomerization transformations of hydrochlorides of bicyclic monoterpenes have been already studied for 80 years [6], the mechanisms of the rearrangements observed remain open to question [7].

The starting BCh was obtained by addition of HCl to α-pinene [4] and, after recrystallization from petroleum ether (40–70°C) and further purification by column adsorption chromatography (silica gel, petroleum ether as eluent), had melting point of 135–136°C [96% main substance according to gas–liquid chromatography (GLC)]. As solvent in the reaction of catalytic treatment served hexane or trichloroethylene. The conditions of the catalytic treatment are listed in the table.

After decomposition and drying, the composition of the reaction mixture was analyzed on a Hewlett–Packard 5995 mass-spectrometer in the programmed-temperature mode. The chromatogram was recorded as the total ion current in the range of masses 50–300.

An analysis of the composition of the reaction products by chromato-mass-spectrometry demonstrated that the catalytic transformations of BCh yield multicomponent mixtures, in which it is difficult to distinguish any main component. The peaks in the chromatograms can be distinctly divided, depending on their retention time, into several groups, among which groups with retention times of 5.5–1.5, 13–18, 20–23, and 33–45 min were distinguished.

An analysis of the mass spectra of the compounds that correspond to each of the groups distinguished showed that the first group comprises hydrocarbons of composition $C_{10}H_{16}$ and $C_{10}H_{18}$, for which the corresponding peaks of molecular ions were recorded. By comparison with a spectrum contained in the database of the spectrometer, one of the compounds was identified as *trans*-decaline, which was additionally confirmed by GLC. A comparison of the mass-spectra obtained with those of trimethyl bicyclo[2.2.1]heptanes, reported in [8], revealed the presence of *endo*-1,2,4-trimethyl, *exo*-1,2,4-trimethyl, and 1,4,7-trimethyl de-

6	1 : 3 : 20	4	20	$C_{10}H_{16}$, $C_{10}H_{18}$, $C_{10}H_{17}Cl$, $C_{10}H_{16}Cl_2$, $C_{20}H_{32}$, $C_{20}H_{34}$, $C_{20}H_{33}Cl$
7	1 : 3 : 200	4	20	$C_{10}H_{16}$, $C_{10}H_{18}$, $C_{10}H_{17}Cl$, $C_{10}H_{16}Cl_2$, $C_{20}H_{32}$, $C_{20}H_{34}$, $C_{20}H_{33}Cl$
8	1 : 3 : 20	4	0	$C_{10}H_{16}$, $C_{10}H_{18}$, $C_{10}H_{17}Cl$, $C_{10}H_{16}Cl_2$, $C_{20}H_{32}$, $C_{20}H_{34}$, $C_{20}H_{33}Cl$
9	1 : 3 : 4	4	0	$C_{10}H_{16}$, $C_{10}H_{18}$, $C_{10}H_{17}Cl$, $C_{10}H_{16}Cl_2$, $C_{20}H_{32}$, $C_{20}H_{34}$, $C_{20}H_{33}Cl$

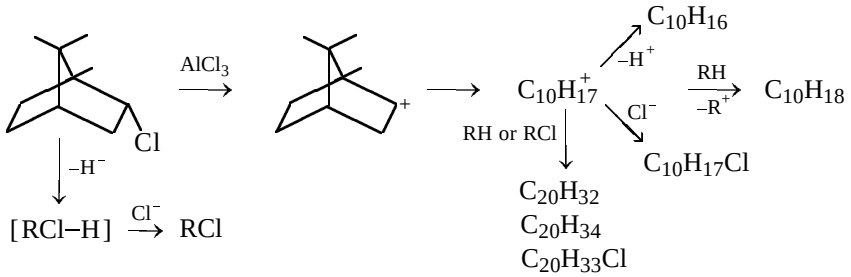
* $ZnCl_2$ was used as catalyst.

rivatives of bicyclo[2.2.1]heptane in the products of catalytic transformations of BCh. 1,7,7-Trimethyl bicyclo[2.2.1]heptane (bornane), whose formation by transfer of the hydride ion to the bornyl cation would be expected, was not found among the reaction products.

In the next (as ranked with respect to retention time, 13–18 min) group of chromatographic peaks, bicycloalkyl chlorides were found. It was impossible to attribute the components of this group to halogenoalkanes by means of mass-spectrometry, because of the absence of peaks related to molecular ions. For this group of compounds, the greatest mass number m/z = 137 corresponds to a fragment ion $[M–Cl]^+$. These compounds were identified as halogenoalkanes by GLC, according to the presence of the peak corresponding to the starting BCh in this group of peaks.

An analysis of the mass-spectra of the compounds responsible for the group of chromatographic peaks with retention time of 33–45 min made it possible to identify these compounds as hydrocarbons of composition $C_{20}H_{32}$ and $C_{20}H_{34}$. The presence of doublet peaks of molecular ions, which are characteristic of chloroderivatives, also revealed compounds of composition $C_{20}H_{33}Cl$ in this group.

Thus, a study of the qualitative composition of a mixture of reaction products made it possible to suggest the following scheme of catalytic transformations of BCh under the action of $AlCl_3$:



CONCLUSIONS

(1) Treatment of bornyl chloride with $AlCl_3$ at 0–20°C yields a complex mixture of bicycloalkanes and bicycloalkyl chlorides. Changing the temperature and concentration of the reaction mixture has no effect on the qualitative composition of the products.

(2) By making smaller, within certain limits, the amount of the catalyst, the reaction time, and the concentration of the reaction mixture, the reaction can be directed toward formation of bicycloalkyl chlorides, whose content in the reaction mixture is at a maximum (60%) under the conditions of run no. 7 (see table).

Received July 1, 2003

Abstract—With the aim to prolong the effect of a wide-spectrum antimicrobial agent, Farmazin (tylosine tartrate), this drug was immobilized on a gel of *N*-vinylcaprolactam–sodium itaconate copolymer, which undergoes a phase transition on heating. The phase transition, accompanied by a change in volume, in aqueous solutions of the pure copolymer gel and that with the immobilized drug was studied.

Hydrophilic network polymers (hydrogels), thanks to the set of their unique physicochemical properties, are widely used in various fields of medicine, agriculture, biotechnology, and electronics [1–5]. For example, some representatives of this class, owing to favorable balance of the hydrophilic and hydrophobic units, undergo thermally induced collapse upon slight variation of the temperature of the ambient [6, 7]. Such polymers find growing applications in pharmaceutics for thermally controlled drug release [8–10].

The goal of this study was to prepare hydrogels based on vinylcaprolactam–sodium itaconate copolymer and containing an immobilized antimicrobial agent, Farmazin, with the aim to provide the release of the drug controlled by the ambient temperature.

EXPERIMENTAL

Hydrogels based on vinylcaprolactam and sodium itaconate (1, 2, and 3 wt %), in the form of disc samples (10 mm in diameter), were placed in a 5 wt % Farmazin solution for 24 h at 10°C for the equilibrium adsorption of the drug. Then the discs were washed with 50 ml of distilled water and placed on a small sieve in stirred saline (250 ml) to monitor the drug release. The Farmazin release was performed under equilibrium conditions at various temperatures. The drug concentration was determined at regular intervals by taking 2-ml samples of the solutions and UV detection (Jasco UV VIS 7850 spectrophotometer, Japan) at 260 nm.

The phase transition temperature of polymer solutions was determined in a stirred temperature-controlled cell heated with a TC Jasco attachment at 0.5°C temperature steps, with spectrophotometric detection at 500 nm.

The vinylcaprolactam–sodium itaconate (1 wt %) hydrogel, when heated, passes into the water-insoluble form at 36°C, collapsing to the nontransparent state (Fig. 1). The photographs of the copolymer gel colored with Malachite Green are shown in Fig. 2 for two different states of the gel: swollen at 22°C and collapsed at 37°C. The complexes of this copolymer with Farmazin also show a phase transition, but the degree of collapsing increases, and the lower critical solution temperature (LCST) decreases to 33°C. Farmazin contains urea groups capable of forming hydro-

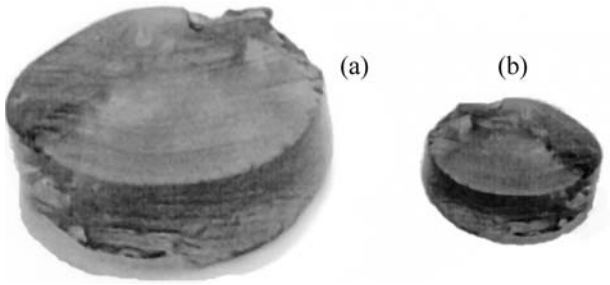

Fig. 2. Photographs of a sample of *N*-vinylcaprolactam–sodium itaconate hydrogel at (a) 22 and (b) 37°C.

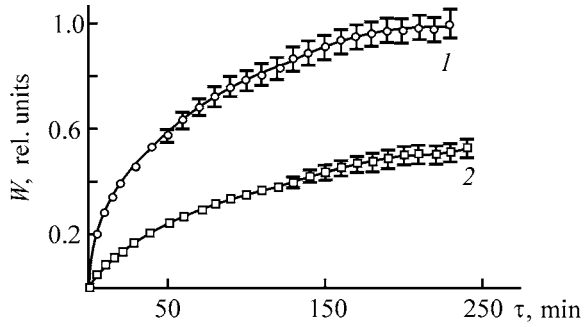

Fig. 3. Release of Farmazin from copolymer gels at (*1*) 22 and (*2*) 37°C into saline (the initial gel temperature corresponded to the temperature of the saline). (*W*) Degree of drug release and (τ) time.

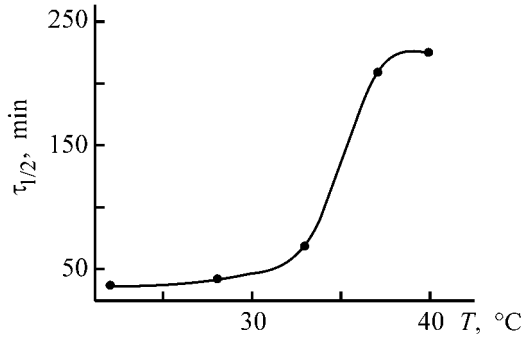

Fig. 4. Half-time $\tau_{1/2}$ of Farmazin release into saline from a vinylcaprolactam copolymer gel vs. temperature *T*.

gen bonds between the copolymer and the drug or between the oxygen of the lactam ring of amide group and the Farmazin. Such interactions are manifested in the IR spectra as a shift of the amide band of Farmazin isolated from aqueous solutions from 1640 to 1670 cm^{-1}. The increased degree of collapsing may be due to an increase in the polymer hydrophobicity upon complexation with Farmazin, causing LCST to decrease.

After immobilization of Farmazin antibiotic on the hydrogels based on a copolymer of vinylcaprolactam and sodium itaconate by equilibrium adsorption, we studied its desorption. At 22°C, the hydrogel is swollen and releases Farmazin (Fig. 3) by the mechanism of equilibrium diffusion into the surrounding solution. As the temperature is elevated to 37°C, the hydrogel collapses to a hard nontransparent state, and the diffusion rate decreases by a factor of 4.5. The weight of the compact gel is 5.5 times lower than that of the swollen gel. Whereas at low temperature Farmazin is fully released within 200–210 min, the gel compacted at elevated temperature releases in this time less than 50% of the drug. Apparently, the major factor responsible for the decreased diffusion in the gel is its phase transition from the swollen state at low temperatures to the compact state at high temperatures. The morphology of the collapsed gel prevents free diffusion of the hydrophilic drug to the environment. At the same time, a well hydrated gel with a low degree of crosslinking, in our case a polyvinylcaprolactam hydrogel, is essentially an aqueous solution of the polymer with a limited degree of freedom of macromolecular segments [11]. The drug diffusion in such a system is essentially the diffusion of Farmazin in water.

We examined the influence of temperature on the rate of Farmazin release the from the hydrogel. We found that, above 35°C, the drug diffusion rate sharply decreases (Fig. 4). The half-time of Farmazin release increases from 60 min at 34.5°C to 220 min at 37°C. It is seen that the ambient temperature is the major factor affecting the diffusion rate, and the effect is exerted in a very narrow temperature range. The suggested design of the gel–polymer–drug system potentially allows its use for controlled release of drugs, stimulated by the ambient temperature or by a discrete temperature factor. Such systems show promise for pharmaceutics, medicine, and biotechnology.

CONCLUSIONS

(1) Immobilization of Farmazin antibiotic on a gel of a copolymer of *N*-vinylcaprolactam and sodium itaconate afforded a new thermosensitive polymeric material allowing control of the rate of drug diffusion from a polymeric matrix by varying the temperature. The half-time of drug release is 32 min at 22°C and 210 min at 37°C.

(2) The shift of the phase transition temperature of the gel with adsorbed tylosine tartrate by 2.5°C to lower temperatures, compared to the gel without the drug, is due to hydrogen bonding of the lactam oxygen atom of the polymer to amino groups of tylosine tartrate.

Academician Lev Vladimirovich Pisarzhevskii (To 130th Anniversary of His Birthday)

L.V. Pisarzhevskii, a scientist, pedagogue, research organizer, and public figure, is one of the most prominent Russian physical chemists of the first half of the XX century. His studies covered a wide variety of problems: chemistry and structure of metal peroxides, nonaqueous solutions, electronic theory of redox processes, and theory of catalysis.

Lev Vladimirovich Pisarzhevskii was born on February 14, 1874, in Kishinev, Bessarabia Province, into the family of a notary. In 1882, after his father's death, the family moved to Odessa, where Pisarzhevskii finished a classical gymnasium and entered the natural-medical faculty of Novorossia University (Odessa). Soon afterwards, however, he went to the chemical department of the physicomathematical faculty and all his subsequent scientific and pedagogical activities were associated with chemistry. Among his teachers at the University were such well-known scientists of that time: A.A. Verigo (1837–1905), P.G. Melikishvili (1850–1927), S.M. Tanatar (1849–1917), and P.I. Petrenko-Kritchenko (1866–1944). Already beginning with his second term at the University, Pisarzhevskii commenced research work under the supervision of professor Melikishvili, analyzed the composition of a meteorite, and later studied peroxy compounds. In 1896, Pisarzhevskii graduated from Novorossia University with first-degree diploma and, on recommendation of professors Verigo and Melikishvili, was left at the university to be trained for professorship.

In 1898, the young scientist passed master's examinations and gained a right to deliver lectures as privatdocent. The courses of lectures, planned to be delivered by him, covered the topical problems of physical chemistry, which originated at that time. In 1899, Melikishvili and Pisarzhevskii were awarded the Lomonosov Prize for the monograph *Issledovaniya nad perekisyami* (Studies of Peroxides). In January 1901, Pisarzhevskii was sent to a business trip to Leipzig, to the laboratory headed by W. Ostwald (1853–1932, 1909 Nobel Prize in chemistry), which was the renowned center of novel ideas and research in physical chemistry at that time. Quite a number of young Russian scientists worked in Leipzig in different years [1, 2]. In the early XX century, the main areas of research conducted by Ostwald and his closest associates were kinetics and catalysis.

At Ostwald's laboratory Pisarzhevskii finished work on his master's dissertation "Peroxides and Peracids," which he successfully defended at Novorossia University on November 20, 1902 [3].

Various peroxide compounds, objects of study of inorganic chemistry, were examined using physicochemical methods, electrical conductivity measurements, as well as thermochemical and kinetic techniques. As a theoretical substantiation served Arrhenius's theory of solutions and the laws of thermochemistry. Melikishvili and Pisarzhevskii studied a wide variety of peroxide compounds, including quite a number of substances synthesized by them for the first time. The structural similarity of hydrogen peroxide, metal peroxides, and peracids was demonstrated. Metal peroxides were regarded as salts of hydrogen peroxide, in which it plays the part of a mono- or dibasic acid. Peracids were regarded as mixed anhydroacids of common acids and hydrogen peroxide. D.I. Mendeleev was much interested in the studies of peroxide compounds. In 1897–1899, Melikishvili and Pisarzhevskii published in co-authorship 16 studies con-

cerned with peroxide compounds; 11 more investigations in this area were published by Pisarzhevskii alone in 1900–1903. The scientist reverted to the subject of peroxide compounds more than once in the subsequent years. A detailed analysis of investigations carried out at Novorossia University by the founders of chemistry of peroxide compounds was made in Turchenko's monograph [4] and in [5, 6].

On January 1, 1903, were commenced diverse Pisarzhevskii's pedagogical activities at Novorossia University. He delivered courses of lectures in inorganic and analytical chemistry to students of various specialties and supervised practical studies in physical chemistry, organized by himself. It so turned out that Pisarzhevskii's work at Novorossia University was not long. In 1903, G. Tammann (1861–1938) moved to Germany, to Göttingen University, and freed the chair of chemistry at Yur'ev (Tartu) University. In the second half of the year of 1904, Pisarzhevskii was invited to this chair as extraordinary professor. Already in the 1904/1905 academic year, he delivered all the lectures in chemical disciplines at the physicomathematical faculty. However, the unfavorable conditions for research work, the lack of necessary equipment, the political circumstances of that time, and the Baltic climate, taken together, resulted in that Pisarzhevskii returned to the Ukraine at the beginning of 1908 to fill a vacant position of a professor of inorganic and analytical chemistry at Kiev Polytechnic Institute.

Nevertheless, Pisarzhevskii in fact started at Tartu the second series of his experimental studies of chemical interaction of solutes with a solvent [5, 7]. In 1904–1908, he published five papers in this field. The area of research, chosen by the scientist, was characteristic and rather important for the understanding of the nature of solutions at the turn of the XX century. Undoubtedly, this choice was affected by the two years' stay of Pisarzhevskii at Ostwald's laboratory. The theoretical concepts of solutions, developed by J. Vant-Hoff (1852–1911, 1901 Nobel Prize in chemistry) and S. Arrhenius (1859–1927, 1903 Nobel Prize in chemistry) provoked objections of a number of leading Russian scientists. Being a supporter of Arrhenius's theory, Pisarzhevskii was aware of the necessity for supplementing this theory with account of Mendeleev's views on the chemical nature of solutions. In his publications, Pisarzhevskii aimed at avoiding the extreme opinions of advocates of the physical and chemical theories of solutions. A detailed analysis of the nature of the difference in opinions was made in Solov'ev's monograph [8] and in some other publications [3–5, 9].

To elucidate the role of chemical factors in solution formation, Pisarzhevskii did not restrict his consideration to a study of solutions in various solvents, as it was done by other scientists concerned with this problem. Contrariwise, he undertook wide-scale investigations of the influence exerted by the solvent on the chemical equilibrium. He studied nine ionic reactions in 47 simple and mixed solvents and calculated more than 100 equilibrium constants [5, 9]. The equilibria were studied both analytically and by measuring the electromotive forces of appropriate circuits. When necessary, the electrical conductivity and viscosity were also measured. It was established that the solvent strongly affects the state of equilibrium. Pisarzhevskii himself formulated the basic conclusion made on the basis of this series of investigations as follows: "... it is necessary to recognize the chemical interaction between the solvent and solutes and to regard the dissolution process as purely chemical phenomenon" [10, 11]. This chemical phenomenon consists in solvation.

Having started lecturing at Kiev Polytechnic Institute in April 1908, Pisarzhevskii paid considerable attention to improvement of the teaching process. He introduced a theoretical course "Introduction into Analytical Chemistry," delivered lectures in terms of the ionic theory, and redesigned the system of practical works in analytical chemistry. In 1908–1911, Pisarzhevskii finished work on his doctoral dissertation "Free Energy of a Chemical Reaction and the Solvent" [10], which he defended successfully at St. Petersburg University in 1913.

Already when being a professor in Tartu, Pisarzhevskii belonged to a revolutionary all-Russian Akademicheskii Soyuz (Academic Society). In 1911, in connection with political unrest in quite a number of higher-school institutions, Pisarzhevskii resigned, together with a group of professors of the Polytechnic Institute, and moved to Moscow, to become there one of founders and editors of a popular-science journal *Priroda* (Nature). At that same time, Pisarzhevskii delivered lectures at Bestuzhev school and Institute of Psychoneurology in St. Petersburg.

In 1913, Pisarzhevskii was elected a professor of general and physical chemistry at the Mining Institute in Yekaterinoslav (now Dneropetrovsk), and all the subsequent pedagogical and scientific activities of the scientist were associated with this institute. Already during the first years of his work there, the third and, probably, the main area of Pisarzhevskii's research was formed: the electron in chemistry and the nature of redox processes. He published a series of articles

"The Electron in Chemistry of Solutions and in Electrochemistry" (1921–1924) and a monograph under the same title (together with M.A. Rozenberg, 1923). As far back as 1914, Pisarzhevskii demonstrated that all chemical processes can be regarded as a result of electron transfer from some atoms or molecules to others, with the interaction of the free electric charges that are generated in the process [9]. The oxidation and reduction processes were interpreted as transfer of electrons from an oxidant to a reducing agent. All these approaches were introduced by Pisarzhevskii and his closest associates into the teaching process and described in understandable form in the textbooks *Vvedenie v khimiyu na osnove stroeniya atoma i elektronnogo stroeniya molekul, chast' 1* (Introduction into Chemistry on the Basis of Atomic Structure and Electronic Structure of Molecules, Part 1) (Dnepropetrovsk, 1928) and *Neorganicheskaya khimiya* (Inorganic Chemistry) (together with Rozenberg; Dnepropetrovsk, 1930; Kharkov, 1933 and 1934).

The concept of redox processes was extended to reactions in solutions, heterogeneous catalysis, and electrochemistry. For his investigations in the field of electronic chemistry, Pisarzhevskii was awarded a Lenin Prize in 1930.

In addition to the Mining Institute, Pisarzhevskii taught at other higher-school institutions of Yekaterinoslav: Institute of People's Education and Medical Institute. In 1923–1926, he held the position of rector of the Mining Institute. In 1922, on Pisarzhevskii's initiative, a research chair of electronic chemistry was created at the Mining Institute. Already in 1927, this chair was reorganized into Ukrainian Research Institute of Physical Chemistry, and in 1934, into the Institute of Physical Chemistry, Academy of Sciences of the Ukrainian SSR (Soviet Socialist Republic). In 1936, the institute was named for L.V. Pisarzhevskii.

In 1925, Pisarzhevskii was awarded a title of Honored professor of the Ukrainian SSR. In the same year, he was elected a full member of the Academy of Sciences of the Ukrainian SSR. He was elected a corresponding member of the Academy of Sciences of the USSR in 1928, and a full member of the Academy in 1930. The contribution made by the scientist to the development of higher technical education in the Ukraine is remarkable. On Pisarzhevskii's initiative, a faculty of chemical engineering was opened at the Mining Institute and the metallurgical faculty was developed further. In 1930, during the period of reorganization of the higher-school institutions in the country, the Institute of Chemical Engineering and Metallurgical Institute were created on the basis of these faculties.

In 1929, Pisarzhevskii was invited to Georgia to create at Tbilisi a chemical research center. This aspect of the scientist's activities has been considered in detail by A.Sh. Avaliani and co-authors [12]. In 1928, the State Polytechnic Institute of Georgia was organized in Tbilisi. This institute, in particular, included a mining-chemical faculty with two departments, mining and chemical. The chemical department was intended to train chemists-technologists and metallurgists. Pisarzhevskii and his closest associate Rozenberg were entrusted with organization of teaching of all the chemical disciplines at the due level. Simultaneously, Pisarzhevskii was engaged in organization of the Research Institute of Chemistry, officially opened on October 1, 1929. Pisarzhevskii was appointed the director of the Institute, and Rozenberg, the head of the department of electronic chemistry. As suggested by the director, the Institute was named after Melikishvili. The stay of Pisarzhevskii in Tbilisi was not long; it coincided with the reorganization of the higher school and scientific institutions in the country, but exerted strong influence on the subsequent development of chemical research in Georgia [12]. In the summer of 1931, Pisarzhevskii returned to Dnepropetrovsk, with, however, his intimate contacts with Georgian colleagues maintained. In 1934, Pisarzhevskii again headed the Institute, which was then already a part of the Georgian branch of the Academy of Sciences of the USSR, for a short time.

Among Pisarzhevskii's pupils and closest associates in the Ukraine were the following, later well-known scientists: A.I. Brodskii (1895–1969, academician of the Academy of Sciences of the Ukrainian SSR since 1939, corresponding member of the Academy of Sciences of the USSR since 1943), a prominent specialist in chemistry of isotopes and author of the textbook *Fizicheskaya khimiya* (Physical Chemistry), which ran into numerous editions; V.A. Roiter (1903–1974, academician of the Academy of Sciences of the Ukrainian SSR since 1961), author of the monograph *Vvedenie v teoriyu kinetiki i kataliza* (Introduction into Theory of Kinetics and Catalysis) (1971); and S.Z. Roginskii (1900–1970, corresponding member of the Academy of Sciences of the USSR since 1939), the founder of a prominent scientific school specialized in the theory of catalysis.

Pisarzhevskii was actively involved in public and political activities in the country and was a member of executive Soviet bodies: he became an alternate member of the Central Executive Committee of the

USSR in 1928, was elected a member of the Central Executive Committee of Georgia in 1930 and 1935, and became a member of Central Executive Committee of the Ukraine in 1935.

Academician Lev Vladimirovich Pisarzhevskii died of a severe illness on March 23, 1938, in Dnepropetrovsk. A vast literature is devoted to his life and scientific activities. Of particular value are papers written by the closest associates of the scientist: Rozenberg, Brodskii, B.Ya. Dain, Roiter, and S.Z. Roginskii [3, 5, 13–15]. Considerable attention was given to Pisarzhevskii's works in the well-known monographs devoted to the development of chemical science in Russia [8, 9, 16, 17] and in the Ukraine [4, 18, 19]. A popular-science sketch of Pisarzhevskii's life and scientific activities has been written by Yu.S. Lyalikov [20]; other popular-science publications are also available [6, 21, 22].

Russian Journal of Applied Chemistry, Vol. 77, No. 2, 2004, p. 346. Translated from Zhurnal Prikladnoi Khimii, Vol. 77, No. 2, 2004, p. 347.

BOOK REVIEWS

Chokhonelidze, A.N., Galustov, V.S., Khlopanov, L.P., and Prikhod'ko, V.P., *Spravochnik po raspylivayushchim, orositel'nym i kapleulavlivayushchim ustroistvam* (A Reference Book of Spraying and Drop-Catching Devices), Moscow: Energoatomizdat, 2002, 608 pp.

Apparatus for spraying and dispensation of liquids are widely used in chemical industry for making larger the contact area in performing a wide variety of heat- and mass-exchange processes. However, the presently available reference literature devoted to the operation of these apparatus has become markedly outdated. The introduction of new types of apparatus and methods for intensification of dispersion processes is hindered, in particular, by the lack of a full-value information that could be used by designers and developers. In the reference book by A.N. Chokhonelidze and co-authors, the domestic and foreign designs in the field of spraying and drop-catching are systematized and generalized for the first time, with the whole material presented in a form convenient for practical use. The book comprises seven parts, which include 25 chapters.

The first part (pp. 7–108, chapters 1–4) presents general evidence that concerns the spraying of liquids, drop carry-over and catching of liquid aerosols, and methods for monitoring of the occurring processes. A refined classification of methods for liquid spraying is presented, the basic parameters of devices employed for liquid spraying are considered, and the influence exerted by various external factors on the characteristics of the gas-liquid flare are analyzed. Of particular interest is chapter 3, which describes stands for determining experimentally the characteristics of spraying devices.

The second part (pp. 109–221, chapters 5–11) contains data on the design and operation of atomizers for hydraulic spraying. Centrifugal, single-flare, jet, and impact-jet atomizers, as well as some other designs of hydraulic atomizers, are described. Considerable attention is given by the authors to apparatus classification and to terminology.

The third part of the reference book (pp. 222–290; chapters 12, 13) is devoted to gas-spraying atomizers (pneumatic and acoustic). A vast body of evidence concerning the principles of their operation, design and application features, and calculation procedures is presented. The fourth part (pp. 291–336; chapters 14, 15) considers the design, application fields, and methods for calculation of mechanical atomizers. The fifth part (pp. 337–383; chapters 16, 17) describes unconventional spraying devices which either have limited application (ultrasonic atomizers or those with electrostatic spraying) or are being developed at present. Also considered are devices for pulsating spraying, atomizers with preliminary gas-saturation, and devices for combined spraying.

The sixth part (pp. 384–476, chapters 18–20) contains extensive evidence concerning the spraying devices and spraying systems used in technological practice. Sprinklers and liquid dispensers, choice of spraying devices, design of spraying systems, and their operation are described. The seventh part (pp. 477–595, chapters 21–25) discusses various drop-catching devices: centrifugal separators, nozzle separators, and also gravitational and combined separators. Fabrication, setting-up, and operation of drop-catchers are described; the efficiency and reliability of their operation is assessed and the fabrication and assembling costs are estimated.

The bibliographic list contains 89 references to publications of exclusively domestic authors. As mentioned in the foreword to the reference book, only those references were included in the bibliographic list, which contain wide generalizations or a previously undiscussed material. In the reviewers' opinion, the number of references should have been considerably greater for such a fundamental publication as the reference book under consideration.

The book is of interest for a wide audience of specialists from a great variety of industries, those who are engaged in design or operation of spraying or dropcatching devices. It may also be of use for lecturers and post- and undergraduate students of higher school institutions specialized in chemical engineering, metallurgy, and power engineering. The reference book is well published and contains a large number of illustrations.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Reactions of Oxides of Some 3*d* Elements with Ammonium Hydrogen Difluoride

V. T. Kalinnikov, D. P. Nesterov, D. V. Makarov, E. A. Steshin, and E. L. Tikhomirova

Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received June 11, 2003

Abstract—Reactions of iron, manganese(II), manganese(IV), copper, and zinc oxides with ammonium hydrogen difluoride were studied by thermogravimetry, X-ray phase analysis, IR spectrometry, and chemical analysis.

Fluorides of 3*d* elements find use as active components of solid lasers and phosphors, as components of chemical current sources and fluoride glasses, and as catalysts in organic synthesis [1]. On the other hand, recently there has been a considerable progress in processing of oxide–silicate raw materials containing 3*d*-metal oxides using ammonium hydrogen difluoride NH_4HF_2 [2]. Therefore, study of reactions of 3*d*-element oxides with NH_4HF_2 is of scientific and practical importance. It is known that NH_4HF_2 is close to anhydrous hydrogen fluoride in reactivity, but has a number of advantages: it can be easily dehydrated and regenerated from gaseous components, and fluoridation reactions can be carried out without sophisticated equipment [3]. In this work we have studied the fluoridation of manganese(II) and (IV), iron(III), copper, and zinc oxides with ammonium hydrogen difluoride by thermogravimetry, chemical and X-ray phase analyses, and crystal optics. The chemically pure grade oxides and double-recrystallized NH_4HF_2 (analytically pure grade) were used as the starting substances.

The thermogravimetric study was carried out on a Q-1500D (Hungary) derivatograph in platinum crucibles using 200–400-mg samples and calcined Al_2O_3 as reference. The experiments were carried out in dynamic and quasi-isothermal modes at the heating rate of 2.5–10 deg min^{-1}.

The X-ray phase analysis of reaction products was performed on a DRON-2 diffractometer with the CuK_α radiation. The IR absorption spectra were recorded on a UR-20 spectrophotometer.

The content of iron was determined by the flame-emission spectrometry, and that of fluoride, by pyrohydrolysis followed by potentiometric determination (using a F^--selective electrode). The ammonia content was determined by Kjeldahl's method.

The following methods of synthesizing FeF_3 have been described in the literature: reaction of $FeCl_3$ with anhydrous HF [4] yielding an amorphous product, which is heated to 1000°C to form a crystalline product; calcination of Fe_2O_3 or hydrated FeF_3 in an HF flow at 1000°C [5]; and thermal decomposition of $(NH_4)_3FeF_6$ at 400–500°C [6], including the reaction in an F_2 atmosphere [7].

These procedures require sophisticated equipment, and the fluoridation proceeds at high temperatures in several stages. It was pointed out in [7] that the absence of iron(II) impurities in the final product is an advantage of obtaining FeF_3 by decomposing $(NH_4)_3FeF_6$ in an F_2 atmosphere.

When $(NH_4)_3FeF_6$ is synthesized by the reaction of natural pyrrhotines $Fe_{1-x}S$ with NH_4HF_2 [7], iron(II)-containing compounds are inevitably formed, which makes necessary the subsequent treatment with F_2. The preparation of $(NH_4)_3FeF_6$ by the reaction of FeF_3 with NH_4F in an inert atmosphere [6] or by the reaction of $FeBr_3$ with NH_4F in methanol [8] was also described.

The derivatogram of a mixture of Fe_2O_3 with NH_4HF_2 in the molar ratio of 1 : 10 is shown in Fig. 1. The DTA curve reveals a number of endothermic effects. The first of them at approximately 115°C corresponds to the melting of NH_4HF_2 [9]. The endothermic effect at 166°C results from the formation of $(NH_4)_3FeF_6$ by reaction (1).

$$Fe_2O_3 + 6NH_4HF_2 = 2(NH_4)_3FeF_6 + 3H_2O. \quad (1)$$

1070-4272/04/7703-0347 © 2004 MAIK "Nauka/Interperiodica"

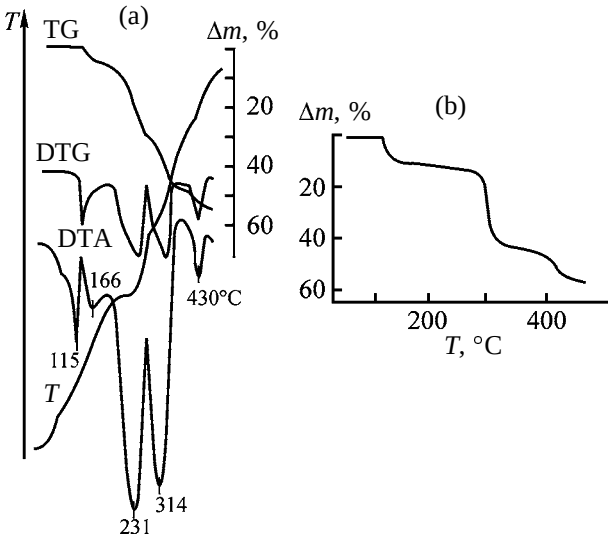

Fig. 1. (a) Derivatogram of a mixture $Fe_2O_3 : NH_4HF_2$ = 1 : 10 and (b) thermogravigram of a mixture $Fe_2O_3 : NH_4HF_2$ = 1 : 6 recorded in the quasi-isothermal mode. (*T*) temperature and (Δ*m*) weight loss; the same for Figs. 3, 5, and 6.

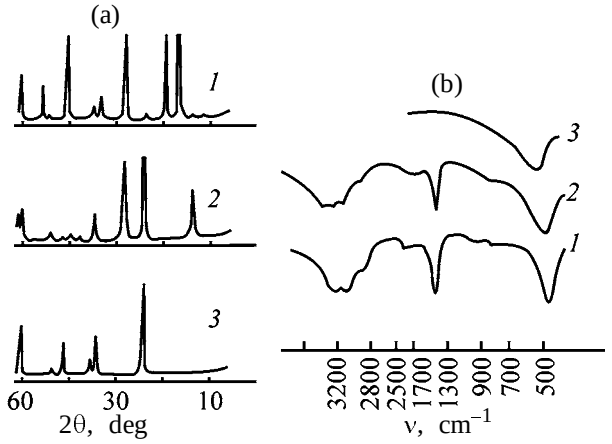

Fig. 2. (a) X-ray patterns of cakes of $Fe_2O_3 : NH_4HF_2$ = 1 : 6 mixtures and (b) IR absorption spectra of the same samples. (2θ) Bragg's angle and (ν) wave number. *T*, °C: (*1*) 180, (*2*) 320, and (*3*) 430.

On further heating, $(NH_4)_3FeF_6$ decomposes by the scheme

$$(NH_4)_3FeF_6 = NH_4FeF_4 + 2HF + 2NH_3. \quad (2)$$

The decomposition is completed at 314°C, as proved by a series of the corresponding endothermic effects. Boiling of excess NH_4HF_2 at approximately 231°C [3, 9] is accompanied by the corresponding endothermic effect. The final stage (3) of the synthesis is completed at approximately 430°C by the formation of anhydrous iron(III) fluoride.

$$NH_4FeF_4 = FeF_3 + HF + NH_3. \quad (3)$$

The thermogravigram obtained in the quasi-isothermal mode contains three plateaus corresponding to the formation of $(NH_4)_3FeF_6$, NH_4FeF_4, and FeF_3, respectively (Fig. 1b). The calculated weight loss in each stage of the synthesis (10.8, 40.3, and 55.0 wt %, respectively) agrees well with the loss observed experimentally (Fig. 1b). The derivatographic results were confirmed by X-ray phase analysis. The X-ray patterns of $Fe_2O_3 : NH_4HF_2$ mixtures with the molar ratio of 1 : 6 at 180, 320, and 430°C are shown in Fig. 2a. It is seen from Fig. 2a, curve *1* that $(NH_4)_3FeF_6$ is the reaction product at 180°C, and at 320°C it decomposes to give NH_4FeF_4 (Fig. 2a, curve *2*). Curve *3* in Fig. 2a is the X-ray pattern of anhydrous FeF_3. Its heating in air results in the following pyrohydrolysis reactions:

$$2FeF_3 + H_2O = Fe_2F_4O + 2HF, \quad (4)$$

$$2FeF_3 + 3H_2O = Fe_2O_3 + 6HF. \quad (5)$$

The formation of Fe_2O_3 was confirmed by X-ray phase analysis. The X-ray patterns of the synthesized compounds coincide with the data given in [6].

The IR absorption spectra of ammonium fluoroferrates(III) and FeF_3 are given in Fig. 2b. The absorption bands in the regions of 2800–3400 and 1430 cm^{-1} in the spectra of ammonium fluoroferrates(III) are assignable to the stretching and bending vibrations of N–H bonds. The absorption band at 450–550 cm^{-1}, which is observed in all the IR spectra under consideration, is characteristic of the Fe–F stretching vibration. A weak absorption band in the region of bending vibrations of water molecules is present in the spectrum of ammonium tetrafluoroferrate(III) at 1630 cm^{-1}. This is apparently hygroscopic water appearing owing to fine dispersity of the substance.

Thus, we found the conditions for obtaining anhydrous FeF_3 by the reaction of Fe_2O_3 with NH_4HF_2. It should be taken into account that a 1.5–2-fold excess of NH_4HF_2 relative to the stoichiometry is required to obtain FeF_3 as a final product free from iron(III) oxide formed by pyrohydrolysis. Depending on the requirements to FeF_3 purity, it is appropriate to synthesize it either in inert or in fluorinating atmosphere, the repeated treatment with a fluorinating agent being possible.

The main method of obtaining MnF_2 is the reaction of $MnCO_3$ with HF [4].

The derivatogram of an $MnO : NH_4HF_2$ mixture with the molar ratio of 1 : 2 is shown in Fig. 3a. A number of peaks corresponding to endothermic effects

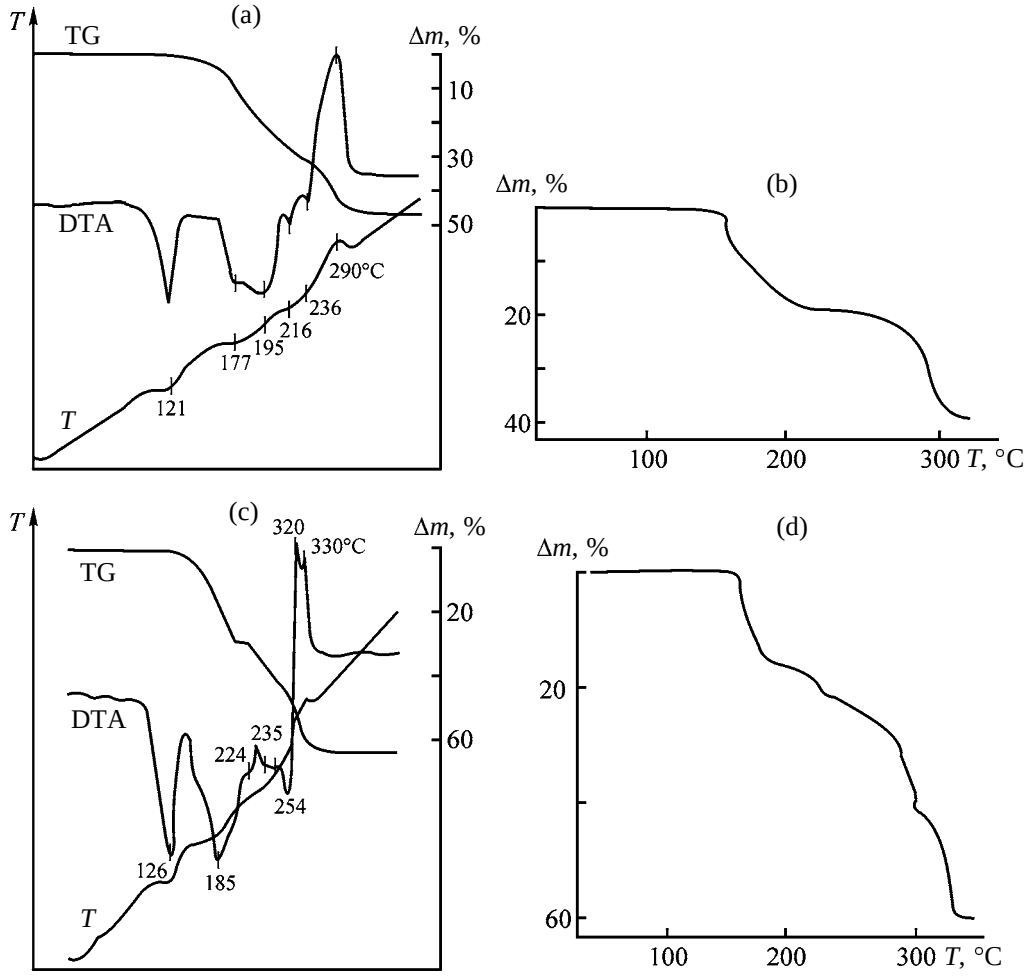

Fig. 3. (a) Derivatogram of an $MnO : NH_4HF_2 = 1 : 2$ mixture; (b) thermogravigram of an $MnO : NH_4HF_2 = 1 : 1.5$ mixture recorded in the quasi-isothermal mode; (c) derivatogram of an $MnO : NH_4HF_2 = 1 : 4$ mixture; and (d) thermogravigram of an $MnO_2 : NH_4HF_2 = 1 : 2.5$ mixture recorded in the quasi-isothermal mode.

are observed in the DTA curve. The endothermic effect at 195°C corresponds to the formation of the complex NH_4MnF_3 by the reaction

$$MnO + 2\ NH_4HF_2 = NH_4MnF_3 + H_2O. \quad (6)$$

As the temperature is increased to 350°C, NH_4MnF_3 decomposes to give MnF_2:

$$NH_4MnF_3 = MnF_2 + HF + NH_3. \quad (7)$$

The scheme of the MnO fluoridation is confirmed by the thermogravigram taken in the quasi-isothermal mode at the molar ratio of components $MnO : NH_4HF_2 = 1 : 1.5$. The experimental weight losses of 17.6 and 42%, respectively, agree well the calculated losses of 17.4 and 41% (Fig. 3b). Compounds identified as NH_4MnF_3 and MnF_2 by X-ray phase and chemical analyses [10] were synthesized at 200 and 325°C, respectively (Figs. 4a and 4b).

The reaction of MnO_2 with NH_4HF_2 was studied by Rakov and co-workers [11]. They found that the reaction proceeded stepwise to give $(NH_4)_2MnF_5$, NH_4MnF_4, and MnF_2 at 175, 230, and 300°C, respectively. Another reaction scheme was given in [12], where the reaction of iron-manganese concretions with NH_4HF_2 was studied. The product of the exothermic reaction of MnO_2 and NH_4HF_2 is a compound isostructural to $(NH_4)_3MnF_6$ but having a 10% deficiency of fluorine as compared to this stoichiometry owing to the isomorphous replacement of fluorine by hydroxide ions. The final stage of the process at 320°C is the formation of MnF_2.

The thermogram of a mixture of MnO_2 with NH_4HF_2 in the molar ratio of 1 : 4 is shown in Fig. 3c. The reaction proceeds in several stages (endothermic effects at 185 and 224°C). The process can be described by the equation

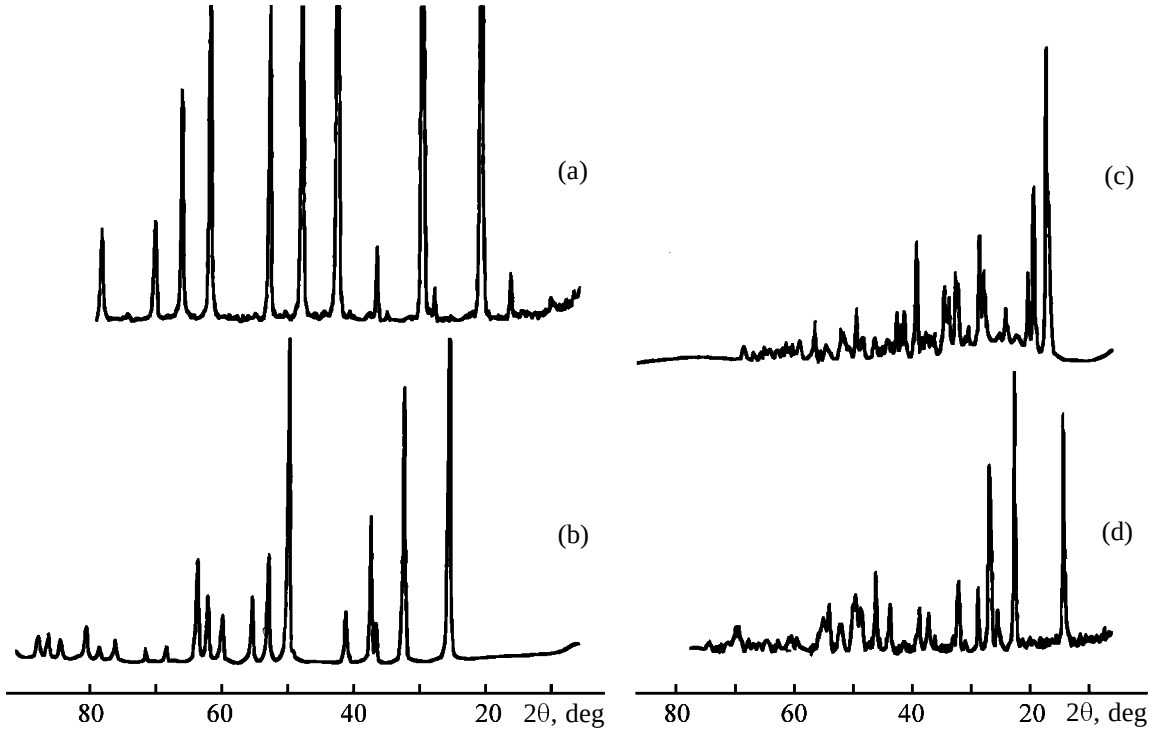

Fig. 4. X-ray patterns of $MnO : NH_4HF_2$ and $MnO_2 : NH_4HF_2$ mixtures at various temperatures: (a) NH_4MnF_3 (200°C), (b) MnF_2 (325°C), (c) $(NH_4)_2MnF_5$ (200°C), and (d) NH_4MnF_4 (300°C).

$$6MnO_2 + 24NH_4HF_2 = 6(NH_4)_2MnF_5 + 18HF + 10NH_3 + N_2 + 12H_2O. \quad (8)$$

A series of endothermic effects observed on further heating (Fig. 3c) correspond to the reactions

$$(NH_4)_2MnF_5 = NH_4MnF_4 + HF + NH_3, \quad (9)$$

$$NH_4MnF_4 = MnF_2 + HF + 1/2F_2 + NH_3. \quad (10)$$

The thermogravigram obtained in the quasi-isothermal mode is shown in Fig. 3d. It contains three plateaus corresponding to the formation of $(NH_4)_2 \cdot MnF_5$, NH_4MnF_4, and MnF_2, respectively. The thermogravimetric data obtained are confirmed by the results of the X-ray phase analysis [13] (Figs. 4c and 4d). The compounds $(NH_4)_2MnF_5$, NH_4MnF_4, and MnF_2 were isolated at 200, 300, and 320°C.

Thus, the established reaction scheme of the fluoridation of manganese(IV) oxide coincides with the results of [11].

The nature of exothermic effects (Figs. 3a, 3c) remains to be elucidated. They may be due to the crystallization of the forming amorphous manganese fluoride.

Preparation of anhydrous copper(II) fluorides is complicated by the reaction with materials of crucibles and by the pyrohydrolysis [14]. The following methods for preparing CuF_2 have been described in the literature: fluoridation of dehydrated $CuCl_2$ crystal hydrates using F_2 or ClF_3 at 400°C [4], dissolution of CuO or $(CuOH)_2CO_3$ in excess 40% hydrofluoric acid with the subsequent dehydration of crystal hydrates of copper(II) compounds ($CuF_2 \cdot 2H_2O$ or $CuF_2 \cdot 5H_2O \cdot 5HF$ according to the data of various authors) in a dry HF flow [4, 14], and the reaction of CuS with SF_4 in an autoclave at 190°C followed by treatment of the resulting products with anhydrous carbon disulfide to remove sulfur [15]. The dehydration of $CuF_2 \cdot 2H_2O$ crystal hydrate both in air and in an inert atmosphere with heating results in the formation of mixtures of CuOHF, CuO, and CuF_2 [16, 17].

Typical thermogravimetric curves of a mixture of CuO with NH_4HF_2 in the molar ratio of 1 : 2 are shown in Fig. 5a. The DTA curve contains a number of endothermic effects. The first effect at 125°C corresponds to the melting of NH_4HF_2 [3, 9]. The endothermic effect at 200°C corresponds to the formation of the complex $(NH_4)_2CuF_4$ by reaction (11):

$$CuO + 2NH_4HF_2 = (NH_4)_2CuF_4 + H_2O. \quad (11)$$

Further heating causes thermal decomposition of $(NH_4)_2CuF_4$ according to scheme (12), completed at 230°C.

$$(NH_4)_2CuF_4 = NH_4CuF_3 + HF + NH_3. \quad (12)$$

The final stage (13) of the synthesis is completed at approximately 290°C by the formation of anhydrous CuF_2.

$$NH_4CuF_3 = CuF_2 + HF + NH_3. \quad (13)$$

At 200, 230, and 290°C, we have synthesized the compounds identified by X-ray phase and chemical analyses as $(NH_4)_2CuF_4$, NH_4CuF_3, and CuF_2 [17]. Three steps corresponding to the formation of $(NH_4)_2 \cdot CuF_4$, NH_4CuF_3, and CuF_2 (Fig. 5b) are detected in the TG curve obtained in the quasi-isothermal mode. The weight loss for process (11) in the established temperature range takes place even under conditions of the quasi-isothermal measurement. An increase in temperature results in the pyrohydrolysis of CuF_2 and in the contamination of the product with copper oxide. In the copper(II) difluoride obtained, the atomic ratio $F : Cu \le 2$. According to the data from [14], the formula of copper(II) fluoride is CuF_{2-x} ($0 \le x \le 0.33$); the stoichiometric samples were synthesized by treatment of CuF_{2-x} with xenon difluoride.

The thermal decomposition of NH_4CuF_3 to anhydrous CuF_2 occurs at a lower temperature than the corresponding processes for NH_4CoF_3 and NH_4NiF_3 (340 and 370°C) [18].

The complete fluoridation is reached with a certain excess of NH_4HF_2 as compared to the stoichiometry of Eq. (11). This is associated with possible partial decomposition of NH_4HF_2 [9]. To obtain the pure product from copper oxide, it is better to perform the synthesis in an inert atmosphere.

Anhydrous ZnF_2 is obtained by the reaction of $ZnCO_3$ with excess hot hydrofluoric acid, followed by heating of the precipitate at 800°C without air access [4]. According to the review [3], zinc(II) forms the complex compounds $(NH_4)_2ZnF_4 \cdot H_2O$ and NH_4ZnF_3. The temperature of NH_4ZnF_3 decomposition is 250°C.

It is seen from Fig. 6a that the reaction in the mixture of ZnO with NH_4HF_2 (molar ratio 1 : 2) starts even before NH_4HF_2 melting and is accompanied by a weight loss. It results in the formation of $(NH_4)_2ZnF_4$:

$$ZnO + 2NH_4HF_2 = (NH_4)_2ZnF_4 + H_2O. \quad (14)$$

Further increase in the temperature above 178°C leads

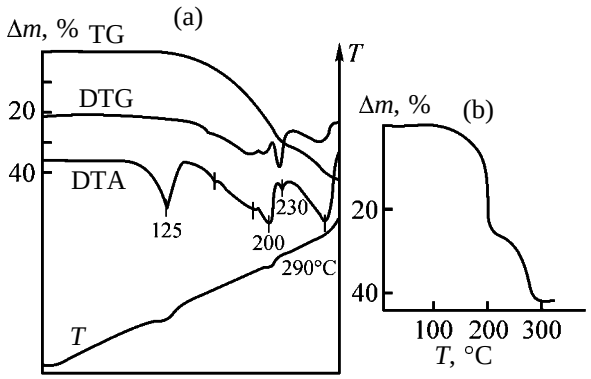

Fig. 5. (a) Derivatogram of a mixture $CuO : NH_4HF_2 = 1 : 2$ and (b) thermogravigram of a mixture $CuO : NH_4HF_2 = 1 : 2$ recorded in the quasi-isothermal mode.

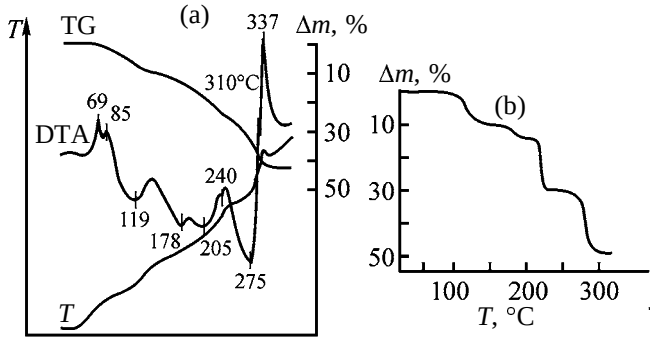

Fig. 6. (a) Derivatogram of a mixture $ZnO : NH_4HF_2 = 1 : 2$ and (b) thermogravigram of a mixture $ZnO : NH_4HF_2 = 1 : 2$ recorded in the quasi-isothermal mode.

to the thermal decomposition of $(NH_4)_2ZnF_4$:

$$(NH_4)_2ZnF_4 = NH_4ZnF_3 + HF + NH_3. \quad (15)$$

It is completed at 240°C, which is confirmed by a series of the corresponding endothermic effects. The final stage (16) of the synthesis proceeds up to approximately 337°C.

$$NH_4ZnF_3 = ZnF_2 + HF + NH_3. \quad (16)$$

Three steps corresponding to the formation of $(NH_4)_2ZnF_4$, NH_4ZnF_3, and ZnF_2 (Fig. 6b) are observed in the TG curve obtained in the quasi-isothermal mode. These compounds were synthesized and isolated at the corresponding temperatures and identified by X-ray phase and chemical analyses.

CONCLUSION

The reaction of ZnO with NH_4HF_2 proceeds similarly to the reactions of NH_4HF_2 with nickel, cobalt, and copper oxides considered in the literature [18].

Received January 29, 2002; in final form, December 2002

Abstract—Transmission electron microscopy and X-ray structural analysis were applied to study the fundamental aspects of formation of the crystal structure of C–SiC–Si–Al composites. The reasons why spatially heterogeneous regions are formed were revealed.

C–SiC composites are commonly obtained by reaction of porous carbon supports with molten silicon [1–3]. To modify the properties of such materials, metal impurities are added to the silicon melt. However, these additives frequently lead to appearance of spatial heterogeneities, which adversely affects the strength properties of composites [4]. This study is concerned with the structure of C–SiC–Si composites with admixture of aluminum.

EXPERIMENTAL

As objects of study were chosen the composites PG–AS, GP–0.5AS, and MG–AS [5], synthesized by reaction of PG-50, PROG-2400, and ARV porous carbon materials with an Si + Al melt. The content of aluminum in the melt was ~10 wt % in synthesizing the PG–AS and MG–AS composites and ~5 wt % in the case of GP–0.5AS. Selected properties and the composition of the composites and the carbon supports, taken from [3, 5], are listed in Table 1.

Samples for comparative X-ray studies were prepared in the form of $100 \times 14 \times 14$-mm slabs. Samples for analysis of how the phase composition varies across the cross section of the MG–AS composite were obtained using a diamond saw in accordance with the scheme shown in Fig. 1.

The X-ray diffraction analysis was carried out with a DRON-3 diffractometer (CuK_α radiation with λ = 0.15418 nm). The phase analysis and indexing of X-ray diffraction patterns were performed using the ASTM file. The profiles of the diffraction peaks were measured at a scanning rate of 0.25 deg min^{-1}. The interplanar spacings d were calculated from the centers of gravity of the diffraction peaks [6]. The average size L of the coherent domains was determined from the integral width β of diffraction peaks [6], with silicon and silicon carbide used as references. The electron-microscopic studies were carried out with a PEM-100 electron microscope.

Typical electron diffraction patterns of C–SiC–Si–Al composites are shown in Fig. 2. An analysis of the

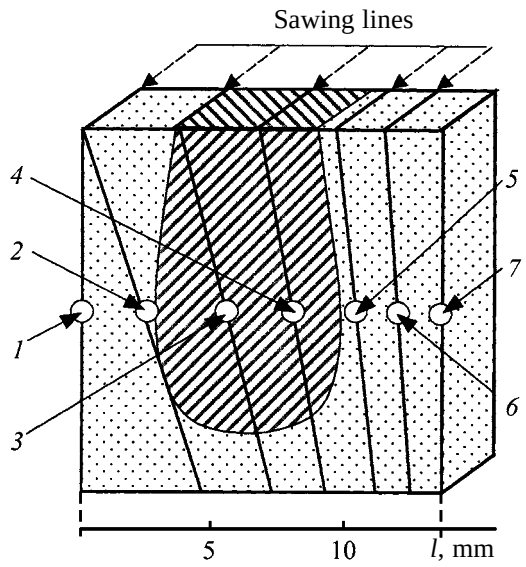

Fig. 1. Schematic of a study of how the phase composition and crystal structure varies across a sample of the MG–AS composite. (*1–7*) Region for which X-ray diffraction patterns were measured. (*l*) Distance; the same for Fig. 4.

electron diffraction patterns demonstrated that they can be related to microdiffraction from turbostratic carbon, silicon carbide, silicon, and aluminum. The probability of observing electron diffraction patterns of various phases widely varies across a sample. Regions that differ in contrast from the bulk of the material can be seen even visually on the edge cross sections of the GP–0.5AS and MG–AS composites. In Fig. 3, they are marked schematically with dark hatching and denoted by symbol C. Only electron diffraction patterns characteristic of carbon are recorded within these regions.

A comparative analysis performed for the MG–AS composite demonstrated that the crystal structure of carbon in the bulk of the composite is markedly different from the structure of carbon in C inclusions. Indeed, four basic types of electron diffraction patterns of turbostratic carbon are observed in the composites under study: (1) annular [characteristic of microscopic volumes occupied by crystals ~1 nm in size (Fig. 2a)], (2) annular with small number of discrete reflections [characteristic of a mixture of crystals ~1 and ~10 nm in size (Fig. 2b)], (3) discrete–ring-like [characteristic of microscopic volumes occupied by crystals ~10 nm in size (Fig. 2c)], and (4) discrete-periodic (characteristic of electron scattering by separate coarse crystals with size of ~100 nm and more (Fig. 2d)].

The probability of observing electron diffraction patterns of various types can be evaluated using the

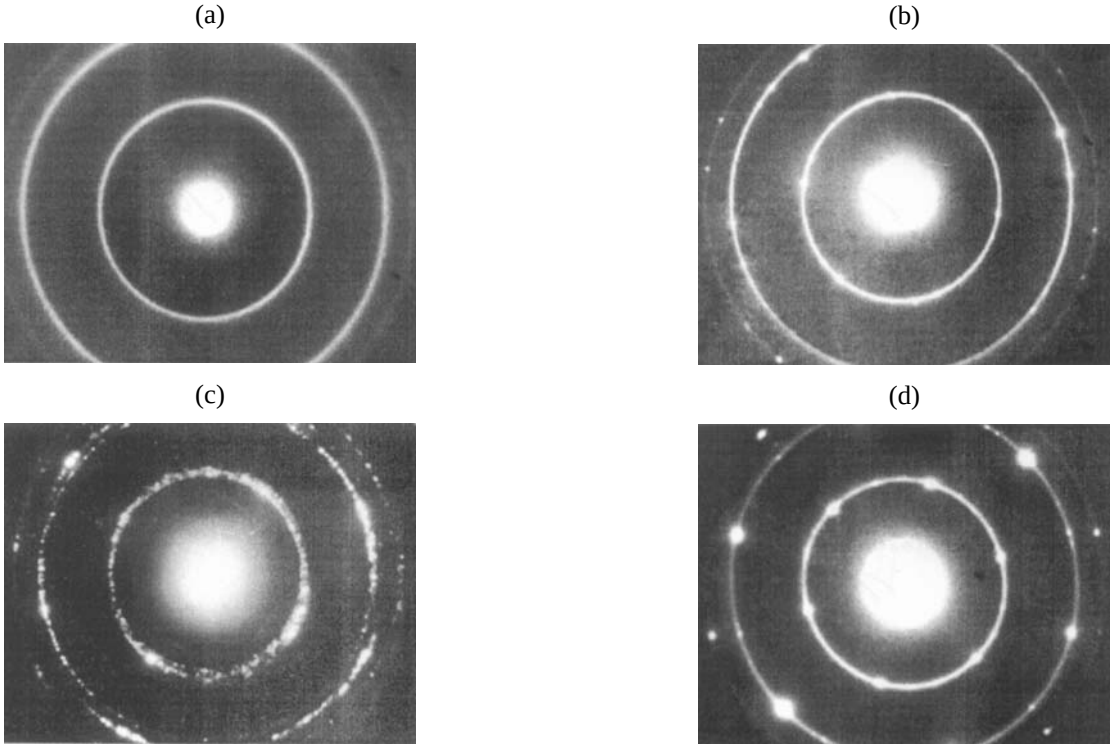

Fig. 2. Typical electron diffraction patterns of turbostratic carbon contained in C–SiC–Si–Al composites. Electron diffraction pattern: (a) ring-like, (b) ring-like with small number of discrete reflections, (c) discrete, and (d) discrete-periodic.

Table 2. Occurrence frequency of various types of electron diffraction patterns of turbostratic carbon in different regions of the MG–AS composite (Fig. 2)

4	72	67	20	19
Σ	107	100	107	100

data in Table 2. The annular electron diffraction patterns of the first type occur five times more frequently in the C regions of the composite. Contrariwise, electron diffraction patterns of the fourth type, which are characteristic of coarse crystals, are found 3.5 times more frequently in the bulk of the composite. The aforesaid suggests that the carbon region C is a volume into which the Si–Al melt did not penetrate and its structure and composition remained similar to those of the starting carbon material. The increase in the share of the coarsely crystalline component in the carbon remaining in the bulk of the composite (Table 2) is presumably due to the following: the finely crystalline component of the graphite phase is the first to be involved in carbide formation.

Part of discrete electron diffraction patterns obtained from the bulk of the composite is attributed to silicon carbide and silicon with a coherent domain size of more than 50 μm. The appearance of the electron diffraction patterns of silicon is virtually the same over the entire cross section of the samples. The interplanar spacings calculated from these diffraction patterns are in good agreement with the ASTM file. Direct measurements of the coherent domains with the use of dark-field images obtained using the reflection 111 demonstrated that they are 70 nm and more in size. The interplanar spacings of silicon exceed by approximately 0.001 nm those from the ASTM file, which indicates the existence of solid solutions of aluminum in silicon. Deviations from the interplanar spacing listed in the ASTM file are observed in the vicinity of the C regions. This may be due to an increase in the concentration of the aluminum impurity. The size of the coherent domain in silicon, measured using the dark-field images obtained with the reflection 110, varies within the range 50–400 nm.

Characteristically, the electron diffraction patterns of aluminum are constituted by nearly solid rings and can only be recorded at the interface between the bulk of the composite and the C regions. The sizes of aluminum crystals, measured from the light-field image, are 8–12 nm.

The X-ray diffraction patterns obtained from the bulk of the PG–AS, GP–0.5AS, and MG–AS composites (Fig. 3, light hatching) show reflections characteristic of β-SiC, turbostratic carbon, and silicon. The intensities of reflections from different phases in the composites (peak heights) are listed in Table 3. It can be seen that the lowest intensity of the diffraction reflections of β-SiC, which is contained in the composites, is observed for PG–AS. For the other two of the materials studied (GP–0.5AS and MG–AS), the intensities of the diffraction peaks of β-SiC are by a factor of approximately 1.3 higher. This indicates that the amount of silicon carbide grows as the density of the starting carbon supports and the concentration of aluminum in the melt become higher (Tables 1, 3).

Table 3 shows that the intensity of carbon lines increases, on the average, by a factor of 1.4 and 2 for GP–0.5AS and MG–AS, respectively, as compared to the PG–AS composite. Such a change in the intensities indicates that the amount of residual carbon, which has not reacted with the silicon melt, becomes greater. The possible reason is the same: the increased density of the carbon materials and higher concentration of aluminum (Tables 1, 3).

The relative intensities of the silicon reflections

7	14.25	31	37.6	0.3376	5.5	0.3145	28	0.2518

are in disagreement with those in the ASTM files (Table 3). In addition, a minor rotation (by ~5°) of the section of a composite leads to a strong (severalfold) change in the intensities of the diffraction peaks of Si. This indicates that the silicon crystals formed in the composites are textured, which hinders a correct comparative analysis. However, judging from the total intensity Σ of all the reflections, it can be stated that the highest concentration of Si is observed in the PG–AS composite (Σ_{PG-AS} exceeds by a factor of approximately 11 the total intensity of the Si lines in the GP–0.5AS composite).

The structural characteristics of the main phases (β-SiC, C, and Si) were determined by analyzing the profiles of the strongest reflections from these phases (Table 3). It was established that the interplanar spacings d_{002} of the carbon phase are in the range 0.3371–0.3377 nm, and the average sizes of the coherent domain, 30.2–37.7 nm. The differences are presumably due to the different structures of the starting carbon materials. Strong differences are observed between the characteristics of crystalline carbon in the bulk of the MG–AS composite and in the carbon region C (Table 4). Table 4 shows that the interplanar spacings and the integral intensity in the C region are larger, and the average size of the coherent domains smaller, than those in the bulk of the composite. In all probability, the finely crystalline component of the carbon material has the highest reactivity and is the first to enter into the reaction with silicon to form a carbide. Noteworthy is one more specific feature of crystal formation: the coherent domains of silicon carbide at the boundary of the C region are smaller than in the bulk of the composite (Table 3). This is due to the fact that β-SiC is formed in the boundary region under the conditions of silicon deficiency.

The interplanar spacings d_{111} of silicon in the composites are 0.3145–0.3153 nm, which exceeds the tabulated value (0.3135 nm) and points to the formation of solid solutions of aluminum in silicon. The average size of the coherent domains exceeds 200 nm.

To elucidate the mechanism of formation of those regions of the composites into which the silicon melt does not penetrate, the variation of the phase composition across a sample of a composite was studied in accordance with the scheme in Fig. 1. The results obtained are listed in Table 4 and shown in Fig. 4. It was established that the content of silicon carbide and silicon in the carbon region C of the composite is

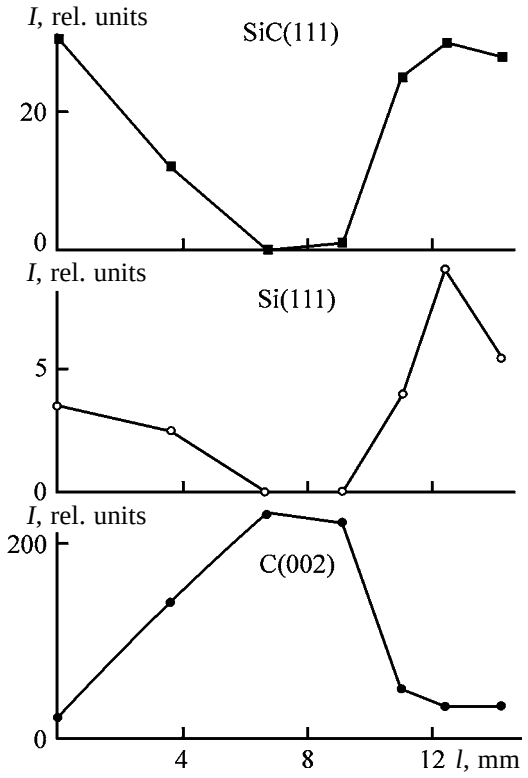

Fig. 4. Variation of the intensity *I* of the reflections 111 for silicon carbide, 111 for silicon, and 002 for carbon across a sample of the MG–AS composite.

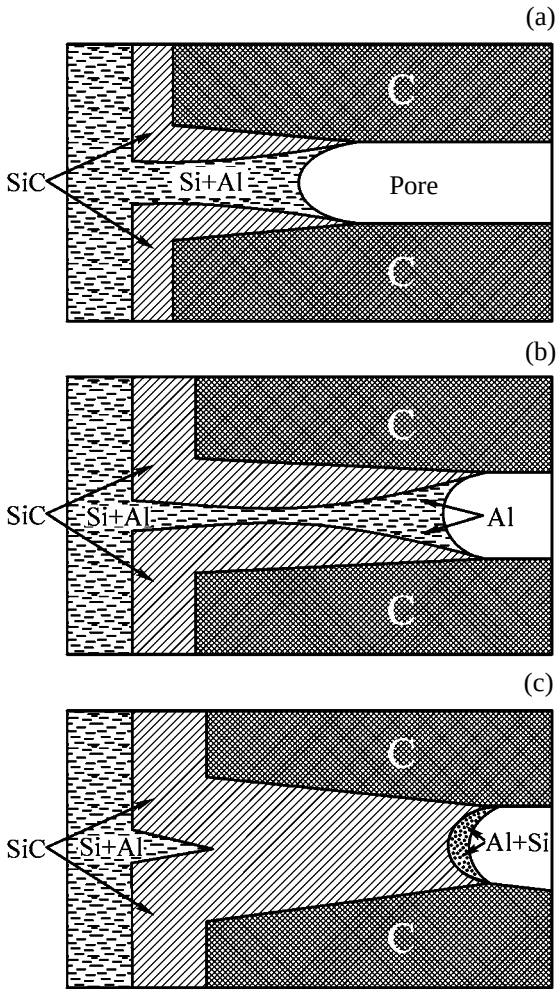

Fig. 5. Mechanism of formation of carbon regions in C–SiC–Si–Al composites: (a) Motion of the Si–Al melt along a pore at the beginning of the process, (b) overgrowth of the pore, and (c) formation of an SiC layer beyond the overgrowth point through spreading of the remaining part of the melt that penetrated into the pore.

virtually zero and their content in the bulk of the composite decreases toward the boundary of the purely carbon region. Contrariwise, the intensity of the line 002 of carbon increases and reaches its maximum value in the C region.

The results obtained suggest the following formation mechanism of the structure of the four-component composite C–SiC–Si–Al. The composites are formed by reaction with the Si–Al melt, which spreads along the capillaries (pores) of the starting carbon supports. Since silicon is constantly spent in the process for SiC formation, the concentration of the impurity (aluminum) at the melt motion front must increase, as it occurs when C–SiC–Si–Cu is formed [4]. This is confirmed by the experimentally observed dependence of the interplanar spacings d_{111} of metallic silicon present in the composite on the cut depth (Table 4). The average interplanar spacing d_{111} varies from 0.3145 to 0.3153 nm and exceeds that for pure silicon (0.3135 nm). The hypothesis is also confirmed by the formation of aluminum crystals at the boundary of the carbon region C. The concentration of aluminum in silicon on the surface of the MG–AS composite, evaluated using Vegard's law [6], is two times smaller than that at the boundary of the volume of the composite in which the reaction with the Si–Al melt did not occur. The increase in the concentration of aluminum at the front of the melt moving along the capillaries must lead to a proportional acceleration of the crystallization of SiC. The catalytic effect of aluminum on the growth rate of SiC is confirmed by the results of comparative studies of carbide formation in Si, Si–Al, and Si– Cu melts brought in contact with a carbon surface in the initial stage (2 to 120 s) of the process, reported in [7].

The motion of the front of the Si–Al melt is illustrated by the scheme in Fig. 5. The amount of SiC formed at the beginning of the interaction between the silicon melt and carbon gradually increases, so that at a small diameter of the pores they must be overgrown with a layer of rapidly formed SiC. As a result, further supply of the melt along the capillaries is terminated (Fig. 5b). Regions into which no melt has penetrated are formed in the composite. A part of the unreacted melt, which is beyond the clogging point, gradually flows toward the defective region (Fig. 5c), with the result that the boundary of this region becomes less abrupt and the amount of SiC formed gradually varies in going from the surface of the composite to the C region. This mechanism of formation of structural heterogeneities differs from that for the case of four-component composites and copper, in which the melt motion terminates as a result of an increase in the contact angle [4]. Strongly different effects of Cu and Al on the phase boundaries of other semiconductors have also been reported [8].

The acceleration of carbide formation at the interface between the Si–Al melt and carbon, compared to that for a system with no aluminum additives, is presumably due to a higher rate of carbon dissolution in the melt at the beginning of the interaction between the melt and the carbon surface. After an SiC layer is formed on the carbon surface, the rate of carbide formation is limited by diffusion of carbon across the carbide layer and the impurities present in the melt cannot affect the process to any noticeable extent. However, at the beginning of the interaction, when the SiC layer is not formed yet, the surface tension at the

melt–carbon phase boundary decreases to zero, and even becomes negative [9]. This may lead to diffusion of carbon particles into the melt, to form a colloid solution [9]. The thickness of the primary SiC layer formed on the carbon surface must be proportional to the amount of carbon dissolved in the melt at the beginning of the interaction. Therefore, the catalytic effect of aluminum on the formation of a carbide is, in the authors' opinion, due to the fact that its presence in the silicon melt leads to dissolution of a greater amount of carbon at the beginning of the interaction between the melt and the carbon surface.

CONCLUSION

Spatially heterogeneous regions are formed in C–SiC–Si–Al composites as a result of a catalytic action of aluminum on the process of carbide formation. The formation of regions into which no melt penetrates can be precluded by lowering the concentration of aluminum in the silicon melt and making larger the capillaries (pores) in the starting carbon support.

Received August 6, 2003; in final form, December 2003

Abstract—The structure of silica formed by carbonation of alkaline silicate solution was studied by adsorption, electron microscopy, and sedimentation analysis.

This study continues our previous work [1] and concerns the structure of silica formed by carbonation of alkaline silicate solution [2]. This kind of silica is considerably less studied than silicas prepared by the reaction of sodium or potassium silicate with acid mineral reagents [3–6].

Silica of pilot-plant production containing ~75 wt % SiO_2 and ~25 wt % Na_2CO_3 was washed with water to remove Na_2CO_3. According to spectral analysis, the washed sample contained about 3.4×10^{-2} wt % sodium ions. The product was studied by adsorption methods (with krypton, methanol, and water as adsorbates) [7], electron microscopy [8], and sedimentation analysis. The fractionation was done under the standard conditions: powder in the form of a turbid aqueous suspension (solid-to-liquid ratio 100 : 10) was poured into a glass cylinder (12 cm in diameter and 20 cm high), and the precipitate was separated from the suspension at regular intervals with a bottom rubber tube. The precipitate (fraction) was dried, weighed, and examined under an optical microscope (magnification 500). The fragments of the micrographs and results of their statistical treatment in the form of particle-size distribution curves are presented in Figs. 1 and 2 and in the table.

The initial (reference) silica had polydispersed granulation and consisted of oval or spherical particles from 2 to 100 μm in size (Fig. 1a). Most (about 85%) of the polydispersed system consisted of 30–50-μm particles (Fig. 1b); about 10%, of 10–20-μm particles (Fig. 1c); and 1%, of 5-μm and finer particles (Fig. 1d).

The comparison of the specific surface areas of the initial silica and its fractions, as calculated from the krypton adsorption isotherms S_{Kr}, $m^2\ g^{-1}$ (true surface

area corresponding to the nonspecific dispersion interaction in the adsorbent–adsorbate system [9]) shows that, though sample nos. 1–8 have different S_{Kr} values, they can be subdivided into two groups (see table). The first group includes coarsely dispersed fractions having somewhat lower S_{Kr} values compared to the initial sample, and the second group, finely dispersed fractions having a more developed surface compared to the initial sample. The similar dependence of the specific surface area on the fraction fineness is also clearly revealed when comparing with S_{Kr} the formal S_{H_2O} and S_{CH_3OH} values as calculated from the corresponding adsorption isotherms of water and methanol vapors. The increased adsorption activity with respect to methanol and water is observed for all the samples, especially for coarse fractions (S_{H_2O}/S_{Kr} = 1.9 and S_{CH_3OH}/S_{Kr} = 1.3).

According to the electron-microscopic study, the initial silica has a corpuscular skeleton formed by corpuscules of size from 70 to 150 Å and aggregated

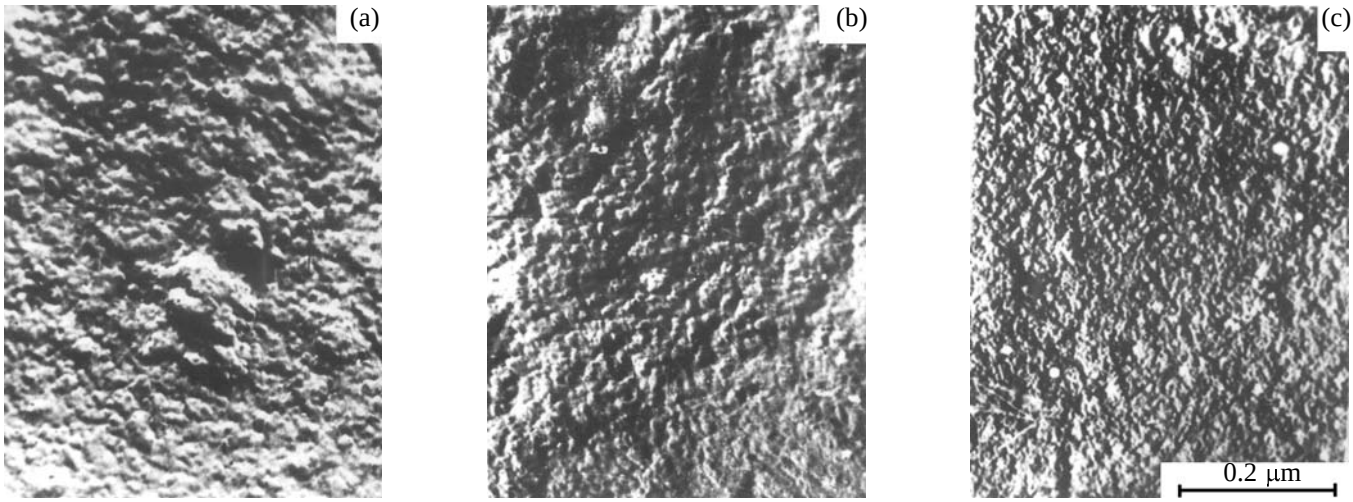

Fig. 3. Electron micrographs taken with self-shaded Pt–carbon replicas prepared on surfaces of the samples. (a) Initial silica; fraction: (b) 8-min and (c) 80-min.

globules of smaller (up to 50 μm) size (Fig. 3a). The coarsely dispersed fractions have the similar skeleton. The micrograph of a sample of the 8-min fraction is given as example (Fig. 3b, sample no. 4). The samples of finely dispersed fractions have the pronounced close-packed skeleton (Fig. 3a) formed by fine globules 30–50 μm in diameter. The average pore volume is from 0.45 to 0.58 and ~0.35 $cm^3\ g^{-1}$ for the samples of the first and second groups, respectively. To these values correspond the average pore diameters of 60 and 30 Å, respectively.[1]

As known, the structure of the silica corpuscular skeleton, globule size and packing, and, consequently, surface area, pore volume, and pore diameter depend on the synthesis conditions (solution pH, reagent concentrations, and temperature [3, 4]). Therefore, it may be suggested that the silica fractions of the first group (the major part of the initial sample) were formed under somewhat different synthesis conditions than samples of finely dispersed fractions. In the traditional method of the synthesis of amorphous SiO_2 [3, 4], the acid is fed into alkaline silicate solution at once (i.e., formation and growth of silica sol occur simultaneously throughout the volume). At the same time, in an alternative method described in [2, 5, 6], silicic acids form and polymerize into more complex cross-linked structures gradually, as CO_2 is fed into the solution. The process is complete at a 104–108% carbonation. Therefore, the conditions of the nucleation and growth of silica sol at each subsequent moment are different.

In the first stages of carbonation, when the concentration of Na_2SiO_3 solution is high and concentration of the acidic reagent is low ($CO_2 + H_2O \rightleftarrows H^+ + HCO_3^-$), the amount of the forming silicic acids cannot ensure bulk polycondensation and solation. As CO_2 is fed, the content of silicic acids increases. However, up to 80–85% carbonation, the degree of polymerization is so low that the solution remains transparent even after prolonged storage (so-called sol phase [3]). After a slight amount of CO_2 is then fed, the solution becomes turbid within a short time, i.e., gelation and subsequent precipitation take place.

The formation, growth, and aggregation of the macromolecules of silicic acids accompany each other during the whole process of the carbonation of alkaline silicate solution. This suggests that most (up to 85%) of the precipitated SiO_2 (namely, coarsely dispersed fractions) is formed in the first stage of the carbonation. Finely dispersed fractions (~10% of the total SiO_2 amount) having finely globular close-packed skeleton are formed in the final stages, when the residual amount of Na_2SiO_3 in the reaction medium is low [4].

The persorption phenomenon, revealed as preferential adsorption of CH_3OH and H_2O in comparison with large spherical Kr atoms, shows that, apart from coarse pores, i.e., voids between the SiO_2 globules in contact, there are very fine pores (ultrapores) accessible mainly to water molecules. The ultrapores or voids of molecular size can be formed in the volume of macromolecules under the certain conditions of the

[1] The average pore volume was determined by the "desiccator" method, i.e., by keeping the sample in benzene vapor till saturation, i.e., at $p/p_S = 1.0$; the average pore diameter was calculated from the $d_{av} = 4V_{av}/S_{cr}$ ratio [9] for corpuscular structures.

silica synthesis or hydrothermal treatment (when, e.g., the polymeric chain terminates upon attachment of the ≥Si–ONa group and continues to grow in another direction) [10, 11]. Such incorporation of the ≥Si–ONa groups into the silica polymeric network is facilitated by the long carbonation time and by gradual accumulation of silicic acids in the bulk. The washout and removal of sodium ions results in the formation of ultravoids in the volume of globules. The extent of termination of the polymeric chain determines the linear size of the ultrapore.

The fact that S_{CH_3OH} slightly exceeds S_{Kr} (corresponding to the true value of the surface area) indicates that a part of ultrapores is also accessible to CH_3OH molecules. When a CH_3OH molecule is favorably oriented with respect to the ultrapore aperture, it can partly enter the ultrapore with its hydroxy group (S_{H_2O}/S_{Kr} is ~1.9 and ~1.1 for coarsely dispersed and finely dispersed fractions, respectively).

According to the experimental data (see table), small H_2O molecules in perceptible amounts penetrate into the silica ultrapores. The amount of such defects in the macromolecule structure is the largest in the samples of coarsely dispersed fractions. The additional surface area accessible for H_2O molecules inside the silica ultrapores is 300–340 $m^2 g^{-1}$ (for fine fractions, 200 $m^2 g^{-1}$). With all the samples without exception, the adsorption equilibrium was attained within 40–45 min for krypton, 1–2 h for methanol, and 10–20 h for water. The long time of attainment of the adsorption equilibrium in adsorption of H_2O vapor shows that the ultrapore length is large.

Silica with the similar structural characteristics can be used as drying agent for various gaseous systems and in manufacture of special-purpose glasses (their production process allows preparation of silica containing ~10^{-3} wt % color impurities [2, 6]).

CONCLUSIONS

(1) Study of the structure and granulometric composition of silica formed by carbonation of alkaline silicate solution showed that the product is a finely dispersed powder system. Most (~85%) of the powder is in the form of 30–50-μm particles having the similar corpuscular skeleton formed by globules 70–150 Å in diameter (S = 360–400 $m^2 g^{-1}$). The remainder is finely dispersed fractions 20 μm in size and less, with close-packed skeleton.

(2) The silica corpuscular skeleton with a pore volume from 0.30 to 0.58 $cm^3 g^{-1}$ and pore diameter in the range 30–60 Å, depending on the fraction dispersion, has the ultrapore structure, i.e., it consists of molecular-size pores accessible to water molecules.

(3) The long time of the formation and polymerization of silicic acids, associated with the prolonged carbonation of alkaline silicate solution, is mainly responsible for the inhomogeneity of the silica structure and granulometric composition.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Combustion in a System of Conjugated Layers and High-Temperature Synthesis of Materials

G. I. Ksandopulo and A. N. Baidel'dinova

Plamya Research and Production Association, Almaty, Kazakhstan
Institute of Combustion Problems, Almaty, Kazakhstan

Received August 29, 2002; in final form, July 2003

Abstract—The possibility of constructing layered systems for high-temperature synthesis of materials is demonstrated. The cases of vertical and horizontal arrangement of layers, which ensure different types of a technological combustion of the initial reactant mixtures with or without subsequent interaction of the reaction products formed, are considered. The conditions are found for the synthesis of alkaline-earth metal titanates and aluminum borides in the layered systems.

The temperature of the combustion wave front in metal–oxide systems may be as high as $(3–4) \times 10^3$ K under quasi-adiabatic conditions. In order to perform a high-temperature synthesis, conditions of this kind can be created if the mixture of reacting components is formed as a layer receiving thermal energy from the side of parallel energy-carrying layers [1].

A stack of layers selected with account of the task to be accomplished is arranged horizontally or vertically (perpendicularly to the horizontal or vertical axis, respectively). In some cases, it can be subjected to the action of a centrifugal force, or an electric or a magnetic field.

This article is concerned with the fundamental aspects of combustion of complex stacks in relation to the mutual arrangement of the constituent layers, their orientation, etc. It is not aimed to establish a strict relationship between the kinetic parameters that govern the chemical process and the parameters determining the removal of heat from the reaction zone. The goal is to consider the phenomenology of combustion in the layers and the propagation of the combustion front in the adjacent layers.

Combustion of a horizontal stack of layers. In the horizontal variant, when the layers are arranged perpendicularly to the horizontal axis (Fig. 1a), the products formed in combustion of oxide system and, in particular, reduced metals, do not penetrate into the adjacent layers. In this case, only conductive heat transfer occurs, since the horizontal stack is composed of chemically independent layers. To ensure a quasi-adiabatic course of the process in the layered system, ignition is performed simultaneously in the adjacent layers. Then the synthesis layers can be repeatedly alternated with the layers that serve as sources of heat, with the maximum heating achieved.

The macrokinetics of combustion in a layer is determined not only by the reactant concentrations, temperature, and pressure, but also by external forces, e.g., those due to centrifugal acceleration in the case of axial rotation.

The characteristic time τ of combustion of a stack is constituted by the times τ_k of burning-through of all

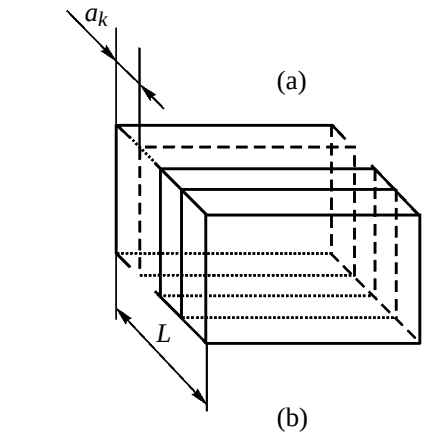

Fig. 1. Schematic of a horizontal stack of layers. Stack: (a) that in the general case and (b) that with a repetitive system of three layers, in which layer no. 2 is the synthesis layer.

1070-4272/04/7703-0364 © 2004 MAIK "Nauka/Interperiodica"

the k layers of the stack:

$$\tau = \sum_{k=1}^{i} \tau_k = \sum_{k=1}^{i} (n\bar{M}/W_k), \quad (1)$$

where n is the number of moles; $\bar{M}$, average molecular weight of the starting substances; and W_k, mass rate of the overall reaction in the kth layer.

The normal combustion velocity U_k in a layer is equal to the thickness of each layer (a_k) divided by the time τ_k of its combustion, and, consequently, the average linear velocity of combustion of the whole stack ($\bar{U}$) in the case of successive ignition of the layers is given by

$$\bar{U} = \tau^{-1} \sum_{k=1}^{i} a_k. \quad (2)$$

Let us assume that the optimal result of synthesis is determined by the average mass velocity of combustion of a stack with substance density ρ_k in the kth layer:

$$\bar{U}_m = S\tau^{-1} \sum_{k=1}^{i} a_k \rho_k. \quad (3)$$

The quantity $\bar{U}_m$ differs from the additive $\bar{U}_{am}$, which is equal to the average velocity of separate combustion of each layer of the stack at average temperature T_{av},

$$\bar{U}_{am} = S \sum_{k=1}^{i} (a_k \rho_k / \tau_k).$$

Let us name the ratio

$$\varphi = \bar{U}_m / \bar{U}_{am} \quad (4)$$

the coefficient of conjugation of layers in a stack. This coefficient characterizes the rise in the rate of the overall reaction in a stack, caused by changes in the heat transfer conditions, number and distribution of ignition points, and mutual arrangement of layers in the stack:

$$\varphi = f(\lambda, \rho, S, P_n), \quad (5)$$

where λ is the heat conductivity; S, cross-sectional area of the stack; P_n, nth permutation, whose total number P_n in a stack composed of k layers is given, with account of the fact that the 1st, 2nd, 3rd, ..., and kth layers are repeated α, β, γ, ... times, by

$$P_n = k!/\alpha!\ \beta!\ \gamma!,... \quad (6)$$

It is noteworthy that the quantity φ we introduced also characterizes the synthesis layers. In this case, the quantity $\bar{U}_{am}$ is equivalent to the rate of accumulation of the product at T_{av}, and $\bar{U}_m$, to the rate of its accumulation in a layer within a stack.

Thus, for any composition of the stack, the value of φ depends on the arguments in expression (5), whose variation mainly affects $\bar{U}_m$. If the parameters λ, ρ, and S are constant within the limits of variations, then the only reason why the coefficient φ changes is transition from one arrangement of the layers to another. The best synthesis effect, to which corresponds the maximum value of φ, is achieved at a certain average value of the mass velocity.

Let us consider a three-layer system repeated in the stack k times (see Fig. 1b). Layer 2, in which the strongest heating conditions are to be created, is in contact with layer 1 on the left and layer 3 on the right. In the case of a simple, nonchain reaction in layer 2, the degree of conversion of the reaction mixture at any point of this layer along the stack axis is determined by the temperature distribution on the left and on the right, attained by the instant of time τ_k. The value of φ in layer 2 is determined in this case by the velocity U_m of the heat wave that arrives from the adjacent layers.

The resulting value of φ for the three layers combined is given by

$$\varphi = \overrightarrow{\varphi_1} - \varphi_2 + \overleftarrow{\varphi_3}.$$

The strongest effect ($\varphi' = 0$, $\varphi'_2 = 0$) corresponds to a numerical equality of the velocities of the oppositely propagating combustion waves in layers 1 and 3:

$$|U_{m_1}| = |U_{m_3}|.$$

The temperature distribution within layer 2 is set by the propagation of the heat waves from the left and from the right. If it is assumed that the total content of enthalpy in layers 1 and 3 much exceeds the heat consumed by the reaction in layer 2, then the reaction rate profile in the synthesis layer is determined by the existing temperature distribution. If, further, the characteristic time of the reaction in the synthesis layer is of the same order of magnitude as the time of propagation of the heat wave (the reaction begins at

its front), then the temperature profile is approximately described by the known Michelson distribution:

$$T_{(x)} \approx T_0 + (T_c - T_0)\exp UXC_t\rho/\lambda. \quad (7)$$

At the point x where the temperature increases by a factor of approximately e ($T_x/T_0 \approx 2.718$ at $T_0 \approx 300$ K), but the reaction rate can still be neglected,

$$(T_x - T_0)/(T_c - T_0) \approx e, \quad (8)$$

$$x \approx \lambda/(UC_p\rho).$$

For the TiO_2–Al reaction mixture diluted with graphite, $C_p = 170$ J g^{-1} deg^{-1}, $\lambda = 0.05$ J cm^{-1} deg^{-1} s^{-1}, $\rho = 2.3$ g cm^{-3}, $U = 0.02$ cm s^{-1}, and the increase in temperature to $T_x/T_0 \approx 2.718$ will occur at a distance $x = 1.5 \times 10^{-3}$ cm from the plane that divides the reaction and heating layers.

In various mixtures of metal oxides with the specific heat $C_p \approx 80$–130 J g^{-1} deg^{-1}, all other conditions being the same, the value $x \approx (1–2) \times 10^{-2}$ is reached within 1 s, and at $U = 1$ cm s^{-1}, at 10^{-3} s. Extrapolation suggests that a layer of thickness 10 cm is heated in 1 s. Since the synthesis layer can be heated both from the left and from the right, the yield of the reaction product is the highest at the boundary of the heat source and the lowest in the middle of the synthesis layer.

The ratio (4) of the mass velocities characterizes rather effectively the relationship between the thermal properties of layers for a three-layer stack, in which the yield of the product is determined by temperature.

Let us assume that at a furnace temperature T_1 the reaction rate in the synthesis layer is infinitely small and the velocity of the combustion wave in the auxiliary layer is U_1. The combination of two auxiliary layers and the synthesis layer that lies in between is a system in which several pathways of the process are possible, depending on the heat-exchange conditions. If the synthesis layer considerably exceeds in mass the auxiliary layers and the contact area is small, then the middle layer acts as a heat insulator, the relative yield of the reaction product in this layer is nearly zero, and φ tends to unity. As the mass of the synthesis layer decreases and the contact area increases, the conditions can be created under which the reactions in the layers of the system go to completion and the velocity of the combustion wave in isolated auxiliary layers is zero. This is the ideal, hardly achievable in practice, case, when φ tends to infinity.

Real layered systems include auxiliary layers in which, when these layers are in the isolated state, the combustion process occurs in the steady-state mode without any change in their shape or disruption of the integrity of their surface, the loss of heat across the lateral surface is at a minimum, and the amount of thermal energy released is sufficient for initiating or maintaining reactions in the synthesis layer.

Synthesis of titanates of alkaline-earth elements in a horizontal stack. The reaction of titanium and barium oxides occurs in the temperature range 1350–1450°C. The composition and parameters of the auxiliary layer were chosen taking into account the endothermic effect of the reaction between the components in the main layer and its geometric dimensions [2].

The starting mixtures were thoroughly mixed. A hydraulic press equipped with a pressure gage for recording the compaction force was used to fabricate samples in the form of cylinders of various diameters or prisms, depending on the aim of a particular experiment. The samples were used to form layered systems, which were then placed in a furnace heated to the temperature of self-ignition of the mixtures used. After the combustion in the auxiliary layers was complete, a sample was either extracted for cooling in air or left in the furnace until equalization of temperatures.

In the case of synthesis of materials of prescribed composition for electronics, the requirements imposed on the product purity are high, and not only chemical interaction between the layers, but even mechanical penetration of the combustion products formed in the auxiliary layer into the synthesis layer are unacceptable. Therefore, the layers were arranged vertically, along the common horizontal axis. The cylindrical shape of the multilayer compound structure was chosen in order to diminish the area of contact with the substrate and, accordingly, to make lower the unproductive heat expenditure. These conditions ensure a sufficiently high ratio of the total weight of the reactants to the total area of the sample surface, across which heat is consumed, and the maximum possible area of contact between the layers. As a result, a steady-state combustion wave was obtained in the auxiliary layer and the most complete energy transfer from one layer to another was achieved. The furnace temperature was maintained at 850°C.

In the course of the experiments, auxiliary layer compositions Al–Cr_2O_3 with varied content of the reducing agent were studied. At a constant layer diameter of 20 mm and an auxiliary to synthesis layer mass ratio of 2, it was found that the temperature to which

the reagent mixture in the synthesis layer is heated varies with the composition and mass of the auxiliary layer. The results obtained are listed in Tables 1 and 2.

The limiting mass ratio in a synthesis layer of composition TiO_2–$BaCO_3$ and an auxiliary layer of composition Al–Cr_2O_3 was 1 : 2 at an aluminum content in the initial composition of the auxiliary layer of 15% and 1 : 1 at 23%. An X-ray phase analysis demonstrated that the finished product in the synthesis layer is the tetragonal modification of barium titanate.

In a similar way, with a minimum energy expenditure, we synthesized magnesium and calcium titanates. In this case, experimental selection of the composition and weight of the layers ensured that, in accordance with a calculation, the temperature in the synthesis layer was as high as 1650–1700°C at the furnace temperature of 850–900°C.

Synthesis of pure strontium titanate is hindered by the inertia of the process. To bring its rate in correspondence with the reaction rates in the auxiliary layers, the stock of the main layer was mechanically activated (the efficiency of this process was demonstrated in preliminary experiments for the example of an Al–Cr_2O_3 mixture [3]).

Thus, the approach developed for synthesis of materials in a layered system was used to obtain a number of compounds whose conventional synthesis involves complicated preparation of starting reactants and prolonged thermal treatment at high temperature. Combining the layer technique with such methods as, e.g., compaction or mechanochemical activation of the starting mixtures makes it possible to improve the control over the process.

Synthesis of aluminum borides in a stack of layers with protective interlayers. In contrast to the case of synthesis of alkaline-earth metal titanates, when it is only important to observe the lower temperature limit, synthesis of aluminum borides of certain compositions, AlB_2, AlB_{10}, and AlB_{12}, is complicated by its rather narrow temperature range (°C):

AlB_2	1000–1100
α-AlB_{12}	1100–1550
β-AlB_{12}	1550–1660
AlB_{10}	1660–1850

Moreover, aluminum borides are, as a rule, formed in the presence of carbon, which takes the uncompensated free bonds of complex boride molecules, and contamination of the finished product with other impurities, which diffuse from the auxiliary layers, significantly changes the electrotechnical properties of the borides.

Table 1. Heating temperature T_{comb} of the synthesis layer in relation to the stock composition of the auxiliary layer

C_{Al}, wt %	Forming density ρ, g cm^{-3}	T_{comb}, °C
12.0	2.726	1250
15.0	2.828	1382
18.0	2.830	1510
20.0	2.726	1648
23.0	2.725	1650
26.5	2.718	1618
32.0	2.692	1600

Table 2. Heating temperature T_{comb} of the substance in the synthesis layer in relation to the weight m of the auxiliary layer at aluminum content in this layer of 18%

m, g	Cylinder height h, mm	T_{comb}, °C
1.84	2.55	1406
3.80	4.46	1470
5.74	6.84	1538
7.64	8.98	1550
9.81	11.0	1580

The low-temperature boride AlB_2 was synthesized in a furnace heated to 870°C in an Al–B_2O_3 layer with additional heating from the side of an auxiliary layer composed of a stoichiometric mixture (Al + V_2O_5): Al_2O_3 (20–25%)–(Al + V_2O_5) (80–75%) or V_2O_5 (20–25%)–(Al + V_2O_5) (80–75%). AlB_{12} was synthesized using a three-layer system with two auxiliary layers situated on both sides of the main layer in which the Al–B_2O_3 mixture is also used as the synthesis layer, and the Al–TiO_2 system with nearly stoichiometric composition, as the auxiliary layer. The furnace temperature was 950°C, and the temperature in the combustion wave, 1500–1600°C.

Further rise in temperature enhances the diffusion interaction between the layers. Titanium penetrates from the auxiliary layer into the main layer and reacts with boron to give titanium boride. To preclude this process in synthesizing AlB_{10}, insulating interlayers of activated carbon were used. The use of inert high-melting interlayers enables a choice of the spatial arrangement of the layered compound structure, a horizontal or a vertical stack. The temperature in the reaction zone was raised by increasing the number of alternating layers in the order 1–2–3–2–1–2–3– etc.

(see Fig. 1b). To improve the mechanical strength of the system, a horizontal arrangement of the layers along a common vertical axis was used. Placing this multilayer system in a cylindrical graphite reactor ensures that the combustion process is highly adiabatic.

CONCLUSIONS

(1) The combustion of layered compound structures with characteristic conjugation of chemical processes in the layers was analyzed.

(2) It was shown that the main and fundamental distinctive feature of the layered combustion is the possibility of performing reactions in deep layers in a quasi-adiabatic mode. The temperatures that can be reached are as high as $(3–4) \times 10^3$ K.

(3) It was demonstrated that, in a horizontal stack with layers arranged perpendicularly to a horizontal axis, the combustion products of oxide system do not penetrate into adjacent layers, the layers are chemically independent, with only conductive heat exchange existing between them. As a characteristic of the compound structure was introduced the coefficient of layer conjugation, which is determined by the relative positions of the layers, changes in the combustion conditions in the case of combustion in a stack, and the number and distribution of ignition points; it characterizes the rise in the rate of the overall reaction. At a furnace temperature of 850°C, alkaline-earth metal titanates and aluminum borides were synthesized.

(4) With the layers lying one above another perpendicularly to a vertical axis, heavy reaction products in a melt pass from upper layers to lower ones and enter into a reaction with new reagents. This scheme is efficient in the case of a stage-by-stage formation of a multicomponent product and can also be used when insulating interlayers are introduced between the layers.

Abstract—A series of framework phosphates with varied ratio of cations $Na_{5-2x}B^{II}_xZr(PO_4)_3$, B^{II} = Mg, Ca, Sr, Ba ($0 \le x \le 2$) and $Na_{5-3x}Fe_xZr(PO_4)_3$ ($0 \le x \le 1.33$) were synthesized and studied under heating. The coefficients of thermal expansion along crystal axes α_a and α_c were calculated, and their dependences on the cationic composition (nature and concentration) and on the occupancy of out-of-framework structural positions were established.

Structural analogs of $NaZr_2(PO_4)_3$ (NZP, or Nasicon) are most studied among framework compounds characterized by the structural motif $[T_2(PO_4)_3]^f$, where T are elements in the oxidation states 1+, 2+, 3+, 4+, and 5+ (A, B, R, M, and C), and f is the framework charge taking values from 0 to 4. These compounds have a number of useful properties, which are often combined successfully in materials based on them. One of such properties is that, when heated in a wide temperature range, these compounds expand only slightly, sometimes do not expand, or even contract.

Phosphates of the NZP structural type (trigonal system, rhombohedral cell) are described by the crystal-chemical formula $(M1)(M2)_3L_2(PO_4)_3$, where L are cationic positions of an anionic framework, and M1 and M2 are positions in framework voids. As cations with varied size, oxidation state, and electronegativity can enter into various nonequivalent crystallographic positions of the structure, formation of wide isomorphous series becomes possible. Iso- or heteropolyvalent replacement of cations, on condition that their ratio is controlled, allows the physical and physicochemical characteristics of the compounds to be regularly varied.

The majority of works on the thermal expansion of phosphates concern double phosphates containing quadrivalent elements M^{IV} (Ti, Zr, Hf, Ge, Sn) in the framework and uni, bi-, or trivalent elements in voids. These phosphates are grouped in series according to the principle of isovalent replacement of A^I, B^{II}, and R^{III} cations. Among them, the following isoformula phosphates were studied: $A^IM^{IV}_2(PO_4)_3$, M^{IV} = Ti, A^I = Na, K [1–5]; M^{IV} = Zr, A^I = Li, Na, K, Rb, Cs [1, 3–8]; M^{IV} = Hf, A^I = Na, K, Rb, Cs [5, 9]; M^{IV} = Ge, A^I = Li, K [10, 11]; M^{IV} = Sn, A^I = Na [1, 5]; $B^{II}_{0.5}Zr_2(PO_4)_3$, A^{II} = Mg, Ca, Sr, Ba, Cd [3, 8, 12–20]; $R^{III}_{1/3}Zr_2(PO_4)_3$, R^{III} = La, Pr, Nd, Sm, Eu, Gd, Tb, Er, Tm, Yb [21].

As the metal–oxygen bonds in L positions do not noticeably elongate with increasing temperature and phosphorus–oxygen bonds become slightly shorter, the framework of such compounds does not noticeably expand on heating, and the thermal behavior of the structure as a whole depends on the nature and number of cations filling the framework cavities. It follows from the equation $\alpha = 32.9(0.75 - zp) \times 10^{-6}$ [22] [α is mean thermal expansion coefficient of the metal–oxygen bond (K^{-1}); z; cation charge; and p, coordination number] that the thermal expansion decreases as the cation charge increases. Increase in the size of cations located in positions of M, as shown for the above-given series with the same frameworks $[Zr_2(PO_4)_3]^-$, causes a decrease in the parameter α_c and an increase in the parameter α_a of a rhombohedral cell (hexagonal setting) with increasing temperature. In this case, the lattice parameters themselves change differently with increasing ionic radii of out-of-framework ions: c increases and a decreases. An increase in the number of M positions not occupied by cations often reduces the thermal expansion, as it was found when studying the phosphates $Sr_{0.5}Ti_2(PO_4)_3$ [23], $Cs_{1.3}R_{0.3}Zr_{1.7}(PO_4)_3$ [24], and the phosphates of the series with varied concentrations of cations and vacan-

cies $Na_{1-x}Nb_xZr_{2-x}(PO_4)_3$, $Na_{1+x}Y_xZr_{2-x}(PO_4)_3$, and $A_{5-4x}Zr_xZr(PO_4)_3$. The role of vacancies has been considered in [23] when discussing the mechanism of thermal expansion of the phosphate $Sr_{0.5}\cdot Ti_2(PO_4)_3$.

The system of zirconium phosphates of the series $A^I_{5-x}A^I_xZr(PO_4)_3$, $A^I_{5-x}B^{II}_xZr(PO_4)_3$, $A^I_{5-3x}R^{III}_x\cdot Zr(PO_4)_3$, $A^I_{5-4x}M^{IV}_xZr(PO_4)_3$, and $A^I_{5-5x}C^V_x\cdot Zr(PO_4)_3$ is of interest for the estimation of contributions of the concentrations n and ν of cations and vacancies, respectively, to the thermal expansion. Variations in the concentration x of cations B^{II}, R^{III}, M^{IV}, and C^V in these series upon their heterovalent substitution for cations A^I are accompanied by a change in the concentration ν of vacancies ($\square$) by the scheme

$$A^+ \rightleftarrows 1/2B^{2+} + 1/2\square,\quad A^+ \rightleftarrows 1/3R^{3+} + 2/3\square,$$
$$A^+ \rightleftarrows 1/4M^{4+} + 3/4\square,\quad A^+ \rightleftarrows 1/5C^{5+} + 4/5\square.$$

Earlier thermal expansion was studied for such series of phosphates with zirconium as M^{IV}, namely, $Na_{5-4x}Zr_xZr(PO_4)_3$ [$Na_{5-4x}Zr_{1+x}(PO_4)_3$] and $K_{5-4x}\cdot Zr_xZr(PO_4)_3$ [$K_{5-4x}Zr_{1+x}(PO_4)_3$] at x varied from 0 up to 1, i.e., from $Na_5(K_5)Zr(PO_4)_3$ to $Na(K)\cdot Zr(PO_4)_3$, and also for the phosphate $NbZrNb(PO_4)_3$ with C^V. The dependences of the thermal expansion parameters on the number of occupied crystallographic out-of-framework positions and, therefore, on the concentration of M^{IV} were revealed [27]. In this work we studied the series with bi- and trivalent elements. We examined the thermal expansion of the phosphates $Na_{5-2x}B_xZr(PO_4)_3$ for B = Mg, Ca, Sr, Ba and $Na_{5-3x}Fe_xZr(PO_4)_3$ with x 0–2 and 0–1.33, respectively, in the range from room temperature to 750°C. For this purpose we prepared the following phosphates of these series:

$Na_5Zr(PO_4)_3$	$x = 0$	$Na_5Zr(PO_4)_3$	$x = 0$
$Na_4Mg_{0.5}Zr(PO_4)_3$	$x = 0.5$	$Na_4Fe_{0.33}Zr(PO_4)_3$	$x = 0.33$
$Na_3MgZr(PO_4)_3$	$x = 1.0$	$Na_3Fe_{0.66}Zr(PO_4)_3$	$x = 0.66$
$Na_2Mg_{1.5}Zr(PO_4)_3$	$x = 1.5$	$Na_2FeZr(PO_4)_3$	$x = 1.0$
$NaMg_2Zr(PO_4)_3$	$x = 2.0$	$NaFe_{1.33}Zr(PO_4)_3$	$x = 1.33$

and similar compounds with Ca, Sr, and Ba.

Apparently, the numbers of occupied (n) and vacant (ν) positions in framework voids of the phosphates change from $n = 4$ and $\nu = 0$ (in this case the positions in the framework voids are fully occupied by cations) to $n = 2$ and $\nu = 2$ for the phosphates with bivalent elements and to $n = 1.33$ and $\nu = 2.67$ for the phosphates with Fe (in this case, the possible number of vacant positions in the framework voids is maximal).

EXPERIMENTAL

The phosphates were precipitated from 1 M solutions of appropriate salts by adding 1 M phosphoric acid. The solution over the precipitate was evaporated, and the precipitate was heated in several stages: at 600, 800, and 1000°C for 24 h in each stage, with intermediate grindings.

The resulting compounds and intermediate products were studied by IR spectroscopy and X-ray phase analysis (XRPA).

The IR spectra were recorded on a Specord 75-IR spectrophotometer in the range of wave numbers 1800–400 cm^{-1} at room temperature. Samples were deposited on a KBr support as finely dispersed suspension in isopropanol. A clean cell was used as a reference (100% transmission).

The X-ray patterns of powder samples were recorded on a DRON-3M diffractometer in filtered CoK_α or CuK_α radiation (λ_1 1.78892 and 1.54078 Å, respectively). The unit cell parameters were determined using Al_2O_3 as reference (a = 4.758, c = 12.991 Å, crystal planes [113] and [116]) in the range of angles 2θ = 10°–80°. The parameters were calculated by the least-squares method, the measurement error being no more than 0.015°. It gave an error in the hexagonal lattice parameters of 0.005 Å for the a-axis and 0.01 Å for the c-axis.

Thermal expansion of the phosphates was studied by high-temperature X-ray diffraction. The coefficients of linear thermal expansion were determined from the shifts of the reflections from crystalline planes [hkl] at varied temperature. The temperature was measured with a Pt–Pt/Rh thermocouple. The temperature readings were checked by simultaneous recording of the reference (Al_2O_3) pattern. The axial coefficients α_a and α_c were calculated using a technique based on the least-squares method.

The samples obtained were colorless finely crystalline powders. Their IR spectra are similar to each other (Figs. 1a and 1b). The character of the spectra points to the presence of orthophosphate groups: the bands in the ranges 1140–900 and 630–540 cm^{-1} correspond to antisymmetric stretching and bending vibrations of PO_4 tetrahedra. The IR data indicate that the compounds under study belong to the class of orthophosphates.

The positions of diffraction peaks and their relative intensities in the X-ray patterns are similar to each

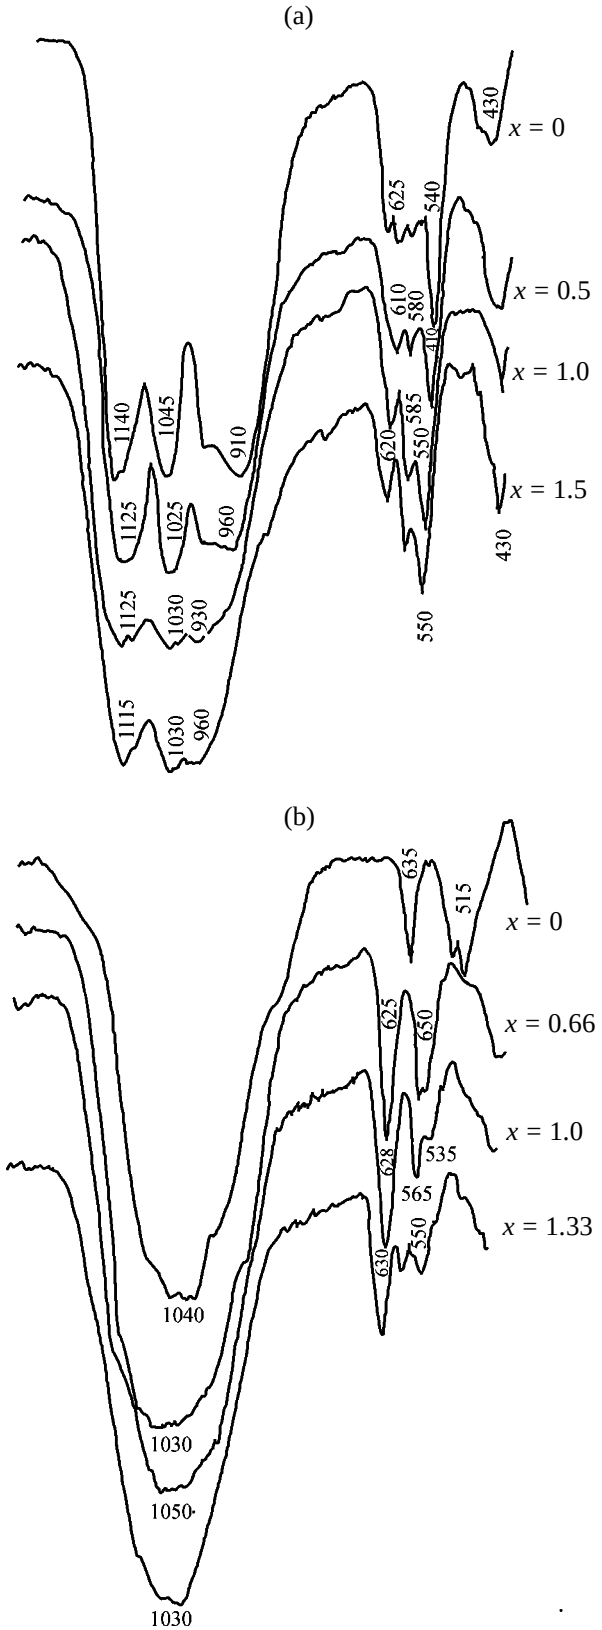

Fig. 1. IR spectra of (a) $Na_{5-2x}Sr_xZr(PO_4)_3$ and (b) $Na_{5-3x}Fe_xZr(PO_4)_3$ (ν, cm^{-1}).

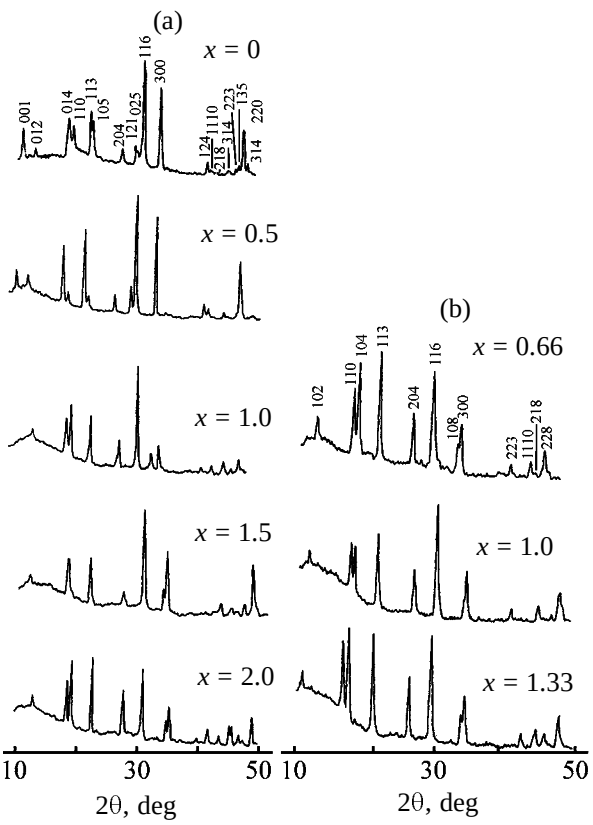

Fig. 2. X-ray patterns of (a) $Na_{5-2x}Sr_xZr(PO_4)_3$ and (b) $Na_{5-3x}Fe_xZr(PO_4)_3$. (2θ) Bragg's angle.

other (Fig. 2). They were indexed using two crystalline modifications of $Na_5Zr(PO_4)_3$ as structural analogs. It was found that the phosphates under study crystallized in two structural forms of trigonal system (space groups $R32$ and $R\bar{3}c$).

Phosphates $Na_{5-2x}B^{II}_xZr(PO_4)_3$ (B^{II} = Ca, Sr, Ba). The phosphate $Na_5Zr(PO_4)_3$, which is an extreme member of the series $Na_{5-2x}B^{II}_xZr(PO_4)_3$ (B^{II} = Ca, Sr, Ba), is characterized, as mentioned above, by two structural modifications with space groups $R\bar{3}c$ and $R32$, with ordered (space group $R32$) and disordered (space group $R\bar{3}c$) arrangement of the NaO_6 and ZrO_6 polyhedra along the c-axis.

According to the XRPA data, the $R32$ modification is formed in the phosphates with a small content of calcium and strontium [up to $x = 0.5$, which corresponds to $Na_{4.5}B_{0.5}Zr(PO_4)_3$]. This conclusion agrees with the IR data. The IR spectra of the phases with space group $R\bar{3}c$ (according to the XRPA data), containing Ca and Sr in concentrations $x > 0.5$ and Ba in concentration $x = 1.0$, exhibit bands typical of the $R32$ modification: 4–5 of five bands allowed by selection rules appear in the region of stretching and bend-

ing vibrations. Hence, as x increases, the ordered arrangement of Na and Zr atoms in the columns of the structure (space group $R32$) is gradually converted to their disordered state (space group $R\bar{3}c$). These structural changes are not obvious from the XRPA data, but the more sensitive IR data reveal them.

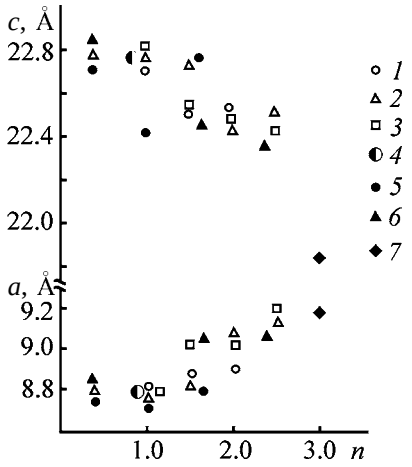

Fig. 3. Unit cell parameters a and c as functions of the occupancy n of M positions in phosphates $Na_{5-qx}T_x\cdot Zr(PO_4)_3$, where T = B = (*1*) Mg, (*2*) Ca, and (*3*) Sr; T = R = (*4*) Al, (*5*) Fe, and (*6*) Dy; (*7*) $Na_5Zr(PO_4)_3$.

Phosphates $Na_{5-2x}Mg_xZr(PO_4)_3$ and $Na_{5-3x}\cdot Fe_xZr(PO_4)_3$. Phosphates of the series $Na_{5-2x}Mg_x\cdot Zr(PO_4)_3$ and $Na_{5-3x}Fe_xZr(PO_4)_3$ with x values covering the whole range were assigned, according to XRPA, to space group $R\bar{3}c$. The observed IR spectra are similar to those of the phases of space group $R\bar{3}c$, which confirms the conclusions on the structure symmetry, made from the XRPA data.

The XRPA and IR data show that, among the phosphates synthesized, there are compounds with the higher concentrations of alkaline-earth cations than those in any known phosphates of the NZP-like structure. These are the phosphates $NaMg_2Zr(PO_4)_3$, $NaCa_2Zr(PO_4)_3$, $NaSr_2Zr(PO_4)_3$, and $Na_3BaZr(PO_4)_3$. Earlier attempts to incorporate alkaline-earth cations into zirconium compounds in greater amounts than in $B_{0.5}Zr_2(PO_4)_3$ failed [29]. The NZP structure of the new compounds seems to be stabilized by sodium cations. A similar effect was also observed for the Li-containing zirconium phosphates $NaLi_4Zr(PO_4)_3$ and $KLi_4Zr(PO_4)_3$ [30].

We calculated the unit cell parameters from the indexing data (see table). It is evident (Fig. 3) that the parameter a increases and the parameter c decreases

as the concentrations of alkaline-earth elements and iron decrease (n increases and ν decreases). The minimal value of the unit cell parameter c and the maximal value of a correspond to the phosphate $Na_5Zr(PO_4)_3$ (all structural positions are occupied and vacancies are absent).

The phosphates were studied in the range from room temperature to 750°C. Changes in their structure on heating were judged from the coefficients of linear thermal expansion $\alpha_a = \Delta a/a\Delta T$ and $\alpha_c = \Sigma c/c\Delta T$. It follows from the coefficients α_a and α_c calculated from the X-ray diffraction data (see table) that the thermal expansion anisotropy characteristic for NZP phosphates is also observed in the compounds obtained. As is the case with the majority of known NZP phosphates, $\alpha_a < 0$ and $\alpha_c > 0$. The expansion along the c-axis is greater than the contraction along the a-axis ($|\alpha_a| < |\alpha_c|$).

At the same time, both coefficients α_a and α_c were positive for certain phosphates in the series under study; these are the phosphates $Na_5Zr(PO_4)_3$ (space group $R32$) and $Na_{5-2x}B_xZr(PO_4)_3$ (B = Ca, Sr) at $0 < x < 1.5$. Especially strong elongation of the structure along the c-axis was observed in the case of the phosphate $Na_5Zr(PO_4)_3$ ($x = 0$, $n = 4$, $\nu = 0$): $\alpha_c = 60.18 \times 10^{-6}$ K^{-1}. In the case of the phosphates of the $R32$ modification with Ca and Sr, α_a and α_c tended to decrease (Fig. 4) as the concentration x of these elements increased and, hence, the number of occupied M positions decreased (and, correspondingly, the number of vacant positions increased); also, growing disordering of the Na and Zr octahedra took place.

The dependences $\alpha_a = f(n)$ and $\alpha_c = f(n)$ for $Na_{5-2x}Mg_xZr(PO_4)_3$ and $Na_{5-3x}Fe_xZr(PO_4)_3$ crystallizing in space group $R\bar{3}c$ are plotted in Fig. 5. The published data for $Na_{5-4x}Zr_xZr(PO_4)_3$ [27] and $NbZr(PO_4)_3$ [28] are also given. These compounds belong to the above-given system of zirconium phosphates: zirconium with M^{IV} and zirconium with C^V cations.

We found that our experimental data for the series with bi- and trivalent B^{II} and R^{III} cations are consistent with published data for the series with quadri- and quinquivalent elements M^{IV} and C^V [26–28]. For all the phosphates of the $R\bar{3}c$ structural modification, the contraction along the a-axis and the expansion along the c-axis took place on heating (Fig. 5). The dependences $\alpha_a = f(n)$ for the phosphates $A^I_{5-2x}Mg_xZr(PO_4)_3$, $A^I_{5-3x}Fe_xZr(PO_4)_3$, $A^I_{5-4x}Zr_xZr(PO_4)_3$, and $A^I_{5-5x}Nb_xZr(PO_4)_3$ with B^{II} (Mg), R^{III} (Fe), M^{IV} (Zr), and C^V (Nb) are very close to each other.

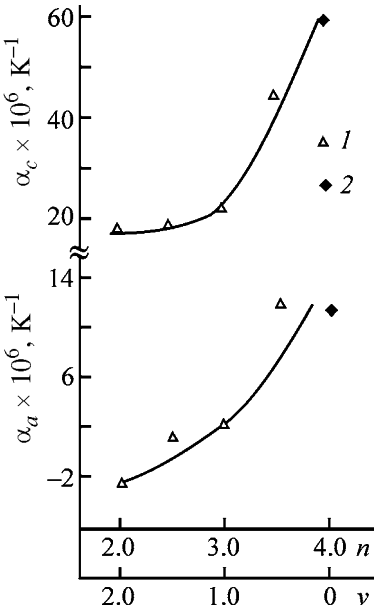

Fig. 4. Plot of axial thermal expansion coefficients α_a and α_c vs. occupancy n of M positions and number ν of vacancies for (*1*) $Na_{5-2x}Sr_xZr(PO_4)_3$ and (*2*) $Na_5Zr(PO_4)_3$.

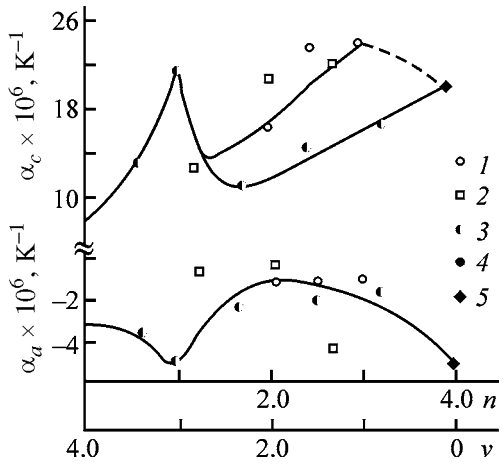

Fig. 5. Plot of axial thermal expansion coefficients α_a and α_c vs. occupancy n of M positions and number ν of vacancies for mixed zirconium phosphates, according to data of various authors: (*1*) $Na_{5-2x}Mg_xZr(PO_4)_3$, (*2*) $Na_{5-3x}Fe_xZr(PO_4)_3$, (*3*) $Na_{5-4x}Zr_xZr(PO_4)_3$ [28], (*4*) $NbZr(PO_4)_3$ [27], and (*5*) $Na_5Zr(PO_4)_3$ [28].

At the same time, the plot of $\alpha_c = f(n)$ for the phosphates $Na_{5-4x}Zr_xZr(PO_4)_3$ [26] lies somewhat lower than that for the phosphates with Mg and Fe. This agrees with the generally accepted mechanism of thermal expansion of phosphates with a $[T_2(PO_4)_3]^f$ framework based on the crystal-chemical model: with increasing cation charge in TO_6 octahedra forming chains along the c-axis, the thermal expansion along this axis decreases (it is assumed that multicharged

cations in the above-mentioned series occupy L positions together with zirconium at $2 \le n < 4$).

The nonmonotonic course of the dependences of α_a and α_c on n (ν) for both newly studied and previously described series is attributable to different effects exerted by multicharged cations (B^{II}, R^{III}, M^{IV}, and C^{V}) and vacancies in occupation of various crystallographic positions of the NZP structure.

(1) An increase in the concentration of multicharged cations in the L-positions upon replacement of sodium by magnesium, iron, and zirconium causes a decrease in α_c and, correspondingly, an increase in α_a.

(2) An increase in the number of vacant M2 positions upon replacement of sodium by magnesium, iron, and zirconium ($4 \le n \le 1$) causes a decrease in α_a (vacancies behave as small-size cations), as noted above when considering the parameters a and c (Fig. 3). They expand to a lesser extent on heating than cation–oxygen bonds in the same positions, which facilitates elongation of bonds along the c-axis (α_c increases).

At $n \le 1$ ($\nu \ge 3$), when all M2 positions are free ($\nu \ge 3$) and the number of free M1 positions decreases, the increase in the number of vacancies causes a decrease in α_c [26]. This causes the O–P–O angles in the PO_4 tetrahedra to decrease and facilitates elongation of bonds along the a-axis (α_a increases) (Fig. 5). This can be followed in the sections of the curves at $n \le 1$ (with the number of vacant positions, correspondingly, varying in the range $3 \le \nu \le 4$). This result agrees well with published data [23] on the behavior of vacancies on heating of $Sr_{0.5}Ti_2(PO_4)_3$. A similar behavior of vacancies in M2 positions should result in the structure contraction along the a-axis, which also agrees with the above-given facts.

The vacancies in the phosphates of $R32$ modification (Fig. 4) affect the structure more strongly along the a-axis (an increase in their number results in a decrease in α_a), whereas an increase in the concentration of multicharged ions in M positions affects the structure more strongly along the c-axis (α_c also decreases).

On the whole, it follows from the experiment that many factors affect the behavior of the structure on heating: the nature of cations T, their concentration, the number of vacant positions, and also the unit cell symmetry. It should be noted that their roles are ambiguous. Their better understanding can be reached only using structure analysis methods allowing estimation of the distribution of cations over three types of nonequivalent positions of the structure.

It should also be noted that our experimental data on the thermal expansion of phosphates allow control of the thermal expansion characteristics of zirconium phosphate materials by choosing appropriate cations and their ratios and concentrations. It is important for practice that $Na_{5-qx}T_xZr(PO_4)_3$ phosphates can be either low-expanding ($\alpha_{av} \le 2 \times 10^{-6}$ K^{-1}), medium-expanding ($2 \times 10^{-6} < \alpha_{av} \le 8 \times 10^{-6}$ K^{-1}), or highly expanding ($\alpha_{av} > 8 \times 10^{-6}$ K^{-1}), so that structurally related substances with a wide range of thermal expansion characteristics become available.

CONCLUSIONS

(1) The thermal expansion of new zirconium phosphates with uni-, bi-, and trivalent elements was studied. These phosphates belong to the family of structural analogs of $Na_5Zr(PO_4)_3$, namely, $Na_{5-2x} \cdot B^{II}_xZr(PO_4)_3$ (B^{II} = Mg, Ca, Sr, Ba) and $Na_{5-3x}Fe_x \cdot Zr(PO_4)_3$.

(2) The dependences of the linear and cubic expansion coefficients on the composition of phosphates with varied combinations and quantitative ratios of Na and Mg, Ca, Sr, Ba, Fe cations were determined. By choosing appropriate cationic composition, the thermal expansion characteristics of zirconium phosphates in the series under study can be adjusted in the following ranges: α_a, from -6 to 13×10^{-6} K^{-1}, α_c, from 17 to 60×10^{-6} K^{-1}; and α_{av}, from 3 to 38×10^{-6} K^{-1}.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Thiophene Vapor on Sodium and Polyhydroxoaluminum Montmorillonites

Received June 3, 2003

Abstract—Changes in the surface properties and pore structure of montmorillonite in substitution of inorganic exchange cations by polyhydroxoaluminum cations were studied by measuring the adsorption of thiophene vapor.

One of the main goals of oil refining and gas processing is to develop efficient processes for removal of sulfur from oil and natural gas, with the sorption method having particular importance [1–4]. Of the three adsorbents (silica gel, alumogel, salica clay) tested in purification of natural gas to remove mercaptans, silica gel has the highest adsorption capacity [2]. According to [3, 4], thiophene is adsorbed by silica gel, alumogel, and zeolite, with its molecules having planar orientation in the monolayer of the adsorbate. Thiophene molecules form in the interlayer space of montmorillonite coordination bonds with exchange cations via sulfur atoms [5]. Elucidating the mechanism of sorption interaction in systems constituted by an organosilicon compound and an adsorbent remains a topical task. Substitution of exchange cations of montmorillonite by polyhydroxoaluminum cations promotes formation of a microporous structure [6]. Data on adsorption and heat of adsorption of a number of polar molecules on the initial and polyhydroxoaluminum montmorillonites (PHAMt) were reported in [7–9].

In this work we studied adsorption of thiophene vapor on dehydrated sodium and polyhydroxoaluminum forms of montmorillonite.

As the initial sorbent we took white bentonite from the Azkamar deposit, which is mainly composed of a sodium montmorillonite mineral (NaMt) and has a cation-exchange capacity E = 0.82 mg-equiv g^{-1} and the following chemical composition (wt %): SiO_2 52.51, Al_2O_3 17.92, Fe_2O_3 3.56, CaO 1.20, MgO 3.62, SO_3 0.28, K_2O 0.27, Na_2O 5.16, and calcination loss 17.16.

The polyhydroxoaluminum montmorillonite was prepared by treating a suspension of Na-montmorillonite with a polyhydroxoaluminum complex [10]. The substitution of the Na^+ ions of the mineral with bulky complex hepta-charged polyhydroxoaluminum cations (PHAC) $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ leads to an increase in the interlayer spacing along the c axis by Δd_{001} = 0.85 nm.

As adsorbate we used thiophene of pure grade, carefully purified and dried with NaA zeolite. Prior to performing adsorption experiments, thiophene was degassed, so that its saturated vapor pressure corresponded to the tabulated value [11].

The adsorption was measured by the gravimetric and isosteric [7] methods. Before measuring the adsorption, NaMt and PHAMt were vacuum-treated at 423 and 773 K for 6–8 h (at a residual pressure in the system of about 1.33×10^{-4} Pa). At these temperatures, the structure of NaMt undergoes characteristic changes: at 423 K it undergoes partial dehydration (this sample is designated as NaMt-1), with exchangeable Na^+ ions introduced into ditrigonal cavities of the aluminosilicate layer; at 773 K, NaMt is totally dehydrated, the structure collapses, and partial dehydroxylation occurs (NaMt-2). Thermal treatment of PHAMt at these temperatures, i.e., below and above the temperature of PHAC transformation into aluminum oxide clusters [12], is accompanied by dehydration and dehydroxylation (samples designated as PHAMt-1 and PHAMt-2). In accordance with the structural changes in the sorbents, it would be expected that the adsorption interaction should change, too, compared to that in NaMt and PHAMt.

The isotherms of thiophene vapor adsorption on Na-montmorillonite (Fig. 1) are S-shaped, with

1070-4272/04/7703-0376 © 2004 MAIK "Nauka/Interperiodica"

hysteresis loops in a wide range of relative pressures P/P_s. Raising the temperature of vacuum treatment of NaMt within the range 423–773 K leads to lower accessibility of the exchange ions to thiophene molecules, and, therefore, the adsorption decreases and the hysteresis loop in the isotherm becomes somewhat narrower. The most probable reason for the change in the width of the hysteresis loop in the isotherms is formation of various ion–molecule complexes with or without residual water molecules, which coordinate the exchange ions. The structural-sorptive properties of NaMt samples, found from the isotherms of thiophene sorption, are listed in Table 1.

In calculating the specific surface areas of NaMt-1 and NaMt-2 by the BET equation, the surface area occupied by a thiophene molecule was taken to be 0.39 nm^2 [1].

It follows from Table 1 that raising the NaMt treatment temperature within the range 423–773 K leads to a decrease in the capacity of the monolayer and, consequently, in the specific surface area by a factor of more than 3; the sorption volume in the state saturated to the maximum possible extent decreased in this case by a factor of approximately 2.2. Undoubtedly, all this is due to differences in the surface properties and in the pore structure of NaMt forming as a result of dehydration and dehydroxylation. The role played by the internal and external surfaces of montmorillonite can be revealed by comparing the adsorption of benzene, whose molecules are mainly adsorbed on the external surface of the mineral (without being incorporated into the interlayer space) with that of thiophene. It was found that the adsorption capacity of NaMt-1 for thiophene exceeds that for benzene by a factor of 3.7. Consequently, thiophene molecules are adsorbed on NaMt-1 not only on the external surface, but also within the internal pore volume. The specific surface areas of NaMt-2 for both the adsorbates are close, which suggests that the adsorption of thiophene and benzene is limited in this case to the external surface of NaMt-2.

Polyhydroxoaluminum montmorillonite is a thermally stable clayey adsorbent [6]. Thermal treatment in a vacuum at 423 K leads to full opening of the sorption volume as a result of dehydration. The transfer of modifying cations into aluminum oxide clusters does not lead to any noticeable change in the interlayer spacing in the mineral [7]. The isotherm of thiophene adsorption on PHAMt-1 (at $P/P_s < 0.01$) has a steeper initial portion (Fig. 1) than that for PHAMt-2. The difference in thiophene adsorption between PHAMt-1 and PHAMt-2 is due to specific

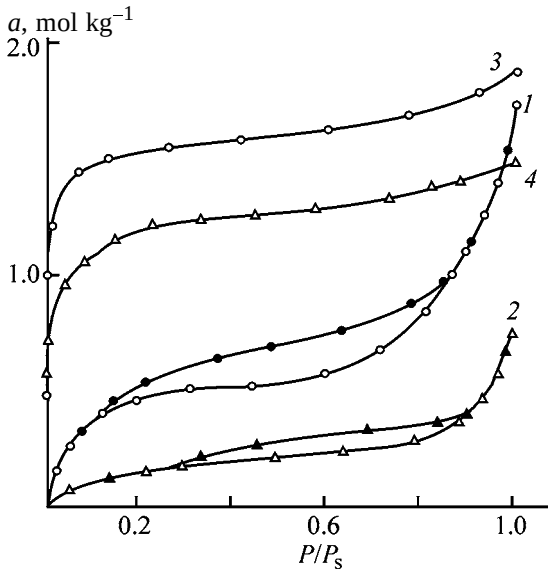

Fig. 1. Isotherms of thiophene vapor adsorption on (*1, 2*) NaMt and (*3, 4*) PHAMt dehydrated at (*1, 3*) 423 and (*2, 4*) 773 K. (*a*) Adsorption and (P/P_s) relative pressure.

adsorption interaction of thiophene molecules with PHAC and aluminum oxide clusters. The fact that both isotherms are virtually Γ-shaped and the adsorption increases only slightly within the range $P/P_s \approx 0.05–0.9$ indicates that the structure of PHAMt is not deformed in the course of thiophene adsorption.

The sorption volumes of PHAMt for thiophene ($m^3\ kg^{-1}$) at P/P_s = 0.2 (W), 0.4 (W_0), and 1.0 (V_s) and the mesopore volumes $W_{me} = V_s - W_0$ calculated from the adsorption isotherms are listed in Table 2.

It can be seen that the volume of micropores, W_0, and that in saturation of PHAMt-1, V_s, markedly exceed the sorption volumes of PHAMt-2. The adsorption of thiophene vapor at P/P_s mainly proceeds with filling of the mesopore volume. Thermal treatment of PHAMt at 773 K, i.e., at a temperature exceeding the onset temperature of aluminum oxide cluster formation, leads to a decrease by 20–25% in the pore volume, compared to the volume of PHAMt dehydrated at 423 K. Comparison of the sorption volumes of PHAMT for thiophene and benzene shows that they are rather close. This indicates that molecules of these organic substances are adsorbed on PHAMt via volume filling of micropores.

The changes in the nature of the surface and in the pore structure of montmorillonite upon substitution of Na^+ ions by $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ can be judged by comparing the heats of thiophene adsorption on NaMt-1 and PHAMt-1. The heats of adsorption were found from the temperature dependence of thiophene adsorption, i.e., from a set of isosteres of thiophene adsorption, measured in the temperature range 260–320 K at fillings from a fraction of V_s to complete saturation. As an example, Fig. 2 shows a family of isosteres of thiophene adsorption, measured on NaMt-1 and plotted in the $\log P$–T^{-1} coordinates. In these coordinates, the isosteres are approximated with straight lines, which indicates that the heat of adsorption is temperature-independent in the temperature range studied. The upper line in Fig. 2 represents the dependence of the logarithm of the saturated vapor pressure on T^{-1} for the bulk phase of thiophene. It can be seen that the slopes of the isosteres vary with the amount of adsorbed thiophene.

The change in the slope of the isosteric straight lines for the systems thiophene–NaMt-1 and thiophene–PHAMt-1 was used to calculate, using the Clausius–Clapeyron equation, the differential isosteric heats of adsorption, *Q* (Fig. 3). For the systems studied, the dependences of *Q* on the amount of substance adsorbed abruptly descend at small fillings, reach a minimum, then pass through maxima at medium adsorption levels, after which the value of *Q* decreases, gradually approaching the heat of condensation of the bulk phase of thiophene (λ = 32.5 kJ mol^{-1}). In this range of fillings, the adsorption in the system thiophene–NaMt-1 mainly occurs at the surface of NaMt-1, but penetration of its molecules into the interlayer space of the mineral cannot be ruled out, either. When thiophene molecules are adsorbed with the plane of their ring parallel to aluminosilicate stacks, Δd_{001} of the mineral remains virtually unchanged [5]. Further, *Q* increases somewhat, to reach its maximum value $Q^{max} \approx 36.5$ kJ mol^{-1} at $a \approx 1.25$ mol kg^{-1}. Beyond the maximum, the value of *Q* gradually decreases, again approaching λ. The increase in *Q* and its extremal behavior can be accounted for by intermolecular interaction in the polylayers.

The minimum in the dependence $Q = f(a)$ is observed for the system thiophene–PHAMt-1 at an adsorption approximately equal to 1.10 mol kg^{-1} (i.e., at micropore volume filling $a/a_0 = 0.68$, where a_0 is the adsorption at $P/P_s = 0.4$), with the minimum value $Q^{min} \approx 45.0$ kJ mol^{-1}. The initial decrease in the heat of thiophene adsorption on PHAMt could have been even more abrupt, if it were not partly compensated for by a rise in the heat because of the increasing intensity of interaction between molecules adsorbed in micropores. At higher adsorption levels, the heat of adsorption increased from 45.0 to its maximum value $Q^{max} \approx 58.5$ kJ mol^{-1} (at $\theta = 0.86$). In this adsorption range, the increase in the heat of thiophene adsorption was about 13.5 kJ mol^{-1}. At $\theta > 0.86$, the heat of thiophene adsorption on PHAMt-1 decreases abruptly to 47.5 kJ mol^{-1} (at $\theta = 1.0$). In the range of mesopore filling at $1.0 < \theta < 1.18$, the value of Q continues to decrease and approaches λ at adsorbent saturation.

The higher heat of adsorption for the system thiophene–PHAMt-1, compared to that for thiophene–NaMt-1, is presumably due to the enhancement of the adsorbate–adsorbent interaction because of structural changes that occur in montmorillonite under modification. As active centers in PHAMt-1 act free hydroxy groups and external oxygen atoms in polyhydroxoaluminum cations, oxygen surface of the silica layer, Al^{3+} ions that isomorphically substitute silicon in the silica layer, and Na^+ ions that are not substituted by polyhydroxoaluminum cations; as active centers in NaMt-1 serve Na^+ ions, surface hydroxy groups, oxygen surface of the silica layer, etc.

CONCLUSIONS

(1) The influence exerted by substitution of Na^+ ions with polyhydroxoaluminum cations on the adsorption properties of dehydrated montmorillonite clay was studied. A set of isosteres of thiophene vapor adsorption were obtained. The changes in the parameters of the adsorption equilibrium in a wide range of fillings were used to calculate the differential isosteric heats of adsorption.

(2) It was established that the increase in the heat of thiophene adsorption on replacing Na^+ ions with polyhydroxoaluminum cations results from the formation of a developed system of slitlike micropores in the interlayer space of montmorillonite; adsorption of thiophene on polyhydroxoaluminum montmorillonite mainly occurs in micropores to give ion–molecule complexes.

Abstract—Powders of copper were obtained by reducing its various salts with hypophosphorous acid and sodium hypophosphite. The influence exerted by various factors on the stability and electrical conductivity of composites on their base was studied.

Thanks to unique physicochemical, electrical, magnetic, and optical properties, polymeric formulations with an ultradispersed metallic filler find wide application in modern science and technology in developing current-conducting pastes, photo- and X-ray-sensitive resists, shielding coatings, and electrodes. Silver is most commonly used in electrically conducting formulations because of its high electrical conductivity and resistance to oxidation [1, 2]. Recently, steadily increasing attention has been given to development of copper-based formulations [3], whose production cost is lower. In this context, the problems associated with stabilization of ultradispersed powders (UDP) of copper and improvement of the service life and electrical conductivity of composites on their base are of current interest.

Previously, methods were developed for obtaining copper UDP with average particle size of 20–40 nm by reducing various copper salts with glycerol and making formulations on their base with epoxy and novolak resins [4–8]. The most efficient is the reduction of basic carbonate, acetate, and tartrate of copper with glycerol, and formulations on their base with novolak resin exhibit higher electrical conductivity [resistivity $\rho = (0.6–1.9) \times 10^{-6}$ Ω m] and stability (more than 6 years).

In addition, it was found that, with appropriate stabilizing agents, it is also possible to prepare formulations based on copper sulfate with the electrical conductivity and stability comparable with those of pastes based on copper UDP obtained by reduction of readily decomposing copper salts. Introduction of organic acid reductants (ascorbic, citric, formic, and acetylsalicylic acids) leads to an increase in the reaction rate by a factor of 5–10, decrease in the process temperature by 20–40°C, and improvement of the stability and electrical conductivity of the pastes.

It was found that epoxy formulations with addition of stabilizers (1-naphthol and *p*-aminophenol) in amount of 1% (relative to the mass of the copper UDP) retain high electrical conductivity without changes for more than 10 years, and formulations with 1-naphthol have the lowest resistivity of $(0.8–1.2) \times 10^{-6}$ Ω m, which is close to that characteristic of metals. It was also found that 1-naphthol is the best oxidation inhibitor for the novolak resin, and addition of glycerol as a plasticizer in a 1 : 3 ratio yields formulations whose electrical conductivity (resistivity 1.2×10^{-6} Ω m) is comparable with that of the best samples with epoxy resin. Pastes based on the novolak resin are only slightly inferior to the above formulations in stability, but they are less expensive and more readily available, and, therefore, primary attention will be given here to novolak formulations.

The study is concerned with reduction of various copper salts with hypophosphorous acid and sodium hypophosphite at a molar ratio $\nu(Cu) : \nu(H_2PO_2^-) = 1 : (1.5–4.0)$. The promise of this method is in that the reduction with hypophosphite ions is carried out under milder conditions (reaction temperature not higher than 95°C, reaction time 2–35 min) than those in reduction with glycerol (130–200°C, 15–240 min). The copper UDP obtained was used to prepare formulations with phenol–formaldehyde novolak resin. The influence exerted by various factors on the stability and electrical conductivity of the formulations ob-

tained was studied. These materials were compared with samples obtained previously by reduction with glycerol and with industrially used pastes based on noble metals.

EXPERIMENTAL

The copper salts were reduced with sodium hypophosphite as follows: into a vessel with a solution of a copper(II) salt heated to 80–90°C, we gradually poured with continuous agitation a solution of sodium hypophosphite heated to 50–60°C. Then the reaction mixture was heated to 80–95°C [depending on a copper(II) salt used] and kept at this temperature until an ultradispersed copper powder precipitated. After that, the UDP was washed with water to neutral reaction of the washing water, treated with solutions of hydroquinone and stearic acid in ethanol, and stored under a layer of the solution of stearic acid in ethanol. According to small-angle X-ray scattering data (Fig. 1), the copper UDP obtained has particle size in the range 8–100 nm, with 45% of the particles (by mass) being less than 30 nm in size. The formulations prepared from SF-010 phenol–formaldehyde resin and copper UDP (with 80 wt % metallic phase) were kept at 140–145°C for 4 h. The dc resistance of the pastes was measured (12 V, 2.5 mA) at room temperature (20–25°C).

To improve their resistance to oxidation, all the copper UDP samples were treated with solutions of hydroquinone and stearic acid in ethanol, as suggested in [4]. The ultradispersed powders of copper obtained by reduction of copper(II) salts (and $CuSO_4 \cdot 5H_2O$, in particular) with sodium hypophosphite are highly active and are readily oxidized in air because of their increased dispersity. As a result, the formulations on their base have relatively high resistivity (10^{-2} Ω m) and are very unstable in storage (Fig. 2, curve *1*). However, it was found that treatment of copper UDP with formic acid leads to a dramatic increase in the electrical conductivity and stability of the formulations (Fig. 2, curve *2*). This is due to the fact that treatment with formic acid removes the oxide film from the surface of UDP particles and stabilizes metallic copper against further oxidation.

Inorganic (nitrate, sulfate, chloride) and organic (acetate, formate, citrate) salts of copper(II) were reduced with sodium hypophosphite. The results are listed in Table 1. It can be seen that the highest reduction rate is observed for copper nitrate, sulfate, and formate (Table 1, sample nos. 1, 2, 5, 6, 8). Copper acetate and nitrate (sample nos. 3, 4, 9) are reduced

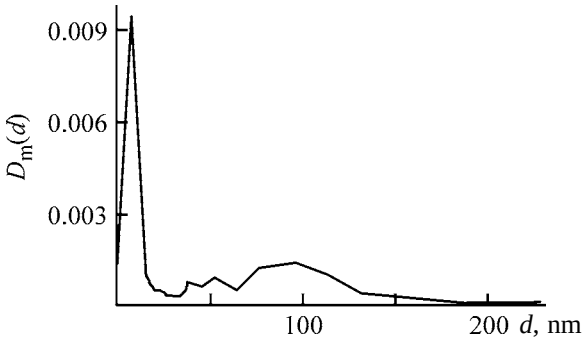

Fig. 1. Mass function $D_m(d)$ of the size (d) distribution of ultradispersed copper particles, calculated from small-angle X-ray scattering curves in the approximation of uniform spherical particles.

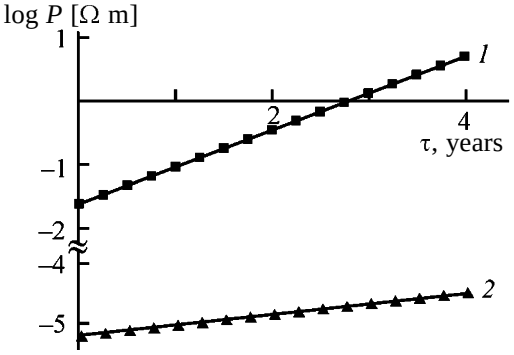

Fig. 2. Electrical resistivity ρ of the formulation (copper UDP + novolak resin SF-010) (*1*) in the initial state and (*2*) after additional treatment with formic acid, vs. the testing time τ.

at a lower rate because of their lower solubility in water. With $CuCl_2$ used, copper UDP was formed, in contrast to the case of reduction with glycerol [8], but formulations on its base could not be obtained because of the decreased stability and increased reactivity of the powder. Before being introduced into formulations, all the copper UDP samples obtained were treated with formic acid.

The copper UDP samples obtained were used to prepare formulations with a novolak resin at a copper UDP to novolak resin ratio of 100 : 25. The highest electrical conductivity and stability were observed for a formulation based on copper formate, since in this case the reaction products (formate ion etc.) stabilize copper (sample no. 8). Only slightly inferior in electrical conductivity to this sample are formulations based on copper sulfate (sample nos. 5, 6) and copper citrate (sample no. 9), but they are unstable in storage. The formulations based on copper nitrate and acetate have even lower electrical conductivity and stability.

Apparently, the presence of an excess amount of sodium hypophosphite leads to higher electrical con-

* τ_r and T_r are the time and temperature of the reduction of copper(II) salt with sodium hypophosphite.

ductivity and stability of copper formulations. This is presumably due to an additional stabilizing effect of unreacted hypophosphite ions, which decompose in the course of the reaction under the action of water, to give hydrogen [9].

We also studied the influence exerted by stabilizers introduced directly into the novolak resin on the electrical conductivity and stability of copper powders. It was noted in [8] that the best stabilizer (for both epoxy and novolak resins) is 1-naphthol, and additional introduction of glycerol as a plasticizer leads to a considerable increase in the stability and electrical conductivity. In this work, we analyzed the effect of the ratio between UDP, novolak resin, 1-naphthol, and glycerol on the stability and electrical conductivity of pastes with novolak resin (Fig. 3). Ultradispersed copper powders were obtained by reducing copper sulfate with sodium hypophosphite at a ratio $\nu(Cu) : \nu(H_2PO_2^-) = 1 : 1.5$ (Table 1, sample no. 5). It was found that, after introduction of 1-naphthol and glycerol, phenol–formaldehyde novolak formulations based on copper UDP obtained by the hypophosphite method become comparable in stability and electrical conductivity with copper ultradispersed powders prepared by reduction with glycerol.

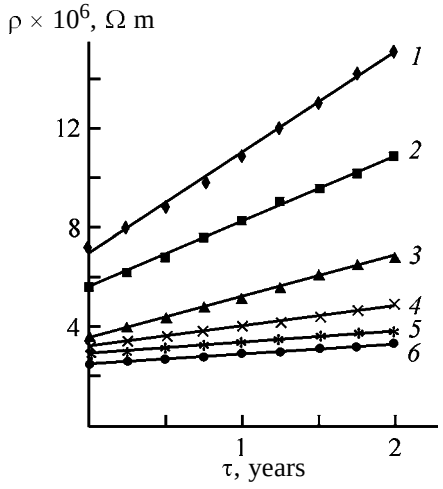

Fig. 3. Effect of stabilizers on the electrical resistivity ρ of formulations with an SF-010 phenol–formaldehyde novolak resin. (τ) Testing time. Weight ratio of copper UDP, SF-010, 1-naphthol, and glycerol (plasticizer): (*1*) 100 : 25 : 0.5 : 1.5, (*2*) 100 : 25 : 0.5 : 3, (*3*) 100 : 25 : 1.0 : 1.5, (*4*) 100 : 25 : 1.0 : 3, (*5*) 100 : 25 : 2.0 : 1.5, and (*6*) 100 : 25 : 2.0 : 3.

It can be seen that the optimal content of 1-naphthol in the formulations is 2 wt % relative to the amount of copper UDP (sample nos. 5, 6). A smaller amount of 1-naphthol is insufficient for obtaining stable formulations with nearly metallic electrical conductivity (sample nos. 1–4). As for the use of a larger amount, it is unfeasible because the electrical conductivity and stability increase in this case only slightly. Apparently, the stability and electrical conductivity also become higher as the amount of glycerol is raised (sample nos. 2, 4, 6). However, a large excess of glycerol may impair the properties of the pastes, because they show poorer hardening and become less stable in storage. Introduction of glycerol in an amount of 1.5–3% (relative to the mass of copper UDP) diminishes the brittleness of the novolak resins. The highest stability and electrical conductivity are exhibited by sample no. 6, stabilized with 2 wt % naphthol and 3 wt % glycerol. The higher optimal content of 1-naphthol in the formulations, compared to that in formulations prepared on the basis of ultradispersed copper powders obtained by reduction with glycerol,

* Formulation prepared on the basis of copper(II) (sample no. 6) a year after UDP synthesis.

is due to the higher dispersity and reactivity of the UDP synthesized by reduction with sodium hypophosphite.

Copper(II) compounds were reduced with sodium hypophosphite both in an aqueous medium and in a mixture of solvents, polar (distilled water) and less polar (hexyl alcohol), at a water : hexanol volume ratio of 5 : 1 and 10 : 1. The reduction was carried out as follows: into a vessel containing a copper(II) salt solution was poured a sodium hypophosphite solution, the mixture was agitated, a necessary amount of hexyl alcohol was added, and the resulting mixture was heated to the reaction temperature of 80–90°C and kept at this temperature for 2–35 min, depending on the copper(II) salt used. Then, the hexanol layer was decanted, and the UDP formed was washed with water and treated with solutions of hydroquinone and stearic acid in ethanol. It was found that the stability of the UDP is enhanced as the amount of hexyl alcohol is increased.

The copper UDP samples synthesized were used to prepare formulations with novolak resin. The results obtained are listed in Table 2. It can be seen that all the samples prepared in the system water–hexanol have higher electrical conductivity and stability, compared to the samples synthesized in an aqueous medium (Table 1). The highest stability and electrical conductivity were observed for the UDP samples based on copper(II) formate and sulfate (even when the UDP was stored for a year). This is due to the action of hexanol, which, being adsorbed on the surface of copper UDP, prevents its oxidation and aggregation. However, the copper UDP samples obtained from copper chloride (Table 2, sample no. 10) are rather unstable, are rapidly oxidized, and formulations based on these UDP samples are not electrically conducting. This is probably due to the presence of chloride ions adsorbed on the UDP surface.

Copper(II) acetate, sulfate, formate, basic carbonate, and oxide were reduced with hypophosphorous acid in a water–hexanol medium at a water : hexanol volume ratio of 5 : 1. It was found that basic copper carbonate and copper oxide can only be reduced in the presence of excess hypophosphorous acid [$\nu(H_3PO_2)$: $\nu(Cu) = 4$], and, being poorly soluble in water, these compounds do not react with sodium hypophosphite. The results obtained are listed in Table 3. Apparently, the reduction of copper(II) compounds with H_3PO_2 occurs more actively than that with sodium hypophosphite.

Comparison of Tables 2 and 3 shows that the highest electrical conductivity is exhibited by formulations based on copper UDP samples obtained by reduction with hypophosphorous acid. This is due to the fact that, according to the results of X-ray phase analysis, virtually no oxides could be found in the samples reduced with hypophosphorous acid even in an aqueous medium, in contrast to the samples synthesized by reduction with sodium hypophosphite. Thus, the highest electrical conductivity and stability of formulations based on copper UDP are attained in the case of reduction of copper(II) formate or sulfate with hypophosphorous acid, and also upon introduction of 2 wt % 1-naphthol and 3 wt % glycerol into the formulations.

These formulations are only slightly inferior in electrical conductivity and stability to those ob-

tained by reduction with glycerol and stabilized with 1-naphthol and glycerol, but their synthesis is characterized by lower consumption of energy and materials (milder conditions, low expenditure of the reducing agent, lower expenditure of a solvent for UDP washing).

Thus, it is preferable to perform the reduction of copper(II) compounds with sodium hypophosphite and hypophosphorous acid in the system water–hexanol, rather than in the aqueous medium. Adsorption of hexyl alcohol on the surface of copper particles substantially improves their stability and raises the electrical conductivity, so that formulations based on the UDPs of this kind become comparable with those prepared on the basis of UDPs synthesized by reduction with glycerol [4–8] and can compete with similar materials based on silver [1–2].

CONCLUSIONS

(1) Ultradispersed copper powders and formulations based on them were synthesized by reducing various copper salts with sodium hypophosphite and hypophosphorous acid.

(2) The ultradispersed copper powders obtained by reduction with sodium hypophosphite and hypophosphorous acid become more stable and electrically conductive upon treatment with formic acid.

(3) The ultradispersed copper powders synthesized in a water–hexanol medium show higher stability and electrical conductivity.

(4) The increased stability and low production cost of these materials make them promising for use in modern nanoelectronics instead of composites based on noble metals.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Solvent and Solute Effects on Electrokinetic Potentials at Interfaces between Air and Aqueous or Formamide Solutions of Alkali Metal Chlorides and Sodium Alkyl Sulfates

K. P. Tikhomolova and T. V. Luzyanina

St. Petersburg State University, St. Petersburg, Russia

Received October 10, 2003

Abstract—Electrokinetic flow in a hydrophilic capillary of a model direct emulsion consisting of a polar liquid (water or formamide) containing an alkali metal chloride or sodium alkyl sulfate and air is studied. The interfacial electrokinetic potentials are determined.

This work is aimed at understanding the constant electric field driven flow of a direct emulsion in a thin capillary wetted with a polar fluid. This problem is of interest not only for chemists, but also for medical men, ecologists, geologists, technologists, etc. For actual systems, parameters of the emulsion flow in a capillary can be predicted only on the basis of experimental data and mostly even qualitatively, because for actual systems exact analytical solution is quite difficult. As a result, in the majority of theoretical works, any mathematical approach developed to reproduce the motion of two fluids in a capillary (regardless of the driving force of this motion) is based on the simplest model (see figure) [1–8]. The same model is also used in experimental works [1, 4, 9–13].

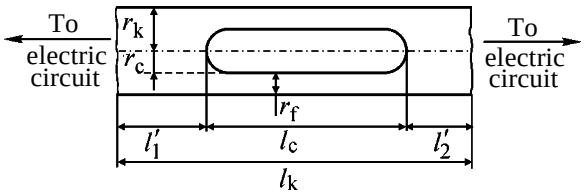
The model system represents a cylindrical or slot-like capillary containing a single fine particle of a nonpolar fluid (liquid or gas). The whole residual volume of the capillary is filled with a dispersion medium (polar liquid). The capillary surface is wetted with the polar liquid. The particle of the nonpolar fluid is a cylinder with the long axis along the capillary axis, faced with half-spheres. The length of the cylindrical part of the particle is larger than the capillary radius. In their experimental works, researchers mostly used cylindrical glass capillaries, an aqueous solution as the polar fluid, and air or a hydrocarbon as the nonpolar fluid.

By virtue of wetting of the capillary with a polar liquid and the occurrence of electrical double layers at the interfaces between the polar fluid and the inner surface of the capillary and also between the polar and nonpolar fluids, a thin film of the polar fluid is formed between the capillary wall and the cylindrical surface of the nonpolar particle (hereinafter, the film of the corresponding dispersion medium). The thickness of this film r_f, assumed constant throughout the surface of the cylindrical part of the particle, ranges from several to thousands nanometers. The thickness depends, particularly, on the nature and concentrations of the components of the polar phase and also on the applied external fields [8, 12–16].

Applying external constant electric field initiates electrokinetic motion of the particle, the velocity of which can be strongly influenced by the film thickness.

The actual structure of the film can be far from the ideal, especially in the initial period after formation of the system, when the film can be strongly nonuniform in its thickness. However, with time, the film shape approaches that predicted by the theory, as demonstrated by the experimental (indirect) data [12–15].

Previously [7] we theoretically considered the problem of steady-state electrokinetic flow in such a model system. As a result, we derived a relationship between the electrokinetic flow velocity u_c with the film thickness r_f and electrokinetic potentials at the interface between two fluids ζ^{p-np} and between the polar phase and the capillary wall ζ^{p-s}.



Schematic of the model emulsion in a capillary (for explanation, see text).

1070-4272/04/7703-0385 © 2004 MAIK "Nauka/Interperiodica"

$$\zeta^{p-np} = \zeta^{p-s} + \frac{\mu^p u_c l'}{\varepsilon^0 \varepsilon^p \Delta H} \frac{(1 - r_{rel}^4 + l_{rel})(1 - r_{rel}^2 + l_{rel})}{(1 - r_{rel}^2)^2 + l_{rel}}, \quad (1)$$

where μ^p is the viscosity of the polar phase; l^1, length of the capillary filled with the polar phase only; ε^0 and ε^p, dielectric constant and dielectric permittivity of the polar phase; ΔH, strength of the external constant electric field at the ends of the capillary; $r_{rel} = (r_k - r_f)/r_k = r_c/r_b$; r_k, capillary cross section; $l_{rel} = l_c/l^1$; and l_c, the length of the particle.

Equation (1) allows estimation of ζ^{p-np}. In addition to this parameter, this equation includes *a priori* unknown r_f. The latter was estimated by Eq. (2) representing the Ohm law for the model system in hand [17]:

$$\frac{\Delta H}{I} = \frac{2}{\chi\pi} \frac{1}{[r_k^2 - (r_k - r_f)^2]^{1/2}} \arctan \frac{(r_k - r_f)}{[r_k^2 - (r_k - r_f)^2]^{1/2}} + \frac{l_c - 2(r_k - r_f)}{\chi\pi[r_k^2 - (r_k - r_f)^2]} + \frac{l_k - l_c}{\chi\pi r_k^2}, \quad (2)$$

where I is the current; χ, specific conductivity of the polar phase; and l_k, length of the capillary.

The main goal of this work is to study the effect of the polar phase components on the interfacial electrokinetic potential ζ^{p-np}. Changing nature of the polar phase components, in principle, can influence the thickness of the polar fluid film, which, in turn, significantly affects the electroosmotic flow velocity and, correspondingly, the reliability of the estimated ζ^{p-np}. In view of the basic principles of the colloid chemistry, it could be suggested that the film thickness is influenced by the structural and mechanical properties of the p–np interface, which, in their turn, depend on the solvent and the presence of organic surfactants in the system. Therefore, among the goals of this work was also to check Eq. (1) for consistency with wide variation in the polar phase composition. Selection of a series of inorganic salts and organic diphilic compounds as electrolytes allowed us to affect various structural and mechanical properties of the p–np interface.

In experiments we used quartz glass capillaries, air as the nonpolar fluid, and water and formamide as the polar solvents. Formamide is one of the most polar liquids ($\varepsilon = 111$; $\mu = 11.24 \times 10^{-30}$ C m). For water, the corresponding values are 81 and 6.5×10^{-30} C m [18]. As inorganic electrolytes, we used Li, Na, K, and Cs chlorides, and as organic electrolytes, sodium alkyl sulfates with 10, 12, 13, and 15 carbon atoms in the hydrocarbon radical (hereinafter, SAS_{10}, SAS_{12}, SAS_{13}, and SAS_{15}) (Table 1). The chlorides (analytically pure grade) were additionally purified by recrystallization. The alkyl sulfates were synthesized and recrystallized from benzene at the Academy of Technology and Design (St. Petersburg). The concentration of the inorganic salts was 0.1 M in aqueous solutions and 0.15 M in formamide. Such a decision on the salt concentration in the aqueous systems was caused by the accuracy of measurement of the characteristic parameters included in Eqs. (1) and (2) [15–17]. The inorganic salt concentrations in formamide were selected so that the specific conductivities of the corresponding aqueous and formamide solutions be equal.

* For system nos. 8–11 and 16–19, the SAS concentrations correspond to those for the first series, and for system nos. 12–15 and 20–22, those for the second series.

The SAS concentrations were taken equal in both aqueous and formamide solutions. Two different concentrations were taken for each SAS in both solvents. In the first series, the SAS concentrations were selected to meet the condition of equal amounts of SAS adsorbed on the solution–air interface Γ (mol m^{-2}),

and in the second series, the concentrations were considerably (by a factor of 3–5) higher. Regardless of the solvent, the SAS concentrations in the first and second series were as follows (mM): SAS_{10} 0.3 and 1.7, SAS_{12} 0.24 and 1.2, SAS_{13} 0.23 and 0.7, and SAS_{15} 0.22 and 0.7. Naturally, the surface tensions σ were different in the aqueous and formamide solutions of each series (64–65 and 53–54 mN m^{-2}, respectively, for the first series). The Γ values were also different, depending on the solvent, being 2.8×10^{-6} and 2×10^{-6} mol m^{-2} in the aqueous and formamide solutions, respectively. All the SAS-containing aqueous solutions were prepared with 0.1 M NaCl as a supporting electrolyte, and all the formamide solutions, with 0.15 M NaCl. Note that the SAS concentrations were lower by 2–3 orders of magnitude than the chloride concentrations. It is clear that the contribution of SAS to the conductivity of the working solutions was negligible as compared to the contribution of NaCl.

The procedures of formulation of the working systems and electrokinetic measurements were described elsewhere [13, 14]. The surface tension σ was determined by the Rebinder's method, and the adsorption Γ was estimated from σ by the Gibbs equation [19].

First of all, note that, in all experiments, we observed some variance of the measured particle velocity and current *I*, i.e., u_c and r_f. Specifically, here we are dealing with the least experimentally obtainable values. Following our previous works [13, 14], these velocities and film thicknesses are referred to as instantaneous and designated hereinafter as u_c^x and r_f^x. The observed behavior of the working systems could be referred to as labile. Previously [13] we reported on the lability of the electrokinetic flow of a nonpolar fluid in a glass capillary filled with an aqueous solution. At the same time, we have demonstrated [13, 14] that, with the use of the average u_c and r_f values, the estimated electrokinetic potentials at the interface between two fluids are reliable from the standpoint of their consistence with ζ^{p-np} as a theoretical physical parameter. However, it should be pointed out that we observed such a lability, even considerably less pronounced, for the average ζ^{p-np} values also. The estimated mean ζ^{p-np} values could range within more or less wide intervals: the more labile is the system, the greater the variance of the estimated potential for a given pair of fluids (Table 2). Even in the experiments with similar geometric parameters of the working systems, the mean u_c and r_f values could appear different, as well as the ζ^{p-np} values (Table 2). Nevertheless, the spread in the potentials estimated from the mean u_c and r_f is a result of experimental errors, and it can be reduced using standard methods, i.e., through performing a series of replicate runs.

The mean velocities are estimated from the path length and the time required for the particle to pass "a sufficiently long path" along the capillary; and the mean film thickness, by averaging over all the instantaneous values measured throughout "a sufficiently long capillary" [14]. In experiments we mostly used capillaries 23–25 cm in length. The instantaneous velocities and the corresponding instantaneous film thicknesses allowed only qualitative characterization of the effect of solution components on the electrokinetic behavior of the working systems. In quantitative estimates of ζ^{p-np}, we used the mean u_c and r_f values.

The equation for ζ^{p-np} includes the potential at the polar phase–glass interface ζ^{p-s}. It was determined as an electroosmotic potential. For this purpose, a capillary was filled with a given solution (without dispersed particle), and the electroosmotic flow velocity was measured [20]. The experiments were carried out with working capillaries of various lengths and cross sections. The ζ^{p-s} was estimated according to the procedure described in [19]. The resulting ζ^{p-s} values were shown to be well reproducible, being independent of the capillary size. The maximal deviations from the mean ζ^{p-s} values in the systems with various salts were as follows: LiCl ±5%, NaCl ±7%, and KCl and CsCl ±10%. The mean ζ^{p-s} values are given in Table 1.

The ζ^{p-s} values obtained in aqueous solutions of alkali metal chlorides, generally, reasonable agree with the published data [21].[1] This parameter slightly depends on the kind of the alkali metal, increasing in the absolute value with the molar weight of the cation. The ζ^{p-s} series obtained in this work differs from that known from the literature, where it was noted that $|\zeta^{p-s}|$ increases with increasing hydration of a cation. This distinction is probably due to different material of the capillaries (we use quartz glass, but not quartz).

The ζ^{p-s} values obtained in the formamide solutions of alkali metal salts have the same sign (minus) as in the aqueous solutions, being considerably higher in their absolute value.[2] The kind of the cation only slightly influences ζ^{p-s}, which changes in the same order as in the aqueous solutions.

[1] Published data mostly refer to KCl or NaCl.

[2] We found no published data on the formamide solutions. Since the formation mechanism of the electrical double layer at the glass–formamide interface is unknown, we offer no explanation for the disagreement.

Introduction of SAS into both aqueous and formamide solutions has practically no effect on ζ^{p-s}. The only exception is the system with SAS_{15}. The results suggest that SAS_{10}–SAS_{13} are not noticeably adsorbed on glass, which is consistent with data from [14, 22] for SAS_{12}. SAS_{15} is adsorbed very slightly.

Analysis of the electrokinetic behavior of the systems consisting of two fluids with the polar phase containing only inorganic chlorides shows that, in the cases of both aqueous and formamide solutions, this behavior was labile. Although the lability was observed in all the systems studied, the trends of variation in u_c^x and I^x (correspondingly, r_f^x) were different, depending on the cation. In aqueous LiCl, the electrokinetic flow oscillated [13] with 10–20% deviation from the mean value. Similar behavior was observed for r_f^x. In the cases of CsCl, NaCl, and KCl, the trends in variation of u_c^x and r_f^x were very diverse. The difference between the maximal and minimal velocities in the CsCl solutions reached 50%, while that in the NaCl and KCl solutions was considerable smaller.

The trends of variation in u_c^x and I^x (correspondingly, r_f^x) as well as their limiting values also depend on the solvent. The orders of variation of these values in the series of cations was the same for both aqueous and formamide solutions. However, the formamide systems were much more labile. In the formamide solutions of CsCl, the characteristic parameters so much widely ranged that we could not realize a statistic representation of the experimental data for estimating ζ^{p-np}. The estimated ζ^{p-np} values are given in Table 2.

The mean r_f values in the working systems approached several thousands of nanometers, which is close to the values reported in [13, 14] for similar systems.

Table 2 shows that, in all the systems with given electrolyte and solvent, the ζ^{p-np} values were mostly somewhat different, even in the cases of practically identical or close geometric parameters of the capillary and the particle. This suggests that the estimated potentials are independent of these parameters, and their variations are determined by labile behavior of the working systems. The independence of the estimated ζ^{p-np} from the geometric parameters is a clear indication of the fact that each of the mean ζ^{p-np} values in Table 2 corresponds (within the experimental error) to ζ^{p-np} as the theoretical physical parameter characterizing the interface between two fluids in each of the systems studied. The reliability of the ζ^{p-np} values obtained in this work is additionally evidenced by the fact that these values are well consistent with the available data on the 0.1 M NaCl–air interface, obtained by various methods. The ζ^{p-np} variation range observed in the working systems depended on the cation, being the wider, the heavier the cation. In each of the solvents, $|\zeta^{p-np}|$ slightly decreased with decreasing molar weight of the cation. Explanation of this finding requires further investigations.

In the systems with the same cation, but different solvents, $|\zeta^{p-np}|$ is slightly higher in the case of formamide solutions, which can be associated with two factors.

(1) Assuming that the intensive properties of the solvents used are constant behind the solution–air interface, the higher ζ^{p-np} values observed in formamide can be attributed to the fact that, in this case, the chloride concentration in the interfacial electrical double layer is higher as a result of the higher dielectric constant of formamide.

(2) Assuming that, in the interfacial layer, water and formamide are structured (structures can be different), deceleration of the electrokinetic flow, caused by structurization, is more strongly pronounced in water, presumably, as a result of stronger interactions of components.

The question about occurrence and properties of structured interfacial layers in aqueous solutions is actively discussed in the literature for a long time. In the case of formamide, such a question has not been raised yet.

Tables 3 and 4 show ζ^{p-np} in SAS-containing systems at various geometric parameters of the capillary and particle.

Tables 3 and 4 show that introduction of SAS into the systems decreases the mean r_f by an order of magnitude. In this case, the variance of the ζ^{p-np} values is considerably lower than in systems without SAS. Therefore, the electrokinetic behavior of SAS-containing systems is more stable as compared to that in the systems containing inorganic electrolytes only.

The estimated ζ^{p-np} values are independent of the geometric parameters of the capillary and particle, also evidencing that the estimated values are consistent with the theoretical physical parameter.

Introduction of SAS did not change the sign of ζ^{p-np} (it remained negative), but its absolute value increased significantly, as compared to the systems containing inorganic chlorides only. All these findings reveal a considerable adsorption of the organic anion

on the interface between air and any polar fluid used. At the same time, the increase in ζ^{p-np} in the absolute value ($\Delta|\zeta^{p-np}| = |\zeta^{p-np}|_{SAS} - |\zeta^{p-np}|$) was considerably higher in the aqueous systems (70 mV against 30 mV in the formamide systems). This difference, without question, can be attributed to the properties of the boundary layers and also to the fact that the adsorption of SAS from aqueous solutions is higher than that from formamide solutions. The higher adsorption of SAS on the aqueous solution–air inter-

face is caused by the hydrophobic effect and arrangement of the SAS molecules in the surface layer, controlled by the hydrophilic–lipophilic balance [23, 24]. Both effects, as known, are typical of water only. As a result of interaction between the polar group of SAS and replacement of the hydrocarbon radical from water (hydrophobic effect), a part of the hydrophobic radical of SAS becomes bound to water molecules [24], promoting strong ordering of the water structure. The thickness of this layer corresponds to the length of the hydrocarbon radical occurring in the solution [23].

CONCLUSIONS

(1) Electrokinetic flow in a hydrophilic capillary of model direct emulsions air–polar fluid (water or formamide) containing alkali metal chlorides was labile in all cases, which was more pronounced in formamide solutions and with cations of higher molar weight. Introduction of sodium alkyl sulfates into solutions stabilizes the electrokinetic flow.

(2) Electrokinetic potentials on the interface between air and aqueous (or formamide) solution of Li, Na, K, or Cs chloride are determined. The zeta-potential increases on passing from aqueous to formamide systems.

(3) Introduction of sodium alkyl sulfates (C_{10}–C_{15}) to both aqueous and formamide solutions does not noticeably influence the zeta-potential at the glass–liquid interface, but strongly increases that at the air–liquid interface, suggesting that sodium alkyl sulfates are not adsorbed on glass but are strongly adsorbed on the air–liquid interface. In this case, the absolute values of the zeta-potential were demonstrated to be considerably higher in the aqueous solutions as compared to the formamide solutions.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Kinetics of Decomposition of Water-Dissolved Phenol under the Action of Ozone and Electric Field

A. G. Bubnov, V. I. Grinevich, A. A. Gushchin, and V. V. Kostrov

Ivanovo State University of Chemical Engineering, Ivanovo, Russia

Received July 29, 2003

Abstract—Kinetics of phenol decomposition in aqueous solution under the combined action of weak electric field and ozone is studied. The possible reaction mechanism is suggested and analyzed.

According to the data obtained by foreign researchers [1], the human health may be 80% determined by the quality of potable water. Therefore, much attention is being given in the United States, Canada, and West Europe both to manufacture of bottle water of improved quality (from Artesian wells) and to problems associated with water treatment. One of the most important tasks of water treatment is to diminish the content of phenol, which is virtually always present in natural surface water basins and in water streams used as sources of potable water (1–5 $\mu g\ l^{-1}$ in natural water reservoirs in Russia [2]), to the level specified by regulations. This is primarily due to the fact that chlorination of phenol-containing water leads to formation of extremely toxic organochlorine compounds [3]. Therefore, introduction of new efficient energy-saving methods for purification of wastewater of various kinds (industrial, municipal, and surface) to remove phenols can improve the quality of water in natural water streams, which receive the above wastewater, and, consequently, can improve the quality of potable water [4]. However, both new, efficient, and old, known since the late 1940s, methods for water purification frequently fail to find wide use only because of the insufficient knowledge of the fundamental aspects of the physicochemical processes and reactions inherent in these techniques. Therefore, the aim of this study was to examine the kinetics of phenol decomposition in aqueous solutions under the action of electric field and ozone.

EXPERIMENTAL

As object of study was chosen an aqueous solution of phenol with an initial concentration of 0.5 $mg\ l^{-1}$. The initial solution was delivered to a feeding tank *1* (Fig. 1) and further, through cock *2*, to the electrochemical cell *3* of "comb" type with rectangular electrodes. The cell casing, anodes, and cathodes were made of 2-M fluoroplastic, titanium, and aluminum, respectively. The flow rate of the phenol solution was varied from 0.07 to 0.8 $ml\ s^{-1}$, which corresponded to a time of contact between the solution and the electrodes in the range from 130 to 1500 s. Ozone was generated using a laboratory ozonizer with coaxial arrangement of electrodes (maximum output of ozone of 0.146 and 0.454 $\mu mol\ s^{-1}$ with the use of air and oxygen, respectively).

The setup was connected to a dc power source *4*. The current strength *I* in the cell was varied from 0.1 to 10 mA (current density of 0.01 to 1.1 $A\ m^{-2}$), and the voltage, from 15 to 65 V.

A solution after treatment was delivered to the receiving vessel *5*. The concentration of phenol in the aqueous solution and in the gas phase at the reactor outlet was monitored photometrically (KFK-2MP colorimeter) by the reaction with 4-aminoantipyrine [5] (λ = 455 nm). The content of ozone in the gas and liquid phases was measured by absorption spectroscopy on the basis of light absorption at λ = 253.7 nm, which corresponds to the maximum cross section of

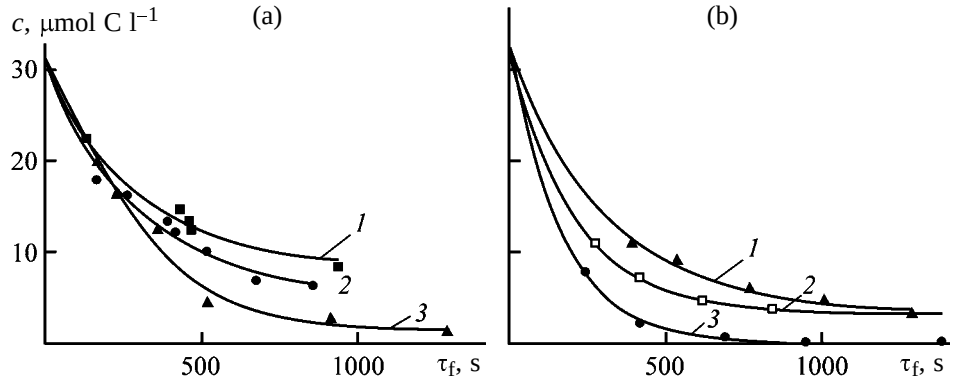

Fig. 2. Kinetics of phenol decomposition. (*c*) Concentration of phenol in terms of carbon and (τ_f) process time. Carrier gas: (a) air and (b) O_2; the same for Figs. 3 and 4. Type of treatment: (*1*) O_3, (*2*) O_3 + electric field, and (*3*) O_3 + electric field in a weakly mineralized medium; the same for Figs. 3 and 4.

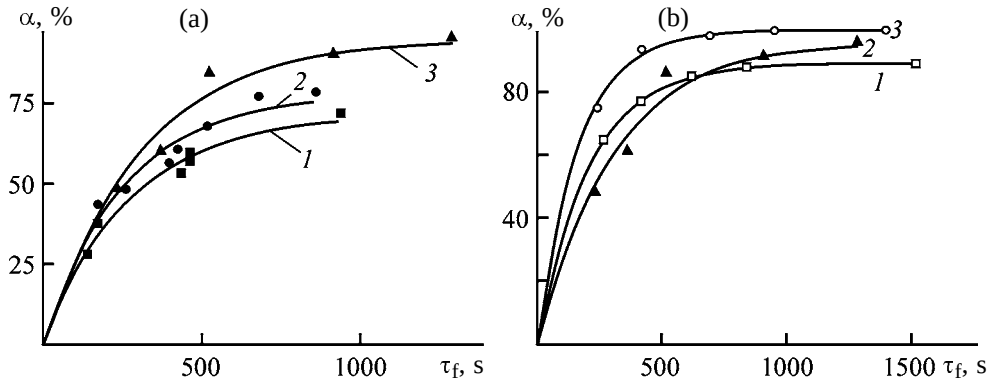

Fig. 3. Efficiency α of phenol decomposition. (τ_f) Time.

photoabsorption by O_3 ($\sigma = 7.8 \times 10^{-18}$ cm^2 [6]). The concentration of ozone, N_{O_3} (cm^{-3}), was calculated using the formula

$$N_{O_3} = \frac{\ln(I_0/I)}{\sigma l},$$

where I_0 is the initial intensity of the resonance emission line of Hg without ozone (rel. units); I, the same, but in the presence of ozone (rel. units); σ, cross section of photoabsorption (cm^2); and l, length of a cell with quartz windows (5.9 and 0.999 cm for the cases of measurement of the O_3 concentration in the gas phase and in the aqueous solution, respectively).

The concentration of carbon dioxide (in terms of the bicarbonate ion) was determined potentiometrically [5]. The pH value of the solution before and after electrochemical treatment was measured with an EV-746 pH meter.

The efficiency α (%) of phenol decomposition was determined using the formula

$$\alpha = \frac{c_{in} - c_f}{c_{in}},$$

where c_{in} and c_f are the concentrations of phenol in terms of carbon before and after treatment (μmol C l^{-1}).

Figures 2 and 3 show the kinetics and efficiency of phenol decomposition in water both in the case of ozonation and under a combined action of ozone and an electric field. It follows from the data presented that the decomposition of phenol is in all cases described by a pseudo-first-order reaction. The efficiency of phenol decomposition under the action of O_3 obtained from air is the lowest, about 60%, and that in the case of a combined action of ozone and an electric field is as high as 75%. If the process is carried out in a weakly mineralized medium (addition of 10 mg l^{-1} of KCl), the decomposition efficiency increases to 85%. The rate of phenol oxidation in the case of a combined purification method (weakly mineralized aqueous medium) exceeds that with only ozonation by a factor of more than 1.8 (Table 1). The efficiency of phenol decomposition in a weakly mineralized medium, with O_2 used to generate O_3, was as high as 99%, and the rate of phenol decomposition increased by a factor of 2.8, compared to that under the action of O_3 obtained from air.

Table 1. Effective rate constants k_{eff} of decomposition of phenol and formation of the final oxidation product in aqueous solution

Type of solution treatment	k_{eff}, s^{-1}			
	air		O_2	
	from decrease in phenol concentration	from increase in HCO_3^- concentration	from decrease in phenol concentration	from increase in HCO_3^- concentration
O_3	$(13 \pm 1.5) \times 10^{-4}$	$(10 \pm 1.1) \times 10^{-4}$	$(17 \pm 1.8) \times 10^{-4}$	$(13 \pm 2.4) \times 10^{-4}$
O_3 + electric field	$(18 \pm 1.5) \times 10^{-4}$	$(11 \pm 1.8) \times 10^{-4}$	$(25 \pm 3.6) \times 10^{-4}$	$(15 \pm 2.4) \times 10^{-4}$
O_3 + electric field in weakly mineralized medium (10 mg l^{-1} KCl)	$(24 \pm 2.7) \times 10^{-4}$	$(18 \pm 4.2) \times 10^{-4}$	$(38 \pm 6.0) \times 10^{-4}$	$(20 \pm 6.4) \times 10^{-4}$

It is known [7] that the yield of ozone increases as the power, which is directly proportional to the voltage applied across the ozonizer electrodes, is raised. Consequently, the efficiency of phenol decomposition in aqueous solutions must increase, too, and this was observed in the experiment.

However, if the conversion is found from the decrease in the concentration of phenol, the completeness of its decomposition cannot be determined adequately. The final products of total breakdown of organic compounds are H_2O and dissolved CO_2. Measurements of the concentration of CO_2 in solution (pH varied in all the experiments within the range 5.2–6.8, and, consequently, the carbonate system is ~90% represented in this case by HCO_3^-) demonstrated that this concentration remains virtually unchanged as the concentration of ozone in solution grows. It is noteworthy that the maximum yield of the final product in ozonation is very low and does not exceed 4% of the initial concentration of phenol, i.e., total decomposition of phenol under the action of O_3 is virtually not observed. This suggests that the rate-determining stage of phenol decomposition in water under the action of ozone is the decomposition of intermediates formed in its oxidation to the final products, i.e., CO_2 (k_3):

$$C_6H_5OH \xrightarrow{k_1} RC(O)H \xrightarrow{k_2} RC(O)OH \xrightarrow{k_3} CO_2 + H_2O.$$

Similar measurements in the case of a combined action on phenol solutions indicate that, at the same doze of ozone, additional application of an electric field leads to an increase in the degree of phenol decomposition to CO_2 by a factor of approximately 3 (at the maximum current density of 1.1 A m^{-2}), i.e., to 15%; however, in this case, too, the yield of HCO_3^- is low.

Combined action of ozone and an electric field on a phenol solution in a weakly mineralized medium (10 mg l^{-1} of KCl) is equivalent to an increase in the current density at the same voltage applied across the ozonizer electrodes. This results in that the efficiency of phenol decomposition to the final products grows to 45% (Fig. 4). The yield of the final oxidation prod-

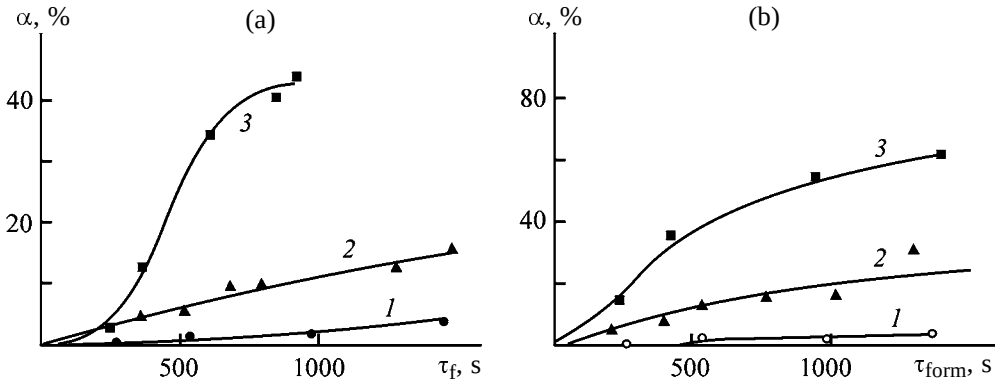

Fig. 4. Efficiency α of phenol decomposition to HCO_3^-. (τ_f, τ_{form}) Time.

uct increases in this case as compared to the treatment of phenol with only ozone by a factor of more than 7.

With oxygen used to generate ozone, the yield of the final product of phenol decomposition (HCO_3^-) was as high as 60% (Fig. 4). Consequently, use of O_2 to obtain O_3 is in this case justified, since the yield of HCO_3^- increases by a factor of 15, compared to treatment of a phenol solution with a mixture of ozone and air.

Consequently, application of electric fields leads to an increase in the concentration of active species initiating decomposition of phenol molecules. The arising additional active species (solvated electrons, hydroxy and hydroperoxy radicals, and chlorine oxides formed by the reaction $Cl + O_3 \rightarrow ClO + O_2$) mostly react with intermediates formed in decomposition of phenol and cause their oxidative breakdown to CO_2 (HCO_3^-).

Table 2 lists the results obtained in measuring the concentration of ozone in the gas (at the reactor inlet) and liquid (at the reactor outlet) phases, with ozone generated from air and O_2 and all other experimental conditions being the same.

The concentration of ozone in the liquid phase in the reactor is proportional to that in the gas phase at the reactor inlet. Only unreacted ozone remains in the liquid phase at the reactor outlet. Complete oxidation of 5.5 μmol of phenol requires 25.7 μmol of O_3, which constitutes 58% of the amount of ozone fed into the reactor in the case of ozone generation from air. The conversion of phenol with ozone obtained from air, measured for different types of treatment, varied between 62 and 88%. With account of the fact that a part of ozone, undissolved in water, is carried away from the reactor by discharged gases, complete decomposition of phenol must not occur in this case, which is confirmed by the experimental data presented above (the yield of the final oxidation products varied from 4 to 40%). With oxygen used to generate ozone, complete oxidation of phenol dissolved in water requires only 18% of O_3 fed into the reactor (Table 2). Consequently, the available O_3 is quite sufficient for complete oxidation of phenol. The experiments performed demonstrated that the yield of the final oxidation products was in this case substantially higher (60%). With aqueous solutions of phenol treated with only ozone, the yield of the final decomposition products was the same (about 4%), with both air and oxygen used to generate O_3. The decomposition rate of phenol is approximately 30–60% higher with O_2 used as the plasma-forming medium in the ozonizer

Table 2. Concentration of ozone in the gas and liquid phases for different methods of treatment of phenol solutions (c_{ph}^{in} = 5.5 μM)

Type of solution treatment	Air		O_2	
	gas	liquid	gas	liquid
O_3	44	3.4	153	5.9
O_3 + electric field	44	0.2	153	1.1
O_3 + electric field in weakly mineralized medium	44	0.6	153	1.0

(Table 1), irrespective of a method used for treatment of the aqueous solution. The experimental data obtained suggest the following: (1) the mechanism of phenol decomposition, including the rate-determining stages of the process, does not vary significantly between different types of solution treatment or different plasma-forming media in the ozonizer; (2) changing the plasma-forming medium in the ozonizer alters only the concentration of active species that initiate decomposition of phenol in an aqueous solution; and (3) use of combined methods for treatment of aqueous solutions results in that the composition of the active species, which cause decomposition of phenol molecules, changes not only quantitatively, but also qualitatively [e.g., chlorine oxides with high oxidizing capacity (ClO and ClO_2) are formed in addition to the OH and HO_2 radicals].

An estimation of the energy expenditure (main component for determining the environmental and economic efficiency of any purification method) for water purification to remove phenol by combining ozonation and application of an electric field in a weakly mineralized medium demonstrated that it does not exceed 3.4 kW h m^{-3}, which is only 1.2 kW h m^{-3} greater compared to treatment by only ozonation (2.2 kW h m^{-3}). Consequently, to reduce the concentration of intermediates formed in oxidative decomposition of phenol in purification of real wastewater or in water conditioning is combined treatment with ozone and an electric field (since wastewater is commonly mineralized to a sufficient extent).

CONCLUSIONS

(1) The degree of phenol decomposition in an aqueous solution in joint ozonation and electrochemical treatment in a mineralized medium is 2.3 times that in ozonolysis.

(2) The yield of CO_2 does not exceed 4% in ozonation of model solutions of phenol and increases to 60% (by a factor of 15) in the case of combined electrochemical treatment and ozonolysis, with the energy expenditure increasing by a factor of only 1.5.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Fundamental Aspects of Recovery of Components from Acid Wastewater in Its Treatment by Galvanocoagulation

Tsvetmetobrabotka Institute, Open Joint-Stock Company, Moscow, Russia

Received November 3, 2003

Abstract—The mechanism and fundamental aspects of recovery of ions of nonferrous metals, chromium(III), and sulfate ions in galvanocoagulation treatment of acid wastewater from plants for processing of nonferrous metals were studied.

At present, the galvanocoagulation method is widely used for treatment of wastewater of various compositions.

This work continues studies concerned with the mechanism of recovery of components in galvanocoagulation treatment (GCT) of acid wastewater (washing water from etching shops) formed at plants for processing of nonferrous metals, with the use of an iron–coke voltaic couple [1, 2].

Acid wastewaters from plants for processing of nonferrous metals have the following average chemical composition (mg l^{-1}): copper(II) ions 100, nickel(II) 5.0, zinc(II) 50, chromium(III) 50, iron(III) 15, sulfate ions 990–2200; pH 1.8–3.5.

Thus, the main contaminating components of acid wastewater are ions of nonferrous metals, chromium(III), and sulfate ions.

It has been shown experimentally [1, 2] that the main mechanism by which ions of nonferrous metals and chromium(III) are recovered from a solution of an acid wastewater in GCT is formation of their ferrites by the reaction with iron oxide and hydroxide compounds. Sulfate ions are recovered from acid wastewater in GCT mainly through their reaction with iron(III) hydroxide compounds, with the positive charge of a micelle of the aquahydroxo complex of iron(III) neutralized by the negative charge of the sulfate ion to form a complex compound of the type $Fe_2(SO_4)_{3-0.5m}(OH)_m(H_2O)_n$.

A minor part of sulfate ions is recovered in the form of poorly soluble iron sulfide (pyrrhotine) [1] through reduction of sulfur(VI) to sulfide.

Ferrites are complex oxides of the general formula $MO \cdot Fe_2O_3$. They can also be regarded as derivatives of hypothetical ferrous acid $H_2Fe_2O_4$, in which hydrogen ions are substituted by metal ions. Ferrites, as a rule, exhibit ferromagnetic properties; their crystals have a cubic structure of the spinel type [3, 4].

The main method for obtaining ferrites is sintering of iron(III) oxide with the oxide of the corresponding metal [3]. Considerably less frequent is the "wet method" in which an alkali solution is added to a solution that contains salts of iron and some nonferrous metal, with joint precipitation of the metal hydroxides in the presence of oxygen and their subsequent dehydration. The wet synthesis of ferrites is a complex process which includes reactions of solid-phase coordination and crystallographic structuring. Lyubman *et al*. [5] describe the formation of ferrites by the "wet method" by the following scheme:

$$M(OH)_2 + Fe(OH)_2 \xrightarrow{O_2} \left[\begin{array}{ccccc} & OH & & OH & \\ Fe & & M & & Fe \\ & OH & & OH & \end{array}\right]_n \longrightarrow MFe_2O_4 \cdot 2H_2O. \quad (1)$$

Apparently, such a scheme is operative in the case of ferrite purification. The key stage of the process is its initial stage, when ions of the metals being recovered are fixed with iron(III) hydroxide by the coordination mechanism. The solid complex compounds formed in the process have a tunnel structure, which favors an additional incorporation of the contaminating components to form clathrates.

A similar "wet technique" of ferrite formation, based on adsorption of ions of bivalent metals (Fe, Zn, Co, Ni, Cu, Cd) on particles of γ-oxyhydroxide of iron(III), γ-FeOOH, was described in [6].

The GCT of acid wastewater using an iron–coke voltaic couple involves anodic dissolution of iron

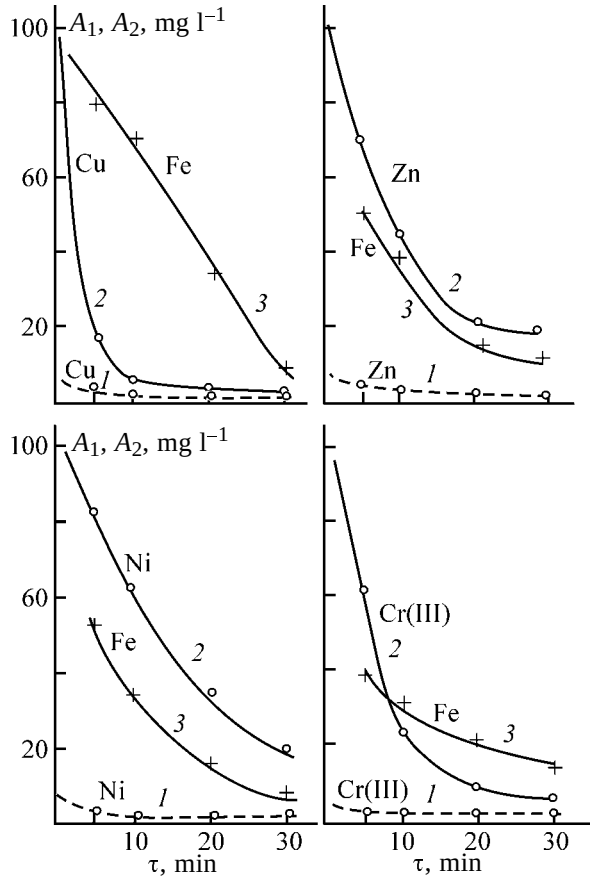

Fig. 1. Effect of the time τ of galvanocoagulation on the concentrations A_1 of copper(II), zinc(II), nickel(II) and chromium(III) and A_2 of iron in the solution after galvanocoagulation. Initial concentration (mg l^{-1}): (*1*) 5 and (*2*) 100.

to form iron(II) ions, which are then oxidized by atmospheric oxygen to iron(III). Simultaneously occurs chemical dissolution of iron in the acid contained in wastewater. In the process, the acid contained in wastewater is neutralized and the pH value increases to 4.0–6.5. As a result, a complex precipitate is formed, which contains a mixture of oxides and hydroxides of bi- and trivalent iron in various modifications, both magnetic and nonmagnetic [1]. At pH 5.0–6.5, hydroxides of nonferrous metals and chromium(III) start to precipitate.

Further, presumably, iron(II) hydroxide reacts with hydroxides of nonferrous metals and chromium(III) in the presence of atmospheric oxygen [5], and Cu(II), Zn(II), Ni(II), Cr(III) ions are adsorbed on γ-FeOOH particles. All these processes lead to formation of ferrites of the corresponding metals, which are thereby recovered from a wastewater solution.

It was shown in [5, 7] that the mixture of hydroxides of bi- and trivalent iron, which is formed both upon addition of an alkali solution to a solution of iron salts and in operation of an iron–coke voltaic couple, is highly active. Under various conditions (pH value, temperature) it gives a number of oxide and hydroxide compounds, both magnetic and nonmagnetic. In [1, 4, 5], it was established that only magnetic oxide and hydroxide compounds of iron are involved in the formation of ferrites. These compounds have a cubic crystal structure of the spinel type [3, 4], which is also typical of ferrites of nonferrous metals and chromium(III).

The aim of this work was to determine the optimal conditions of recovery by the galvanocoagulation method of ions of nonferrous metals and chromium(III), and also sulfate ions, from a solution of an acid wastewater of the composition specified above, to make it conform to the MPC (maximum permissible concentration) requirements imposed on purified water to be discharged into Moscow municipal sewage [8].

EXPERIMENTAL

The components of acid wastewater were recovered by the galvanocoagulation method under dynamic conditions, with the wastewater solution passed through a laboratory electrocoagulator (length 35 cm, diameter 10 cm, working zone volume 0.5 l) charged with a mixture that is an iron–coke (5 : 1) voltaic couple.

The concentration of ions of nonferrous metals and chromium(III) in the solutions before and after galvanocoagulation was determined by atomic absorption spectroscopy on a Perkin–Elmer spectrophotometer [9], and that of sulfate ions, by the volumetric method.

The kinetics of recovery of ions of nonferrous metals and chromium(III) was studied with individual sulfate solutions of these components, which contained 100 and 5 mg l^{-1} of the corresponding metals and had pH 2.5–2.7, which corresponds to the pH of acid wastewater.

The solutions under study were passed through the galvanocoagulator at different flow rates, with the time of contact between the solution being purified and the voltaic couple varied from 5 to 30 min. The results obtained (Fig. 1) indicate that, for copper(II), nickel(II), zinc(II), and chromium(III) ions to be effectively recovered in the course of galvanocoagulation, a 20–30-min time of contact between the solution being purified and the voltaic couple is sufficient at the ion concentration in the starting solution equal to both 5 and 100 mg l^{-1}. Figure 1 also shows that the concentration of iron decreases dramatically as the time

of contact is made longer, from 50–80 mg l^{-1} at a time of contact of 5 min to 5–10 mg l^{-1} at 20–30 min. This means that, as complete recovery of the corresponding elements is achieved, iron precipitates to form magnetic oxide and hydroxide compounds, including ferrites. The results of an X-ray phase analysis of this precipitate, performed on a DRON-2 diffractometer, demonstrate that it contains (%): lepidocrocite γ-FeOOH, 30–60; magnetite Fe_3O_4, 10–25; ferrites, 3–10; and goethite α-FeOOH, trace amounts.

A study of the kinetics of recovery of sulfate ions was studied with sulfuric acid solutions that contained 500 mg l^{-1} of sulfate ions, which corresponds to pH 3.0–3.5. The solution was passed through the galvanocoagulator, with the time of contact between the solution and the voltaic couple varied from 5 to 30 min. The results shown in Fig. 2 indicate that the recovery of sulfate ions in the time range specified is insignificant. At a time of contact between the solution under study and the voltaic couple equal to 30 min, the concentration of sulfate ions in a solution subjected to galvanocoagulation decreases from 500 to 300 mg l^{-1}. In this case, the concentration decreases from 300 to 60 mg l^{-1}.

Thus, the we found that the rate at which ferrites and also the sulfate–hydrate complex of iron (form in which sulfate ions are recovered in the galvanocoagulation process) is very low. For complete recovery of components from acid wastewater, the time of its contact with the voltaic couple should be 20–30 min. This time was used in our further experiments aimed to find how the recovery depends on the pH of the starting solution and on the concentrations of components in it.

Also, we studied how the galvanocoagulation recovery of copper(II), nickel(II), zinc(II), and chromium(III) ions from individual sulfate solutions containing 100 mg l^{-1} of each component depends on pH, which was varied from 1.5 to 5.5. The results obtained are shown in Fig. 3. It can be seen that copper is rather efficiently recovered in a wide range of pH values, 1.5–5.5. The most efficient recovery of chromium(III) is observed at pH 2.0–2.5, and that of zinc(II), at pH 2.7. Nickel(II) is an exception: it is recovered to the maximum extent at pH 3.0–4.0.

As seen from Fig. 3, the pattern is the same as before (Figs. 1, 2): At the instant when the maximum recovery of all the components is achieved, the concentration of iron in solution abruptly decreases, because iron passes into a precipitate in the form of oxide and hydroxide compounds. The pH of the solutions increases from 1.5–5.5 to 3.0–8.5 after galvanocoagulation.

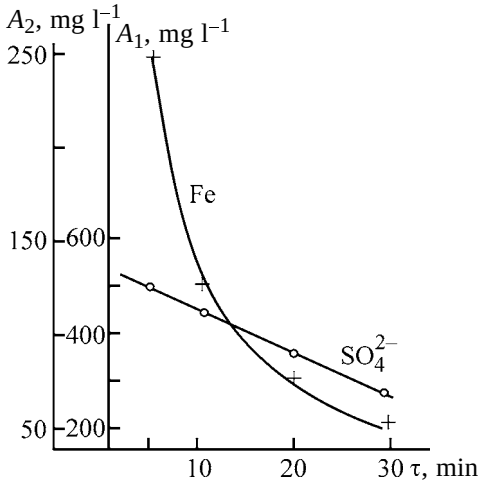

Fig. 2. Effect of the galvanocoagulation time τ on the concentrations A_1 of sulfate ions and A_2 of iron in the solution.

The dependence of the galvanocoagulation recovery of ions of nonferrous metals and chromium(III) on their concentration in the starting solution was studied by varying the concentration of each component in individual sulfate solutions from 50 to 200 mg l^{-1}. In doing so, the pH of the sulfate solutions of copper, zinc, and chromium(III) was maintained at 2.5–2.7, and that of nickel solutions, at 3.5–3.7, which corresponds to the pH value at which the recovery of these components from sulfate solutions is at a maximum.

Figure 4 shows that copper(II) and chromium(III) ions are efficiently recovered in the concentration range studied, 50–200 mg l^{-1}. Nickel(II) ions are well recovered in a rather narrow concentration range 50–100 mg l^{-1}, and recovery of zinc(II) ions is efficient only at low concentrations of ≤50 mg l^{-1}. These data allow the components of acid wastewater to be ranked in the following order of their decreasing recoverability in GCT with an iron–coke voltaic couple: Cu = Cr(III) > Ni > Zn, which corresponds to the series of ferrite-forming ability of nonferrous metal ions, reported in [5].

A study of how the recovery of sulfate ions in GCT depends on the concentration and pH of sulfate solutions showed (see table) that, at equal concentrations in the starting solution, the recovery of sulfate ions is the most efficient at pH of the starting solution equal to 2.0–4.0.

Zolotova and Ass [7] established that, in hydrolysis of a mixture of salts of bi- and trivalent iron, the following species are at equilibrium in the solution: Fe^{2+}, $Fe(OH)^+$, $Fe(OH)_2^0$, $Fe(OH)_3^-$, Fe^{3+}, $Fe(OH)^{2+}$,

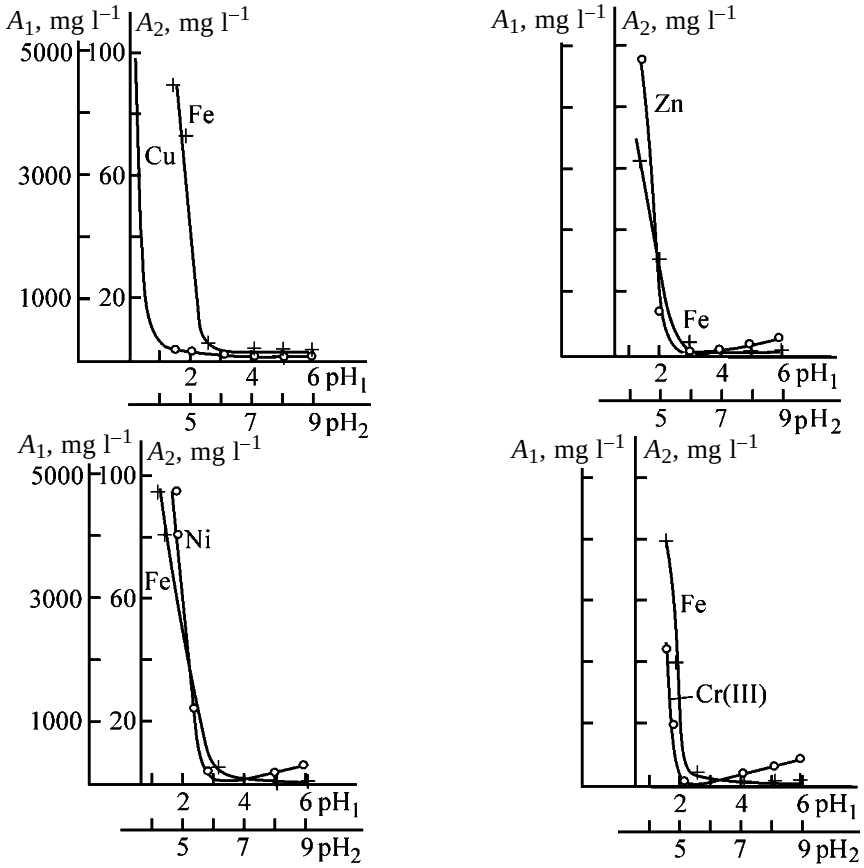

Fig. 3. Effect of the pH_1 of the starting solution on the content A_1 of copper(II), zinc(II), nickel(II), and chromium(III) ions and A_2 of iron in the solution after galvanocoagulation, with pH_2.

$Fe(OH)_2^+$, $Fe(OH)_3^0$, $Fe(OH)_4^-$, and $Fe(OH)_4^{2-}$.

It has been shown previously [1] that the main part of sulfate ions is recovered in GCT through their reaction with iron(III) hydroxo compounds, in which the positive charge of the aquahydroxo complex of iron(III) is neutralized by the negative charge of the sulfate ion. Therefore, it may be assumed that sulfate ions react with $Fe(OH)^{2+}$ and $Fe(OH)_2^+$ ions. It was shown in [10] that the maximum amounts of these ions are present in products of hydrolysis of iron salts at various concentrations of iron in aqueous solutions at pH 2.0–4.0. Thus, the pattern of recovery of sulfate ions in galvanocoagulation, revealed in this study, is in good agreement with these data.

The fundamental aspects of recovery of acid wastewater components, studied under laboratory conditions, made it possible to develop a process for purification of this wastewater and test it on the semicommercial scale. As a result, facilities for GCT of acid wastewater from the Moscow plant for processing of nonferrous metals were designed and constructed.

Galvanocoagulation recovery of sulfate ions at varied pH and concentration of the starting solution

Concentration of sulfate ions, mg l^{-1}		pH		Recovered amount of sulfate ions	
in the starting solution	after galvanocoagulation	of the starting solution	after galvanocoagulation	mg	%
520	208	3.5	6.0	312	60
532	364	6.0	8.5	168	30
1020	504	2.85	5.5	516	50
1030	950	5.8	8.0	80	12

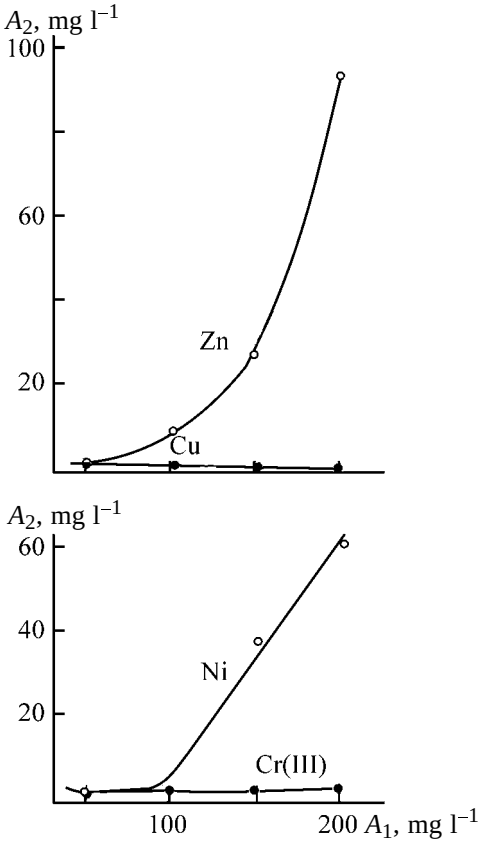

Fig. 4. Effect of the initial concentration A_1 of copper(II), zinc(II), nickel(II), and chromium(III) ions on the concentration A_2 of these components in a solution subjected to galvanocoagulation.

However, the dependences presented in this communication cannot be used for developing a process for GCT of acid wastewater of other compositions without a preliminary experimental study.

CONCLUSIONS

(1) The minimum time required for galvanocoagulation treatment of sulfate solutions to remove ions of copper(II), nickel(II), zinc(II), and chromium(III) and sulfate ions is 20–30 min.

(2) Copper(II) ions are efficiently recovered by galvanocoagulation treatment in a wide range of pH values and concentrations of the starting solution; chromium(III) ions, at pH of the starting solution equal to 2.0–2.5 in a wide range of initial concentrations; zinc(II) and nickel(II) ions, in a narrow range of pH values of the starting solution (2.7 for zinc and 3.0–4.0 for nickel) at their concentrations in the starting solution equal to 50–100 mg l^{-1}.

(3) The components of the acid wastewater from plants for processing of nonferrous metals can be ranked in the following order of decreasing recoverability in galvanocoagulation treatment: Cu = Cr(III) > Ni > Zn.

(4) In galvanocoagulation treatment, sulfate ions are efficiently recovered at pH 2.0–4.0.

(5) The revealed pattern is used in galvanocoagulation treatment of acid wastewater from the Moscow plant for processing of nonferrous metals.

Received April 22, 2003

Abstract—The solubility and stability of the peroxo solvates $KF \cdot nH_2O_2$ ($n \geq 1$) and disinfectants based on them was studied in organic and aqueous-organic solvents. Polyhydric alcohols (glycerol and ethylene glycol) and Tosol (commercial antifreeze) were used as solvents.

Potassium fluoride peroxo solvates (PFP) $KF \cdot nH_2O_2$ (n = 1–3) are well soluble in water. The solubility of the monoperoxo solvate $KF \cdot H_2O_2$ is 51.5 wt % at 0°C and 60.7 wt % at 20°C. The solutions are stable [1]. The PFP disinfectants developed on the basis of peroxo solvates (aqueous solutions) show a wide spectrum of antimicrobial activity. The preparations are effective against bacteriological and virus infections (including hepatitis and AIDS) [2]. At the same time, for treating many objects, it is appropriate to use disinfectants in the form of solutions in viscous organic or aqueous-organic solvents. A viscous organic medium ensures a better contact with the object to be treated. Slow evaporation of a viscous solvent results in the formation of a stock of hydrogen peroxide, which diffuses from the solvent to the treated surface gradually, thus prolonging the exposure. Aqueous-organic compositions with low freezing point allow the use of disinfectant solutions at negative temperatures.

In this work, we studied the solubility and stability in organic solvents and aqueous-organic media of the peroxo solvates $KF \cdot nH_2O_2$ ($n \geq 1$) and PFP disinfectant prepared on their basis with a potassium hydrofluoride stabilizing additive, which were obtained on a pilot-plant installation made of 12Cr18Ni10Ti steel. As solvents were studied glycerol, ethylene glycol, and Tosol (commercial antifreeze), which is a promising solvent of PFP preparations to perform the disinfection of various objects, including military objects, at low temperatures.

EXPERIMENTAL

Glycerol in the form of an 85% medical preparation (which has an optimal viscosity), chemically pure ethylene glycol, and the A40M grade Tosol (Rospolimer, Podolsk, Moscow oblast, Russia) were used without additional dehydration and purification. The liquid base of Tosol is aqueous ethylene glycol; it also contains a set of environmentally clean additives, which are not specified by the producer.

Since preparation of saturated solutions with a magnetic stirrer resulted in the decomposition of a part of hydrogen peroxide, solutions were prepared by the following procedure. To solid peroxo solvates or PFP preparations, the solvent prepared in advance was added in an amount ensuring preservation of one third of the solid bottom phase. The mixture prepared was manually stirred for 1–2 h and kept for a day. In so doing, the solid phase slowly precipitated onto the bottom. Then, the solution was stirred again to constant content of hydrogen peroxide, filtered through a polymer film with small apertures, and placed into polymer vessels for storage. The solutions were analyzed for the content of H_2O_2 by permanganometric titration. The content of potassium fluoride was determined gravimetrically. In ethylene glycol containing systems, the volatile components were removed by keeping the weighed portions of the solution at 130–150°C and by calcining the residual KF at 200°C to constant weight (temperature of complete dehydration of $KF \cdot 2H_2O$ is 40°C). Because of the high boiling temperature of glycerol, removal of volatile components in glycerol-containing systems at

59.5	18.66	27	–	1.5 ± 0.9

* $[H_2O_2]_s$ is H_2O_2 content in solid product.

200°C is accompanied by the appearance of carbon black traces on the surface of residual potassium fluoride. Therefore, the analysis for the content of potassium was done by atomic absorption spectrophotometry [AAS-1(3) abhvs spectrophotometer, Carl Zeiss, Jena]. The decomposition rate constant was calculated by the equation $\ln(c_0/c) = k(\tau - \tau_0)$, where c_0 is the concentration of the initial solution and c, the solution concentration in time τ. The hydrogen peroxide concentration in the stored solutions was measured at 5–7-day intervals. The values averaged over 5–8 measurements are given in Tables 1–4.

It was established that the solubility of $KF \cdot H_2O_2$ in a mixed glycerol–water solvent at a ratio (wt %) $C_3H_8O_3 : H_2O$ 85.0 : 15.0 is 9.06 wt % in terms of H_2O_2. As the content of water in the solvent increases, the $KF \cdot H_2O_2$ solubility grows, reaching the value of 14.5 wt % for the glycerol–water ratio of 59.5 : 40.5 (Table 1).

The solubility of $KF \cdot 1.23H_2O_2$ and samples of PFK-1 and PFK-2 preparations increases similarly.

The analysis of $KF \cdot H_2O_2$ solutions in water–glycerol systems for the content of KF showed that, at all water–glycerol ratios, hydrogen peroxide passes into the solution in excess compared to the value calculated from the KF content. For example, in $KF \cdot H_2O_2$ solution in 85% glycerol, the KF content is 11.22%, which corresponds to 6.58% H_2O_2. The

80	16.60	34	1.2 ± 0.4	0.34 ± 0.07
70	18.92	34	2.1 ± 0.3	0.49 ± 0.06

found content of H_2O_2 (9.06%) exceeds the calculated value by 2.48%.

The data obtained confirm both the sufficiently high solubility of the $KF \cdot H_2O_2$ peroxosolvate in a water–glycerol mixture (9–22 wt % in terms of H_2O_2) and the ability of the water–glycerol solvent to extract into a solution excess hydrogen peroxide owing to the dissociation:

$$KF \cdot H_2O_2(s) \rightleftarrows KF(s) + H_2O_2(sol). \quad (1)$$

As the water content in the solvent grows, the solubility of $KF \cdot H_2O_2$ itself and the amount of excess hydrogen peroxide passing into the solution increase (Table 2).

We believe that the ability of the solvent to extract hydrogen peroxide from the solid peroxo solvate depends on the following factors: difference in the solubilities in the chosen solvent of H_2O_2 and the solvated salt itself, solvent polarity, and the binding energy of hydrogen peroxide in the peroxo solvates. For example, complete extraction of H_2O_2 with water from $BaF_2 \cdot 2H_2O_2$ is mainly determined by the difference in the hydrogen peroxide and BaF_2 solubilities in water [3]. The binding energy of H_2O_2 in $BaF_2 \cdot 2H_2O_2$ does not play a significant role, though, according to our estimates, it is fairly high. On heating the barium fluoride peroxo solvate at 100°C in a vacuum, no more than 30% of hydrogen peroxide is evolved into the gas phase [3]. The amount of H_2O_2 evolved from $KF \cdot H_2O_2$ at this temperature is similar (50%). The enthalpy of the $KF \cdot H_2O_2(s)$ dissociation into KF(s) and $H_2O_2(g)$ is 85.5 kJ mol^{-1} [4]. Apparently, the enthalpy of dissociation of $BaF_2 \cdot 2H_2O_2$ is close to this value.

The solutions of $KF \cdot nH_2O_2$ and PFP preparations in glycerol–water mixed solvents are stable. The $KF \cdot H_2O_2$ and $KF \cdot 1.23H_2O_2$ samples obtained under laboratory conditions in the (85.0 : 15.0)–(68.0 : 32.0) range of the solvent compositions and stored for 14–24 days decompose at the average rates of 0.3–0.8 % day^{-1} relative to the initial content of H_2O_2. At the glycerol–water ratio of 59.5 : 40.5, the rate of the H_2O_2 decomposition somewhat increases (to 1.0–1.6 % day^{-1}). The PFK-1 sample obtained in the presence of the KHF_2 stabilizing additive appeared to be

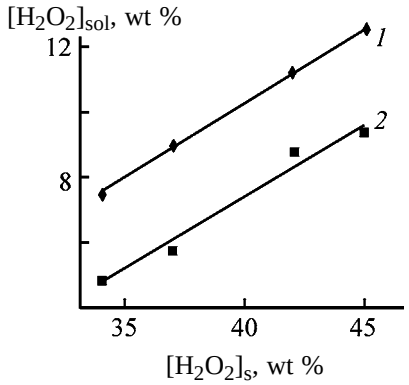
the most stable. The PFK-1 preparation loses H_2O_2 at an average rate not exceeding 0.23 % day^{-1}. The PFK-2 preparation is less stable.

According to published data [5], glycerol, hydrogen peroxide, and water under certain concentrations form explosive mixtures. The method of internal ignition in a tin tube showed that only compositions containing more than 40% H_2O_2, from 0 to 45% water, and from 0 to 15% glycerol are explosive. The solutions obtained by us contain hydrogen peroxide and water in small concentrations [9.1–21.6 and 12–28%, respectively)] and glycerol in high concentration (42–68%), i.e., the solutions are far from being explosive. Such solutions are not dangerous for practical use.

Potassium fluoride peroxosolvates are also soluble in another polyhydric alcohol, ethylene glycol. The solubility of the monoperoxo solvate $KF \cdot H_2O_2$ in anhydrous ethylene glycol is 5.83 wt % in terms of hydrogen peroxide. The solutions are stable: in 50 days of storage, the average rate of the H_2O_2 decomposition does not exceed 0.6 % day^{-1}. At the ethylene glycol : water ratio of 70 : 30, the decomposition rate somewhat increases (to 1.66 % day^{-1}, Table 3).

The solubility and stability of the PFK-1 and



Dependence of the hydrogen peroxide concentration in solution $[H_2O_2]_{sol}$ on its content in the solid product $[H_2O_2]_s$. Solvent composition: (*1*) 85 wt % glycerol–15 wt % water and (*2*) anhydrous ethylene glycol.

PFK-2 preparations in ethylene glycol mixtures are of the same order as those of the peroxo solvate samples obtained under laboratory conditions.

For all the solvates studied, the hydrogen peroxide concentration in ethylene glycol solutions and in glycerol solutions are the higher, the higher its concentration in the solid preparation (see figure). A study of the ethylene glycol systems using PFK-2 preparation showed that excess hydrogen peroxide passes into both water–glycerol solutions and water–ethylene glycol solutions (Table 2). The amount of excess H_2O_2 in ethylene glycol is lower than that in glycerol, though glycerol was studied with individual $KF \cdot H_2O_2$, in which the binding energy of H_2O_2(g) is 85.5 kJ mol^{-1}, whereas ethylene glycol was studied with the PFK-2 preparation, a mixture of monoperoxo solvate $KF \cdot H_2O_2$ and diperoxo solvate $KF \cdot 2H_2O_2$. The second H_2O_2 molecule in the diperoxo solvate has a lower binding energy (70.88 kJ mol^{-1}) [4], which must assist the dissociation. Evidently, the weaker capability of ethylene glycol to dissolve $KF \cdot nH_2O_2$ and extract excess hydrogen peroxide into a solution owing to dissociation mainly results from the fact that ethylene glycol is less polar than glycerol: the dielectric constant ε is 42.5 for glycerol and 37.7 for ethylene glycol [6].

Potassium fluoride peroxo solvates and PFP preparations are soluble in water–Tosol mixtures. In the case when the content of hydrogen peroxide in the peroxo solvates is higher than unity, the admixtures contained in Tosol produce a slight catalytic effect on the decomposition of peroxo solvates and a more considerable effect on their dissociation (Table 4).

The average rate of the $KF \cdot H_2O_2$ decomposition is 0.8–1.8 % day^{-1}. The PFK-1 preparation is more stable. In the same composition range, the average rate of the PFK-1 decomposition is 0.2–0.9 % day^{-1}. The peroxo solvate containing more than one hydrogen peroxide molecule and the PFK-2 preparation, while dissolved, undergo fast dissociation, with passing of excess hydrogen peroxide into the solution. In storage of such solutions, potassium fluoride gradually precipitates owing to further dissociation, without decrease in the hydrogen peroxide concentration. The PFK-1 solutions formed in the Tosol systems and the PFK-2 heterogeneous mixtures can be used in disinfectology.

CONCLUSIONS

(1) Potassium fluoride peroxosolvates and disinfectants based on them are soluble in polyhydric alcohols, such as glycerol and ethylene glycol, and in Tosol (commercial antifreeze).

(2) The solutions are reasonable stable. The average rate of the H_2O_2 decomposition does not exceed 1.7 % day^{-1} in solvents containing from 100 to 60 wt % alcohol.

(3) The dissolution of peroxosolvates is accompanied by the additional dissociation $KF \cdot nH_2O_2$(s) = KF(s) + H_2O_2(sol), with the excess hydrogen peroxide passing into the solution. In Tosol and its mixtures with water, the dissociation is accompanied by KF precipitation.

(4) The fact that potassium fluoride peroxosolvates and preparations based on them are soluble and stable in organic and aqueous-organic mixtures extends the range of their application in disinfectology.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Performance Criteria for Compositions Based on Cationic Polyelectrolytes as Reagents for Treating Wastewaters from Pulp-and-Paper Works

N. B. Mel'nikova, V. G. Sokolov, and L. I. Molvina

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received February 11, 2003

Abstract—Colloid-chemical properties of cationic polyelectrolytes and their mixtures with iron(III) chloride are studied, including the viscosity, adsorption on the cellulose surface, capillary imbibition and rise, and apparent charge density on the polymer. Selection criteria are proposed for polyelectrolytes as reagents for thickening and compaction of sludge from pulp-and-paper works.

Cationic polyelectrolytes are widely used in pulp-and-paper industry for treating wastewaters by flocculation and also in paper-making [1, 2]. Wastewaters from pulp-and-paper works contain negatively charged cellulose dispersions. Flocculation of such dispersions with polyelectrolytes proceeds through aggregation of particles by virtue of neutralization of the charge and bridge formation, and also as a result of mosaic binding [2, 3]. Low-molecular-weight fractions of cellulose are involved in the formation of a structured gel network capable of retaining particles of the disperse phase [2, 3]. In selecting polyelectrolytes as flocculants, such factors should be taken into account as the cationic demand of cellulose suspensions, apparent cationic charge, adsorption a polyelectrolyte on a given dispersion, viscosity, and other characteristics of both polyelectrolytes and the disperse system as a whole.

In this work we developed criteria for evaluating the performance of polyelectrolyte-based compositions as flocculants for treating wastewaters derived from paper making and also express tests for these compositions.

In formulating the compositions we used copolymers of acrylamide with nitrogen-containing bases such as Polymin KP, Kat-floc-487F, Praestol (MW > 500 000); a series of polymers of various natures with MW 10 000–30 000 (modified polyimines Polymin SK and Katiofast SF); and also poly(dimethyldiallylammonium chloride).

It was demonstrated previously that blends of cationic polyelectrolytes and inorganic coagulants show promise as flocculants [4]. Therefore, in this work we studied compositions based on a cationic polyelectrolyte and iron(III) chloride, which showed high performance in flotation treatment of wastewaters derived from paper-making.

EXPERIMENTAL

In the work we used $FeCl_3$ [pure grade, GOST (State Standard) 4147–74]; concentrated hydrochloric acid (chemically pure grade, GOST 3118–77); cationic polymers Praestol-644BC, 650BC, 611BC, 851, and 853 (Moscow–Stockhausen–Perm Closed Corporation, Russian–German Enterprise); Polymin SK, Katiofast SF, Polymin KP (BASF, Germany), Katfloc-487F (KEM-TRON Inc., Germany); decyldimethylbenzylammonium chloride $[(C_{10}H_{21})(CH_3)_3N(C_7H_7)Cl]$; poly(diallyldimethylammonium chloride) (poly-DADMAC); Toluidine Blue O; anionic polymer, potassium polyvinyl sulfate (PVSK) (MW 162.2, n = 1500, Lot/Contr. no. 04290, Serva Feinbiochemica GmbH & Co K G); and paper filter [TU (Technical Specifications) 6-09-1678–95].

The specific viscosity η_{sp} of polymer solutions was measured on an Ubbelohde viscometer with a 0.56-mm capillary. The correction factor due to the flow kinetic energy was estimated to be no more than 1.5%, and was neglected in estimating the viscosity number η_{sp}/c ($l^3\ g^{-1}$) (c is the polymer concentration in the solution, $g\ l^{-1}$).

The specific viscosity is defined as

$$\eta_{sp} = \eta_{rel} - 1,$$

1070-4272/04/7703-0407 © 2004 MAIK "Nauka/Interperiodica"

where $\eta_{rel} = \tau/\tau_0$, and τ and τ_0 are the outflow times of the colloid solution and water, respectively.

The cationic demand (CD) of cellulose dispersions was determined by colloid titration as follows. 25 ml of the filtrate of cellulose suspension (pulp + wastewater derived from paper-making) was charged into a 250-ml flask, and 10 ml of a cationic polymer solution (0.5 g l^{-1}) and 5 ml of Toluidine Blue (40 mg l^{-1}) were added. The volume was adjusted to 100 ml with distilled water, and the mixture was titrated with 65 mg l^{-1} PVSK until the color changed to violet.

In the blank experiment, we similarly titrated distilled water. The cationic demand (mg l^{-1}) was estimated by Eq. (1).

$$CD = \frac{(V^0_{PVSK} - V_{PVSK})x_p}{V_f}, \quad (1)$$

where V^0_{PVSK} is the volume of the PVSK solution (l) consumed for blank titration; V_{PVSK}, that consumed for titration of the working sample (l); x_p, concentration of the polymer solution (mg l^{-1}); and V_f, volume of the filtrate sample (l).

Also CP of the cellulose dispersion was determined by radio-frequency titration with a TV-6L1 radio-frequency conductometer. A pulp suspension (100 ml; 0.666 mg l^{-1}) containing a cationic polymer was placed into a cell of the radio-frequency conductometer. As a titrant we used 65 mg l^{-1} PVSK solution. The end point was determined graphically [5, 6].

The specific charge of the macromolecules was determined by colloid titration of 0.01% polyelectrolyte solution with 0.000388 N PVSK (MW 243 000) in the presence of Toluidine Blue [5]. The PVSK concentration was initially determined more precisely by colloid titration with a standard solution of decyldimethylbenzylammonium chloride. Assuming

$$N_{PVSK}V_{PVSK} = N_p V_p, \quad (2)$$

where N_p is the polymer concentration in the polyelectrolyte (g-equiv l^{-1}); N_{PVSK}, PVSK concentration (g-equiv l^{-1}); and V_p, volume of the polymer (l), the apparent density of the cationic charge on the macromolecules ρ (mg-equiv g^{-1}) was estimated by Eq. (3).

$$\rho = \frac{N_p \times 10^3}{m}, \quad (3)$$

where m is the polymer weight (g).

To determine the adsorption of the polymers, a piece of paper filter of a fixed area was immersed into 10 ml of 0.01% polymer solution. The paper was taken out after 30 s, and the volume of the residual solution was measured. The adsorption A_{eff} (g-equiv cm^{-2}) was estimated by Eq. (4).

$$A_{eff} = \frac{N_{cat}(V_{in} - V_{fin})}{S}, \quad (4)$$

where N_{cat} is the concentration of the cationic charges in 0.01% polymer solution (g-equiv ml^{-1}); V_{in} and V_{fin} are the volumes of the polymer solution before immersing and after removal of the paper filter, respectively (ml); and S is the area of the paper piece (cm^2).

In control experiments, we titrated the polymer before and after adsorption with 65 mg l^{-1} PVSK. The A_{eff} (g-equiv cm^{-2}) was estimated by Eq. (5):

$$A_{eff} = \frac{N_{PVSK}(V^0_{in} - V^0_{fin})}{S}, \quad (5)$$

where N_{PVSK} is the PVSK concentration (g-equiv ml^{-1}) and V^0_{in} and V^0_{fin} are the volumes of the PVSK solution (ml) consumed for titration of the initial 0.01% polymer solution and that after adsorption on paper, respectively.

The UV absorption spectra of aqueous solutions were recorded on an SF-46 spectrophotometer over the range 190–700 nm against water as a reference using 1-cm cells. The influence of oxygen on the optical density of the polymer solutions over the range 190–230 nm was studied by comparison of the UV spectra with those obtained on a Specord M-40 instrument after thorough purging of the sample with argon.

The efficiency of sludge thickening was characterized by the velocity of the motion of the interface between the clarified and unclarified volumes in a 2-l volumetric cylinder.

The capillary imbibition was determined as follows. A sample of filter paper (S = 20.4 cm^2) was fastened with a lifting holder arranged on a stand. A 0.01% polymer solution (10 ml) was charged into a 50-ml beaker. The paper sample was immersed in the solution to a depth of 0.5 cm, and the capillary rise was monitored as a function of time. The total experiment time was no more than 5 min.

The solution pH was measured with a pH 320 SET pH-meter (Wissenschaftlich–Technische–Werkstatten GmbH).

The method for determination of the absorption of a cationic polyelectrolyte by a negatively charged surface of cellulose fibers was proposed in [5]. Its essence is that, in solutions, negatively charged polymers react with cationic polymers practically stoichiometrically, forming a precipitate. For example, it was demonstrated that colloid titration of a cationic polymer, methyl glycol chitosan, with PVSK results in formation of an insoluble nonionic precipitate near the isoelectric point [5, 7]. The end point is determined using Toluidine Blue O as an indicator, which is adsorbed on the surface of an anionic polymer, changing its color from blue to purple or rosy at the end point.

If a fixed volume of a standard solution of the test cationic polymer is added to a cellulose suspension in distilled water and contacted for a sufficiently long time, the above-described method can be used for determination of the excess of a cationic polymer remaining in the solution after the cellulose precipitate was filtered out. Using PVSK as a titrant and knowing the stoichiometry of interaction of a cationic polymer with PVSK, we can estimate the adsorption of the polymer on cellulose and determine the adsorption characteristics of the cellulose dispersion such as the cationic demand, adsorption power, and apparent cationic charge density.

The adsorption properties of cationic polymers were evaluated using two parameters: the adsorption on filter paper and cationic demand of the cellulose dispersion, the latter corresponding to the amount of a cationic polymer bound to the carboxy groups of cellulose in unit volume of the dispersion. In determining both parameters, colloid titration was used to measure the excess amount of the cationic polymer remaining in the solution after a sufficiently long contact time.

The PVSK to test polymer stoichiometric ratio was determined by UV spectroscopy. It was demonstrated that the light absorption D_{rel} of an aqueous solution of a mixture of the modified cationic polyimine, Polymin SK, and PVSK in the UV range (190–220 nm) is an additive function of the concentrations of the individual components (Fig. 1). Titration of an aqueous solution of Polymin SK with PVSK in the presence of Toluidine Blue, which changes its color from blue to violet at the end point, revealed 1 : 1 stoichiometry. The UV spectra showed that the absorption follows the Beer–Lambert–Bouguer law over the concentration range from 0 to 1×10^{-3} g-equiv l^{-1} for both the initial polyelectrolytes and their mixtures with PVSK (Fig. 2).

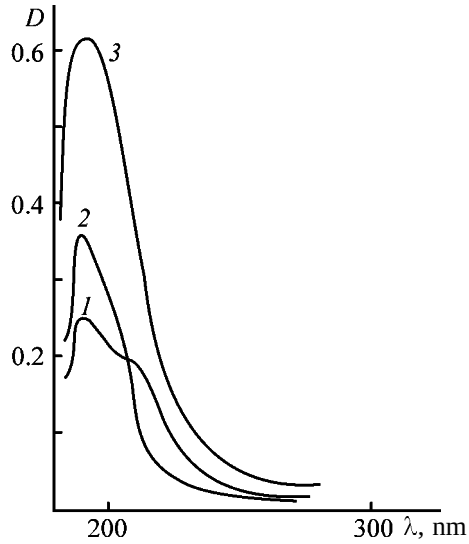

Fig. 1. UV spectra of polymer solutions: (*1*) 4.615×10^{-4} g-equiv l^{-1} PVSK, (*2*) 5×10^{-4} g-equiv l^{-1} Polymin SK, and (*3*) 5×10^{-4} g-equiv l^{-1} Polymin SK + 4.615×10^{-4} g-equiv l^{-1} PVSK. (*D*) Optical density and (λ) wavelength; reference: water; the same for Fig. 3.

Therefore, colloid titration with PVSK allows determination of the amount of a cationic polymer in the system over the indicated concentration ranges. Table 1 shows the characteristics of polyelectrolyte solutions, determined by colloid titration.

Note that cationic polymers with high molecular weight (nos. 1–5) have a low concentration of charged nitrogen-containing groups (ρ = 1–3 mg-equiv g^{-1}), and their 0.05% solutions demonstrate weakly acidic pH. Cationic polymers with relatively low molecular

weight from 10000 to 30000 g mol^{-1} (nos. 6–8) are characterized by high ρ and neutral pH.

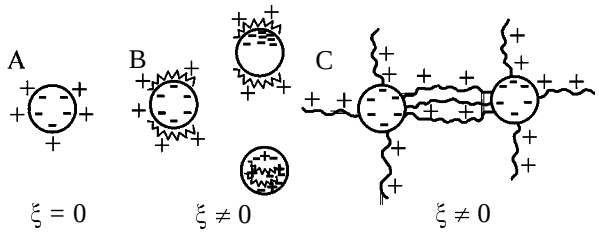
In addition, the cationic demand was determined by high-frequency titration of the paper suspension [6, 8].

Table 1 shows that the adsorption of polymers with low apparent charge density (nos. 1–5) is considerably lower than in those with high ρ (nos. 6–8). Therefore, in the latter case, larger amount of the cationic polymer is required to neutralize the net negative charge of the cellulose surface. This conclusion is also supported by data on the cationic demand (Table 2).

The results show (Table 2) that the decrease in the cationic demand for Polymin KP (ρ = 1.0 mg-equiv g^{-1}) from 559.4 to 452 mg l^{-1} ($\Delta CD/CD_{in}$ = 19%) is more significant as compared to Katiofast SF having ρ = 14 mg-equiv g^{-1} (from 520 to 500 mg l^{-1}; $\Delta CD/CD_{in}$ = 4%). Correspondingly, the consumption of a cationic polymer is much higher for polymers with high charge density. At the same time, the highest effect toward decrease in CD was obtained with a mixture of cationic polymers with high and low ρ (Table 2, no. 4).

Table 2 reveals satisfactory agreement of data obtained by colloid and high-frequency titration methods. The cationic demand depends on both the structure of the polyelectrolyte and composition of the polyelectrolyte system.

The mechanism of interaction of a cationic polyelectrolyte with a negatively charged cellulose surface is shown in the picture below.



It is a common view that fixation of a cationic polymer on cellulose particles is a resultant of two simultaneous processes, namely, ionic interaction of accessible surface carboxy groups (A, B) and adsorption through van der Waals or hydrogen bonding (C). Ionic mechanism dominates in the case of highly charged cationic polymers, e.g., Katiofast SF, representing, in essence, organic coagulants. Adsorption of such kind of polyelectrolytes was attributed in [9] to neutralization of the surface charge (B). Combined effect of high-molecular-weight polymers Polymin KP

and Katiofast SF with a low specific charge is, most likely, associated with bridging according to scheme C. In the case of efficient flocculation, smaller amount of the polyelectrolyte is consumed for neutralization of negatively charged cellulose particles, and, larger amount of the polyelectrolyte remains in the filtrate. Correspondingly, the amount of PVSK consumed for colloid titration of the filtrate will be higher than in the case of weak flocculation, and CD, according to Eq. (1), will decrease more strongly.

Evidently, in using polymers like Katiofast SF, poly-DADMAC, and high-molecular-weight polymers in combination, neutralization of negatively charged cellulose particles occurs most efficiently. Polyelectrolytes form complexes with the carboxy groups of cellulose and functional groups of hemicelluloses and lignin [2], resulting in formation of associates of various kinds. These associates, in turn, can form labile 3D networks, promoting flocculation. In order to further improve the efficiency of wastewater treatment, we proposed to use a composition based on a low-charged polyelectrolyte and the highly effective coagulant, $FeCl_3$, capable of forming polyelectrolyte complexes, as flocculants for cellulose suspensions. Our results showed that better flocculation and higher degree of decontamination are realized with a mixture of Kat-floc-487F and Polymin KP in combination with $FeCl_3$ (Table 3).

The UV spectra show that addition of $FeCl_3$ to Polymin KP and Kat-floc-487F polymer solution increases the absorption at 190–220 nm by a factor of about 1.5, the component concentrations in the solution being the same (Figs. 3a, 3b).

At the same time, in the case of highly charged

low-molecular-weight polyelectrolytes like Katiofast SF and Polymin SK, addition of $FeCl_3$ does not changes significantly the UV spectra (Figs. 3c, 3d).

Since hydrolysis of $FeCl_3$ produces hydrochloric acid, we studied the effect of addition of 0.5 g l^{-1} HCl on the properties of polyelectrolyte solutions. As seen from Fig. 3, HCl has no significant effect on the optical density over the range 190–220 nm.

The influence of atmospheric oxygen on the UV absorption of cationic electrolyte solutions was insignificant, since we used water as a reference.

The observed considerable changes in the optical density, initiated by addition of $FeCl_3$ to solutions of cationic polymers with low ρ (1–3 mg-equiv g^{-1}), are probably due to formation of polyelectrolyte complexes with $FeCl_3$.

Another practically significant characteristics of the polyelectrolyte-based compositions is their viscosity. In this work, the viscosity of 0.2% polymer solutions (120–130 m^3 kg^{-1}) remained unchanged at 10°C for a year. Also, we observed no noticeable changes in the flocculating properties of the compositions.

The efficiency of flocculation of cellulose particles depends on their wettability with a polymer solution. Therefore, we studied this effect by the kinetic method, i.e., by measuring the capillary rise along the paper [2]. The features of capillary imbibition of a liquid into a porous body can be described as follows.

On immersing a porous body into a liquid, a capillary pressure arises in the pores, given by the Laplace equation (6).

$$P_{cap} = (2\sigma\cos\theta)/r, \quad (6)$$

where *r* is the pore radius; σ, surface tension of the liquid; and θ, contact angle.

If a body has a hydrophilic surface, a fluid in pores forms concave meniscus, and the capillary pressure initiates capillary rise of the liquid in a capillary (imbibition).

The equilibrium height of the liquid rise in the case of ideal wetting (θ = 0) can be estimated by Eq. (7)

$$\eta_{max}c = 2\sigma/(r\rho g), \quad (7)$$

where *g* is the gravity acceleration.

The kinetics of capillary rise is described by the Poiseuille and Washburn equations:

$$dh/d\tau = (2\sigma\cos\theta/r - \rho gh)r^2/(8\eta h). \quad (8)$$

where η is the polyelectrolyte viscosity.

Since the hydrostatic pressure driven by the gravity is mostly considerably lower than the capillary pressure, the product ρ*gh* can be neglected, and Eq. (8) can be reduced to obtain Eq. (9).

$$dh/d\tau = 2\sigma r\cos\theta/(8\eta h). \quad (9)$$

Integrating (9) gives

$$h^2 = K\tau. \quad (10)$$

The empirical constant *K* reflects the capillary rise velocity, being controlled by the ratio between the surface tension and polyelectrolyte viscosity.

We studied capillary rise of 0.1% polyelectrolyte solutions using filter paper as a porous body. The measured height of the liquid rise as a function of the time is shown in Fig. 4.

The results were fit to the form of Eq. (11).

$$h^2 = a + K\tau, \quad (11)$$

where *a* is the constant reflecting the nonlinearity of imbibition in the initial period of time.

These results in combination with data given in Table 3 show that polyelectrolytes demonstrating the best flocculating action in thickening and clarification of cellulose suspensions have $K = 5 \pm 2$ mm^2 s^{-1}. The flocculating action decreases as *K* increases.

The capillary imbibition method can also be used for estimating the adsorption of a polyelectrolyte on the cellulose surface. In this case, the same batch of filter paper should be used as a support.

CONCLUSIONS

(1) The wastewater treatment efficiency increases if a composition based on a low-charged polyelectrolyte and an inorganic coagulant, $FeCl_3$, capable of forming polyelectrolyte complexes is used as a flocculant.

(2) The effective adsorption of a polymer as well as the cationic demand difference of cellulose, obtained by colloid titration, can be used as criteria in evaluating the flocculation efficiency of wastewater treatment and pulp thickening.

(3) An express method is proposed for testing the flocculating action, based on the capillary rise measurements. The empirical constant K in Eq. (11) should be 5 ± 2 $mm^2\ s^{-1}$ for polyelectrolytes having a considerable flocculating action in cellulose suspensions.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Aggregation of Rhodamine B in Water

N. O. Mchedlov-Petrosyan and Yu. V. Kholin

Karazin Kharkov National University, Kharkov, Ukraine

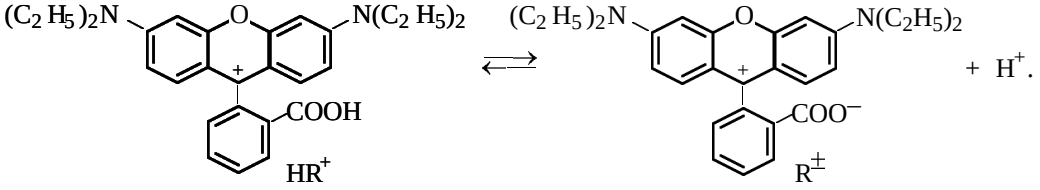
Received March 4, 2003

Abstract—Protolytic and associative equilibria in aqueous solutions of rhodamine B were studied. The curves of potentiometric titration with NaOH solution of the dye hydrochloride within the 5×10^{-4}–3×10^{-2} M range and at an ionic strength of 0.1 M (NaCl or KCl) were treated by chemometric methods of successive modification of the equilibrium system models with regard to spectrophotometric data. The most probable value of the equilibrium constants of the reaction $i\mathrm{H}^+ + j\mathrm{R} \rightleftarrows \mathrm{H}_i\mathrm{R}_j^{i+}$ were determined.

Thanks to the unique spectral-luminescence properties, rhodamine dyes are widely used as markers and probes in studies of various objects including biological systems [1], in sensors [2], including those based on Langmuir–Blodgett films [3], in supramolecular chemistry [4], and in studies of nanoobjects prepared by the sol–gel method [5]. The most part of rhodamines in aqueous solutions show deviations from Bouguer–Beer's law even at concentrations of 10^{-4} M. Spectrophotometry and the other methods show dye association [6–8]. Nevertheless, in many cases, e.g., in laser beam technology, concentrated solutions of rhodamines are required. As a rule, dyes are characterized by step (but not cooperative) association [6, 7], i.e., by successive formation of dimers, trimers, etc. Therefore, the state of dyes in solutions in the concentration range between the infinitely dilute and concentrated solutions is of interest.

In this work, the state of rhodamine B in water within the 2×10^{-6}–3×10^{-3} M concentration range was studied spectrophotometrically and potentiometrically. In water, HRCl salt dissociates with formation of the HR^+ cation.

In contrast to many other rhodamines, such as rhodamines 6Zh and 3B, rhodamine B participates in acid–base reaction not only at pH < 1.7 but also in less acidic medium because of the presence of a carboxy group. Its dissociation produces zwitterion $R^{\pm}$, which is the main form of the neutral species R in aqueous solution:



The fraction of molecules R converting in water into a colorless, low-polarity lactone R^0 amounts to 0.5–1% [10]. In general, rhodamine B transformations in the solution, depending on the acidity and dye concentration c_d, can be expressed by the equation

$$i\mathrm{H}^+ + j\mathrm{R} \rightleftarrows \mathrm{H}_i\mathrm{R}_j^{i+};\ \beta_{ji}, \qquad (1)$$

where β_{ji} is the equilibrium constant.

Although in aqueous solution the absorption bands of HR^+ and $R^{\pm}$ are ill-resolved (λ_{max} = 556–557 and 553–554 nm, respectively, at virtually the same extinction coefficient), it is possible to determine $\log\beta_{11}(\mathrm{R} + \mathrm{H}^+ = \mathrm{RH}^+)$ spectrophotometrically at $c_d \le 10^{-5}$ M ($\log\beta_{11}$ = 3.22 [9]; thermodynamic value at the ionic strength $I \to 0$). The $\log\beta_{11}$ values obtained potentiometrically are necessarily determined at substantially greater c_d. Because of association (dimerization), the standard method gives substantial difference in $\log\beta_{11}$ values measured at different rhodamine concentrations (from 3.2 to 4.1) [11–13] and drift of the calculated $\log\beta_{11}$ along the titration curve [14].

Dimerization of rhodamines was studied spectrophotometrically in [9, 11, 15–17]. Structural features of rhodamine B allow complete conversion of the HR^+ cation into the readily soluble in water zwitterion $R^{\pm}$, which prevents precipitation of HR^+X^- on adding salts and allows complete transformation of the dye

1070-4272/04/7703-0414 © 2004 MAIK "Nauka/Interperiodica"

into the dimer even at $c_d \sim 10^{-4}$ M [15]. The dimerization constants β_{20} at high I produced by inert salts[1] are listed in Table 1:

$$2R \rightleftarrows R_2;\ \beta_{20}. \quad (2)$$

A typical spectrum of the dimer R_2 is shown in Fig. 1a. In accordance with [9, 11, 18], the HR^+ cation can also dimerize in water. Variation of the dye concentration at pH 1.8–2.0 reveals a typical dimer band in the spectrum; however, in this case, λ_{max} is 526–527 nm, against 524 nm for R_2 [9, 15] (Fig. 1b). In dilute solutions, in which HR^+ species prevails (the fraction of H_2R^{2+} species is less than 3%), the band maximum lies at 556–557 nm as compared to 553–554 nm for R. The equilibrium constant of the $2HR^+ \rightleftarrows H_2R_2^{2+}$ equilibrium is calculated by standard procedure [15], $(1.6 \pm 1.1) \times 10^3$ [19], which agrees with the known value of 1.4×10^3 [18]. The band maximum at 526 nm was observed at pH 1.3 and I = 1.0 (KCl) [11].

We suggested previously [14, 19] that HR_2^+ species are formed along with cation dimers. Such complexes between the base and its protonated form, similarly to those between the acid and its anion, are usually formed in bipolar aprotic solvents, e.g., acetonitrile [20]. However, formation of $C_6H_5COOH\cdots {}^-OOCC_6H_5$ and $FH\cdots F^-$ species in water is also known [21]. We suggested that systematic deviations in calculations of $\log\beta_{11}$ made by simplified methods from the results of the pH-metric titration in water can be used as a source of information on association processes (dimerization in the simplest case). In this work, we studied rhodamine B association using data of HRCl titration with alkali and simulated the equilibria by the methods of quantitative physicochemical analysis (QPCA) [22].

EXPERIMENTAL

Chromatographically pure grade rhodamine B (as HRCl) [9, 10, 23, 24] was used. Chemically pure grade salts were additionally purified by recrystallization. An NaOH reference solution prepared from carbonate-free alkali solution and standardized by titration with double-recrystallized adipic acid was protected from atmospheric CO_2. β-Cyclodextrin (β-CD) produced by the Chinoin Company (Hungary) was used; in calculation of its concentration, it was assumed that this preparation contained 9 water molecules per macrocycle molecule. The absorption spectra of solutions were measured previously [9, 23]; additional measurements were performed on an SF-46 spectrometer. The pH values were measured with a glass electrode in an electric circuit with transfer vs. AgCl or calomel electrode; the bridge (contacting through a ground-glass joint) was filled with a KCl saturated solution (in special experiments, 1 M KCl solution was used). The electric circuit was standard-

[1] Here and hereinafter, dimensions of the constants are not indicated; the M concentration scale was used.

Table 1. Dimerization constant of rhodamine B zwitterions [15] at 20°C

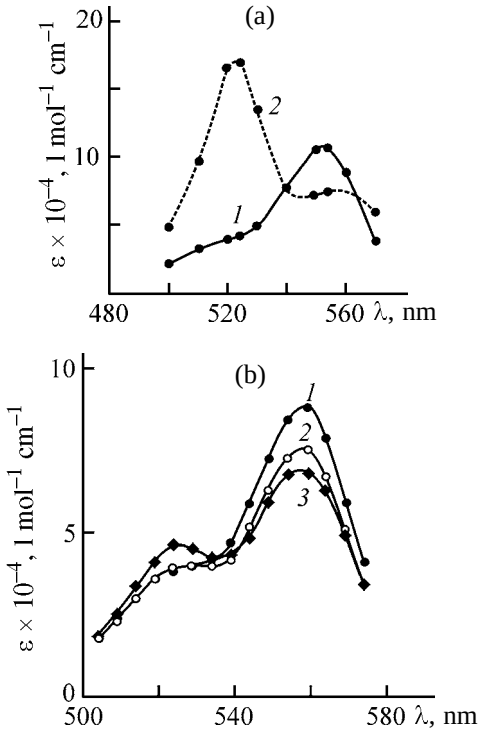

Fig. 1. (a) Absorption spectra of rhodamine B (*1*) monomer R and (*2*) dimer R_2 in 4.6 M $NaClO_4$ solution at pH 10–11, and (b) rhodamine B spectra at pH 2 (HCl) at various dye concentrations, M: (*1*) 1×10^{-4}, (*2*) 3×10^{-4}, and (*3*) 7×10^{-4}. (ε) Molar extinction coefficient and (λ) wavelength.

ized using reference buffer solutions with pH 1.68, 4.01, and 6.86. The hydrogen function of ESL-63-07 and ESL-43-07 glass electrode corresponded to the calculated function. In some cases, titration was performed in the presence of salts (NaCl, KCl), total I values were 0.05, 0.08, or 0.1 M; higher Cl^- concentrations can precipitate the dye as HRCl. The results were well reproduced; equilibria were reached virtually instantly. Prolonged contact of the solutions with glass surfaces causes adsorption of up to 5% of dye within 3 h under unfavorable conditions. A total of 55 titrations were performed at various dye (from 5×10^{-4} to 3×10^{-2} M) and alkali (from 1×10^{-3} to 3×10^{-2} M) concentrations, excluding preliminary experiments.

The number of species, stiochiometry, and stability constants of complexes are calculated from the dependence of any property (light absorption, concentration or activity of a system component) of the equilibrium system on its composition (composition–property dependences) [22]:

$$A_{lk} = \zeta(\lambda_l, n_{*k}), \quad (3)$$

where A is a property of the equilibrium system; k, the number of the mixture measured, $1 \le k \le N$; N, the number of mixtures measured; λ, analytical position (e.g., wavelength of the light absorbed in the method of multiwave spectrophotometry); l, the number of the analytical position, $1 \le l \le A$; A, the total number of analytical positions (channels of the simultaneous measurement of the properties of the equilibrium system); n_{*k}, vector of the initial (known from the conditions of mixing) reagent amounts in kth mixture studied; and ζ, any function whose form is determined by the features of the system studied and experimental method taken.

In studying equilibria in the solutions by pH-metry or spectrophotometry, the model structure is set by three groups of equations: connection of a measured property A with equilibrium composition, material balance, and law of mass action. Mixed equilibrium constants are calculated when estimations of hydrogen ion activities $h = 10^{-\mathrm{pH}}$ are used as approximated property A, and concentration constants, when the equilibrium concentration $[H^+] = 10^{-\mathrm{pH}} f_H^{-1}$ (where f_H is the hydrogen ion activity coefficient) is approximated by the model.

In this work, to find the number of species and stoichiometric composition of reaction products in rhodamine B solutions, we used the method of "successive correction of trial models" [25] for the case when experimentally measured quantities are the equilibrium concentrations of one of reagents [M]. In modeling, we formulated a trial hypothesis on reactions proceeding in the system, calculated for it the unknown equilibrium constants and reactant concentrations in all the experimental points, found weighted discrepancies $\xi_k = w_k^{1/2}$ {where k is the number of the experimental point, $\Delta_k = [M]_k^{cal} - [M]_k^{exp}$; $w_k + \sigma^{-2}(\Delta_k)$, statistic weight of kth measurement; and $\sigma^2(\Delta_k)$, variance of Δ_k}, and checked the model adequacy. When the statistic criteria showed lack of fit of the trial model to the experiment, parts of the experimental plan with higher absolute values of discrepancies $|\xi_k|$ were considered.

To compensate large discrepancies ξ_k, the model was supplemented with a new chemical species L_{new}, whose inclusion *a fortiori* improves the experiment description. Rules of the selection of L_{new} stoichiometric composition are described in [25, 26] in detail. Then, the calculation procedure was repeated.

It should be noted that the composition–property dependences are preset in the tabulated form, the arguments and responses contain errors, with information on only "typical" errors of the experimental values being accessible, and in this case the calculation of the parameters becomes a mathematically incorrect task. As a result, inclusion of excess chemical species in the models, wrong choice of the criterion of the mismatching between the model and experiment, erroneous estimation of the confidence intervals of parameters, uncritical estimation of the model adequacy, and other defects substantially decreasing reliability of the proposed models of the equilibrium systems are possible.

The work with fairly concentrated rhodamine B solutions caused the choice of pH-metric titration as the method of investigation, although the above disadvantages are characteristic of it in full measure. To make maximally reliable the information obtained from titration curves, in the stages of calculation of unknown stability constant, check of the model adequacy, and estimation of parameter significance, we used the methods of the data analysis theory. The traditional least-squares techniques was supplemented by Huber's robust M-assessments of the model validity (cross validation), singular analysis, and combining of local and global criteria of the model adequacy. Detailed description of the calculation methods used and CLINP 2.1 computer software is presented in [26–28].

To assess the adequacy of the models, we used the global criterion χ^2 (after preliminarily introducing the

necessary corrections when M-assessments were used) [29]. The model was considered to be adequate if

$$\chi^2_{\text{exp}} = s_0^2 f < \chi^2_f(\alpha), \quad (4)$$

where $f = N - z$ is the number of degrees of freedom; z, the number of unknown parameters of the model;

$$s_0^2 = f_k^{-1} \sum_{k=1}^{N} \xi_k^2, \quad (5)$$

residual variance; $\chi^2_f(\alpha)$, 100α% point of the distribution of χ^2 for f degrees of freedom at the preset significance level $\alpha = 0.05$ [30].

Additionally, we used cross validation [31]. For this purpose, we eliminated the gth dimension from N experimental points, calculated from the remaining data the fitting parameters, and found A_k^{cal} and weighted discrepancy of cross validation $d_g = w_k(A_k^{\text{cal}} - A_k^{\text{exp}})$. Calculations were performed for all N possible subdivisions of the set of experimental points, and cross-validation variance was found:

$$\bar{s}_0^2 = (N - z)^{-1} \sum_{g=1}^{N} d_g^2. \quad (6)$$

Cross validation reveals the presence in the model of "risk parameters" found using measurements only in one or in a few experimental points ("out-of-balance").

After our publication [15], along with monomers and dimers, the existence of rhodamine B trimers in concentrated ethanolic solutions was reported [32]. We additionally treated previously published spectrophotometric measurements [15] by the method of equilibrium model. It was found that, at c_d within the 4×10^{-4}–9×10^{-4} M range, pH 10–11, and the absence of the supporting electrolyte $\log\beta_{20} = 3.275(0.08)$[2] and $\varepsilon(R_2) \times 10^{-3} = 93(4)$ and 225(6) l cm^{-1} mol^{-1} for 524 and 554 nm, respectively. For the monomer, the $\varepsilon(R) \times 10^{-3}$ values are equal to 108 and 40 l cm^{-1} mol^{-1}, respectively. Thus, the result obtained previously was confirmed (Table 1). The model including only monomers and dimers well describes the experiment. At c_d within the 6×10^{-5}–6×10^{-4} M range, pH 10–11, and $I = 1.0$ M (KCl), similar procedure gave $\log\beta_{20} = 3.25(0.08)$, also without including more complex species.

In simulating the equilibria in more concentrated solutions (Fig. 2), the thermodynamic values of $\log\beta_{11} = 3.22$ and $\log\beta_{20} = 3.25$ (at $I = 0.1$ M, 3.30 and 3.30, respectively) found earlier from spectrophotometric data [9, 15] were considered to be known precisely. Variation of $\log\beta_{11}$ and $\log\beta_{20}$ within ± 0.3 had virtually no effect on the results of simulating the equilibria in the concentrated solutions because of low yield of HR^+ and R_2 species.

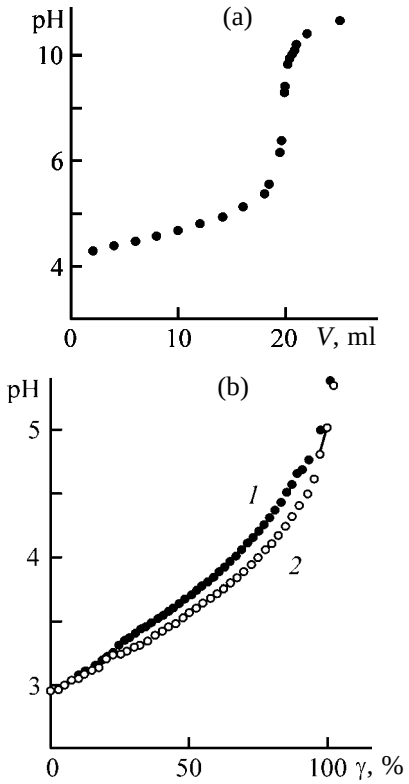

Fig. 2. Curves of titration of 20 ml of (a) 1.958×10^{-2} M rhodamine B (HRCl) solution with NaOH solution of the same concentration and of (b) 3.9×10^{-3} M rhodamine B solution with NaOH solution of the same concentration (*1*) in the presence of β-cyclodextrin and (*2*) without it. (V) Volume of NaOH solution added and (γ) degree of titration.

The estimated equilibrium hydrogen ion concentration $[H^+]$ was taken as a property approximated by the models. The experimental pH and f_H taken from the monograph [33] (for 0.1 M solutions of the supporting electrolytes NaCl and KCl, f_H is equal to 0.85 and 0.83, respectively) were used in calculation of $[H^+] = 10^{-\text{pH}} f_H^{-1}$. Prescribing the statistic weights w_k, we assumed the relative standard deviations $\sigma_r([H^+]) = 0.069$. This corresponds to the standard deviations in measuring pH $\sigma(\text{pH}) = 0.03$. In calculations, unless otherwise stated, unknown parameters were calculated by the nonlinear least-squares method.

[2] Here and hereinafter, the rms deviations of parameters are given in parentheses.

* Values obtained using Huber parameters of M-assessment.
** Logarithms of mixed equilibrium constants.
*** Values were not refined.

For the equilibrium in the solution with the initial HRCl concentration of 5×10^{-4} M (supporting electrolyte 0.1 M NaCl), a set of the permissible chemical species in the initial model was restricted to H^+, HR^+, R, and R_2, and a single parameter $-\log\beta_{11}$ ($H^+ + R = HR^+$) was calculated. Testing of the trial model gave $\log\beta_{11} = 3.50$, $\chi^2_{exp} = 42.3 > \chi^2_{f=10}(\alpha = 0.05) = 18.3$, i.e., the model is inadequate to the experiment. The local adequacy criteria, weighted discrepancies ξ_k, are large and systematic (Fig. 3, curve *2*). In Fig. 3, the vertical straight line divides the titration curve in two parts: In part *A*, the prevailing species are H^+ and R, while in part *B*, where ζ_k values are maximal, H^+ and R_2. To compensate the largest discrepancies, we supplemented the model by the HR_2^+ species, which is a product of the reaction between H^+ and R_2. After parametric identification of the supplemented model, we obtained the following results. $\log\beta_{11}$ cannot be determined from the data obtained (the yield of HR^+ in any point of the titration curve does not exceed 0.01% of the total rhodamine B concentration); $\log\beta_{21} = 7.37$; $\chi^2_{exp} = 16.7 < \chi^2_{f=9}$ ($\alpha = 0.05$) = 16.9, i.e., the model is adequate to the experiment with respect to χ^2 test. The local adequacy criteria ξ_k also substantially decreased (Fig. 3, curve *3*); only in the last point, the discrepancy ξ_k was still abnormally high. This result can be interpreted in two ways: either measurement in the last point of the titration curve is erroneous, or, with increase in pH, along with HR_2^+, other rhodamine B associates are formed.

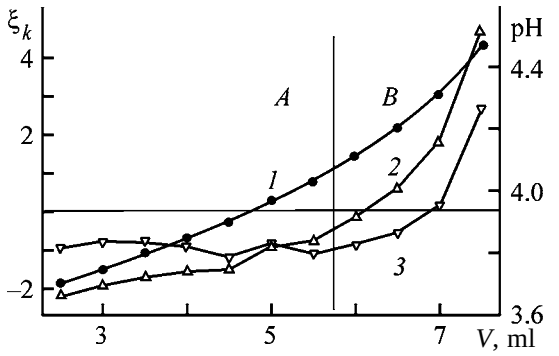

Fig. 3. Weighted discrepancies ξ_k for the initial model of equilibria. (*V*) Volume of NaOH solution added. (*1*) experimental titration curve; (*2*), (*3*) ξ_k.

In the end of the titration curve, the chemical species R and HR_2^+ prevail; the large positive discrepancy in the last experimental point is compensated by inclusion in the model of the product of reaction between them, HR_3^+. Testing of the model with a set of H^+, HR^+, R, R_2, HR_2^+, and HR_3^+ showed that the quality of the experiment approximation increased: $\chi^2_{exp} = 14.5 < \chi^2_{f=9}$ ($\alpha = 0.05$) = 16.9, and the HR_3^+ species is a significant component of the model; its yield exceeds 10% of total c_d. However, cross validation showed that $\log\beta_{31}$ ($H^+ + 3R \rightleftarrows HR_3^+$) is a risk parameter, since elimination of only one (last) point from the set of data treated drastically changes its value. Thus, it is impossible to make any reliable conclusion on formation of the HR_3^+ species under these conditions. The use of M-assessment gave the robust estimation of $\log\beta_{21} = 7.40$ (Table 2).

Spectrophotometric measurements performed at pH 1.8–2.0 for solutions within the $c_d = 1.0\times10^{-4}$–$1.0\times$

Table 3. Molar extinction coefficients ε of rhodamine B species

Species	ε, l cm^{-1} mol^{-1}, at indicated λ, nm	
	554	524
R	1.08×10^5	4.03×10^4
R_2	1.0×10^5	2.24×10^5
HR^+	1.1×10^5*	4.0×10^4**

* At 559 nm. ** At 529 nm.

10^{-3} M range at λ 559 and 529 nm (0.013 cm cell length) allowed verification of the above model. The previously found [9, 15] values of ε for various rhodamine B species are listed in Table 3.

Considering that $\log\beta_{20}$, $\log\beta_{21}$, and molar extinction coefficients of the above chemical species are known precisely, we calculated $\log\beta_{11}$($H^+ + R = HR^+$) and the extinction coefficient of HR_2^+ from the spectrophotometric data. The value found, $\log\beta_{11} = 3.5(0.05)$, coincides within the determination error with the value published in [9]; the model is adequate to the experiment: estimation of the relative standard deviation of the light absorption gave $s_r(A) = 0.05\chi^2_{exp} = 18.25 < \chi^2_{f=10}(\alpha = 0.05) = 18.31$. The equilibrium model proposed is also applicable to describing the potentiometric titration curve of rhodamine B solution with $c_d = 1.6 \times 10^{-3}$ M (supporting electrolyte 0.1 M KCl) (Table 2).

For the initial HRCl concentrations of 0.004 M (without supporting electrolyte) and 0.005 M (supporting electrolyte 0.1 M KCl), the simplest model with R, R_2, and HR_2^+ species fails to describe the experimental results. For instance, for the system with $c_d = 0.005$ M, $\chi^2_{exp} = 43.3 > \chi^2_{f=10}(\alpha = 0.05) = 18.3$, with substantial positive discrepancies ξ_k being concentrated in the region of the experiment plan with the prevailing species H^+ and HR_2^+. After supplementing the model with the reaction

$$H^+ + HR_2^+ \rightleftarrows H_2R_2^{2+},$$

we obtained an adequate model (Table 2). Similar results were obtained for the titration curve at the initial HRCl concentration of 4.0×10^{-3} M (Table 2).

Let us consider equilibria with the initial HRCl concentrations of 2×10^{-2} and 3×10^{-2} M (supporting electrolyte 0.1 M NaCl). Using the method of "successive correction of trial models," we reached in several steps the model adequate to the experiment (Table 4). Nevertheless, for this model, the weighted discrepancies ξ_k in the region with the prevailing species R and HR_3^+ are also systematic. At [R] < [HR_3^+], $\xi_k < 0$, and vice versa, at [R] > [HR_3^+], $\xi_k > 0$. This means that associates consisting of more than three rhodamine B molecules probably occur in the solutions. We tested the corresponding hypotheses (Table 4) and found that inclusion of these species, indeed, improves the agreement between the model and experiment; however, differences in the values of the criterial function χ^2_{exp} for different models are not so large to prefer one model to the others. Under these

Table 4. Procedure for construction of the model of equilibria in solutions with $c_d = 2 \times 10^{-2}$ M

Step of modeling*	Species	$\log\beta$	χ^2_{exp}	f	χ^2_f ($\alpha = 0.05$)

	R_6	15.05(0.14)			
	HR_6^+	19.17(0.15)			

* It was suggested to supplement the model with the reactions between the prevailing components, which improves the quality of the experiment description in the region of the experiment plan with maximal discrepancies ξ_k: $3R = R_3$ (step 1), $H^+ + R_3 = HR_3^+$ (step 2).

** Parameter was not refined.

Table 5. Parameters of equilibria in 3.9×10^{-3} M rhodamine B solutions with additions of 0.01 M β-CD at 25°C

Reaction	log β	χ^2_{exp}	f	χ^2_f ($\alpha = 0.05$)
$H^+ + R \rightleftarrows HR^+$	3.45(0.005)			
$2R \rightleftarrows R_2$	Parameter is insignificant: R_2 is absent	18.3	45	59.3
$H^+ + 2R \rightleftarrows HR_2^+$	6.03(0.02)			

conditions, we prefer the simplest hypothesis on the composition of the reaction products, though understanding that this hypothesis is approximate and partially conventional. Figure 4 shows the degrees of formation α_c(%) of rhodamine B chemical species H_iR_j (charges are omitted), calculated in the points of the titration curve.

$$\alpha_c = \frac{j[H_iR_j]}{\sum_j j[H_iR_j]} \times 100.$$

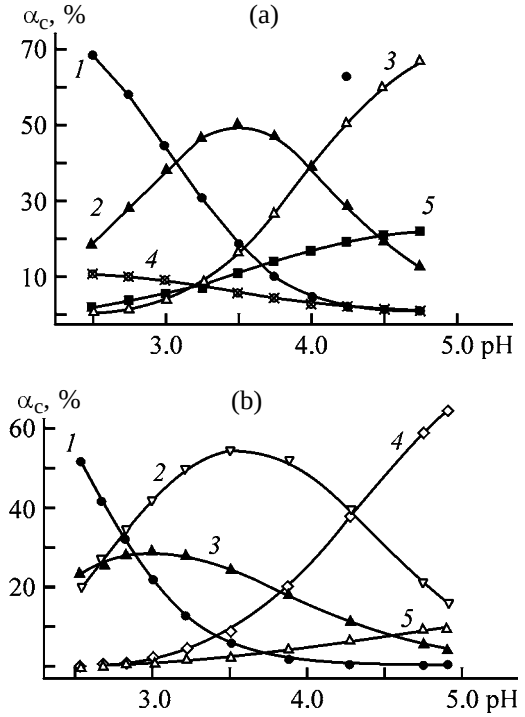

Fig. 4. pH dependence of the degree of formation α_c of various rhodamine B species. c_d (M): (a) 4×10^{-3} and (b) 2×10^{-2}. (a) (*1*) $H_2R_2^{2+}$, (*2*) HR_2^+, (*3*) R_2, (*4*) HR^+, and (*5*) R. (b) (*1*) $H_2R_2^{2+}$, (*2*) HR_3^+, (*3*) HR_2^+, (*4*) R_3, and (*5*) R_2; the degree of formation of HR^+ does not exceed 3.9%, and that of R, 6.7% (not shown in Fig. 4b).

It is interesting to determine how the presence of β-CD in the highest possible concentration of 0.01 M will affect the equilibria in HRCl solutions. It is known that β-CD forms complexes with rhodamine B monomers, decomposing the dimers [16].

Using the same scheme, we studied equilibria in the solutions with $c_d = 3.9 \times 10^{-3}$ M by titration with an NaOH solution of the same concentration (Fig. 2b). The simulation results (Table 5) convincingly show that, indeed, the association processes are sharply suppressed: R_2 fully disappears, and the HR_2^+ stability constant decreases by a factor of more than 10.

On the whole, the simulation results prove the fact that association of rhodamine B molecules in aqueous solutions is not limited to formation of the dimers R_2, HR_2^+, and $H_2R_2^{2+}$. With increasing c_d, the composition of the prevailing species changes: from monomers and dimers in dilute solutions to at least trimers in concentrated solutions. Additions of β-CD do not completely decompose the HR_2^+ species, but substantially suppress rhodamine B association.

The steric structure of rhodamine B dimers was considered in [17, 32, 34]; in all the cases, the mutual orientation of the chromophoric systems is close to parallel. Such an orientation does not exclude the interaction of carboxyphenyl fragments with each other. Probably, this causes association of R with HR^+ with the highest constant of 1.2×10^4 exceeding the constant of R dimerization (2×10^3). It is likely that, along with hydrophobic and π–π electronic interaction of the chromophoric systems, the $-C_6H_5-COOH\cdots OOC-C_6H_5-$ coupling, similar to that occurring between benzoic acid molecule and benzoate ion, makes a significant contribution.

However, stronger, as compared to R dimerization, association of HR^+ with HR^+ (equilibrium constant 5×10^3) is still difficult to explain (and this is in conflict with certain spectrophotometric data [11, 18, 34]). In this case, participation of Cl^- in formation of more complex associates can be assumed. However, experiments performed with a membrane ion-selective electrode in the absence of supporting electrolyte do not allow reliable conclusion because of insufficient reproducibility of pCl measurements under these conditions. As to the steric structure of R_3 or HR_3^+, we cannot make any definite assumptions. As a whole, within the concentration range studied, rhodamine B solutions can be considered as systems intermediate between solutions of monomers and of aggregates with less ordered structures and size approaching that of colloid particles.

CONCLUSIONS

(1) In 5×10^{-4} M solutions of rhodamine B (R), the pH-metric study revealed, along with neutral molecules R and cations HR^+, also the dimeric species R_2 and HR_2^+.

(2) Within the intermediate concentration range (~0.004–0.005 M), the dimeric species R_2, HR_2^+, and $H_2R_2^{2+}$ prevail in the solution, while the content of the monomeric species does not exceed 25%.

(3) In concentrated solutions of rhodamine B, associates consisting of at least three dye molecules exist, with the content of monomeric species being less than 10%.

(4) Using chemometric methods, the most probable values of the equilibrium constants of reaction (1) were determined: $\log\beta_{21}$ = 7.25–7.4, $\log\beta_{22}$ = 10.1–10.4, $\log\beta_{30} \approx 6.4-6.8$, and $\log\beta_{31} \geq 10$.

(5) β-Cyclodextrin introduced into the dye solution decomposes the dimers R_2 and decreases the stability constant of HR_2^+ by more than an order of magnitude.

(6) On the whole, solutions of rhodamine B in the concentration interval studied can be considered as transition systems between solutions of monomers and aggregates with less ordered structure and the size approaching that of colloid particles.

Abstract—The kinetics and mechanism of reaction of arylhydrazones with molecular oxygen were studied by gas volumetry. The reaction rate was studied in relation to the structure of arylhydrazone and kind of the solvent. The inhibiting power of the compounds toward initiated oxidation of ethylbenzene was evaluated, and the most effective compounds were found, judging from the ratio of the rate constants of the reactions with molecular oxygen and with peroxy radicals arising in the course of ethylbenzene oxidation.

We found previously [1, 2] that arylhydrazones derived from aromatic and heterocyclic aldehydes exhibit pronounced antioxidant properties. The inhibiting effect of these compounds in radical chain oxidation of organic substances is due to termination of oxidation chains by reaction with the peroxy radicals $RO_2^{\bullet}$ arising in the course of the substrate oxidation. However, despite the high activity of virtually all the tested arylhydrazones toward peroxy radicals, the stoichiometric inhibition coefficient *f* (number of radicals decaying on one antioxidant molecule) and induction period τ (time during which the agent inhibits oxidation), characterizing their overall antioxidant effect, are relatively low and depend on the structure of the compounds. This may be due to participation of antioxidant molecules in side reactions (nonproductive consumption). Since the reaction system in the course of oxidation contains not only $RO_2^{\bullet}$ radicals but also other oxidants such as molecular oxygen, partial consumption of hydrazones in reaction with this oxidant should be expected.

Studying oxidation of arylhydrazones with molecular oxygen is necessary for gaining better insight into the mechanism of the effect of such active radical scavengers as arylhydrazones. Furthermore, studying the reactivity of arylhydrazones toward oxygen is closely related to the problem of stabilization of organic compounds, since this reaction largely determines the performance and service life of these oxidation inhibitors. Available data [3] on the mechanisms and kinetics of oxidation of arylhydrazones with molecular oxygen are scarce and do not allow definite conclusions concerning the influence of the structure of arylhydrazones and oxidation conditions on their reactivity and the role of this reaction in inhibited oxidation processes. This problem is considered in our paper.

EXPERIMENTAL

The reactivity of arylhydrazones of the general formula $R^2R^3C{=}NNHR^1$ (R^1 = Ph; R^2 = Ar; R^3 = H, Me) toward molecular oxygen was studied in the temperature range 303–358 K in various solvents (chlorobenzene, ethylbenzene, ethanol) by gas volumetry [4]. The antioxidant activity of arylhydrazones in initiated [azobis(isobutyronitrile) initiator] oxidation of ethylbenzene was studied by a chemiluminescence method [4]. The products of arylhydrazone oxidation with molecular oxygen were identified by UV spectroscopy (Specord UV VIS spectrophotometer, chloroform solutions) and TLC (Silufol plates, eluent chloroform–benzene–hexane–methanol, 30 : 6 : 1 : 1).

The kinetic curves of oxygen uptake in oxidation of various arylhydrazones (Fig. 1a) show that these compounds actively react with oxygen. In the initial portions of the curves, oxidation occurs at a constant rate depending on the structure of the compound and its initial concentration. As judged from the dependences of the reaction rates on the oxygen and arylhydrazone concentrations, with all the arylhydrazones studied the reaction is first-order with respect to both reactants. The reaction rate constants are listed in Table 1. The inertness of the disubstituted hydrazone toward molecular oxygen suggests that the oxidation primarily involves the NH group of the hydrazone moiety. The autooxidation of hydrazones occurs by the radical mechanism [3]; the primary reaction is formation of the *N*-hydrazonyl radical:

$$R^2R^3C{=}N{-}NHR^1 + O_2 \xrightarrow{k_{O_2}} R^2R^3C{=}N{-}\dot{N}R^1 + HO_2^{\bullet}.$$

This radical occurs in an equilibrium with the

C-radical:

$$R^2R^3C{=}N{-}\dot{N}R \rightleftarrows R^2R^3\dot{C}{-}N{=}NR.$$

Then the radicals add oxygen to form azo hydroperoxides or recombine to form dimeric products. UV spectroscopic and chromatographic study shows that the final product of benzaldehyde phenylhydrazone oxidation is N^1,N^3-diphenyl-N^4-benzylidenebenzhydrazidine (λ 288, 345 nm; R_f 0.87) formed by recombination of the *C*- and *N*-radicals.

Table 1 shows that electron-acceptor substituents in the aldehyde moiety decelerate, and electron-donor substituents accelerate oxidation of arylhydrazones with O_2.

In contrast to other electron-donor substituents, the hydroxy group introduced into the aldehyde moiety considerably enhances the resistance of the arylhydrazone to oxidation with molecular oxygen. The kinetic curves of the oxygen uptake with hydroxybenzaldehyde arylhydrazones show well-defined induction periods (Fig. 1b), which is apparently due to participation of phenolic hydroxyl in inhibition of the radical oxidation of the NH group with oxygen. This assumption is confirmed by the fact that the kinetic curve of the oxygen uptake in oxidation of benzaldehyde phenylhydrazone in the presence of Ionol (well-known phenolic antioxidant) has a similar shape.

The higher, compared to other hydrazones, rate constant of the reaction of acetophenone phenylhydrazone with oxygen is apparently due to existence of this hydrazone in the enehydrazine form, which is more readily oxidizable than the hydrazone form [3].

A study of the solvent effect on the oxidation rate shows (Fig. 2) that the reaction of phenylhydrazones with O_2 in ethanol is considerably slower than in aromatic solvents, which is due to hydrogen bonding of ethanol with the reaction center of arylhydrazone. Oxidation of arylhydrazone with oxygen in ethylbenzene does not lead to additional chain initiation and hence to acceleration of the hydrocarbon oxidation. This fact indicates that the radicals generated in oxidation of arylhydrazones show no initiating effect, since they recombine with each other to form a dimer; this dimer was detected experimentally.

In the course of ethylbenzene oxidation inhibited with arylhydrazones, the inhibitor will be consumed both in the reaction with peroxy radicals generated from the hydrocarbon [5]

$$R^2R^3C{=}N{-}NHR^1 + RO_2^{\bullet} \xrightarrow{k_{RO_2^{\bullet}}} R^2R^3C{=}N{-}\dot{N}R^1 + ROOH,$$

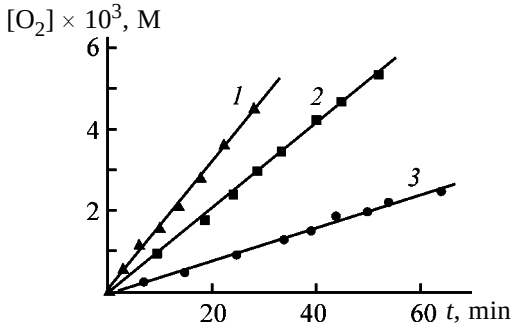

Fig. 2. Kinetic curves of oxygen uptake in oxidation of 4-chlorobenzaldehyde phenylhydrazone (5×10^{-2} M) in (*1*) chlorobenzene, (*2*) ethylbenzene, and (*3*) ethanol. T = 343 K; $[O_2] = 10^{-2}$ M.

and in the reaction with oxygen. Comparison of the rate constants of the reactions of arylhydrazones with oxygen and peroxy radicals (Table 1) shows that the contribution of the reaction with oxygen to the total consumption of arylhydrazones is in some cases low. This primarily concerns phenylhydrazones containing hydroxy groups in the aldehyde moiety, namely, the derivatives of 5-bromo-2-hydroxybenzaldehyde and salicylaldehyde. Specifically these compounds, being fairly active toward peroxy radicals generated from ethylbenzene, are of practical interest as antioxidants.

The majority of the arylhydrazones studied are relatively reactive toward molecular oxygen. As oxidation of arylhydrazones involves homolytic cleavage of the N–H bond, the rate constants k_{O_2} and $k_{RO_2^{\bullet}}$ linearly correlate with the dissociation energy of the N–H bond, D_{N-H}. This quantity was calculated by the PM3 semiempirical method using MOPAC-97 software. The low dissociation energies of the N–H bonds (Table 1), on the one hand, are responsible for the high reactivity of arylhydrazones toward radicals, but, on the other hand, result in nonproductive consumption of the antioxidants in side reactions.

Therefore, to develop new antioxidants of the hydrazone series, it would be appropriate to decrease somewhat the activity of the NH group in oxidation by increasing the strength of the N–H bond. This can be done by introducing heterocyclic substituents into the hydrazine moiety. As seen from Table 2, good results are obtained with hydroxybenzaldehyde quinoxalinohydrazone **III**. This compound is characterized by high rate constant of peroxy radical termination $k_{RO_2^{\bullet}}$ and high stoichiometric coefficient of inhibition; at the same time, it shows low reactivity toward molecular oxygen. Furthermore, antioxidants of such a structure exhibit biological activity. Our results will be useful in further search for effective antioxidants of the hydrazone series.

Table 2. Parameters of the antioxidant effect of hydrazones in initiated oxidation of ethylbenzene (V_i = 5.4 × 10^{-7} mol l^{-1} s^{-1}, T = 343 K)

CONCLUSIONS

(1) A kinetic study of the reaction of arylhydrazones with molecular oxygen showed that the reactive fragment is the NH group of the hydrazone moiety.

(2) Electron-donor substituents in the aldehyde moiety enhance the activity of arylhdyrazones, and electron-acceptor substituents decrease it.

(3) The strength of the N–H bond in hydrazone molecules correlates with their reactivity in oxidation with both peroxy radicals and oxygen. High reactivity toward O_2 decreases the performance of antioxidants.

(4) Arylhdyrazones derived from hydroxybenzaldehydes are more resistant to oxidation with oxygen and are therefore effective antioxidants.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Kinetics of Hydroxyethylation of Dimethylamine

S. M. Danov, V. A. Kolesnikov, R. V. Efremov, and D. Yu. Mezhenin

Dzerzhinsk Branch, Nizhni Novgorod State Technical University, Dzerzhinsk, Nizhni Novgorod oblast, Russia

Received October 6, 2003

Abstract—The kinetics of hydroxyethylation of dimethylamine with oxirane was studied in the temperature interval 20–50°C at the oxirane : dimethylamine molar ratio of 1 : 3. The influence exerted on the reaction rate by the reaction product, dimethylethanolamine, was examined.

Dimethylethanolamine (DMEA), hydroxyethylation product of dimethylamine (DMA), is widely used in basic organic synthesis, as solvent in paint-and-varnish production, and as a component of cleansing, degreasing, preserving, hydraulic, and cutting fluids.

DMEA is synthesized in industry by liquid-phase hydroxyethylation of DMA. At one of the enterprises, the synthesis is performed in a coaxial-pipe reactor at 80–175°C, pressure of 5–6 MPa, and DMA : oxirane (OX) molar ratio of 3 : 1.

However, the quality of the DMEA produced is poor, because the conditions in the reactor are far from being optimal. Because of inefficient heat exchange, the temperature in the reactor rises to 175°C, whereas the available papers recommend much lower synthesis temperatures.

In this work we studied the kinetics of DMA hydroxyethylation with the aim to obtain data required for optimizing the reactor design and operation conditions. It is known that, in the absence of proton donors, amines do not react with oxirane or react very slowly [1]. Lebedev and Smirnova [2–5] studied the reaction of oxirane with various amines manometrically. They found that proton donors (water, alcohol, phenols, acids) accelerate the reaction and that the reaction follows the first-order kinetic equation. The amino alcohol formed in the reaction also acts as a proton donor, causing an autocatalytic effect. The reaction follows the Brønsted relationship, and for each type of proton donors the logarithms of the rate constants correlate with the pK_a values.

In experiments without catalysts, in agreement with data of [1], no reaction initially occurred; the induction period became shorter with increasing temperature, but fully disappeared only at 230°C. After the end of the induction period, the reaction rate sharply grew, and the nitrogen atom underwent fast and selective hydroxyethylation. After completion of the substitution, at temperatures above 110°C, the reaction decelerated again, and above 150°C it almost fully stopped. However, at 70–100°C the reaction continued after substitution completion, yielding polyoxyethylated products. This phenomenon was explained by Sorokin and Shode [6–8]. They reported on formation of minor amounts of quaternary ammonium bases which catalyze successive hydroxyethylation as efficiently as do, e.g., alkali metal alcoholates. However, quaternary ammonium bases are unstable and decompose above 100°C with the regeneration of the tertiary amine.

It is also known that, in DMA hydroxyethylation, formation of the desired DMEA is accompanied by side reactions such as formation of dimethylaminoethoxyethanol (DMAEE), isomerization of oxirane into acetaldehyde, and dimerization and polymerization of oxirane [9]. The resulting products can undergo further transformations.

Preliminary experiments showed that the side reactions were insignificant at 20–60°C and DMA : oxirane molar ratio of 3 : 1. This ratio is used in the commercial synthesis, and therefore we chose it in our kinetic experiments.

The reaction rate was evaluated from accumulation of DMAE in the reaction mixture, monitored chromatographically. Figure 1 shows the kinetic curves of DMEA formation at various temperatures.

It is seen that the kinetic curves are S-shaped, which is typical of autocatalytic reactions. The DMEA formed in the process can donate protons activating the oxirane molecule. To confirm the occurrence of autocatalysis, we performed some experiments at 30°C with addition of DMEA to the starting mixture. The results are shown in Fig. 2.

Points are experimental data, and lines are calculated; the same for Fig. 2.

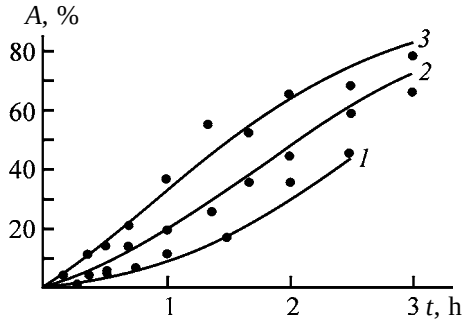

Fig. 2. Kinetic curves of DMEA formation at 30°C with addition of the target product to the starting mixture. $n^0_{OX} \times 10^4$, mol: (*1*) 203.4, (*2*) 420.1, and (*3*) 334.1. $n^0_{DMA} \times 10^4$, mol: (*1*) 613.4, (*2*) 1187.0, and (*3*) 965.8. $n^0_{DMEA} \times 10^4$, mol: (*1*) 0, (*2*) 30.1, and (*3*) 82.6.

Figure 2 shows that, as the concentration of DMEA in the starting mixture is increased, the curves lose their S-shape, and the reaction rate grows, confirming the occurrence of autocatalysis.

When developing a kinetic model, we assumed the reaction orders with respect to OX and DMA to be unity, in accordance with [2–5]. The reaction order with respect to DMEA was calculated from the experimental data. Thus, the rates of the noncatalytic (r_1) and catalytic (r_2) reactions were described by the equations

$$r_1 = k_1 c_1 c_2, \qquad r_2 = k_2 c_3^n c_1 c_2,$$

where k_1 is the rate constant of the noncatalytic reaction; k_2, that of the catalytic reaction; c_i, concentration (M) of component *i* (1, OX; 2, DMA; 3, DMEA); and *n*, reaction order with respect to DMEA.

The number of moles decreases in the course of the reaction; this decrease reaches 12% at complete conversion of OX. Therefore, the material balance equations for the components

$$dVc_i/dt = \nu_i V(r_1 + r_2),$$

were solved simultaneously with the equation for the volume change in the course of the reaction,

$$dVc_i/dt = \sum_{i=1}^{3} \nu_i V(r_1 + r_2)/\rho_i,$$

where *V* is the reaction mixture volume; *t*, time (min); ν_i, stoichiometric coefficient at component *i* ($\nu_1 = -1$, $\nu_2 = -1$, $\nu_3 = 1$); and ρ_i, molar density of component *i*.

The system of equations was integrated numerically by the fourth-order Runge–Kutta method. The order of the catalytic reaction with respect to DMEA was estimated from the kinetic curves (Fig. 2) obtained at different initial concentrations of DMEA in the reaction mixture. The reaction order with respect to DMEA *n* and the rate constants of the noncatalytic (k_1) and catalytic (k_2) reactions at $T = 30$°C were calculated so as to minimize the sum *F* of squared deviations between the calculated (b_i^c) and experimental (b_i^e) yields of DMEA in each point *i* for all the kinetic curves, taking into account the weight factors w_i ($T = 30$°C):

$$\min_{n,k_1,k_2} F = \sum_{i=1}^{N} w_i (b_i^c + b_i^e)^2,$$

where *N* is the number of experimental points.

To find the minimum of the function *F*, we used the modified gradient method.

We obtained the following values: $k_1 = 9.41 \times 10^{-5}$, $k_2 = 3.95 \times 10^{-4}$, and $n = 0.92$. As seen from Fig. 2, the calculated and experimental yields are well consistent. Since the reaction order with respect to DMEA is close to unity, in the subsequent calculationed we assumed $n = 1$.

The rate constants calculated similarly from the experimental data for various temperatures (Fig. 1) with $n = 1$ are listed in the table.

The parameters of the temperature dependence of the rate constants [$k = A\exp(-E/RT)$] of the noncatalytic (A_1, E_1) and catalytic (A_2, E_2) reactions were calculated so as to minimize the sum *F* of squared deviations between the experimental and calculated DMEA yields for all the experimental points shown

Rate constants k_i at various temperatures

T, °C	k_1, l mol^{-1} min^{-1}	k_2, l^2 mol^{-2} min^{-1}
20	2.85×10^{-5}	2.87×10^{-4}
30	9.41×10^{-5}	3.95×10^{-4}
40	6.13×10^{-5}	1.80×10^{-3}
50	2.96×10^{-4}	1.53×10^{-3}

in Figs. 1 and 2 and obtained at T = 20, 30, 40, and 50°C and different initial compositions of the reaction mixture:

$$\min_{A_1, E_1, A_2, E_2} F = \sum_{i=1}^{N} w_i (b_i^c + b_i^e)^2.$$

The calculated parameters of the Arrhenius equation are given below:

Rate constant	A	E, kJ mol^{-1}
k_1	9.25×10^5	58 800
k_2	1.75×10^5	49 800

The points in Fig. 1 show the experimental yields of DMEA, and lines correspond to the values calculated with these parameters.

Thus, our kinetic model adequately describes the experimental data and can be used to optimize the reaction unit for DMEA production.

EXPERIMENTAL

Oxirane [GOST (State Standard) 7568–88] and dimethylamine (GOST 9967–74) were used without additional purification. Dimethylethanolamine [TU (Technical Specifications) 6-02-1086–91] was purified by distillation on a 20 TP laboratory column. The moisture content in the purified product did not exceed 0.05%.

The starting mixture was prepared in a hermetically sealed glass ampule at –20°C. The mixture was charged into 0.5–0.7-ml ampules 5 mm in diameter, precooled to –20°C. The ampules were sealed and kept for a prescribed period in a water thermostat. Then the ampules were quickly cooled with water and then with an ice–salt mixture to –20°C. A 0.1–0.2-g sample was withdrawn from each ampule and transferred into a hermetically sealed vessel with a solvent (hexane, 10 ml). The solution was analyzed chromatographically (2000 × 3-mm column; stationary phase 3% OV-225 on Inerton; flame ionization detector; carrier gas N_2, flow rate 2 l h^{-1}; vaporizer and detector temperatures 170°C; programmed heating: 80°C, 3 min; heating to 140°C, 20 deg min^{-1}; and 140°C, 3 min).

CONCLUSIONS

(1) Hydroxyethylation of dimethylamine is an autocatalytic reaction. At the dimethylamine : oxirane molar ratio of 3 : 1, in the temperature interval 20–50°C, the reaction selectivity is close to 100%.

(2) A kinetic model of dimethylamine hydroxyethylation, adequately describing the experimental data, was suggested. The parameters of the temperature dependence of the rate constants of the catalytic and noncatalytic reactions were calculated.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

NMR Determination of the Total Composition of Commercial Absorbents Based on Monoethanolamine

V. P. Talzi

Omsk Branch, Boreskov Institute of Catalysis, Siberian Division, Russian Academy of Sciences, Omsk, Russia

Received October 10, 2003

Abstract—The composition of aqueous solution of monoethanolamine used in various units of gas treatment of the Omsk Oil-Refining Plant, Joint-Stock Company, was studied by the ^{13}C NMR spectroscopy. The components of the gases to be purified and the reactions producing the impurities were established.

Recently we studied by NMR the composition of absorbents used for treatment of processing gases to remove acidic impurities CO_2, H_2S, CS_2, and COS at the Omsk Oil-Refining Plant (ORP) [1]. This paper completes the development of a procedure for analysis of the total composition of absorbents produced on the basis of aqueous solutions of monoethanolamine (MEA), substantially refining the published data [1] on identification of components and schemes of side reactions.

As known, the absorption capacity and corrosive and surface activities of MEA solutions, which govern the efficiency of absorber operation, depend on the content of MEA decomposition products. Despite the lack of a procedure for direct analysis of the total composition of the absorbents in hand, decades of operation of amine gas treatment units resulted in correct identification of the absorbent components and development of a correct concept of their formation pathways. A practically complete review on the problem in hand was published 40 years ago in [2]. According to published data [1, 2], under the conditions of industrial gas treatment, carbamates and thiocarbamates **I**–**III**, respectively, are formed in the reaction of MEA with CO_2, COS, and CS_2:

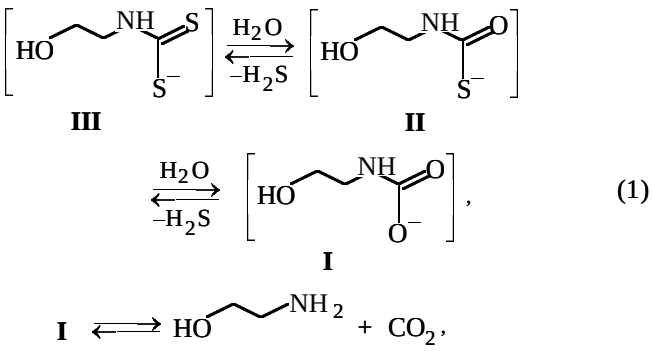
$[HOCH_2CH_2NHCO_2^-][H_3N^+CH_2CH_2OH]$ (**I**),

$[HOCH_2CH_2NHCOS^-][H_3N^+CH_2CH_2OH]$ (**II**),

$[HOCH_2CH_2NHCSS^-][H_3N^+CH_2CH_2OH]$ (**III**).

Sulfide, a product of the reaction of hydrogen sulfide with MEA, gives a total NMR signal averaged with the amine signal; therefore, its content in the solution cannot be determined from the NMR data. Among compounds **I**–**III**, only carbamate **I** is contained in industrial absorbents. As a rule, it is a main component of saturated and regenerated MEA solutions at various treatment units.

Thio analogs of carbamate **I** are much more stable with respect to decomposition under conditions of absorbent regeneration into COS or CS_2 and MEA; therefore, Kohl and Riesenfeld believe [2] that any reaction of MEA with carbonyl sulfide and carbon disulfide results in irreversible loss of the absorbent. However, as mentioned in [1], after absorption of COS and CS_2, MEA can be regenerated by hydrolysis of thiocarbamates **II** and **III** to form carbamate **I**. The latter decomposes in regeneration to form MEA and carbon dioxide practically without by-products:



(1)

In our earlier work [1] we have not clearly formulated the established fact that compounds **IV**–**VII** are formed by the reaction of MEA with COS or CS_2 and subsequent transformations of the resulting carbamate **II**. In particular, it was suggested that carbamate **I** can also give impurities not removed in regen-

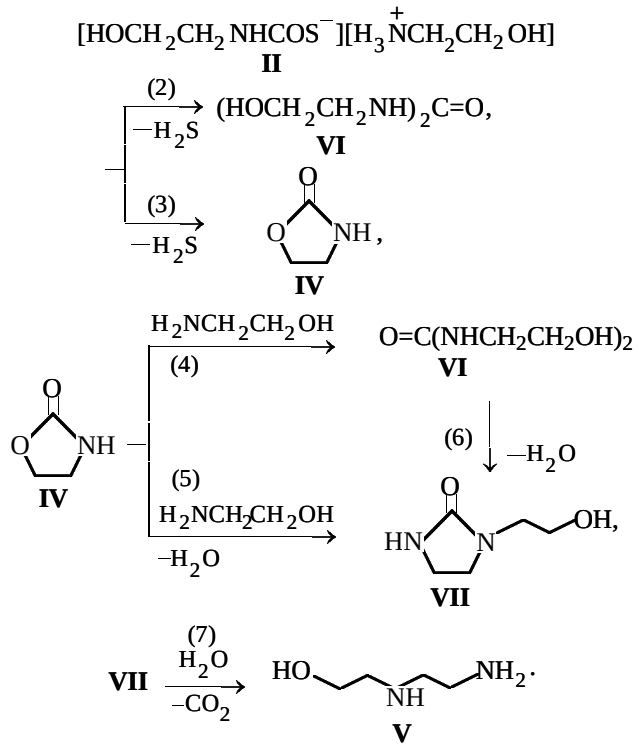
eration, e.g., **IV**, in a noticeable yield:



The above pathways of formation of impurities **IV**–**VII** [2, 3] were confirmed in [1] with significant refinement considering that, in the industrial saturated and regenerated absorbents, compound **IV** is absent completely and the main impurity originating from thiocarbamate **II** is urea analog **VI**. According to the NMR spectra, the concentrations of impurities **V**–**VII** are approximately 0.1–0.5%. Significant amounts of **V** and **VII** were detected only in a certain period of operation of absorption gas-fractionation unit (AGFU) at the Omsk ORP [1], and also small concentrations of **V** and **VII** were found in the similar absorbers used for gas treatment in catalytic cracking. We think that the most probable pathway of formation of **VII** is pathway (6), since at high intensities of the NMR signals of **V** and **VII** in the corresponding spectra the signals of **IV** are absent (Fig. 1a). Factors favoring conversion of **VI** to **VII** and then to diamine **V** are not exactly established. Under laboratory conditions, the attempts to attain reproducible formation of **V** and **VII** by heating of mixtures formed in saturation of MEA solutions with carbonyl sulfide failed [1]. It is likely that the catalyst of this reaction is iron chloride.

Thus, the content of **VI** or, more precisely, the total

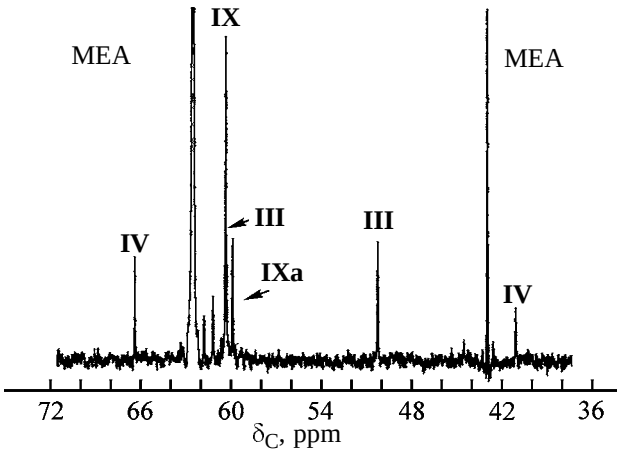


Fig. 2. Fragment of the ^{13}C NMR spectrum of carbon disulfide solution in aqueous MEA (15%) after keeping at 90°C for 0.5 h. Signals of **IV** appear as a result of hydrolysis of **III** with formation of **II**; ^{13}C signals of OCH_2 fragments of **III** and **IX** overlapp.

content of **V**–**VII** in MEA solutions varies in parallel with the concentration of carbonyl sulfide and carbon disulfide in the gases to be purified. In absorption of carbon disulfide, these compounds are formed by hydrolysis of dithiocarbamate **III** to thiocarbamate **II**.

The ^{13}C NMR spectra of two samples of the absorbent taken from the AGFU and the sulfur production unit (SPU) of the Omsk ORP are shown in Fig. 1. The concentrations of absorbent components can be estimated from the integral intensities of the corresponding signals by the standard procedure. In so doing, the contents of MEA and carbamate **I** can be determined fairly accurately from the ^{1}H NMR spectra discussed previously [1].

The series of compounds whose signals were correctly identified previously [1] in the spectra shown in Fig. 1 (see table) is restricted to **I**, **V**–**VII**, and diethanolamine (DEA). It turned out that one of the most typical groups of the signals at approximately 39, 49, 56, 58, and 59 ppm, observed in the spectra of the samples withdrawn from all the gas-treatment units at the Omsk ORP with exception of the hydrorefining unit, belongs to two compounds, as suggested previously [1]. The signals at 39, 49, 56, 58, and 172 ppm correspond to one compound, and the signal at 59 ppm, to another compound. This fact was established by analyzing the spectra of various absorbents and model solutions obtained by heating a mixture of aqueous MEA and carbon disulfide at 80–100°C.

According to reference data and reactions (2)–(6) [4], the signals at 39, 49, 56, 58, and 172 ppm belong to **VIII**, which is thio analog of **VII** and was identified in bottoms of a unit for amine treatment of coke-chemical gases [3]. The identification of the second compound formed owing to the presence of carbon disulfide in the gases to be purified is not so evident as in the case of **VIII**. The signal at 59 ppm was initially assigned to the CH_2OH group of a thiourea analog **IX**. We assumed that the signals of carbon atoms of the fragments C=S and NCH_2 structure (**IX**) are not observed because of broadening caused by hindered rotation around the thioamide bond N–CS. The similar phenomenon was observed in studying the ^{13}C NMR spectra of thiocarbamates derived from secondary amines [5]. Actually, in the spectrum of the model system formed by heating of a mixture of aqueous MEA and carbon disulfide to 100–120°C (Fig. 2), only the signal at 60 ppm corresponds to **IX**. At the same time, there is less strong signal at 59 ppm, which apparently belongs to analog **IXa** formed from **IX** by elimination of ethylene oxide molecule [reaction (9)]. Thus, the signal at 59 ppm observed in the spectra of absorbents presented in Figs. 1a and 1b can be assigned to **IXa**. This assumption is indirectly confirmed by signals at 162.2, 61.75, and 42.51 ppm, constantly appearing in the ^{13}C NMR spectra of MEA solutions saturated with carbonyl sulfide under laboratory conditions upon their heating at 120°C for approximately 0.5 h. These signals are observed along with much stronger signals of **VI** (see table) and apparently belong to an urea analog $NH_2(C{=}O)NHCH_2CH_2OH$ (**IVa**) formed from **VI** by elimination of ethylene oxide molecule.

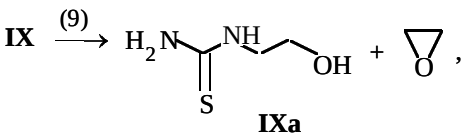
Only some spectra of similar laboratory samples obtained by heating of a mixture of carbon disulfide and MEA contain the above signals at 39, 49, 56, and 58 ppm of **VIII**, and these signals are very weak:

$$[HOCH_2CH_2NHCSS^-][H_3\overset{+}{N}CH_2CH_2OH]$$

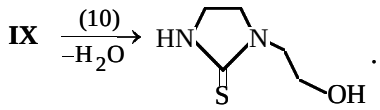
III

$$\xrightarrow[-H_2S]{(8)} (HOCH_2CH_2NH)_2C{=}S,$$

IX



IXa



VIII

Thus, the content of **VIII** and **IXa** in the ab-

sorbents varies in parallel with the concentration of carbon disulfide in the gases to be treated.

Diethanolamine was correctly identified in the composition of the commercial absorbents previously [1], but a too complicated pathway of its formation was suggested. Actually, under conditions of gas treatment, MEA apparently decomposes to form ammonia and ethylene oxide. The latter gives DEA and also ethylene glycol [reactions (11)–(13)]. A weak signal at 64 ppm observed in the spectra of some samples corresponds to ethylene glycol but not to dioxolane considered in [1], which was proved by addition of the corresponding reagent to the absorbent:

$$HOCH_2CH_2NH_2 \xrightarrow{(11)} NH_3 + \text{ethylene oxide},$$

$$HOCH_2CH_2NH_2 + \text{ethylene oxide} \xrightarrow{(12)} \underset{\text{DEA}}{HN(CH_2CH_2OH)_2},$$

$$\text{ethylene oxide} + H_2O \xrightarrow{(13)} HOCH_2CH_2OH.$$

Under the conditions of gas treatment, decomposition of MEA to ammonia and ethylene oxide is catalyzed by acidic impurities to be absorbed. This conclusion was made based on the spectra of MEA solutions saturated with hydrogen sulfide and then regenerated under laboratory conditions. In some absorbers of the hydrofining unit, which purify hydrogen sulfide gases containing no carbonyl sulfide and carbon disulfide, the impurities in MEA solutions include only DEA and carbamate **I** (less than 0.1%). On other columns of this unit, an oxidation product of MEA, substituted oxamide **X**, is also detected.

Oxidation of MEA is one of the main causes of absorbent loss and deterioration of its performance. Oxidation of MEA yields oxalic acid and its amides [2]. The signal of oxalic acid at 174 ppm in the spectra of absorbent samples was correctly assigned previously, while the signals of **X** (see table, Fig. 1) were incorrectly assigned to another compound [1]. Under laboratory conditions the signals of **X** at 42.5 and 60.4 ppm and also signals with chemical shifts close to that of the corresponding monooxamide were observed in heating of a mixture of MEA and oxalic acid to approximately 150°C. With increasing excess of MEA with respect to oxalic acid, the intensity of signals of diamide increases relative to the monoamide and the intensity of carbonyl signals of amides at approximately 166–167 ppm decreases, so that at the concentration of **X** in the commercial absorbents of approximately 0.1% this signal of carbonyl, as a rule, is not observed:

Assignment of signals in the ^{13}C NMR spectra of model compounds and samples of industrial absorbents, aqueous solutions of monoethanolamine

Compound	Assignment of ^{13}C NMR signals, δ_C, ppm		
	NCH_2	CH_2OH	COX, X = O, S
MEA	43.89	63.57	
I	44.93	63.00	166.1

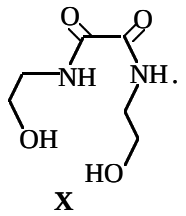
IX	None*	60.24	None
IXa	″	59.13	″
DEA	51.24	60.32	
X	42.5	60.37	None

* Signals not detected for various reasons considered in the text.

$$H_2NCH_2CH_2OH \xrightarrow[\text{Oxidation, } +O_2]{(14)} HOOCCOOH$$

$$2H_2NCH_2CH_2OH \xrightarrow[-2H_2O]{(15)}$$



X

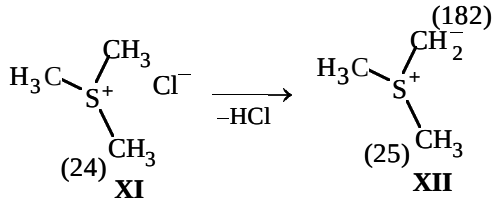
The content of amide **X** in the absorbent varies in parallel with the degree of its oxidative decomposition under the conditions of gas treatment.

The strongest signals in the ^{13}C NMR spectrum of the absorbent withdrawn from AGFU after regeneration (excluding MEA) (Fig. 1a) are the signals assigned to amide **X**; in this case, the signal of carbamate **I** is weak. According to process information for the absorbent in hand, the absorption of carbon dioxide was low. It is reasonable to explain this fact by the general acid catalyst of carbamate **I** decomposition to form MEA and CO_2 under the action of acids present in the absorbent. These acids can be oxalic

acid, since the content of oxamide **X** in these samples is noticeably higher than that in the samples withdrawn from the SPU (compare Figs. 1a and 1b), or hydrogen chloride present in these samples.

Actually, the spectrum of absorbents withdrawn from AGFU contains the signals of two carbon atoms of methyl groups (24 and 25 ppm) and associated signal of a quaternary carbon atom at approximately 182 ppm. The signals of methyl groups belong to different compounds, according to their relative intensities in the spectra. The intensity of these signals is comparable with the intensity of other signals in Fig. 1a. In the ^{1}H NMR spectra, the corresponding methyl protons give two singlets in the region of 1.8 ppm.

It is likely that the signals in hand belong to trimethylsulfonium chloride **XI** and the corresponding ylide **XII** formed in alkaline medium of the absorbent, which arise from chloromethane and dimethyl sulfide present in gases to be purified:



EXPERIMENTAL

The ^{13}C NMR spectra of absorbents and model mixtures were recorded by the standard procedures on a Bruker ACP 200-P spectrometer.

Under laboratory conditions, the gas treatment process was simulated on a setup consisting of a flask for generation of gases and absorption bottles. CO_2 and COS were generated by the action of sulfuric acid on sodium hydrocarbonate and potassium (or ammonium) thiocyanate, respectively. H_2S, CS_2, and ethylene glycol, used for synthesis and identification, were commercial chemicals of chemically pure grade.

Regeneration of absorbents was simulated ether by heating on a water bath or by boiling.

CONCLUSION

An NMR-based procedure was developed for determination of the total composition of industrial absorbents based on aqueous solutions of monoethanolamine. The impurities formed from carbonyl sulfide, carbon disulfide, oxygen, dimethyl sulfide, and chloromethane present in the gases to be purified, not removed in regeneration, were identified. These results allow better understanding of the dependence of the operation characteristics of the absorbent on its composition.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Process Parameters of Oxidative Chlorination of Benzene with the Participation of Nitrogen(IV) Oxide

A. I. Morozovskii, A. B. Solomonov, and V. I. Skudaev

Perm State Technical University, Perm, Russia

Received May 16, 2003

Abstract—The efficiency of replacing oxygen with nitrogen(IV) oxide in oxidative chlorination of benzene was studied. The optimal process parameters: temperature, time of contact, and relative content of reagent, were determined.

Synthesis of organochlorine compounds involves heavy loss of hydrogen chloride. Utilization of hydrogen chloride is possible in some cases, e.g., in synthesis of trichloroethylene and tetrachloroethylene by oxidative chlorination of hydrocarbons [1]. In these processes, a hydrocarbon is chlorinated with a mixture of hydrogen chloride with oxygen on a catalyst. Wide introduction of these processes is hindered by their low output capacity. Oxidative chlorination can be intensified by using oxidizing agents with activity exceeding that of oxygen. In this work we studied oxidative chlorination of benzene with a mixture of hydrogen chloride and nitrogen(IV) oxide on a solid catalyst based on copper(II) chloride.

EXPERIMENTAL

Nitrogen(IV) oxide obtained in the first oxidation reactor by mixing nitrogen(II) oxide with oxygen at room temperature was fed into the second oxidation reactor together with hydrogen chloride. The gaseous products (nitrosyl chloride, chlorine, and excess oxygen) and also benzene were delivered to a heated quartz reactor 1.4 cm in diameter and 50 cm high, packed with a fixed bed of a catalyst. The products obtained were analyzed chromatographically for the content of chlorobenzene. The efficiency of an oxidizing agent and a catalyst was evaluated by the conversion *A* of hydrogen chloride and specific yield *B* of chlorobenzene per 1 kg of the supported catalyst in 1 s.

Table 1 shows how the catalyst composition affects the specific yield of chlorobenzene at 250°C and benzene : hydrogen chloride : nitrogen(II) oxide : oxygen molar ratio of 5 : 2 : 1 : 1. The content of a supported catalyst is given in weight percents. The time of contact was 3 s at 250°C and reagent feeding rate of 390 μmol s^{-1}. It was found that the optimal catalyst is that containing copper(II) chloride (10%) and potassium chloride with $Cu^{2+} : K^+$ molar ratio of 1 : 1 on a KSS-3 support with the specific surface area of about 500 $m^2 g^{-1}$. Potassium chloride does not enhance the activity of the catalyst, but markedly prolongs its service life. It was established experimentally that the activity of the catalyst does not decrease during 42 h.

Data on the efficiency of replacing oxygen with nitrogen(IV) oxide at a time of contact of 1.6 s are listed in Table 2. The use of nitrogen(IV) oxide leads to a 17-fold increase in the conversion of hydrogen chloride at 250°C and to the corresponding rise in the yield of chlorobenzene. If account is taken of the fact that, in contrast to nitrogen(IV) oxide, oxygen can be used at higher temperatures without being decomposed, the intensification of oxidative chlorination can be estimated as tenfold.

Table 1. Influence exerted by the $CuCl_2$ content in supported catalyst on the specific yield of chlorobenzene *B*

Table 2. Influence exerted by the temperature and the type of an oxidizing agent on the conversion of hydrogen chloride *A*

T, °C	Oxidizing gent	*A*, %
200	Oxygen	1.8
250	"	2.5
300	"	3.9
250	Nitrogen(IV) oxide	42.9

Oxidative chlorination of benzene can be described by the following basic set of reactions:

$$C_6H_6 + 2CuCl_2 = C_6H_5Cl + 2CuCl + HCl, \quad (1)$$

$$2NO_2 + 4HCl = 2NOCl + Cl_2 + 2H_2O, \quad (2)$$

$$NOCl + CuCl = CuCl_2 + NO, \quad (3)$$

$$2CuCl + Cl_2 = 2CuCl_2, \quad (4)$$

$$C_6H_6 + 2NOCl = C_6H_5Cl + 2NO + HCl, \quad (5)$$

$$C_6H_6 + Cl_2 = C_6H_5Cl + HCl, \quad (6)$$

$$2CuCl + NO_2 = CuOCuCl_2 + NO, \quad (7)$$

$$CuOCuCl_2 + 2HCl = 2CuCl_2 + H_2O, \quad (8)$$

$$2NO + O_2 = 2NO_2. \quad (9)$$

Chlorobenzene can be formed both at the catalyst surface, by reaction (1), and in the gas phase, by reactions (5) and (6). Regeneration of copper(II) chloride may occur in a reaction of copper(I) chloride with nitrosyl chloride (3) and chlorine (4) or with nitrogen(IV) oxide (7) and then with hydrogen chloride (8). Reactions (2) and (9) may proceed not only in the oxidation reactors, but also in chlorination reactors.

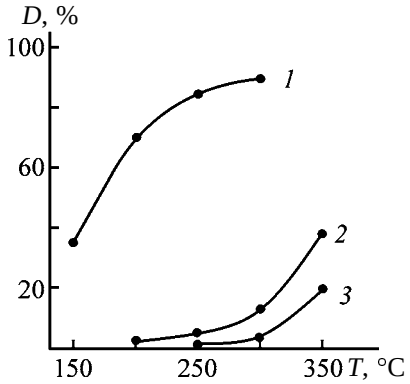

Fig. 1. Conversion *D* of chlorine and nitrosyl chloride vs. temperature *T*. Chlorination: (*1*) catalytic with nitrosyl chloride, (*2*) gas-phase with chlorine, and (*3*) gas-phase with nitrosyl chloride.

To evaluate the contribution of the gas-phase reactions, processes of separate chlorination of benzene with chlorine and nitrosyl chloride were studied in a reactor without catalyst at flow rates of benzene, chlorine, and nitrosyl chloride of 207, 21, and 42 μmol s^{-1}, respectively. Nitrosyl chloride was obtained using the known method [2] by the reaction of chlorine and nitrogen(II) oxide at 60°C, followed by condensation of the product at –20°C. The conversion *D* of the reactants at different temperatures, calculated from the amount of the chlorobenzene formed, is plotted in Fig. 1. The contribution of the gas-phase chlorination becomes noticeable only at temperatures higher than 250°C, whereas in catalytic chlorination the conversion at this temperature exceeds 80%. Consequently, chlorobenzene is mainly formed by reaction (1). It is more probable that the catalyst regeneration occurs by reactions (3) and (4), rather than by reactions (7) and (8), since the rate of oxidation of copper(I) chloride with nitrogen(IV) oxide exceeds that with oxygen by a factor of only 2 [3].

A number of process parameters were studied. It was found that, in catalytic oxidative chlorination, raising the linear flow velocity of gases from 0.1 to 0.4 m s^{-1} and the grain size of the support from 0.3 to 5 mm did not lead to any change in the yield of chlorobenzene and, consequently, outer or inner diffusion is not the rate-determining stage of the process.

The influence exerted by the time of contact between the gases and the catalyst on the conversion of hydrogen chloride was studied at varied height of the catalyst bed and flow rate of reactants. The results obtained are shown in Fig. 2a. It can be considered that 2.5–3 s is a sufficient time of contact at 250°C.

An excess of nitrogen(II) oxide or oxygen over the stoichiometric amount in reaction (9) strongly affects the process. To study this influence, nitrogen(II) oxide and oxygen, taken in the stoichiometric ratio of 2 : 1, were fed into the oxidation reactor, and additional amounts of these reagents were delivered directly to the chlorination reactor, bypassing the oxidation reactor. The reagent excess factor *q*, equal to the ratio of the total volume of a reagent to the volume of this reagent fed into the oxidation reactor, was varied from 1 to 2.5. In this case, the other conditions were as follows: flow rate of reactants 330 μmol s^{-1}, benzene : hydrogen chloride : nitrogen(IV) oxide molar ratio 5 : 2 : 1, temperature 250°C, time of contact 1.6 s; the results obtained are shown in Fig. 2b.

With an excess amount of nitrogen(II) oxide, the conversion of hydrogen chloride decreases, which is accounted for by partial binding of chlorine into nitro-

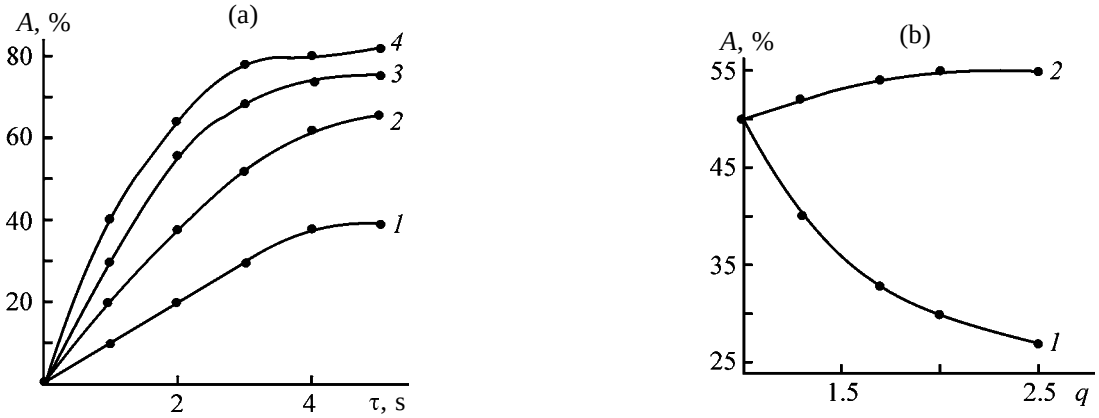

Fig. 2. Conversion *A* of hydrogen chloride vs. (a) the time τ of contact between the reactants and the catalyst and (b) reagent excess factor *q*. (a) *T* (°C): (*1*) 150, (*2*) 180, (*3*) 210, and (*4*) 250. (b) (*1*) Nitrogen(II) oxide and (*2*) oxygen.

syl chloride, which is a less active chlorinating agent. An increase in the content of nitrosyl chloride at the reactor outlet was revealed by IR spectroscopy. By contrast, an excess amount of oxygen leads to an increase in the conversion of hydrogen chloride because of the oxidation of nitrogen(II) oxide and secondary hydrogen chloride formed by reaction (1) directly in the chlorination reactor. It is advisable to use a twofold excess of oxygen over its stoichiometric amount.

The selectivity *S* of the process with respect to monochlorobenzene as a function of the conversion *R* of benzene is plotted in Fig. 3. The main product formed in oxidative chlorination, even at high conversion of benzene, is chlorobenzene.

Nitrogen(II) and nitrogen(IV) oxides are not among the products formed. The absence of nitrobenzene in the products was established by gas chromatography. In the process flowsheet, nitrogen(II) oxide, secondary hydrogen chloride, and unchanged benzene should be recycled after separation of the target products.

The output capacity of the reactor for oxidative chlorination of benzene with the use of nitrogen(IV) oxide is about 350 kg h^{-1} per 1 m^3 of the reactor volume. This value is no less than the output capacity of the reactor for direct chlorination of benzene [4]. At the same time, use of waste hydrogen chloride, instead of the more expensive chlorine, makes lower the manufacture cost of the product.

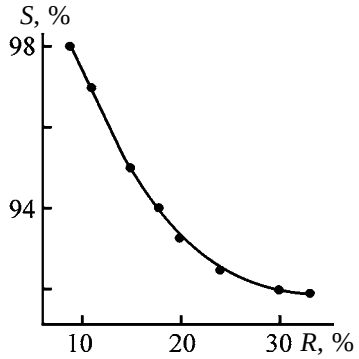

Fig. 3. Selectivity *S* with respect to monochlorobenzene vs. the conversion *R* of benzene.

CONCLUSIONS

(1) Use of nitrogen(IV) oxide, an active oxidizing agent, instead of oxygen makes it possible to intensify the oxidative chlorination of benzene by a factor of more than 10.

(2) The optimal catalyst for intensive oxidative chlorination of benzene is copper(II) chloride supported by KSS-3 silica gel and stabilized with potassium chloride at $Cu^{2+} : K^{+}$ molar ratio of 1 : 1.

(3) The optimal conditions for the synthesis of monochlorobenzene are as follows: temperature 250°C, time of contact 2.5–3 s, nitrogen(II) oxide : oxygen molar ratio 1 : 1, and conversion of benzene <30%.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Physicochemical properties of Water-Soluble Fullerene C_{60}–Carbohydrate Composites

L. S. Litvinova, A. V. Gribanov, M. V. Mokeev, and V. N. Zgonnik

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg

Received October 22, 2003

Abstract—Water-soluble composites of fullerene C_{60} with carbohydrates (saccharose, fructose, and dextrans) prepared by the mechanochemical procedure were analyzed by electronic absorption and ^{13}C NMR spectroscopy, thin-layer chromatography, and differential scanning calorimetry.

Fullerenes and their derivatives readily form complexes with electron donors [1–7]. In particular, some complexes of fullerene C_{60} are water-soluble and can be used in medicine and biochemistry. A series of water-soluble fullerene-containing compounds has been prepared. In this work we studied water-soluble composites prepared by solid-phase reaction of C_{60} with low and high-molecular-weight carbohydrates. The fullerene concentration in the samples ranged from 0.1 to 30 wt %. Prominence was given to the mechanism of C_{60}–carbohydrate interactions and its strength as influenced by the molecular weight of the carbohydrate.

The C_{60}–carbohydrate composites were prepared by a mechanochemical procedure [6]. Appropriate carbohydrate was suspended in a definite volume of 0.1 mg ml^{-1} C_{60} solution in CCl_4. The solvent was evaporated in air, and the residue was ground in an agate mortar and dried in a vacuum oven at 40°C for 48 h. A water aliquot (3–5 ml) was added to the resulting fine powder. The mixture was stirred for 1 min and centrifuged. The solution was decanted from the precipitate.

To determine the concentration and extinction coefficients of the water-soluble fullerene by spectrophotometry, the fullerene was isolated from an aqueous solution of the composite by semipreparative thin-layer chromatography (TLC). For this purpose, an aliquot of the aqueous solution was applied in the form of a band on a chromatographic paper (6 × 10 cm). The sample was dried and eluted with toluene to the height of 6 cm. The fullerene was eluted with the solvent front. The fullerene-containing section of the paper was cut out, and the fullerene was extracted with carbon tetrachloride. The solution was weighed and its volume was calculated. Then the spectrum of the solution was recorded. Given the extinction coefficient of C_{60} solution in CCl_4 at 330 nm, the concentration and the extinction coefficient of the aqueous solution of the fullerene–carbohydrate composite were determined. The relative standard deviation s_r of the calculated concentration was no more than 15% at $n = 3$. The extinction coefficients of the water-soluble fullerene complexes depends on its concentration in water (see table). Hence, the composition of the water-soluble forms depend on the fullerene content in the composite.

The water-soluble fraction of the composite was studied by electronic absorption spectroscopy on a Specord M40 spectrophotometer (Carl Zeiss, Jena, Germany). As compared to the UV spectrum of the initial C_{60}, the following transformations were observed: broadening of the bands, bathochromic shift of their maximum, change in the intensity ratio, and change in the absorption in the long-wave region (λ 440 and 470 nm). These transformations suggest aggregation of the fullerene in the aqueous phase [8, 9], i.e., occurrence of the fullerene–fullerene interaction. The optical density of the solution depends on the fullerene content in the initial composite (see table). When the content of saccharose and monosaccharides in the composite increases to more that 90% (molar ratio 1 : 20) and that of dextran increases to more than 98% (molar ratio 1 : 1) at a constant C_{60} content, the optical density increases: first sharply and then smoothly. The optical densities and the concentration of the water-soluble fractions for the dextran composites are lower than those for the saccharose composite.

It should be noted that aqueous solutions of the

* *n* is the carbohydrate/C_{60} molar ratio in the initial solid composite; *D* is the optical density.

fullerene–carbohydrate composites are stable to toluene and chloroform used as solvents for C_{60}. This can be due to shielding or protection of fullerene in the composite by the carbohydrate.

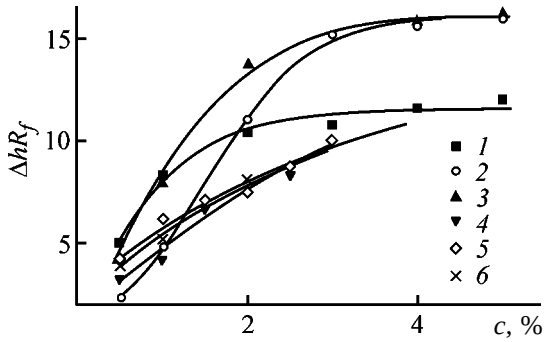
The fullerene–carbohydrate interaction in the solid state was studied by ^{13}C NMR spectroscopy. High-resolution ^{13}C NMR spectra of solid samples were recorded at room temperature on a Bruker CXP-100 spectrometer using the magic angle spinning (MAS) and cross polarization (CP MAS) techniques. The MAS spectrum of the 20% C_{60}-dextran composite contains the signal typical for C_{60} (δ = 143.6 ppm). The half-width of this signal is larger (1.2 ppm) compared to pure fullerene (0.16 ppm). The CP MAS spectra also contain the C_{60} signal, suggesting the presence of proton-containing groups near the fullerene surface. The C_{60} signal in the MAS NMR spectrum of 20% C_{60}–saccharose composite is also broadened (half-width 1.2 ppm) and is shifted upfield in the spectra recorded by both procedures (δ_{MAS} = 141.3 ppm).

The upfield region of the CP MAS spectrum contain a new signal with a lower intensity ($\delta_{CP\ MAS}$ = 139.2 ppm). The splitting of the C_{60} signal and its upfield shift can be due to interaction of the fullerene with hydroxy groups of the carbohydrate. This assumption agrees with results of [2, 10, 11]. Thus, the fullerene–carbohydrate interaction occurs in the examined composites. Probably the hydroxy groups of the carbohydrate form donor–acceptor bonds with the fullerene.

The comparative study of the fullerene–carbohydrate interaction was performed by TLC. Since there are no solvents in which both C_{60} and the carbohydrates are soluble, we failed to determine the stability constants of the complexes by the conventional methods [12, 13]. The complexation was examined by TLC [14]. TLC plates (Sorbfil, Sorbpolimer JSC, Krasnodar) were impregnated with 0.5–5% solutions of the carbohydrates in hand and dried. The fullerene was chromatographed on the resulting plates using hexane as eluent. The change in the retention factor of C_{60} on the initial and impregnated plates was calculated by the equation

$$\Delta hR_f = hR_{f(SiO_2)} - hR_{f(carbohydrate)}.$$

As seen from the figure, ΔhR_f increases with increasing concentration of the impregnating solution. At the concentration at which the curves flatten out



Change in the retention factors of C_{60} ΔhR_f in elution with hexane of TLC plates impregnated with 0.5–10% solutions of (*1*) glucose, (*2*) fructose, (*3*) saccharose, and (*4*–*6*) dextrans with molecular weight $M \times 10^{-3}$: (*4*) 20, (*5*) 40, and (*6*) 110, as a function of the solution concentration *c*.

(~3%), the interaction strength decreases in the following order: saccharose > fructose > glucose > dextrans. The higher the molecular weights of dextrans, the weaker complexes with C_{60} are formed.

The 20% C_{60}–saccharose composite was studied by DSC (Mettler–Toledo DSC 20, heating rate 10 deg min^{-1}). It was found that the transition temperature of the A form increases, and that of the B form decreases in the presence of C_{60}.

Based on the features of preparation of water-soluble fullerene, the dependence of the extinction coefficients of the aqueous solutions on the fullerene concentration, and the features of electronic absorption spectra of aqueous solutions of the composites, we suggest that the water-soluble form consists of fullerene aggregates surrounded by carbohydrate molecules. The fullerene–carbohydrate interaction in the solid phase was detected by DSC and ^{13}C NMR spectroscopy. Thus, two main interaction types in the solid composites and in the water-soluble fractions were revealed: formation of donor–acceptor bonds between the fullerene and carbohydrate and fullerene–fullerene interaction in C_{60} aggregates. As determined by TLC, the fullerene–carbohydrate interaction with monosaccharides and saccharose are stronger than that with dextrans. The procedure developed in this work for determining the fullerene content in the aqueous phase shows that monosaccharides and saccharose are more efficient than dextrans for preparing water-soluble fullerene forms.

CONCLUSIONS

(1) Water-soluble fullerene C_{60}–carbohydrate composites were prepared by the mechanochemical procedure and were studied by electronic absorption spectroscopy, NMR, TLC, and DSC.

(2) The water-soluble fraction consists of C_{60} aggregates coated by carbohydrate molecules, which are bound to the fullerene core by van der Waals bonds.

(3) A procedure for determining the fullerene content in water was developed. The concentration of C_{60}–saccharose composite in the aqueous phase is higher than that of C_{60}–dextran composite.

(4) The energy of fullerene–carbohydrate interaction decreases in the following order: saccharose > fructose > glucose > dextrans.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Quantitative Aspects of the Competition of Substitution and Addition Pathways in Polyisobutylene Chlorination

A. A. Goryacheva, V. A. Alferov, and V. A. Aver'yanov

Tula State University, Tula, Russia

Received February 19, 2003

Abstract—The competition of the substitution and addition chlorination pathways was studied. A quantitative model was developed to describe the rate ratio of the substitution and addition pathways in chlorination of polyisobutylene.

In the world polymer industry, the modern trends in development of new valuable polymeric materials are toward chemical modification of known polymeric products, rather than toward construction of facilities for large-scale production of new synthetic polymers by polymerization and polycondensation [1]. Modification of known polymers allows substantial saving of material and power resources and does not require large capital investments, as it is based on successfully mastered, economically efficient, and environmentally sound processes. One of the main routes of chemical modification of polymers, which is being actively developed today, is chlorination. Production of new materials by this method offers an opportunity to replace expensive materials by more durable and cheaper formulations showing higher performance. In this context, it becomes urgent to study quantitative characteristics of polymer chlorination. In this work we studied quantitatively the competition of substitution and addition pathways in chlorination of P-1 polyisobutylene.

The properties of the chlorination products can be optimized by properly choosing the balance between the contents of chlorine and residual double bonds in the polymer. The presence of chlorine enhances the fire resistance, chemical stability, and elasticity of materials, but, as the extent of chlorination grows, the content of residual double bonds responsible for the strength of the finished items decreases. At deficiency of residual double bonds, a chlorinated polymer becomes less capable of covulcanization with nonchlorinated analogs. In this connection, it seems necessary to study the competition of substitution and addition chlorination pathways as a factor controlling the ratio of the amounts of incorporated chlorine and residual double bonds.

EXPERIMENTAL

Chlorination of polyisobutylene was performed in chloroform without initiation. The polyisobutylene concentration in chloroform was 5 wt % in all cases. The reaction was performed in a glass vessel equipped with a temperature-control jacket, a bubbler for feeding chlorine, a reflux condenser, and a thermometer. Gaseous chlorine from a cylinder was passed through a Tishchenko bottle with concentrated H_2SO_4 and mixed in an equimolar ratio with argon; the resulting gas mixture was fed to the reactor. The constant flow rate of chlorine was maintained with a manostat and monitored with a rheometer. The required temperature was provided by circulation of water from a thermostat through the reactor jacket. Hydrogen chloride and unchanged chlorine present in off-gases were absorbed in a bottle filled with aqueous KI and arranged at the reactor outlet. After chlorination completion, the setup was purged with argon for 40 min to quantitatively remove Cl_2 and HCl from the reactor. The solvent was removed from the reaction mixture on a rotary evaporator, and the bottoms were kept in a vacuum to constant weight and then weighed. The iodine released from the KI solution under the action of Cl_2 was titrated with a 0.1 N $Na_2S_2O_3$ solution, after which the absorbed HCl was titrated with a 0.2 N NaOH solution in the presence of phenolphthalein. From this value, we estimated the content of C–Cl bonds formed in the polymer by the substitution pathway. The contents of total chlorine and chlorinated double bonds in the samples were determined by the difference between the actual sample weight and the value calculated from the content of C–Cl bonds formed by substitution.

Preliminary experiments showed that, in the initial

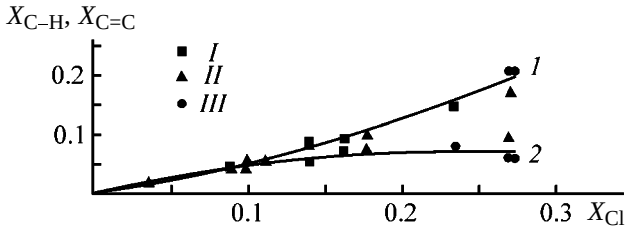

Fig. 1. Influence of the rate of feeding chlorine on the yields of polyisobutylene chlorination by (*1*) substitution and (*2*) addition pathways. ($X_{C=C}$, X_{C-H}) Amounts of chlorinated C=C and C–H bonds (mole per mole of monomeric units), respectively; (X_{Cl_2}) amount of chlorine taken up (mole per mole of monomeric units); the same for Fig. 2. Rate of feeding Cl_2, mol min^{-1}: (*I*) 0.9×10^{-3}, (*II*) 1.26×10^{-3}, and (*III*) 9.3×10^{-3}.

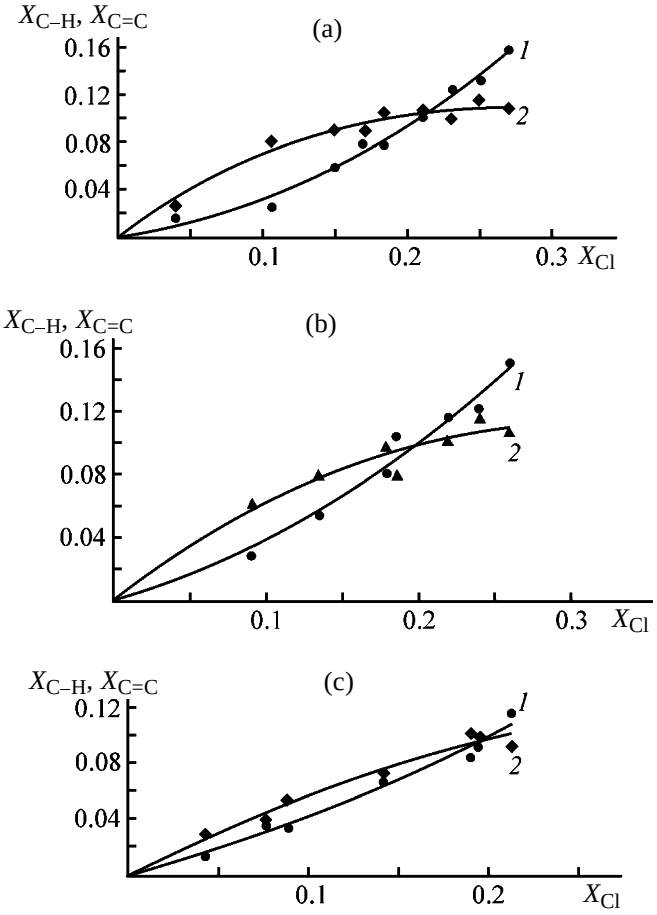

Fig. 2. Degrees of chlorination of (*1*) C–H (substitution pathway) and (*2*) C=C bonds (addition pathway) as functions of the degree of chlorination at (a) 10, (b) 35, and (c) 58°C.

chlorination period, the concentration of molecular chlorine in the reaction mixture is appreciably lower than the solubility of chlorine in chloroform. This fact suggests that the reaction is diffusion-controlled. Under these conditions, the chlorine concentration should depend on the intensity of its bubbling through the reaction mixture. In this connection, we first studied how the rate of feeding chlorine affects the ratio of substitution and addition products. Typical results are shown in Fig. 1 as the amounts (mole) of the C=C and C–H bonds per mole of monomeric units of polyisobutylene ($X_{C=C}$, X_{C-H}) vs. amount (mole) of chlorine taken up per mole of monomeric units (X_{Cl_2}).

It is seen that the data corresponding to different rates of feeding molecular chlorine fall on common curves, i.e., the ratio of the products formed by the competing chlorination pathways is insensitive to the rate of feeding chlorine. This fact indicates that the orders of both reactions with respect to chlorine are equal. Correspondingly, the ratio of the contributions of the substitution and addition pathways does not depend on whether the process is performed under conditions of diffusion or kinetic control; therefore, our results are valid for any mode of liquid-phase chlorination.

Then we studied how the contributions of the substitution (X_{C-H}) and addition ($X_{C=C}$) pathways of polyisobutylene chlorination depend on temperature and degree of chlorination (X_{Cl_2}). Typical results are shown in Figs. 2a–2c as plots of X_{C-H} and $X_{C=C}$ vs. X_{Cl_2} at various temperatures.

These data show that, with increasing conversion, the content of chlorinated double bonds monotonically grows, flattening out at certain X_{Cl_2}. At the same time, the content of chlorinated C–H bonds grows with autoacceleration, suggesting the free-radical mechanism of the process: For the reaction to develop, a certain autocatalytic period is required for accumulation of active radical centers. At the same time, this result is consistent with the growth of the inducing power of double bonds with accumulation of chlorine atoms in their surrounding; this trend is typical of free-radical chlorination of organic compounds [2].

The plots of X_{C-H} and $X_{C=C}$ vs. X_{Cl_2} were approximated by polynomials of the second degree,

$$X_{C-H} = a + bX_{Cl_2} + c(X_{Cl_2})^2, \quad (1)$$

$$X_{C-C} = m + nX_{Cl_2} + p(X_{Cl_2})^2, \quad (2)$$

using the least-squares method. The results are listed in the table.

Differentiation of Eqs. (1) and (2) leads to the

expressions

$$\frac{d[X_{C-H}]}{d[X_{Cl_2}]} = b + 2cX_{Cl_2}, \quad (3)$$

$$\frac{d[X_{C=C}]}{d[X_{Cl_2}]} = n + 2pX_{Cl_2}. \quad (4)$$

By dividing Eq. (3) by Eq. (4), we obtain

$$\frac{d[X_{C-H}]}{d[X_{C=C}]} = \frac{b + 2cX_{Cl_2}}{n + 2pX_{Cl_2}}. \quad (5)$$

Apparently, the left side of Eq. (5) corresponds to the rate ratio of the substitution and addition chlorination pathways. Then Eq. (5) takes the form

$$\frac{r_s}{r_{ad}} = \frac{b + 2cX_{Cl_2}}{n + 2pX_{Cl_2}}. \quad (6)$$

Expression (6) allows calculation of the rate ratio of the substitution and addition chlorination pathways in the examined range of X_{Cl_2} using data from the table. The calculated ratios r_s/r_{ad} are plotted in Fig. 3 vs. the content of residual double bonds $Y_{C=C}$ (mole per mole of monomeric units of polyisobutylene).

It is seen that the relative contribution of the substitution pathway monotonically grows as the content of double bonds in the polymer increases. This means that the substitution pathway has a higher order with respect to the double bond concentration than the addition pathway, which indirectly confirms the free-radical mechanism of induced substitution chlorination. The plots in Fig. 3 can be approximated by

$$r_s/r_{ad} = \alpha + \beta Y^n_{C=C}. \quad (7)$$

The values of α determined by extrapolation of the r_s/r_{ad} vs. $Y_{C=C}$ plots to zero concentration of the double bonds are given below:

T, °C	α	β	*n*
10	0.168	11.74	1.20
35	0.379	11.74	1.20
58	0.512	11.74	1.20

To determine the parameters β and *n*, Eq. (7) was transformed to

$$\log(r_s/r_{ad} - \alpha) = \log\beta + n\log Y_{C=C}. \quad (8)$$

The plots of $\log(r_s/r_{ad} - \alpha)$ vs. $\log Y_{C=C}$ are shown in Fig. 4.

Parameters of Eqs. (1) and (2)

T, °C	Eq. (1)			Eq. (2)		
	a	*b*	*c*	*m*	*n*	*p*
10	–	0.141	1.660	–	0.859	–1.660
35	–	0.274	1.145	–	0.726	–1.145
58	–	0.338	0.844	–	0.662	–0.844

It is seen that the results obtained for polyisobutylene at different temperatures fall on a common straight line characterized by the same values of β and *n*. These values, determined from the slope and the portion intercepted on the ordinate, are given above. The Arrhenius treatment of the α values gives the expression

$$\alpha = 10^{2.63}\exp(-18.25 \text{ kJ mol}^{-1}/RT).$$

This difference between the activation energies of the competing substitution and addition chlorination pathways is consistent with the difference between the activation energies of these pathways under conditions of molecular reaction mechanism [3]. This fact is natural, as the parameter α reflects the competition of the substitution and addition chlorination pathways

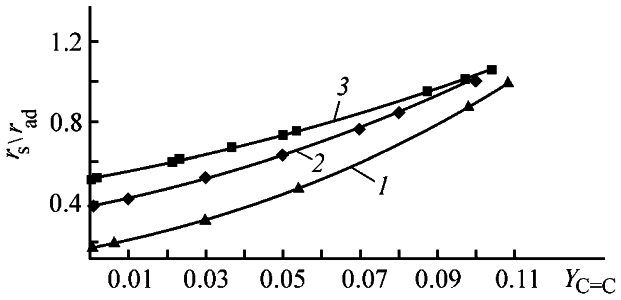

Fig. 3. Rate ratio of the substitution and addition chlorination pathways r_s/r_{ad} as a function of the content of residual double bonds $Y_{C=C}$. Temperature, °C: (*1*) 10, (*2*) 35, and (*3*) 58.

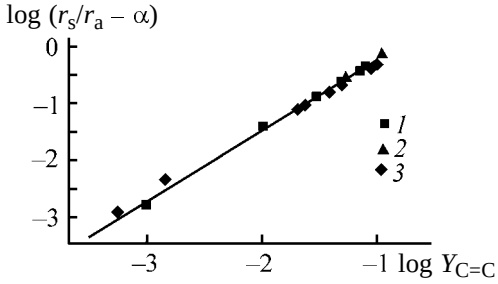

Fig. 4. Determination of the parameters β and *n*. Temperature, °C: (*1*) 35, (*2*) 10, and (*3*) 58.

under conditions when double bonds inducing the radical chlorination mechanism are virtually absent.

Thus, we have obtained an expression for the rate ratio of substitution and addition pathways in chlorination of P-1 polyisobutylene.

Received October 10, 2003

Abstract—Specific features of thermal oxidative degradation of polypropylene and its composite with $Mg(OH)_2$ were studied by pyrolytic gas chromatography–mass spectrometry and thermal gravimetric analysis.

An urgent problem of the modern polymer industry is to reduce the combustibility of polymers and polymeric materials. Of particular interest are fireproofing agents that combine high performance with environmental safety. One of a few fire retardants meeting these criteria is magnesium hydroxide, $Mg(OH)_2$. It is commonly believed that its fireproofing effect is due to dilution of gaseous pyrolysis products with water vapor formed by endothermic (ΔH 1450 J kg^{-1}) decomposition of $Mg(OH)_2$ above 340°C [1]:

$$Mg(OH)_2 = MgO + H_2O\uparrow.$$

The heat consumed in this reaction considerably decreases the temperature on the surface of the degrading polymer. On the other hand, large amount of the released water vapor dilutes the mixture of volatile degradation products, altering the thermal balance in the combustion zone.

Since the decomposition point of $Mg(OH)_2$ is higher than the temperatures of industrial processing of such polymers as ethylene–vinyl acetate copolymer, polypropylene, and polyamides and corresponds to the temperatures at which these polymers start to degrade, there are no problems with preparing composites of reduced combustibility from these components.

Polymeric composites of polypropylene, Nylon 6, and ethylene–vinyl acetate copolymer, containing 50 wt parts of $Mg(OH)_2$ and more, showed considerably decreased combustibility, as determined from the oxygen index and concalorimeter method [2].

In this work, the fire-retarding effect of $Mg(OH)_2$ on polypropylene was evaluated by mass-spectrometric analysis of polypropylene pyrolysis products.

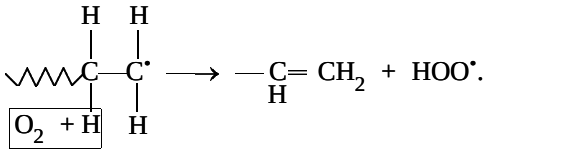
The mechanism of thermal degradation of polypropylene (PP) at temperatures close to the processing temperatures had been comprehensively studied [3–7]. It is known that, in the absence of oxygen, PP decomposes without residue to give large amounts of aliphatic compounds: alkanes, alkenes, and dienes. The primary thermal degradation of the polymeric chain involves scission of the weakest bonds. Oxygen chemisorbed on the polymer surface initiates radical formation at approximately 250°C and causes ignition at 470–540°C:

$$RH + O_2 \rightarrow R^{\bullet} + HO_2^{\bullet}.$$

Furthermore, peroxy radicals are formed at approximately 350°C:

$$-R^{\bullet} + O_2 \rightarrow -ROO^{\bullet}.$$

Above this temperature, dehydrogenation of polymeric radicals results in formation of a polyene and $HO_2^{\bullet}$:



This reaction pathway prevails in the range 350–500°C.

According to the classical scheme of radical initiation [7], the peroxy radicals initiate the following reactions of chain propagation:

$$HOO^{\bullet} + RH = H_2O_2 + R^{\bullet},$$

$$HOO^{\bullet} + CH_4 = H_2O_2 + CH_3^{\bullet},$$

1070-4272/04/7703-0445 © 2004 MAIK "Nauka/Interperiodica"

$$HOO^{\bullet} + H_2 = H_2O_2 + H^{\bullet},$$

$$H_2O_2 = 2HO^{\bullet},$$

$$HO^{\bullet} + RH = R^{\bullet} + H_2O,$$

$$HO^{\bullet} + H_2 = H^{\bullet} + H_2O,$$

and chain branching:

$$H^{\bullet} + O_2 \rightarrow HO^{\bullet} + O^{\bullet},$$

$$O^{\bullet} + H_2 \rightarrow HO^{\bullet} + H^{\bullet},$$

$$ROOH \rightarrow RO^{\bullet} + HO^{\bullet}.$$

It is generally accepted that fire retardants can actively participate in pyrolytic reactions and inhibit radical generation in the combustion zone or directly before it. Jha *et al.* [8] subdivided fire retardants with respect to the mechanism of their effect into two groups: (1) additives acting in the gas phase (terminating generation of free radicals in the preliminary flash and combustion front zones); (2) additives acting in the solid phase (decelerating common pyrolysis by increasing the amount of coke, thus insulating the polymer melt from the intense high-temperature flame flow or ignition source, or altering the pyrolysis course so as to prevent dropping of the polymer melt).

It is commonly believed that magnesium hydroxide belongs to the first group.

In this work we studied how magnesium hydroxide affects solid-phase coke formation enhancing the fire resistance of polypropylene.

EXPERIMENTAL

Polypropylene was of BE677MO brand (Borealis), and its composite with magnesium hydroxide (FD905-U brand, Borealis) contained 40% $Mg(OH)_2$.

Pyrolysis of pure polypropylene and its composite with $Mg(OH)_2$ was performed at 300, 500, and 700°C in a tubular flow-through pyrolytic cell in air (flow rate ~40 ml min^{-1}). The outflowing gases were passed through a bubbler filled with 4 ml of hexane and cooled on an ice bath, to trap the pyrolysis products.

The thermal gravimetric analysis of PP and its composite with $Mg(OH)_2$ was performed on a 950Q derivatograph in air at a heating rate of 10 deg min^{-1}.

The screening analysis of the pyrolysis products was performed on a Tsvet 500 M gas chromatograph (electron capture detector, ECD; 4000 × 3-mm packed glass column; stationary phase OV-17 phenylmethylsilicone; column and injector temperatures 230°C; detector temperature 290°C; carrier gas nitrogen, flow rate 16 ml min^{-1}; sample volume 2 μl).

Analysis of the most representative samples by gas chromatography–mass spectrometry was performed on a laboratory complex consisting of a Varian 3300 gas chromatograph, a Finnigan MAT ITD 800 mass spectrometric detector of the ion trap type, and a computer system for data processing. Separation was performed on a quartz capillary column (30 m long, 0.32 mm i.d.) coated with a 0.25-μm film of DB-5 phenylmethylsilicone. The column was heated at a 10 deg min^{-1} rate from 50 to 270°C; the injector temperature was 200°C. The carrier gas was helium (inlet pressure 0.1 MPa). Samples (1 μl) were injected without flow division; the time before the start of purging of the sample inlet unit was 30 s. The mass spectra were taken with the electron impact (70 eV) ionization mode at a scanned rate of 1 mass spectrum per minute; the scanning range was 40–650 amu.

At 300 and 500°C, the major reaction products are alkenes, alkanes, dienes, and also alcohols and ketones. The composition and percent content of components in pyrolysis products of PP and its composite with $Mg(OH)_2$ are given in the table. The strongest peaks in the chromatograms correspond to 2,4-dimethyl-1-heptene, 4-methyl-2-heptanone, 2,6-dimethyl-4-heptanone, isomers of dimethyloctanol, and some other hydrocarbon derivatives. At low pyrolysis temperatures, $Mg(OH)_2$ exerts no noticeable effect on the composition of pyrolysis products, whereas at higher temperatures this effect becomes significant. Benzene derivatives appear at 500°C. At this temperature, we identified allylbenzene. Its content in the pyrolysis products of the composite (1.5%) was lower compared to pure PP (2.8%). At 700°C, the number and content of aromatic compounds grow. We identified toluene, ethylbenzene, xylenes, and isomeric ethyltoluenes and methylstyrenes. As seen from the table, their content in pyrolysis of the composite is considerably higher compared to pure PP. As for compounds with fused benzene rings, the pyrolysis products of pure PP contain no methylnaphthalene and dihydronaphthalene isomers detected in pyrolysis of the composite. The content of naphthalene in the pyrolysis products of the composite was two times higher compared to pure PP. In pyrolysis products of the composite, we also identified biphenyl. Thus, in the presence of $Mg(OH)_2$ formation of aromatic compounds (mononuclear compounds, naphthalenes, biphenyls) is more intense.

The TG analysis of the composite revealed forma-

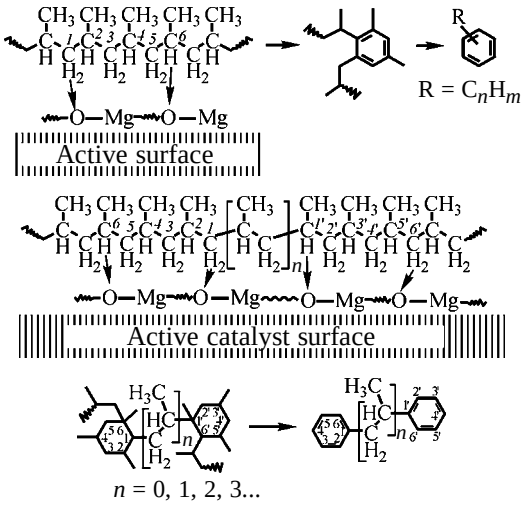
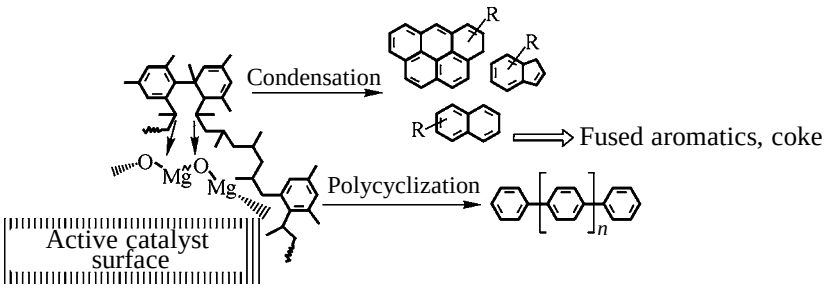
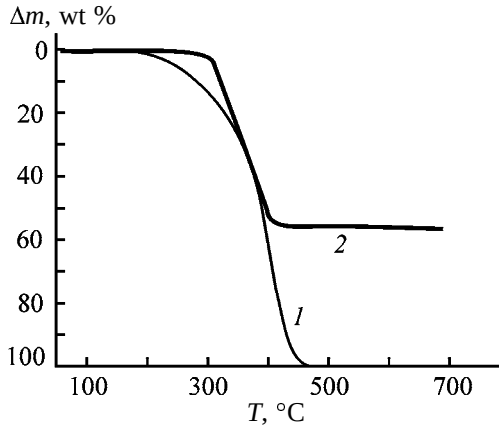
tion of a coke residue under conditions of thermal oxidative degradation, whereas with pure PP virtually no residue was obtained (see figure). The amount of the coke residue was about 15%. To account for formation of the coke residue and aromatic compounds, we suggested a scheme of solid-phase catalysis. Magnesium hydroxide starts to decompose at 340°C. The nonvolatile magnesium oxide formed on the polymer surface protects deeper layers of the material. Thus, at elevated temperatures magnesium oxide starts to behave as active fire retardant. Due to the weak basic properties and large active surface area, magnesium oxide is used as additive to oxide catalysts for dehydrogenation of aliphatic compounds [9]. In pyrolysis of polypropylene, apparently, MgO behaves similarly.

The possible mechanism of formation of aromatic compounds and coke with nonfused and fused benzene rings is shown in the scheme:





The products of PP thermal degradation undergo dehydrogenation on the active MgO surface, yielding aromatic compounds. A similar mechanism involving catalysis with MgO explains formation of structures with benzene rings linked by an alkyl bridge. Then two pathways are possible. The first pathway is formation of diphenylalkanes. The second pathway involves catalytic solid-phase condensation followed by polycyclization, yielding coke on the MgO surface via intermediates with fused benzene rings, such as naphthalene and its derivatives. The detection of naphthalene, methylnaphthalenes, azulene, and biphenyl, and also of benzene derivatives shows that this process is primary.



TG curves of (*1*) PP and (*2*) PP–40 wt % $Mg(OH)_2$ composite, recorded in air. Heating rate 10 deg min^{-1}. (Δm) Weight loss and (T) temperature.

CONCLUSION

Compounding polypropylene with $Mg(OH)_2$ enhances its resistance to combustion in both the gas and solid phases; one of the factors responsible for this effect is MgO-catalyzed coke formation on the polymer surface.

Abstract—Terpolymers of ethylene with propylene and higher α-olefins with various compositions and molecular weights were synthesized, as well as copolymers with higher poly-α-olefins with various molecular weights. The possibility of laboratory assessment of the antiturbulent power of polymers and turborheometric determination of the volumes and molecular weights of poly-α-olefin macromolecules was examined.

Introduction of polymer additives to a turbulent flow of a liquid increases its viscosity but decreases the hydrodynamic resistance coefficient and, thus, increases the average flow rate or decreases the friction loss of the pressure (Toms effect [1]).

The mechanism of this somewhat unusual phenomenon remains the subject of heated discussions, but the ability of polymers to decrease the turbulent flow resistance has found wide application, in particular, in oil and oil product transportation via pipelines [2, 3].

By now, hydrodynamic properties of a large number of polymer samples of different chemical nature have been studied. It was found that many of them exhibit the Toms effect [4] under laboratory conditions, but only a few proved to be suitable for and demanded by commercial oil and oil product pipelines. The divergence between the results of laboratory and field experiments can be explained in part as follows. The Toms effect, %, is quantitatively described by the formula

$$DR = (\lambda_s - \lambda_p)/\lambda_s \times 100, \quad (1)$$

commonly used in hydrodynamics. Here, *DR* is the magnitude of the Toms effect, and λ_s and λ_p, hydrodynamic resistance coefficients for pure solvent and polymer solution, respectively.

The coefficients λ_s and λ_p can be determined only after conducting appropriate experiments and processing the experimental data by the Darcy–Weissbach equation.

The main drawback of formula (1) is that it does not implicitly reflect the dependence of the Toms effect on numerous hydrodynamic flow parameters and physicochemical characteristics of polymer solutions (shear stress and Reynolds number, concentration and molecular weight of the polymer additive, and temperature, density, viscosity, and thermodynamic quality of the solvent) affecting the structure of the turbulent flow and, thus, is unsuitable for predicting the effect before experiments.

Comparative assessment of the antiturbulent powers of polymer additives is typically based on analysis of the plots of the Toms effect, *DR*, vs. the polymer concentration in solution, constructed after laboratory bench experiments. Hydrodynamic studies of a wide spectrum of polymers (polystyrene, polyisobutylene, polybutadiene, polymethacrylates, polysiloxanes, etc.) showed that, with increasing amount of the additive, *DR* initially tends to linearly increase within the range corresponding to very dilute solutions and attains a maximal value DR_{max} at a certain optimal concentration c_{opt}, whereupon it slowly decreases with increasing concentration. Samples having the greatest DR_{max} at the smallest c_{opt} are regarded as the most effective.

Figure 1 presents a typical concentration dependence of *DR*, obtained after a laboratory test with oil solutions of two natural rubber (polyisoprene) samples with different molecular weights (MWs). It is seen that, at identical concentrations of solutions, *DR* is the greater, the higher the MW of the sample (Fig. 1, curves *2, 3*) and the greater the shear stress τ_ω on the tube wall (Fig. 1, curves *1, 3*), c_{opt} being the smaller,

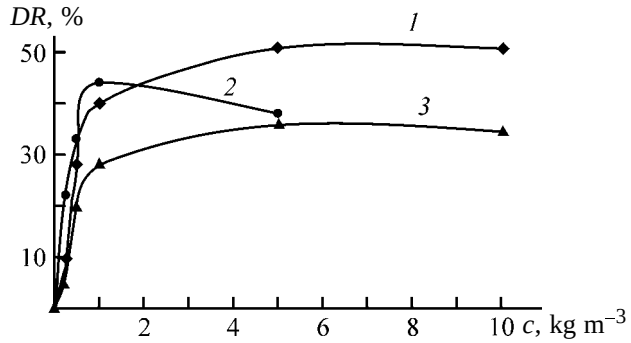

Fig. 1. Hydrodynamic resistance reduction effect *DR* as a function of the concentration *c* of natural rubber in oil. Molecular weight: (*1*, *3*) 2.4×10^5 and (*2*) 5.5×10^5. Intrinsic viscosity [η], $m^3\,kg^{-1}$: (*1*, *3*) 0.20 and (*2*) 0.35. Shear stress τ, Pa: (*1*) 240 and (*2*, *3*) 120.

the higher the MW. From the technological and economical viewpoints, the polymer additive concentration within $0–c_{opt}$ seems optimal for commercial pipeline applications. Thus, practically applicable are polymers with very low optimal concentrations (c_{opt} < 0.05 kg m^{-3}).

Figure 1 presents the results of hydrodynamic tests for three natural rubber samples, which not only show poor performance, not satisfying the concentration criterion (a high-molecular-weight polyisoprene sample has c_{opt} of 1 kg m^{-3} and a sample with a lower molecular weight, 5 kg m^{-3}), but also show no promise for commercial pipelines characterized by typical shear stresses no greater than 10 Pa. These natural rubber samples were studied under the laboratory conditions at arbitrarily chosen and much higher shear stresses (120 and 240 Pa), which are not limited by expression (1).

A change in the quantitative description of the Toms effect from *DR* to a relative parameter $(Q_p - Q_s)/Q_s$ (where Q_p and Q_s are the flow rates of the polymer solution and solvent, respectively) obviates the drawbacks of formula (1). The $\Delta Q/Q_s$ ratio, %, characterizes the increase in the throughput of a tube in which the liquid flow rate increases from Q_s of a pure solvent to Q_p upon introduction of a polymer additive. The dependence of the flow rate increment on various hydrodynamic and physicochemical factors of flowing polymer solutions [5] is described by the equation

$$\Delta Q = S\Psi\tau_\omega\left(\frac{V_g}{\rho kT}\right)^{1/2}\left[1-\left(\frac{kT}{\tau_\omega V_g}\right)^{1/2}\right], \qquad (2)$$

where $\Delta Q = Q_p - Q_s$ is the flow rate increment of a polymer solution relative to the solvent; $S = \pi R_\omega^2$, cross-section area of the cylindrical channel; $\Psi = [\eta]c_p/(1 + [\eta]c_p)$, volume fraction of the macromolecular globules in solution, which depends on the intrinsic viscosity [η] and concentration of the polymer solution c_p; $\tau_\omega = \Delta P R_\omega/2L$, shear stress on the wall of a tube with radius R_ω and length L at a given pressure gradient ΔP; V_g, volume of a macromolecular globule with immobilized solvent; ρ, density of the solvent; *k*, Boltzmann constant; and *T*, temperature.

It is seen that Eq. (2) is consistent with the currently available empirical data and allows predicting not only the magnitude of the effect (i.e., increase in the average flow rate), but also the conditions of its manifestation. It was found experimentally that the Toms effect is observed in the turbulent region of flow (Re > 2300, where Re is the Reynolds number) at shear stresses exceeding a certain "threshold" parameter τ_{thr} which for each particular sample is the smaller, the higher the MW. Clearly, Eq. (2) suggests that the effect ($\Delta Q > 0$) can be manifested only at $[1 - (kT/\tau_\omega V_g)^{1/2}] > 0$, or at $\tau_\omega V_g > kT$. Using the latter inequality, we can estimate the minimal (threshold) shear stress above which the turbulent flow rate of the polymer solution will exceed the flow rate of the solvent:

$$\tau_{thr} = kT/V_g. \qquad (3)$$

Using the well-known Flory–Fox formula $V_g \approx M[\eta]/N_a$ connecting the volume of the macromolecule with its molar mass *M*, intrinsic viscosity [η], and Avogadro number N_a, we can modify expression (3) into

$$\tau_{thr} = RT/M[\eta]. \qquad (4)$$

Thus, the threshold shear stress for a particular polymer sample is the smaller, the larger its molar mass and intrinsic viscosity or their proportional globule volume. For the two natural rubber samples (Fig. 1) with molar masses M_1 = 240 kg mol^{-3} (MW = 2.4×10^5) and M_2 = 550 kg mol^{-3} (*MW* = 5.5×10^5) and intrinsic viscosities $[\eta]_1 = 0.2$ and $[\eta]_2 = 0.35$ $m^3\,kg^{-1}$ at *T* = 293 K, the threshold shear stresses were estimated at $\tau_{thr1} \approx 50$ and $\tau_{thr2} \approx 13$ Pa. These exceed the actual shear stresses in main pipelines ($0 < \tau_\omega < 10$ Pa), which suggests that introduction of these polymer additives into pipelines will not increase the flow rate.

In the case of developed turbulent flows, i.e., at fairly large Reynolds numbers and shear stress on the wall τ_ω, when the algebraic sum $[1 - (kT/\tau_\omega V_g)^{1/2}]$ in

Eq. (2) tends to unity, this equation acquires a simpler form

$$\Delta Q = S\Psi\tau_\omega\left(\frac{V_g}{\rho kT}\right)^{1/2}. \quad (5)$$

Therefore, the flow rate increment for a polymer solution is the larger, the larger the size and concentration of the macromolecules with the solvent immobilized, as well as the shear stress. Based on the data of a turborheometric test with polymer solutions, the volume of the macromolecular globules can be calculated by Eq. (5). Next, it is possible to estimate the molar mass of the polymer sample by the modified Flory–Fox formula

$$M = V_g N_a/[\eta]. \quad (6)$$

EXPERIMENTAL

The above analysis of the flow rate increment as dependent on various factors allows formulation of economically and technologically sound requirements for candidate agents decreasing the hydrodynamic resistance in main oil pipelines. These requirements include a fairly low prime cost (which is primarily determined by the price of the monomer); no adverse effect on oil processing; a fairly high molecular weight; and a good compatibility (solubility) with oil and its individual fractions, that is, the polymer additive must have fairly high intrinsic viscosities in hydrocarbon liquids of different polarities.

Among a great number of well-characterized polymers of different chemical nature, these requirements are most adequately satisfied by higher poly-α-olefins and their X-ray amorphous copolymers prepared using Ziegler catalysts. It is well known [6] that the rate of polymerization proceeding by the ion-coordination mechanism and the molecular weight of the resulting product are governed by numerous factors such as the chemical nature of the monomer and of the catalytic system, concentration of the monomer in the initial reaction mixture and its conversion (the degree of the monomer conversion into polymer within a certain period), temperature, and some other parameters.

High-molecular-weight X-ray amorphous terpolymers (ethylene/propylene/α–olefin) were prepared using a highly active vanadium-magnesium catalyst. It was synthesized by the procedure from [7], by applying vanadium compounds (VCl_4, $VOCl_3$) onto finely dispersed magnesium chloride (the vanadium content in the catalyst was 2–3 wt %). High-molecular-weight homopolymers of higher poly-α-olefins were synthesized using two modifications of titanium–magnesium catalysts. They were prepared by applying $TiCl_4$ onto finely dispersed magnesium chloride containing modifying additives (2–4 wt % titanium in the samples).

The olefins were polymerized in a 1-l steel autoclave under vigorous stirring at 293–323 K. As cocatalyst served triethylaluminum or triisobutylaluminum. The concentration of the catalyst was 0.4 g l^{-1}, and that of the cocatalyst, 5 mM.

The composition of terpolymers (C_2, C_3, C_α) was determined by ^{13}C NMR spectroscopy on a Bruker DRX-250 instrument at 393 K and 62.91 MHz. The samples were prepared in the form of solutions in 1,2-dichlorobenzene with a polymer concentration of 0.07–0.12 g ml^{-1}.

The hydrodynamic properties of terpolymers and poly-α-olefins were studied in the laminar and turbulent flow modes. The intrinsic viscosities of poly-α-olefins in benzine and of terpolymers in three solvents (heptane, benzine, and toluene) were determined by capillary viscometry. The use of different solvents allows estimation of the degree of crystallinity of the resulting products. Terpolymers with a high ethylene content and, consequently, prone to formation of crystallinity zones, are well soluble in toluene and less soluble in heptane. Benzine, which is a mixture of alkanes and aromatic compounds, is intermediate in solvency.

We determined the flow rates Q_s and Q_p at the shear stress on the tube wall τ_ω = 4 Pa in a turbulent rheometer [8] measuring flow rates of solvents and polymer solutions of different concentrations in a cylindrical channel in the turbulent flow mode (Re > 2300). Then, we calculated the $\Delta Q/Q_s$ parameters. The choice of benzine as the solvent was dictated by two reasons. First, as one of oil fractions, benzine is close in solvency to the mixed oil transported by main pipelines. Second, being a low-viscosity solvent, benzine is suitable for measurements in a turbulent-flow region at shear stresses close to those actually occurring in commercial main pipelines. The parameters V_g, M, and τ_{thr} were calculated by formulas (5), (6), and (3).

Polyolefins and their copolymers prepared at lower temperatures usually have higher molecular weights [6]. This is true for the samples of ethylene-, propylene-, and 1-dodecene-based terpolymers synthesized at 293–323 K (Table 1).

Table 1 shows that the intrinsic viscosity of solu-

Table 1. Composition and hydrodynamic properties of solutions of terpolymers synthesized at different temperatures T_s

T, K	Composition of copolymer, wt %			Intrinsic viscosity [η], $m^3\ kg^{-1}$			$V_g \times 10^{21}$, m^3	τ_{thr}, Pa	c_{opt}, $kg\ m^{-3}$	$(\Delta Q/Q_s)_{max}$, %
	C_2	C_3	C_{12}	heptane	benzine	toluene				
323	33	36	31	0.14	0.16	0.17	0.19	21.3	–	0
313	39	37	24	0.31	0.33	0.38	1.15	3.5	0.55	44
303	50	30	20	0.29	0.34	0.41	1.61	2.5	0.25	47
293	56	29	15	0.26	0.28	0.42	1.45	2.8	0.35	46

tions in toluene tends to increase with decreasing temperature of the sample synthesis, which, most probably, suggests a growth of the molecular weight. The intrinsic viscosity of the same samples in heptane exhibits an opposite trend. Visual examination of the solutions in toluene and heptane revealed the absolute transparency of the former (which allows their classification with true solutions) and pronounced opalescence of the latter (suggesting the presence of heterogeneous inclusions of microgels). A decrease in the solubility in heptane for the terpolymers prepared at relatively low temperatures is due to a decrease in the content of propylene and 1-dodecene units in them and to a growth in the proportion of ethylene units (Table 1) enhancing the microblock structure.

Benzine is intermediate in solvency between toluene and heptane; consequently, the hydrodynamic properties of solutions of terpolymers in benzine are determined by the ratio of the molecular weight of the samples to the content of α-olefin units in them (Table 1). It is seen that the maximal antiturbulent power is exhibited by the polymer prepared at T = 303 K. Further decrease of the synthesis temperature, though affording higher molecular weights of terpolymers, decreases the proportion of 1-dodecene. This worsens the solubility and thus decreases both the volumes of macromolecular globules with the solvent immobilized and the resistance reduction effect $(\Delta Q/Q_s)_{max}$.

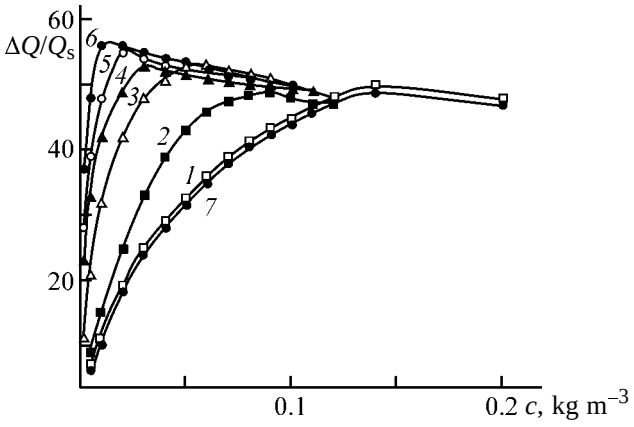

Fig. 2. Flow rate increment $\Delta Q/Q_s$ as a function of the polymer concentration c. Polyolefin: (*1*–*6*) poly-1-hexene (for characteristics of the samples, see Table 2), (*7*) $C_2/C_3/C_6$ ternary copolymer ([η] = 0.41 $m^3\ kg^{-1}$, V_g = 3.79×10^{-21} m^3).

A change to a monomer with a lower molecular weight (from 1-dodecene to 1-hexene) in copolymerization at 293 K allowed preparation of a terpolymer with enhanced content of α-olefin in the polymer chain (25 wt %). This improved the solubility of the terpolymer in benzine ($[\eta]_{benz}$ = 0.41 $m^3\ kg^{-3}$), increased the volume of the macromolecular globule ($V_g = 3.79 \times 10^{-21}$ m^3), and decreased the "threshold" shear stress (τ_{thr} = 1.1 Pa).

The resulting ternary copolymer has the highest hydrodynamic power $(\Delta Q/Q_s)_{max}$ = 48% at τ_ω = 4 Pa) among all the terpolymers synthesized. At the same time, the maximal (by a factor of nearly 1.5) increase in the flow rate is achieved at a too high concentration of 0.14 $kg\ m^{-3}$ (Fig. 2, curve *7*). This sends us in a further search for optimal catalytic systems and copolymer combinations, as well as for conditions of synthesis of well soluble terpolymers with the aim to prepare samples with a maximal $\Delta Q/Q_s$ at concentrations under 0.05 $kg\ m^{-3}$.

Experiments on polymerization of individual 1-hexene, 1-octene, and 1-dodecene in heptane showed that the maximal activity and, thus, the rate of conversion into polymer are exhibited by 1-hexene, which made specifically this monomer preferable for homopolymerization.

Test syntheses at various temperatures also showed that the MW of the resulting product increases with decreasing temperature and that polymers with molecular weights over 10^6 are formed below 300 K. Therefore, we carried out polymerization of 1-hexene at 293 K, which yielded a suitable product ($M[\eta] > RT/\tau_\omega$) at an acceptable rate.

Table 2 presents the results of a hydrodynamic test

Table 2. Synthesis conditions and hydrodynamic properties of poly-α-hexene samples

of poly-1-hexene samples prepared in a number of synthesis runs at varied initial concentration of the monomer in the reaction medium c_m and synthesis time τ_s.

Table 2 and Fig. 2 show that the concentration of the polymer additive c_{opt} corresponding to the maximal flow rate increment $(\Delta Q/Q_s)_{max}$ is the smaller, the larger the size of its macromolecular globules with the solvent immobilized. In accordance with the kinetic relationships in the polymerization process, the molecular weight of the forming macromolecules (globule volume) is the larger, the higher the monomer concentration in the reaction medium. Therefore, the antiturbulent power of the resulting samples increases with increasing initial concentration of the monomer charged into the reactor and decreasing synthesis time (conversion). Figure 2 (curve *7*) shows that the most effective terpolymer is surpassed in hydrodynamic properties by all the homopolymers synthesized. Table 2 and Fig. 2 also suggest that the samples of poly-1-hexene (sample nos. 3–6) are suitable for commercial application in main oil pipelines.

CONCLUSIONS

(1) A procedure, based on two criteria, was proposed for assessing under the laboratory conditions the suitability of candidate agents to reduce the hydrodynamic resistance. The necessary condition is a turbulent flow mode (Re > 2300) in the experimental setup, and the sufficient condition, measurement of the antiturbulent properties of polymer additives at shear stresses in the turborheometer equivalent to those actually occurring in main pipelines.

(2) Terpolymers (ethylene/propylene/α-olefin) synthesized on vanadium–magnesium catalysts are able of reducing the hydrodynamic resistance by 40–50% when introduced into turbulent flow in amounts of 0.15–0.55 kg m^{-3}.

(3) Samples of homopolymer (polyhexene) synthesized on titanium–magnesium catalysts below 300 K and having a molecular weight of $(1–10) \times 10^6$ are able of reducing the hydrodynamic resistance by 50–55% at concentrations of $(10–50) \times 10^{-3}$ kg m^{-3}.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Energy Characteristics of the Surface of Modified Phosphorus-Containing Epoxy Polymers

L. M. Amirova and A. F. Magsumova

Tupolev Kazan State Technical University, Kazan, Tatarstan, Russia

Received April 22, 2003

Abstract—The Fowkes and van Oss–Good approaches were used for assessing the energy characteristics of the surface of the epoxy–amine systems modified with triglycidyl phosphate. Variation of these characteristics with the modifier content and polymer curing conditions was studied.

Modification of the initial oligomer systems allows control of the surface properties of cured polymers. It is known [1, 2] that the components of compounds differ in the adsorbability, which can be responsible for differences in their distribution in the bulk and at interfaces [1, 2]. This allows formation of surfaces with desired energy characteristics.

The surface energy γ_S of solids at the solid–liquid or solid–gas interfaces is often assessed using the Fowkes–Owens [3, 4] and van Oss–Good [5, 6] approaches. They are based on measuring the contact angles of wetting of the surface with test liquids. The surface energy and its components were estimated for a number of epoxy polymers [1, 2, 7, 8]. Rudoi and co-workers [1] and Chalykh and co-workers [2] showed that the surface activity of modified epoxy systems is governed by a number of factors such as ratio of the rates of the chemical reaction and diffusion, molecular weight, and the curing mode chosen. However, the above-cited works, even though concerned with the same epoxy systems, report different surface energies. Van Oss and co-workers [5, 6] assessed the acid–base properties of the surface of epoxy polymers and revealed their basic nature.

We found earlier [9–13] that modification of epoxy–4,4'-isopropylidenediphenol oligomers with glycidyl esters of phosphorus-containing acids (GEPs) yields materials with enhanced thermophysical, physicomechanical, and optical properties. At the same time, when the developed phosphorus-containing epoxy compounds are intended as adhesives, preparation of coatings requires knowledge of the surface and interphase properties of both uncured oligomer systems and polymers thereof.

The aim of this work is to quantitatively estimate the energy characteristics of the surface of polymers based on ED-20 epoxy-4,4'-isopropylidenediphenol oligomer modified with triglycidyl phosphate.

EXPERIMENTAL

We used ED-20 epoxy–4,4'-isopropylidenediphenol oligomer **I**, triglycidyl phosphate $P(O)(OCH_2\text{–}\underset{\backslash\ /}{CH}\text{–}CH_2)_3$ **II**, and 4,4'-diaminodiphenylmethane (DADPM).

Oligomer **I** was vacuum-treated at 80–90°C, whereupon the contents of epoxy and hydroxy groups were estimated by chemical methods [14] (at 21.5 and 1.3%, respectively). Triglycidyl phosphate **II** was synthesized as described by Rizpolozhenskii *et al.* [15], purified by vacuum distillation, and kept in sealed glass ampules. The compound was identified by elemental analysis and IR and ^1H, ^{13}C, and ^{31}P NMR spectroscopy.

The compatibility of **I** and **II** was checked by microinterferometry on an MI-2 instrument. Based on the data obtained, we constructed phase diagrams.

Mixtures of **I** and **II** of different compositions were cured with a stoichiometric amount of DADPM in a stepwise mode (heating to 60°C and curing for 6 h at 20°C) and postcured in a stepwise mode as well (heating for 1 h at 100–170°C with a 10°C step).

The surface energy of the resulting polymers and its components were estimated from the angle of wetting with test liquids. The contact wetting angles were determined using a horizontal microscope equipped with a goniometric accessory, under saturated liquid

vapor in a chamber kept at a constant temperature of 20°C. The test liquids were chosen by the criteria suggested by Kwok *et al*. [16]. The surface energy components and the equilibrium contact wetting angle θ for the contacting solid and liquid phases are linked by the Owens–Wendt relationship [3, 4]

$$(\cos\theta + 1)\gamma_L = 2(\gamma_S^d\gamma_L^d)^{1/2} + 2(\gamma_S^p\gamma_L^p)^{1/2}, \quad (1)$$

where, γ_L is the surface tension at the liquid–gas interface; γ_S^d and γ_L^d are the dispersion, and γ_S^p and γ_L^p, polar components of the surface energy of a solid and a liquid, respectively.

The total surface energy γ_S can be represented as

$$\gamma_S = \gamma_S^d + \gamma_S^p. \quad (2)$$

The polar component γ^{SR} of the surface energy of cured polymers and its acidic γ_S^+ and basic γ_S^- constituents were estimated taking into account the Lifshits–van der Waals nonpolar component γ^{LW} which is virtually identical to the dispersion component γ^d in terms of the approach suggested in [5, 6]. This approach implies that the polar component of the surface energy γ^{SR} is due to electron donor–acceptor (acid–base) interactions and is determined by the relationship

$$\gamma^{SR} = 2(\gamma^-\gamma^+)^{1/2}, \quad (3)$$

where γ^- and γ^+ are the donor (basic) and acceptor (acidic) components of the surface energy, respectively.

The major equation linking the acid–base and nonpolar interactions with the contact wetting angle θ is

$$(\cos\theta + 1)\gamma_L = 2[(\gamma_S^{LW}\gamma_L^{LW})^{1/2} + (\gamma_S^+\gamma_L^-)^{1/2} + (\gamma_S^-\gamma_L^+)^{1/2}], \quad (4)$$

where the subscripts "S" and "L" refer to the solid and liquid phases, respectively.

The surface energies of the **I**–**II**–DADPM solid polymers yielded by curing of the oligomer systems were estimated from the contact angles of wetting with a number of test liquids (see table). Figure 1 (curves *1*–*3*) shows how the energies of the surface formed at the epoxy polymer–air interface, estimated by Eqs. (1) and (2), vary with the content of triglycidyl phosphate **II** for epoxy polymers postcured in a stepwise mode to 150°C.

It is seen that γ_S is virtually independent of triglycidyl phosphate concentration up to 70 wt %. At the same time, at the modifier content within 0–10 wt %, the dispersion component γ_S^d tends to significantly decrease, and the polar component γ_S^p, to increase. Figure 1 shows that the increased surface energy of the polymers containing over 70 wt % triglycidyl phosphate **II** is due to increased contribution from the polar component, the dispersion component being virtually unchanged.

Dogan *et al*. [7] and Chung *et al*. [8] showed that the surface of epoxy–amine polymers is virtually monopolar and basic. Our data (Fig. 2) suggest that the surface basicity is enhanced by introduction of triglycidyl phosphate **II** into the polymer. This is evidently due to increases in the number of oxygen atoms in the polymer network and of secondary hydroxy groups and to appearance of phosphoryl groups.

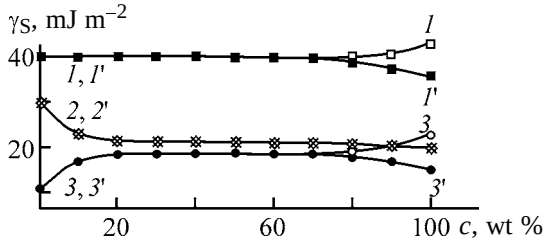

Fig. 1. (*1*, *1*') Surface energy γ_S and its (*2*, *2*') dispersion, γ_S^d, and (*3*, *3*') polar, γ_S^p, components as functions of the triglycidyl phosphate concentration *c* in the epoxy–amine polymer heat-treated at (*1*–*3*) 150 and (*1*'–*3*') 170°C.

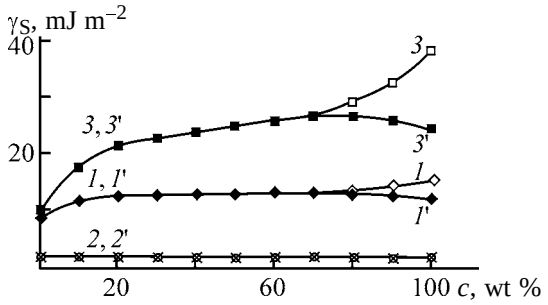

Fig. 2. Variation of (*1*, *1*') polar component γ_S^{SR} and (*2*, *2*') acidic, γ_S^+, and (*3*, *3*') basic, γ_S^-, constituents of the surface energy γ_S with the triglycidyl phosphate concentration *c* in the epoxy–amine polymer heat-treated at (*1*–*3*) 150 and (*1*'–*3*') 170°C.

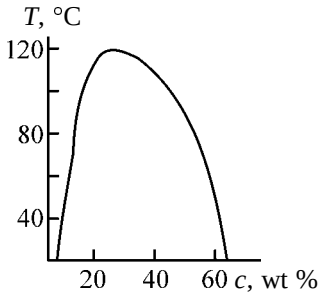

Fig. 3. Phase diagram of the **I**–**II** system. (*T*) Temperature and (*c*) triglycidyl phosphate concentration.

To explain the nonuniform variation of the energy characteristics of the epoxy polymer surface with increasing content of triglycidyl phosphate **II**, we will turn to the phase diagram of the **I**–**II** system (Fig. 3). It is seen that, with <8 and >65 wt % **II**, the system is compatible, and within 8–65 wt %, incompatible with the upper critical solution point (UCSP) of 120°C. Similar phase diagrams were obtained previously by Amirova *et al*. [13] for a number of GEPs and E-40 epoxy polymer. It was shown that, in the region of incompatibility of the epoxy oligomer–GEP system, stratifying emulsions are formed, whose curing yields polymers exhibiting a composition gradient over the sample cross section. The upper layer of such polymer is formed from the epoxy–4,4'-isopropylidenediphenol oligomer containing ca. 10 wt % GEP. The lower layer is formed by GEP saturated with the dissolved epoxy–4,4'-isopropylidenediphenol polymer. Elemental analysis suggested similar segregation and formation of a gradient polymer in the **I**–**II** system studied by us.

Thus, invariant energy characteristics of the surface of epoxy–amine polymers of the **I**–**II** system with the triglycidyl phosphate content within 10–70 wt % (Figs. 1, 2) are due to invariant composition of their surface containing 8–10 wt % triglycidyl phosphate **II**. In the regions of compatibility, enhancement of the polarity (and basicity) of the surface of these polymers with increase in the concentration of **II** is due to increase in the concentration of **II** in the upper layer.

Recently, Amirova [17] showed that heat treatment at 170°C of the triglycidyl phosphate based epoxy polymer cured with DADPM results in water elimination and decrease in the content of the secondary hydroxy groups. This is accompanied by increases in the glass transition point and elastic modulus. A similar effect is also observed for polymers prepared by curing mixtures of **I** and **II** with DADPM, whose glass transition points are above 170°C. This holds for polymers containing over 10 wt % triglycidyl phosphate **II** [10]. In this connection, it was of interest to elucidate how such heat treatment affects the energy characteristics of the surface of the polymers under study.

Figure 1 (curves *1*'–*3*') shows the plots of the surface energy for the polymer–air interface formed by epoxy polymers with different contents of triglycidyl phosphate **II**, cured stepwise to 150°C and heat-treated at 170°C. It is seen that heat treatment does not noticeably affect the run of curves *1* and *3* for triglycidyl phosphate concentrations within 0–70 wt % and the run of curve *2* throughout the modifier concentration range. At 70–100 wt % content of triglycidyl phosphate, the polar component γ_S^p and, thereby, the surface energy of the polymer as a whole, significantly decrease (Fig. 1).

The runs of the curves for the polar component and its basic constituent as calculated by Eqs. (3) and (4) were also different in the region of 70–100 wt % triglycidyl phosphate (see curves *1*' and *3*' in Fig. 2), while the acidic constituent remained unchanged (Fig. 2, curve *2*'). Weakening basicity of the surface of polymers with these compositions during heat treatment can be probably explained by the above-mentioned decrease in the amount of polar hydroxy groups on the polymer surface during annealing at 170°C. The fact that the heat treatment does not affect the nature of the surface of the polymers containing up to 10 wt % triglycidyl phosphate **II** is evidently due to the lacking water elimination and unchanged content of the surface polar groups. As mentioned above, for polymers containing 10–70 wt % triglycidyl phosphate **II**, the surface layer was formed by epoxy–4,4'-isopropylidenediphenol oligomer with a constant content of triglycidyl phosphate which is unaffected by heat treatment at 170°C. In our opinion, this adequately explains the fact that the energy character-

istics of the surface of polymers containing 0–70 wt % triglycidyl phosphate **II** are unaffected by annealing at 170°C.

CONCLUSIONS

(1) Triglycidyl phosphate introduced into epoxy–4,4'-isopropylidenediphenol oligomer modifies the energy characteristics of the resulting polymer in the region of compatibility of epoxy compounds.

(2) Heat treatment of the resulting polymer decreases the polar component of the surface energy and its basic constituent at triglycidyl phosphate concentrations above 70 wt %.

Received April 16, 2003

Abstract—Polyfunctional anion exchangers were prepared by copolymerization of allyl glycidyl ether with polyamines in the presence of a promoter. The synthesis conditions were optimized. The composition and physicochemical features of the resins prepared were studied.

It is known that, in storage, pretreatment, and practical application of sorbents, their characteristics are deteriorated. Therefore, development of polymeric sorbents with stable physicochemical and sorption characteristics is an urgent problem. In this respect, allylic resins show much promise. These polymers are formed by slow radical polymerization of allyl monomers. Their molecular weight is usually low because of degradation chain transfer to the monomer [1]. This process is widely used for preparating polymers with stable physicochemical features [2, 3].

In this work we prepared polyfunctional anion exchangers by copolymerization of allyl glycidyl ether (AGE) and polyamines [polyethylenimine (PEI), poly-2-methyl-5-vinylpyridine (PMVP) in the presence of initiator (H_2O_2)]. The composition, structure, and acid–base properties of the anion exchangers were studied by IR and ^{13}C NMR spectroscopy and potentiometric titration.

EXPERIMENTAL

The AGE–PEA (or PMVP) copolymers were prepared in dimethylformamide (DMFA) at 70–80°C. Before polymerization, a portion of 30% aqueous hydrogen peroxide was added as initiator into the reaction mixture. The initially formed gel-like polymer was cured at 80–120°C. The solid polymer was crushed, and the fraction with the granule size of 0.25 mm was separated by sifting [4, 5].

The pretreatment of the polymer and determination of its physicochemical characteristics were carried out by common technique [6].

The IR spectra of polimerization products formed in the initial, intermediate, and final polymerization stages were recorded on a Specord M80/M85 spectrophotometer [KBr pellets (200 mg KBr + 1 mg polymerization product), thin film of the product placed between plates]. The ^{13}C NMR spectra of polymerization products were recorded in dimethyl sulfoxide solution on a Mercury-300 NMR spectrometer (75 MHz) at room temperature.

The potentiometric titration of the anion exchanger was carried out by contact of its air-dry weighed samples (0.20–0.25 g) with different amounts of 0.1 N aqueous HNO_3 at the ionic strength (KNO_3) of 1 M. After the equilibrium was attained (within 7–10 days), the pH was measured on an EV-74 universal ionometer.

In order to optimize the conditions for preparing the polyelectrolytes, their static exchange capacity (SEC) and swelling (V_{sp}) were studied in relation to the main preparation parameters: AGE : polyamine ratio, polyamine type, temperature, and prepolymerization time.

We found (Table 1) that, with increasing the polyamine : AGE weight ratio in the reaction mixture above unity, both the SEC of anion exchanger (prepared in the presence of H_2O_2) for HCl and its swelling decrease. The increase in the H_2O_2 concentration in the reaction mixture from 0.1 to 0.3% also negatively affects the polyelectrolyte characteristics.

Table 1 shows that the polymer prepared without adding H_2O_2 has a lower anion-exchange capacity and higher swelling as compared to the anion exchanger prepared in the presence of hydrogen peroxide. Thus, introduction of hydrogen peroxide into the reaction mixture improves the resin characteristics.

We found that EGA–PEI anion exchanger exhibits higher sorption exchange capacity for chloride anions than AGE–PMVP resin. The EGA–PEI resins also have increased nitrogen content c_N, apparently due to the fact that PEI contains larger amount of primary and secondary amino groups than PMVP. What is more, the branched PEI structure is favorable for the formation of chemically and thermally stable polymers.

It is known [7] that polymerization time and temperature strongly affect the physicochemical characteristics of polymeric sorbents. Table 2 shows that AGE–PEI copolymer prepared at 80°C has the highest anion-exchange capacity. In copolymerization under these conditions, the opening of the epoxy rings is the most complete. In polymerization at temperatures higher than 80°C, the static exchange capacity of the polymer decreases. We found that the optimal polymerization time is 4 h. In further keeping of the reaction mixture under these conditions, the sorption characteristics of the resin did not change. The yield of the polymeric sorbent exceeds 80%.

The IR spectrum of AGE–PEI anion exchanger contains no absorption bands at 760 and 848 cm^{-1} belonging to the epoxy ring. This spectrum contains the absorption bands of the N–H bending vibrations (3200–3500 and 1600–1700 cm^{-1}) and the bands of C–N stretching vibrations of polymeric anion exchangers (1020–1220 cm^{-1}). The asymmetric and symmetric stretching vibrations of the CH_2 groups are manifested as the absorption bands at 2940 and 2840 cm^{-1}, respectively. The absorption at 1460–1470 cm^{-1} is due to the bending vibrations of the C–H bonds. The IR spectra show that polymerization sharply decreases the intensity of the absorption bands of the out-of-plane vibrations of the vinyl groups at 910 cm^{-1}.

The precondensation of AGE and PEI was studied by ^{13}C NMR technique (Table 3, 4). The signals in the ^{13}C NMR spectra of AGE–PEI copolymers (prior to postcuring) in DMSO were assigned to particular structural fragments by their comparison with the ^{13}C NMR spectra of AGE

$$\overset{116.2}{CH_2}=\overset{134.9}{CH}-\overset{71.1}{CH_2}-O-\overset{70.7}{CH_2}-\overset{50.2}{CH}(O)-\overset{43.3}{CH_2}$$

and PEI [8, 9] (Table 3).

The ^{13}C NMR spectra show that AGE–PEI anion exchanger (prior to postcuring) contains significant amount of linear-branched fragments containing secondary and tertiary amino groups.

One of important physicochemical characteristics of polymeric sorbents is their chemical and thermal stability. These characteristics were evaluated by changes in the sorption capacity of the resins after their treatment with 5 M aqueous H_2SO_4, 5 M aqueous NaOH, and 10% H_2O_2 (Table 5). Taking into account that replacement of OH anions in the polymeric anion exchanger by other anions increases its stability, we tested for chemical and thermal stability the anion exchangers in the OH form. The chemical and thermal stability of resins prepared by polymerization for 4 h in the presence of H_2O_2 exceeds that of the polymers prepared without H_2O_2. We believe that enhanced thermal stability of anion exchangers prepared in this work as compared to that of commercial anion exchangers (EDE-10P, AV-17 and AN-31) is caused by more regular structure of AGE–PEI resins and uniformity of functional groups in them. We found that AGE–PEI anion exchanger is less stable against aqueous acids, alkalis, and oxidants than AGE–PMVP resin, apparently owing to the presence of the aromatic ring in the PMVP molecule.

The basicity of particular amino groups in anion exchangers was determined by potentiometric titration. The pK_a values of ionic groups of the anion exchangers and the empirical coefficients *m* were determined graphically (Figs. 1, 2). It is known [11] that low and medium-basic anion exchangers exhibit the highest complexing power. Therefore, the content of particular amino groups of different basicity was determined by titration of separate weighed samples of anion exchanger in aqueous supporting electrolyte.

Since anion exchangers under consideration contain secondary and tertiary amino groups, they are polyfunctional resins. However, due to small difference in pK_a of particular amino groups, there is only one inflection point in the potentiometic titration curve, which reflects the total content of functional groups in the resin.

The pK_a values of the functional groups of the resins were calculated from the potentiometric titration curve by the Henderson–Hasselbach method [12]. The factor *m* (empirical coefficient reflecting interunit interactions in polymeric chain) was calculated graphically. The *m* and pK_a values obtained in this work are given below:

Anion exchanger	*m*	pK_a
AGE–PEI	1.9	5.3
AGE–PMVP	2.2	4.9

The pK_a values calculated by us are fairly well consistent with the published data [13]. Considerably

1.0 : 2.5	0.1	6.1	4.8	4.3
3.0 : 1.0	0.1	3.6	0.7	0.5
1.0 : 2.5	–	2.3	0.8	0.5
AGE–PMVP				
1.0 : 1.0	0.1	4.3	2.5	2.2
2.0 : 1.0	0.1	3.1	1.6	1.2
1.0 : 2.0	–	2.2	0.8	0.6

decreased basicity of AGE–PEI and AGE–PMVP anion exchangers in comparison with the basicity of the corresponding initial polyamines is apparently due to increased degree of substitution at the nitrogen atom, i.e., increased content of the secondary and tertiary amino and substituted pyridinium groups in the polymers.

As seen from Table 6, AGE–PEI and AGE–PMVP anion exchangers have fairly high sorption capacity for transition metals (Table 6). These data show that anion exchangers prepared by us are promising sorbents for recovery of transition metals from wastewater from hydrometallurgical plants.

CONCLUSIONS

(1) The sorption characteristics and stability of polyfunctional anion exchangers prepared by copolymerization of allyl glycidyl ether and polyamines are dependent on their ratio in the initial reagent mixture, polymerization time, and temperature. The anion exchangers prepared in the presence of hydrogen peroxide as promoter have improved characteristics.

(2) The use of allyl glycidyl ether allows preparation of three-dimensionally cross-linked highly permeable polymeric sorbents suitable for use in hydrometallurgical production.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Flocculation Activity (with Respect to Ocher) of Anionic Copolymers of Acrylamide in the Mode of Restricted Sedimentation as Influenced by Their Chemical Heterogeneity

V. A. Myagchenkov and V. E. Proskurina

Kazan State Technological University, Kazan, Tatarstan, Russia

Received October 22, 2003

Abstract—The kinetics of sedimentation of an aqueous ocher suspension in the presence of ionic (anionic) acrylamide copolymers in the mode of restricted sedimentation was studied; the effect of composition and of the composition polydispersity of the copolymer on the flocculation activity with respect to ocher was evaluated.

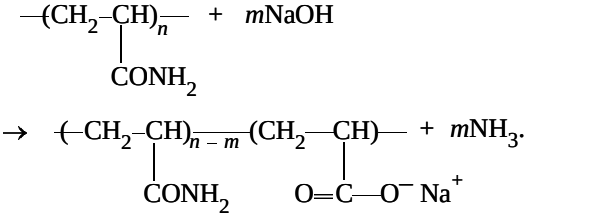
Search for practicable and effective ways for direct control of the aggregation and sedimentation stability of disperse systems is of particular interest in many branches of national economy [1]. In this connection, synthetic or natural macromolecular compounds being added in small amounts and acting as flocculants or stabilizers of a disperse system [2, 3] show much promise. The direction (decrease or increase in the sedimentation stability of the system) and magnitude of the resultant effect in addition of polymeric compounds depend on numerous parameters of the dispersion medium, dispersed phase, (co)polymer-flocculant, and process characteristics [4]. Ionic and nonionic copolymers of acrylamide find wide use as flocculants thanks to their high performance and availability.

Proceeding with systematic studies aimed to improve the flocculation parameters of this promising class of water-soluble copolymers, we examined in this paper the sedimentation stability of concentrated ocher solutions as influenced by the concentration, composition, and chemical heterogeneity of random copolymers of acrylamide and sodium acrylate. Available data on the effect of copolymer composition polydispersity on the flocculation characteristics of model and real disperse systems are scarce [4].

EXPERIMENTAL

In our work we used an ocher suspension ["golden" brand, TU (Technical Specifications) 301-10-019–90] with the average particle radius $R = 9.25 \times 10^{-6}$ m. The sedimentation kinetics of the 10% ocher suspension in the mode of restricted sedimentation in the presence of polymeric additives was studied in 100-ml cylinders by the shift of the boundary between the clarified and unclarified fractions of the suspension. The samples of acrylamide anionic copolymers were prepared by base hydrolysis (NaOH) of the initial polyacrylamide (hydrolysis degree α = 1.5% and molecular weight $\overline{M}_\eta = 7.4 \times 10^6$) under mild conditions. Hydrolysis was performed at 35°C for 180 min using 0.5% polymer solution; a total of seven different copolymer samples were obtained.

The simplified scheme of base hydrolysis of polyacrylamide can be presented as follows:



The degree of hydrolysis α was calculated from Eq. (1):

$$\alpha = \frac{7.1(V - V_0)N}{0.01cq - 0.023(V - V_0)N}, \qquad (1)$$

where V and V_0 are the volumes of NaOH solution in the working and blank tests (cm^3), N is the molarity of the alkali solution (M), c is the concentration of the copolymer (wt %), and q is the volume of the copolymer solution sample (cm^3).

The potentiometric measurements were carried out

on an I120-M digital pH-meter. The viscosity of the aqueous solutions of acrylamide anionic copolymers was measured on an Ubbelohde viscometer (0.56 mm capillary diameter). The correction for the kinetic flow energy was lower than 2% and was neglected in the calculations of the reduced viscosity η_{sp}/c.

In general case, in preparation of copolymers by polymerization or polycondensation, the products at final stages of conversion are nonuniform in molecular weight and composition of macromolecules [5–7]. Data for a wide range of carbon- and heterochain copolymers show that the main properties (including flocculation parameters) of copolymers and composites based them depend on both the molecular weight *M* and degree of hydrolysis α [4, 5]. The dependence of the flocculation properties on the copolymer composition α becomes more pronounced with increasing difference in the properties of the repeating units in the copolymer macromolecules, in particular, on passing from nonionic to ionic acrylamide copolymers [4]. As seen, all the seven samples studied strongly differ in α (from 1.5 to 63.7%) and in the properties of the repeating units in the copolymer macromolecules: from nonionic (acrylamide) to ionic (acrylate). These two factors obviously caused more pronounced dependence of the flocculation activity on the composition and on the composition polydispersity of acrylamide copolymers and formulations based on them. The dependence of the flocculation effect *D* on *M* and α was observed in a series of model and real dispersed systems based on anionic copolymers of acrylamide and sodium acrylate. This suggests that the correct dependences $D = f(M)$ can be obtained in the experiments at constant α, and vice versa, $D = f(\alpha)$, at constant *M*. Fulfillment of the latter condition for acrylamide anionic copolymers ("warranted" by the mild hydrolysis conditions) was confirmed by the data on the viscosity of the samples in question using constants *K* and *a* in the Staudinger–Mark–Houwink equation tabulated for various α [8]:

$$[\eta] = KM^a. \quad (2)$$

To evaluate the effect of the copolymer composition on the flocculation parameters, we first studied the kinetics of the ocher sedimentation as influenced by concentration and composition of polymeric flocculants. For example, the kinetic data registered for acrylamide copolymer samples with minimal and maximal α are shown in Fig. 1. From these kinetic curves, we calculated the flocculation effect *D*:

$$D = \bar{v}/\bar{v}_0 - 1, \quad (3)$$

where $\bar{v}$ and $\bar{v}_0$ are the average rates of the ocher sedimentation to the clarification ratio $Q = 0.5$ in the presence of polymer flocculant (concentration *c*) and without it, respectively.

When comparing the flocculation properties of copolymers with various *c* and α, it is advisable to use not the parameter *D*, but the flocculation activity λ [4]:

$$\lambda = (\bar{v}/\bar{v}_0 - 1)c^{-1}. \quad (4)$$

The selected data on the concentration dependences of the flocculation activity of three samples of hydrolyzed polyacrylamide with different α are shown in Fig. 2. The maximum in the $\lambda = f(c)$ curve is indicative, on the one hand, of certain deficiency of the polymeric component in the course of formation of

three-dimensional aggregates at small concentrations $c < c_{max}$, and, on the other hand, of certain trend to stabilization on addition of new portions of the copolymer at its relatively high concentrations ($c > c_{max}$). In terms of the modern concepts of the flocculation by the bridging mechanism [3], appearance of a maximum in the dependences of the flocculation activity on the concentration α of ionic groups in the copolymer macromolecule (Fig. 2, curves *1–3*) is quite natural, especially taking into account significant differences in the macroscopic processes of adsorption of the ionic and nonionic fragments of acrylamide copolymer macromolecules [9].

The generalized dependences of the flocculation activity of acrylamide copolymers as influenced by their composition for three test series (with fixed c) are shown in Fig. 3. As seen, the experimental dependences $\lambda = f(\alpha)$ have well-defined maxima. Analysis of experimental data show that changes in the molecular parameters of the flocculant samples of various composition produce no problems. The maxima in the $D = f(\alpha)$ and $\lambda = f(\alpha)$ dependences at flocculation with ionic copolymers of acrylamide in a series of real and model disperse systems were revealed previously in [4]. The nonmonotonic dependences of λ on the composition of macromolecules of anionic acrylamide copolymers are not unambiguously due to the specific features of macroscopic processes of adsorption and formation of structural elements (aggregates) from dispersed particles and copolymer macromolecules [3, 10–12]. Obviously, the conformation of macromolecules noticeably affects the $\lambda = f(\alpha)$ dependences, especially taking into account that the concentration of the ionic units in the copolymer macromolecules was varied in a wide range. This is also confirmed by the pronounced maxima in the dependences of the viscosity numbers η_{sp}/c [and thus of the root-mean-square size of the macromolecule globules $(\bar{R}^2)^{0,5}$] on the degree of hydrolysis α (Fig. 4). We should note that the quantities η_{sp}/c and $(\bar{R}^2)^{0,5}$ vary in similar direction [13].

The maxima in the dependences $\lambda = f(\alpha)$ (Fig. 3) and $\eta_{sp}/c = f(\alpha)$ (Fig. 4) and complex mechanism of macroscopic processes of adsorption and flocculation suggest the possibility that the flocculation properties of the systems in question can also depend on the composition polydispersion of anionic acrylamide copolymers. The copolymer samples with various composition polydispersion were prepared using several standard samples with fixed α (the average composition $\bar{\alpha}$ being constant 14]).

For example, for the simplest binary composition

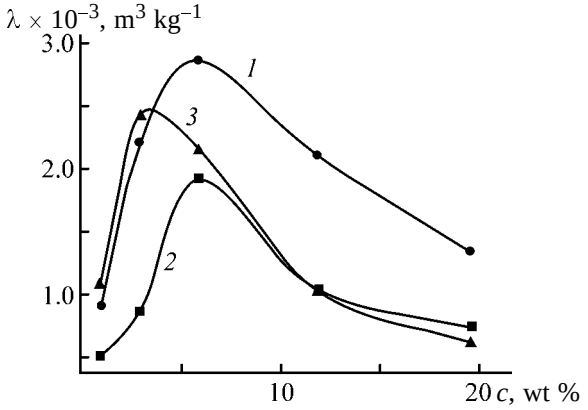

Fig. 2. Flocculation activity λ as a function of the copolymer concentration c. α (%): (*1*) 36.2, (*2*) 47.93, and (*3*) 63.7.

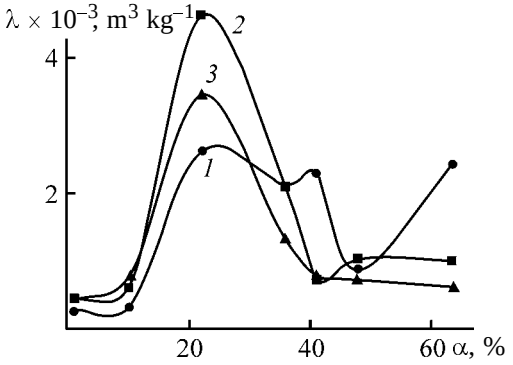

Fig. 3. Flocculation activity λ as a function of the composition of acrylamide copolymers with sodium acrylate α. $c \times 10^4$ (wt %): (*1*) 2.99, (*2*) 11.9, and (*3*) 19.6.

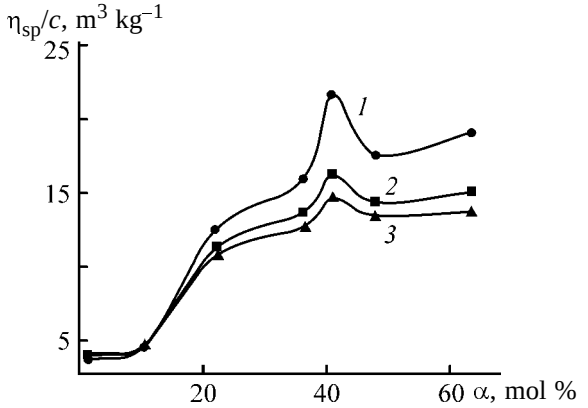

Fig. 4. Viscosity number η_{sp}/c of copolymers as influenced by the copolymer composition α. c (kg m^{-3}): (*1*) 0.4, (*2*) 0.2, and (*3*) 0.1.

with $\bar{\alpha} = \alpha_a$, the weight fraction of the reference sample w_1 with a small degree of hydrolysis $\alpha_1 < \alpha_a$ was calculated from the following expression:

$$\alpha_a = w_1\alpha_1 + (1 - w_1)\alpha_2, \quad (5)$$

where α_2 is the degree of hydrolysis of the reference

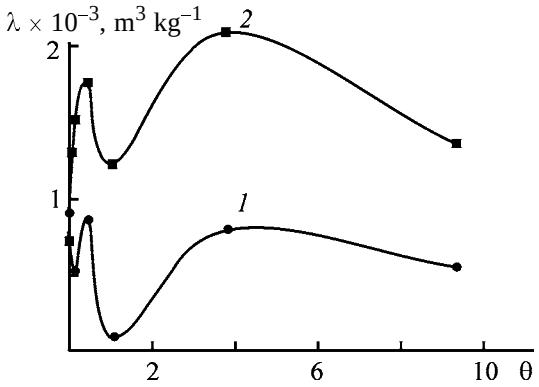

Fig. 5. Flocculation activity λ as a function of parameter θ in the presence of mixed acrylamide copolymers with $\bar{\alpha}$ = 41.02 mol %. $c \times 10^4$ (wt %): (*1*) 0.999 and (*2*) 11.9.

sample with a high degree of hydrolysis (obviously, $\alpha_2 > \alpha_a$).

The criterion θ was used to characterize the chemical heterogeneity of the mixed systems:

$$\theta = \sum_{i=1}^{k} w_i \alpha_i \sum_{i=1}^{k} w_i/\alpha_i - 1, \qquad (6)$$

where α_i and w_i are the degree of hydrolysis and weight fraction of the *i*th reference sample in the mixture and *k* is the number of the reference components in the mixture.

As seen from expression (6), θ parameter is essentially similar to the composition dispersion of copolymers [15, 16] often used for quantitative evaluation of the chemical heterogeneity of copolymers.

For mixed copolymers with $\bar{\alpha}$ = 41.02% ($\overline{M}$ being constant), Fig. 5 shows the dependence of the flocculation activity with respect to ocher as influenced by the chemical heterogeneity of the hydrolyzed polyacrylamide copolymers. Based on general considerations, we believe that the effect of chemical heterogeneity of the ionic copolymers of acrylamide on the flocculation parameters of the system will be more pronounced with complication of the disperse system [e.g., on passing from the model (ocher) to the real systems] and dispersion medium.

CONCLUSIONS

(1) Seven samples of ionic (anionic) acrylamide copolymer with identical molecular weights *M* and *M* polydispersity, but different compositions were prepared by hydrolysis of polyacrylamide under mild conditions using sodium hydroxide.

(2) The effect of composition and of the composition polydispersity of anionic acrylamide copolymers of constant molecular weight on the flocculation activity with respect to ocher was analyzed. The extrema in these dependences are largely due to the conformation state of copolymer macromolecules in the dispersion medium.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Acidity and Uranyl Nitrate Concentration on the Efficiency of Recovery of Uranium(VI) from Aqueous Solutions with Hydrolytic Wood Lignin

N. G. Rachkova, I. I. Shuktomova, and A. I. Taskaev

Institute of Biology, Komi Scientific Center, Ural Division, Russian Academy of Sciences, Syktyvkar, Komi Republic, Russia

Received August 18, 2003

Abstract—The efficiency of recovery of uranium(VI) from aqueous solutions with hydrolytic lignin and strength of binding of uranium to lignin were studied in relation to the uranium concentration and acidity. The mechanisms of sorption of uranium were analyzed by the methods of sequential leaching of uranium from lignin and IR spectroscopy.

In recent years it was repeatedly reported that hydrolytic lignin efficiently sorbs lead, zinc, and copper [1–4]. The possibility of using hydrolytic lignin for decontamination of aqueous solutions from natural heavy radionuclides was analyzed in [5–7]. These works show that hydrolytic lignin is a promising material for this purpose. For example, it was found [6] that hydrolytic lignin prepared from coniferous wood practically completely recovers uranium(VI) from 1×10^{-2} g l^{-1} aqueous $UO_2(NO_3)_2$. The high affinity of lignin for uranium(VI) is manifested in formation of very stable chelates between uranium(VI) and products of lignin humification [8]. Taking into account the availability of hydrolytic lignin and the fact that lignin is a precursor of humus substances in soils, recovery of uranium with lignin from aqueous media of different composition, among them from soil solutions, deserves attention. The urgency of this problem increases due to growing contamination of environment with natural radionuclides.

In this work we studied recovery of uranium(VI) with hydrolytic wood lignin from aqueous solutions as influenced by acidity and uranium concentration.

EXPERIMENTAL

In our experiments we used fractions of hydrolytic lignin with granule size of 0.25–0.5 mm. The content of Komarov's lignin in these samples was 82.5%, and their ash residue was 6%. The sorption of uranium(VI) was studied under static conditions at room temperature. The acidity of the initial uranium aqueous solutions was adjusted by adding concentrated (13 M) aqueous $NH_3 \cdot H_2O$. The pH was measured on an Inolab pH Level I pH meter (Wissenschaftlich–Technische Werkstatten GmbH, Germany). Before contact with uranium(VI)-containing aqueous solution, the samples of hydrolytic lignin were kept in distilled water for a day. This procedure facilitates access of lignin sorbent sites for uranium. To ensure high specific surface area of the sorbent, we used the fractions of lignin of small size. After contact of lignin with uranium-containing aqueous solution, lignin was separated from solution by filtration, and uranium concentration in the liquid phase was determined. The sorption capacity of lignin, the uranium distribution coefficient, and the degree of uranium recovery were determined by the difference between the uranium concentrations in the liquid phase before and after contact with lignin. Saturation of lignin with uranium was reached by its repeated contact with uranium-containing solution. In order to determine the strength of uranium association with lignin, its sample saturated with uranium was separated from aqueous solution and sequentially treated with different leaching solutions: distilled water (water-soluble uranium species), 1 M aqueous CH_3COONH_4 (exchangeable uranium species), and HCl (acid-soluble species). This leaching technique, widely used in soil science, allows isolation of relatively uniform fractions of uranium species associated with lignin by particular mechanisms and bound to lignin with a certain strength.

The IR spectra of hydrolytic lignin saturated with

Degree of recovery of uranium(VI) with hydrolytic lignin α from aqueous solution as function of pH. U(VI) concentration (mg ml^{-1}): (*1*) 0.1 and (*2*) 0.01.

uranium (VI) were recorded in the range 400–4000 cm^{-1} on a Specord M-80 IR spectrometer (KBr pellets). The quantitative calculation of the relative optical density was carried out by the baseline method. The band at 1518 cm^{-1} was used as the internal reference. The uranium content was determined by luminescent technique [9]. The HCO_3^- content was determined by the back-titration [10].

The efficiency of metal sorption on proton-exchange sorbents is a function of acidity of the aqueous phase. In sorption of heavy natural radionuclides on hydrolytic lignin, the sorption is complicated by hydrolysis of these radionuclides. It is known that uranium(VI) is present in the form of UO_2^{2+} cations only in acid solutions free of complexing agents. At low acidity, uranium(VI) forms several coexisting mononuclear and polymeric (among them colloid) hydrolyzed species [5, 11–15]. In neutral and alkaline carbonate-containing media, stable uranyl carbonate anionic complexes are formed. When the carbonate concentration exceeds $n \times 10^{-3}$ M, the hydrolysis of uranium(VI) is completely suppressed by formation of uranyl carbonate complexes [16]. Another reason hindering the sorption of uranium on lignin is the competitive uranium complexation with fulvic and humic acids always present in lignin in sufficiently large amount [17]. It is known that approximately one fifth of organic carbon of hydrolytic lignin belongs to humus substances present in lignin. Therefore, recovery of uranium from aqueous solution with hydrolytic lignin to some extents models the recovery of uranuim from soil solutions containing humus acids.

Our experiments showed (see figure) that from 59 to 93% of uranium is recovered with hydrolytic lignin from neutral and alkaline solutions containing 0.1 and 0.01 mg ml^{-1} U. In acid solutions (pH < 5), the degree of recovery of uranium does not exceed 29%. We believe that the decrease in uranium recovery is caused by suppression of ionization of the acid ion-exchange groups in lignin. Therefore, in sorption of uranium from acidic media, the fraction of its exchangeable species considerably decreases (see table).

Another reason for decreased uranium recovery from acidic solutions is specific behavior of fulvic acids in the systems under consideration. On the contact of lignin with acidic uranium-containing aqueous solution, the fulvic acids associated with lignin pass into the aqueous phase. Since fulvic acids do not form complexes with uranium in acid solutions [18–22], their liberation from lignin does not affect the recovery of uranium with lignin. However, fulvic acids liberated from lignin can be repeatedly sorbed on the lignin surface. As a result, the sorption centers of lignin get shielded with fulvic acid molecules, and uranium sorption on lignin becomes suppressed.

To elucidate how uranium(VI) carbonate complexes formed in the presence of atmospheric CO_2 influence the recovery of uranium(VI) with lignin, the uranium(VI)-containing aqueous solutions were kept in air for 24 h before introduction of lignin. We found that, under these conditions, the CO_2 concentration in aqueous solutions was 1.6, 1.7, and 2.6 mM at pH 7, 8 and 9, respectively. The equilibrium concentrations of CO_3^{2-} and HCO_3^- calculated by common methods do not exceed $n \times 10^{-3}$ M. These results showed that, under our experimental conditions, the contribution of uranium(VI) carbonate complexes is very small, and hydrolyzed uranium species prevail [16]. Therefore, in further analysis of uranium(VI) recovery with lignin, the contribution of uranium carbonate complexes was not taken into account.

With increasing pH, the content of soluble hydrolyzed uranium species [$UO_2(OH)^+$, $(UO_2)_3(OH)_5^+$, $(UO_2)_3(OH)_4^{2+}$, $(UO_2)_4(OH)_7^+$] and $UO_2(OH)_2$ sol increases. All these species exhibit enhanced sorbability on lignin. With increasing pH, ionization of both the carboxy and phenolic hydroxy groups of lignin and humus acids associated with it increases and, as a result, sorption of uranium on lignin by ion-exchange mechanism is enhanced. Due to ion-exchange sorption, the aqueous phase is acidified, and the content of the exchangeable uranium species associated with lignin increases to 19%.

We found that, at pH within 5–8, the fraction of uranium species strongly bound to lignin increases. This effect can be caused by formation of stable uranium(VI) complexes with humus acids entering into the composition of lignin. Among these species,

Influence of acidity and uranyl nitrate concentration on efficiency of uranium(VI) recovery from aqueous solutions with hydrolytic lignin (lignin to aqueous phase ratio 1 : 20)

poorly soluble stable compounds can be formed [8, 19–22, 24]. Beyond the above-noted pH range, the total recovery of uranium and its fraction strongly bound to lignin slightly decrease.

Our experiments showed that recovery of uranium with lignin is dependent on uranium concentration in the aqueous phase. At low uranium concentrations, the pH range of optimal recovery of uranium is shifted to alkaline region, the sorption curve flattens, and the uranium fraction strongly bound to lignin substantially increases. These results are consistent with the well-known effect of dilution of aqueous solution on the behavior of hydrolyzable metals. According to this effect, we can expect that, in dilution of uranium solution, the hydrolysis of uranium is facilitated, its hydrolyzed species are stabilized in solution, and deposition of $UO_2(OH)_2$ sol on the lignin surface is hindered. It is known that hydrolyzable metals form the most stable complexes with natural organic compounds in the range of formation of hydrolyzed metal species [5, 25].

To elucidate the mechanism of uranium recovery with hydrolytic lignin, we studied its IR spectra before and after saturation with uranium. On saturation of lignin with uranium from aqueous uranyl nitrate (0.1 mg l^{-1}) at pH 6, the intensity of the absorption band of the stretching vibrations of the carboxy groups at 1716 cm^{-1} decreases. The absorption band at 1600 cm^{-1} becomes 21% more intense and is shifted, presumably due to structural changes in the phenolic fragments of lignin macromolecule. The broadening of the band of the OH stretching vibrations with 8% change in its asymmetry index suggests that more kinds of hydrogen bonds are formed. The formation of the carboxylate groups is manifested as a new absorption band at 1390 cm^{-1}. Thus, our spectroscopic data show that one of the main mechanisms of recovery of uranium with lignin is substitution of protons of carboxy and phenolic groups by uranim-containing cations. Therefore, in recovering uranium with lignin, the aqueous phase is acidified.

CONCLUSIONS

(1) Hydrolytic lignin efficiently recovers uranium(VI) from weakly acidic and alkaline solutions.

(2) The IR spectra of hydrolytic lignin saturated with uranium and the data on uranium speciation obtained by sequential leaching show that lignin recovers uranium from aqueous solutions not only by the mechanism of ion exchange of uranium(VI)-containing cationic species for acid protons of carboxy and phenolic groups of lignin and humus acids as-

sociated with them, but also by donor–acceptor interaction of lignin oxygen atoms with uranyl ions.

(3) Hydrolytic lignin recovers uranium(VI) most efficiently from weakly acidic and neutral solutions. Under these conditions, uranium is recovered by various mechanisms: ion exchange of uranim(VI)-containing cationic species for protons of carboxy and phenolic groups, sorption of $UO_2(OH)_2$ sol on the lignin surface, and formation of insoluble uranium(VI) compounds with humus acids entering into the lignin composition.

(4) In dilution of uranium solution, the pH of optimal recovery of uranium is shifted to alkaline range and the fraction of uranium(VI) species strongly bound to lignin substantially increases.

Abstract—Complexation of iron(III), aluminum(III), and chromium(III) cations with monocarboxy cellulose was studied by potentiometric titration and IR spectroscopy. The composition and stability constants of the complexes were determined.

Monocarboxy cellulose is used as a suture material in surgery and as a sorbent of heavy metals. Therefore, the study of reactions of metal ions with functional groups of monocarboxy cellulose and determination of factors affecting the metal sorption on monocarboxy cellulose are of both scientific and practical interest.

Cellulose containing hydroxy and carboxy groups is prepared by oxidation with nitrogen(IV) oxide. Oxidized cellulose selectively sorbs some multicharged metal cations which behave as cross-linkers [1, 2].

In this work we studied complexation of Al^{3+}, Cr^{3+}, and Fe^{3+} with monocarboxy cellulose (MCC). No data are available on the stability of complexes of these metals with functional groups of MCC.

EXPERIMENTAL

The mechanism of sorption of the multicharged cations on MCC was studied by potentiometric titration in the presence and in the absence of the metal and by IR spectroscopy.

We used oxidized viscose cord threads (184 tex) and cotton threads (100 tex) containing from 0.4 to 1.4 mmol g^{-1} of carboxy groups in the H form. The threads were prepared by treatment with 5 or 10% solutions of nitrogen(IV) oxide in tetrachloromethane for 7 h [3]. Some physicochemical properties of the samples are summarized in Table 1.

The procedure for calculating the stability constants and the experimental procedure are described in [4, 5].

The MCC samples were titrated under static conditions. The ionic strength was kept constant (0.5) by adding Na_2SO_4 and NaCl to the solutions of metal sulfates and metal chlorides, respectively. The total solution volume was 40 ml; the sample weight was 0.3 g. After the equilibrium was attained (24 h), pH of the solution and the metal concentration in the sorbent were determined.

To analyze the cellulose samples for Al^{3+}, Cr^{3+}, and Fe^{3+}, they were dissolved in H_2SO_4 solution containing H_2O_2. The content of these metals in the resulting solution was determined, respectively, by complexometric titration with Dithizone indicator, chromatometric titration, and colorimetry in the presence of sulfosalicylic acid [6].

The procedure for preparing KBr pellets of cellulose samples was described in [7]. The IR spectra were recorded on a Specord 75-IR spectrophotometer.

The OH bands in the range 3000–3700 cm^{-1} were characterized by the following parameters: ν_{OH}, frequency of the absorption maximum; a/b, symmetry index equal to the ratio of the right (a) and the left (b) parts of the band at the half-maximum [8, 9].

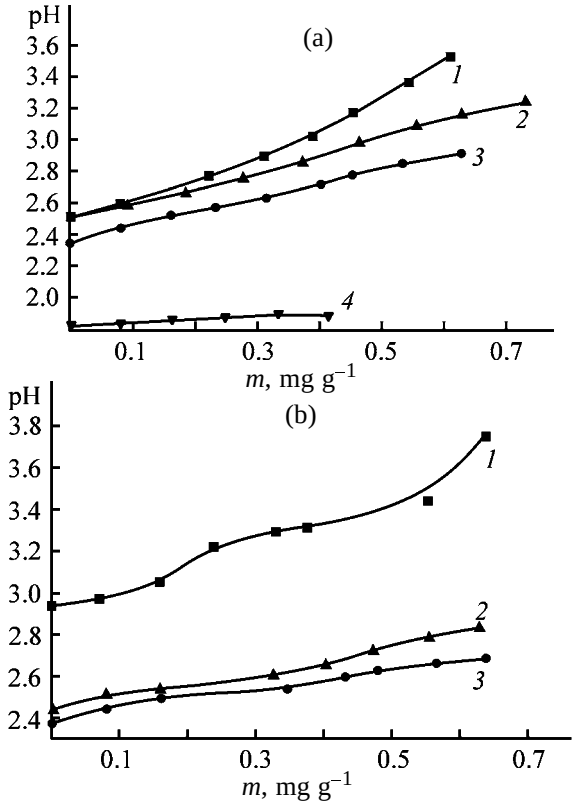

Fig. 1. Potentiometric titration curves of MCC (EC_{COOH} = 0.8 mmol g^{-1}) (*1*) in the absence of triple-charged cations and in the presence of (*2*) Al^{3+}, (*3*) Cr^{3+}, and (*4*) Fe^{3+} cations. Ionic strength I = 0.5 was produced by (a) hydrochloric acid and (b) sulfuric acid solutions of the metals(III) and sodium. (*m*) NaOH amount.

Sorption of Al^{3+}, Cr^{3+}, and Fe^{3+} cations on the cellulose cation exchanger is caused by both electrostatic attraction and formation of strong donor–acceptor bonds.

Formation of MCC–M^{3+} intrapolymeric complex can be described by the following equilibrium:

$$n\overline{\text{celCOOH}} + M^{3+} \rightleftarrows \overline{[(\text{celCOO})_nM]^{(3-n)}} + n^+H^+,$$

where M^{3+} is the metal cation; n is the mean content of carboxy groups coordinated to one metal cation.

The concentration equilibrium constant K of complexation is related to the stability constant of the complex in the sorbent phase K_{st}:

$$K = \frac{\bar{c}_M(H^+)^n}{c_M\overline{(COO^-)^n}} = K_{st}(H^+)^n.$$

To calculate these constants, n should be determined by the equation

$$n = \frac{EC - [COOH] - [COO^-]}{\bar{c}_M},$$

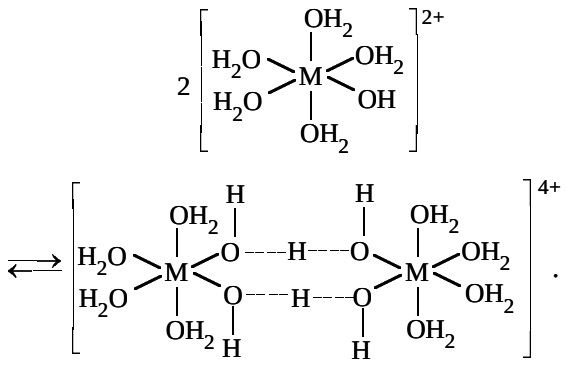
where EC is the exchange capacity of the cation exchanger (mmol g^{-1}); [COOH] and [COO$^-$] are the concentration of protonated and deprotonated (coordination-active) carboxy groups (mmol g^{-1}), respectively; $\bar{c}_M$ is the metal concentration in the sorbent phase (mmol g^{-1}).

The pontiometric titration curves of MCC taken in the presence of Al^{3+}, Cr^{3+}, and Fe^{3+} cations are shown in Figs. 1a and 1b. The solubility of iron sulfate was insufficient to construct the curve of MCC titration in the presence of this salt. Furthermore, the potentiometric titration curves were measured only in acidic solution (Fig. 1), since at higher pH metal hydroxides precipitated. Based on the results obtained, the relative stability of MCC–M^{3+} complexes can be ranked in the following order: $Fe^{3+} > Cr^{3+} > Al^{3+}$. It should be noted that more stable chromium and aluminum complexes with MCC are formed when these metals are sorbed from sulfuric acid solutions.

This may be due to the fact that the composition of Al^{3+} and Cr^{3+} complexes substantially depends on the nature of anions of their salts, all other conditions being the same [10–13]. It is known [13] that these metal cations form aqua complexes in aqueous solutions, which hydrolyze with increasing pH.

$$[M(H_2O)_6]^{3+} \rightleftarrows [M(H_2O)_5OH^-]^{2+} + H^+.$$

The hydroxo complexes can condense to form polynuclear species.



Unlike $CrCl_3$ solution, positively charged hydroxosulfate complexes are formed along with hydroxocomplexes in equilibrium $Cr_2(SO_4)_3$ solution [12].

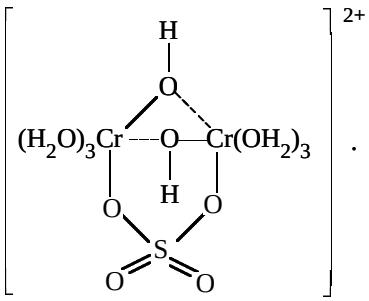
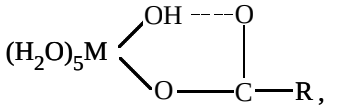
* K_1 and K_2 are the stability constants of complexes with the composition M : COO^- = 1 : 1 and 1 : 2, respectively.



Hence, higher selectivity in sorption of Al^{3+} and Cr^{3+} cations on MCC from sulfuric acid solutions, as compared to the sorption from hydrochloric acid solutions, may be due to different absorption energy of the aqua, hydroxo, and polynuclear complexes whose relative content depends on the anion.

The composition and stability constants of the complexes were calculated from the results of potentiometric titration (Table 2). Complexes with the composition M(III) : COO^- = 1 : 2 are mainly formed in the Fe(III)–MCC and Cr(III)–MCC systems at pH of equilibrium solutions $pH_{eq} \le 1.98$ and $pH_{eq} \le 2.50$, respectively. Aluminum cation ($pH_{eq} \le 2.51$; $pH_{in} \le 3.60$) mainly coordinates a single carboxy group. Determination of the composition of the intrapolymeric complexes at higher pH failed owing to substantial influence of the hydrolysis and polycondensation on the equilibrium. The stability constants in a wider pH range can be calculated assuming that their composition in the sorbent phase remains the same [13, 14].

As seen from Table 2, the stability of M(III)–MCC complexes depends on the pH of the solution. This is due to the fact that the fraction of stable six-membered rings



(where R is cellulose residue) formed by the hydroxo complexes in the sorbent phase increases with pH.

The calculated stability constants of the polymeric complexes at pH_{eq} from 1.98 to 2.51 are as follows:

pK_2	System	EC, mol g^{-1}	pH
7.0	$FeCl_3$–MCC	1.4	1.98
4.8	$Cr_2(SO_4)_3$–MCC	0.7	2.50
1.9	$CrCl_3$–MCC	0.7	2.50
2.8(pK_1)	$Al_2(SO_4)_3$–MCC	0.7	2.51

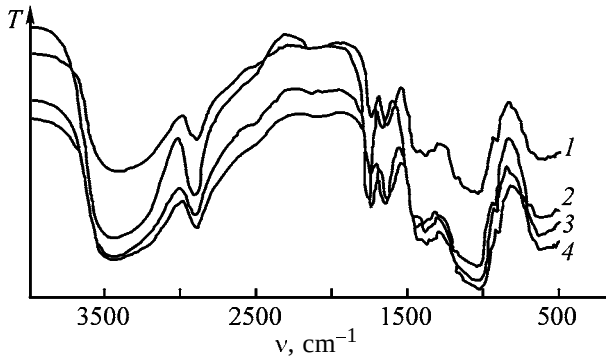


Fig. 2. IR spectra of (*1*) MCC (EC_{COOH} = 0.7 mmol g^{-1}), and its complexes (*2*) Fe^{3+}–MCC (c_{Fe} = 0.34 mmol g^{-1}), (*3*) Al^{3+}–MCC (c_{Al} = 0.50 mmol g^{-1}), and Cr^{3+}–MCC (c_{Cr} = 0.41 mmol g^{-1}). (ν) Wave number and (*T*) transmission; the same for Fig. 3.

Al^{3+}	0.50	3440	0.45
MCC (EC = 1.4 mmol g^{-1}) viscose fiber			
H^+	–	3350	0.88
Cr^{3+}	0.11	3395	0.80
Fe^{3+}	0.42	3425	0.61

To confirm the proposed composition of Fe(III)–MCC intramolecular complex, let us consider complexation of Fe^{3+} cations with dicarboxylic acids. The pK_2 of $FeOx^+$ complexes formed in the Fe(III)–oxalic acid (H_2Ox) system is 7.54 (the hydrolytic equilibrium was not considered). At the same time, the stability constants of Cr^{3+} complexes with anions of malonic, succinic, and phthalic acids [Cr(III) : L = 1 : 2] are 12.85, 10.99, and 10.00 [15] (pH of the solution was not reported).

The IR spectra of Cr(III)–MCC and Al(III)–MCC complexes isolated form sulfuric acid solutions and those of Fe(III)–MCC complexes isolated from hydrochloric acid solutions are shown in Figs. 2 and 3, respectively. The intensity of the band at 1720 cm^{-1} decreases and that of the band at 1610 cm^{-1} increases after treatment of MCC with the metal salt. The appearance of absorption in the ranges 1610–1550 and 1450–1350 cm^{-1} with simultaneous weakening of the C=O band at 1750–1720 cm^{-1} was believed [1, 7] to be due to the ion-exchange reaction. However, as the metal content in the MCC increases, the intensity of the absorption with the main maximum at 1610 cm^{-1} grows, but the intensity of the $\nu_{C=O}$ band at 1720 cm^{-1} does not decrease. This trend is the most pronounced in the IR spectra of Cr–MCC complexes (Fig. 3).

As the Cr^{3+} content in the samples increases by a factor of 2, the intensity of the band at 1610 cm^{-1} increases, whereas the intensity of the band at 1720 cm^{-1} decreases negligibly. These results confirm our assumption that the OH group of the coordinated metal hydroxo complexes forms hydrogen bonds with carboxy group of MCC to give a stable six-membered ring.

The parameters of the OH band of MCC salts are presented in Table 3. Intramolecular bonds of MCC are partially ruptured after introduction of the metal cation into the sorbent phase. The higher the content of carboxy groups in MCC, the stronger is this effect. However, the symmetry indices and the frequencies at the maxima of bands of the OH groups forming hydrogen bonds depend mainly on the content of carboxy groups in the oxidized cellulose rather than on the nature of the sorbed metal cation.

The 40 cm^{-1} shift of the OH band to high frequencies and the decrease in the symmetry index with an increase in the content of carboxy groups of MCC indicate that the sample structure becomes not only looser but also less uniform [8, 9].

The higher the content of carboxy groups in MCC, the stronger the high-frequency shift of the OH bands

in the spectra of MCC salts. The 10–70 cm^{-1} high-frequency shift of the OH bands in the spectra of MCC salts containing more that 0.8 mmol g^{-1} carboxy groups suggests partial rupture of the H bonds in the cellulose matrix after introduction of the metal cations. At the same time, the parameters of the OH band in the spectra of MCC samples with a low content of carboxy groups (EC = 0.4 mmol g^{-1}) change insignificantly after the metal sorption, suggesting preservation of the polymer structure.

CONCLUSIONS

(1) As determined by IR spectroscopy, Al^{3+}, Cr^{3+}, and Fe^{3+} cations are sorbed on monocarboxy cellulose by ion exchange and formation of hydrogen bonds between the OH group of the hydroxo complex and carboxylate anion of the sorbent. Intramolecular bonds in monocarboxy cellulose are partially ruptured after metal sorption.

(2) The stability constants of the complexes of Al^{3+}, Cr^{3+}, and Fe^{3+} cations with monocarboxy cellulose increase with increasing pH of the solution. The stability of these complexes at pH 1.98–2.51 decreases in the following order: $Fe^{3+} > Cr^{3+} > Al^{3+}$.

Institute of Chemistry of Solutions, Ivanovo, Russia

Received July 8, 2003

Abstract—Structuring and viscosity of solutions of cellulose derivatives as influenced by mechanical treatment under high shear stresses were studied.

In exploitation and processing, polymer systems are exposed to various mechanical impacts modifying the structure of their solutions and affecting the compatibility of their components, which, in turn, affects the properties of films and coatings thereof. Prediction of such changes requires knowledge on the influence of mechanical impacts on structuring in polymer solutions.

In this work, we consider how the mechanical activation parameters affect the structure and viscosity of aqueous solutions of cellulose ethers, namely, hydroxypropyl cellulose (HOPC), methyl cellulose (MC), hydroxyethyl cellulose (HOEC), and methyl hydroxypropyl cellulose (MHPC).

EXPERIMENTAL

We studied samples of HOPC, MC, HOEC, and MHPC with the degrees of polymerization of 810, 800, 920, and 840, respectively, synthesized by Politsell Closed Joint-Stock Company (Vladimir). Double-distilled water served as solvent. The solutions were prepared by dissolving weighed portions of polymers in water under continuous stirring with a magnetic stirrer at 298 K. To attain an equilibrium, the solutions were kept for 3 days. The resulting systems were treated on a rotary-pulse installation for 1 min at the activator rotor rate w within 500–3000 rpm. This corresponded to shear strain rate varying from 0.5×10^3 to 3×10^3 s^{-1}. The viscosity of the initial and mechanically treated solutions was measured on a Rheotest 2.1 rheoviscometer (coaxial-cylinder working unit) at shear rates within 0.0167–145.8 s^{-1} at 293–318 K. Before measurements, the treated solutions were kept at rest for 4 h. The heterogeneity parameters of aqueous solutions of cellulose ethers (turbidity t_λ, disperse phase particle size r, and content of disperse particles in 1 m^3 N) were determined by the turbidity spectrum method on a Specord M-40 spectrophotometer in the wavelength range from 240 to 450 nm.

The radius of the disperse phase particles and the content of disperse particles in 1 m^3 were determined by the formulas [1]

$$r = \alpha\lambda_0/2\pi n_0, \quad (1)$$

$$N = \tau_\lambda/K_1\pi r^2, \quad (2)$$

respectively. Here, r is the disperse phase particle radius; α, relative particle size; λ_0, average wavelength in the measurement range; n_0, refractive index of the disperse phase under study; N, content of disperse particles in 1 m^3; t_λ, turbidity at the wavelength λ; and K, dissipation constant.

Figure 1 presents the log–log plots of the viscosity η vs. shear stress τ for aqueous solutions of cellulose

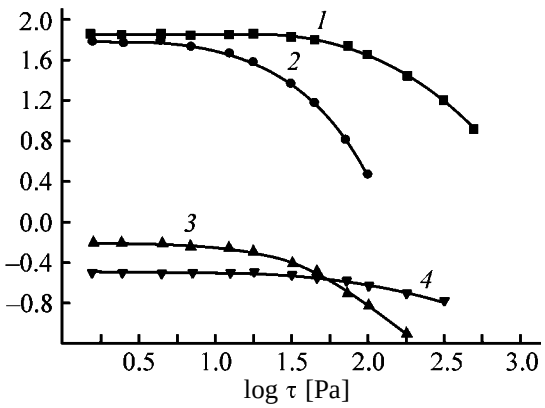

Fig. 1. Viscosity η as a function of the shear stress τ for aqueous solutions (5 wt %) of cellulose ethers at 298 K. (*1*) HOEC, (*2*) MC, (*3*) HOPC, and (*4*) MHPC.

ethers at 293 K. The systems under study are non-Newtonian liquids. The viscosities of equiconcentrated aqueous solution of cellulose ethers (Fig. 1) increase in the series MHPC < HOPC < MC < HOEC. The lowest viscosity is characteristic of aqueous solutions of MHPC which exhibit a close-to-Newtonian flow under shear stress throughout the temperature range studied. Increase in viscosity along the above-mentioned series of systems is accompanied by deterioration of the polymer affinity for the solvent. This is confirmed by increase in the structuring coefficient (from 1.07 for MHPC solutions to 1.49 for MC solutions) as calculated by the formula [2]

$$\gamma = K\tau^n, \quad (3)$$

where n is the structuring coefficient; γ, shear rate; τ, shear stress; and $K = 1$ for Newtonian liquids.

It was shown in [3–5] that the main contribution to the mechanical impacts exerted on liquid-phase systems when treated in rotary-pulse activators comes from shear stress, cavitation, and its accompanying physical and physicochemical phenomena. Figure 2 presents the plots of extremal viscosity vs. mechanical impact for the cellulose ether solutions at 298 K. It is seen that mechanical treatment strongly affects the shear viscosity of all the systems studied. Solutions of MC, MHPC, and HOPC are characterized by a maximum, η_{max}, in the plot of the viscosity vs. mechanical impact, the largest viscosity increment being observed at w = 1000 rpm. Increase in the viscosity is evidently due to unfolding of the macromolecular chains in a flow, which yields additional intermolecular hydrogen bonds in the system. This, in turn, yields a new, larger, supramolecular structure. For the HOEC–water system, the viscosity tends to sharply decrease with increasing w. The decline in viscosity is due to disturbed intermolecular interaction of the macromolecules in solution, which is responsible for conformational changes. Khailenko *et al*. [6] reported similar results for structuring in cellulose ether solutions as influenced by mechanical treatment.

The more developed structure of polymers is confirmed by the structuring coefficients calculated from the rheological data and by the microheterogeneity parameters of the solutions. The plots of the structuring coefficients n vs. the rotor rotation rate w for HOPC, MC, and MHPC (but not HOEC) exhibited a maximum near 1000 rpm (Fig. 3). This suggests that the mechanically treated cellulose ethers (1000 rpm) are liquids that surpass the initial polymers in the degree of structuring.

Table 1 lists the sizes of the supramolecular forma-

tions in aqueous solutions of cellulose ethers. For systems based on MC, MHPC, and HOPC, the largest supramolecular formations are observed at w = 1000 rpm, which agrees well with the $\eta = f(w)$ plots. In the HOEC–water system, the size of these formations tends to decrease with increasing mechanical impact.

Table 2. Viscous flow activation energy for cellulose ether solutions (5 wt %) at different rotor rotation rates

w, rpm	E_a, kJ mol^{-1}			
	MHPC	MC	HOEC	HOPC
0	30.6	25.0	63.3	22.4
1000	73.3	71.1	43.7	35.6
2000	26.4	34.0	17.2	30.6
3000	13.3	31.5	5.6	27.9

Further information about the structure of polymer solutions can be derived from the temperature dependences of the viscosity. Figure 4 shows as an example the plot of the viscosity vs. rotor rotation rate for 5 wt % MHPC solution at different temperatures. With increasing temperature, the viscosity of both the initial and mechanically activated solutions of MHPC, HOPC, and HOEC tends to decrease, suggesting a change in their degree of structuring, and the maximum in the η_{max} vs. w plot gets more flattened (Fig. 4).

Solutions of MC exhibit an opposite trend (Fig. 5), i.e., the viscosity of the system tends to increase with rising temperature. As known, heating of aqueous MC solutions results in degradation of, above all, the weakest H-bonds linking the oxygen atoms in the methoxy groups with water molecules. This enhances hydrophobic interactions (association) and changes the size and shape of the associates in solution. Further increase of temperature can result in gelation [7]. However, our experiment showed that methyl cellulose solutions within the temperature range studied, both with and without strong mechanical impact, did not form gels, as confirmed by polarization-microscopic examination.

We found that the dependence of E_a on w is nonlinear (Table 2). With rotor rotation rate w increasing to 1000 rpm, the solutions of MHPC, MC, and HOPC exhibited an increase in E_a, but E_a tended to decrease with further enhancement of the mechanical impact. The viscous flow activation energy is associated with scission of the secondary bonds or temporary contact points of the fluctuation network. Therefore, increase in the absolute value of E_a suggests formation of new, stronger, bonds. The hydrodynamic field near 1000 rpm, evidently, modifies the structural organization (shape and size of associates) of the solutions. In the case of HOEC solutions, enhancement of the mechanical impact tends to decrease E_a.

CONCLUSION

At certain shear stresses, systems based on MC, MHPC, and HOPC exhibit a maximal increase in viscosity due to increase in the size of supramolecular formations, which tends to increase the viscous flow activation energy. This pattern is not characteristic of hydroxyethyl cellulose solutions.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Thermal Treatment on the Fine Structure of Cellulose Materials

T. V. Smotrina, A. T. Kynin, and S. F. Grebennikov

Mari State Technical University, Ioshkar-Ola, Mari-El Republic, Russia
St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received March 21, 2003

Abstract—The effect of thermal treatment in the range 110–250°C on the structural and sorption characteristics of cellulose was studied by ^{1}H NMR and sorption methods.

Production of composite materials based on renewable raw materials is an urgent problem. One of the most abundant natural materials suitable for production of various items in the form of composites and in the pure state are cellulose materials, among them wastes formed in production of these materials. These materials are widely used in many branches of industry. One of the problems in production of efficient cellulose-containing composites is estimation of relaxation characteristics of macromolecules and the number of active centers in cellulose material, since precisely these characteristics govern the adhesion and ultimately consumers' characteristics of finished products.

In production of textiles and their service, the materials based on cellulose are subjected to thermal action (drying, ironing, and fixation of dyes), which can result in degradation of the polymer and, hence, deterioration of its performance. Under the action of elevated temperatures, the least ordered areas of the cellulose matrix are altered first. These variations in the amorphous component of cellulose can be significant even under the action of temperatures that do not exceed the point at which cellulose starts to actively degrade.

Despite the publications [1–3] devoted to thermal degradation of cellulose, variation of its fine structure and hydrophilic and relaxation characteristics as a result of thermal action was not studied in detail.

Here, the effect of thermal treatment on the state of amorphous areas of cellulose and its water absorption capacity was analyzed on the basis of NMR relaxation data and sorption data.

EXPERIMENTAL

For the samples of cotton cellulose heat-treated at 105, 150, and 175°C (below the point of intense thermal degradation of cellulose), the dependences of the proton spin–spin relaxation time of the sorbate T_{2d} on the equilibrium moisture content coincide within the limits of the experimental error, i.e., under these conditions the thermal treatment does not noticeably affect the structure of amorphous areas of cellulose and, hence, the mobility of sorbed water. The general shape of the dependences of T_{2d} on the moisture content shows two linear portions (Fig. 1, curves *1–3*), corresponding to fractions of firmly bound (the initial portion) and relatively weakly bound water, which is characteristic of native cellulose fibers. Further increase in the treatment temperature (200–250°C)

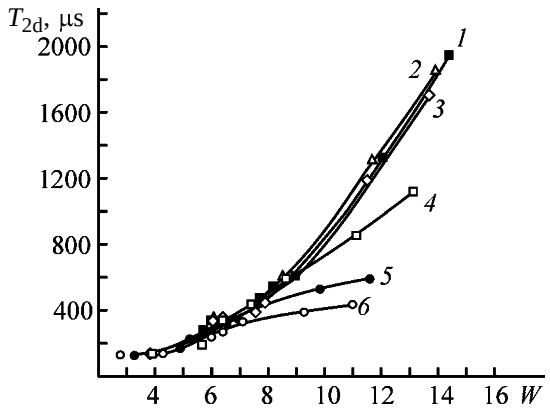

Fig. 1. Spin–spin relaxation time of water T_{2d} as a function of equilibrium moisture content W (g H_2O per 100 g cellulose) for cotton cellulose. (*1*) Initial cellulose; treatment temperature, °C: (*2*) 150, (*3*) 175, (*4*) 200, (*5*) 225, and (*6*) 250.

1070-4272/04/7703-0480 © 2004 MAIK "Nauka/Interperiodica"

results in changes in the curve shape (Fig. 1, curves *4* and *5*). Relatively stable values of spin–spin relaxation time of sorbate protons at moisture content above 5–6 wt % (up to the maximum moisture capacity from the vapor phase) suggest transformation of the cellulose structure as a result of thermal treatment. In our opinion, thermal treatment under the above conditions is favorable for formation of stable microareas with bounded geometry, hindering development of rotation mobility of water molecules with increasing moisture content of cellulose.

Above 200°C, the mobility of macromolecules increases due to devitrification of a significant fraction of the amorphous phase of the polymer, which provides favorable conditions for the mutual approach of the macromolecules and intermolecular dehydration with formation of cross-links. The presence of strong interchain bonds provides the stability of the resulting quasi-network microstructure and, hence, low mobility of sorption water even at high relative vapor pressure. The similar results were obtained for wood cellulose with the only difference that the mobility of water sorbed on wood cellulose is somewhat lower compared to cotton cellulose and stabilization of the microstructure is observed at lower temperatures, which is caused by lower thermal stability of wood cellulose in comparison with cotton cellulose.

The experimental dependences of spin–lattice relaxation time of cellulose protons T_{1c} on the equilibrium moisture content is typical for cellulose materials (Fig. 2). The position of the minimum of T_{1c} depends on the accessibility of the sorption surface for sorbate molecules and its nature. An increase in the treatment temperature results in a shift of the T_{1c} minimum toward lower W, which is caused by partial changes in the nature of relaxation centers, in particular, by formation of carboxy groups as a result of thermal oxidation [4]. The shift of the left branches of the dependences toward lower moisture content suggests an increase in the number of functional groups available in the initial stages of sorption, more pronounced at temperatures above 200°C. At treatment temperatures below 175°C, this is apparently caused by compaction of amorphous areas of cellulose due to removal of the fraction of residual water most firmly bound to the polymer and not removed in drying [5].

Additional data on variation of supramolecular and chemical structure of the cellulose samples were obtained in processing of sorption isotherms of water with the use of thermal equation of sorption (1) [5, 6]

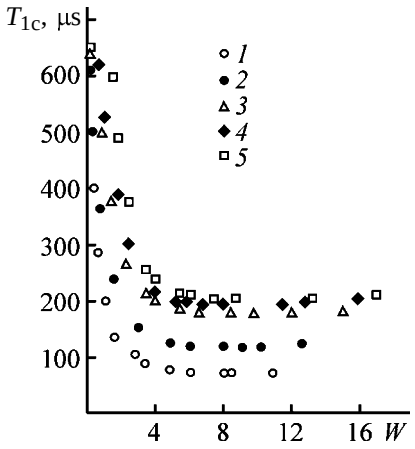

Fig. 2. Spin–lattice relaxation time of thermally treated cotton cellulose T_{1c} as a function of equilibrium moisture content W (g H_2O per 100 g cellulose). Treatment temperature, °C: (*1*) 150, (*2*) 175, (*3*) 200, (*4*) 225, and (*5*) 250.

and equation for quasi-chemical model of sorption equilibrium (2) [7]:

$$a = a_0^a(1 - X_c)\exp[-(-\Delta\mu_1/E)^n + \alpha(T - T_0)], \quad (1)$$

$$a = a_m\alpha' h/\{(1 - \beta h)[1 + (\alpha' - \beta)h]\}, \quad (2)$$

where a_0^a is the limiting sorption in amorphous areas of the fiber at the standard temperature T_0 = 293 K and the pressure of saturated vapor p_0, X_c is the degree of crystallinity, E (the characteristic energy of sorption) and n = 0.7 are the equation parameters, $\Delta\mu_1 = RT\ln h$, α is the thermal factor of sorption, β and α' are the parameters of the quasichemical model of the sorption equilibrium, a_m is the concentration of active centers in the free volume of the polymer, $h = p/p_0$, and β is a constant mostly related to the rigidity of the polymer structure: the lower the mobility of the macromolecule, the lower the constant.

In Eq. (1), a_0^a, E, and α allow estimation of the integral heat of sorption

$$q_i = \frac{E a_0^a}{M_{H_2O} n}(1 - \alpha T)\Gamma(n^{-1}), \quad (3)$$

where Γ is gamma-function (for cellulose Γ = 0.8861) and M_{H_2O} is the molecular weight of water.

We found that a_0^a and E remain unchanged up to the treatment temperature of approximately 175°C and then regularly decrease. This causes the constancy of the heat of sorption, i.e., the energy of the interaction of water with the polymer is constant up to the above temperature (Fig. 3a) and then decreases. The latter

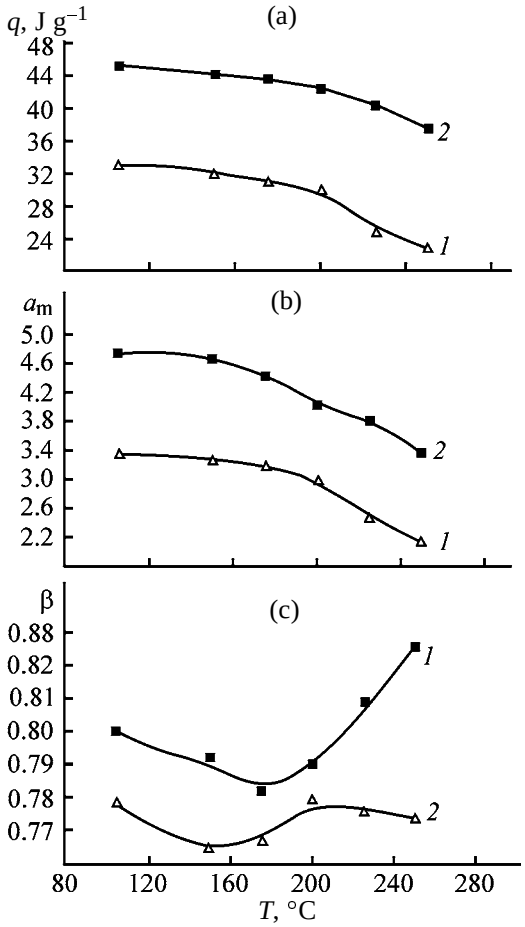

Fig. 3. Variation of (a) heat of sorption q and (b, c) constants a_m and β of Eq. (2) in thermal treatment of (*1*) cotton and (*2*) wood cellulose. (a_m) Concentration of active centers (g H_2O per 100 g cellulose) and (T) temperature.

can be caused by changes in the chemical structure of cellulose, e.g., by formation of carboxy groups.

The a_m value regularly decreases in thermal treatment of cellulose materials (Fig. 3b), which correlates with the NMR data and suggests that these changes in the cellulose structure are observed even at low temperatures, while the main changes begin at a temperature above 180–200°C. It is seen from Fig. 3c that, with increasing temperature to 150–170°C, β somewhat decreases, which can be caused by the transition of cellulose into a more equilibrium state. At higher temperatures, dehydration and thermal oxidation processes begin, which are accompanied by formation of carboxy groups and rupture of intermolecular hydrogen bonds; therefore, β somewhat increases.

Higher heats of sorption of wood cellulose and lower values of β in comparison with cotton cellulose suggest higher strength of bonds of water molecules with active groups of the polymer [7], which is confirmed by the NMR data.

EXPERIMENTAL

We used samples of cotton cellulose [GOST (State Standard) 595–79] and whitened sulfate cellulose (GOST 9571–89). The samples were subjected to isothermal drying at 105°C to constant weight (GOST 6839–54), after which the samples were heat-treateded in air at 150, 175, 200, 225, and 250°C for 1 h. Under these conditions, the temperature affects only amorphous areas of cellulose and does not noticeably affect the crystalline areas. For moistening, the thermally treated cellulose samples were placed over saturated solutions of crystal hydrates producing constant water vapor pressure. The amount of sorbed water was determined gravimetrically. The ^1H NMR relaxation parameters were measured on an NMR spectrometer operating at 42 MHz with an amplitude detector; the 90° pulse length was 3 μs. The free induction delay for the system cellulose–water is two-component. There are short (fast relaxation) and long (slow relaxation) components corresponding to relaxation of cellulose protons and water protons, respectively. The values of transverse relaxation time for each components differ by two orders of magnitude; therefore, approximation by two exponents is justified. The proton spin–spin relaxation time of sorbed water was determined by the Carr–Purcell method (the determination error did not exceed 5%). The spin–lattice relaxation time of cellulose protons was determined by measuring the curve of reduction of longitudinal magnetization [4] (the determination error did not exceed 3%).

CONCLUSION

Data furnished by ^1H NMR and sorption methods allow elucidation of changes in the chemical and supramolecular structure of cellulose materials under thermal treatment in the range 110–250°C and the influence of these changes on the state of sorbed water.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Acid Hydrolysis of Chitin and Chitosan

V. Yu. Novikov

Knipovich Arctic Research Institute of Fishery and Oceanography, Murmansk, Russia

Received December 17, 2002; in final form, January 2004

Abstract—Acid hydrolysis of chitin and chitosan recovered from shells of sea Crustacea was studied by exclusion high-performance liquid chromatography.

Antiarthrosis preparations based on chitin oligomers and glucosamine salts attract growing attention [1, 2]. The yield and quality of glucosamine hydrochloride produced from chitin[1] depend in a complex manner on the chitin properties [3]. To understand this dependence, the mechanism of acid hydrolysis of chitin was studied in more detail.

Acid hydrolysis of chitin (CTN) and chitosan (CSN) was examined in [4–8]. The aim of this work was to determine the limiting degree of chitosan deacetylation suitable for preparing glucosamine. For this purpose, the influence of the degree of chitosan deacetylation on its acid hydrolysis was studied by exclusion high-performance liquid chromatography (HPLC).

EXPERIMENTAL

We used CTN prepared by deproteinization and demineralization of shell of North shrimp (*Pandalus borealis*) by the procedure in [9]. The chitosan content in the sample was 97 wt %; the ash content was lower than 0.1 %; the particle size was no larger than 2 mm.

The chitosan samples were prepared by deacetylation of CTN and CSN. Chitosan with the 68.0% degree of deacetylation (DD) (CSN-1) was obtained by treatment of CTN with 50% aqueous NaOH at 95 ± 5°C for 30 min. The samples with DD of 88.0 (CSN-2) and 92.0% (CTN-3) were prepared under similar conditions from CSN-1 and CSN-2, respectively.

Chitin and chitosan were hydrolyzed with 36.5% HCl at 50 and 70°C. The resulting hydrolyzates were diluted with distilled water, neutralized to pH 3, and filtered through a glass filter with pore diameter of no more than 10 μm (POR 10).

The degree of CSN deacetylation was determined by potentiometric titration of a 2% CSN solution with 0.1 M HCl by the procedure in [10]. The absolute error of the determination was 0.5%.

The hydrolysis products of CTN and CSN were separated by HPLC on an $LC10A_{vp}$ chromatograph (Shimadzu, Japan) with TSK-gel Alpha-2500 (30 × 0.78 cm) column and TSK-guardcolumn Alpha (6 × 0.4 cm) precolumn (TOSOH, Japan). The hydrolyzate samples were applied in the form of 0.1% solutions in the eluent (0.3 M NaCl acidified with HCl to pH 3). The hydrolysis products were detected by the absorption at 210 nm.

The UV detection of the hydrolysis products allowed us to monitor changes in the concentration of acetylated compounds and acetic acid. The considerably weaker absorption of deacetylated CSN oligomers and *D*-glucosamine (GA) was obscured by the strong band of the acetylated products. Monomeric *N*-acetylated glucosamine (AcGA) was identified by comparing its retention time (9.78 min) with that of pure GA (9.86 min). For this purpose, a 5% GA solution in the eluent was used.

Based on the published chromatographic data on CTN oligomers [5–7], we assigned the other chromatographic peaks to the acetylated oligomers (Fig. 1). If peak *2* is due to AcGA, then peaks *3* and *4* are assigned to *N*,*N*'-diacetylchitobiose and *N*,*N*',*N*''-triacetylchitotriose, respectively. The semilog plot of the molecular weight (MW) of these compounds on the elution time τ is linear. The nonlinear deviation for GA can be due to either characteristics of the linearity the column or structural difference of the deacetylated monomer from AcGA. Hence, GA cannot be used to construct the calibration curve.

It is known [4, 8] that the rate of formation of AcGA and GA in the course of acid hydrolysis of CTN and CSN decreases with an increase in their DD.

The influence of DD on the rate of acid hydrolysis of CTN and CSN is seen from the chromatograms of their hydrolyzates. At 50°C, CTN is hydrolyzed incompletely to form a mixture of macromolecular and low-molecular-weight products (Fig. 2). As the hydrolysis time increases, the peaks of the macromolecular products shift toward lower molecular weights and decrease in the integral intensity; the intensity of the peaks of the oligomers and monomers increases. It should be noted, however, that the integral intensity of peaks cannot be a measure of chitin depolymerization, since depolymerization is accompanied by formation of deacetylation products whose molar extinction coefficient is lower than that of the acetylated products.

The content of the macromolecular compounds in the products of hydrolysis of CTN and CSN-1 (DD = 68%) at 70°C sharply decreases (Fig. 3). The products of hydrolysis performed for more than 10 min contain mainly oligomers, monomers, and acetic acid; the polymer concentration is very low.

In the products of hydrolysis of CSN-2 and -3 (DD 88 and 92%), the peak of macromolecular fractions is preserved even after hydrolysis for 300 min. It should be noted that a chitosan precipitate in the form of a fine dispersion and with the outward appearance of the initial sample was observed after 5-h hydrolysis of CSN-2 and CSN-3, respectively.

The degree of hydrolysis was estimated from the AcGA yield. The AcGA amount was recalculated to the number of acetyl groups in CTN with DD = 0%, taking the initial DD into account. The AcGA yield increases in the first hydrolysis steps owing to cleavage of glycoside bonds of the macromolecules and then decreases owing to deacetylation (Fig. 4). The AcGA yield in hydrolysis of CTN and CSN, performed for the same time, sharply decreases with an increase in DD of the polysaccharide (Fig. 5).

This result agrees with the fact that the glycoside bond in acetylated monomeric chains is more readily hydrolyzed than the bond in deacetylated chains [8]. Based on relative deceleration of depolymerization with respect to the deactylation rate at high acid concentrations, Varum *et al*. [8] suggested different hydrolysis mechanisms of *N*-acetyl and glycoside bonds. Probably the *N*-acetyl bond is hydrolyzed by the S_4N2 mechanism in which the rate-determining step is addition of water molecule to the carbocation. As the acid concentration increases, the concentration of water

molecules decreases and the reaction decelerates. The glycoside bond is hydrolyzed by the S_N1 mechanism in which the rate-determining step is the proton attack to form carbocation. In this case, the reaction rate is independent of the water concentration.

However, the influence of the acetyl substituent at the nitrogen atom of a CTN molecule on the depoly-

merization rate cannot be explained within the framework of the proposed hydrolysis mechanism of the glycoside bond. Computer simulation of the electron density distribution in the molecule showed no appreciable increase in the excess negative charge on the atoms of the glycoside bond after acetylation of the amino group. This charge promotes the proton attack. To understand the hydrolysis mechanism of glycoside bonds in a chitin molecule, more comprehensive studies are required.

It is of practical importance that partially deacetylated CTN or CSN are completely hydrolyzed to AcGA and GA in a time longer than that required for hydrolysis of CTN with minimal DD.

The GA concentration in the CTN hydrolyzate is low, and this product cannot be detected by UV absorption since its molar extinction coefficient is small. Therefore, deacetylation of the acetylated products was monitored by the rate of acetic acid formation (Fig. 6).

The AcOH amount was estimated in relative units from chromatographic peak area (retention time 14.14 min). The amount of AcOH that could be released upon complete acid hydrolysis of CTN with DD = 0% was taken as the maximal. A sample containing the calculated amount of AcOH was introduced in the column, and the peak area was measured.

As seen from Fig. 6, the deacetylation rate is almost independent of the initial DD. This is also the case for the deacetylation of CTN and CSN in alkaline solution [11].

Thus, Figs. 4 and 6 show that depolymerization of CTN and CSN depends on the initial degree of their deacetylation. The higher DD, the lower is AcGA yield. The deacetylation course depends only on the experimental hydrolysis conditions and is independent of DD of CTN and CSN. Hence, the steps of deproteinization and demineralization of chitin production should be performed with care to avoid uncontrolled deacetylation affecting the GA yield.

The limiting degree of deacetylation providing optimal hydrolysis of CTN can be estimated from the dependence of the AcGA yield on DD, assuming that this dependence is linear in the DD range from 15 to 68%. We suggest that a decrease in the monomer yield in the course of hydrolysis should not exceed 10% of its yield in hydrolysis of commonly used CTN with DD ~15%. Our calculations show that the DD of CTN should not exceed 26%. The yield estimated by extrapolation to zero DD is higher by 14% than that of AcGA formed in hydrolysis of commonly used CTN. Hence, the production process of glucosamine can be further improved.

CONCLUSIONS

(1) The study of acid hydrolysis of chitin and chitosan by HPLC shows that accumulation of oligomers and monomers of chitin and chitosan decelerates with

increase in the degree of deacetylation and the deacetylation rate is independent of the initial degree of deacetylation of chitin and chitosan.

(2) The minimal degree of deacetylation of chitin suitable for glucosamine production is 26%.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation and Properties of Blends of Ion-Containing Polyurethane with Polyvinylpyrrolidone

L. V. Stepanenko, A. A. Brovko, T. I. Novikova, L. M. Sergeeva, and A. A. Chernobai

Received June 6, 2003; in final form, January 2004

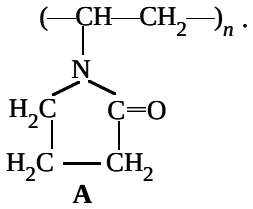
Abstract—Binary blends of linear polymers, segmented polyurethane [derived from oligooxytetramethylene glycol (MW 1000), toluene diisocyanate (65 : 35 isomer mixture), and magnesium *p*-hydroxybenzoate] and poly-*N*-vinylpyrrolidone (MW 10 000), were prepared and studied.

Polymer blends and interpenetrating polymer networks (IPNs) whose components are capable of forming a three-dimensional system of stable physical bonds offer wide opportunities for preparing composite materials with diverse properties, which can be readily processed in any step [1–3]. Segmented polyurethanes (SPUs) show much promise as such components. In these polymers, microphase segregation results in formation of hydrogen-bonded aggregates of rigid blocks, domains, acting as centers of cross-linking [4, 5]. This accounts for the rubber-like properties of SPUs. When ion-containing SPUs are used for preparing blends or IPNs, not only hydrogen bonds but also ionic bonds can participate in formation of the material structure, significantly affecting the microphase structure and properties of the composite [1–3, 6, 7]. Therefore, the researchers' interest in polyurethane ionomers is steadily high. However, data on blends based on SPUs with ionic groups in the backbone are extremely scarce. We have recently initiated studies in this field [7, 8].

Proceeding with this research, we have studied blends of an ion-containing polyurethane with polyvinylpyrrolidone.

EXPERIMENTAL

The polyurethane component was a linear polyurethane ionomer (PUI) derived from oligooxytetramethylene glycol (OTMG, MW 1000), toluene diisocyanate (TDI), and magnesium *p*-hydroxybenzoate (Mg-PHOB). The PUI was prepared in two steps following the general procedure described in [8]. In the first step, a prepolymer with terminal NCO groups was prepared by the reaction of OTMG with TDI (65 : 35 isomer mixture) in the molar ratio OH : NCO = 1 : 2. In the second step, the prepolymer was extended with Mg-PHOB, and ionic magnesium dicarboxylate fragments were thus introduced. The polyurethane ionomer had MW ~40 000; the anionic group content was about 2%. The second component of the blends was a linear polymer with a pendant five-membered heteroring, commercially available polyvinylpyrrolidone (PVP, **A**) with mean MW 10 000:



A

Blends were formed by chemical mixing of the two polymers [1]. The starting prepolymer and the chain-extending agent were added to a solution of PVP in dimethylformamide, and PUI was formed in a PVP solution upon vigorous stirring at room temperature for 2 h. The reaction mixture was cast on Teflon supports, and the reaction was completed by drying for 5–7 days at 353 K. The weight fraction of PVP in the blend samples was varied from 0 to 90%.

To study intermolecular interactions in polymer blends, we recorded the IR spectra of blend samples in KBr on a Specord M-80 spectrophotometer in the range 600–4000 cm^{-1}. To study the viscoelastic properties of the blend samples and qualitatively estimate the extent of their microheterogeneity, we used a relaxometer with automatic recording of the phase shift angle [9]. Measurements were performed at a

1070-4272/04/7703-0488 © 2004 MAIK "Nauka/Interperiodica"

100 Hz frequency of induced sinusoidal vibrations in the temperature range 173–513 K. The dynamic modulus of elasticity E' (MPa) and modulus of loss E'' (MPa) were calculated from the experimental values of the complex modulus of elasticity and mechanical loss tangent $\tan\delta$. The glass transition points T_g were determined graphically from the temperature dependences of tthe viscoelastic characteristics. The sample length, width, and thickness were about 0.06, 0.03, and 0.005 m, respectively. We also evaluated the physicomechanical properties of films prepared from the blends.

The polyurethane ionomer is a segmented polyether urethane; its flexible segments (or blocks) are formed by oligooxytetramethylene glycol **B**:

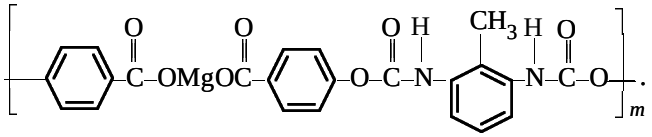
B

The rigid blocks of PUI are formed by reaction of the terminal isocyanate groups of the prepolymer with the chain-extending agent; their structure can be schematically shown as structure **C**:



C

Various kinds of intermolecular bonds (H bonds, ion–ion, ion–molecule bonds) are possible in this PUI. These bonds can be revealed by IR spectroscopy [7].

Figures 1 and 2 show the IR spectra of the starting polymers and some blends therefrom. We analyzed in more detail the range 1800–1500 cm^{-1} corresponding to stretching vibrations of various kinds of carbonyl groups (urethane, ester, ionic, heterocyclic).

The spectrum of PUI (Fig. 1, spectrum *1*) in the range 1600–1730 cm^{-1} contains weak ill-resolved bands at 1730, 1710, and 1675 cm^{-1}; also, there is a band at 1610 cm^{-1} with a shoulder at 1630 cm^{-1}. It is known [7] that the carbonyl group in urethane fragments of SPUs gives bands at 1730 (free C=O groups) and 1710 cm^{-1} (C=O groups involved in H bonding with NH groups). It is also known that the carbonyl group in polymers can interact with metal ions, especially with those having high ionic potential such as, e.g., Mg^{2+} [7]. Such interaction gives rise to a new, lower-frequency C=O stretching band in the IR spectra. Therefore, we believe that the band at 1675 cm^{-1} characterizes the ion–molecule bonds $C{=}O\cdots Mg^{2+}$ in PUI. The band at 1630 cm^{-1}, observed as a shoulder, is due to vibrations of the carboxylate anions $RCOO^-$ coordinated with the metal ion [7]. The nonassociated carboxylate anions absorb at 1580–1610 cm^{-1} [7]. The benzene rings also absorb in this range; therefore, the band at 1610 cm^{-1} is the strongest in this part of the spectrum.

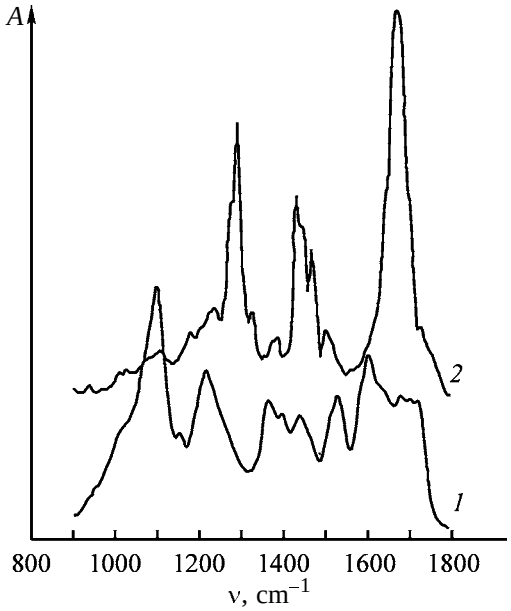


Fig. 1. UR spectra of (*1*) PUI and (*2*) PVP. (*A*) Absorption and (ν) wave number; the same for Fig. 2.

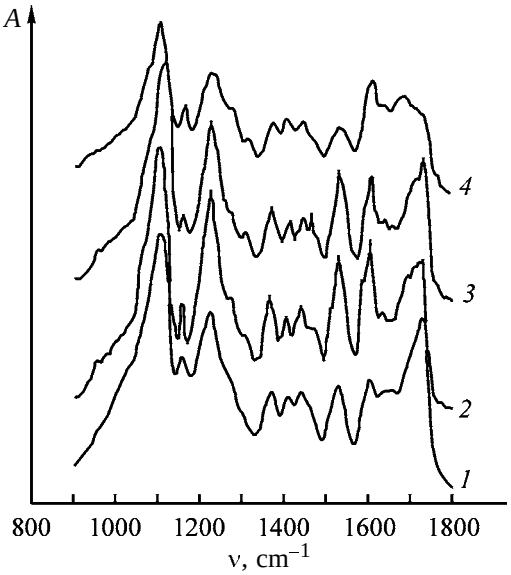

Fig. 2. IR spectra of PUI–PVP blends with the PVP content (wt %) of (*1*) 10, (*2*) 20, (*3*) 30, and (*4*) 70.

The most characteristic bands in the spectrum of PVP (Fig. 1, spectrum *2*) are those of the lactam carbonyl groups at 1680–1690 cm^{-1} and of the pyrrolidone ring [10] at 1290 cm^{-1}.

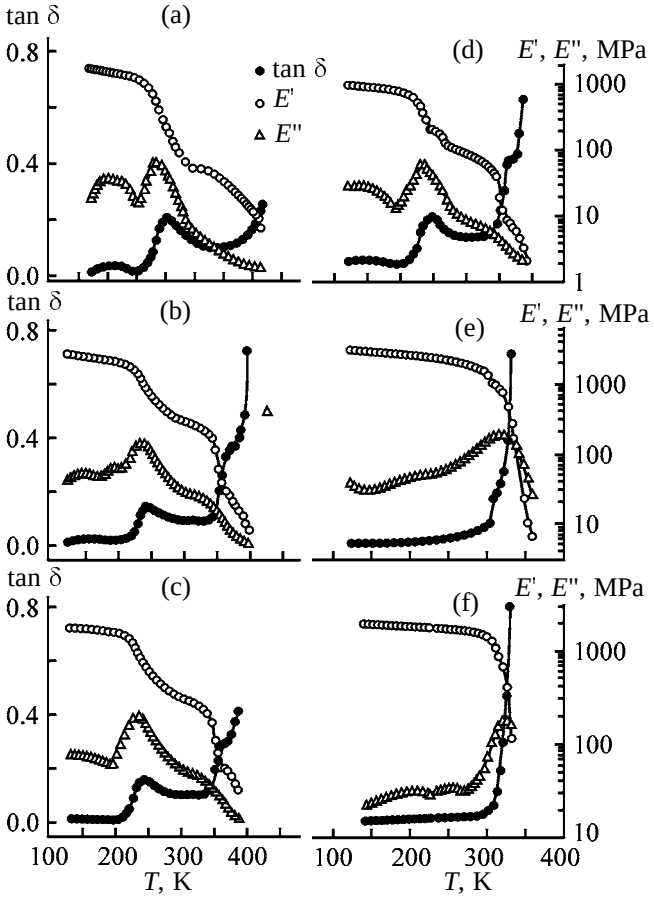

Fig. 3. Temperature dependences of the mechanical loss tangent tan δ, dynamic modulus of elasticity E', and modulus of loss E'' for PUI–PVP blends. PVP content, wt %: (a) 0, (b) 10, (c) 20, (d) 30, (e) 90, and (f) 100.

Comparison of the IR spectra of the polymer blends and their components reveals appreciable changes in the carbonyl absorption pattern depending on the component ratio (Fig. 2). In the spectrum of the blend containing 10 wt % PVP (Fig. 2, spectrum *1*), compared to the spectrum of PUI, the intensity of the band at 1730 cm^{-1} grows, and that of the bands at 1610 and 1630 cm^{-1} sharply decreases. This fact suggests the prevalence of intermolecular interactions between the blend components. For example, the PVP amide group as a strong H-bond acceptor (stronger than the urethane ester group) can participate in hydrogen bonding with the NH groups of urethane fragments. As a result, the content of bound urethane CO groups decreases, and the content of urethane carbonyl groups not involved in hydrogen bonding grows.

A decrease in the intensity of the bands at 1610 and 1630 cm^{-1} may also be due to interpolymer interactions of free $RCOO^-$ groups of PUI with the nitrogen atoms of PVP and of Mg^{2+} ions with the C=O groups of PVP.

As the PVP content in the blend is increased to 20 wt % (Fig. 2, spectrum *2*), the intensity of the band at 1610 cm^{-1} appreciably grows. In the carbonyl absorption range, ill-resolved maxima are observed at 1695, 1710, and 1730 cm^{-1}. These data suggest predominant formation of an ion–molecule bond between the CO groups of PVP and Mg^{2+} ions in PUI. Such interaction is energetically preferable compared to H bonding between two urethane fragments [7].

As the PVP content in the blend is further increased to 30 and 70 wt % (Fig. 2, spectra *3*, *4*), the shape and position of the absorption bands (for all kinds of C=O groups and ionic groups) undergo changes suggesting partial break of the main types of bonds between the components.

The character of intermolecular interactions in polymer blends is closely related to their microstructure. In this connection, we compared the IR data with the viscoelastic properties of the composites, which were studied by dynamic mechanical thermal analysis (DMTA). It is known that the viscoelastic characteristics, especially tan δ, are extremely sensitive to all kinds of relaxation processes, structural nonuniformities, and morphological features of multiphase systems; they can be efficiently used for qualitative characterization of the microphase structure [11]. Figure 3 shows the temperature dependences of tan δ, E', and E'' for PUI, PVP, and a series of blends therefrom.

For PUI (Fig. 3a), the temperature dependence of tan δ shows two relaxation transitions. The first transition in the range 250–275 K corresponds to the flexible (polyester) block. The second transition reflects processes in rigid blocks; it has the shape of an ascending curve in the range 400–420 K.

The temperature dependence of the viscoelastic characteristics of PVP (Fig. 3f) shows a transition in the range 300–330 K.

The temperature dependences of the viscoelastic characteristics of the polymer blends containing 10, 20, and 30 wt % PVP show two temperature transitions: at 230–260 and above 300 K. This unambiguously indicates that two-phase systems are formed. In the blends, the low-temperature (polyether) PUI transition is slightly shifted toward lower temperatures (Figs. 3b–3d, cf. Fig. 3a), and the tan δ peak becomes less pronounced (from the $T > T_g$ side). The temperature dependences of the viscoelastic characteristics of the polymer blends (Figs. 3b–3e) are characterized by

Physicomechanical properties of PUI–PVP blends

50	50	–	–	–	0.7

a shoulder appearing in the high-temperature branch of the $\tan\delta$ curve ($T > T_g$). This is the temperature range of relaxation processes associated with the mobility in microareas of rigid blocks (rigid domains) and with the breakdown of these domains [12], and also with transition of PVP from the glassy to hyperelastic state. This shoulder is not observed in the temperature dependences of $\tan\delta$ of the starting polymers. These effects may be due to more pronounced microphase segregation in preparation of blends with small (≤20 wt %) PVP content. This, in turn, causes T_g of the polyether blocks to decrease [12].

As shown by the IR spectra, the intermolecular interactions of the two polymers are the strongest specifically in this concentration range. The DMTA data reveal changes in the structure formation: new structural groups arise, favoring more pronounced microphase segregation [12]. It should be noted that the temperatures at which these structural formations are broken down in blends are lower than the temperatures at which rigid PUI blocks are broken down (Figs. 3b–3d, cf. Fig. 3a).

The DMTA results for blends containing 30 wt % PVP and more are also consistent with the IR data. The temperatures and intensities of the peaks of the relaxation processes in the temperature dependences of the dynamic characteristics approach those observed with the starting polymers. The lower stability of the interpolymer structural formations at temperatures above T_g follows from the facts that the temperature of their breakdown decreases to 300–330 K (Figs. 3d, 3e), the shoulder in the temperature dependence of $\tan\delta$ becomes less pronounced, and the modulus of elasticity decreases.

The system of the forming physical bonds and the participation of ionic groups in formation of additional ionic "cross-links" are responsible for formation of a definite microphase structure of the blends, affecting their physicomechanical properties. Elucidation of the interrelation of all these factors in multicomponent polymer sysrtems is very important, as being related to development of new valuable materials [1–3, 8, 11]. The physicomechanical properties of films prepared from some PUI–PVP blends are listed in the table.

It is seen that the physicomechanical parameters of blends depend on the ratio of the polymeric components. At a PVPO content of 1–20 wt %, the strength of the composites exceeds that of the components taken separately. The maximal tensile strength is attained in the 5–15 wt % range of PVP content. As noted above, at these compositions the redistribution of intermolecular bonds is the most pronounced, and the active groups of both polymers are involved in the interaction to the greatest extent. As a result, according to DMTA data, the extent of microphase segregation increases. As the PVP content in blends is increased to 40 wt %, the strength decreases significantly, and the modulus of elasticity decreases slightly. These results are also consistent with the IR and DMTA data.

CONCLUSIONS

(1) According to the IR spectrum, the synthesized segmented polyurethane ionomer is characterized by a system of intermolecular interactions such as urethane–urethane hydrogen bonds, ion–ion bonds, and ion–molecule bonds. These interactions are responsible for formation of a two-phase microstructure.

(2) In blends of the polyurethane ionomer with small amounts (up to 20 wt %) of polyvinylpyrroli-

done, the intermolecular interactions between the polymers are the strongest. As follows from the results of dynamic mechanical thermal analysis, these interactions cause formation of structural groups that are less stable than domains of rigid polyurethane blocks. The network of intermolecular interactions and the microphase structure of the systems in this composition range ensure the maximal tensile strength of the composites.

(3) As the polyvinylpyrrolidone concentration in the blends is increased above 40 wt %, the main intermolecular bonds between the polymers are gradually broken down, the microphase structure of the blends becomes similar to that of the individual polymeric components, and the strength of the material decreases.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Activating Mixing in Modification of Rubbers in Solution

B. L. Smirnov, A. E. Tubolkin, V. P. Britov, O. O. Nikolaev, and V. V. Bogdanov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 4, 2003

Abstract—The applicability of the previously developed principles of activating mixing to modification of rubbers in solutions was tested, and a process was developed for mechanochemical modification of *cis*-1,4-polyisoprene in rotary pulsation apparatus.

Activating mixing can significantly intensify processes involved in production of synthetic rubber. Among such processes are distribution of catalyst suspensions in the monomer and solvent prior to polymerization, deactivation, stabilization, activation, and washing. Activating mixing may be of particular importance in chemical modification of rubbers in the step of polymer preparation (these processes will be considered below for modification of *cis*-1,4-polyisoprene as example).

Progress of studies on rubber modification allowed development of commercial brands of modified *cis*-1,4-polyisoprene (SKI-3-01 and DKI-3-OK rubbers). Their production involves reactions with aromatic *C*-nitroso compounds. Nitroso derivatives are widely used as modifying agents, stabilizers, and promoters of the interaction of rubber with carbon black in the course of preparation of rubber stocks and vulcanizates. Among numerous *C*-nitroso amines and nitroso compounds tested as modifying agents, much promise is shown by *p*-nitrosodiphenylamine (PNDPA) owing to a wide spectrum of its modifying effect and insignificant contribution of side reactions to the molecular structure of the final product.

The diphenylamine fragment, which can bind to the polymeric chain via nitrogen atom, shows antioxidant properties; therefore, PNDPA can act not only as modifier, but also as stabilizer [1].

It is very interesting to prepare *cis*-oligoisoprene with nitroso amine groups (SKI-3-NA) formed by reactions of high-molecular-weight *cis*-1,4-polyisoprene (SKI-3) with nitroso compounds. The reaction of *cis*-1,4-polyisoprene with PNDPA in solution involves successive and parallel addition of the nitroso compound dimer, cleavage of the resulting tetrahydrooxadiazole ring, and branching of the polymeric chain with the participation of double bonds and groups [2, 3].

The use of SKI-3-NA in preparation of tire stocks not only improves such propertiers of tires as heat and ozone resistance but also considerably enhances the fatigue resistance, stability in prolonged vulcanization, and tear resistance—the parameters responsible for the quality and service characteristics of large tires. Nevertheless, no high-capacity process for production of SKI-3-NA have been developed up to now.

We noted recently [4] that rotary pulsation apparatus (RPA) show much promise in modification of polymers using activating mixing. This fully concerns the modification of SKI-3. The use of activating mixing opens wide prospects for the process intensification and improvement of the product quality.

The goals of this study are to analyze the possibilities of modifying rubbers under conditions of activating mixing and to reveal qualitative and quantitative correlations between the criteria of mechanochemical transformations and criteria describing the external mechanical field acting on a material.

EXPERIMENTAL

We used the substances required for development of a process for modification of isoprene rubber: solutions of *cis*-1,4-polyisoprene in hexane of various concentrations, solutions of *p*-nitrosodiphenylamine sodium salt of various concentrations, phosphoric acid (grades A, B), and other solvents (isopentane, toluene).

Modification of isoprene rubber was performed on an installation schematically shown in Fig. 1.

The starting components for modification of isoprene rubber were prepared as follows. First, we pre-

1070-4272/04/7703-0493 © 2004 MAIK "Nauka/Interperiodica"

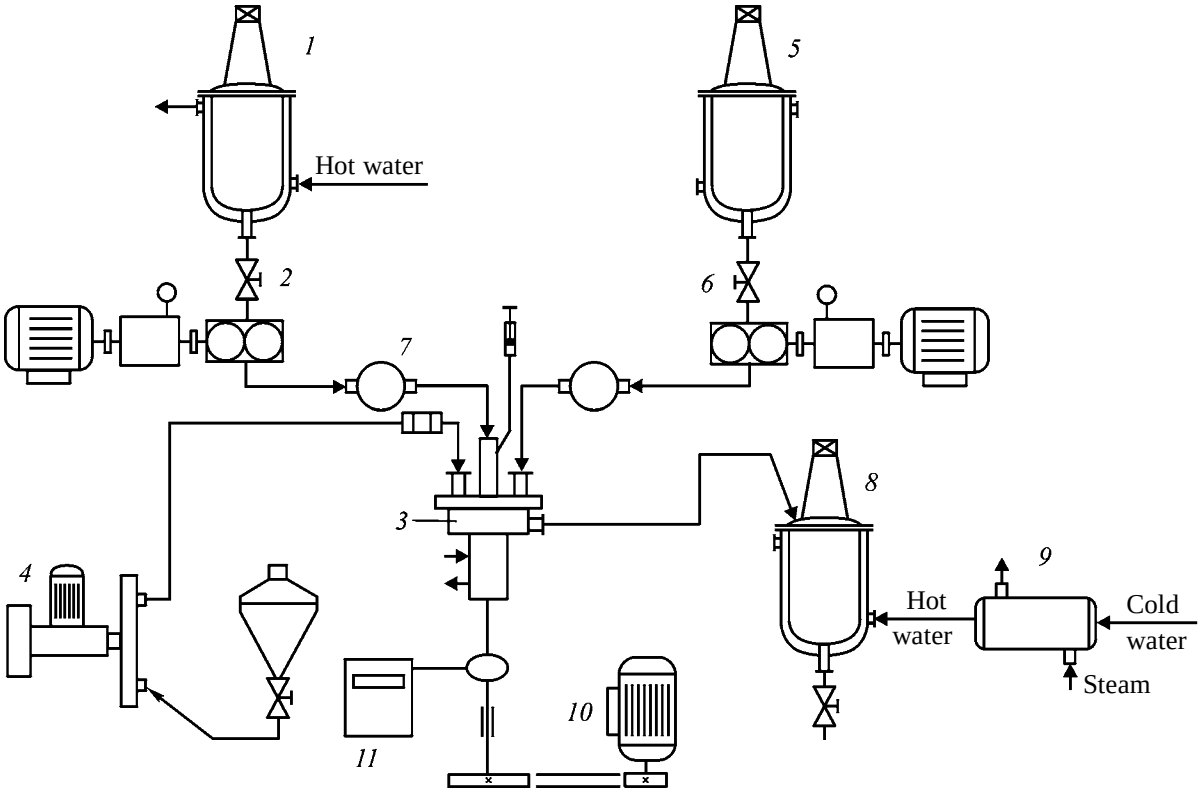

Fig. 1. Installation for modification of isoprene rubber.

pared in stirred vessels a 10% solution of SKI-3 rubber in hexane and a 20% solution of the PNDPA salt. Phosphoric acid was added in amount of 1 mol per mole of PNDPA sodium salt to convert the salt to free *p*-nitrosodiphenylamine. Toluene was added in an amount of 150 ml per liter of solution. The sodium salt was added in an amount of 15 wt % relative to the rubber.

A solution of the rubber in hexane was fed from reactor *1* with a gear pump *2* to RPA *3*. An aqueous solution of PNDPA sodium salt was also fed to the RPA with a piston pump *4*. Feeding of phosphoric acid from reactor *5* with a gear pump *6* to RPA was also provided. The process was monitored visually through a window *7*. After passing RPA, the modified rubber solution was collected in reactor *8* in which it was heated to 80°C for 5 h under stirring with an anchor stirrer (n = 500 rpm). The temperature in the reactor was maintained by passing hot water heated in a heat exchanger *9* through the reactor jacket. The rate of RPA rotor rotation was varied from 1000 to 4400 rpm with a hydraulic drive *10* connected to a hydrosystem. The rotation rate was measured with a digital tachometer *11*. The temperature of the medium was measured with a Chromel–Copel thermocouple connected to a PM-66 potentiometer. Samples for quantitative determination of the extent of physicochemical transformations were taken after 1, 3, and 5 h. Analyses were performed spectrophotometrically [5]. The physicomechanical and service properties of the materials were determined according to the corresponding GOSTs (State Standards): 270–75, 10722–76, 19338–90, 19816.4–74, and 27109–86.

First, we analyzed the effect of various solvents on the structure and properties of oligoisoprenes. The oligoisoprenes prepared in different solvents appreciably differed in the molecular characteristics. For example, samples prepared in toluene had lower values of the intrinsic viscosity, weight-average molecular weight, and polydispersity.

The range of molecular weights of oligoisoprene fractions prepared in a 100 : 200 isopentane : toluene is considerably wider, especially for high-molecular-weight fractions. The differential molecular-weight distribution (MWD) curves calculated from the gel chromatograms show significant differences in the position of the maximum and number of fractions for the oligomers prepared in different solvents. The differences in the MWD parameters of oligoisoprenes can significantly affect the course of modification. Significant microheterogeneity observed with the

isopentane–toluene mixture used as solvent can lead, upon mechanical treatment, to formation of both the initial SKI-3 rubber fractions (high-molecular-weight MWD branch) and oligomeric molecules formed by degradation (low-molecular-weight MWD branch).

At large extents of degradation, the MWD should tend to that characteristic of random bond cleavage ($M_w/M_n \to 2$). The fact that the MWD of oligoisoprenes is considerably wider suggests abnormal process conditions due to heterogeneity of the system; this ultimately depends on the solvent used.

The second step of our study concerned features of chemical modification. The chemical degradation of SKI-3 with PNDPA occurs under microheterogeneous conditions. Therefore, different fractions of the rubber participate in the reaction to different extents, depending on the solubility of PNDPA in these fractions. In particular, Fig. 2 shows that the PNDPA concentration in oligoisoprene fractions can vary from 9 to 50–60 wt % in the range of molecular weights from 500 to $(40–50) \times 10^3$. The functionality of the fractions increases from 1.5–1.7 to 15–20 in the same range of molecular weights. Hence, the low-molecular-weight fraction is polyfunctional to a significant extent.

In the third step of our study, we analyzed the possibility of activation of polymer solutions. It is known that mixing, along with equalization of the concentrations of the component being distributed and with its dispersion, can induce mechanochemical transformations in the system. Such transformations are often undesirable. In our case, however, they allow the SKI-3 modification process to be considerably intensified.

We studied solutions of isoprene rubber in various solvents to reveal their tendency to degrade. By subjecting the material to various actions in an RPA, we determined the percentage of free and bound PNDPA. The material was analyzed after keeping the solution in the reactor for 1, 3, and 5 h.

Figure 3 shows the results obtained as a correlation between the extent of mechanochemical modification and parameters describing the external effect on the system. It is seen that treatment in an RPA, even at relatively low strain energy densities $\tau\gamma$, considerably increases the amount of bound PNDPA, thus decreasing the residence time of the solution in the reactor.

This effect is determined by the mechanism of the treatment process in an RPA. Modifying agents are mixed with the polymer matrix to form a system with a large interface area, due to dispersion and homogenization. The mixed system moves from the apparatus

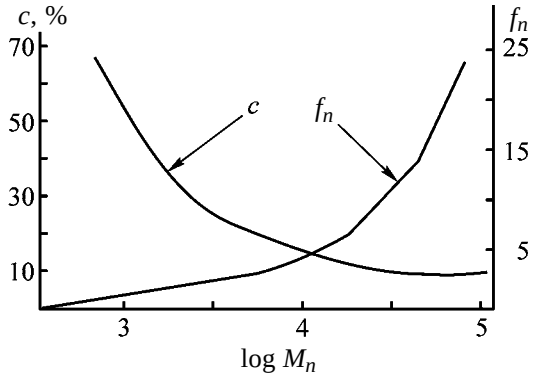

Fig. 2. PNDPA content c and functionality f_n vs. the molecular weight M_n of the oligomer fractions (oligomer prepared in toluene).

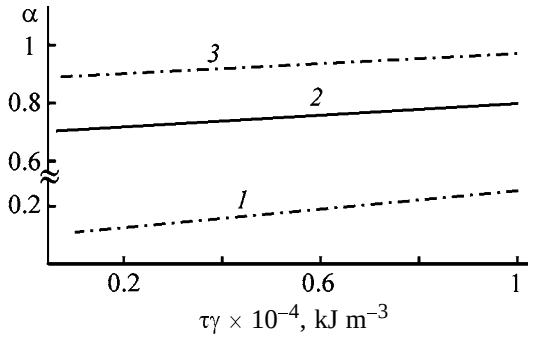

Fig. 3. Influence of the strain energy density $\tau\gamma$ on the reaction of 10% SKI-3 solution in hexane with PNDPA. (α) Fraction of bound PNDPA. Reaction time, h: (*1*) 1, (*2*) 3, and (*3*) 5.

center to the region of increasing shear rates and stresses. In the process, the polymer gets activated, which may cause both generation of active radicals and redistribution over the polymer chains of the vibration energy of the initial highly active state that arose upon local supply of excess mechanical energy. Thus, favorable conditions are created for the reaction of the polymer with modifying agents.

The results of our study were used in development of a flowsheet for producing SKI-3-OK rubber–oligomer formulation for big tires, using RPA as the main equipment. The efficiency of using RPA for modifying *cis*-1,4-polyisoprene is confirmed by the results of industrial tests at the Sintezkauchuk Production Association (Togliatti, Samara oblast, Russia).

The activating mixing in RPA ensured satisfactory agreement between the amount of PNDPA sodium salt added and the sum of free and bound PNDPA in the reaction mixture after mixing the components. Without RPA treatment, the PNDPA content in the reaction mixture was lower by a factor of 1.5–2, indicating that mixing was unsatisfactory; furthermore,

the PNDPA salt precipitated, and its significant fraction was lost in side reactions. With activating mixing, the reaction temperature could be decreased from 65 to 50°C, the polymer concentration could be increased from 11 to 13%, and two vessels could be eliminated from the polymerization battery.

CONCLUSIONS

(1) Activating mixing in rotary pulsation apparatus, used in modification of *cis*-1,4-polyisoprene, allows significant intensification of the process: increase in the polymer concentration from 11 to 13%, elimination of a part of equipment from the flowsheet, decrease in the process temperature, and shortening of the treatment cycle.

(2) Intensification of the modification by activating mixing is due to the following factors: (a) formation of a large interface area between the modifying agents and polymer matrix as a result of homogenization and dispersion; (b) activation of the polymer, which can cause generation of active radicals or redistribution over the polymer chains of the vibration energy of the initial highly active state that arose on local supply of excess mechanical energy.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Optimization of Coagulation and Flocculation in Fat-Containing Highly Dispersed Systems

A. F. Dobrynina, G. G. Faizullina, and V. P. Barabanov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received April 22, 2003

Abstract—The coagulation activity of aluminum sulfate and products of its hydrolysis was analyzed. Formation of particles in fat-containing disperse systems in the presence of both the coagulant and its mixtures with flocculants based on polyacrylamide was studied.

Treatment to remove impurities from wastewater of food and light industry is an important environmental problem. The most difficult is removal of emulsified fats, which is often performed using traditional coagulants [sulfates and chlorides of aluminum, iron(III), etc.] and mixtures of coagulants with various flocculants, in particular, water-soluble polyacrylamide copolymers [1]. However, due to unpredictable results obtained with aluminum oxysulfate (AOS) coagulant, it is necessary to find empirically the optimal conditions of coagulation and flocculation [2, 3].

EXPERIMENTAL

In this work, we used the wastewater from a fur-processing plant; its average composition is given Table 1.

As seen from the IR spectra [4] (Specord 71-IR spectrophotometer), before treatment the disperse phase contains both aliphatic (methyl and methylene) structural groups and heteroatomic groups (sulfoxides, acids, and esters). The broad band of OH vibrations confirms the presence of fatty (e.g., oleic, palmitic, and, partially, stearic) acids. The group of bands in the 1240–1170 cm^{-1} range indicates the presence of various oxygen-containing compounds. Among the organic components, polyfunctional heteroatomic compounds are predominant.

In our work we used AOS [GOST (State Standard) 3758–65] containing 15.3 ± 0.4 wt % aluminum oxide as coagulant, and anionic (PAA1 and PAA2) and cationic (PAA3) polyacrylamide copolymers as flocculants. The average molecular weight M_η of PAA1 and PAA2 was 12.6×10^6 (Technical Certificate) and 4.46×10^6, respectively; and the molecular weight of the acrylamide copolymer with dimethylaminoethyl methacrylate hydrochloride (PAA3) was 3.5×10^6. The content of the ionic units in PAA1, PAA2, and PAA3 was 19.8, 20, and 42%, respectively [5, 6].

The systems in question were studied by sedimentation [7], optical microscopy [7], and colorimetry [8]. The kinetics of sedimentation in the presence of coagulant and flocculants was studied on a VT-500 torsion balance using 1000-ml beakers. The particle-size distribution in the untreated disperse system was studied by optical microscopy (Biolam microscope). The experimental data obtained by this method in 20 series of measurements were treated according to the procedure given in [9]. The particle size in the untreated disperse system was 2.76×10^{-6} m. The colorimetric measurements were carried out on a KFK-2 photocolorimeter (λ = 440 nm, l = 10 mm) using the middle supernatant fraction.

The flocculation power of polyacrylamide copolymers can be quantitatively evaluated using the dimensionless parameter D:

$$D = V/V_0 - 1, \quad (1)$$

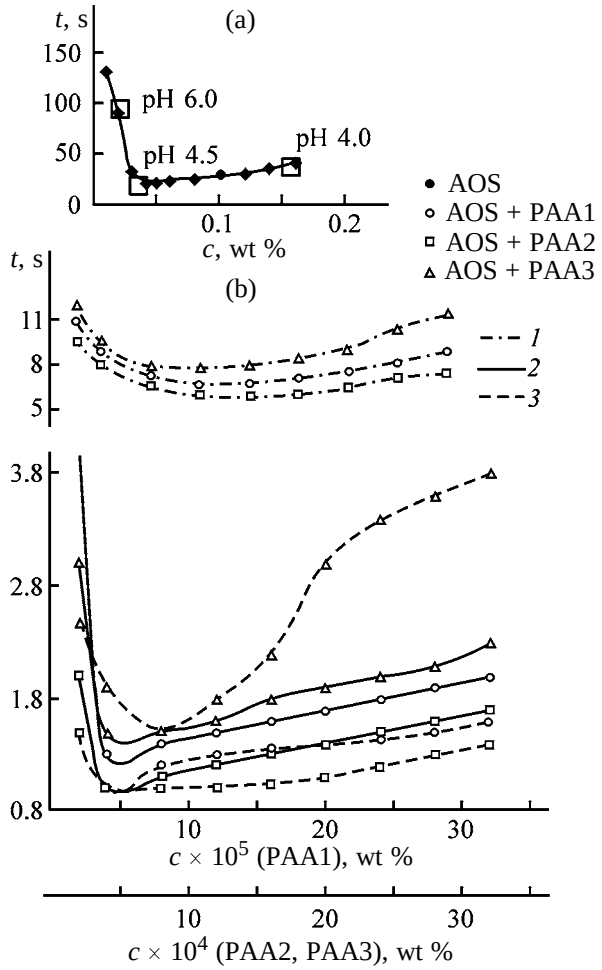

Fig. 1. Time of formation of primary flakes t as influenced by the concentration c of (a) AOS and (b) PAA additives (c_{AOS} = 0.04 wt %). The flocculant was added after AOS coagulant in (*1*) 10 s, (*2*) 20 s, and (*3*) 10 min.

where V and V_0 are the sedimentation rates of the dispersed phase in the presence of the flocculant and without it [10]. We also calculated the flocculating activity λ of each additive:

$$\lambda = D/c = (V/V_0 - 1)c^{-1}, \quad (2)$$

where c is the flocculant concentration.

Available data on the coagulation and flocculation in model and real multicomponent disperse systems [11] show that the study of the mechanisms of interaction involving the dispersed phase (e.g., between the coagulant aggregates and dispersed particles or between the flocculant and coagulant macromolecules, etc.) is of particular importance. The mechanisms of the interparticle interactions between the dispersed phase and dispersion medium can be judged from such macroscopic parameters as the rate of formation of primary flakes, sedimentation rate, etc.

In this work we attempted to evaluate the correlations between the kinetic parameters of flocculation and sedimentation in the presence of AOS and polyacrylamide flocculants.

The dependences of the time of formation of the primary flakes in the disperse system on the concentration of various flocculants and coagulant are shown in Fig. 1. The curve in Fig. 1a exhibits pronounces steep section, which, in our opinion, is probably due to the latent coagulation and formation of the adsorption-active centers and primary aggregates of aluminum hydroxide. The flat section of the curve is related to structuring of the resulting particles and formation of the products of AOS hydrolysis with various size and density parameters, lime factors, and other characteristics [12]. The coagulant concentration corresponding to the inflection in the curve determines the boundary of the optimal concentration range of the coagulant for the given disperse system; the solution pH in this point is 4.5.

As seen from the IR data, the content of paraffin (especially branched) structures strongly decreases after treatment of the disperse system with AOS coagulant. Simultaneously, the contribution of the carboxy groups belonging to acids and esters also decreases, which suggests predominant coagulation of branched aliphatic oxygen-containing compounds.

Thus, we determined the optimal concentration of the coagulant it the stage of formation of the primary flakes (c = 0.04%). Now, by adding flocculant in various time intervals (10 s, 20 s, and 10 min) after the coagulant, we can determine the optimal concentration range of flocculants (Fig. 1b). The flocculant shows high activity, probably related to the intensity and diversity of intermolecular interactions of the flocculants with primary and relatively open mosaic structure of the coagulant. Formation of the secondary particle structures in the presence of the coagulant after prolonged exposure (10 min) does not noticeably affect the interparticle interactions between the coagulant and flocculants as compared to the experiment in which the flocculant was added in 20 s after coagulant addition.

The second series of flocculation experiments was carried out at various pH using different concentrations of the coagulant. As seen from Fig. 2 (pH 6.0, 5.4, 4.0), the flocculation rate is relatively high. Moreover, we can determine the optimal concentrations of flocculants already in the initial stage of flocculation, which is probably due to the properties of aluminum hydroxo complexes.

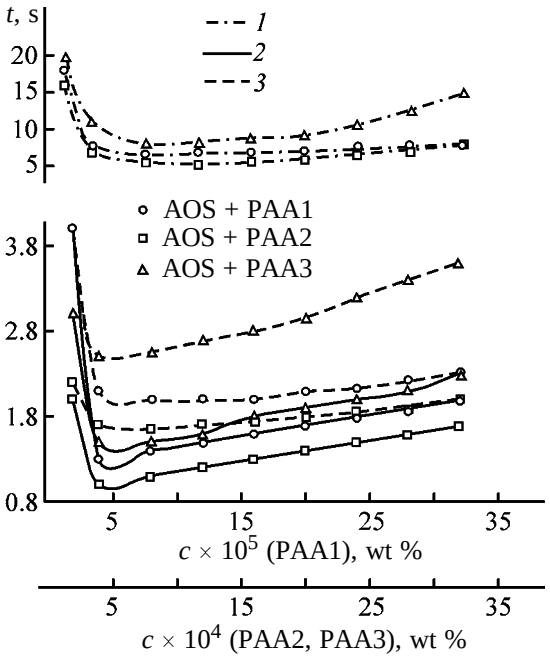

Fig. 2. Time of formation of primary flakes *t* as influenced by the concentration of additives *c*. pH: (*1*) 6.0, (*2*) 4.5, and (*3*) 4.

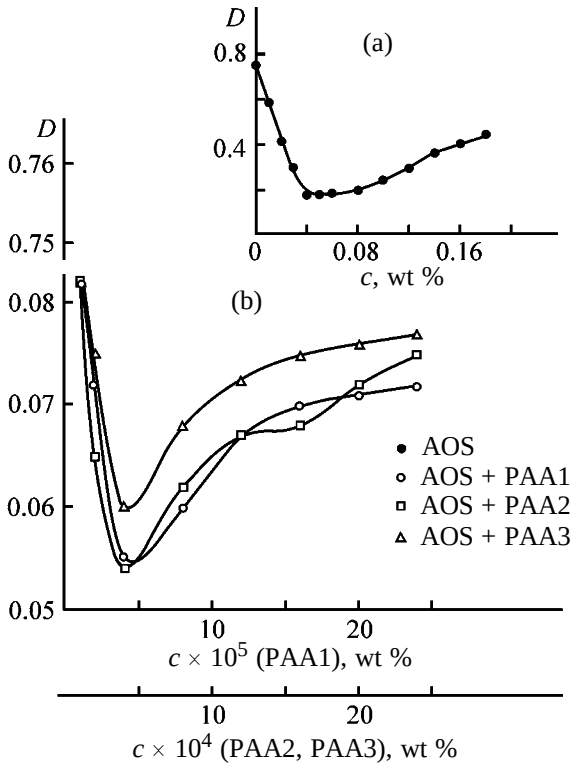

Fig. 3. Optical density *D* of a fat-containing disperse system as influenced by the concentration of additives *c*. Optimal concentration, wt %: AOS 0.04, PAA1 4×10^{-5}, PAA2 4×10^{-4}, and PAA3 4×10^{-4} (recorded 30 min after flocculant addition).

The dependences of the optical density of a fat-containing dispersion on the concentrations of the coagulant and its mixtures with flocculants allow determination of the optimal concentration range for AOS (Fig. 3a). The maximal coagulation power of the reagent is observed in the concentration range 0.04–0.08 wt %; thus, addition of the coagulant to the smallest optimal concentration would considerably decrease its consumption in industry.

Addition of flocculants to the disperse system containing coagulant in the optimal concentration strongly improves the purification quality. The optimal concentrations of the flocculants correspond to the minimum in the curves plotted in the optical density–flocculant concentration coordinates (Fig. 3b).

Further stage in purification of a disperse system is related to formation of the chain structures and coarser aggregates. The curves of the particle sedimentation in the presence of the coagulant and flocculants added in the optimal amounts are shown in Fig. 4.

As seen from Fig. 4, addition of both cationic or anionic flocculants increases the rate of the particle sedimentation. The flocculation power increases with increasing polymer concentration to some optimal value and then decreases (Fig. 5).

Our results (Fig. 5) showed that, at optimal coagulant concentration, the flocculation power of

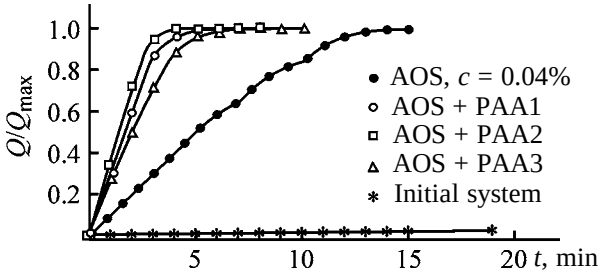

Fig. 4. Kinetic curves of sedimentation of fat dispersions at optimal doses of coagulant and flocculants; (*Q*) sediment amount and (*t*) time. Optimal concentration, wt %: AOS 0.04, PAA1 4×10^{-5}, PAA2 4×10^{-4}, and PAA3 4×10^{-4}; the same for Fig. 5.

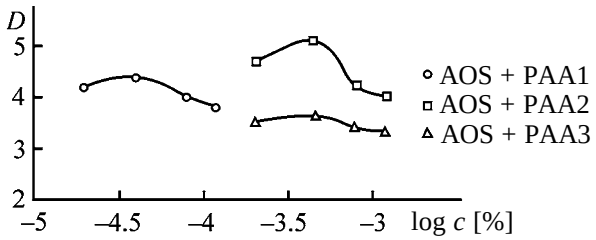

Fig. 5. Flocculation parameter *D* as a function of the flocculant concentration *c*.

anionic acrylamide copolymers is higher than that of the cationic compound. This difference is probably due to the nature of interactions between the negatively charged copolymer macromolecules and positively charged products of coagulant hydrolysis. Formation of hydrogen bonds between the functional groups of the copolymer with the AOS hydroxy groups can also be considered. The repulsion between the dispersed particles and similarly charged flocculant particles levels off the interaction with the primary coagulant structure. Comparison of the flocculation data for similarly charged copolymers PAA1 and PAA2 reveals that the molecular weight of the copolymer strongly affects formation of intermolecular bridges between the flocculant particles and coagulant structures.

The effect of the cationic flocculant added to the disperse system containing coagulant (c_C = const) is slightly lower that that of the anionic copolymers. This is probably due to some "blocking" effect of the positively charged AOS particles and repulsion of similarly charged flocculant and coagulant structures. In this case, the role of hydrogen bonds between the coagulant structures and cationic copolymer macromolecules in the course of flocculation is predominant.

Analysis of the composition of organic compounds remaining in the system after its treatment with AOS and flocculants indicates strong decrease in the optical density of solutions in the 1240–1170 cm^{-1} range.

CONCLUSIONS

(1) Data on sedimentation, primary flocculation, and optical density of fat-containing disperse system demonstrate the possibility of using aluminum oxysulfate as coagulant. The optimal concentration range of the coagulant was determined.

(2) The optimal properties of the coagulant are due to the primary coagulant structure formed by the products of aluminum sulfate hydrolysis.

(3) The data on sedimentation, primary flocculation, and optical density demonstrate rapid particle formation in the presence of flocculants in the stage of flake formation.

(4) The strongest flocculation effect is observed for anionic flocculants. At similar content of the ionic units in macromolecules, the flocculation power of polyacrylamide copolymers increases with increasing molecular weight of the polymer.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Properties of Asphalt–Lime-Containing Mineral Powder System

V. V. Yadykina

Shukhov State Technological University, Belgorod, Russia

Received May 6, 2003

Abstract—Strength and water, frost, and heat resistance of asphalt binding compound were studied in relation to the content of calcium oxide.

Asphalt–mineral composite is the main structural component of asphalt concrete; it acts as binder and strongly affects such properties of concrete as density, strength, deformability, resistance to water, frost, and heat, etc. [1].

The quality of asphalt binder (asphalt–mineral powder binary system) is characterized by structural-mechanical properties and their changes under the action of external factors, especially, temperature and water [2].

The stability of these properties depends on the organic binder and mineral powder and their ratio. Since asphalt binder is an ultimately concentrated disperse system, the interaction of the mineral surface with asphalt provides the decisive effect. Hence, the nature of the boundary and, especially, adhesion interaction between the filler and binder determine the properties of composites and their operation stability [2, 3].

It is known that the adhesion of asphalt to mineral materials is determined by their chemical composition. Numerous studies and factory experience show that the best components are finely ground limestone and dolomite [1, 2] chemically interacting with asphalt. These powders are recommended for production of asphalt concrete by GOST (State Standard) 16557–78.

In some cases, industrial wastes can also be used as fillers in production of asphalt concretes, but, according to GOST 9128–97, the content of active CaO + MgO must not exceed 3 wt %.

This limit has virtually no substantiation. Moreover, to activate acidic mineral fillers (rubble and sand) and improve their adhesion to asphalt, lime is added in asphalt concrete mixture in amounts of 1–2% of the total system weight (i.e., 15–20% of the weight of mineral powder) [1, 4].

The data on utilization of finely dispersed industrial wastes containing 15–25% CaO as mineral filler of asphalt concretes indicate that they improve the concrete properties [5].

The aim of this work was to determine the optimal content of calcium oxide in the mineral powder and to study its effect of structuring and properties of the asphalt–lime-containing mineral powder system.

EXPERIMENTAL

We used limestone from the Elets field and lime purchased from the Stroimaterialy Joint-Stock Company (Belgorod, Russia). These mineral components were thoroughly mixed in certain ratios; the properties of the resulting powders are listed in Table 1.

The size distribution and specific surface area of the mineral powders tested were similar (100% sifting through sieve 0.071, 4500 $cm^2\,g^{-1}$ specific surface area).

The asphalt binder was prepared by mixing of the preheated components at 150–160°C for 5–6 min to obtain a uniform mixture.

The optimal charge of asphalt for each composition was determined by the procedure given in [6]. We used BND-60/90 asphalt with the following properties: penetration 21×10^{-1} and 83×10^{-1} mm at 0 and 25°C, respectively; softening point 41°C; extensibility 3.8 and 70 cm at 0 and 25°C, respectively; brittle point 17°C; and flash point 246°C.

The properties of the asphalt–lime-containing mineral powder binary system were studied using cylindrical samples (25 mm in diameter) according to GOST 12784–78.

The interaction with asphalt and structuring processes as influenced by the properties of mineral

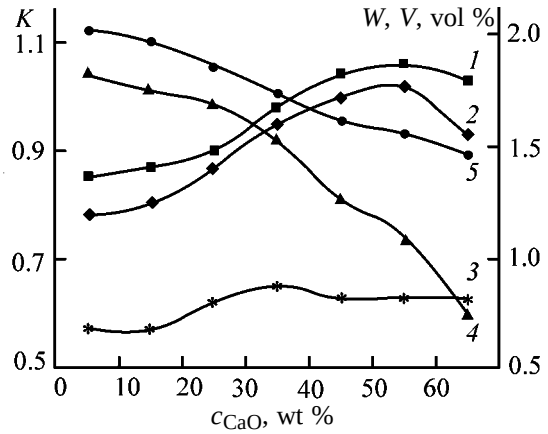
powders were studied by IR spectroscopy and conical plastometry.

The results of physicomechanical tests of the asphalt binder shown in Table 2 and in the figure indicate that calcium oxide contained in the mineral powder noticeable affects the properties of the asphalt–lime-containing mineral powder system. With increasing content of CaO to 60%, the average density of the samples increases from 2170 to 2240 kg m^{-3}. Simultaneously, water saturation and swellability decrease from 1.81 and 2.01 to 0.75 and 1.46%, respectively; the sample strength increases. All these facts suggest more active interaction of asphalt with mineral lime-containing filler as compared to the composite based on limestone. This is probably due to the acid–base reaction of asphaltic and naphthenic acids with calcium oxide in the mineral powder and chemisorption on its surface of aromatic acids and other organic compounds (with unsaturated bonds) contained in asphalt.



Properties of asphalt binder as influenced by the content of calcium oxide in the mineral powder c_{CaO}. Coefficient *K* of (*1*) water resistance, (*2*) water resistance at prolonged storage, (*3*) heat resistance; (*4*) water saturation *W*, and swellability *V*.

The above assumptions are confirmed by the IR data. The decrease in the intensity of the absorption bands in the 1720–1700 and 1600 cm^{-1} ranges indicates that the content of acids and aromatic compounds participating in the interaction of asphalt with lime-containing mineral powder is smaller than that with the filler based on calcium carbonate.

Formation of calcium hydroxide in the presence of water and mudding of the pores (due to new growths [7]) probably explains the increasing density and decreasing water saturation of the samples.

It was found [1] that free lime, being added in

certain amounts, acts as active filler of asphalt concrete and promotes its structuring.

Our data on structural-mechanical properties of asphalt binder confirmed the above assumption. As seen, in the case of lime-containing mineral powders, the inflection in the dependence of the ultimate shear stress on the degree of filling of the disperse systems is observed at lower degrees of filling as compared to the composites based on limestone. The structuring effect is proportional to the content of calcium oxide in the filler. For example, at 40% content of the limestone-containing mineral powder, the ultimate shear stress was 0.53, and at addition of 20% and 40% lime, the ultimate shear stress increased to 0.69 and 0.79 MPa, respectively. At 60% degree of filling, the ultimate shear stress comprised 1.28, 1.55, and 1.70 MPa, respectively.

With increasing content of calcium oxide in the mineral powder to 50%, the ultimate compression strength at 20°C increases, and at $c_{CaO} > 50\%$ this parameter decreases for samples in both dry and water-saturated states (Table 2).

As seen, maximal increase in the strength of the dry samples is 32.4%, whereas in the case of water-saturated samples it is greater (64.5%); this fact confirms formation of calcium hydrate and filling of the pores.

When the content of lime in the mineral powder is higher than 30%, the compression strength of water-saturated samples at 20°C is greater than that of the dried samples, i.e., the water resistance coefficient is greater than 1 (figure, curve *1*) and reaches a maximum (1.06) at 50 wt % content of CaO in the filler. Though with further increase in the lime content the water resistance coefficient slightly decreases (to 1.03), it does not meet the GOST requirement (no more than 0.8). Similar dependence was registered for the water resistance coefficient at prolonged storage (figure, curve *2*). According to [8], specifically the water resistance of the binary systems exactly determines the intensity of adhesion at the mineral powder–binder boundary.

The ultimate compression strength at 50°C increases in the entire concentration range studied, probably due to the increase in the adhesion, and the maximal increase is 45.2%. This fact is of particular importance, because at 50°C the adhesion of asphalt sharply decreases [9]. The increase in the compression strength at 50°C improves the heat resistance of the samples (figure, curve *3*).

It was found that, after prolonged storage, the strength of the samples based on lime-containing mineral powder with an optimal content of CaO was greater as compared to the limestone-containing samples. For example, the ultimate compression strength of the samples (based on mineral powder containing 40% CaO) stored for 30 days at room temperature and tested at 20 and 50°C increased by 12–14%, whereas the compression strength of the limestone-containing samples remained virtually constant. The tests performed after 6-month storage of the samples showed no changes in the compression strength, i.e., structuring processes were completed.

These results indicate elevated adhesion of the mineral powder and asphalt, which was confirmed in [10], and intensive structuring in the presence of lime. The optimal content of CaO in the mineral powder is 20–50%. At greater content of calcium oxide the parameters of asphalt concrete become worse, probably due to insufficient content of the active components in asphalt, such as naphthenic acids and other oxygen-containing compounds able to bind the reactive mineral component.

CONCLUSIONS

(1) Calcium oxide being added in optimal amounts (20–50 wt %) to the mineral powder increases the strength and water, frost, and heat resistance of the asphalt binder and decreases its water saturation and swellability, which is probably due to the active sorption of asphalt on the mineral powder surface, hydration of lime, and its structuring effect on asphalt.

(2) The experimental data obtained allow prediction of physicomechanical and operation properties of the asphalt concrete pavement at utilization of the lime-containing mineral powder.

An Electrochemical Method for Creating a pH Gradient in a Microflow of an Electrolyte

E. A. Ostrovidov and M. N. Ryabova

North-West State Extramural Technical University, St. Petersburg, Russia

Received December1, 2003

Abstract—A method for creating a pH gradient in a microflow of an electrolyte and an installation for the same purpose without any moving parts were developed.

Modern high-performance liquid chromatography (HPLC) is frequently carried out by the method of gradient elution in order to optimize the determinations. In doing so, a modifying substance, which changes the eluting capacity of the mobile phase, is introduced into its flow in the form of a compact zone. By now, introduction techniques based on mechanical agitation of the eluting mixture in mixing chambers of liquid chromatographs have been developed in ample detail [1]. In addition to being technologically complicated, such an approach is hardly possible in microcolumn chromatographic analysis, when the volume of the eluting mixture is several microliters [2]. The method of preformed gradient, which is frequently used in the microcolumn version of HPLC and consists in introducing precisely measured volumes of the eluent of various compositions, is rather laborious [3].

A flow-through porous electrode (FPE) can be used to meter a marker substance into the flow of the mobile phase. In polarization of an FPE made of glassy or activated carbon, there occurs, depending on the polarization sign, a change in the pH of the aqueous mobile phase:

$$\left.\begin{aligned} 2H_2O + 2e &\rightarrow 2OH^- + H_2\uparrow \\ 2H_2O - 4e &\rightarrow 4H^+ + O_2\uparrow. \end{aligned}\right\} \quad (1)$$

The electrochemical method for changing the pH value in a microflow of the electrolyte makes it possible to vary the pH of the mobile phase within six pH units using an FPE with a microvolume of the mobile phase of up to 2–3 μl.

The need in such a method for varying the pH in a microflow of an electrolyte is acute in analysis of amino acids [4]. The schematic of an electrochemical installation that can be used for this purpose is shown in the figure. The mobile phase, which fills vessel *1*, is driven therefrom by compressed helium delivered into the vessel from cylinder *2*. The flow of the mobile phase is directed into the electrochemical cell that contains a graphite FPE through whose pores the mobile phase is filtered. The vessel *1* contains an auxiliary electrode made of platinum-plated titanium and used to polarize the FPE. Depending on the polarization sign, the pH of the mobile phase changes as a result of occurrence of reaction (1) in the pores of the FPE. Further, the modified flow of the mobile phase is delivered to the measuring unit of the installation, which contains a flow-through capillary in-

0.91	1.6	2.83	2.78

dicator electrode made of Corning 015 glass and having a hydrogen function [4].

The volume of the measuring capillary of the transducer was 20 mm^3. The geometric thickness of the generator FPE was found from the condition of decay of the electrochemical process in the porous medium of the electrode. The calculations performed demonstrated that the thickness of the generator FPE should be 0.4–0.5 cm.

With the four-electron mechanism of the electrode reaction, the concentration c of ions being regenerated was calculated using the Faraday law:

$$c = \frac{I}{4Fu},$$

where I is the polarization current; F, the Faraday number; and u, the filtration rate of the mobile phase.

The table lists the calculated and experimental pH values of the mobile phase composed of a 0.1 M KCl solution.

The table shows that the results of calculation coincide with the experimentally measured pH values. In solutions having higher buffer capacity, compared to an aqueous solution of potassium chloride, the current of polarization of the generator FPE should be raised to 200–500 mA, depending on the buffer capacity of the mobile phase used. For example, to change the pH of a citrate buffer solution that contains potassium citrate, hydrochloric acid, thiodiglycol, detergent, and caprylic acid [1] from 4.26 to 8.30 at a filtration rate of the mobile phase equal to 5 $cm^3\ s^{-1}$, it is necessary to maintain the current at about 240 mA.

CONCLUSION

An electrochemical method for creating a pH gradient in a microflow of an electrolyte and an installation for this purpose, which contains no moving parts and makes it possible to vary the pH value within six units, were suggested. The volume of the generation chamber is about 20 mm^3.

New Cooling Mixtures Containing Sodium Acetate Trihydrate

I. M. Osadchenko and A. P. Tomilov

State Research Institute of Organic Chemistry and Technology, Moscow, Russia

Received December 30, 2003

Abstract—Binary cooling mixtures consisting of $CH_3COONa \cdot 3H_2O$ and NH_4NO_3, $Al(NO_3)_3 \cdot 9H_2O$, or $Ni(NO_3)_2 \cdot 6H_2O$ were developed. They allow the initial temperature to be decreased by 18–19°C. Application of the mixtures does not require additional consumption of water.

Recently there has been an interest in problems of small-scale power engineering for the purpose of power saving. One of the routes to power saving is the development of materials and devices based on the use of physicochemical properties of substances, e.g., of cooling mixtures. Cooling mixtures as autonomous sources of cold are used in laboratory and everyday practice and for cooling and transportation of biological materials (e.g., vaccines, blood, etc.) [1–3].

Numerous compositions of cooling mixtures containing solid salts and water (ice) have been described. A temperature decrease on mixing them is due to the absorption of heat upon salt dissolution [1]. For example, a ternary mixture containing (wt %) NH_4NO_3 40.62, Na_2CO_3 40.62, and $CuSO_4$ 0.76 is produced for everyday use under the Shal'tis brand name [2]. The temperature decrease on dissolving this mixture in water is 10°C (difference in the temperatures before and after mixing). The drawback of this mixture is relatively low performance. A search for new mixtures is an urgent problem.

Mixtures containing $CH_3COONH_4 \cdot 3H_2O$ were tested previously. The test procedure is described in [4].

The tests performed showed that mixtures containing $CH_3COONa \cdot 3H_2O$ and NH_4NO_3, $Al(NO_3)_3 \cdot 9H_2O$, or $Ni(NO_3)_2 \cdot 6H_2O$ are the most effective. It is important that the binary mixtures found are applied without using free water. Evidently, the process occurs with participation of water of crystallization. We found no data on such mixtures in the literature.

Let us give a typical example of application of the cooling mixture. A 100-ml beaker was charged with 5.0 g of $CH_3COONa \cdot 3H_2O$ and then 7.0 g of NH_4NO_3 (as powders), and the temperature was recorded with a thermometer placed inside the beaker. The initial temperature was 21.5°C. The minimal temperature was 2.0°C after stirring for 2.0–2.5 min and 3.0°C after stirring for 4.0–5.0 min. The temperature difference was 19.5°C. The mixture after stirring becomes a suspension. The results of similar tests with mixtures of other compositions are presented in the table. The table shows that, at the component weight ratios from 1 : 0.5 to 1 : 2.9, the temperature decrease is from 17.5 to 29.5°C, i.e., the mixtures show considerably higher performance than Shal'tis. Moreover, the mixture proposed is simpler in use.

Thermochemical Characteristics of a Series of Terpenoids, Alkaloids, and Flavonoids

B. K. Kasenov, Zh. K. Tukhmetova, Sh. B. Kasenova, A. Zh. Abil'daeva, and S. M. Adekenov

Institute of Phytochemistry, Ministry of Education and Science of the Kazakhstan Republic, Karaganda, Kazakhstan

Received November 13, 2003

Abstract—The heats of combustion and melting of a series of natural terpenoids, alkaloids, and flavonoids were estimated by approximate thermochemical methods. From these quantities, the standard heats of formation of the compounds in the liquid (molten) and solid states were calculated.

Natural terpenoids, alkaloids, and flavonoids exhibit a wide spectrum of biological activity, and valuable drugs have been developed on their basis. However, data on the thermochemical and thermodynamic characteristics of these natural compounds, required to simulate physicochemically their synthesis and to reveal correlations between structural and energy characteristics of these substances, are lacking. Our goal was to estimate the thermochemical characteristics (heats of combustion, melting, and formation) of some terpenoids, alkaloids, and flavonoids using indirect approximate methods.

The standard enthalpies of combustion of the compounds were calculated by the Karash and Frost equations [1] applicable to complex organic substances in the liquid state. The heats of combustion calculated by both methods, and also the mean values, are given in the table.

The Karash method takes into account the presence of lactone rings, various functional groups, and number of shifted electrons. The Frost method takes into account the presence of aromatic rings, cyclenes, and double bonds in rings and side chains of cyclenes.

From the mean values of ΔH^0_{comb}, using the Hess law and proceeding from the reactions

$$C_aH_bO_{c(l)} + (a + b/4 - c/2)O_{2(g)} = aCO_{2(g)} + b/2\,H_2O_{(l)} - \Delta H^0_{comb}, \quad (1)$$

$$C_aH_bN_dO_{c(l)} + (a + b/4 - c/2 + d/4)O_{2(g)} = aCO_{2(g)} + b/2H_2O_{(l)} + d/2N_2 - \Delta H^0_{comb}, \quad (2)$$

we calculated the standard enthalpies of formation of the compounds in the liquid state (see table). The quantities $\Delta_f H^0(298.15)$ for CO_2(g) and H_2O(l) were taken from [2].

Since at the standard temperature (298.15 K) the compounds are in the crystalline state, it is necessary to calculate $\Delta_f H^0(298.15)$ for the solid compounds. To do this, we estimated ΔH^0_m of these compounds by the Gambill equation recommended in [3]:

$$\Delta H^0_m/T_m = 20.72 \times 10^{0.00324M}, \quad (3)$$

where M is the molecular weight of the compound.

The results of calculation of ΔH^0_m are given in the table. The melting points of terpenoids, alkaloids, and flavonoids were taken from [4–10].

From the equations

$$\Delta_f H^0(298.15)\,C_aH_bO_{c(s)} = \Delta_f H^0(298.15)\,C_aH_bO_{c(l)} - \Delta H^0_m, \quad (4)$$

$$\Delta_f H^0(298.15)\,C_aH_bN_dO_{c(s)} = \Delta_f H^0(298.15)\,C_aH_bN_dO_{c(l)} - \Delta H^0_m, \quad (5)$$

we calculated the standard enthalpies of formation of the compounds in the crystalline state (see table).

CONCLUSIONS

(1) Previously unknown enthalpies of combustion, melting, and formation of a series of terpenoids, alkaloids, and flavonoids were calculated.

(2) The results are of interest for predicting the thermodynamic properties of related compounds and simulating their synthesis. They can also be included in basic handbooks and data bases.

ACKNOWLEDGMENTS

The study was financially supported by the Grant Agreement of the Science Foundation of the National Academy of Sciences of the Kazakhstan Republic, Research Program PFI 2-2-2.4-2 (31)–II of March 11, 2003.

Hydrogenation of Ethyl *p*-Nitrobenzoate on Carbon-Supported Palladium–Triphenylphosphine Catalyst

I. I. Obraztsova and O. A. Efimov

Kemerovo Branch, Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Kemerovo, Russia

Received August 6, 2003

Abstract—Hydrogenation of ethyl *p*-nitrobenzoate on carbon-supported palladium–triphenylphosphine catalyst at 40°C and atmospheric pressure of H_2 was studied.

Hydrogenation of ethyl *p*-nitrobenzoate (ENB) attracts particular attention, since the reaction product is ethyl *p*-aminobenzoate (EAB), which is an anesthetic (medical name Anesthesin) and an intermediate in synthesis of novocaine.

Anesthesin is synthesized in industry by reduction of ENB in aqueous solution with the system iron powder–ammonium chloride [1–3]:

$$p\text{-}NO_2C_6H_4CO_2Et + Fe + NH_4Cl \leftrightarrows p\text{-}NH_2C_6H_4CO_2Et + H_2O. \quad (1)$$

Reaction (1) is performed at 96–98°C; the yield of the target product does not exceed 90%, and it requires additional time-consuming purification. The synthesis is labor-consuming; it is performed under severe conditions, is accompanied by formation of colored by-products, and involves dilution of the reaction mixture with water, washing, and separation of the metallic slime, which gives rise to environmental problems.

The majority of the above problems can be avoided by performing catalytic hydrogenation of ENB with molecular hydrogen:

$$p\text{-}NO_2C_6H_4CO_2Et + H_2 \xleftrightarrow{\text{Cat.}} p\text{-}NH_2C_6H_4CO_2Et + H_2O. \quad (2)$$

Some implementations of this process are reported in [4–8]. In some cases [4–6], classical heterogeneous hydrogenation catalysts based on platinum group metals were used. The reaction was performed at atmospheric or elevated [4] H_2 pressure; the reaction temperature was varied from 20 to 80°C. The yield of Anesthesin did not exceed 90%. The drawbacks of these procedures are high consumption of Pd (5 wt%), its inefficient utilization, the necessity of the catalyst purification after every run, and severe reaction conditions (high pressure, elevated temperature, corrosive medium). In other works [7, 8], EAB was prepared on metal–polymer catalysts such as palladium-containing anion exchangers A-17-8-Pd and AN-1-Pd. The reaction was performed at 30–45°C and H_2 pressure of 1 atm; the yield was 98–100%. The major drawback of the process is relatively low reaction rate on such catalysts (by an order of magnitude lower than on Pd/C catalysts).

Thus, search for new, more effective catalysts of reaction (2) remains an urgent problem. In this connection, we studied hydrogenation of ENB on carbon-supported palladium–triphenylphosphine catalyst.

EXPERIMENTAL

Carbon-supported palladium–triphenylphosphine catalyst was prepared as follows: 2.11 g of palladium acetate and 0.985 g of triphenylphosphine were dissolved in 200 ml of acetone in an inert atmosphere (N_2, Ar), 50 g of a carbon support was added in an inert gas flow, and the mixture was stirred at room temperature until the solution became fully colorless. Then the reactor was purged with H_2 for 5 min, and the catalyst was reduced at 20–40°C for 4–6 h with vigorous stirring. The catalyst was filtered off, dried in a vacuum, and stored in an inert atmosphere. The resulting catalyst contained no more than 2 wt % Pd.

Reduction of ENB was performed in ethanol or 2-propanol at 40°C with H_2 at atmospheric pressure. The reactants were loaded in an inert gas atmosphere.

1070-4272/04/7703-0511 © 2004 MAIK "Nauka/Interperiodica"

Hydrogenation of ENB was also performed at atmospheric pressure in a temperature-controlled reactor at 30–40°C. The components were also loaded in an inert gas atmposphere (N_2 or Ar) to prevent their oxidation with atmospheric oxygen and thus improve the product quality. After loading the catalyst prepared, ENB, and solvent, the whole system was kept at the required temperature for 3–5 min and purged with H_2 for 5 min, after which vigorous stirring was started. After the uptake of the theoretical amount of hydrogen, the reaction stops. The next portion of ENB is fully hydrogenated in the same time. The catalyst can effect hydrogenation of up to 50 portions of ENB without noticeable loss in the activity.

The total amount of converted ENB per gram of Pd is 29250 g on the average. The yield of Anesthesin is quantitative (chromatographic analysis data).

The spent catalyst can be separated, regenerated, and then reused without noticeable loss in the activity.

The high activity and long life of the suggested catalyst are due to its structural features. As shown in [9], deposition of palladium on carbon supports followed by reduction with hydrogen results in formation of cluster complexes in which triphenylphosphine molecules stabilize palladium particles of definite size (optimal ratio $PPh_3/Pd \approx 0.4$), exhibiting the highest catalytic activity. This allows the hydrogenation rate and yield of the target product to be considerably increased; it also ensures long working life of the catalyst without noticeable loss in the activity.

The preservation of the catalyst activity is also favored by mild synthesis conditions (H_2 pressure 1 atm; temperature up to 40°C; anhydrous medium; single-component solvent readily removable by evaporation in isolation of the target product). It is also important that the solvents used are not involved in side reactions and are not so toxic as, e.g., toluene, benzene, or methanol used in alternative procedures [4, 8] (which is very important in preparation of pharmaceuticals); also, they do not require time-consuming washing of the finished product.

It should be noted that, with ultradispersed diamond used as catalyst support, the hydrogenation rate appreciably increases [10].

Thus, we have improved the hydrogenation process: the service life of the catalyst was increased many-fold; the process was made simpler and shorter; the high pharmacopoeia quality of the finished product and its ~100% yield were attained.

CONCLUSIONS

(1) A carbon-supported palladium–triphenylphosphine catalyst was suggested for preparation of Anesthesin of high pharmacopoeia quality in a quantitative yield.

(2) Anesthesin is prepared in one step under mild conditions without by-products. Fifty synthesis runs can be performed with one catalyst portion, after which it can be regenerated and reused.

BRIEF COMMUNICATIONS

Chloromethylation of Benzyltoluenes with Chlorodimethyl Ether

D. A. Pisanenko and Yu. I. Smirnov-Zamkov

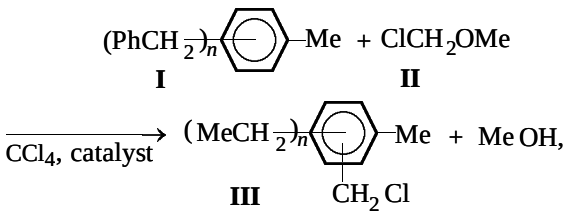
Kiev Polytechnic Institute, National Technical University of Ukraine, Kiev, Ukraine

Received November 6, 2003

Abstract—Chloromethylation of a mixture of benzyltoluenes with chlorodimethyl ether in CCl_4 at 65°C in the presence of Fe, FeO, Fe_3O_4, Fe_2O_3, $ZnCl_2$, $FeCl_3$, and a cation-exchange resin (KU-2 × 8chS) was studied.

Macromolecular chloromethylated derivatives are used for preparing metal corrosion inhibitros, antimicrobial agents, and anion-exchange resins [1–3]; they show increased performance when used in multicomponent mixtures. It is interesting to test as components of such mixtures chloromethylation products of commercial hydrocarbons, e.g., diarylmethanes used as liquid dielectrics and heat carriers [4, 5]. Their chloromethylation with chlorodimethyl ether allows HCl to be eliminated from the process [6].

Here we report on chloromethylation of a 35 : 55 : 10 mixture of mono-, di-, and tribenzyltoluenes (**I**) with chlorodimethyl ether **II** in CCl_4 at 65°C in the presence of various catalysts:



where n = 1–3 (see table).

The chloromethylation efficiency was studied in relation to the molar ratio of benzyltoluenes **I** to chlorodimethyl ether **II**, kind and amount of the catalyst, and reaction time. The number of incorporated CH_2Cl groups was determined from the intensity of the methylene proton signals in the ^1H NMR spectra [7]; both reaction mixtures and final products were sampled. The conditions and results of the experiments are given in the table.

As seen from the table, Fe_2O_3, $FeCl_3$, and $ZnCl_2$ show high catalytic activity in the process; the number of incorporated CH_2Cl groups can be controlled by varying the amount of the catalyst (run nos. 15–21) and the excess of chlorodimethyl ether (run nos. 8–11). At too long reaction time, the content of CH_2Cl

groups starts to decrease (run no. 19), probably owing to condensation of chloromethylated benzyltoluenes. The optimal content of anhydrous $ZnCl_2$ is 2 wt % relative to benzyltoluenes, as with larger amounts of the catalyst (run nos. 20, 21) the content of CH_2Cl groups does not noticeably grow, whereas at smaller amounts (1 wt % and less) it drastically decreases (run nos. 15–17). A cation-exchange resin, KU-2 × 8chS, is also suitable as catalyst, but it should be taken in amount as large as 25 wt % relative to benzyltoluenes (run nos. 24–26).

Iron(III) oxides are promising as catalysts of this reaction, as they show high performance and can be readily separated by filtration. Chloromethylated benzyltoluenes, after purging with nitrogen and distilling off the solvent, can be used in various processes as compounds with a labile chlorine atom [8]; unchanged benzyltoluenes can be reused.

EXPERIMENTAL

Chlorodimethyl ether was prepared by passing HCl through a mixture of paraform and methanol [6]; a 35 : 55 : 10 mixture of mono-, di- and tribenzyltoluenes was prepared by alkylation of toluene with benzyl chloride in the presence of anhydrous $FeCl_3$ [9] or taken as a ready commercial product (used as liquid dielectric) [4]. The GLC analysis was performed on a Biokhrom device (5% SE-30 on Chromosorb W, carrier gas He). The ^{1}H NMR spectra were recorded on a Tesla BS-487 spectrometer (80 MHz); internal reference tetramethylsilane.

Chloromethylation was performed following the procedure from [6]. A reactor was charged with 50 g of a mixture of benzyltoluenes, and 100 ml of CCl_4 and the required amount of the catalyst were added. The mixture was heated with stirring to 65°C, and a solution of the required amount of chlorodimethyl ether in 50 ml of CCl_4 was added over a period of 0.5 h. Then the stirring was continued for the required time. After reaction completion, the catalyst was filtered off, the filtrate was purged with nitrogen, the solvent was distilled off, and a sample was withdrawn for taking a ^{1}H NMR spectrum. Samples of the reaction mixture in the course of the reaction were taken and treated similarly. Characteristic results are given in the table.

BRIEF COMMUNICATIONS

Asphaltic Dispersion and Its Evolution in Manufacturing Asphaltic Concrete

E. S. Levchenko, D. A. Rozental', and G. D. Zalishchevskii

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received June 25, 2003

Abstract—Evolution of properties of cold asphalt is investigated. The time required for establishment of adsorption equilibrium in preparation of asphaltic concrete is determined.

The asphaltic dispersion differs from the classical colloidal systems in that its dispersed phase is formed from molecules similar to those of the dispersion medium. The molecules with a polynuclear condensed structure consisting of 3–4 aromatic and 2–3 naphthene rings represent planes with alkyl substituents bound around. Four to six molecules are arranged in parallel to each other to form a quasispherical stack associate.

Thanks to π-electron systems of the aromatic and heteroaromatic rings, the intermolecular bonds in the associate appear to be rather strong, and their dissociation starts only above 300°C. It was demonstrated by X-ray diffraction that, in supramolecular structures of this kind, the stack thickness is well comparable with the diameter of the molecules (~0.8–1.7 nm), that including the solvate shell being about 2.0–2.3 nm [1, 2]. These structures are known as asphaltenes, even though it is not absolutely correct.

In practice, by asphaltenes is meant a mixture of compounds precipitated from a toluene solution of asphalt under the action of *n*-pentane or *n*-hexane. Along with high-molecular-weight aromatic molecules, this mixture can contain low-molecular-weight polar molecules insoluble in the indicated solvents. Therefore, asphaltenes thus isolated can differ significantly from those forming the dispersed phase of asphalt. Furthermore, asphalt contains a great amount of molecules also tending to association, but with a lower energy of intermolecular interaction. In all cases, association proceeds by random diffusion of molecules in the asphalt bulk, until molecules of the appropriate structure come into collision. This requires a time increasing with decreasing temperature, because of increasing viscosity of the system and decreasing energy of the molecules.

Therefore, it takes a long time to form a thermodynamically stable asphalt structure. The lower the temperature of asphalt, the longer this time. This may be clearly demonstrated by measuring the penetration of asphalt without intermediate softening in eight days under oxygen-free conditions in the dark. The results of such experiments are given in the table.

As seen, the penetration of asphalt decreased with time, which is due to solely structural transformations. Such an aging effect was attributed to oxidation in the course of storage. However, in fact, it is a result of high-temperature oxidation of asphalt. Structural transformations accompanying establishment of thermodynamically stable state are very typical of oxidized asphalts. In the course of asphalt oxidation, naphtheno–aromatic oils undergo oxidative dehydrogenation to form asphaltenes. At 220–280°C, this is a kinetically controlled process, while association is controlled by diffusion, proceeding at a considerably lower rate.

Another consequence of aging, but of asphaltic concrete pavements, which has not been taken into consideration until now, is structural transformation of

Variation in the penetration of asphalt in aging at room temperature

Asphalt	Π_{25},* 0.1-mm units, in aging for indicated time, days

asphalt caused by adsorption of certain components on the mineral ballast. In fabrication of asphaltic concrete at an asphalt plant, the time of contact of asphalt with mineral ballast is 20 min at 160°C. A short time after asphaltic concrete is laid to the roadbed. Thus, apparently, asphaltic concrete is cooled before reaching the adsorption equilibrium.

It was demonstrated by the hot centrifugation method that the adsorption equilibrium of asphalt on both acidic and basic rocks is established in 3–4 h at 160°C and somewhat more rapidly at higher temperatures. At room temperature, this takes 6–7 months. Adsorption of asphalt on the mineral ballast surface is a selective process, resulting in extraction of the most readily adsorbed components from asphalt, which, in its turn, distorts the thermodynamic equilibrium in the asphaltic dispersion system. As a result, transformation of the asphalt structure changes its characteristics: the penetration considerably decreases and softening point increases.

The effect of heating time τ on the performance characteristics (penetration $\prod_{25}$ and softening point T_s) of centrifuged asphalt is illustrated below.

τ, h	0	1/2	1	2	3	4
$\prod_{25}$, 0.1-mm units	88	71	59	46	39	37
T_s, °C	48	50	54	62	66	67

The observed considerable decrease in the penetration and increase in the softening point suggest an increase in the rigidity of the asphalt structure and decrease in its volume. Detachment of asphalt from a mineral material always proceeds via break of the cohesion bonds, whose strength is lower as compared to the adhesion bonds. Therefore, in asphalt cooled before reaching the adsorption equilibrium, inner stresses are realized in its bulk between the mineral ballast grains, which may result in microcracking, penetration of water, and deterioration of the road pavement. Therefore, the primary cause of deterioration of a road pavement is not an oxidation, but structural transformation of asphalt. Oxidation contributes only at the next stage, i.e., after microcracks are formed in the asphaltic mass.

As a conclusion, our results show that, to improve the durability of asphaltic concrete, it is necessary to hold it at high temperature (160°C) for at least 3–4 h, i.e., until reaching the adsorption equilibrium.

BOOK REVIEWS

Beloglazov, I.N., Golubev, V.O., Tikhonov, O.N., Kuukka, J., and Jäskeläinen, Ed., *Fil'trovanie tekhnologicheskikh pul'p* (Filtration of Process Pulps)

Moscow: Ruda i Metally, 2003, 320 pp.

A group of authors, headed by known scientists in the field of simulation of metallurgical processes and apparatus (prof. I.N. Beloglazov) and concentration of mineral resources (prof. O.N. Tikhonov), published, together with the leading specialists of the Finnish Larox Oy company, a manufacturer of filtering equipment, a monograph that summarizes a vast material on dehydration of industrial pulps and slurries. In the four chapters of the book, the authors presented the basic concepts of the theory of dehydration processes and data on technical means used in filtration separation of solid–liquid systems and provided the description with their own recommendations and examples of original engineering decisions from the world practice.

The brief foreword (pp. 3–5) notes the importance of developing, as fast as possible, high-intensity process filters that would meet the requirements of modern industry and enable optimization of the operation modes of the already existing equipment. Tackling with such a task requires a detailed development of appropriate mathematical models and algorithms. The first chapter (pp. 6–109) presents information concerning the theoretical description of filtration processes. A classification of pulps and sediments and of methods for changing their moisture content is given. Reference data on physical properties of various real process pulps, cakes, and gas mixtures and methods for determination of these are presented. The fundamental aspects of hydrodynamic and heat- and mass-exchange processes, which are taken into account by the theory of filtration separation of pulps, are considered. In the main part of the chapter, the fundamental aspects of the processes of filtration, filtration washing, and drying are presented. The authors suggest a unified algorithm for calculating filtration–dehydration processes, based on classical theories of filtration and drying.

The second chapter (pp. 110–143) contains detailed evidence concerning methods for intensifying variously implemented filtration processes. Various methods for improving the filterability of pulps are described, the most effective flocculants lowering the stability of pulps are indicated, and the mechanism by which auxiliary substances affect the course of filtration is analyzed. Also, the main methods for physical or physicomechanical intensification are considered. In particular, studies concerned with the influence exerted by mechanical vibrations with various frequencies, amplitudes, and inducing methods are discussed. A method for improving the filterability of pulps by destruction of the sediment is analyzed.

The third chapter (pp. 144–213) reviews various apparatus implementations of the filtration process. Designs, operation principles, and technical characteristics of a great number of filters are described. These include rotary and plate filters, cartridge and leaf filters, band vacuum filters, plate-and-frame pressure filters, drum and disc filters, automated press filters with horizontal chambers of the FPAKM type, and other special types of filters. The authors note advantages and disadvantages of filters of various designs and give recommendations on choice of the filtration equipment for particular industries. Special attention is given to filtering partitions, their classification is given, and data on their chemical stability and mechanical properties, as well as strength and durability, are given. A summary table of technical characteristics of filtering fabrics of Russian manufacture is presented.

The fourth chapter (pp. 214–305) of the monograph is devoted to recent achievements of world's filter-manufacturing industry. Recently, a tendency toward organization of low-waste plants has been manifested in the development of world's industry, which is due to global economical and environmental problems. This tendency is particularly pronounced for plants of mining, concentrating, and metallurgical industries. In this context, the requirements to particular processes, including separation of process pulps by

1070-4272/04/7703-0517 © 2004 MAIK "Nauka/Interperiodica"

filtration, become increasingly stringent. The authors formulate the requirements to modern filters. The contribution of Russia's specialists to the creation of new filtering technologies and development of the FPAKM family of filters is noted. Modern varieties of filters of this kind are represented by those manufactured by a Finnish company Larox Oy. The manufactured set of press filters is described, with all technical characteristics listed and designs, operation principles of separate units of the filters, and conditions of their industrial use described. Also, the laboratory and pilot equipment for testing of process pulps is described, and results of laboratory tests of pulp samples from a number of domestic and foreign plants are presented. Of particular interest is the material concerning the reconstruction of filtration processes at the largest plants of mining, metallurgical, foodstuff, paint-and-varnish, pharmaceutical, and other industries. Larox LSF filters, which serve for deep purification of various objects: for recovery of solid suspended particles from industrial solutions, electrolytes, and wastewater even at very low content of these particles, are briefly described. The operation of the Larox LSF deep-purification filters is based on the phenomenon of adsorption filtration, which ensures adhesion of micrometer- and submicrometer-size particles to fibers of the filtering fabric, even despite the much smaller size of these particles as compared to the sizes of pores in this fabric. This phenomenon makes it possible to diminish the content of solid particles in media being processed to a level of several ppm (by volume).

The bibliographic list (pp. 306–311) contains 125 references to studies by domestic and foreign researchers. The book is very well printed, it includes illustrative graphical material and useful reference data.

The monograph by Beloglazov and co-authors is of interest for a wide audience of engineers and scientists engaged in process design and modification in a wide variety of industries. The book may be of use for teachers, postgraduate students, masters, and undergraduate students specializing in chemical engineering and metallurgy.

BOOK REVIEWS

Krasovitskii, B.M. and Afanasiadi, L.M., *Mono- i bifluofory* (Mono- and Bifluorophores)

Kharkov: Inst. Monokristallov (with Participation of Folio Publishing House), 2000, 448 pp.

The book, published in the framework of the annual series *Sostoyanie i perspektivy razvitiya funktsional'nykh materialov dlya nauki i tekhniki* (State and Prospects for Further Development of Functional Materials for Science and Technology), reviews, systematizes, and generalizes the results of investigations in the field of synthesis, study, and use of organic luminophores, which have been carried out during more than 40 years under supervision of Professor B.M. Krasovitskii at the Institute of Single Crystals, Academy of Sciences of Ukr. SSR (now National Academy of Sciences of Ukraine).

These investigations were commenced at the time when the main task of the Institute of Single Crystals was to provide the nuclear engineering with effective means for monitoring the nuclear radiation. Therefore, the main goal was to obtain luminophores that served as activators of liquid and plastic scintillators. Later, the scope of the investigations was substantially expanded because of the steadily increasing demand for effective luminophores for a wide variety of fields of science and technology. A necessity arose for a search for new classes of luminescent substances, improvement of methods for their synthesis, study of the relationship between their structure and spectral-fluorescent properties, and optimization of conditions of their use. The main feature of the investigations performed was the synthesis of compounds with two fluorophore groups, bifluorophores.

The results obtained in all of these studies are presented in the book, which comprises three parts. The first part ("Monofluorophores") considers successively the synthesis, structure, and use of the following compounds: polycyclic aromatic hydrocarbons and their functional derivatives, vinyl-substituted aromatic hydrocarbons, diaryl-substituted ethylene and polyenes, Schiff bases, dibenzofulvenes and their azomethine derivatives, compounds with five- and six-membered nitrogen-containing heterocyclic rings (derivatives of oxazole, aryl-hetaryl-substituted azoles, imidazoles, and compounds with a pyrazoline ring) and those with carbonyl-containing fluorophore groups (α,β-unsaturated ketones, substituted benzanthrone and anthrapyridone, anthraquinonediazoles, derivatives of oxazolone and imidazolone, benzoxazin-4-ones, substituted 9-akridones), sulfonyl-containing heterocyclic rings, and also derivatives of naphthalimide, *N*-aminoimides, and hydrazides of naphthalic acid, and 1,8-naphthoylene-1',2'- benzimidazole and its derivatives. Thus, the variety of the objects studied is exceedingly wide.

The second part ("Bifluorophores") is devoted to luminophores with conjugated fluorophore groups (both symmetric and asymmetric), polycondensed bifluorophores, luminophores with unconjugated fluorophore groups (with "insulating" groups, with *meta*-position of fluorophore groups in the common aromatic ring, and also with a bridging amide group), as well as to sterically hindered bifluorophores, bifluorophores with ionic structure, and compounds containing more than two fluorophore groups.

The third part ("Luminescent Materials") contains a wide variety of data on day-glo fluorescent and decorative paints and printing inks, use of day-glo fluorescent pigments in translucent screens and in visualization of latent electrostatic images, as well as on day-glo fluorescent pigments and paints based on polyester resins. Luminescent dyes for plastics and synthetic fibers (polystyrene and polymethyl methacrylate, polyethylene, polyvinyl chloride and polyacrylonitrile) and epoxy resins and luminescent organosilicon dyes are considered in detail. Considerable attention is given to organic scintillators, materials for detection and dosimetry of the ionizing radiation. The chapter concerned with fluoroscopic flaw detection considers fluorescent dye penetrant testing, magnetic luminescent materials, and the luminescent technique for determining the chemical stability of rubbers. Further, a review is given of a valuable information about fluorescent markers and probes for biological studies and medical diagnostics. The same chapter considers luminescent markers for indication of proteins and fluorescent probes for fast analysis of cholesterol and triglycerides in the diagnostics of

1070-4272/04/7703-0519 © 2004 MAIK "Nauka/Interperiodica"

atherosclerosis, determination of the binding capacity of albumin, and study of the structure of biomembranes and lipoproteins. Finally, there are special chapters devoted to lasers operating on organic luminophores, to organic luminophores in chemi- and electroluminescent formulations, and to thermoindicating coatings and photographic materials. In a form that is concise, but convenient for readers, the book presents the most important data on synthesis, structure, and spectral-luminescent properties of organic compounds; polarographic studies of the luminophores considered here are also briefly reported. The text is provided with a great number of structural formulas. The book has a particular practical value because of the numerous indications of the application fields of luminophores and vast bibliography: the book contains a total of more than 1200 references, including 45 references to reviews and monographs by Krasovitskii and co-authors.

The scale of investigations whose results are generalized in the book is indicated by the mere fact that only joint investigations, performed in cooperation with other organizations, involved 24 institutes of the Academies of Sciences of the Sovient Union and CIS countries, 28 industrial research institutes and research-and-production associations, 21 higher-school institutions, and 14 industrial plants.

The book will be of use for organic chemists, biohemists, scientists dealing with spectroscopy and laser technology, and specialists working in various fields of applied chemistry, associated with synthesis, study, and use of luminophores.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Physicochemical Principles of Synthesis of Liquid Fertilizers Based on Potassium Hydrophosphate

A. Sviklas and R. Paletskene

Kaunas Technological University, Kaunas, Lithuania

Received July 15, 2003

Abstract—Technological prerequisites for obtaining special liquid fertilizers with potassium and ammonia hydrophosphates as components were studied. The solubility in the multicomponent $(NH_4)_2HPO_4$–K_2HPO_4–NH_4NO_3–H_2O and $(NH_4)_2HPO_4$–K_2HPO_4–$CO(NH_2)_2$–H_2O systems was studied. The chemical composition of the liquid compound fertilizers obtained was determined.

About 5% of the world output of fertilizers is used to grow vegetable, fruit, and berry cultures [1]. Special types of fertilizers are used with this aim, their main function being to satisfy to the maximum possible extent the needs of plants for mineral nutrition during various periods of their development [2]. Therefore, with regard to a great variety of agricultural crops and their special features, a wide assortment of fertilizers of this kind is necessary. The most efficient for these purposes are liquid compound fertilizers (LCF) that contain ammonium phosphates as the main components [3, 4]. Potassium phosphates are hardly used in the production of LCF owing to their high cost, though they are characterized by a high solubility and high content of potassium and phosphorus [5]. Potassium hydrophosphate contains 40.7% P_2O_5 and 54.0% K_2O and is readily soluble in water. At 20°C, the maximum content of K_2HPO_4 in water is as high as 61.6 wt %. Thus, K_2HPO_4 is a promising source for the production of special liquid fertilizers. When cultivating hot-house cultures, the expenditure for fertilizers is comparatively small, and, therefore, use of potassium phosphates is promising.

The aim of this study was to create technological prerequisites for production of special liquid fertilizers based on potassium hydrophosphates. To this end, it was necessary to solve the following problems: (i) to study the solubility in the multicomponent $(NH_4)_2HPO_4$–K_2HPO_4–NH_4NO_3–H_2O and $(NH_4)_2HPO_4$–K_2HPO_4–$CO(NH_2)_2$–H_2O systems and (ii) to find the chemical composition of liquid compound fertilizers and to determine the physicochemical properties of the products on the basis of solubility data.

To study the solubility, we used K_2HPO_4, $(NH_4)_2HPO_4$, $CO(NH_2)_2$, NH_4NO_3 reagents of analytically pure grade and distilled water. To obtain LCF, we also used technical-grade K_2CO_3, orthophosphoric acid of pure grade (concentration 86%), technical-grade aqua ammonia NH_4OH (concentration 25%), and technical-grade 58% HNO_3.

We determined the composition of substances by chemical and physicochemical methods of analysis. The concentration of ammonia nitrogen was found using the formaldehyde method [6, 7], and that of nitrate nitrogen, by the titration method based on the reduction of nitrates with a titration standard of iron(II) sulfate in an acid medium with the subsequent titration of the excess of iron(II) salt with a potassium permanganate solution in the presence of ammonium molybdate as a catalyst [8], or by the photometric method [9]. The concentration of potassium ions was determined by flame photometry on a Jenway PFP-7 flame photometer, and the concentrations of P_2O_5 and amide nitrogen, by the photometric method [7, 10, 11] on a KFK-2 photocolorimeter.

The solid phases were analyzed using IR spectrometry, thermogravimetry, and X-ray phase analysis.

IR spectra were recorded on a Specord M-80 spectrometer. Samples for recording were compacted into pellets with KBr.

The thermogravimetric experiments were carried out on a Du Pont Instruments 990 Thermal Analyzer, with the temperature raised at a rate of 10 deg min^{-1}.

The X-ray phase analysis was made on a DRON-3 device with a cobalt anode, the interval of diffraction angles was 0°–166.5°, the error did not exceed 0.5%.

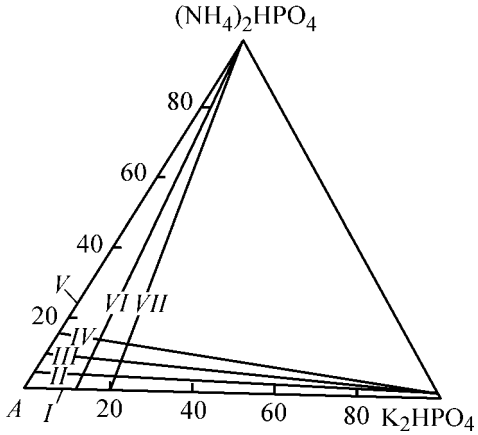

Fig. 1. Sections in the $(NH_4)_2HPO_4$–K_2HPO_4–NH_4NO_3–H_2O system, studied by the polythermic method. Point *A* corresponds to 20% NH_4NO_3 + 80% H_2O; the same for Fig. 3.

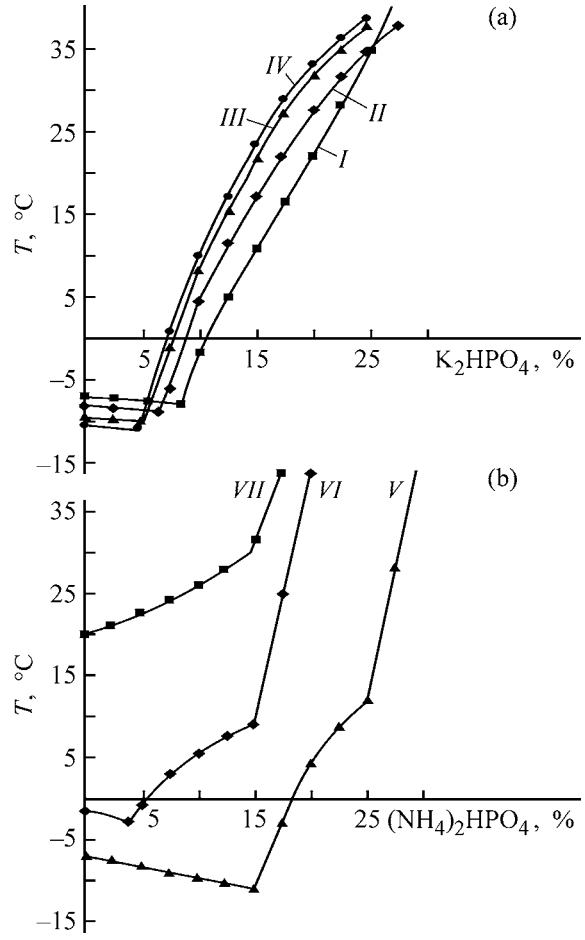

Fig. 2. Polytherms in the $(NH_4)_2HPO_4$–K_2HPO_4–NH_4NO_3–H_2O system. (*T*) Temperature, and K_2HPO_4 and $(NH_4)_2HPO_4$ content of the corresponding compounds; the same for Fig. 4. Section: (a) (*I*) $A \rightarrow K_2HPO_4$, (*II*) [5% $(NH_4)_2HPO_4$ + 95% *A*] $\rightarrow K_2HPO_4$, (*III*) [10% $(NH_4)_2HPO_4HPO_4$ + 90% *A*] $\rightarrow K_2HPO_4$, (*IV*) [15% $(NH_4)_2HPO_4$ + 85% *A*] $\rightarrow K_2HPO_4$; (b) (*V*) $A \rightarrow (NH_4)_2HPO_4$, (*VI*) [10% K_2HPO_4 + 90% *A*] $\rightarrow (NH_4)_2HPO_4$, (*VII*) [20% K_2HPO_4 +80% *A*] $\rightarrow$ $(NH_4)_2HPO_4$.

The properties of solutions and LCF were determined using a pH-673 pH-meter, a VPZh-2 viscometer, a set of AON-1 areometers for measuring the density of solutions of compound fertilizers, an IRF-2 refractometer for finding the refractive indexes, and a Radelkis conductometer for measuring the electrical conductivity.

We determined the solubility of the salts in water by the visual-polythermic method [12, 13]. Depending on a required temperature, a mixture of ice, sodium chloride, and ammonium chloride (nitrate) or a mixture of dry ice and ethanol was used as a cooling agent.

To identify the composition of solid phases, the compounds were isolated in the crystalline state. The crystals obtained at the inflection points and in the characteristic intervals of the resulting polytherms were separated using a centrifuge condenser (at low crystallization temperatures) or a Nutsch filter (at crystallization temperatures higher than 0°C) and subjected to the chemical and instrumental analysis.

To determine the composition of liquid special compound fertilizers, the data on the solubility in the $(NH_4)_2HPO_4$–K_2HPO_4–NH_4NO_3–H_2O and $(NH_4)_2HPO_4$–K_2HPO_4–$CO(NH_2)_2$–H_2O systems were necessary.

We studied each system by the method of inner sections. We constructed solubility polytherms along the sections on the basis of experimental data and then obtained triangular section diagrams for the system in the region under study. All the systems were studied in the range from the temperature of complete freezing to +40°C.

The $(NH_4)_2HPO_4$–K_2HPO_4–NH_4NO_3–H_2O system was studied at concentrations of ammonium hydrophosphate and potassium hydrophosphate in the ranges from 0 to 30 and from 0 to 25 wt %, respectively. The ratio of ammonium nitrate and water was maintained constant at 1 : 4. The study was carried out along seven sections, four of which were directed toward increasing potassium hydrophosphate concentration, and three toward increasing ammonium hydrophosphate concentration. The location of the sections is shown in the triangular diagram in Fig. 1. The curves of solution crystallization are shown in Fig. 2.

Crystallization curves of sections *I–IV* are of the same nature. Each section consists of two crystallization branches. The inflections in the curves occur owing to changes in the phase composition. In sections *V–VI*, two inflection points are formed, and the crystallization from solutions of section *VII* occurs only at positive temperatures.

The solid compounds formed within the range of the solution concentrations under study were identified using chemical and instrumental analyses and stoichiometric calculations of the composition.

The crystallization temperatures of eutonic points, T_{cr}, and the chemical compositions of precipitated solid phases of the $(NH_4)_2HPO_4$–K_2HPO_4–NH_4NO_3–H_2O system were determined within the indicated range of the component concentrations (Table 1). The eutonic point of section *IV* corresponds to the lowest crystallization temperature (–10.9°C). Its chemical composition corresponds to (wt %): $(NH_4)_2HPO_4$ 14.36, K_2HPO_4 4.25, NH_4NO_3 16.28, and H_2O 65.11. The total concentration of nutritious substances is 20.50%.

Based on the data obtained, we constructed a triangular diagram of the $(NH_4)_2HPO_4$–K_2HPO_4–NH_4NO_3–H_2O system (Fig. 3). The boundary lines of the crystallization fields are plotted in the diagram on the basis of the polythermic and chemical analysis data. A study of the bottom phases precipitated from supersaturated solutions in various regions of the system at the appropriate temperatures, demonstrated that no new compounds are formed in the system. A comparison of derivatograms, X-ray diffraction patterns, and IR absorption spectra confirmed these conclusions.

To determine the chemical composition of liquid compound fertilizers, we calculated the composition of saturated solutions with the crystallization temperature of 0°C. The results are listed in Table 2.

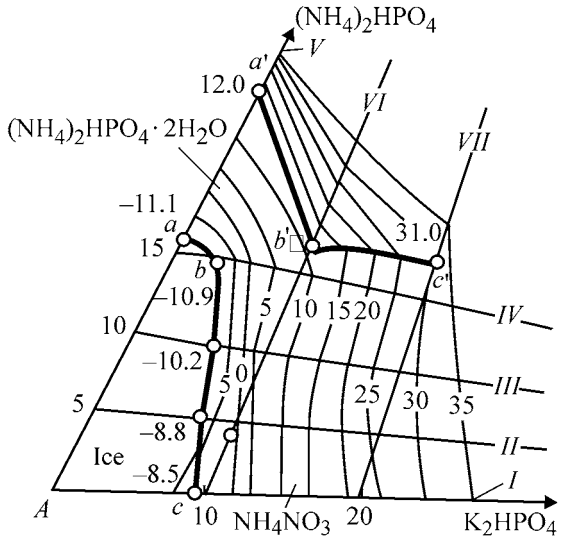

Fig. 3. Solubility polytherm of the $(NH_4)_2HPO_4$–K_2HPO_4–NH_4NO_3–H_2O system.

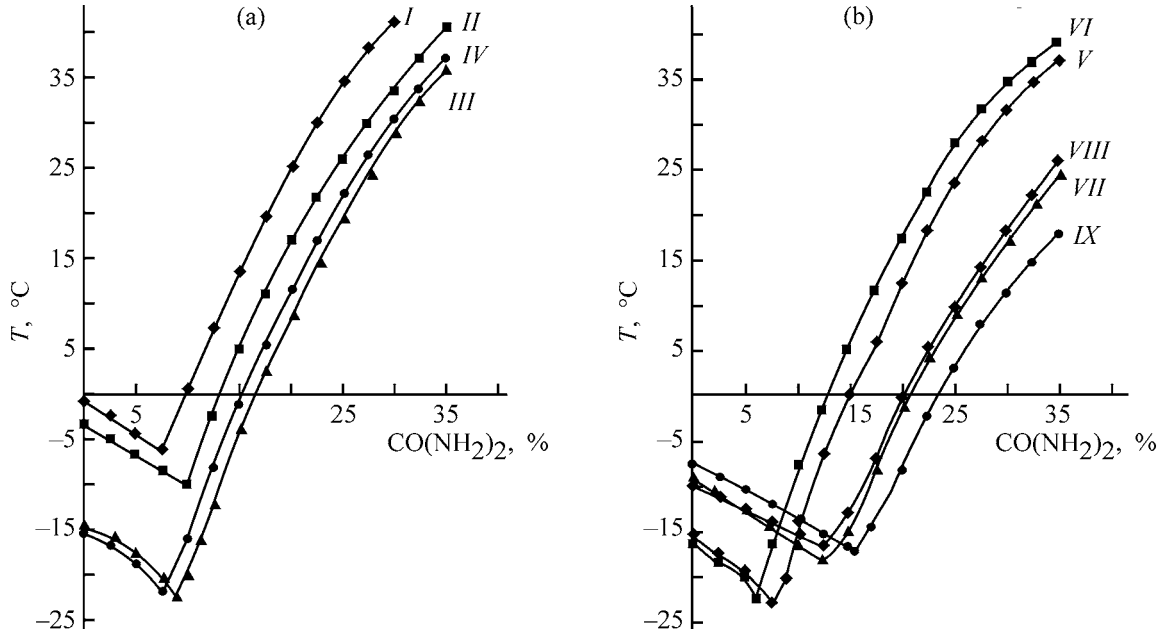

Fig. 4. Polytherms of the $(NH_4)_2HPO_4$–K_2HPO_4–$CO(NH_2)_2$–H_2O system. Section: (a) (*I*) [5% $(NH_4)_2HPO_4$ + 55% K_2HPO_4 + 40% H_2O] → $CO(NH_2)_2$, (*II*) [55% $(NH_4)_2HPO_4$ + 45% H_2O] → $CO(NH_2)_2$, (*III*) [5% $(NH_4)_2HPO_4$ + 45% K_2HPO_4 50% H_2O] → $CO(NH_2)_2$, (*IV*) [10% $(NH_4)_2HPO_4$ + 40% K_2HPO_4 + 50% H_2O] → $CO(NH_2)_2$, (b) (*V*) [15% $(NH_4)_2HPO_4$ + 35% K_2HPO_4 + 50% H_2O] → $CO(NH_2)_2$, (*VI*) [25% $(NH_4)_2HPO_4$ + 25% K_2HPO_4 + 50% H_2O] → $CO(NH_2)_2$, (*VII*) [5% $(NH_4)_2HPO_4$ + 35% K_2HPO_4 + 60% H_2O] → $CO(NH_2)_2$, (*VIII*) [10% $(NH_4)_2HPO_4$ + 30% K_2HPO_4 + 60% H_2O] → $CO(NH_2)_2$, (*XI*) [5% $(NH_4)_2HPO_4$ + 30% K_2HPO_4 + 65% H_2O] → $CO(NH_2)_2$.

It is seen from Table 2 that the maximum concentration of nutritious substances is 22.79 wt % at the ratio $N : P_2O_5 : K_2O = 2.2 : 2.7 : 1$.

The replacement of ammonium nitrate with carbamide is known to raise, as a rule, the total concentration of nutritious substances in LCFs [3, 14]. With this in mind, we studied the solubility of the $(NH_4)_2HPO_4$–K_2HPO_4–$CO(NH_2)_2$–H_2O system. We analyzed the solutions at ammonium hydrophosphate, potassium hydrophosphate, and carbamide concentrations of 5 to 25, 25 to 55, and 0 to 35 wt %, respectively. The solubility polytherms were plotted using the results of the polythermic studies. The analysis was made for nine sections, with varied chemical composition of the system (wt %):

I: $[5(NH_4)_2HPO_4 + 55K_2HPO_4 + 40H_2O] \rightarrow CO(NH_2)_2$,

II: $[55(NH_4)_2HPO_4 + 45H_2O] \rightarrow CO(NH_2)_2$,

III: $[5(NH_4)_2HPO_4 + 45K_2HPO_4 + 50H_2O] \rightarrow CO(NH_2)_2$,

IV: $[10(NH_4)_2HPO_4 + 40K_2HPO_4 + 50H_2O] \rightarrow CO(NH_2)_2$,

V: $[15(NH_4)_2HPO_4 + 35K_2HPO_4 + 50H_2O] \rightarrow CO(NH_2)_2$,

VI: $[25(NH_4)_2HPO_4 + 25K_2HPO_4 + 50H_2O] \rightarrow CO(NH_2)_2$,

VII: $[5(NH_4)_2HPO_4 + 35K_2HPO_4 + 60H_2O] \rightarrow CO(NH_2)_2$,

VIII: $[10(NH_4)_2HPO_4 + 30K_2HPO_4 + 60H_2O] \rightarrow CO(NH_2)_2$,

IX: $[5(NH_4)_2HPO_4 + 30K_2HPO_4 + 65H_2O] \rightarrow CO(NH_2)_2$.

The general shape of the curves obtained is shown in Fig. 4.

All the crystallization curves are of the same nature. They consist of two crystallization branches. The indices of eutonic points of the crystallization curves are listed in Table 3.

To determine the chemical composition of LCF, we calculated the chemical composition of saturated solutions with the crystallization temperature of 0°C. The data are listed in Table 4.

Use of carbamide instead of NH_4NO_3 sharply increases the concentration of nutritious substances. The maximum sum of nutritious substances in section *I* is 54.94 wt %. High concentrations are attained with popular ratios of nutritious substances. For example, at the ratios $N : P_2O_5 : K_2O$ of 1 : 2 : 2, 1 : 2 : 1, and 1 : 1 : 1 the sum of nutritious substances is 45.61, 43.00, and 35.5%, respectively. This indicates that $(NH_4)_2HPO_4$, K_2HPO_4, and $CO(NH_2)_2$ can be used

Note. Liquid compound fertilizers based on potassium hydrophosphate, ammonium hydrophosphate, and ammonium nitrate or carbamide can be used under both field and greenhouse conditions, irrespective of a plant species and the period of its vegetation.

as components in production of highly concentrated liquid compound fertilizers.

Based on the results of our chemical and physicochemical studies, we developed a procedure and a technology for manufacture of LCF [15]. K_2CO_3, $CO(NH_2)_2$, $NH_3 \cdot H_2O$, H_3PO_4, and HNO_3 as the raw materials for production of special-purpose LCF. Using this procedure, we prepared LCF solutions under laboratory conditions and determined their properties (Table 5). These properties were found to be close to those of standard fertilizers.

CONCLUSIONS

(1) The solubility in the $(NH_4)_2HPO_4$–K_2HPO_4–NH_4NO_3–H_2O and $(NH_4)_2HPO_4$–K_2HPO_4–$CO(NH_2)_2$–H_2O systems was studied within the temperature range from complete solidification to +40°C. The crystal-

lization polytherms and the compositions of liquid and solid phases were determined and also the concentrations of the saturated solutions with the crystallization temperature of 0°C were found.

(2) With carbamide, the concentration of nutritious substances in solution increases to 54.94 wt %, whereas with ammonium nitrate, the concentration of nutritious substances is only 22.79 wt %.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Recovery of Palladium(II) from Hydrochloric Solutions with Fullerene Black Impregnated with Trioctylamine

A. N. Turanov and N. K. Evseeva

Institute of Solid-State Physics, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received July 8, 2003

Abstract—Distribution of HCl and Pd(II) among aqueous solutions of HCl and the product of electric-arc evaporation of graphite, fullerene black, impregnated with trioctylamine was studied.

Recently, macroporous sorbents impregnated with extracting agents of various classes have found wide application in the analytical and preparative practice of recovery and concentration of metal ions from aqueous solutions [1, 2]. Pd(II) has been recovered from hydrochloric solutions with the use of macroporous polymeric sorbents impregnated with trialkylamines [3], trioctylphosphine oxide [4], sulfoxides [5], dialkylthiophosphoric acids [6], and nitrogen-containing phenolformaldehyde oligomers [7]. Hydrocarbon materials as a matrix for obtaining impregnated sorbents have been studied to a lesser extent. Recovery of Pd(II) from hydrochloric solutions with an intercalated compound of trioctylamine (TOA), based on fluorinated graphite, has been reported [8]. With the development of research aimed to synthesize fullerenes, attention was given to the high specific surface area and sorption capacity of the fullerene black (FB), an amorphous carbon material obtained in exhaustive extraction of fullerenes C_{60} and C_{70} from the product formed in electric-arc evaporation of graphite [9].

In order to assess the possibility of using FB as a matrix for obtaining an impregnated sorbent, some aspects of how Pd(II) is distributed among HCl solutions and FB impregnated with TOA were examined in the present study.

EXPERIMENTAL

The fullerene black was synthesized by exhaustive extraction of fullerenes C_{60} and C_{70} with toluene in a Sohxlet apparatus from a fullerene-containing carbon black. The black was obtained by electric-arc evaporation of graphite on an installation described in [10]. As the active component of the impregnated sorbent was used TOA (Merk) without additional purification. The FB was impregnated with trioctylamine by the procedure similar to that described previously in [7]. The content of TOA in the sorbent was 0.1–11.26 mol kg^{-1} of FB.

The starting aqueous Pd(II) solutions with a concentration of 5×10^{-3} M were prepared by dissolving $PdCl_2$ of pure grade in a 6 M solution of HCl, with subsequent dilution of the resulting solution to obtain required concentrations of Pd(II) and the acid. Sorption experiments were performed under static conditions at a temperature of $18 \pm 2°C$. The aqueous solution with a sorbent was agitated with a magnetic stirrer for 2 h, which is sufficient for constant distribution coefficients D_{Pd} of Pd(II) to be attained. The ratio between the volume of the aqueous phase and the sorbent mass was 300 : 1.

The concentration of Pd(II) in the aqueous solutions before and after sorption was determined photometrically with KNCS [11], and that in the sorbent phase, using the material balance equation. The distribution coefficients of Pd(II) were calculated as a ratio of Pd(II) concentrations in the equilibrium solid and aqueous phases. The concentration of HCl in the equilibrium aqueous phases was determined by potentiometric titration with a NaOH solution.

It is known that, when brought in contact with HCl solutions, TOA forms trioctylammonium chloride (TOAHCl) [12]. Extraction of Pd(II) with TOAHCl solutions in organic solvents has been studied rather well [13–17]. It was established that Pd(II) is extracted into the organic phase from solutions with

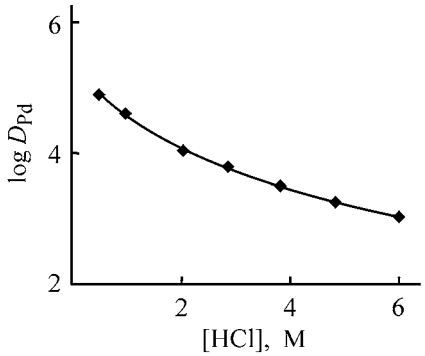

Fig. 2. Distribution coefficient of Pd(II), D_{Pd}, vs. the concentration of HCl in the equilibrium aqueous phase, [HCl], in sorption with a fullerene black containing TOA in amount of 1.26 mol kg^{-1} of FB.

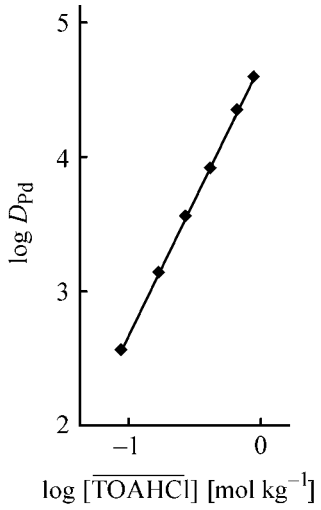

Fig. 3. Distribution coefficient of Pd(II), D_{Pd}, vs. the content of TOAHCl, [$\overline{\text{TOAHCl}}$], in the sorbent phase in sorption from a 1 M solution of HCl.

1–6 M of HCl as a result of occurrence of the anion-exchange reaction

$$PdCl_4^{2-} + 2\overline{TOAHCl} \rightleftarrows [\overline{PdCl_4}](\overline{TOAH})_2 + Cl^-, \quad (1)$$

where the overline designates components in the non-aqueous phase.

In addition, Pd(II) passes into the organic phase in the form of a binuclear complex $[Pd_2Cl_6](TOAH)_2$ under the conditions of deficiency of an extracting agent [15]. It has been shown by means of IR and Raman spectroscopy that complexes of the same kind are also formed upon interaction of hydrochloric solutions of Pd(II) with TOA in the absence of an organic solvent [8].

To study equilibria in the system Pd(II)–HCl–TOA–FB, recovery of HCl from its aqueous solution with an impregnated sorbent was examined preliminarily. Since FB does no extract HCl from a solution in the absence of trioctylamine, the rise in the concentration of HCl in the sorbent phase with increasing concentration of TOA in the solid phase or of HCl in the aqueous phase (Fig. 1) can be attributed to the formation of the complex $\overline{\text{TOAHCl}}$ in the sorbent phase [18]:

$$H^+ + Cl^- + \overline{TOA} \rightleftarrows \overline{TOAHCl}. \quad (2)$$

The equilibrium constant of reaction (2), found from the data in Fig. 1, $K_{HCl} = 1.5 \times 10^4$.

At a constant concentration of TOA in the sorbent phase, the recovery of Pd(II) into the solid phase decreases as the concentration of HCl in the aqueous phase becomes higher (Fig. 2), which is due to a shift of the equilibrium of reaction (1) to the left. The rise in the concentration of TOA in the sorbent phase is accompanied by an increase in the sorption of Pd(II) (Fig. 3), with the slope of the dependence of log D_{Pd} on log [$\overline{\text{TOA}}$] equal to 2, which corresponds to recovery of Pd(II) in the form of the complex $[PdCl_4](TOAH)_2$ by reaction (1). The equilibrium constant of the process of interphase distribution of Pd(II)[Eq. (1)], found from the data in Fig. 3, $K_{Pd} = 5.62 \times 10^4$.

The isotherm of Pd(II) adsorption from a hydrochloric solution with an impregnated sorbent (Fig. 4a) can be described using the Langmuir equation

$$[\overline{Pd}] = \frac{K[\overline{Pd}]_{max}[Pd]}{1 + K[Pd]}, \quad (3)$$

where [Pd], [$\overline{\text{Pd}}$] are the equilibrium concentrations of Pd(II) in the aqueous and solid phases; $[\overline{Pd}]_{max}$,

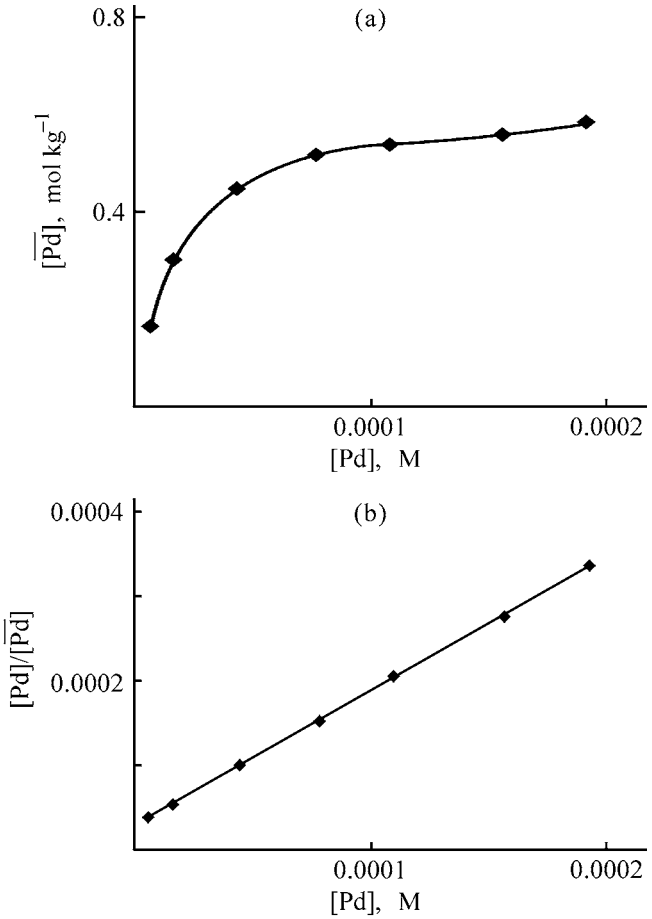

Fig. 4. (a) Distribution of Pd(II) among a 1 M solution of HCl, and an impregnated sorbent containing TOA in an amount of 1.26 mol kg^{-1} of FB, $[\overline{Pd}]$. (b) Linearization of Eq. (3).

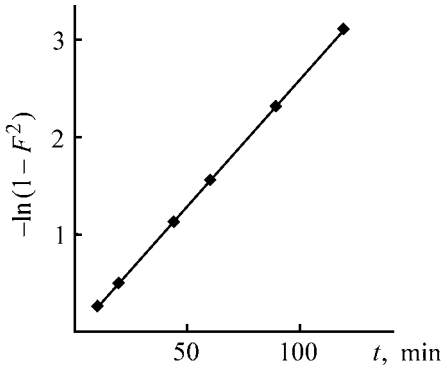

Fig. 5. Sorption of Pd(II) from a 1 M solution of HCl with an impregnated sorbent vs. the agitation time *t*.

maximum concentration of Pd(II) in the sorbent phase under the conditions of monolayer formation; and *K*, the equilibrium constant of the sorbent–sorbate system.

The value of $[\overline{Pd}]_{max}$, found from the data in Fig. 4b upon linearization of Eq. (3), is 0.63 mol kg^{-1} of FB, which corresponds, with account of the initial concentration of TOA (1.26 mol kg^{-1}) to the following stoichiometry of the complex being sorbed: Pd(II) : TOA = 1 : 2. The value $K = 5.88 \times 10^4$ corresponds to the equilibrium constant of the anion-exchange reaction (1), found above. This indicates that at the metal concentrations studied, the process of sorption recovery of Pd(II) from hydrochloric solutions is adequately described, by the equation of reaction (1).

According to the existing concepts [19], a sorbed TOAHCl molecule is oriented so that its hydrophobic moiety is directed toward the carbon matrix, and its polar reaction center, toward the aqueous phase. Thus considerably facilitates the anion exchange at the phase boundary. The rate of Pd(II) sorption is independent of the agitation rate in the range 50–1000 rpm, i.e., it is determined by the diffusion of the tetrachloropalladate anion being recovered within the pores of the sorbent [20]. The experimental dependence of Pd(II) sorption on the time of contact between the phases is described by the equation

$$-\ln(1 - F^2) = \overline{K}t, \qquad (4)$$

where *F* is the degree of completeness of sorption, calculated as a ratio of the sorption capacity at an instant of time t to the equilibrium capacity of the sorbent for Pd(II), and $\overline{K}$ is the apparent rate constant, found from the data in Fig. 5 to be $\overline{K} = 4.3 \times 10^{-4}$ s^{-1}.

The data presented above show that fullerene black impregnated with TOA can be used for recovery of Pd(II) from aqueous solutions.

CONCLUSIONS

(1) Fullerene black impregnated with trioctylamine effectively recovers Pd(II) from hydrochloric solutions.

(2) In the concentration range studied, $[PdCl_4]^{2-}$ is sorbed as a complex $[PdCl_4](TOAH)_2$ through an anion-exchange reaction with trioctylammonium chloride. The equilibrium constant of this reaction is $(5.75 \pm 0.13) \times 10^4$.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Micro- and Nanoporous Materials from Silicon Carbide in Ultradisperse Reaction Systems

V. G. Gilev

Scientific Center for Powder Materials Science, Perm', Russia

Received March 20, 2004; in final form, December 2003

Abstract—The synthesis of porous sorption-active materials and membranes from SiC in the reaction system composed of 70% Si and 30% C was studied. The influence exerted by the conditions under which the reaction mixture is dispersed and compacted samples are thermally treated on the porous structure, specific surface area, permeability, and strength of the resulting materials was analyzed.

Silicon carbide is of interest as a basis for sorption-active and membrane materials owing to its chemical activity, abrasion resistance, temperature stability, and ability to sorb organic pollutants from water filtered through filters based on this compound [1–3]. A high temperature stability of micro- and mesoporous materials and nanoporous membranes based on silicon carbide would be expected in view of the high melting point of SiC and the covalent nature of atomic bonds in this compound [4].

Methods for production of membranes and porous materials with pore size of 1–2 μm from silicon carbide have been sufficiently well developed [1–3, 5, 6]. However, it is difficult to obtain a ceramic with a smaller pore size by usual sintering of ceramic powders. For example, when ultradisperse powders (UDP) of the high-melting compounds TiN and AlN are sintered, raising the temperature to $0.45–0.6T_m$ leads to shrinkage, with the pore size simultaneously increasing [5].

To synthesize microporous materials and membranes from silicon carbide, it has been suggested to use the following solid-phase reaction [7]:

$$Si_s + C_s = SiC. \quad (1)$$

The thus obtained silicon carbide materials with pore size of 0.4–0.7 μm demonstrate highly selective properties in purification of water [8]. It has been found [7] that lowering the temperature of synthesis from 1600 to 1300°C results in an increase in the specific surface area of silicon carbide materials to more than 20 $m^2 g^{-1}$, which opens up opportunities for creating sorption-active materials. Furthermore, estimates of the pore size by the formula $r_{ef} = 2\Pi/S_{sp}$ (Π is the porosity, and S_{sp}, the specific surface area) give a value of about 20 nm. At this pore size, free-molecular gas flow or Knudsen diffusion, on which membrane separation of gases is based [9], becomes possible.

The aim of this study was to develop further this method for obtaining sorption-active materials and membranes based on nanoporous silicon carbide with the use of highly dispersed Si–C reaction mixtures with 30% C.

EXPERIMENTAL

Dry mixtures of KR1 silicon and S-1 colloidal graphite with Si : C weight ratio of 70 : 30 were ground with steel balls of diameter 5.2 and 6.8 mm in an AGO-3 high-energy planetary activator for 3–10 min. The weight of the mixture was 100 g, and that of steel balls, 2000 g. In some cases, thermally expanded graphite (TEG) manufactured by Novomet-Perm Closed Joint-Stock Company was additionally introduced into the resulting highly dispersed mixture. Samples of the materials were compacted under a pressure of 50–150 MPa with a technological binder composed of a 5% aqueous solution of polyvinyl alcohol (PVA), in amount of 1–4 ml per 10 g of the mixture. Mixtures with TEG additive were compacted without a binder. A thermal treatment was carried out in argon, nitrogen, and carbon dioxide, and in a vacuum with a residual pressure of 10 Pa in a furnace with a graphite heater.

* Atmosphere of dissociated ammonia.
** Sample with an addition of 17% TEG.

Supports for silicon carbide membranes were prepared from SiC powders with addition of SiO_2 and CaO in amounts of 10 wt % each [10]. The dry mixture was ground with hard-alloy balls for 24 h in a ball mill lined with a hard alloy, compacted using a 5% aqueous solution of PVA as a temporary technological binder under a pressure of 100 MPa, and sintered in argon at 1620°C for 30 min. The preparation of the supports was described in detail in [10]. To obtain double-layer membranes, a layer of highly dispersed reaction mixture containing 17% TEG was fixed by pressing on a support, and a synthesis was carried out in argon at 1100°C for 30 min. Layers of thickness 200 μm, firmly adhering to the supports, were obtained in this way.

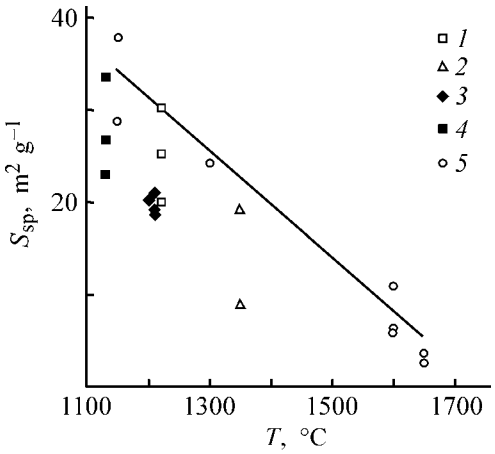

Fig. 1. Specific surface area S_{sp} of a porous silicon carbide material synthesized from a 70% Si–30% C mixture vs. temperature of synthesis, T. (*1*) CO_2, (*2*) vacuum, (*3*) N_2, (*4*) $N_2 + H_2$, and (*5*) Ar.

The gas-permeability was determined in accordance with GOST (State Standard) 25283–82, and the maximum and average sizes of channel pores were found from the gas-driving pressure in accordance with GOST 26849–86 (bubble method).

The phase composition of the samples was analyzed on a DRON-4-13 diffractometer with the λ_{K_a}(Co) radiation and a graphite monochromator. The recording was done point-by-point with a scanning step of 0.02°–0.05° and a 10-s exposure at each point. The specific surface area was determined by the BET method on a GKh-1 gas-meter. Nitrogen adsorption isotherms were obtained on a Carlo Erba Strumentazone Sorbtomatic 1800 device (Italy). The sample strength was determined with a three-point bend on an Instron 1195 test machine on samples in the form of $3 \times 5 \times 40$-mm bars.

The use of a highly dispersed reaction mixture (70% Si–30% C) with S_{sp} of up to 115 $m^2\ g^{-1}$ makes it possible to obtain materials with a specific surface area of pores of up to 48 $m^2\ g^{-1}$ (Fig. 1). The temperature of synthesis strongly affects S_{sp}. Furthermore, S_{sp} increases when the isothermal exposure becomes shorter and when the specific surface area of the initial mixtures increases. The data scatter in Fig. 1 is due to variation of these parameters.

As the compacting pressure is raised from 50 to 150 MPa, S_{sp} increases from 5.9 to 11.0 $m^2\ g^{-1}$ in the case of synthesis in argon at 1600°C for 1 h and from 39.2 to 42.4 $m^2\ g^{-1}$ in synthesis at 1100°C for 0.5 h. The materials synthesized in argon have the highest specific surface area.

The possibility of using these materials as membranes is determined not only by the average pore size r_{ef}, but also by the pore size distribution and especially by the presence of larger pores. When the temperature of synthesis is lowered, the maximum pore size decreases to 0.2–0.3 μm and less (Table 1). Making longer the isothermal exposure at 1600°C results in an increase in the maximum pore size. These changes indicate that the materials obtained with short isothermal exposures are in a nonequilibrium state and, in spite of a rather low temperature {1600°C corresponds to 0.63 T_m (SiC), and sintering of silicon carbide begins at 0.8 T_m (SiC) [4]}, structural transformations take place. Addition of 17% TEG to the 70% Si–30% C mixture with S_{sp} = 115 $m^2 g^{-1}$ leads to an increase in porosity, but the gas permeability and the maximum pore size do not increase significantly in this case (Table 1).

Lowering the temperature and making shorter the duration of isothermal exposure should result in a decelerated and incomplete synthesis and crystallization of a new phase. An X-ray structural analysis demonstrated that, if a 70% Si–30% C mixture is converted to a highly dispersed state with S_{sp} = 115 $m^2 g^{-1}$, the synthesis of SiC is strongly accelerated, and its temperatures decrease substantially. Thus, after a 20-min exposure in argon at 1150°C no graphite lines were found in the X-ray diffraction pattern, with only two weak lines of silicon present. When a mixture with S_{sp} = 61 $m^2 g^{-1}$ is used under the same conditions, a significant amount of unreacted silicon remains (Fig. 2). The X-ray diffraction pattern of a sample of the mixture with S_{sp} = 115 $m^2 g^{-1}$, sintered at 1650°C within 0.5 h, shows that the high-temperature synthesis provides a full expenditure of the reagents, with, however, the ratio of line intensities not coinciding with tabulated data for the equilibrium SiC phases (6H, 15R, 3C).

When a dispersed mixture with S_{sp} = 115 $m^2 g^{-1}$ is subjected to a short (0.17 h) heat treatment at a low temperature (1200°C) in nitrogen, a significant amount of silicon nitride Si_3N_4 is formed alongside with SiC (Fig. 3). It is known [11] that the conventional technologies based on nitriding of silicon involve long exposures at temperatures of at least 1300°C. The content of silicon nitride in the materials synthesized from mixtures with S_{sp} = 61 $m^2 g^{-1}$ is lower, and it does not increase on heating to 1600°C. Apparently, both silicon nitride and silicon carbide are synthesized in early stages of heating. In this case, the amount of silicon nitride is mainly determined by the kinetic opportunities for delivery of nitrogen to within a sample. Therefore, the extent of the nitriding

reaction in samples of a mixture with S_{sp} = 115 $m^2 g^{-1}$ is greater not only because of the particle size, but also owing to the higher porosity of a sample.

An analysis of the porous structure on the basis of isotherms of nitrogen adsorption demonstrated that

the total volume of the sorption space of SiC materials is considerably smaller than that of sorbents based on active coals [12] (Table 2). However, a positive point is that they contain an appreciable volume of micropores. Micropores are completely absent in the materials obtained by sintering of UDP of AlN, TiN, and Al_2O_3 [5, 13].

The volume of micropores and the total sorption space grow in proportion to the increase in the specific surface area. Introduction of thermally expanded graphite as an additive to the 70% Si–30% C mixture with S_{sp} = 115 $m^2\ g^{-1}$ in amounts of 17 and 33 wt % changes the shape of adsorption isotherms and raises the total sorption volume W_s mainly because of an increase in the fraction of micropores. Simultaneously, the fraction of micropores decreases somewhat. The effective pore size $r_p = W_s/S_{BET}$ increases when TEG is added. The properties of thermally expanded graphite essentially differ from those of ordinary graphite, and, therefore, the synthesis of silicon carbide in mixtures of silicon and TEG has its own specificity. The authors of [14] believe that the honeycomb structure of particles of thermally expanded graphite, which is retained on its mixing with dispersed silicon, decelerates the exothermic reaction of synthesis. Thus, elevating the temperature and making longer the synthesis leads to a more complete consumption of reagents and, simultaneously, to a decrease in the specific surface area and in the volume of micropores.

There exists an opinion [15] that pores of size 2 nm and less can be obtained only in materials of two types: in those based on carbon and in zeolites. Sorbents based on carbon are produced either by pyrolysis of hydrocarbons [12] or by treatment of carbides with chlorine [6, 16]. Recently, the preparation of silicon carbide with a pore size of less than 1 nm by pyrolysis of organosilicon precursors has been reported [17].

The experimental results obtained in this study and published data suggest that micropores are formed in the carbon phase. In this case, the decrease in S_{sp} and V_{mi} with increasing synthesis temperature and annealing duration are readily attributable to the decrease in the amount of carbon remaining in the course of reaction (1). We can also assume that micropores are formed in silicon carbide, but this microstructural state of SiC is metastable. It is evident that the mechanism of micropore formation is associated with diffusion processes that accompany reaction (1). A more detailed discussion of the micropore formation requires an additional study.

Usually, mechanical properties of materials obtained by sintering of powders are improved as the temperature of sintering is raised. However, if materials are synthesized by reactive sintering with the use of reaction (1), the strength increases when the sintering temperature is somewhat lowered (Table 3). The high strength of the materials sintered in the atmosphere of nitrogen results from their greater density and from the presence of silicon nitride in their composition. It is also seen that lowering the temperature of synthesis from 1600 to 1220°C results in a higher strength in this case, too.

Commonly, the limiting stress at which cracks appear in fragile materials is determined by the size of the largest defects. In our case, we cannot attribute the rise in strength on lowering the temperature of synthesis to the corresponding change in the maximum size of channel pores, measured by the bubble method (Table 1), as they are not the largest. The structure contains pores about 1 μm in size (Fig. 4), which are the compaction defects. The microstructure of an Al–SiC composite obtained by impregnation of the pore space of the ceramic under study with a molten aluminum alloy under a pressure is shown in Fig. 4. The increase in the material strength in the case of the low-temperature synthesis seems to be attributable to structural features on a deeper level of the hierarchy. For example, we can assume that the size of SiC crystallites forming the skeleton is comparable with the pore size, i.e., SiC crystals are nanosize.

The materials synthesized can be used in double-layer membranes as a nanoporous selective layer. Double-layer membranes with a coating of nanoporous SiC on silicon carbide supports were fabricated.

To obtain selective layers of double-layer membranes, we used a highly dispersed 70% Si–30% C mixture with a specific surface area of 115 $m^2\ g^{-1}$. We additionally introduced 17% TEG into this mixture. An even layer of the mixture was deposited on a support and fixed on its surface at a pressure of 25 MPa under isostatic conditions. The selective layers were sintered in argon at 1100°C in the course of 30 min. The thickness of the membrane layer, estimated by the weight of the coating deposited, was about 200 μm. The firm adherence of the selective layer to the sup-

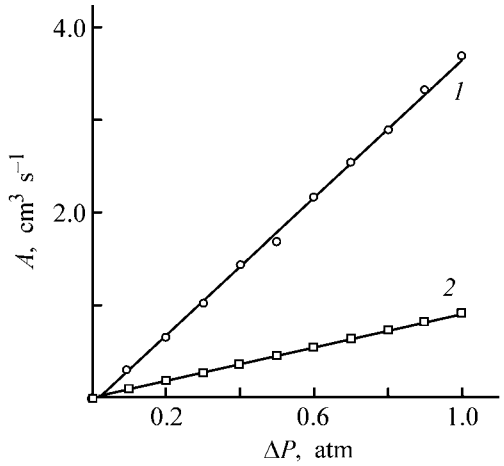

Fig. 5. Flow rate A of (*1*) hydrogen and (*2*) nitrogen vs. the pressure difference ΔP across a double-layer membrane with a silicon carbide support.

port is confirmed by the fact that a silicon carbide double-layer silicon carbide membrane sustained a return gas purging under a pressure of 5 atm.

The gas permeability of double-layer membranes in the case of hydrogen is 3.3 times that for nitrogen (Fig. 5). This ratio is close to a value of 3.7 given by the equation for the Knudsen diffusion coefficient:

$$D_i^K = \frac{l}{3}\sqrt{\frac{8\overline{RT}}{\pi\overline{M_i}}}.$$

Here M_i is mass of molecules; R, the universal gas constant; and T, temperature (K).

The dependence of the gas flow rate on the pressure difference is linear. Usually, deviations from a linear dependence are observed in the case of a viscous flow.

Furthermore, the viscosities of nitrogen and hydrogen differ by no more than a factor of 2 [18]. All the aforesaid suggests that the Knudsen gas flow prevails in the selective layer, which is attained under common pressures only in nanoporous materials.

A double-layer membrane with a silicon carbide support was tested in filtration of artesian water containing 1.2 mg l^{-1} of manganese ions. According to an atomic-absorption analysis carried out on a Proton instrument, the concentration of manganese ions in this water after the filtration decreased to below 0.1 mg l^{-1}.

CONCLUSIONS

(1) It was shown that use of reaction mixtures of silicon with graphite with a specific surface area of 120 $m^2 g^{-1}$ makes it possible to synthesize at rather low temperatures (1100–1200°C) porous silicon carbide materials with a porosity of 45–60%, a high (up to 48 $m^2 g^{-1}$) specific surface area, and a significant fraction of micropores (up to 0.020 $cm^3 g^{-1}$).

(2) Addition of 17 wt % thermally expanded graphite to a reaction mixture results in an increase in the total sorption space W_s to 0.11 $cm^3 g^{-1}$ because of the growing volume of mesopores.

(3) Raising the temperature of synthesis to 1600°C leads to a decrease in the specific surface area of the resulting material, an increase in the pore size, and a decrease in the material strength.

(4) Selective nanoporous layers (200 μm thick) of double-layer membranes firmly adhering to a silicon carbide support were obtained by synthesis of SiC at 1100°C from highly dispersed mixtures of silicon with graphite.

Received December 29, 2003

Abstract—Molybdenum oxide groups were synthesized on a porous glass surface by the molecular layering technique. Kinetic features of Mo(V) $\rightleftarrows$ Mo(VI) transitions in thermal oxidation and photoreduction were studied for a set of samples containing 0.02–0.12 mmol g^{-1} of molybdenum.

Recently, photochromic properties of polyoxomolybdates in solutions, films, and solids have been intensively studied [1–5]. A typical blue color arising under UV irradiation is, as a rule, caused by the transition of a part of Mo(VI) atoms to the Mo(V) state. The appearance, in this case, of an electron on the 4*d* orbitals of the metal makes possible *d*–*d* transitions and gives rise to optical absorption in the visible range. The fact that photochromism is a characteristic feature of molybdenum clusters, which is not observed in the case of the $[MoO_4]^{2-}$ monomer, allows it to be regarded as a "dimensional" property. In this context, it may be assumed that an increase in the number of molybdenum atoms in oxide particles stabilizes the photoreduced form through delocalization of $4d^1$ electrons over its "metal core." However, this assumption has not been confirmed experimentally because of certain difficulties in reliable identification, of molybdenum-oxide clusters in solutions, and especially in their isolation in the solid state [1–5].

In the present study, we examined the influence exerted by collective *d*–*d*-electron interactions on the Mo(V) $\rightleftarrows$ Mo(VI) intervalence transitions via thermal oxidation and photo-reduction of molybdenum-oxide groups grafted to the porous glass surface by the molecular layering technique [6]. Previously, we have shown [7–9] that the reaction of $MoCl_5$ with a completely hydroxylated silica surface presumably occurs by the scheme

$$3(\equiv Si–OH) + MoCl_5 \rightarrow (\equiv Si–O–)_3MoCl_2 + 3HCl. \quad (1)$$

The treatment of the resulting chlorine-containing product with water vapor lead to the formation of Mo(V) hydroxy groups chemically bound to a support:

$$(\equiv Si–O–)_3MoCl_2 + 2H_2O \rightarrow (\equiv Si–O–)_3Mo(OH)_2 + 2HCl. \quad (2)$$

It has been established [7, 8] on the basis of IR spectral data that the thermal oxidation of Mo(V) silica involves the formation of Mo–O–Mo bridging bonds between adjacent molybdenum-oxide groups (in this case, a partial "inner-sphere" condensation of hydroxy groups occurs to give Mo=O molybdenyl bonds). The kinetic features of their oxidation, their possible relationship with the degree of filling of the SiO_2 surface with grafted groups, and the possible photochromic properties of oxidized Mo(VI) silica remain unstudied.

EXPERIMENTAL

Thin polished plates (1 mm thick) of porous glass (PG) were used in the experiments. The porous glass was obtained by leaching of the DV-1M sodium-borosilicate glass thermally pretreated (6 days at 530°C with subsequent annealing at 480°C for 3 h). The specific surface area of PG (80 $m^2 g^{-1}$) was determined from low-temperature adsorption of argon. The average pore radius (4.5 nm) was found from parameters of the hysteresis loop in the region of capillary condensation of water [10].

1070-4272/04/7704-0538 © 2004 MAIK "Nauka/Interperiodica"

The modification reaction (1) was carried out as described earlier [7–9] at room temperature in solutions of $MoCl_5$ in dried CCl_4. After 2 h of contact, the solution was removed, the glass plates were thoroughly washed with the solvent to complete removal of trace amounts of molybdenum(V) in the washout. The content of Mo(V) in the grafted groups was varied by changing the concentration of the working solutions. To carry out a quantitative analysis, the modifying component was dissolved by boiling in 0.1 M sulfuric acid. Molybdenum(V) was determined by photocolorimetry in the presence of ammonium thiocyanate [11]. The surface of the modified PG [reaction (2)] was hydroxylated at 180°C in a flow of nitrogen saturated with a water vapor. The completion of the reaction was judged from the absence of hydrogen chloride at the reactor outlet.

The molybdenum(V)-containing plates were oxidized in air in the temperature range 100–160°C. The oxidation process was monitored by their spectra in the visible range (SF-56 spectrometer). To study the photochromic properties of thermally oxidized glasses, they were irradiated with an unfiltered light of an SVD-120A mercury lamp.

The spectra of glass plates modified with molybdenum(V) oxide groups are shown in Fig. 1. A weak absorption peak at 760 nm is observed for all the samples. The strong band in the short-wavelength region corresponds to charge transfer from pseudo-atomic nonbonding oxygen orbitals to 4*d* molybdenum orbitals $2p^n(O) \rightarrow 4d(Mo)$. The poor resolution of the spectra in the visible range seems to be determined not only by the vibronic, but also by the exchange interaction of Mo(V) $4d^1$ electrons of neighboring groups [9]. For the set of the glasses obtained, the linear dependence of the optical density D at λ = 760 nm on the Mo(V) content in a grafted layer is well observed.

To study the stability of the molybdenum(V) state, we plotted time dependences of D for the oxidation of the modified plates in air. The corresponding experimental data, shown in Fig. 2 for three compositions, are described by the second-order kinetic equation

$$\Delta D/\tau = kD_0(D_0 - \Delta D), \quad (3)$$

where k is the oxidation rate constant and D_0 is the initial optical density.

Linearization of the kinetic curves in the coordinates of Eq. (3) allows us to determine the constants and their temperature dependences, which are shown

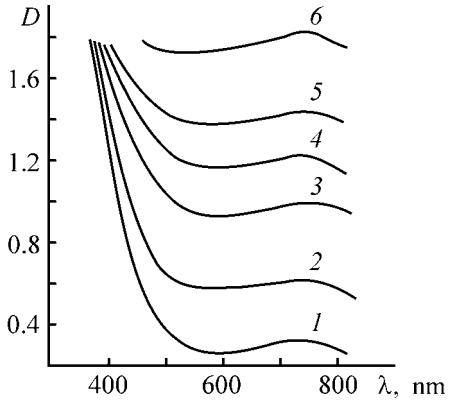

Fig. 1. Spectra of PG plates modified with Mo(V) oxide groups. (D) optical density and (λ) wavelength. Content of molybdenum(V) oxide groups (mmol g^{-1}): (*1*) 0.021, (*2*) 0.043, (*3*) 0.068, (*4*) 0.087, (*5*) 0.098, and (*6*) 0.127.

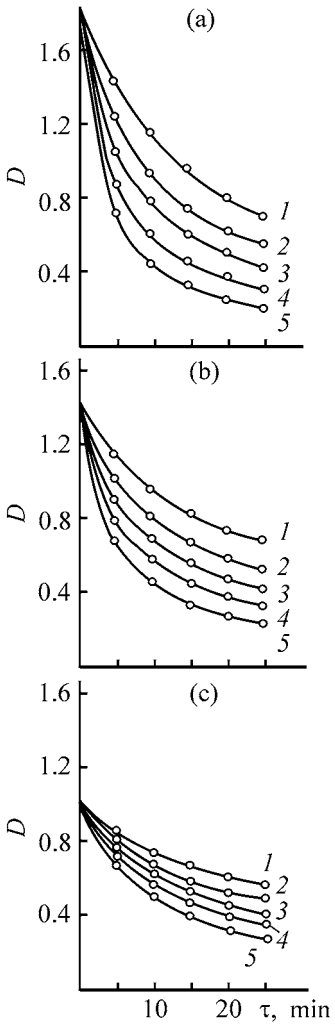

Fig. 2. Kinetic curves for oxidation of Mo(V)-containing PGs at various temperature. (D) optical density and (τ) time; the same for Fig. 5. T (°C): (*1*) 100, (*2*) 110, (*3*) 125, (*4*) 140, and (*5*) 160. Content of Mo(V) in the samples (mmol g^{-1}): (a) 0.127, (b) 0.087, and (c) 0.068.

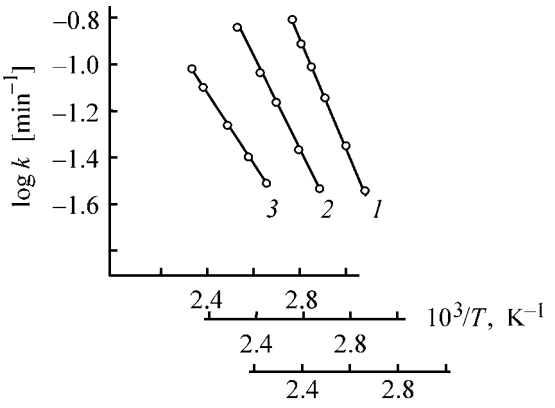

Fig. 3. Logarithm of the rate of oxidation of Mo(V)-containing PGs vs. temperature *T*. Content of Mo(V) in the samples (mmol g^{-1}): (1) 0.127, (2) 0.087, (3) 0.068.

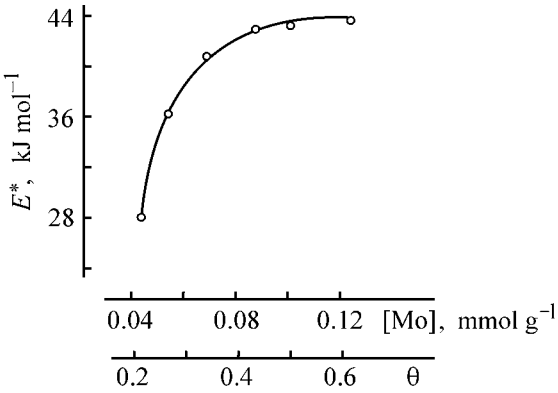

Fig. 4. Activation energy E^* of the oxidation reaction vs. the content of Mo(V) oxide groups, [Mo], and the degree of filling of the porous glass surface with these groups, θ.

for three selected compositions in Fig. 3, and to calculate the activation energies of oxidation, E^*. The fact that these energies are low (Fig. 4) indicates that the reaction occurs in the diffusion region. However, it is not improbable that the values obtained correspond to oxidation, which occurs with an appreciable rate even at moderate temperatures.

The clearly pronounced and characteristic change in the activation energy for the set of samples under study can be interpreted as an evidence of the increasing stability of Mo(V) state at higher concentrations of the component deposited. The most probable reason for the stabilization of molybdenum(V) oxide groups are the lateral Mo(V)···Mo(V) interactions, which predetermine the delocalization of $4d^1$ electrons of molybdenum within the surface layer [9]. In terms of the general theory of conjugated systems, an increase in the conjugation area (chain length) results in a fast manifestation of the basic energetic contribution to the stability. The observed dependence of the activation energy of oxidation on the content of Mo(V) in the grafted layer (Fig. 4) well corresponds to this behavior. The degree of surface filling with grafted groups can be estimated to a first approximation as:

$$\theta = 3[\mathrm{Mo}]/\alpha_{\mathrm{OH}}S_{\mathrm{sp}}. \quad (4)$$

Here [Mo] is the content of molybdenum(V) in the porous glass (μmol g^{-1}); α_{OH} = 7.5 μmol m^{-2}, the average "concentration" of OH groups on a completely hydroxylated surface of silica [12]; S_{sp} = 80 m^2 g^{-1}; and the coefficient 3 corresponds to the dominant grafting mode [reaction (1)].

The role of the "concentration" contribution to the stabilization of molybdenum(V)-containing glasses, discussed here, is also clearly seen when studying the photochromic properties of oxidized samples. It is typical that a prolonged UV irradiation of a glass with a low [Mo(VI)] content of 0.021 mmol g^{-1} does not lead to any observable consequences, whereas an increase in the degree of filling of the PG surface with molybdenum(V) oxide groups leads to the appearance and enhancement of the photochromic properties. In this case, the spectra of plates reduced under UV irradiation are close to those of the initial molybdenum(V)-containing samples.

The kinetics of photoreduction of modified PG plates is illustrated in Fig. 5 by the plots of optical density *D* at λ = 760 nm against the duration of irradiation. It is typical that the *D*–τ curves are almost linear in their main portions and rapidly level off at τ > 40 min. The observed constant oxidation rate may be due to the compensation of the decrease in the content of the oxidized form by the acceleration of the reaction by the progressive Mo(V)···Mo(V) cation–cation interactions. A significant deceleration of the process at τ > 40 min is most likely due to a limited penetration of the UV irradiation into the plate, which corresponds to a strong absorption in the range of charge-transfer transitions (Fig. 1).

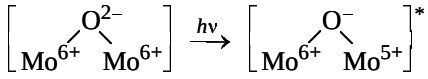
The degree of photoreduction can be judged from the parameter

$$\eta = (D^*/D_0) \times 100\%.$$

Here D_0 is the initial optical density of Mo(V)-containing plates and *D* is the optical density after a 1-h irradiation of oxidized samples.

The character of the resulting dependence of η on the content of the photochromic component (Fig. 5) is one more indication of the increasing stability of molybdenum(V) oxide groups at their higher content in the glass.

The photoreduction is completely reversible. The absorption in the visible range is eliminated by annealing the samples in air at 100–150°C. The observed photochromic properties of molybdenum-containing porous glasses are independent of the humidity and possible presence of reducing molecules in air. Moreover, the dehydration of oxidized samples and their subsequent UV irradiation in a quartz cuvette in a flow of helium give rise to a moderate, but clearly observable acceleration of the photoreduction as compared with the photoreduction in air. It is likely that the equilibrium is shifted in the inert gas toward detachment and desorption of the mobile "bridging" oxygen, which determines the state of molybdenum in the grafted groups [9].



$$\xrightarrow{-\frac{1}{2}O_2} [Mo^{5+}]\cdots[Mo^{5+}].$$

In fact, the Mo(VI) → Mo(V) transition occurs even upon excitation in the charge-transfer band $2p^n(O) \rightarrow 4d(Mo)$. The formation of metal–metal bonds and the delocalization of Mo(V) pseudoatomic $4d^1$ electrons over these bonds stabilize the reduced state.

In conclusion it may be noted that the structural features and the "topographical density" of grafting of molybdenum-oxide groups on the accessible PG surface, which depend on the method of synthesis, determine the clearly pronounced photochromic properties of the samples under study. The photochromism appears to a considerably lesser extent in most of the known molybdenum-oxide media [1–5]. The mobility of oxygen in the Mo–O–Mo bonds in molybdenum-containing porous glasses produced by molecular layering is reflected both in the rate and extent of photoreduction and in the readily occurring thermal regeneration of the oxidized state.

CONCLUSIONS

(1) Molybdenum-oxide groups were synthesized on a porous glass surface in amounts of 0.02–0.12 mmol g^{-1}. The rate constants of oxidation of Mo(V)-containing porous glasses by atmospheric oxygen at 100–160°C were determined. The activation energies of oxidation indicate that the stability of the Mo(V) state grows as the content of grafted groups increases.

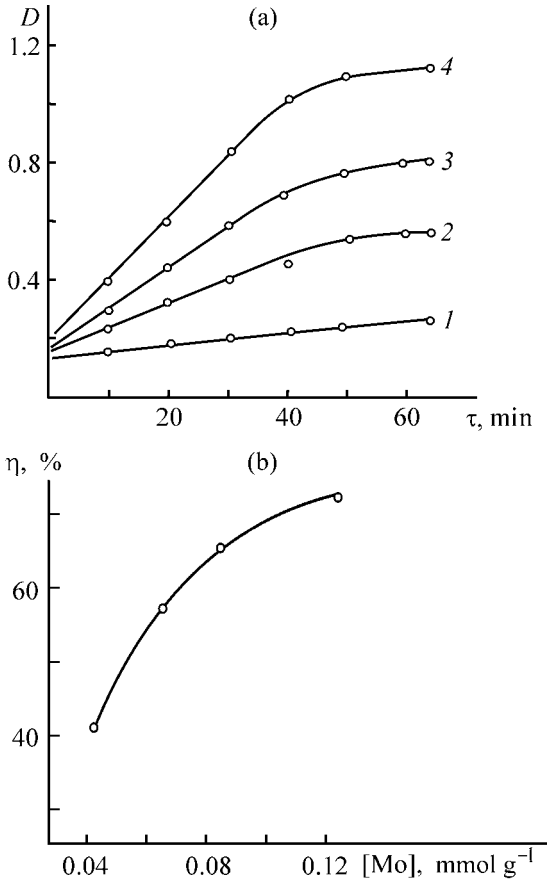


Fig. 5. (a) Kinetics of photoreduction of modified PGs with varied content of Mo(VI) and (b) dependence of the degree of reduction, η, on the content of Mo(VI) in the PG. Content of Mo(V) in the samples (mmol g^{-1}): (*1*) 0.043, (*2*) 0.068, (*3*) 0.087, and (*4*) 0.127.

(2) The photochromic properties of Mo(VI)-containing porous glasses were revealed. The rate and degree of photoreduction are determined by the content of a grafted component. The reversibility of Mo(V) ⇄ Mo(VI) transitions was attributed to the mobility of oxygen in the Mo–O–Mo bonds between the neighboring molybdenum-oxide groups. The attention is called to the possibility of stabilization of the reduced forms through delocalization of molybdenum(V) $4d^1$ electrons within the system of metal–metal bonds.

Received September 11, 2003; in final form, February 2004

Abstract—The kinetics and thermodynamics of formation of chloromagnesium cements, which involves magnesium oxide, the main component of metallurgical sludge produced in manufacture of magnesium, were studied. The rate constants, activation energy, frequency factor, and thermodynamic constants of the reactions in which crystalline hydrates of composition $3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O$ and $5Mg(OH)_2 \cdot MgCl_2 \cdot 2H_2O$ are formed were calculated.

It has been shown previously that metallurgical sludge that contains magnesium oxide MgO and carnallite $KMgCl_3 \cdot 6H_2O$ exhibits binding properties and can be used as a chloromagnesium binder in manufacture of composite wood-mineral construction materials.

In this study, the reactivity of MgO contained in sludge was analyzed by means of thermodynamic calculations and experimentally, as a component of the chloromagnesium cement (Sorel cement).

EXPERIMENTAL

The thermodynamic studies were carried out using the known calculation techniques.

In the experimental part of the study, stoichiometric calculations were performed using the equations of the following chemical reactions

$$MgO + H_2O = Mg(OH)_2, \quad (1)$$

$$3MgO + MgCl_2 + 11H_2O = 3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O. \quad (2)$$

The interaction in the system $MgO–H_2O$ was analyzed in order to reveal the part played by reaction (1) in the mechanism of hardening through formation of basic magnesium chlorides, which can occur, in particular, via reaction (2). MgO necessary for reactions (1) and (2) was obtained by washing soluble salts out of the sludge with water at room temperature, with subsequent drying of the resulting solid residue with acetone on a filter. The amount of water in all the experiments corresponded to the mass ratio $MgO : H_2O = 1 : 1.5$. In studying the interaction in the system $MgO–MgCl_2–H_2O$, a stoichiometric amount of $MgCl_2$ of pure grade was dissolved in this amount of water.

Mixtures of MgO with water or a $MgCl_2$ solution were kept in a thermostat at prescribed temperatures and experiment durations. Then the reaction mixture was rapidly freed of the excess amount of water by filtration and washed with acetone on a filter.

The process of MgO hydration was studied by thermogravimetry; the composition of the products formed in the hydration reaction was determined by X-ray phase analysis and IR spectroscopy. Separate samples were subjected to physicomechanical tests.

It is known from the laboratory and industrial practice that the main products of reactions of MgO with $MgCl_2$ are crystalline hydrates of composition $3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O$ (I) and $5Mg(OH)_2 \cdot MgCl_2 \cdot 2H_2O$ (II) [2], which are formed in accordance with the equations of the following reactions

$$3MgO + Mg^{2+} + 2Cl^- + 11H_2O = 3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O, \quad (3)$$

$$5MgO + Mg^{2+} + 2Cl^- + 7H_2O = 5Mg(OH)_3 \cdot MgCl_2 \cdot 2H_2O. \quad (4)$$

Table 1. Thermodynamic constants of compounds formed in reaction of MgO with $MgCl_2$ solutions

Compound	$-\Delta H^0_{298.15}$	$-\Delta G^0_{298.15}$	$S^0_{298.15}$	$C^0_{P(298.15)}$
	kJ mol^{-1}		J mol^{-1} K^{-1}	
$3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O$	5973.52	5179.28	563.46	589.12
$5Mg(OH)_2 \cdot MgCl_2 \cdot 2H_2O$	6009.90	5396.95	509.11	468.04
$3Mg(OH)_2 \cdot MgCl_2$	3517.71	3200.10	296.09	259.87
$5Mg(OH)_2 \cdot MgCl_2$	5379.20	4882.06	430.99	385.73

Thermodynamic calculations of these and other reactions were carried out using thermodynamic constants obtained by the authors of this study (Table 1) or those taken from [3–6]. The calculated values refer to basic magnesium oxides. The enthalpy and Gibbs energy of formation of basic magnesium chlorides were calculated in terms of the theory of regular solutions, which makes it possible to determine the excess functions of mixing at a minimum amount of experimental data [7, 8].

Actually, the concept of basic salts as isomorphous mixtures of a hydroxide and a neutral salt [$Mg(OH)_2$ and $MgCl_2$ in the case in question] was used in the calculations. Also, account was taken of the fact that the formation of basic chlorides of variable composition is characteristic of hydroxochloride systems [9].

The excess function of mixing of $Mg(OH)_2$ and $MgCl_2$ was found to be 133.98 ± 2.1 kJ mol^{-1} on the basis of the known values of $\Delta H^0_{298.15}$ and $\Delta G^0_{298.15}$ for MgOHCl and $0.5NaCl \cdot MgOHCl$ [5]. The excess functions of addition of crystalline-hydrate water was determined using the known data for $MgCl_2$ crystalline hydrates. The temperature dependences of the Gibbs energy were found using the simplified formula

$$\Delta G_T = \Delta H^0_{298.15} - T\Delta S^0_{298.15}. \quad (5)$$

The equilibrium constants K were determined using the equation

$$\Delta G = -RT \ln K, \quad (6)$$

where ΔG is the energy of the reaction; R, the universal gas constant; and T, temperature (K).

In these calculations, account was taken of the fact that the activities of the solid reactants and liquid water are taken to be unity for the standard conditions and only the activities of the solutes or the partial pressure of gaseous reactants appear in the equation for the equilibrium constants.

To analyze the stability of phases in hydrolysis, solubility, and dehydration, the following reaction equations were considered:

$$3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O = \frac{2}{3}[5Mg(OH)_2 \cdot MgCl_2 \cdot 2H_2O] + \frac{2}{3}H^+ + \frac{2}{3}Cl^- + 6H_2O, \quad (7)$$

$$3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O = 4Mg(OH)_2 + 2H^+ + 2Cl^- + 6H_2O_l, \quad (8)$$

$$3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O = 3Mg(OH)_2 \cdot MgCl_2 + 8H_2O_l, \quad (9)$$

$$3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O = 3Mg(OH)_2 \cdot MgCl_2 + 8H_2O_g, \quad (10)$$

$$3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O = 4Mg(OH)_2 + 2HCl_g + 6H_2O_g, \quad (11)$$

$$5Mg(OH)_2 \cdot MgCl_2 \cdot 2H_2O = 6Mg^{2+} + 10OH^- + 2Cl^- + 2H_2O_l, \quad (12)$$

$$3Mg(OH)_3 \cdot MgCl_2 \cdot 8H_2O = 4Mg^{2+} + 6OH^- + 2Cl^- + 8H_2O_l. \quad (13)$$

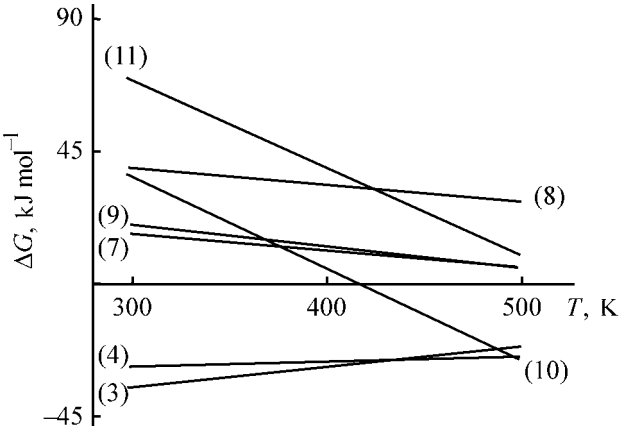

Fig. 1. ΔG for the processes that occur in the system MgO–$MgCl_2$–H_2O by reactions (3), (4), and (7)–(11) vs. temperature T.

Table 2. Results of thermodynamic calculations of chemical reactions

Reaction	$-\Delta H^0_{298.15}$, kJ mol^{-1}	$-\Delta G^0_{298.15}$, J mol^{-1}	$S^0_{298.15}$, J mol^{-1} K^{-1}	log K	Type of equation for K_{eq}
(3)	–224.16	–140.72	–279.89	24.64	$1/[Mg^{2+}][Cl^-]^2$
(4)	–200.51	–168.14	–108.56	29.44	$1/[Mg^{2+}][Cl^-]^2$
(7)	139.17	69.67	233.12	–12.2	$[H^+]^{2/3}[Cl^-]^{2/3}$
(8)	222.11	155.96	219.35	–27.31	$[H^+]^2[Cl^-]^2$
(9)	167.47	80.39	292.07	–	–
(10)	519.83	149.38	1242.47	–26.16	$P^8_{H_2O}$
(11)	636.18	279.72	1195.58	–48.98	$P^2_{HCl}P^6_{H_2O}$
(12)	29.48	352.36	–1082.96	–61.70	$[Mg^{2+}]^6[OH^-]^{10}[Cl^-]^2$
(13)	121.54	251.25	–435.05	–44.00	$[Mg^{2+}]^4[OH^-]^6[Cl^-]^2$

The results obtained in thermodynamic calculations for the standard conditions (298.15 K, 1 atm) are listed in Table 2 and shown in Fig. 1.

The values of ΔG in Fig. 1 refer to one atom of magnesium for all the reactions. For example, $\Delta G^0_{298.15}$ = –140.72/4 = –35.18 kJ mol^{-1} for reaction (3) and –168.14/6 = –28.02 kJ mol^{-1} for reaction (4). In plotting Fig. 1, account was also taken of the fact that the dependences ΔG–T can be represented in the temperature range under study, to a good approximation, as formula (5).

It should be noted that the exothermic effects in the reactions of formation of compounds (I) and (II) [reactions (3), (4)] are strong. For example, calculations by the equation $\Delta T = \Delta H/C_P$ show that the heat of the reaction is sufficient for heating compound (I) by 653 K and compound (II) by 701 K.

Analysis of the data in Tables 1 and 2 leads to a number of technologically important conclusions.

In particular, the data for reactions (12), (13) indicate that compounds (I) and (II) have exceedingly low solubility, which decreases as temperature becomes higher. Compound (I) is thermodynamically stable in the presence of a liquid phase up to 437 K, and, accordingly, its solubility is lower. Possibly, compound (II) is formed as an intermediate metastable phase, which is present in the reaction products at temperatures below 437 K for kinetic reasons only. The thermodynamic stability of compound (I) is also indicated by the data for reaction (7). The presence of a metastable phase in the reaction products, mentioned above, is a widely occurring and well-known fact of formation of a stable phase via metastable intermediates [10].

The thermodynamic calculations also indicate that the compound (I) is stable against loss of crystallization water in the form of a liquid phase in the whole temperature range studied [reaction (9)] and as a gas up to 418 K [reaction (10)]. This compound is also stable against hydrolysis [reactions (7), (11)].

Thus, from the thermodynamic standpoint, the formation of the magnesian stone in a wide temperature range must not be complicated by loss of crystallization water or by hydrolysis.

The influence exerted by the temperature factor on the degree of hydration of magnesium oxide was revealed experimentally. The time dependences of the degree of MgO hydration in the systems MgO–H_2O and MgO–$MgCl_2$–H_2O at different temperatures are shown in Fig. 2. These kinetic curves were used to

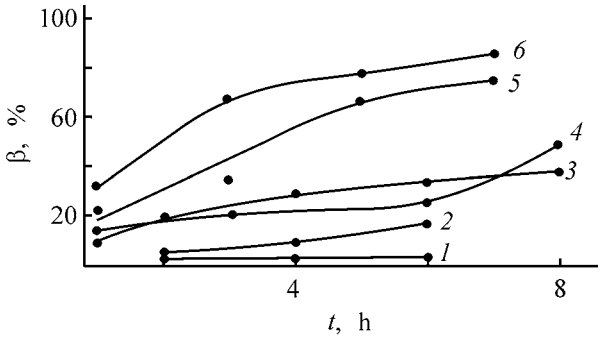

Fig. 2. Degree of MgO hydration, β, in the systems (*1*–*3*) MgO–H_2O and (*4*–*6*) MgO–$MgCl_2$–H_2O vs. time *t*. Temperature (K): (*1*, *4*) 313, (*2*, *5*) 333, and (*3*, *6*) 353.

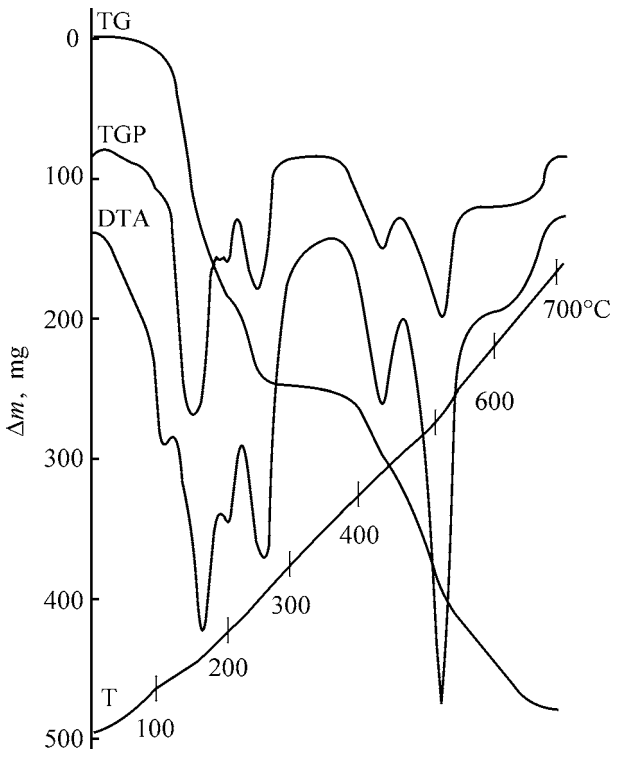

Fig. 3. Derivatogram of the products formed in interaction of MgO in sludge with a $MgCl_2$ solution. (Δm) Loss of mass and (T) temperature.

calculate the rate constants of the reactions of MgO hydration for both of the systems studied. The experimental value of the degree of MgO hydration was calculated on the basis of derivatograms. For this purpose, the total loss of mass by the dried samples was related to the stoichiometric amounts of the products formed in the reactions of thermal decomposition

$$Mg(OH)_2 = MgO + H_2O_g, \quad (14)$$

$$3Mg(OH)_2 \cdot MgCl_2 \cdot 8H_2O = 4MgO + 2HCl_g + 11H_2O_g. \quad (15)$$

The stoichiometric amounts were calculated according to reaction (14) for the system MgO–H_2O and reaction (15) for MgO–$MgCl_2$–H_2O. The assignment of the loss of mass was the simplest for the first of these systems, for which only a single endothermic effect of loss of mass in decomposition of $Mg(OH)_2$ by reaction (14) was present in the derivatograms. For the second system, the derivatograms exhibited several effects. Figure 3 shows a derivatogram of the product formed in interaction of MgO in sludge with a $MgCl_2$ solution at 353 K in the course of 3 h. Published data on the thermal behavior of crystalline hydrates of $MgCl_2$ and also crystalline hydrates of its double salts with sodium and potassium chlorides [11, 12] make it possible to assign the endothermic effects observed in the derivatograms.

At temperatures of 433, 473, and 533 K there occur processes of steplike dehydration, which are mainly associated with removal of physically bound water and are accompanied by partial hydrolysis of $MgCl_2$ with evolution of hydrogen chloride.

$Mg(OH)_2$ formed in interaction of MgO with an aqueous solution of $MgCl_2$ decomposes at a temperature of 693 K. In the process, chemically bound water is removed.

The endothermic effect at 783 K is associated with decomposition of anhydrous basic magnesium chloride MgOHCl to give MgO and HCl.

The assignment of the endothermic effects to the corresponding chemical transformations is also confirmed by thermodynamic calculations, e.g., for the reactions

$$5Mg(OH)_2 \cdot MgCl_2 \cdot 2H_2O = 5Mg(OH)_2 \cdot MgCl_2 + 2H_2O_g, \quad (16)$$

$$5Mg(OH)_2 \cdot MgCl_2 = 6MgO + 2HCl_g + 4H_2O_g. \quad (17)$$

Zero free energy is reached at 490 K for reaction (16) and at 714 K for reaction (17).

Thus, the whole amount of crystallization and hydroxide water, and also chloride ions in the form of HCl, were removed when the samples under study were heated to 1073 K.

The conversion was found as the ratio of the experimental loss of mass to that furnished by calculation. The mathematical processing of the kinetic curves shown in Fig. 2 was performed using the Kolmogorov–Erofeev equation [13]

$$\alpha = 1 - e^{-kt^n}, \quad (18)$$

where α is the conversion; t, the process duration (h); and k, n, temperature-dependent constants.

The reaction rate constants K were found using the Sakovich equation [13]

$$K = nk^{1/n}, \quad (19)$$

where n, k are the constants of the Kolmogorov–Erofeev equation.

The statistical processing of the results obtained was made using the STATGRAPHICS software. In

doing so, the constants k and n were found by approximation of the experimental data with straight lines obtained by rearranging terms and taking double logarithm of Eq. (18):

$$\ln[-\ln(1 - \alpha)] = \ln k + n \ln t. \quad (20)$$

The results of regression and correlation analyses demonstrated that the Kolmogorov–Erofeev equation describes the kinetics of reactions (1) and (2) with high precision: at a 95% confidence level (p-value < 0.05) the correlation coefficients varied within the range 0.91–0.98. The calculated constants are listed in Table 3.

The rate constant of MgO hydration grows as temperature becomes higher, and its values for reaction (2) were found to exceed those for reaction (1). The resulting values of K were used to determine the apparent activation energy ΔE and the frequency factor A by the equation

$$K = Ae^{-\Delta E/RT}. \quad (21)$$

The regression equation $\ln K(1/T)$ was used to determine the values of ΔE and A, which were found to be 14.61 kJ mol^{-1} and 1.196×10^8, respectively, for reaction (2). The activation energy obtained suggests that the heterogeneous processes under study occur in the diffusion region (ΔE < 16.7 kJ mol^{-1}), in which the rate of diffusion is the limiting factor. The same conclusion follows from the relatively low value of the frequency factor. However, the reaction of MgO hydration is not rate-limiting in the process of formation of the magnesian stone. The kinetics of the processes under study is also strongly affected by nucleation of the new phase on the reaction surface.

On the whole, the kinetic studies demonstrated that MgO contained in sludge exhibits a chemical activity that enables its use as a magnesium binder. Mixing MgO with $MgCl_2$ solutions with a density of 1.18–1.20 g l^{-1} leads to formation of the magnesian stone. However, initiation of hardening requires that the magnesian paste should be preheated to 343 K. Control samples formed from such a magnesian paste and hardened for 3, 7, and 28 days were subjected to strength tests. The breaking compression stress was 18.7, 31.2, and 53.1 MPa, respectively.

CONCLUSIONS

(1) The investigation performed demonstrated that magnesium-containing sludge can be used as a mineral binder; a preliminary heating of the reaction mixture to 343–353 K can be recommended for industrial conditions. After that the process may occur in the auto-thermal mode with a transition to the autoclave region, in which the magnesian stone will be formed at a high rate.

Table 3. Constants calculated by the Kolmogorov–Erofeev and Sakovich equations

Constant	Temperature, K		
	313	333	353
Reaction (1)			
k	0.0191	0.0200	0.0227
n	0.416	1.225	1.711
K	3.077×10^{-5}	5.026×10^{-2}	1.871×10^{-1}
Reaction (2)			
k	0.1382	0.2202	0.4009
n	0.618	0.930	0.859
K	2.513×10^{-2}	1.827×10^{-1}	2.964×10^{-1}

(2) At the same time, the high exothermicity of the main reactions requires that special measures should be taken to perform the process under controllable conditions. The thermodynamic and kinetic data obtained make it possible to carry out the necessary technological calculations.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Dependence of Separation Characteristics of Pervaporation on Parameters of Membranes Composed of Cellulose Myristinate and Polyphenylene Oxide

Abstract—Experimental data on evaporation of binary mixtures composed of ethanol and water, ethyl acetate and acetic acid, water and acetic acid, and ethyl acetate and water in a wide range of concentrations, across film membranes composed of cellulose myristinate and polyphenylene oxide are presented.

Membrane separation of substances have attracted increasing attention in recent decades in both technological and scientific regards. In the course of pervaporation, a liquid mixture is brought in contact with a polymeric or inorganic membrane, commonly nonporous polymeric membrane, with a vapor (permeate) that contains mostly the target component removed from its back side. Therefore, the liquid–vapor phase transition is an integral part of this process. The interface between the liquid and vapor frequently lies within a membrane, and the contribution of this phase transition to selectivity of pervaporation may be significant, compared with the part played by physicochemical interactions between the material of the membrane and molecules transported across the membrane, which are specific to this process.

The aim of this study was to analyze the contribution of the liquid–vapor phase transition to the characteristics of pervaporation and to examine the evaporation across a membrane composed of cellulose myristinate and polyphenylene oxide of binary mixtures of water, ethanol, acetic acid, and ethyl acetate.

Modeling of pervaporation for engineering purposes is commonly based on Fick's law equations, which relate fluxes of substances to gradients of their concentrations. In a more correct form, the gradient or difference of the chemical potentials of substances in the liquid and vapor phases are to be used as driving forces of the process.

The conditions for equilibrium between binary liquid and vapor phases are as follows:

$$\left.\begin{aligned} \mu_1^{(l)} &= \mu_1^{(v)}, \\ \mu_2^{(l)} &= \mu_2^{(v)}, \\ P^{(l)} &= P^{(v)}, \\ T^{(l)} &= T^{(v)}, \end{aligned}\right\} \quad (1)$$

where μ is the chemical potential of substances 1 and 2 in the liquid (l) and vapor (v) phases; P and T are, respectively, the pressure and temperature of the coexisting phases.

When one of these quantities changes, there arise fluxes of substance or heat, which results in that an equilibrium is established. For example, a pressure difference across the membrane gives rise to substance fluxes that compensate for this difference. If the difference is created by a vacuum pump that removes the vapor (permeate), and the feeding liquid is at the atmospheric pressure, then the pressure difference cannot exceed 760 mm Hg. However, there are no data indicating that creating such a pressure difference by raising the pressure in the liquid, with the atmospheric pressure maintained in the permeate, gives rise to any noticeable fluxes. In other words, overcoming the hydraulic resistance of the membrane is not the principal condition for the appearance of significant fluxes.

The role of the vacuum consists to a greater extent in diminishing the partial pressure of substances in the permeate, i.e., in lowering the chemical potentials of the substances in the vapor phase. In Onzager's notation, the flux J_1 of substance 1, assumed to be

1070-4272/04/7704-0549 © 2004 MAIK "Nauka/Interperiodica"

independent of the flux of substance 2, has the form

$$J_1 = K_1(\mu_1^{(l)} - \mu_1^{(v)}), \quad (2)$$

where K_1 is the proportionality factor.

The chemical potential $\mu_1^{(l)}$ of the component 1 in the liquid phase is given by

$$\mu_1^{(l)} = \mu_1^{0(l)}(T, P) + RT \ln \gamma_1 x_1, \quad (3)$$

where $\mu_1^{0(l)}$ is the standard value of the potential in the liquid phase; γ_1, the activity coefficient; x_1, the mole fraction of substance 1 in the liquid phase; and R, the gas constant.

The chemical potential $\mu_1^{(v)}$ of component 1 in the vapor (permeate) is expressed as

$$\mu_1^{(v)} = \mu_1^{0(v)}(T) + RT \ln Py_1, \quad (4)$$

where P is the permeate pressure, and y_1 is the mole fraction of component 1 in the vapor.

In the course of pervaporation, the value of P, which is set by the vacuum pump, is equal to the sum of partial pressures of components 1 and 2.

With account of formulas (3) and (4), the flux J_1 in expression (2) takes the form

$$J_1 = J_1^0 + B(-\ln y_1 - \ln P), \quad (5)$$

where $J_1{}^0 = K_1(\mu_1^{0(l)} - \mu_1^{0(v)})$ is the flux determined by the difference of the standard chemical potentials, and $B = K_1RT$.

In deriving formula (5), it was assumed that the composition of the liquid remains unchanged in the course of its evaporation across the membrane. This assumption is well substantiated, since the fluxes across the membrane are relatively small, and is commonly confirmed in experimental studies.

The separating ability of membranes in pervaporation is commonly characterized by the selectivity factor

$$\alpha_{PV} = (y_1/y_2)/(x_1/x_2), \quad (6)$$

where the concentrations of the substances in the liquid (x) and vapor (y) phases are more frequently expressed in weight percent.

Attempts to prognosticate the selectivity of the process are commonly made in terms of the dissolution–diffusion model. In accordance with this model, the feeding liquid does not wet the membrane and transforms into vapor at the boundary of the membrane on the side of the liquid. In accordance with the concept of a local equilibrium, the composition of the vapor is considered to be in equilibrium with that of the liquid. The vapor selectively diffuses across the membrane and is collected at its back side in the form of the permeate. Thus, the selectivity factor is expressed as the product

$$\alpha_{PV} = (y_2^*)/y_2^*(x_1/x_2)(y_1/y_2)/(y_1^*/y_2^*) = K\alpha_{GS}, \quad (7)$$

where y_1^*, y_2^* represent the composition of the vapor in equilibrium with a liquid of composition x_1, x_2.

The coefficient K, equal to the first multiplier in formula (7), is known in the equilibrium thermodynamics as the coefficient of relative fugacity. The second multiplier, α_{GS}, is the selectivity of gas separation on the membrane of a vapor of composition y_1^*, y_2^* to give a permeate of composition y_1, y_2. Such a representation of the selectivity of pervaporation as a product of the coefficient of relative fugacity by the selectivity of gas separation was made in [1, 2]. In [1], the coefficient α_{GS} was named the pervaporation improvement factor E[1]. The author of the monograph [2] introduced the notion of selectivity β_{evap} of the liquid–vapor phase transition, then equating it, however, to K.

Apparently, with formula (6) used to calculate the selectivity and nonselective membranes ($\alpha_{GS} = 1$), the coefficient α_{PV} may be large and nearly equal to the coefficient of relative fugacity, K. For example, for a mixture of esters with water, K = 100–300. Thus, the high selectivity of some membranes is determined by characteristics of the liquid–vapor phase transition, rather than by the properties of a polymer. Therefore, to ascertain the separation characteristics of the polymer constituting the membrane, it is necessary to divide the selectivity factor found from experimental data by the coefficient of relative fugacity:

$$\alpha_{MS} = \alpha_{PV}/K, \quad (8)$$

where α_{MS} is the selectivity of the process, determined by the interaction of the polymer with flows of liquid and vapor dissolved in it.

In this case, as always, to α_{MS} values greater than unity correspond organophilic properties of the membrane with respect to the readily volatile substance being isolated. If the coefficient α_{MS} is close to, but less than unity, the membrane may be both nonselective (chemically inert or interacting in the same manner with the substances transported across it) and or-

ganophobic with respect to the readily volatile substance being isolated. In the former case, if the flux across the membrane is lowered by making higher the permeate pressure and the compositions of the liquid and vapor approach their equilibrium values, α_{MS} tends to unity. In the latter case, α_{MS} is always smaller than K and may be substantially less than unity.

However, such a comparison, which takes into account the contribution from the selectivity of the liquid–vapor phase transition to the total selectivity of pervaporation is, as a rule, not made. Data on the liquid–vapor equilibrium, presented in some papers, serve for comparison of pervaporation and simple distillation as methods for separation of liquid mixtures.

Meanwhile, the selectivity of the liquid–vapor phase transition can be equated to the coefficient of relative fugacuty if, as it is commonly assumed in the dissolution–diffusion model, such a transition occurs outside the membrane. However, the problem of where the phase transition occurs has not been solved conclusively. The author of the monograph [3] believes that the liquid is transformed into a vapor "along the entire way from the entrance into the membrane to permeate formation" at the exit. In the model of a flow within pores [4], the liquid evaporates at a certain depth within the pores penetrating through the bulk of the membrane. If such a transition occurs within the membrane, the applicability of the concept of a local equilibrium is unobvious.

Indeed, this concept assumes that the fluxes across the phase boundary in the forward (from liquid to vapor) and reverse directions are so large that the resulting flux in the forward direction is small and does not affect the phase compositions on both sides of the surface. These compositions correspond to those in equilibrium. If, however, the phase transition occurs within the membrane, the diffusion resistance of the polymer makes the fluxes smaller, so that the resulting flux may become comparable with them. Then, the composition of the vapor no more corresponds to an equilibrium with the liquid. For a nonequilibrium process, which the pervaporation is, the content of, e.g., the more volatile component in the vapor is lower than the equilibrium value. Therefore, in the case of nonselective membranes, the selectivity is somewhat lower than the coefficient of relative fugacity and approaches it asymptotically as the flux decreases. This point will be confirmed when discussing the experimental results.

The setup for studying the pervaporation process included a 200-ml glass reactor thermostated with an internal heat exchanger. The liquid placed in the reactor was agitated with a magnetic stirrer at a rate of 1000 rpm, which is commonly [1] considered sufficient for preventing concentration polarization near the membrane surface. The bottom of the reactor was in the form of a porous fluoroplastic plate on which a membrane was placed. The under-membrane space was connected by means of a vacuum tube to a glass trap cooled with liquid nitrogen. The trap was connected with a 20-l evacuated vessel, which made it possible to maintain the rarefaction created by the vacuum pump.

The temperature of the liquid mixtures used in all the experiments was maintained equal to $30 \pm 0.1°C$. The residual pressure in the vacuum system was 10 ± 0.5 mm Hg. In the case when the dependence of the flux across the membrane on the vapor (permeate) pressure was studied, this pressure was varied within the range 1–100 mm Hg.

As membranes served 40-μm-thick films of cellulose myristinate and 65-μm-thick films of polyphenylene oxide.

The liquid mixtures were prepared from ethyl acetate, ethanol, and acetic acid of chemically pure grade and distilled water. Evaporation across the membrane of binary mixtures composed of ethanol and water, water and acetic acid, ethyl acetate and acetic acid was studied over the entire range of concentrations. The compositions of the liquid mixtures and the permeate were determined by gas chromatography. The fluxes were calculated gravimetrically with account of the membrane area and experiment duration.

In some reported experimental studies of pervaporation, the selectivity factors α_{PV} do not exceed the coefficients of relative fugacity, K. To membranes of this kind belongs, e.g., a polydimethylsiloxane film in isolation of methanol and ethanol from their 10 and 30 wt % solutions in water. The selectivities of this process, α_{PV}, taken from [5] and the coefficients of relative fugacity, K, [6] are listed below

Alcohol	α_{PV}	K	α_{PV}	K
	10 wt %	10 wt %	30 wt %	30 wt %
MeOH	6.03	8.21	4.72	8.06
EtOH	7.44	7.66	5.79	7.00

A film composed of cellulose myristinate is also distinguished by low values of α_{PV}, compared with K,

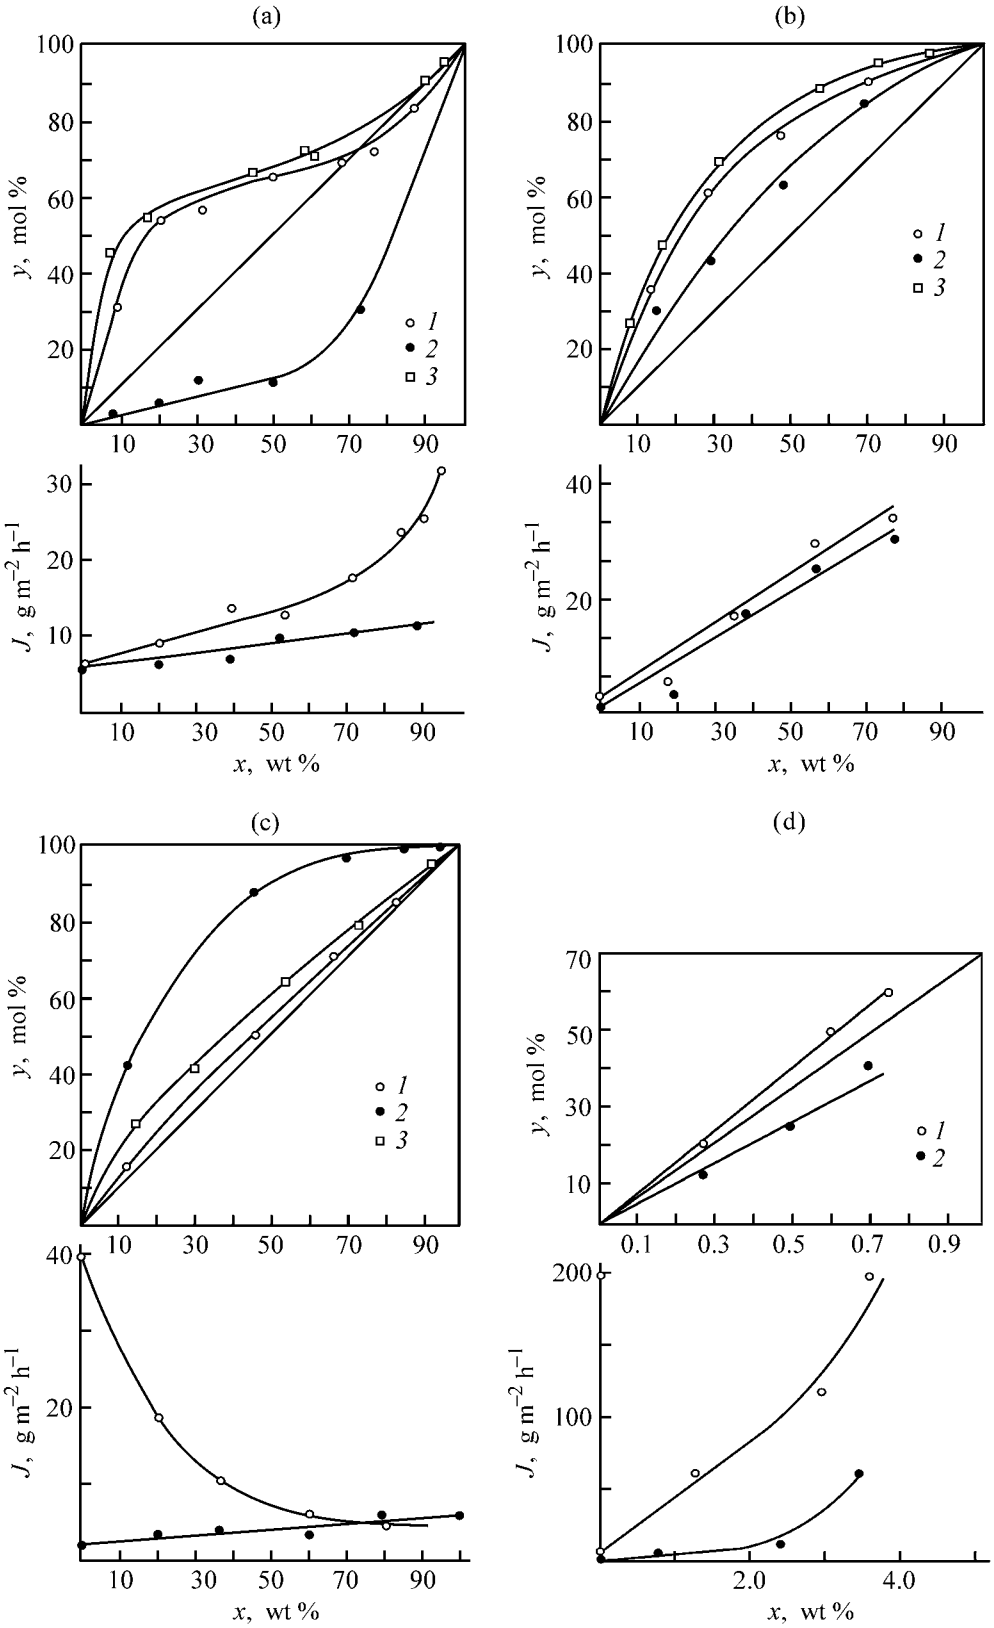

Fig. 1. Composition *y* and flux *J* of the permeate vs. the composition *x* of the liquid in evaporation across a film membrane composed of (*1*) cellulose myristinate and (*2*) polyphenylene oxide; (*3*) vapor composition for a liquid–vapor equilibrium. Liquid mixture: (a) ethanol and water, (b) ethyl acetate and acetic acid, (c) water and acetic acid, and (d) ethyl acetate and water.

for all of the mixtures studied. Figures 1a–1d show how the vapor (permeate) composition depends on the composition of the liquid for the binary mixtures composed of ethanol and water, ethyl acetate and acetic acid, water and acetic acid, and ethyl acetate and water. The same figures show, for comparison, the lines of composition of a vapor that is in equilibrium with the liquid. The plots for pervaporation and an equilibrium with a somewhat lower content of readily volatile substances in the vapor, compared with the equilibrium values, apparently coincide in shape. For example, the azeotropic point characteristic of the equilibrium in the system ethanol–water corresponds to the permazeotropic point with a higher content of water. It is of interest to study how the composition corresponding to the permazeotropic point is related to departure of the process from the equilibrium state.

Figure 2 shows the experimentally determined dependence of the composition of the vapor phase and the flux of ethanol on the permeate pressure. The composition of the liquid phase corresponded to that of the permazeotropic point (28 mol % water, 72 mol % ethanol) at 10 mm Hg and remained constant to within analytical error during the experiments. It can be seen that the flux decreases (which corresponds to an approach to equilibrium) and the composition of the vapor phase (permeate) asymptotically tends to the value in the liquid–vapor system as the flux decreases. Thus, when the flux decreases, the composition of the permazeotropic point shifts toward the equilibrium azeotropic composition. In the process, the selectivity factor α_{MS}, which characterizes the interaction of the polymer constituting this membrane with ethanol and water diffusing across the membrane, becomes equal to unity. When the flux is raised (pressure is lowered from 10 to 1 mm Hg), the content of water at the permazeotropic point increases. With account of the constant composition of the liquid phase, the flux of ethanol can be calculated using formula (5) for $J_1^0 = 0.58$, $B = 0.13$. The results of calculation are shown graphically in Fig. 3.

At the same time, use of expression (5) for calculating the fluxes at constant temperature and pressure and varied compositions of the liquid and vapor phases failed to furnish an agreement with the experimental data at a high content of ethanol in water. Presumably, this is due to strong changes in the properties of the membrane (wettability and plastification) at high concentrations of ethanol. Experimental data on fluxes of substances across cellulose myristinate in the mixtures studied are shown in Figs. 1a–1d. It

Fig. 2. Temperature of the liquid 30°C, its composition: 28 mol % water and 72 mol % ethanol; the same for Fig. 3.

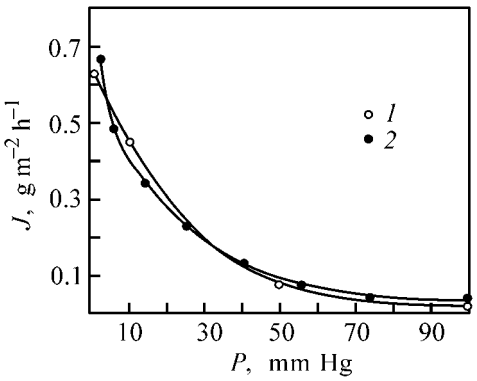

Fig. 3. Ethal flux J vs. the permeate pressure P in evaporation of a liquid mixture ethanol–water across a film membrane composed of cellulose myristinate. (*1*) Experimental data and (*2*) results of calculation by formula (5).

can be seen that the fluxes are only significant for ester-containing liquid mixtures.

In contrast to the film composed of cellulose myristinate, a polyphenylene oxide film exhibits hydrophobic properties, and the permeate formed in evaporation of water-containing binary mixtures of ethanol or acid contains mainly water, as it is shown in Figs. 1a, 1b. For a mixture composed of ethyl acetate and acetic acid, the run of the dependence of the composition of the liquid on that of the vapor is similar to that in the equilibrium case. However, the vapor

contains a smaller amount of the ester, compared with the case of cellulose myristinate (Fig. 1c). Figures 1a–1d show dependences of the mass fluxes of the substances on the composition of the liquid. As in the case of cellulose myristinate, their values are higher for ester-containing mixtures.

CONCLUSIONS

(1) The selective properties of a film membrane composed of cellulose myristinate are determined for the binary mixtures studied by the parameters of the liquid–vapor phase transition. The flux of ethanol across the membrane was calculated at vapor pressures in the range 1–100 mm Hg using the formula of nonequilibrium linear thermodynamics.

(2) A film membrane composed of polyphenylene oxide exhibits similar properties in separation of nonaqueous mixtures, but demonstrates hydrophilicity in the case of organic-aqueous mixtures.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Phase Separation in the Systems Constituted by Tetradecane (Hexane, Decane), Tri-*n*-Butyl Phosphate, and Cerium(III) Nitrate Solvate with Tri-*n*-Butyl Phosphate

A. K. Pyartman, A. V. Kudrova, and V. A. Keskinov

Received April 16, 2003

Abstract—Phase diagrams of ternary liquid systems constituted by tetadecane (hexane, decane), tri-*n*-butyl phophate, and cerium(III) nitrate solvate with tri-*n*-butyl phosphate $Ce(NO_3)_3(TBP)_3$ with phase separation into liquid phases I and II were studied at 298.15 K. Phase I is enriched in the hydrocarbon diluent, and phase II, in $Ce(NO_3)_3(TBP)_3$. The distribution of components between phases I and II was considered.

Extraction of rare-earth elements (REE) with neutral organophosphorus compounds, e.g., tri-*n*-butyl phosphate (TBP) in hydrocarbon diluents (HCDs), is widely used in their recovery and separation. The concentration and type of a diluent affect the extraction isotherms and element separation factors [1]. At a low TBP content in HCD, phase separation of the organic phase into two phases is possible. This effect has been studied in detail for actinides [2]. At the same time, phase diagrams of ternary liquid systems constituted by tetadecane (hexane, decane), TBP, and lanthanide(III) nitrate solvate with TBP in the region of phase separation are unknown, although such diagrams can be of practical interest in the choice of HCD and component concentrations for extraction systems.

Vacuum-distilled TBP (density ρ = 0.9727 g cm^{-3} at 298.15 K) and tetradecane (0.7592 g cm^{-3}), decane (0.7263 g cm^{-3}), and hexane (0.6548 g cm^{-3}) of chemically pure grade were used. Cerium(III) nitrate solvate, $Ce(NO_3)_3(TBP)_3$ (S), was prepared by threefold saturation of TBP with fresh portions of a saturated aqueous solution of cerium(III) nitrate [3]. The "concentration" of $Ce(NO_3)_3(TBP)_3$ in pure S was 1.12 M (ρ = 1.2755 g cm^{-3}). The S concentration in the organic phase was determined complexometrically [4]. The phase densities were determined pycnometrically. The binodal curves of the ternary systems were measured by Alekseev's method [3] by titration of binary systems with different compositions with the third component under the temperature control.

Mixtures of tetradecane (hexane, decane) and S taken in various volume ratios (2.5–10 cm^3) (heterogeneous systems) were titrated with TBP, using a microburet, until the system became homogeneous. In parallel experiments, mixtures of TBP and S (homogeneous systems) were titrated with the diluent until the second organic phase formed.

The formation of the second organic phase was additionally monitored by nephelometry with a Kernco 966 R turbidimeter equipped with a color filter (λ = 850 nm). To determine the nodes (compositions of the coexisting phases), the phase volumes were measured (in special experiments, we showed that, within the error of ±0.2%, the system volume is equal to the sum of the component volumes). With regard to binodals and solution densities, the concentrations of TBP and diluent were determined from the S concentration [5]. In this case, a binodal was plotted using volume fractions under the condition that the total volume remains unchanged when the components are mixed. Later on, the phase composition was recalculated to weight fractions to obtain the phase density.

Additionally, the TBP content was determined as the difference between the total TBP concentration and TBP concentration in S, evaluated after cerium stripping into water, the subsequent saturation of the organic phase with cerium(III) nitrate, and determination of the S concentration. The TBP concentration was determined from the phosphorus content measured with an SF-26 spectrophotometer in 1-cm

quartz cells after decomposition of samples with sulfuric acid [6].

All the results are presented as phase diagrams, using the second Roozeboom triangle: rectangular coordinates (weight fraction scale) for two components of ternary liquid systems; for the third component, $\omega_3 = 1 - \omega_1 - \omega_2$. Errors in ω determination did not exceed ±(0.001–0.002).

Figure 1 and the table show that the binary systems S-TBP and TBP-HCD are homogeneous at any component ratios. By contrast, the S-HCD system has the solubility limits; between them, the system forms two liquid phases I and II. Phase I is enriched in HCD, and phase II, in S. The solubility (weight fractions) of S in HCD increases in the order: tetradecane (0.081) decane (0.163), and hexane (0.178). The solubilities of tetradecane and decane in S are close (0.056 and 0.060) and lower than the solubility of hexane (0.180).

The phase diagrams of ternary liquid systems S–TBP–HCD consist of fields of homogeneous organic solutions (Fig. 1, field *B*) and fields of separation into two liquid phases (Fig. 1, field *A*) bounded by binodals. In all the cases, the points of critical composition of the ternary system are compositions with approximately equal fractions of S and HCD and different TBP contents depending of HCD chain length. At the point of critical composition, the TBP content (ω_{2cr}) is proportional to the number of the carbon atoms in HCD C_x and, to a first approximation, obeys the equation

$$\omega_{2cr} = -(0.062 \pm 0.013) + 0.0181 \pm 0.0012C_x.$$

This equation allows prediction of the field of phase separation of the ternary system for various HCDs. In practice, HCDs with lower molecular weight are preferable, because in this case, the minimum content of free (not bound in S) TBP is required to prevent phase separation. The analysis of nodes of ternary liquid systems with phase separation (see table and Fig. 1) shows that, along with binary systems of the S–HCD type, two liquid phases I and II are formed. Phase I is enriched in HCD, and phase II, in S. Figure 2 presents a plot of the TBP distribution between phases I and II for hexane, decane, and tetradecane. It was shown that, for the systems with phase separation, the TBP weight fraction in phase II is substantially higher than that in phase I and grows in the order hexane < decane < tetradecane, i.e., with

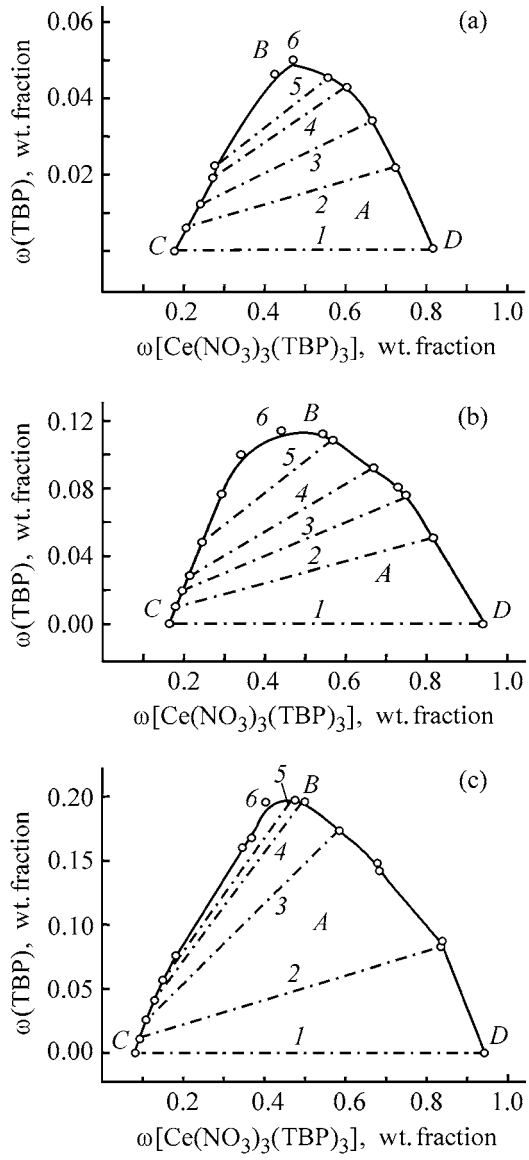

Fig. 1. Phase separation diagram of the ternary systems $Ce(NO_3)_3(TBP)_3$–TBP–C_nH_{2n+2} at 298.15 K. (*A*) Field of phase separation into two liquid phases, (*B*) field of homogeneous organic solutions, (*CD*) binodal, (*1*–*5*) nodes (see table), and (*6*) critical point; (a) hexane, (b) decane, and (c) tetradecane.

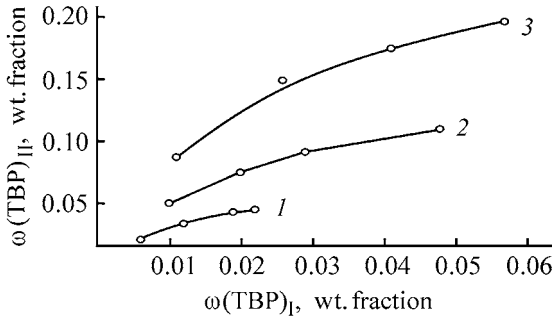

Fig. 2. TBP distribution between phases I and II. $\omega(TBP)_I$ and $\omega(TBP)_{II}$ are the weight fractions of TBP in phases I and II. Phase I is enriched in C_nH_{2n+2}, and phase II, in $Ce(NO_3)_3(TBP)_3$; the same for Figs. 3, 4. (*1*) Hexane, (*2*) decane, and (*3*) tetradecane; the same for Figs. 3, 4.

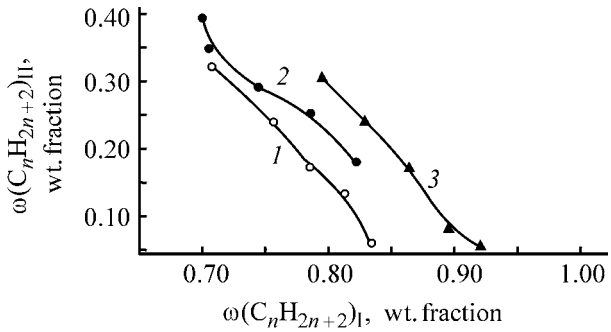

Fig. 3. C_nH_{2n+2} distribution between phases I and II. $\omega(C_nH_{2n+2})_I$ and $\omega(C_nH_{2n+2})_{II}$ are weight fractions of C_nH_{2n+2} in phases I and II.

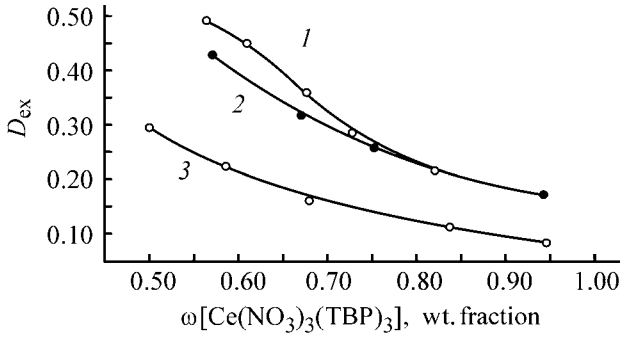

Fig. 4. Dependence of the distribution coefficients, D_{ex}, of $Ce(NO_3)_3(TBP)_3$ between phases I and II on the $Ce(NO_3)_3(TBP)_3$ weight fraction in the phase II.

an increase in the HCD chain length. The curves of HCD distribution between phases I and II are shown in Fig. 3. As can be seen, the HCD weight fraction in phase I is higher than that in phase II and increases in the order: tetradecane < hexane < decane.

The S distribution coefficients between phases I and II for various HCDs are shown in Fig. 4. As can be seen, the S weight fraction in phase II is higher than that in phase I and increases in the order: hexane < decane < tetradecane.

The extraction of cerium(III) nitrate from aqueous-salt solutions with TBP in HCD proceeds by the equation [1]

$$Ce^{3+}_{aq} + 3NO^{-}_{3\,aq} + 3TBP_{org} \rightleftarrows [Ce(NO_3)_3(TBP)_3]_{org},$$

where aq denoted the aqueous phase, and org, the organic phase.

At equilibrium TBP content (weight fraction) higher than 0.2, only one liquid phase exists, which separates into two phases when this fraction decreases.

After saturation of the organic phase with Ce(III) nitrate, two organic liquid phases coexist (phase I is enriched in HCD, and phase II, in S). To use extraction systems based on TBP and HCD in practice, the equilibrium TBP content (weight fraction) should be of 0.17–0.20, i.e., it is necessary to operate with organic phases unsaturated with respect to cerium(III) nitrate, or to use commercial solvents with a low content of long-chain hydrocarbons.

CONCLUSIONS

(1) Phase diagrams of ternary liquid systems constituted by tetradecane (decane, hexane), tri-*n*-butyl phophate, and $Ce(NO_3)_3(TBP)_3$ consist of the field of homogeneous solutions and the field of phase separation (phases I and II). Phase I is enriched in hydrocarbon diluent, and phase II, in cerium nitrate solvate. The phase separation area diminishes in the order tetradecane > decane > hexane with shortening of the hydrocarbon chain length.

(2) At the point of the critical composition of the ternary systems, the TBP content ω_{2cr} is proportional to the number of carbon atoms in the solvent, C_x.

(3) In the phase separation field, the TBP fraction in phase II is substantially higher than that in phase I; the weight fraction of the diluent in phase I is higher and increases in the order: hexane < decane < tetradecane. The solvate weight fraction in phase II tends to increase in the order: tetradecane < decane < hexane.

(4) In practice, to use extraction systems with TBP and hydrocarbon diluent, it is necessary to keep the equilibrium TBP content (weight fraction) no less than 0.17–0.20 or to use commercial solvents with a low content of long-chain hydrocarbons.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Phase Separation in Ternary Liquid Systems Containing Rare-Earth Metal(III) Nitrate Solvates with Tri-*n*-butyl Phosphate

A. K. Pyartman, A. V. Kudrova, and V. A. Keskinov

Abstract—Phase diagrams of ternary liquid systems constituted by tetradecane, tri-*n*-butyl phosphate, and lanthanide(III) nitrate solvates with tri-*n*-butyl phosphate {$[Ln(NO_3)_3(TBP)_3]$, Ln = La, Pr, Nd, Sm} were studied at 298.15 K. The distribution of the components between the phases under stratification conditions was considered.

In this study, we examined phase diagrams of ternary liquid systems constituted by tetradecane, tri-*n*-butyl phosphate, and lanthanide(III) nitrate solvate with TBP in the region of phase separation. Solvates $Ln(NO_3)_3(TBP)_3$ were prepared by a threefold contact of TBP with lanthanide(III) nitrate saturated aqueous solutions [1]. The "concentrations" of $Ln(NO_3)_3(TBP)_3$ in the phase of the pure solvate were 1.08–1.12 mol dm^{-3}, $\rho = 1.2755 \pm 0.0012$ g cm^{-3}. Binodals and nodes were plotted by the method described in [2].

The analysis of the data obtained (see table and Fig. 1) showed that the binary systems $Ln(NO_3)_3(TBP)_3$–

TBP and TBP–$C_{14}H_{30}$ the components are homogeneous at any component ratios. The mutual solubility of the components in the $Ln(NO_3)_3(TBP)_3$–$C_{14}H_{30}$ systems is limited, and, as a result, two liquid phases I and II are formed. Phase I is enriched in $C_{14}H_{30}$, and phase II, in $Ln(NO_3)_3(TBP)_3$. The solubility (weight fraction) of $Ln(NO_3)_3(TBP)_3$ in $C_{14}H_{30}$ is virtually independent of a particular lanthanide and amounts to 0.081. The solubility of tetradecane in the solvate is also independent of a particular lanthanide.

The phase diagrams of ternary liquid systems $Ln(NO_3)_3(TBP)_3$–TBP–$C_{14}H_{30}$ consist of fields of homogeneous organic solutions (Fig. 1, field *B*) and fields of phase separation into two liquid phases (Fig. 1, field *A*), bounded by binodals. The points of the critical composition of the ternary systems (ω_{2cr}) are compositions with approximately equal weight fractions of $Ln(NO_3)_3(TBP)_3$ and $C_{14}H_{30}$ and different TBP contents, depending on a lanthanide. At the point ω_{2cr}, the TBP weight fraction tends to increase from La(III) to Pr(III) and then to decrease from Pr(III) to

Nd(III), while the TBP contents in the systems with Nd and Sm are close (see table).

Nodes of ternary liquid systems with phase separation (see table and Fig. 1) show that, as in the case of binary systems $Ln(NO_3)_3(TBP)_3$–$C_{14}H_{30}$, two liquid phases I and II are formed; phase I is enriched in $C_{14}H_{30}$, and phase II, in $Ln(NO_3)_3(TBP)_3$.

The dependences of the solvate distribution coefficients between phases I and II on the solvate weight fractions in phase II are shown in Fig. 2. As can bee seen, the distribution coefficients decrease with increasing solvate weight fraction. At the solvate weight fraction of 0.5, the distribution coefficients depend on a particular lanthanide and decrease in the order La, Sm, Pr, Nd. At the solvate weight fraction in phase II of 0.95, the distribution coefficients are virtually independent of a particular lanthanide.

Figure 3 shows that the TBP weight fraction in phase II is substantially higher than that in phase I. The maximal TBP accumulation in phase II is observed for Pr and Nd solvates, and the minimum accumulation, for La and Sm solvates.

It follows from Fig. 4 that the $C_{14}H_{30}$ weight fraction in phase I is higher than that in phase II.

Lanthanides(III) substantially (La and Nd, more strongly, and Sm and Pr, more weakly) affect the tetradecane distribution between phases I and II. To use extraction systems based on TBP and hydrocarbon diluent in practice, the TBP equilibrium concentration (weight fraction) should be 0.17–0.20, i.e., it is necessary to operate with organic phases unsaturated with respect to lanthanide(III) nitrate, or to use commercial solvents with a low content of long-chain hydrocarbon fractions.

CONCLUSIONS

(1) Phase diagrams of ternary liquid systems constituted by tetradecane, tri-*n*-butyl phophate, and $Ln(NO_3)_3(TBP)_3$ (Ln = La, Pr, Nd, and Sm) consist of the field of homogeneous solutions and the field of phase separation (phases I and II). Phase I is enriched in tetradecane and phase II, in lanthanide(III) nitrate solvate.

(2) At the point of the critical composition of the ternary systems, the weight fractions of $Ln(NO_3)_3(TBP)_3$ and tetradecane are approximately equal at different TBP contents, depending on particular lanthanide. At the point ω_{2cr}, the TBP weight fraction

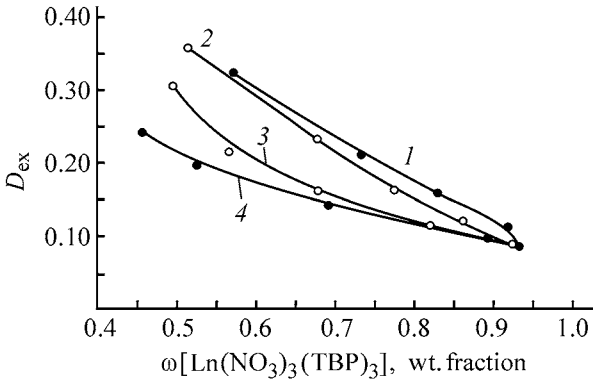

Fig. 2. Distribution coefficients of $Ln(NO_3)_3(TBP)_3$, D_{ex}, between phases I and II vs. ω $Ln(NO_3)_3(TBP)_3$, in phase II. Phase I is enriched in $C_{14}H_{30}$, and phase II, in $Ln(NO_3)_3(TBP)_3$; the same for Figs. 3, 4. (*1*) La, (*2*) Sm, (*3*) Pr, and (*4*) Nd.

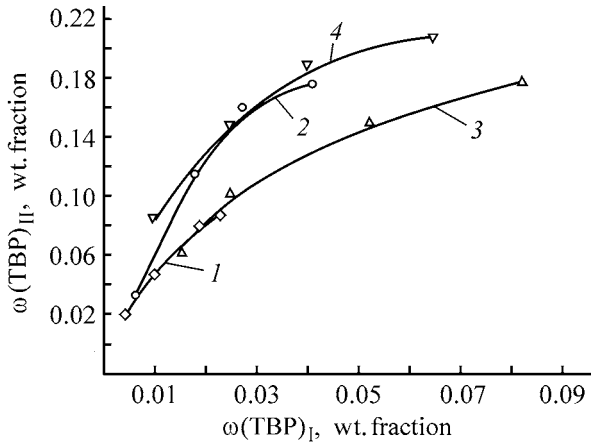

Fig. 3. Distribution of TBP between phases I and II. $\omega(TBP)_I$ and $\omega(TBP)_{II}$ are weight fractions of TBP in phases I and II, respectively. (*1*) La, (*2*) Nd, (*3*) Sm, and (*4*) Pr.

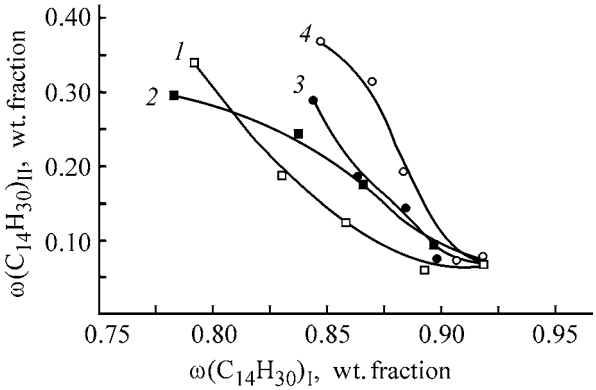

Fig. 4. Distribution of $C_{14}H_{30}$ between phases I and II. $\omega(C_{14}H_{30})_I$ and $\omega(C_{14}H_{30})_{II}$ are weight fractions of tetradecane in phases I and II, respectively. (*1*) La, (*2*) Nd, (*3*) Sm, and (*4*) Pr.

tends to increase from La(III) to Pr(III) and then to decrease from Pr(III) to Nd(III), while the TBP content in the systems with Nd and Sm is about the same.

(3) In the phase separation field, the TBP and $Ln(NO_3)_3(TBP)_3$ weight fractions in phase II are substantially higher than those in phase I; the tetradecane weight fraction in the phase I is higher than that in phase II. The distribution of the components in the ternary systems depends on a particular lanthanide.

(4) In practice, to use extraction systems with TBP and tetradecane, it is necessary to keep the equilibrium TBP content (weight fraction) no less than 0.17–0.20 or to use commercial solvents with a low content of long-chain hydrocarbons.
