aqueous solutions of PAA and APHC also exhibit high flocculation capacities. Figure 1b shows how the clarification effect for a dilute kaolin dispersion is influenced by the composition and dose of PCM. Similarly to PCPs, the clarification effect tends to grow with increasing APHC content in the poly complex and attains a maximum at the mole ratio of Al^{3+} to the PAA unit equal to 2. Further increase in the content of APHC in the PCs is accompanied by a decrease in the clarification effect. The optimal concentrations of the reagents in the case of PCMS are lower than for PCPs, namely, 6–8 mg l^{-1}.

It is known that the surface of the kaolin dispersion particles carries a negative charge [23], which makes cation-active flocculants the most effective reagents for their separation. Taking into account the nature of polymeric APHC particles, it can be assumed that the PCCs synthesized by us belong to cation-active reagents as well. In this context, we studied the flocculation capacity of PCP-2 and PCM-2 relative to the most widely used highly effective cationic flocculants Praestol-650, Zetag-92, and KF-91, as well as to nonhydrolyzed PAA (Fig. 2). We found that PCM-2 produces the strongest clarification effect,

Table 1. Clarification effects in sedimentation of the kaolin suspension with various flocculants

Flocculant	E_{clar} at indicated flocculant content, mg l^{-1}						
	0.5	1	1.5	2	3	4	5
PAA	1.6	3.0	4.5	8.5	13.5	14.7	14.2
Praestol-650	0.8	–	4.8	9.7	14.8	18.0	16.0
Zetag-92	–	6.1	10.8	12.8	14.5	32.5	28.7
KF-91	–	–	–	8.9	–	–	–
PCP-2	–	2.0	–	12.6	14.3	13.3	12.5
PCM-2	6.8	11.1	21.2	16.8	16.6	–	–

which significantly exceeds those of PAA and Praestol-650; it is no less effective than Zetag-92, even in a wider concentration range. Notably, PCM-2 was prepared from PAA of a relatively low molecular weight of 5.2×10^5 (according to viscometric data), against 20×10^6 for Zetag-92.

Of much importance for clarification of dispersions are kinetic parameters and, above all, the sedimentation rate of the dispersion particles in the presence of a flocculant. For concentrated dispersions (c_d = 5–8 wt %), this parameter is mostly estimated from the velocity of migration of the interface between the clarified and thickened layers of the suspension [24, 25]. We studied a kaolin dispersion prepared in distilled water with pH 7.35. In preliminary experiments, we determined the optimal flocculation conditions: kaolin concentration in water 5 wt %, and concentration of the flocculant solution to be introduced, 0.1 g l^{-1}. Figures 3a–3c show the kinetic curves for flocculation of a kaolin suspension in the presence of PAA, PCP-2, and PCM-2. Similar curves were obtained for Praestol-650, Zetag-92, and KF-91. Based on these data, we calculated the flocculation effects (see Table 1).

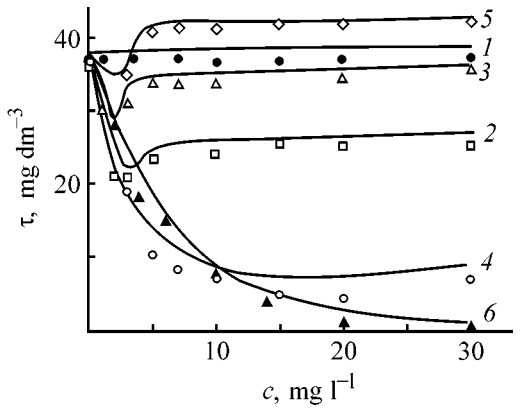

Fig. 4. Variation of the turbidity τ of the treated kaolin dispersion (c_d = 37 mg dm^{-3}) with the concentration c and type of the reagent. (*1*) PAA, (*2*) Praestol-650, (*3*) Zetag-92, (*4*) APHC, (*5*) PCP-0.5, and (*6*) PCP-2.

Table 1 suggests that the poly complexes exceed in the clarification effect PAA and some cationic flocculants and are equal in performance to Zetag-92. The flocculation capacity of the poly complex tends to grow with increasing molar ratio of Al^{3+} to the PAA unit and attains a maximum at the molar ratio of 2 (PCM-2, PCP-2).

The sedimentation of low-concentration dispersions (c_d < 1 wt %) predominantly occurs by the neutralization mechanism. The specific structure of the PCCs prepared (the relatively low molecular weight of PAA and charged particles arranged on the coil surface) can make them effective reagents in coagulation. In this context, we studied the performance of the PCCs in separation of a low-concentration kaolin dispersion prepared from a 0.8 wt % kaolin dispersion in distilled water. The content of the dispersed phase in the decanted liquid was 30–40 mg dm^3, and the particle size, 1.6–2.5 μm, according to the sedimentation analysis. On a certain assumption, such a system can be regarded as a model of natural water in terms of its dispersion composition [26]. The coagulation efficiency was estimated from the change in the water turbidity after treatment with the reagent. Figure 4 shows the plots of the turbidity of the water treated by various reagents at concentrations within 2–40 mg l^{-1}. It is seen that, under the actual conditions, PAA is inactive. Polycationic flocculants Praestol-650, Zetag-92, and PCP-0.5 cause coagulation when present in low concentrations, but the degree of purification is not high; an increase in the concentration results in stabilization of the system. As expected, APHC is an effective reagent under the actual conditions, but PCP-2 also exhibits a high coagulation activity: At concentrations above 12 mg l^{-1}, it exceeds APHC in the degree of purification, and at concentrations above 30 mg l^{-1}, all the reagents stabilize the system. Evidently, the ratio of the reagents (PAA and APHC) in the poly complex, required for attaining the maximum coagulation efficiency, can have an optimum, as in the case of flocculation. Therefore, we studied the coagulation activity of the PCCs (prepared by polymerization) at different molar ratios of the reagents (Al^{3+} to the PAA unit) (Table 2).

Table 2. Degree of purification in coagulation of a low-concentration kaolin dispersion with PCPs of various compositions

* Successive addition of the reagents.

Table 2 suggests that, at concentrations of 20 mg l^{-1} and over, virtually all the reagents are equally effective. The concentration of aluminum-containing coagulants of 20 mg l^{-1} is typical of breaking-down model kaolin dispersions [27]. The poly complexes prepared by mixing of the reagents also exhibit a high coagulation activity (Table 3).

Our experimental data suggest that the PCCs based on PAA and APHC, prepared both by mixing aqueous solutions of the reagents and by polymerization of AA in aqueous solutions of APHC, combine the properties of polymeric cationic flocculants and coagulants acting by the neutralization mechanism.

The known water treatment procedures involve a combined use of aluminum hydroxochloride and a flocculant, PAA [1]; it is recommended that the reagents should be introduced into the mixing chamber separately. Thus, a question arises as to whether such a treatment procedure will be similar to that in the case of PCCs. Table 4 compares the degrees of clarification, achieved with various reagents tested in coagulation of a low-concentration (30 mg dm^{-3}) kaolin dispersion. It is seen that introduction of PAA into the dispersion after its coagulation with APHC improves water purification, but the degree of purification in this case is lower, compared to PCCs. Notably, the concentrations of the reagents in the latter case are much lower.

Studies of model systems make it possible to tentatively by estimate the flocculation and coagulation capacities of a reagent or to compare these parameters

for a set of reagents under identical conditions. Under real conditions, the effect produced by a reagent is determined by the characteristics of the medium in which it is applied (pH, ionic strength, salt content, etc.). Natural water and wastewater are polycomponent systems, which prevents taking a uniform theoretical approach to selection of the concentrations and optimal conditions for their purification, despite the advancement of modern theories of coagulation and flocculation. In practice, empirical formulas are sometimes used for tentative estimation of the reagent concentration [28]. However, a commonly used method is test coagulation (flocculation) [29], whose modified version [30] is presently applied to real systems being treated.

In this study, we carried out an experiment in which we treated water with a turbidity of 25 mg dm^{-3} (taken from the Volga river in a flood period). The results (Table 5) suggest a better, compared to separate addition of the coagulant and the flocculant, performance of the PCCs in water treatment.

In this experiment, we also used two types of wastewater, namely, wastewater from production of dielectric gloves (prepared by depositing a latex composition onto molds covered with a fixative, containing up to 40% kaolin) and wastewater from an oil refinery.

The wastewater from glove production is distinguished by a high concentration of the dispersed phase and a complex composition, which is responsible for the high sedimentation stability of the dispersion. The treatment efficiency was judged from the motion velocity of the interface between the clarified and thickened layers of the suspension, as well as from the residual turbidity above the precipitate after the suspension was allowed to stand for 1.5 h. Table 6 shows that the PCCs afford a faster sedimentation and a higher degree of purification at much lower concentrations.

Wastewater containing emulsified oil products is frequently treated with aluminum sulfate or its mixture with cation-active macromolecular flocculants [31] and, in particular, a mixture of aluminum sulfate (AS) with VPK-402. Oil-containing wastewater is usually treated by pressure flotation [32]. In our experiment, we used wastewater samples taken in the wastewater treatment shop of an oil refinery. The treatment was carried out on a model installation simulating a pressure flotator [33]. Table 7 lists the experimental degrees of purification of the wastewater with various reagents at various concentrations of oil products at the flotator inlet. It is seen that the poly complexes are significantly more effective than other reagents tested in treatment of oil-containing water, and in much lower concentrations. In the PCC series, the efficiency tends to increase with increasing APHC content in the poly complex, from PCM-1 to PCM-6. The reason is that, in treatment of oil emulsions, the first stage of the process consists in breakdown of the

emulsion droplets and their coalescence [33]. Air bubbles are adsorbed on the surface of large oil droplets and float them as a foam. The role of demulsifiers is usually played in this case by ions of polyvalent metals (Al, Fe). When the molar ratio of Al^{3+} to the PAA unit in the PCCs is over 4, the solution contains particles of aquahydroxo complexes of aluminum, which are not bound to the PCCs. They act as demulsifiers and break down the oil emulsion, thereby enhancing the purification effect.

CONCLUSIONS

(1) The flocculation and coagulation activities of water-soluble polymer-colloid complexes of aluminum polyhydroxochloride and polyacrylamide were tested in separation of model dispersed systems and real media. These complexes effectively combine the properties of coagulants, destabilizing the colloid and emulsified systems, and of cation-active flocculants favoring faster and more exhaustive separation of dispersions and suspensions.

(2) The polymer colloid complexes synthesized from relatively inexpensive commercially produced reagents are suitable as highly effective reagents for water treatment and purification.

Abstract—The behavior of a film material based on polyvinyl chloride in air and aqueous media, as influenced by individual plasticizers and their binary mixtures, was studied by gravimetry, thermogravimetry, and IR spectroscopy. The effect of these factors on the frost resistance and other physicochemical properties of the films was studied.

Polymer films based on polyvinyl chloride (PVC) with a one-side adhesive layer are used for waterproofing and corrosion protection of oil, gas, and material pipelines [1, 2]. These films necessarily contain plasticizers and other low-molecular-weight additives, which can pass into air or wet soil during operation. The decrease in the plasticizer content can deteriorate the physicochemical properties and frost resistance of the polymer material [3, 4] and increase its cracking; as a result, the films can lose continuity and, hence, protecting properties. Water sorption is an important characteristic of a polymeric material operating in a moist environment. Small water sorption reduces the sensitivity of the polymer material to freezing-defrosting cycles typical of the Russian climate and favors preservation of its protecting properties.

One of procedures for preparing a polymeric material with required properties is its plasticization with a plasticizer mixture [3, 5]. The aim of this study was to improve the frost resistance of a PVC film for production of tapes with an adhesive layer by using mixtures of plasticizers of varied nature and to examine their behavior in air and aqueous media. We studied PVC films plasticized with individual plasticizers [di(2-ethylhexyl)-*o*-phthalate (DOP), dibutoxyethyl adipate (DBEA), dibutyl sebacate (DBS)] and their mixtures. Di(2-ethylhexyl)-*o*-phthalate is the common PVC plasticizer, whereas DBEA and DBS containing no aromatic groups, were used to improve the frost resistance of the films [3, 6].

EXPERIMENTAL

We studied plasticized PVC films with 100 : 45 PVC–plasticizer weight ratios, used in production of tapes with an adhesive layer. These formulations were prepared from industrial components: S-70 brand suspension PVC and DOP, DBEA, and DBS plasticizers. All the formulations contained talc as a filler and BAC-S-20 as a stabilizer.

The films were prepared by rolling on a laboratory masticating mill at 140°C for 10 min. The film thickness was about 0.3 mm. The samples were studied approximately three months after their preparation.

In this study, we determined the composition of compounds released from the film into air and aqueous media under various operation conditions.

The weight loss by the samples in air at normal atmospheric pressure was studied by gravimetry under the isothermal conditions at 90°C. The thermal analysis was performed in air on an MOM Q-1500 derivatograph (Hungary) in the 25–300°C temperature range at a heating rate of 10 deg min^{-1}, with Al_2O_3 as a reference.

The qualitative composition of the compounds released from the films into air and the kinetics of their liberation at 90°C under a dynamic vacuum (residual pressure ~30 Pa) were studied by IR spectroscopy in a heated vacuum cell [7]. In this procedure, a sample was placed on the bottom of the temperature-controlled

cell and heated to a prescribed temperature. The volatile components of the sample condensed on the cooled KBr windows.

The spectrum of the condensate was recorded on a Specord 75-IR spectrophotometer. This procedure combines release of volatile compounds, their directed condensation, and recording of a spectrum without transfer of the condensate. The cell design allows operation at both atmospheric and reduced pressures.

To study the behavior of films in water, we recorded changes in the sample weight at room temperature and analyzed the composition of the liquid phase brought in contact with these samples. The weight changes Δm (%) of the samples in water were studied by gravimetry and calculated by the expression:

$$\Delta m = [(m - m_0)/m_0] \times 100,$$

where m_0 is the initial sample weight and m is the sample weight at a given time τ.

The relative weight Δm_r (%) of compounds liberated from the film in water during the experiment was calculated as follows:

$$\Delta m_r = [(m_0 - m_d)/m_0] \times 100,$$

where m_0 is the initial sample weight and m_d is the sample weight at the end of an experiment, after drying to constant weight at 50°C and atmospheric pressure.

Then, using Δm and Δm_r, we calculated the swelling index α (%) of the sample:

$$\alpha = \Delta m - \Delta m_r.$$

To determine the composition of compounds released from the film in water, the aqueous solution was evaporated at 50°C and atmospheric pressure to a solid residue. This residue was poured over with tetrahydrofuran (THF) and transferred onto a KBr window, after which THF was evaporated and the IR spectrum of the residue was recorded. The removal of THF was monitored spectrophotometrically.

The interaction of components in the films was judged from changes in the absorption bands of the functional groups in the IR spectra of model plasticizer-polymer systems. The model films were prepared by evaporation of 1% THF solutions on glass supports at room temperature. Then, the films were heated for 7 h at 70°C to remove the residual solvent; the THF content was monitored spectrophotometrically. The IR spectra were recorded on a UR-20 spectrometer.

The frost resistance was evaluated from the brittle point according to GOST (State Standard) [8].

The stress–strain curves were recorded at room temperature on an RT-250M-2 tensile-testing machine in the 0.0–0.5 kN load range. The extension rate was 25 mm min^{-1}. The samples were cut out as blades with 6.5-mm width of the working part. The stress in the samples was calculated as follows:

$$\sigma = P/S,$$

where σ is the stress (kPa), P is the load (kN), and S is the cross section of the working part of the sample at the beginning of an experiment (m^2).

The physicomechanical properties of the samples were characterized by the rupture stress σ_r and elastic modulus E characterizing the material rigidity and calculated from the following expression:

$$E = \sigma/\varepsilon,$$

where σ is the stress and ε is the strain in the initial section of the strain curve.

The data on the film frost resistance are listed in Table 1. As can be seen, the PVC films containing DBEA and DBS and their mixtures with DOP are more frost resistant then the films with DOP plasticizer.

Our further experiments were performed using the films containing individual plasticizers and their mixtures, with brittle point $T_{br} \approx 50$°C. We studied films with a smaller content of DBEA and DBS in the mixtures, because these plasticizers are more expensive than DOP.

Table 2. Deformation–strength properties of the films

Plasticizer	Composition, %	E, MPa	σ_t, MPa
DOP	100	63.6	18.2
DOP–DBEA	70 : 30	35.2	14.3
DBEA	100	18.0	12.1
DOP–DBS	70 : 30	28.8	13.2
	50 : 50	21.7	12.7
DBS	100	16.9	11.4

Table 3. Diffusion coefficients of plasticizers in PVC films and their volatility

Plasticizer	$D \times 10^{-15}$, $m^2\ s^{-1}$ (atmospheric pressure)	$D \times 10^{-12}$, $m^2\ s^{-1}$ (vacuum)	ν, $g\ cm^{-2}\ s^{-1}$ (atmospheric pressure)
DOP	0.3	0.3	0.2
DBEA	1.3	1.1	1.8
DBS	–	1.3	0.6

The stress–strain curves of the films are shown in Fig. 1, and their deformation–strength characteristics are listed in Table 2.

With addition of DBEA and DBS, the rigidity E of films decreases with a simultaneous decrease in their strength σ_s.

The kinetic dependences of the weight loss by the samples in air at atmospheric pressure and 90°C are shown in Fig. 2. In the samples plasticized with individual compounds, the weight loss changes in the following order DOP < DBEA << DBS. The samples containing mixtures of plasticizers occupy the intermediate positions. The IR spectra of the compounds released from the samples indicate that it is the plasticizers added to the polymer that pass into the atmosphere. Since the samples contain a stabilizer, we assumed that no HCl is liberated under the experimental conditions (90°C) due to PVC decomposition and the weight loss is related to migration of the plasticizers. This is also confirmed by the fact that the DTA curves of the films exhibit the endothermic peaks corresponding to the PVC degradation only at $T > 210$°C.

It is known that the plasticizer migration from the polymeric film involves diffusion of the compound from the film bulk to the surface and its removal from the surface. Under different conditions, the migration kinetics can be limited by the rate of one or another reaction [9, 10]. The weight loss by the films under the isothermal conditions (Fig. 1) was described by the following equation:

$$M_\tau/M_\infty = (4/\pi^{1/2})(D\tau/l^2)^{1/2}, \quad (1)$$

where M_τ is the amount of plasticizer released from the sample at moment τ, i.e., the weight loss by the sample; M_∞, initial plasticizer content in the sample; l, sample thickness; τ, experimental time; and D, diffusion coefficient of the plasticizer.

Equation (1) is a partial solution to the second Fick's law for diffusion in the initial stages of desorption ($M_\tau/M_\infty \le 0.6$) under certain initial and limiting conditions [11, 12]. The linear portions of the dependences $M_\tau/M_\infty = f(\tau^{1/2})$ for DOP and DBEA suggest that in these portions, the migration of plasticizers is controlled by their diffusion in the sample and allow calculation of the diffusion coefficients (Table 3),

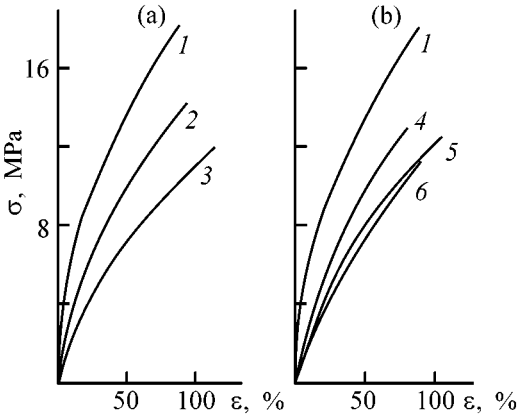

Fig. 1. Stress–strain curves for films containing (a) DOP–DBEA and (b) DOP–DBS. (σ) Stress and (ε) strain. (*1*) DOP, (*2*) DOP–DBEA, (*3*) DBEA, (*4*, *5*) DOP–DBS, and (*6*) DBS. Plasticizer ratio in the mixture, wt %: (*2*, *4*) 70 : 30, and (*5*) 50 : 50; the same for Fig. 2.

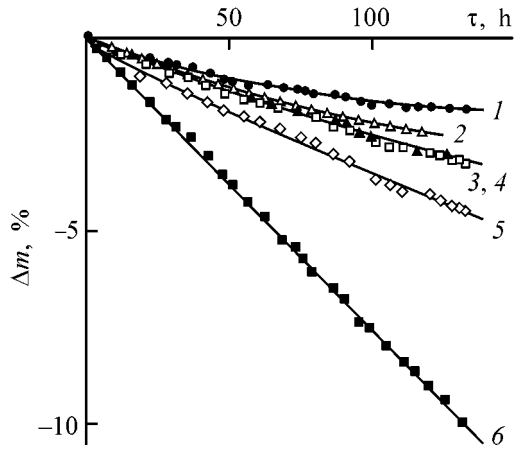

Fig. 2. Weight loss Δm in air at 90°C and atmospheric pressure vs. heating time τ of the samples containing (*1*) DOP, (*2*) DOP–DBEA, (*3*) DBEA, (*4*, *5*) DOP–DBS, and (*6*) DBS.

which can be used in this case as a criterion of migration rate [13, 14].

As can be seen, D_{DBEA} is greater than D_{DOP}. No linear portion was found for DBS plasticizer. This indicates that the migration of DBS in the film at 90°C and atmospheric pressure is limited not by diffusion in the sample, but by its removal from the surface, i.e., by its volatility.

We also studied the plasticizer recovery from the film under the conditions of its forced removal from the sample surface. For this purpose we performed experiments at 90°C under a dynamic vacuum, using a heated vacuum cell. The IR spectra of the volatile compounds released from the film containing DOP are shown in Fig. 3. As can be seen, the amount of DOP released from the sample grows with increasing time. Similar data were obtained with polymeric films containing DBEA and DBS. The spectroscopic results were presented as time dependences of the optical density of the absorption band of the plasticizer (~1720, ~1130, and ~1175 cm^{-1} for DOP, DBEA, and DBS, respectively) (Fig. 4a) and then in the coordinates of a modified Eq. (1):

$$A_\tau/A_\infty = (4/\tau^{1/2})(D\tau/l^2)^{1/2}, \quad (2)$$

where A_t is the optical density of the absorption band at instant of time τ and A_∞ is the initial optical density of the absorption band corresponding to the initial content of the plasticizer in the film (Fig. 4b).

The optical densities were determined taking into account the baseline of the corresponding absorption band [15], and A_∞ was calculated as follows:

$$A_\infty = A_e m_0/\Delta m_e,$$

where A_e is the optical density of the absorption band at the end of the experiment; m_0, initial plasticizer content in the sample; and m_e, weight loss by the sample at the end of the experiment, equal to the amount of the plasticizer released.

The initial nonlinear portion of the curve in Fig. 4b (~16 min) corresponds to the time in which the temperature in the heated vacuum cell increases from room temperature to 90°C. In contrast to the experiments at atmospheric pressure under the conditions of forced removal of plasticizer from the film surface, the linear portions [in the coordinates of Eq. (2)] are

The arrow indicates the order of recording of the spectra.

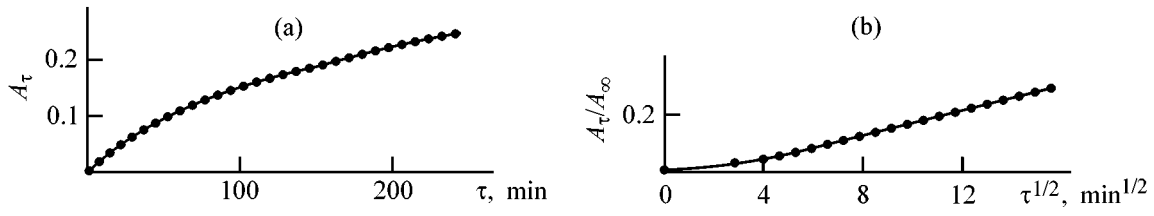

Fig. 4. Variation with time τ of the (a) optical density A_τ of the absorption band ν_{CO} (~1720 cm^{-1}) in the IR spectra of the plasticizer and (b) relative optical density in the coordinates of Eq. (2) for the film containing DOP.

observed with all the samples. This suggests that, under these conditions, migration of all the plasticizers, including DBS, is controlled by their diffusion in the sample. The diffusion coefficients D of the plasticizers, calculated from the linear portions of the curves, are listed in Table 3. An independent experiment showed that D values calculated using different absorption bands in the IR spectra of the recovered compound are similar. As can be seen from Table 3, D_{DBEA} and D_{DBS} are close and exceed D_{DOP}. Previously, we suggested that, the migration of DBS at atmospheric pressure, in contrast to that of DOP and DBEA, is controlled by its volatility. In this context, we studied the kinetics of the weight loss by individual plasticizers at 90°C and atmospheric pressure and calculated the plasticizer volatilities in 10 h (Table 3). The volatility of DBS appeared to be three times lower that that of DBEA. This confirms our assumption that the DBS volatility controls the plasticizer migration from the PVC film under the experimental conditions.

It is known [4, 13] that, the difference in the diffusion coefficients may be due not only to steric factors, but also to the chemical nature of the diffusion agent and, in particular, to the difference in interaction of its molecules with the polymer macromolecules. The IR spectra in the region of the stretching vibrations of the carbonyl group $\nu_{C=O}$ of individual plasticizers and of PVC-plasticizer mixtures are shown in Fig. 5 (curves *1* and *2*, respectively). The absorption bands of the plasticizers are complex because of the formation of molecular associates of various strengths [7, 16, 17]. In the presence of PVC, the absorption intensity is redistributed in all the systems toward the low-frequency component of the carbonyl band. The appearance of the low-frequency components of the $\nu_{C=O}$ bands is probably due to the formation of hydrogen bonds between the ester C=O groups of the plasticizer and CHCl groups of PVC [18]. However, we failed to evaluate unambiguously the contribution of this factor for all the plasticizers in question. Along with the formation of hydrogen bonds, an additional interaction is possible in the PVC–DOP system: formation of the donor–acceptor bonds between π electrons of the DOP benzene ring and free 3*d* orbitals of chlorine atoms in the PVC macromolecules [19]. Possibly, the stronger total interaction of PVC with DOP and the steric hindrance to diffusion of DOP in the film due to the presence of the benzene ring and branched hydrocarbon radicals lead to a decrease in the diffusion coefficient of DOP in comparison with DBEA and DBS.

The TG data for the films with individual plasticizers show that the weight loss by samples containing DBS begins at a lower temperature (~100°C), compared to DOP (~170°C) and DBEA (~160°C). However, the thermal stabilities of all the samples, defined as the temperature at which the sample loses 10% of its initial weight (TG data) differ only slightly.

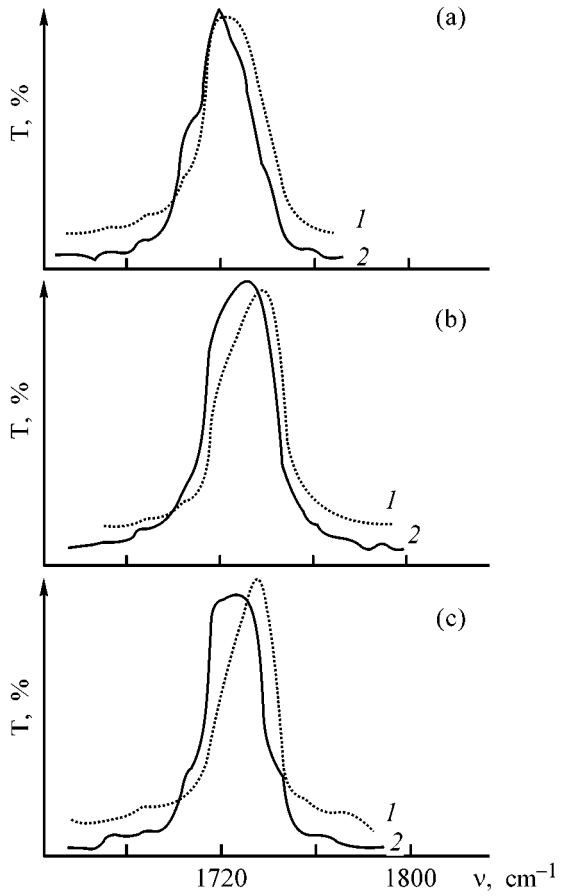

Fig. 5. IR spectra of (*1*) plasticizers and (*2*) PVC–plasticizer systems. (*T*) Transmission and (ν) wavenumber. Plasticizer: (a) DOP, (b) DBEA, and (c) DBS.

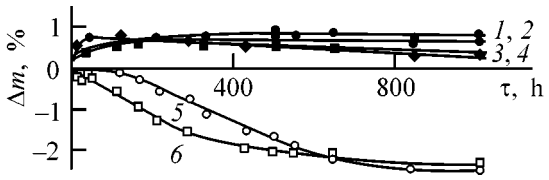

Fig. 6. Weight change Δm in water at room temperature vs. storage time τ of the samples containing (*1*) DOP, (*2*, *3*) DOP–DBS, (*4*) DBS, (*5*) DOP–DBEA, and (*6*) DBEA. Plasticizer ratio, wt %: (*2*, *5*) 70 : 30 and (*3*) 50 : 50.

These data suggest that the samples containing DBS are less stable in operation in air in comparison with the films containing DBEA and DOP plasticizers.

The changes in the film weight upon storage in water at room temperature are illustrated by Fig. 6. After storage, the weight of the films containing DOP and DBS increases by approximately 1%. With in-

Table 4. Weight changes of the films after storage in water at room temperature for 1000 h as influenced by the plasticizer

Plasticizer	Composition, %	Δm, %	Δm_w, %	α, %
DOP	100	0.9	0.8	1.7
DOP–DBEA	70 : 30	–2.4	4.0	1.6
DBEA	100	–2.4	4.1	1.7
DOP–DBS	70 : 30	0.8	1.1	1.9
	50 : 50	0.5	0.8	1.3
DBS	100	0.4	1.0	1.4

creasing DBS content in the film, the sample weight slightly decreases upon prolonged storage. After storage in water, the weight of the films containing DBEA and DOP–DBEA mixture decreases by ~2%. These changes in the sample weight are probably due to two opposite processes: swelling (α) increases the sample weight, whereas plasticizer washout (Δm_w) causes its decrease. The results of separation of the effects of these processes for the final point of the dependences (Fig. 6) are listed in Table 4.

As can be seen, the swellabilities of all the samples in water are similar, but the formulations containing DBEA exhibit a significant weight loss. The IR spectra of the dry residues show that the films release the plasticizer and a hydroxyl-containing compound, which is probably a component of the stabilizer. The stronger plasticizer washout from the films containing DBEA is due to the presence of the polar C–O–C groups accessible to interaction with water (in contrast to DOP) and smaller nonpolar fragments of the DBEA molecule [–$(CH_2)_4$–] as compared to DBS [–$(CH_2)_8$–].

CONCLUSIONS

(1) Properties of polyvinyl chloride films containing individual plasticizers and their mixtures and migration of plasticizers from the films into air and water strongly depend on the chemical structure of a plasticizer.

(2) Addition of dibutyl sebacate and dibutoxyethyl adipate to di(2-ethylhexyl)-*o*-phthalate increases frost resistance and decreases the strength of the films.

(3) Films containing mixtures of di(2-ethylhexyl)-*o*-phthalate with dibutoxyethyl adipate are more stable in air, whereas dibutyl sebacate enhances the stability of films in water.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Correlation Analysis of Diffusion of Organic Solvents across Synthetic Low-Polar Polymeric Membranes

R. G. Makitra and R. E. Pristanskii

Pisarzhevskii Institute of Physical Chemistry, Ukrainian National Academy of Sciences, Lviv, Ukraine

Received April 6, 2004

Abstract—The influence exerted by physicochemical characteristics of organic solvents on their diffusion across polymeric membranes can be quantitatively using linear multiparametric equations.

There is a steadily growing interest in the problems of diffusion of liquids and gases in polymers, which is stimulated, in particular, both by the development of membrane technologies and by biochemical research concerning the penetration of ionic species, toxic substances, and drugs across cell membranes.

The diffusion of substances in a homogeneous medium has been thoroughly studied and can be described by well-known Fick's law, Einstein–Stokes equation, etc. However, the problem of quantitative evaluation of the effects of physicochemical characteristics of a penetrating liquid on its diffusion coefficient, even though being a subject of extensive studies, has not been satisfactorily solved as yet [1–3]. Khinnavar *et al.* [3] analyzed the transport of esters across ethylene–propylene membranes using the relationship

$$Q_t/Q_\infty = kt^n,$$

where Q_t and Q_∞ are the current and limiting solvent uptakes; and k and n, the constants.

It was found [3] that found $n = 0.5$, which suggests that this process obeys Fick's law. For films prepared from other materials (natural and synthetic rubber and polyurethane) $n \approx 0.6$, which points to partial transfer to so-called anomalous transport caused by different effects of particular units of the polymer chain on the sorption processes [3]. Even more pronounced deviations from Fick's law were observed in studying the diffusion of aromatic hydrocarbons and dimethylformamide across polyurethane membranes [1, 4].

Since the diffusion across a polymeric membrane follows the stage of sorption of a solvent, and these processes are interrelated, the diffusion parameters are commonly determined from the sorption kinetics, i.e., from the swelling data. Therefore, approaches to analysis of features of both processes are similar. Swelling of natural (rubber, coal) and synthetic polymers have been intensively studied in the last five decades, inparticular, in context of the problem of the stability of polymeric materials in various media. However, the traditional approaches based on the Flory–Huggins [5] and Hildebrand [6] theories allow only semiquantitative estimates, which is not surprising in view of the fact that these theories consider solely physical effects.

In fact, the solvation interactions occurring between a diffusing solvent and a polymeric material affect the energy-related parameters and the kinetics of diffusion. These interactions can be included in consideration semiempirically by using the principle of linear free energies (LFE). This approach is used, in particular, for generalization of data on the effect of solvents on rates of the chemical reactions, solubility of gases, distribution of substances between two phases, etc. Among such relationships, the Koppel–Palm equation is the most widely used. It includes the influence exerted by the polarity and polarizability of solvents and also by their capacity for acid–base interaction with a substrate. In studying the swelling of polymers and diffusion of solvents across polymeric membranes, it is necessary to take additionally into account the geometric factor (molecular size): the larger the size, the more difficult the penetration into the free volume of the polymer, whereas solvation of the polymer units will facilitate the diffusion. This suggestion logically follows from the Einstein–Stokes equation

$$D = kT/6\pi\eta r,$$

according to which the diffusion coefficient D in homogeneous media is inversely proportional to the

* Solvents excluded from calculation by Eq. (3).

radius *r* of a diffusing particle. Similar suggestions were also stated earlier [7, 8].

Aminabhavi *et al.* [9] studied the diffusion of various solvents in six different polymers. All these polymers, except polyurethane rubber, were vulcanized and contained (wt %) carbon black 50, zinc oxide 5, sulfur 2–2.5, and also some other additives. The diffusion coefficients in 0.1–0.15 thick membranes were determined at 25, 44, and 60°C.

log *D* values were calculated from the slopes of the linear portions of the sorption curves. They decrease in parallel with an increase in the molecular weight or molar volume V_M of the solvent. However, a satisfactory linear correlation between these parameters was observed only in the series of *n*-alkanes, and all efforts to extend this correlation to solvents belonging to other classes failed. Even data for isooctane and cyclohexane deviated from the linear correlation.

We attempted to generalize data on the diffusion coefficients of 27 solvents across a butadiene–styrene polymeric membrane [9], using the following six-parametric equation

$$\log D = a_0 + a_1\frac{n^2 - 1}{n^2 + 2} + a_2\frac{\varepsilon - 1}{2\varepsilon + 1} + a_3B + a_4E_T + a_5\delta^2 + a_6V_M. \quad (1)$$

Here $f(n)$ is the polarizability and $f(\varepsilon)$, polarity of the solvent, which are responsible for nonspecific solvation (*n* and ε are the refractive index and dielectric constant of the solvent); *B*, Palm's basicity [11], and E_T, Reichardt's electrophilicity index [12], which control the specific solvation; δ^2, squared Hildebrand's solubility parameter proportional to the cohesion energy density of the solvent; and a_1–a_6, regression coefficients.

Assuming that the penetrability of solvents decreases with increasing size of their molecules, we introduced the molar volume V_M as a parameter. This parameter appeared to be quite significant for generalization of data on swelling of polyethylene and butyl rubber in organic solvents [13]. Characteristics of the solvents were taken from the review [14]. Calculations were performed in accordance with the recommendations of the IUPAC Group on Correlation Analysis in Chemistry [15].

The use of Eq. (1) allowed a satisfactory generalization of data on the diffusion coefficients *D*,taken from [9] . Previously, we have shown [10] that, in accordance with the suggestion made by Aminabhavi *et al.* [9], the molar volume V_M has the most significant effect on log *D*. However, these are correlated, but not proportional parameters: for the entire set of 27 solvents, the pair correlation factor $r_6 = 0.708$, and for the set of 24 solvents, $r_6 = 0.858$. Therefore, to describe adequately the solvent effect, it is needed to take into account the factor of specific solvation. The sign "minus" at the corresponding terms of the correlation equation shows that an increase in the size of the organic molecules and also in their ability to nucleophilic solvation, i.e., in the basicity, results in decreasing log *D*. The term E_T, by contrast, stands with a sign "plus", which suggests that electrophilic solvation promotes the diffusion. This becomes clear in view of the presence of cyclic units with their π-electron systems in the structure of the butadiene–styrene rubber. However, further calculations showed that the capacity of solvents for nonspecific solvation has no significant effect on the diffusion.

To verify the applicability of this approach and also to study the possible interrelation between the structure of polymers and the significance of the factors included in Eq. (1), we generalized of the log *D* values for other hydrocarbon polymers studied in [9]. The results are summarized in Tables 1–3. In all

* Solvents excluded from calculation by Eq. (7).

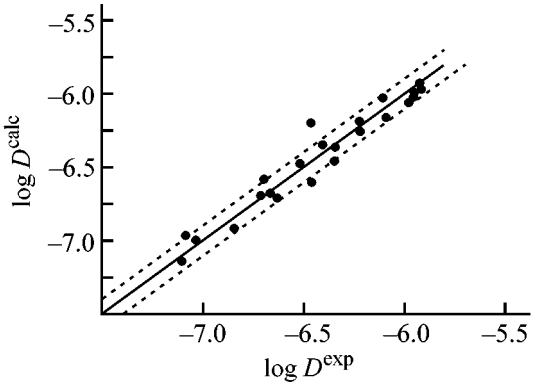
cases, the effect of solvent on the diffusion could be adequately by Eq. (1) after exclusion of the most deviating data for two or three solvents. In most cases, only two or three factors among the six were actually significant.

Table 1 lists the coefficients of diffusion of 27 solvents across the ethylene–propylene–butadiene copolymer (density 1.02 g cm^{-3}) at 25°C. For the entire set of the solvents studied, calculation by Eq. (1) gives a multiple correlation factor $R = 0.888$, which is unacceptably low. After excluding data for only three solvents (nitrobenzene, tetralin, and cyclohexane, as the most outlying), R increased to 0.972. In this case, we obtain Eq. (2) adequately describing the effect of solvents on the diffusion.

$$\log D = -6.01 + (3.77 \pm 1.45) f(n) + (0.01 \pm 0.92) f(\varepsilon) - (3.76 \pm 0.59) \times 10^{-3} B + (16.9 \pm 29.4) \times 10^{-3} E_T - (2.35 \pm 1.20) \times 10^{-3} \delta^2 - (6.90 \pm 0.57) \times 10^{-3} V_M, \quad (2)$$

$N = 24$, $R = 0.972$, standard deviation $S = 0.104$.

For comparison, the figure shows the experimental and theoretical [calculated by Eq. (2)] logarithms of the diffusion coefficients. The factors of polarity [$f(\varepsilon)$], cohesion energy density (δ^2), and capacity for electrophilic solvation (E_T) appeared to be insignificant, and



Comparison of theoretical [calculated by Eq. 2)] and experimental [9] diffusion coefficients D of various solvents across ethylene–propylene–butadiene polymer ($S = 0.104$).

their exclusion in accordance with the recommendations of IUPAC [15] only slightly decreased the multiple correlation factor. Therefore, we obtain a simplified three-parameter equation (3), which is also adequate.

$$\log D = -5.59 + (1.45 \pm 0.76) f(n) - (4.02 \pm 0.29) \times 10^{-3} B - (6.36 \pm 0.52) \times 10^{-3} V_M, \quad (3)$$

$R = 0.960$, $S = 0.114$.

The observed insignificant effect of E_T can be attributed to the fact that the ethylene–propylene copolymer contains no electron-donor structures capable of interacting with electrophilic solvents. Parameter $f(n)$ is relatively insignificant also. However, its exclusion decreases R more noticeably, to 0.953. It is seen that, as in the case of the butadiene–styrene copolymer, the most significant factors controlling (decreasing) the diffusion rate are the basicity and molar volume of the solvents. It should be pointed out that the polarizability factor has even less significant, but favorable effect on the diffusion.

Table 1 shows that the deviations of the diffusion coefficients calculated by Eq. (3) from the experimental data are mostly within $S = 0.114$. A more pronounced difference is observed only for three solvents, which were excluded from consideration.

The same approach appeared to be effective for generalization of data on the diffusion coefficients in membranes prepared from synthetic poly(*cis*-isoprene) (density 1.04 g cm^{-3}) (Table 2) and poly(chloroprene) (Neoprene) (density 1.42 g cm^{-3}) (Table 3).

In the former case, we obtain $R = 0.903$ for the entire set of 27 solvents. After exclusion of the most deviating data for nitrobenzene and tetralin we obtain a quite adequate equation.

$$\log D = -5.65 + (5.68 \pm 1.75) f(n) + (1.17 \pm 1.12) f(\varepsilon) - (2.91 \pm 0.71) \times 10^{-3} B - (19.9 \pm 34.8) \times 10^{-3} E_T - (2.19 \pm 1.43) \times 10^{-3} \delta^2 - (6.09 \pm 0.57) \times 10^{-3} V_M, \quad (4)$$

$N = 25$, $R = 0.956$, $S = 0.127$.

As in the case of the ethylene–propylene copolymer, the factors of polarity, cohesion energy density, and electrophilicity are insignificant, so that the effect of solvent on the diffusion can be adequately described by a three-parameter equation.

$$\log D = -6.03 + (3.07 \pm 0.85) f(n) - (3.51 \pm 0.32) \times 10^{-3} B - (6.69 \pm 0.57) \times 10^{-3} V_M, \quad (5)$$

$R = 0.947$, $S = 0.128$.

Table 2 shows the $\log D$ values calculated by Eq. (5) and their deviations from the experimental data.

In the case of chloroprene, the six-parameter equation for the entire set of solvents is characterized by lower R (0.875), so that exclusion of even four solvents (cyclohexane, isooctane, nitrobenzene, and tetralin) appears to be needed to obtain an adequate equation.

$$\log D = -5.12 + (3.91 \pm 2.81) f(n) + (3.53 \pm 1.75) f(\varepsilon) - (2.37 \pm 1.07) \times 10^{-3} b - (49.4 \pm 53.7) \times 10^{-3} E_T - (1.20 \pm 2.41) \times 10^{-3} \delta^2 - (9.52 \pm 1.06) \times 10^{-3} V_M, \quad (6)$$

$N = 23$, $R = 0.954$, $S = 0.189$.

In this equation, the δ^2 and E_T terms are insignificant, and, after their exclusion, we obtain an adequate four-parameter equation.

$$\log D = -6.26 + (2.06 \pm 1.25) f(n) + (1.85 \pm 0.76) f(\varepsilon) - (3.18 \pm 0.66) \times 10^{-3} B - (9.00 \pm 0.92) \times 10^{-3} V_M, \quad (7)$$

$R = 0.951$, $S = 0.185$.

Further exclusion of the parameter $f(n)$ decreases R to 0.943. Table 3 includes the $\log D$ values calculated by Eq. (7) and the corresponding $\Delta \log D$.

It is not improbable that, for the polymers studied, the components added in the course of vulcanization (carbon black, zinc oxide, etc.) can affect the diffusion parameters. However, their amounts are nearly the same in all the cases, and our thought is that the in the diffusion processes for separate polymers are apparently controlled just by their structure.

A similar generalization is possible for the diffusion coefficients determined in [9] at 44 and 60°C and also for the activation energies of diffusion, E_D, although in the latter case, the quality of the correlation appeared to be lower, evidently, as a result of insufficient accuracy of determination of the activation energies from $\log D$ values for only three temperatures.

The similarity of the diffusion mechanisms in the polymers studied is also supported by the fact that, in all the three cases, the most deviating data were obtained for the same solvents (nitrobenzene, tetralin, and cyclohexane), which were excluded to obtain a satisfactory quality of correlation. Most likely, this can be attributed to steric effects. For the solvents indicated, the theoretical values considerably exceed the experimental data. It is noteworthy that cyclohexanone also demonstrates a relatively large differ-

ence between the theoretical and experimental values. At the same time, the theoretical log D values for aromatic hydrocarbons with less bulky substituents (benzene, toluene, xylene, and even mesitylene) are in satisfactory agreement with the experimental data.

CONCLUSIONS

(1) The linear relationship between log D and the molar volume of solvents V_M, obtained by Aminabhavi *et al*. [9], is valid only for particular groups of solvents. At the same time, use of multiparametric equations taking into account various solvent effects allows generalization of the all available experimental data. Log D decreases in parallel with an increase in V_M. However, the process can be described adequately only if the effect of solvation of the polymer is taken into account.

(2) The correlation equations are similar for all the "hydrocarbon" polymers. The significant parameters are the basicity and molar volume of the solvents (their increase results in a decrease in log D); the coefficients at the corresponding terms of the simplified regression equations are close: $\sim 3.0 \times 10^{-3}$ at B and $\sim 6.0 \times 10^{-3}$ at V_M, which suggests a certain similarity of the diffusion mechanisms in these polymers.

(3) The approach suggested can be used for a rough estimation (on the basis of a limited body of experimental data) of the diffusion coefficients of organic solvents in various polymeric membranes.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Composites Based on Vinyl Tetrazole–Acrylate Copolymers and Hollow Glass Spheres

M. V. Uspenskaya, N. V. Sirotinkin, and I. V. Masik

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received April 26, 2004

Abstract—Hydrogel composites based on sodium acrylate, 2-methyl-5-vinyltetrazole, and *N,N'*-methylenebisacrylamide, modified with hollow glass spheres during radical polymerization were prepared and studied. The influence of the modifying additives on the physicochemical properties of the composites was elucidated. A mechanism of modification of vinyl tetrazole–acrylate copolymers with hollow glass spheres was suggested. The materials synthesized are suitable for preparing articles with desired shape and good performance characteristics.

Tetrazole derivatives are promising heterocyclic modifiers of acrylic water superabsorbents, because, similarly to sulfo, phosphate, and other acidic groups, introduction of nitrogen-containing heterocyclic moieties into hydrogels increases the absorption power with respect to aqueous electrolyte solutions [1].

Modification of copolymers with various functional groups and other fragments by grafting or other procedures improves the physicochemical properties and thus extends the application field of these materials [2]. The modified materials are suitable as components of information-recording and environment-protection systems, as binders in high-energy-capacity formulaitions, and also as flocculants, ion-exchange resins, catalysts, and immobilizers of various media [3–5].

Among the most important characteristics of water superabsorbents are mechanical strength and water absorption rate. Gels can be strengthened by several procedures, e.g., by increasing the number of cross-links in the polymer or by introducing fillers into the copolymer. The former procedure can be performed by introducing a large amount of a cross-linking agent during polymerization or by additional cross-linking after the main polymerization to afford a denser cross-linking in the surface layer of the particles.

In the former case, gel strengthening is accompanied by a significant decrease in the absorption capacity, since the monomer mixture usually contains 0.2–1.0 mol % methylenebisacrylamide (MBAA) (in terms of the monomer). The tensile strength of the acrylonitrile–acrylamide copolymer is governed by the concentration of the cross-linked polymer in the gel, and, as the acrylonitrile content becomes higher, it increases to 500 kPa, which exceeds 4–5-fold the tensile strength of the polyacrylamide gel [6].

In the latter case, the gel can be strengthened via creation of additional cross-links after the main polymerization process.

A drawback of water superabsorbents based on acrylic acid is their low strength, which makes them unsuitable for production of articles with a desired shape: membranes, filters, sensor elements. In [7], it was shown that hydrogels based on alkaline metal acrylates have a surface strength of up to 800 Pa at water absorption of 650 g g^{-1}.

When active additives, such as chalk, are introduced during synthesis of water superabsorbents, a twofold effect is achieved, namely, the strength increases owing to additional cross-linking with the Ca^{2+} ion and the resulting copolymer is foamed by carbon dioxide released during neutralization of the acidic groups. The latter factor accelerates the absorption and reduces the time of drying of the water superabsorbent, but the mechanical strength increases insignificantly [8].

When an inert inorganic powder, such as silicon, titanium, or aluminum oxide, is introduced into

1070-4272/04/7710-1704 © 2004 MAIK "Nauka/Interperiodica"

Table 1. Deformation and strength characteristics of the acrylic hydrogel based films modified with glass spheres

Formulation			Tensile strength σ, MPa	Relative elongation ε, %

0.2	27	80	18.5	360

the composition, the strength of the gel increases to 6 kPa, and the water absorption decreases to 350 g g^{-1} [9].

Glass fillers have a spherical shape (10–200 μm and more in diameter), low density, reasonable strength, and high adhesion to the majority of polymers, which make them widely applicable. Among the most important application fields for hollow glass spheres are preparation of polymer materials for various purpous, filling of varnishes and paints, and preparation of composite polymeric spackles, polymer compositions for electronics, and abrasives.

In this study, we prepared composites based on vinyl tetrazole–acrylate copolymers and hollow glass spheres and examined their physicochemical properties.

EXPERIMENTAL

Tetrazole-containing acrylic films filled with hollow glass spheres in the preparation stage were synthesized by copolymerization at 30°C. The glass spheres were introduced in an amount of 80 wt % with respect to acrylic acid (AA) into the prepared reaction mixture after adding the initiator, ammonium persulfate (APS).

Sodium acrylate and 2-methyl-5-vinyltetrazole (MVT) served as reagents, and *N*,*N*'-methylenebisacrylamide, as cross-linking agent. The degree of neutralization of acrylic acid with sodium hydroxide was 0.9. The fraction of monomers in the monomer mixture was 30 wt %; served as initiator the redox system constituted by ammonium persulfate and tetramethylethylenediamine. The MVT and APS concentrations were 10–50 and 0.8 wt %, respectively. Before polymerization, 2-methyl-5-vinyltetrazole was purified by recrystallization. The characteristics and methods of purification of other reagents, as well as the copolymerization procedure, were presented in [10].

The resulting films were dried at room temperature to constant weight. The moisture content of the films was 30%.

The degree of equilibrium swelling was measured by a standard gravimetric method and calculated by the formula

$$Q = \frac{m - m_0(1-\gamma)}{m_0(1-\gamma)}.$$

Here, Q is the degree of swelling of the hydrogel, g g^{-1}; m_0, initial mass of the gel sample, g; m, mass of the swollen sample, g; and γ, moisture content of the gel sample, weight fraction.

The degrees of swelling calculated for five analogous samples were averaged.

The rate and degree of swelling of hydrogels depend on the method and formulation of the reaction mixture of their synthesis, as well as on the medium in which the swelling occurs, and the swelling temperature and time. For the absorbents studied by us, the equilibrium swelling was reached within 6–13 h (for large pieces characterized similarly to films, within 24 h).

The tensile strength of the films was tested on an RMI-5 tensile machine. We prepared 1–1.5-mm-thick films, dried them at room temperature, cured, and cut into strips 6 cm long and 1 cm wide. The measurements followed GOST (State Standard) 270–75.

Table 1 lists the deformation and strength characteristics of the films based on vinyl tetrazole–acrylate gel and hollow glass spheres.

Table 1 shows that the acrylate films modified with glass spheres exhibit high deformation and strength characteristics. Upon introduction of glass spheres, the tensile strength of the film increases, but its relative elongation decreases twofold. The mutual influence of

Table 2. Characteristics of acrylic hydrogel-based films modified with glass spheres

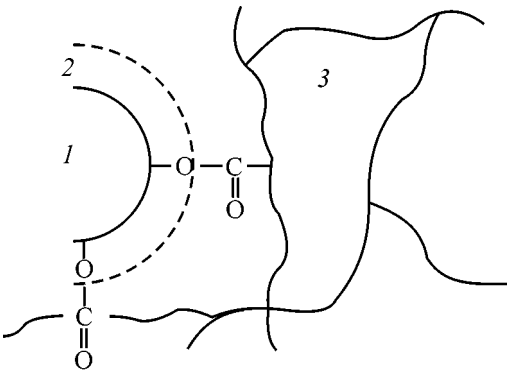
Formulation			Equilibrium swelling degree Q, g g^{-1}, at 16°C		
MBAA, wt % relative to [MVT + AA]	MVT, wt % relative to [MVT + AA]	glass spheres, wt % relative to AA	in water		in 0.9% NaCl, rod
			film	rod	
0.2	0	80	240	270	50
0.2	0	0	300	600	65
0.2	27	0	320	640	85
0.2	27	80	285	480	80

the glass spheres, solvent, and cross-linked acrylate copolymer during synthesis of the composite is so specific that the results obtained can only be understood in terms of the polymer adsorption theory.

The low relative elongation of vinyl tetrazole–acrylate films is due to a strong intermolecular interaction of the carboxylate groups and tetrazole ring [11] with the hydrophilic groups of the glass spheres, as well as to dipole–dipole hydrophobic interaction between the glass sphere surface and the corresponding groups in the copolymer.

The improved strength characteristics may be due to the presence of additional "cross-links." Also, aggregation of the glass spheres in a strongly polar solvent (water in our case) cannot be ruled out, which additionally increases the strength.

The chemical properties of the composites are strongly dependent on the chemical composition of the surface of hollow glass spheres. The surface of hollow glass spheres has pH 8–9, and its alkalinity does not exceed 0.4–0.5 mg-equiv. g^{-1}. At a sufficiently high water concentration in the hydrogel, the surface can be neutralized by free carboxy groups, forming a strengthening adsorption-hydration layer, and the adjacent adsorption-hydration layers may overlap, which significantly strengthens new composites (see figure).



Formation of a strengthened structure of acrylic copolymers with hollow glass spheres: (*1*) a hollow glass sphere (*2*) adsorption-solvation layer (*3*) cross-linked acrylate copolymer.

The swelling rate of the films filled with hollow glass spheres exceeds by a factor of 1.5 that of the films without modifiers. Also, the film with glass spheres preserves its shape in the swollen state, which can be of great practical significance.

Table 2 presents the equilibrium degrees of swelling of the composites as dependent on their composition.

Table 2 suggests that the degree of equilibrium swelling of analogous cylindrically shaped hydrogel samples with a diameter of 2 mm, synthesized at 60°C, exceeds by a factor of 1.5–2 that of the film samples.

The degree of equilibrium swelling of the modified hydrogel samples is only slightly smaller than that of unfilled samples.

CONCLUSIONS

(1) Composites based on vinyl tetrazole–acrylate copolymers with hollow glass spheres were prepared for the first time.

(2) Introduction of glass spheres into tetrazole-containing acrylic hydrogels gives films with high deformation and strength characteristics, namely, tensile strength σ = 18.5 MPa and relative elongation ε = 350%.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Specific Features of Vulcanization of Unsaturated Rubbers with Polymeric *p*-Dinitrosobenzene

G. E. Zaikov, O. R. Klyuchnikov, T. V. Makarov, and R. Ya. Deberdeev

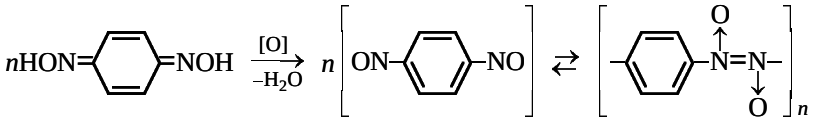
Received June 1, 2004

Abstract—Conditions of vulcanization of unsaturated rubbers were studied.

p-Dinitrosobenzene (DNB), an agent for low-temperature vulcanization of rubbers and rubber–metal adhesives [1, 2], is produced in industry by oxidation of *p*-benzoquinone dioxime. *p*-Dinitrosobenzene is a straw-yellow finely dispersed polymeric substance [3] with the poly(*trans*-azo-*N*,*N*'-dioxy-1,4-phenylene) structure (poly-DNB) [4–7]:



Poly-DNB is virtually insoluble in organic solvents under ordinary conditions [3–5], which complicates elucidation of its structure. Monomeric DNB is prepared by fast heating in xylene [3] or vacuum sublimation onto a surface cooled with liquid nitrogen; the resulting dark green monomeric DNB rapidly transforms at room temperature into straw-yellow poly-DNB [6].

Therefore, it was assumed that the molecular weight of poly-DNB should grow, and its vulcanizing activity change, in the course of storage. Indeed, we found that the vulcanizing activity of poly-DNB at low temperatures (20–60°C) is largely influenced by the time of its storage.

We compared the vulcanizing activity of poly-DNB produced in 1986 (Shostka Plant of Chemicals) and stored in dark glass bottles in a cold storehouse (DNB-sh) with that of freshly prepared DNB (DNB-fp) (for synthesis protocol, see [3]). The time elapsed from the synthesis of DNB-fp to its tests did not exceed 5 h. The analytical data for both samples were identical and consistent with the empirical formula $C_6H_4N_2O_2$. The IR spectra (Bruker Vector-22 IR Fourier spectrometer, KBr pellets) of both samples were, on the whole, similar; in particular, a characteristic strong band of *trans*-azo-*N*,*N*'-dioxy group was observed at about 1264 cm^{-1}. The difference was observed only in the region of 1533 cm^{-1} (stretching vibrations of monomeric nitroso groups [5]). In the spectrum of DNB-fp, the absorption in this region is approximately two times that in the spectrum of DNB-sh, which suggests for DNB-fp a higher concentration of monomeric nitroso groups, lower degree of polymerization,

Rate constants of vulcanization of NR solution

T, °C	*k*, s^{-1}	
	DNB-fp	DNB-sh
20	5.7×10^{-5}	–
30	1.3×10^{-4}	–
40	3.9×10^{-4}	1.4×10^{-5}
50	–	5.4×10^{-5}
60	–	2.1×10^{-4}

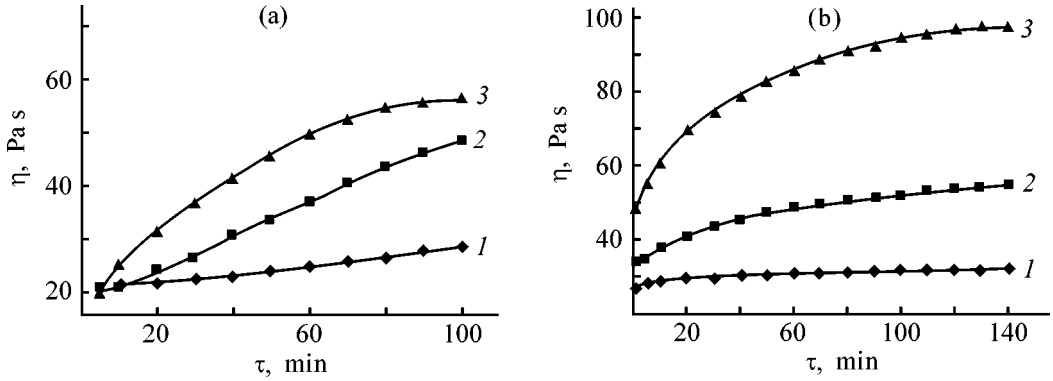

Fig. 1. Kinetic curves of NR vulcanization with (a) DNB-fp and (b) DNB-sh. (η) Viscosity and (τ) time. Temperature, °C: (a) (*1*) 20, (*2*) 30, and (*3*) 40; (b) (*1*) 40, (*2*) 50, and (*3*) 60.

and accordingly higher vulcanizing activity (or higher vulcanization rate constant).

The kinetic studies of vulcanization were performed with a 10% toluene solution of natural rubber (NR) preliminarily rolled out for 3–4 min. Poly-DNB was added to the solution in an amount of 1 wt % relative to the rubber. The growth of the solution viscosity with time was monitored on a Rheotron Brabender rotary viscometer at a cylinder rotation rate of 5 rpm. The kinetic curves were satisfactorily described by a first-order equation; the semilog plots were linear. The apparent rate constants of vulcanization k (s^{-1}) were calculated by the formula

$$k = \frac{1}{\tau} \ln \frac{\eta_{max} - \eta_0}{\eta_{max} - \eta_\tau}, \qquad (1)$$

where τ is time (s), and η_{max}, η_0, and η_τ are the maximum, initial, and running viscosities of the reaction mixture (Pa s).

The initial portions of the kinetic curves for vulcanization of NR with DNB-fp and DNB-sh are shown in Figs. 1a and 1b, and the rate constants of vulcanization are listed in the table.

The temperature dependences of the apparent rate constants of vulcanization are as follows:

$$k_{DNB\text{-}fp} = 10^{8.7} \exp(-72.8\ \text{kJ}/RT),$$

$$k_{DNB\text{-}sh} = 10^{14.3} \exp(-114.6\ \text{kJ}/RT).$$

As a quantity characterizing the reactivity of poly-DNB samples, we chose the temperature T_r (°C) at which the apparent rate constant $k = 1 \times 10^{-6}$ s^{-1}:

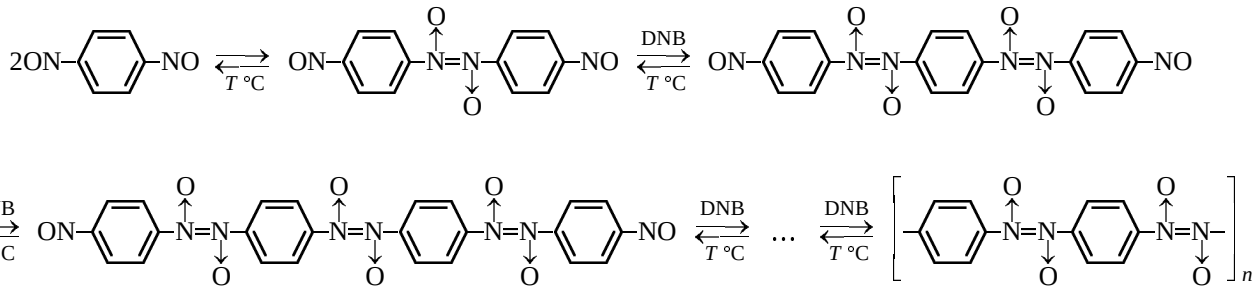
$$T_r = \frac{E}{19.142(6 + \log A)} - 273.15, \qquad (2)$$

where E is the activation energy, kJ. T_r is –15.1 and 22.6°C for DNB-fp and DNB-sh, respectively.

The quantity T_r also characterizes the thermal stability of the systems [8], in our case, the limiting temperature of storage of the system to be vulcanized, at which scorching leads to an approximately 2% rise in viscosity in 6 h.

DNB-fp appeared to be more active than DNB-sh also with respect to toluene solutions of other unsaturated rubbers: SKDK, SKN-3, and SKEPT-ENB.

The different T_r can be attributed to different degrees of polymerization of poly-DNB samples, which grow in storage, with the corresponding decrease in the relative concentration of monomeric terminal nitroso groups and in the apparent rate constant of vulcanization:



The vulcanizing activity of DNB-fp and DNB-sh at 100–130°C was studied with a Monsanto-100S rheometer. Samples were introduced into SKI-3 polyisoprene rubbers on cold rollers. The time of mixing on the rollers was 3–4 min.

In so doing, the major problem was to choose the optimal rolling time to ensure an effective mixing of the vulcanizing agent with the rubber and, at the same time, to avoid any appreciable scorching.

The kinetic curves were satisfactorily described by a first-order equation; the semilog plots were linear.

The apparent rate constants of vulcanization (s^{-1}) were calculated by the formula

$$k = \frac{1}{\tau_{90\%}} \ln \frac{M_{max} - M_{min}}{M_{max} - M_{90\%}}, \quad (3)$$

where $\tau_{90\%}$ is the time in which the vulcanization optimum (90%) is attained, s; M_{max}, M_{min}, and $M_{90\%}$ are the torque values: maximum, minimum, and that in vulcanization optimum (90% of the maximum), dN m.

Our study shows that, at relatively high temperatures (100–130°C), the apparent rate constants of vulcanization of SKI-3 with DNB-fp and DNB-sh do not differ appreciably: in both cases, $k_{130°C} = 6.4 \times 10^{-3}$ s^{-1}.

The temperature dependence of the vulcanization rate constant (s^{-1}) with DNB-fp and DNB-sh is

$$k = 10^{5.8 \pm 1} \exp(-6.2 \pm 8 \text{ kJ}/RT),$$

with $T_r = 0 \pm 10°C$.

According to previous data, DNB-fp, DNB-sh, and poly-DNB stored for 30 years show about the same activity in vulcanization of butyl rubber stocks in a mold at 100°C. The resulting vulcanizates had comparatively close values of the nominal tensile strength, $\sigma = 14 \pm 0.8$ MPa [9].

Apparently, under conditions of hot vulcanization, poly-DNB undergoes fast depolymerization, with the reaction of monomeric DNB with unsaturated rubber macromolecules being the limiting step.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Use of Latex Systems for Controlling the Properties of Urea–Formaldehyde Resins

S. S. Glazkov

Voronezh State Academy of Forestry Engineering, Voronezh, Russia

Received April 15, 2004

Abstract—The influence of latex formulations and a filler, Vulkasil, on the processing and physicochemical properties of urea–formaldehyde resins was studied.

Urea–formaldehyde resins (UFSs) are widely used for gluing of wood and wood materials in furniture and wood-working industry [1]. In world's production of chip boards and plywood, the consumption of these resins reaches 90% [2]. Despite the relatively high strength, UFRs have significant drawbacks: presence of cancerogenic free formaldehyde and low moisture and water resistance, especially under conditions of varying humidity and high temperatures. Numerous studies show that these drawbacks can be eliminated both in the synthesis stage [3] and by modification of the ready urea–formaldehyde oligomer [4]. The second alternative seems to be more promising, as it allows a comprehensive control over the properties of the resin and resin-containing wood materials depending on the conditions of service of ready items.

In this study we examined how a latex system based on butadiene–styrene copolymer affects the UFR properties.

EXPERIMENTAL

Latexes are colloidal systems [5]; the most readily available are butadiene–styrene latexes widely used in production of composite materials. However, in contrast to functional polymers, latexes require additional stabilization to enhance the stability of latex systems in contact with fillers and UFRs. The formula of an adhesive latex composition (ALC) based on a butadiene–styrene latex can include the following ingredients: thickener (protective colloid); agent that enhanced the adhesiveness; stabilizing emulsifier OP-10; trisodium phosphate (TSP, 20% solution); and active filler (Aerosil, Vulkasil). The stabilization of butadiene– styrene latexes is provided by introducing water-soluble polymers (polyvinyl alcohol; carboxymethyl cellulose, CMC; casein; etc.). In particular, it was shown for BS-65A latex (Fig. 1) that the stabilization of the colloidal system with 10% CMC solution is accompanied by changes in the surface tension σ and wetting angle θ. At CMC concentrations of 2 to 6%, these quantities pass through a maximum and a minimum, respectively. The thermodynamic work quantities pass in this range of CMC concentrations through maxima (Fig. 2), reaching the values that exceed those for the initial latex by a factor of 2–3. Acting as a protective colloid, CMC molecules link, via their polar (hydroxy) groups, the col-

loidal particles of a latex into coarser agglomerates. The introduction of a polar compound and structural processes account for the shape of the curves for the works of cohesion W_c, adhesion W_a, and wetting W_w.

The sizes of wood capillaries (20–40 to 100–200 nm, depending on the kind of wood), interfibrillar pores (7–10 nm), and oligomer molecules (7–40 nm) are comparable [6]. Latex particles are coarser (100 to 1000 nm, depending on the kind of latex).

Thus, introduction of latexes into UFR-based binders will (1) of the the surface tension, wetting angle, and viscosity, which will favor better wetting and more uniform coverage of the external surface of the wood filler with the binder, and (2) retard penetration of the binder into the capillary-porous structure of wood particles, ensuring more uniform thickness of the adhesive layer.

According to the modern adsorption theory, the formation of a glue joint is a multistep process. Wetting of the substrate surface with the adhesive and the spill of the adhesive over the surface are accompanied by diffusion of polymer molecules and establishment of an adsorption equilibrium. Introduction of small amounts of latex compositions with the particle size reaching 300–400 nm (in synthetic latexes) should decrease the adsorption. Latex globules act as an active filler deposit on the substrate surface and plug the porous structure of the adsorbent, thus increasing the number of contact points. Acting as a peculiar "lock," latex particles favor an increase in the thickness of the adhesive layer and decrease the risk of formation of a discontinuous glue joint.

The specific adsorption (amount of the polymeric substance taken up by the wood filler) is at a maximum (0.17 g g^{-1}) for the straight resin. With the modified resin (KFZh brand), the specific adsorption steadily decreases as the latex content increases, amounting to 0.09, 0.058, and 0.042 g g^{-1} at a latex content of 0.05, 0.1, and 15.0 wt %, respectively. With straight latex, the specific adsorption is at a minimum: 1.5×10^{-2} g g^{-1}.

Latex formulations decrease the UFR viscosity (Table 1) and improve the wetting of the wood surface. The decrease in the wetting angle is apparently due to the effect of the emulsifier present in the latex.

Latex particles, being thermodynamically unstable, possibly initiate polycondensation processes. This is suggested by the shortening of the gelation time, i.e., by an increase in the UFR reactivity at low latex concentrations (Table 1). The modifying effect of the latex system is manifested in an enhanced strength of the glue joint (Table 1). The ultimate shear strength with the modified binder increases by 50–80% at the ALC content of up to 3–4%.

An examination of photomicrographs (Fig. 3) confirmed the assumed mechanism of the ALC effect on formation of a glue joint. In contrast to the initial UFR (Fig. 3a), which gives of discontinuous glue joint with large thickness and large penetration depth, the modified UFR (Fig. 3b) ensures a thinner and more uniform glue joint without apparent discontinuities.

The binder composition was optimized using the Statgraphics for Windows software.

As follows from Fig. 4, there exists an optimal latex content, determined primarily by the existence of extrema in the glue joint strength, free formaldehyde content, and gelation time. The influence of the filler (Vulkasil) content on the first two parameters is about the same but less pronounced, and the gelation time steadily increases with increasing filler content. Presumably, formaldehyde can by physically bound to

with the surface of the latex particle. This is indirectly suggested by the fact that the content of the dispersed component (Fig. 4b, X_1) strongly affects that of free formaldehyde (decrease by almost a factor of 2, compared to the initial UFR). Figure 4b shows that this effect is similar in magnitude to that exerted by the filler, Vulkasil (X_3).

The optimal binder formulation was used in production of chip boards with various kinds of wood fillers (Table 2). At the optimal content of the latex system in the binder, the resulting boards based on secondary raw materials exhibit satisfactory chemical and physicomechanical characteristics and have decreased content of free formaldehyde.

CONCLUSIONS

(1) Introduction of the latex system based on BS-65A latex into urea–formaldehyde resin improves the processing and physicochemical parameters of the binder and of the composite as a whole.

(2) As the content of the adhesive latex composition in the urea–formaldehyde oligomer increases, the penetration of the oligomer into the wood substrate decreases, and thereby the distribution of the binder over the glue joint surface becomes more uniform.

(3) The vulkasil filler makes lower the residual formaldehyde content in the urea–formaldehyde oligomer and in finished chip boards.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Polyurethanes with *B,P*-containing Polyols

S. N. Bondarenko, T. V. Khokhlova, S. A. Orlova, and O. I. Tuzhikov

Volgograd State Technical University, Volgograd, Russia
Volzhskii Polytechnic Institute, Volzhskii, Volgograd oblast, Russia

Received July 9, 2004

Abstract—Polyurethanes were prepared from diphenylmethane-4,4'-diisocyanate, poly(tetramethylene ether) glycol, and *B,P*-containing polyols. The structure and properties of these polyurethanes were studied in relation to the synthesis conditions, including the functional group ratio and temperature. The heat resistance of the polyurethanes was evaluated.

Preparation of polymers containing boron atoms in the macromolecule was discussed in an analytical review [1]; in particular, methods for preparing polyurethanes containing carborane and borinane structures were considered. Such polymers are synthesized from low-molecular-weight carborane-containing ethers and esters and aliphatic diisocyanates, or from carboranylene diisocyanates and various diols.

However, factors that control the lengthening of the polymeric chain and properties of the polymers prepared using oligomeric chain-lengthening organometallic agents were not analyzed comprehensively in [1].

Our goal was to reveal a relationship between the molecular parameters of the starting polyols containing borate and phosphonate groups, on the one hand, and the properties of polyurethanes prepared from these polyols, on the other.

EXPERIMENTAL

Polyurethanes were prepared by a two-step procedure. The reaction of a twofold excess of diphenylmethane-4,4'-diisocyanate (DMI) with poly(tetramethylene ether) glycol (PTMEG) yielded a macromolecular diisocyanate (MDC). The resulting MDC was brought into the reaction with a *B,P*-containing polyol (BPP) as a chain-lengthening agent.

Polyurethanes and MDC were prepared in a high-speed (1400 rpm) temperature-controlled mixer in an argon flow in dimethylformamide (DMF).

B,P-Containing polyols BPP-1, BPP-2, BPP-3, and BPP-4 were prepared according to [2] by reactions of glycols (ethylene glycol, diethylene glycol, glycerol, and 1,4-butanediol, respectively) with the phosphorus-containing oligomer [3]. The reaction occurs on heating of the equimolar amounts of the reactants under Ar at 453–463 K without a catalyst for 5 ± 1 h. The reaction products are viscous liquids with the color varying from light yellow to brown. The main physicochemical parameters of BPPs are listed in Table 1.

The structure of the BPPs obtained was confirmed by ^{1}H and ^{31}P NMR and by IR spectroscopy. The

NMR spectra were recorded on a Bruker AC-200 spectrometer (working frequency for ^1H 200 MHz). The IR spectra of BPPs and polyurethanes were recorded on a Specord-M82 spectrometer.

Oligomer samples were dried at 353 K/0.66 kPa; the moisture content in BPPs did not exceed 0.02 wt%. Their molecular weight (MW) was determined cryoscopically in cyclohexanone. The molecular weight of polyurethanes was evaluated by the change in the viscosity of their solutions. The viscosity was measured with a Rheotest-2 cone–plate rheoviscometer in the shear rate range 5.6 – 4860 s^{-1}.

Diphenylmethane-4,4'-diisocyanate was distilled in a vacuum at 323–328 K/0.66 kPa and stored in sealed glass ampules. The urethane formation kinetics was monitored chemically (by consumption of isocyanate groups) and IR spectroscopically [by variation of the optical density at the wave numbers corresponding to the characteristic bands of the isocyanate (–N=C=O, 2275 cm^{-1}) and –NH (3400 cm^{-1}) groups]. The sol and gel fractions of the polyurethanes were separated in a Soxhlet apparatus.

Samples for tests were prepared as free films by casting from 65% DMF solutions according to GOST (State Standard) 14243–78. The mean film thickness was about 200 μm. Before tests, the films were heat-treated at 393 K for 6 h. The tensile characteristics of the materials were determined according to GOST 18299–72 at a loading rate of 20 mm min^{-1}. Each experimental point was obtained with no less than ten samples; the variance coefficients did not exceed 9% for the tensile strength σ and 15% for relative elongation at break, ε.

The heat resistance of polyurethane sample was evaluated under static (from the amount of oxygen taken up in 180 min at 453 K) and dynamic [by thermal gravimetric analysis in air, MOM derivatograph (Hungary), atmospheric pressure, 273–1273 K] conditions. The thermodynamic characteristics of the degradation processes were evaluated by the procedure described in [4].

B,P-Containing polyurethanes were prepared as follows.

First step:

$$2O{=}C{=}N{-}R{-}N{=}C{=}O + H{-}[{-}O({-}CH_2{-})_4]_n{-}OH \rightarrow O{=}C{=}N{-}R{-}NH{-}C(O){-}[O{-}(CH_2{-})_4]_n{-}O{-}C(O){-}NH{-}R{-}N{=}C{=}O,$$

Second step:

$$O{=}C{=}N{-}R{-}NH{-}C(O){-}[O{-}(CH_2{-})_4]_n{-}O{-}C(O){-}NH{-}R{-}N{=}C{=}O + HO{-}R_1\text{-}OH$$

$$\rightarrow O{=}C{=}N{-}[{-}R{-}NH{-}C(O){-}[O{-}(CH_2{-})_4]_n{-}O{-}C(O){-}NH{-}R{-}NH{-}C(O){-}O{-}R_1{-}O{-}]_m{-}H,$$

$$R = -\langle\bigcirc\rangle-CH_2-\langle\bigcirc\rangle;$$

$$R_1 = OH{-}[{-}R_2{-}O{-}P({=}O)({-}H){-}[{-}O{-}B({-}O{-}R_2{-}OH){-}O{-}P({=}O)({-}H){-}]_p[{-}O{-}B({-}OH){-}O{-}P({=}O)({-}H){-}]_q O{-}B({-}OH){-}O{-}P({=}O)({-}H){-}O{-}]_h R_2{-}OH;$$

$$R_2 = -CH_2{-}CH_2-,\ -CH_2{-}CH_2{-}O{-}CH_2{-}CH_2-,\ -CH_2{-}CH_2{-}CH_2{-}CH_2-,\ -CH_2{-}CH(OH){-}CH_2-;$$

where $n \approx 26$, $m \approx 10$, $p + q = 4–5$, $h = 1–2$.

The *B,P*-containing polyols used as chain-lengthening agents in the second step of polyurethane synthesis have close molecular weights and about the same content of terminal hydroxy groups. BPP-3 contains, along with primary hydroxy groups, also secondary groups; therefore, formation of a cross-linked polymer in the initial step of the synthesis can be expected, with a steeper rise in the viscosity of the reaction mixture. BPP-2 has a lower viscosity, which may be due to a higher mobility of oligomeric molecules containing ether fragments [5].

The reactions of MDC with BPPs were performed in DMF. The degree of conversion was evaluated from the consumption of NCO groups. With all the BPPs studied, the consumption of the isocyanate groups is determned by the amount of the BPP added and by the content of hydroxy groups in it (Figs. 1a, 1b). The higher rate of MDC consumption in the reaction with BPP-3 is apparently due to a higher content of hydroxy groups in this polyol.

The maximum molecular weight of polyurethanes prepared under conditions of migration polymerization is obtained at the [NCO]/[OH] molar ratio of 1 : 1. When the isocyanate groups are in deficiency, the MW of the polyurethanes is about 10^4 (left part of the curves, Fig. 2). Excess isocyanate groups, as shown in [6, 7], cause formation of allophanate fragments and give rise to branched structures.

The reaction temperature was varied within 333–363 K. The upper temperature limit was determined by the onset of side cross-linking reactions due to formation of allophanate branching sites, and also by the possibility of cyclization. The lower limit was determined by the polyaddition rate, which appreciably decreased below 333 K.

The variation of the concentration of NCO groups in the reaction mixture is shown in Fig. 3. Since the viscosity of the reaction mixture decreases with increasing temperature, the hydroxy groups are accessible in any position in the first step of the reaction. The gel fraction starts to be formed from the examined BPPs starts only after the residual content of NCO groups decreases to 0.6 wt % and less.

The intensity of consumption of NCO groups appreciably depends on the temperature and amount of BPP. Even at 363 K, the gel fraction content increases slowly, and the polyol preserves the weakly branched structure. Since the isocyanate groups cannot be determined by the chemical method in the final step of the polyaddition (residual content of NCO groups ≤0.6 wt %) because of the formation of a three-dimensional cross-linked structure, the completeness of consumption of the NCO groups was judged from the IR spectra of the polyurethanes.

The concentration of NCO groups was determined from the intensity of the absorption band at 2275 cm^{-1} [6, 8]. According to [9], the concentration of residual isocyanate groups in polyurethane does not exceed 0.1–0.12 wt %. The absorption bands at about 3400 and 3440 cm^{-1}, corresponding to the NH groups involved in hydrogen bonding and free NH groups, respectively, simultaneously grow in intensity. Accord-

ing to the IR data, the accumulation of NH groups corresponds to consumption of NCO groups, indicating that formation of allophanate and biuret structures is insignificant.

The temperature dependences of the reaction rate constants are linear in the Arrhenius coordinates (Fig. 4). From these data, we determined the thermodynamic parameters of the reaction (Table 2). The reaction rate constants were determined using a system of differential equations that describe the variation of the reactant concentrations in the initial period.

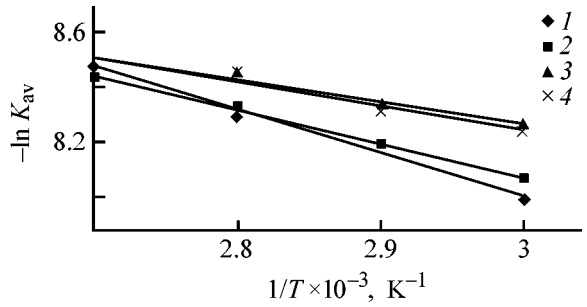

Fig. 4. Plot of $-\ln K_{av}$ vs. $1/T$ (c_{BPP} = 0.04 M).

The activation energies obtained show that the BPPs derived from 1,4-butanediol and ethylene glycol have close activities. The higher activity of the BPP derived from glycerol is apparently due to the higher content of hydroxy groups.

The IR spectra of polyurethanes derived from BPPs contain absorption bands at about 1730 (C=O), 1410–1480 (CH_2), and 3400–3500 cm^{-1} (–NH, both free and hydrogen-bonded with OH groups). Also present are the absorption bands belonging to the P=O (1230 cm^{-1}) and P–O–C (1008 cm^{-1}) groups; a medium-intensity band at about 2460 cm^{-1} is due to P–H stretching vibrations, and the band at 1456 cm^{-1} is assignable to B(III)–O stretching vibrations [10]. These bands somewhat differ in intensity and position, depending on the steric structure of BPP and the conformation of the chain fragments.

The differences in the properties of polyurethanes (Table 3) can be accounted for by structural features of the oligomers and polymers derived from them.

Table 3 shows that changing of the [MDC]/[BPP] molar ratio from 1 : 1 to 1.4 : 1 is accompanied by

Table 4. Parameters of thermal oxidative degradation of polyurethanes derived from BPPs and of a commercial polyurethane sample (PU)

Parameter	PU	BPP-1	BPP-2	BPP-3	BPP-4
Activation energy, kJ mol^{-1}	112.0	166.9	170.8	181.4	175.4

20%	533	613	603	613	608
50%	558	653	643	663	663
Coke residue at 873 K, %	2	10	9	12	11

an increase in the gel fraction content; the tensile strength of the samples, σ_t, accordingly increases, and the relative elongation ε_{rel} decreases. Thus, at decreased content of BPP in the reaction mixture, MDC reacts with OH groups situated in different positions, which results in an increased cross-linking. At increased content of BPP, the gel fraction content decreases, which results in a decreased tensile strength and an increased relative elongation; consistent results were obtained in measuring the residual elongation ε_{res} (Table 3). The polyurethane derived from BPP-3 has a higher tensile and tearing strength, which is attributable to the more rigid three-dimensional structure of the polymer (maximum content of the gel fraction), due to the possibility of reaction of MDC with secondary OH groups of the glycerol moiety; this is also confirmed by the low residual elongation.

The resistance of the polymers to thermal oxidative degradation was studied under static and dynamic conditions. Figure 5 shows data on thermal oxidative degradation of BPP-based polyurethanes under static conditions; data for a commercial PU sample containing no BPP fragments are given for comparison. It is seen that the commercial sample (curve *5*) actively degrades after a short induction period. Thermal oxidative degradation of BPP-containing polyurethanes under these conditions is considerably slower (curves *1*–*4*).

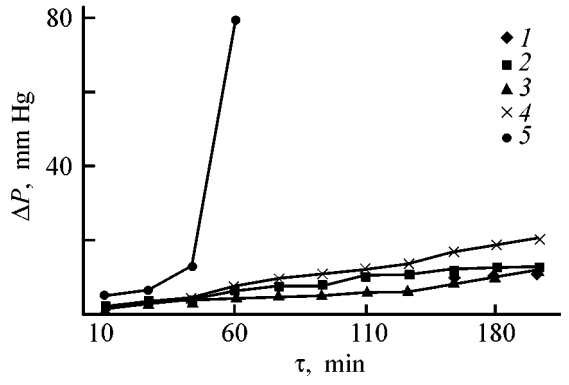

Fig. 5. Oxygen uptake ΔP vs. time τ at T = 453 K. Polyurethane derived from (*1*) BPP-1, (*2*) BPP-2, (*3*) BPP-3, and (*4*) BPP-4; (*5*) commercial PU.

The results of dynamic (TGA) experiments are given in Table 4. The BPP-based polyurethanes prepared at the [MDC] : [BPP] molar ratio of 1.2 : 1 have increased values of activation energy of thermal oxidative degradation, higher temperatures of decomposition onset and intense decomposition, and higher yield of the coke residue.

The oxygen index is 28.0–27.6% for polyurethane samples prepared at [MDC]/[BPP] ranging from 1 : 1 to 1 : 1.4 and 18% for the commercial PU sample.

CONCLUSIONS

(1) A macromolecular diisocyanate was prepared by the reaction of diphenylmethane-4,4'-diisocyanate with poly(tetramethylene ether) glycol and was then brought into reactions with *B,P*-containing polyols (chain-lengthening agents) to obtain elastic polyurethanes. The thermodynamic parameters of the polyaddition were determined.

(2) The polyurethanes synthesized exhibit improved physicomechanical properties and decreased combustibility.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Bleaching of Kraft Cellulose by the ClO_2–H_2O_2 Scheme

T. P. Shcherbakova and V. A. Demin

Institute of Chemistry, Komi Scientific Center, Ural Division, Russian Academy of Sciences, Syktyvkar, Komi Republic, Russia

Received April 22, 2004

Abstract—The influence of conditions of a two-stage treatment of deciduous and coniferous kraft cellulose (by the ClO_2–H_2O_2 scheme) on the degree of its delignification and bleaching was studied. The optimum ratio of reagents in each stage of the treatment was elucidated.

According to published data [1–3], the action of bleaching reagents on lignin involves parallel or successive attack of electrophilic and nucleophilic agents. It has been shown previously that the most efficient and selective processes of cellulose bleaching meet two conditions: first, alternation of the action of electrophilic and nucleophilic agents on the residual lignin in the successive stages of treatment; second, treatment with an electrophilic reagent in an acidic medium (acid catalysis), and with a nucleophilic reagent, in an alkaline medium (base catalysis) [4]. Along with alternation of the stages and catalysis conditions, the quantitative ratios of electrophic and nucleophilic agents in stages of treatment are very important for attaining the best whiteness and the highest degree of delignification with the minimum degradation of cellulose. In industry, the expenditure of reagents is commonly chosen empirically without considering their nature. Most of bleaching reagents-oxidants and, in particular, hydrogen peroxide in an alkaline medium, form numerous reactive species in oxidation of lignin. These include free radicals, singlet oxygen ($^{\cdot}OH$, $^{\cdot\cdot}OOH$, $^1O_2$), and hydroperoxide anion HOO^-. Free radicals induce cellulose degradation. To hamper the reactions of free radicals and to perform delignification of kraft cellulose in the stage of treatment with hydrogen peroxide by the ionic (nucleophilic) mechanism, H_2O_2 is stabilized with sodium silicate. The use of H_2O_2 for bleaching of kraft cellulose by this procedure offers some advantages over other industrially used procedures: it results in a 10–30% weaker degradation of cellulose and in a higher degree of delignification, allowing attainment of better whiteness [5, 6].

This study is aimed at examined the influence of the reagent ratio used in the successive stages of treatment (ClO_2 and H_2O_2) on the whiteness, degree of delignification, and selectivity of bleaching of coniferous and deciduous kraft cellulose.

EXPERIMENTAL

The conditions of the first stage were as follows: expenditure of chlorine dioxide 2% relative to the weight of absolutely dry cellulose, concentration of cellulose suspension 10 wt %, duration 120 min, and temperature 60°C.

The conditions of the second stage were as follows: expenditure of hydrogen peroxide 2.13, NaOH 1.3, and sodium silicate ($Na_2SiO_3 \cdot 9H_2O$) 5% relative to the weight of absolutely dry cellulose; concentration of a coniferous cellulose suspension 20 wt % (deciduous, 15 wt %); duration 120 min; and temperature 100°C. In the second mode of treatment, we used, along with H_2O_2, NaOH with the same expenditure (4% relative to the weight of absolutely dry cellulose); no sodium silicate was added.

The whiteness of the resulting samples was determined on an FKTsSh-M color comparator. In the standard methods, the reflectivity in blue light (457 nm) is taken as the degree of cellulose whiteness. A $MgSO_4$ plate whose whiteness was taken as 100% [GOST (State Standard) 30113–94] was used as a reference. The hardness of cellulose, which characterized the content of residual lignin in the sample, was determined by the method based on oxidation

Table 1. Quality characteristics of cellulose, in relation to depending on the conditions of bleaching with ClO_2–HO_2^- and ClO_2–($H_2O_2 \rightarrow O_2$)

Step I, ClO_2 expenditure, %	Step II, expenditure of reagents,* %			Cellulose

* Temperature 60°C; treatment duration at high ClO_2 expenditure was increased to make complete the absorption of chlorine dioxide.

of the residual lignin in the cellulose material with $KMnO_4$ in an acidic medium, according to GOST 10070–74 (permanganate units, p.u.) [7]. The degree of polymerization of cellulose (DP) was evaluated from the viscosity of its solution in Cadoxene [8].

Here, we compare the results of treatment of non-whitened kraft cellulose with H_2O_2 by the ionic (pH ~10, in the presence of a stabilizing agent) and radical (pH ≥ 12) mechanisms in the two-stage scheme. The results are presented in Table 1.

As can be seen from Table 1, the maximum whiteness is reaches 85% for deciduous cellulose and almost 86% for coniferous cellulose (here, coniferous cellulose was treated at a higher concentration of pulp).

Then, we studied the characteristics of cellulose after the first step of treatment and the dependence of the whiteness on the ClO_2 expenditure in the range 1.0–3.1% ClO_2 relative to the weight of absolutely dry cellulose (Table 2, Fig. 1).

* Bleaching at a constant total expenditure of oxidants equivalent to 9.7% active chlorine relative to the weight of absolutely dry cellulose.

** Expressed in equivalent amounts of active chlorine.

*** Expressed in Kapp units.

Similar dependences were obtained for two samples of deciduous cellulose: at 60°C for the sample with a hardness of 75 p.u. (Fig. 2) and in the range 60–90°C for cellulose with a hardness of 84 p.u. (Table 3).

The results obtained suggest that there is no reason to raise the temperature of treatment with ClO_2 above 70°C. The minimum hardness of cellulose at this temperature is 7.5 p.u., and the maximum whiteness, 73.1%. In this case, the expenditure of ClO_2 is $3.12 \times 2.63 = 8.21\%$ active chlorine relative to the weight of absolutely dry cellulose.

It can be concluded from Fig. 2 that, in treatment of deciduous kraft cellulose with a hardness of approximately 75 p.u. with ClO_2, an increase in the ClO_2 expenditure above 1.5% does not result in any noticeable intensification of delignification.

The ClO_2 expenditure for the first delignification stage in treatment of kraft cellulose (both coniferous and deciduous) was estimated in the specific expenditures per unit degree of cooking by the Kapp method. The results of bleaching of kraft cellulose are presented in Table 4.

The index of cellulose whiteness has a maximum at the equivalent dose of ClO_2 equal to 55% of the total expenditure of oxidants. The maximum whiteness is 85.9%. An increase in the fraction of ClO_2 causes a noticeable increase in the degree of polymerization of cellulose (890–1110) and an insignificant increase in the yield of whitened cellulose, from 95.0 to 95.7%. Varying the fraction of ClO_2 in the total expenditure of oxidizing agents insignificantly affects the hardness of cellulose (4.3–2.2 p.u.), since virtually no lignin remains in cellulose.

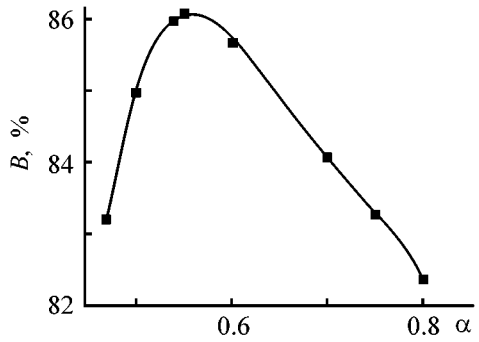

Fig. 3. Influence of the equivalent fraction of ClO_2, α, in the total expenditure of reagents on the whiteness of coniferous cellulose, *B*.

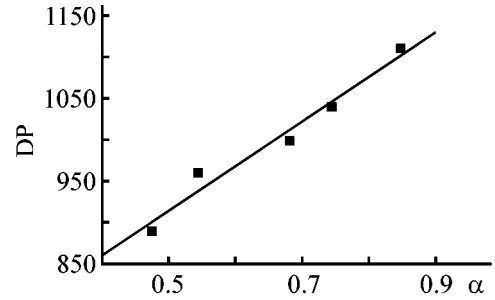

Fig. 4. DP of coniferous whitened cellulose vs. ClO_2 fraction α in the total expenditure of oxidizing agents.

The dependence of the whiteness of coniferous cellulose on the fraction of ClO_2 in the total expenditure of oxidants in two-stage bleaching is shown in Fig. 3.

The dependence of DP of the whitened coniferous kraft cellulose on the fraction of ClO_2 in the expenditure of oxidants is shown in Fig. 4. The degree of polymerization of cellulose increases in direct proportion to the fraction of ClO_2 in the total expenditure of reagents for bleaching. This confirms the well-known fact that, among bleaching reagents, ClO_2 is the most selective oxidant for lignin [9].

CONCLUSIONS

(1) Treatment of kraft cellulose with hydrogen peroxide in the presence of a stabilizing agent, sodium silicate, providing predominance of the ionic mechanism of delignification, results in a 7–8% higher whiteness of kraft cellulose, compared to that obtained under conditions favoring radical decomposition of hydrogen peroxide.

(2) The dependence of the whiteness of coniferous kraft cellulose on the fraction of chlorine dioxide in the total expenditure of reagents has a maximum. To reach the maximum whiteness, the fraction of ClO_2 should be approximately 0.5–0.6 (with respect to oxidation equivalents).

(3) The scheme of bleaching of kraft cellulose in two stages ClO_2–H_2O_2 (stabilizing agent), ensuring the whiteness index of 84% (deciduous cellulose) and 86% (coniferous cellulose), was developed.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polychronous Kinetics of Oxidative Delignification of Coniferous Kraft Cellulose with Hydrogen Peroxide

T. P. Shcherbakova, V. A. Demin, and A. I. Mikhailov

Institute of Chemistry, Komi Scientific Center, Ural Division, Russian Academy of Sciences, Syktyvkar, Komi Republic, Russia

Institute of Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Abstract—The kinetics of oxidative delignification of coniferous kraft cellulose with hydrogen peroxide in the temperature range 60–100°C was studied.

A study of kinetic features of oxidative delignification of kraft cellulose is of interest for improvement of the cellulose production process, in particular, cellulose bleaching, in which molecular chlorine, a source of dangerous pollution of the environment with toxic chlorophenols and polychlorodibenzodioxins, is still used in the Russian Federation.

New approaches based on the methods of polychromous kinetics, which take into account the dynamics of molecular motion and structural micro- and nanoheterogeneity of a matrix, have been developed recently [1–3] for kinetic studies of processes in solid and viscous media, among them polymeric materials. As applied to the kinetics of delignification of wood (cooking) and industrial cellulose (bleaching), the methods of polychromous kinetics have been developed for description of procedures of nitric acidic, soda, and kraft cooking and bleaching [4–7]. As chemical bonds and reaction centers in lignin (component of such a polymer composite as unbleached cellulose), are widely diverse, the formulation and correct solution of the direct kinetic problem for oxidative delignification is difficult. Therefore, it is appropriate to use in this stage of the study a phenomenological formalistic kinetic approach. The results obtained in studying the kinetics of oxidative delignification of deciduous kraft cellulose with hydroxoperoxide anions have been published previously [8]. Here, we studied the oxidative delignification of coniferous kraft cellulose produced by the Neusiedler Syktyvkar Joint-Stock Company.

Depending on the treatment conditions in alkaline medium, H_2O_2 reacts with the residual lignin localized in a cellulose fiber by two mechanisms: free-radical (in the absence of stabilizing agents) and ionic [9]:

$$H_2O_2 + OH^- \rightarrow HO_2^- + H_2O. \quad (1)$$

For lignin to be oxidized by the second mechanism, free-radical decomposition of H_2O_2 is suppressed by adding Na_2SiO_3. In this case, as shown previously [10], delignification of kraft cellulose under conditions of bleaching proceeds with a higher degree and selectivity and minimum degradation of cellulose.

Oxidative delignification of coniferous kraft cellulose with a hardness of 103 permanganate units (by Bjerkman) was carried out in an 88 mM H_2O_2 solution at pH 10.2 ± 2 in the presence of a stabilizing agent ($Na_2SiO_3 \cdot 9H_2O$ in the form of a solution with an expenditure of 5% relative to absolutely dry cellulose) with the liquor ratio of 200 : 1. We used a 20-fold excess of H_2O_2 with respect to lignin. Order of adding reagents: NaOH solutions (before thermostat), Na_2SiO_3, and H_2O_2. The temperature range was from 333 K to 373 K. A flask filled with cellulose and calculated amounts of water and alkali was placed in a temperature-controlled water bath. The bath was heated to the working temperature, Na_2SiO_3 and H_2O_2 were added and vigorously stirred to be mixed with the pulp; simultaneously with their addition, a stopwatch was switched on. The samples were with-drawn at certain intervals, rapidly washed on a porous glass filter, and dried. Then, the content of residual lignin in the resulting samples was determined on a KFK-3 photometer [11]. The experimental data were normalized to the initial content of lignin in kraft cellulose (Table 1).

The kinetic curves of delignification of kraft coniferous cellulose in bleaching with stabilized H_2O_2 are shown in Fig. 1.

18 000	0.61	0.45	0.37	0.24	0.14

As can be seen from Fig. 1, in delignification of coniferous kraft cellulose, the reaction does not go to completion (kinetic termination).

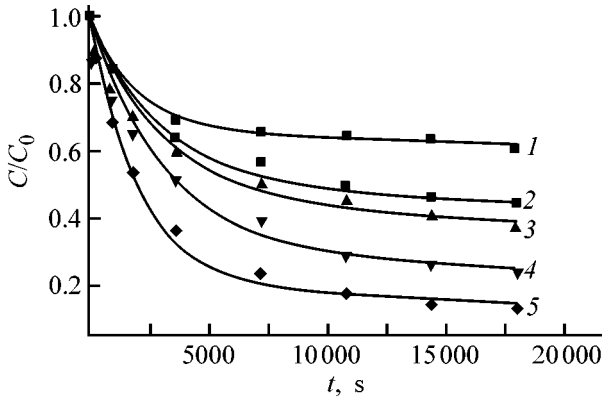

Fig. 1. Kinetic curves of delignification of kraft coniferous cellulose in bleaching with stabilized hydrogen peroxide. Temperature, K: (*1*) 333, (*2*) 343, (*3*) 353, (*4*) 363, and (*5*) 373; the same for Fig. 3. C_0 = 103 permanganate units; (*t*) time.

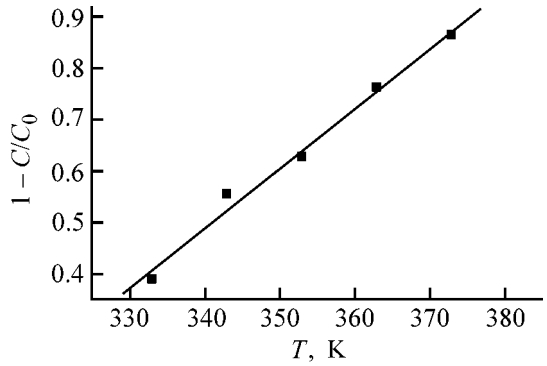

Fig. 2. Limiting degree of conversion $\theta_\infty = 1 - C/C_0$ vs. the process temperature *T*.

The reaction termination under isothermal conditions and the linear dependence of the limiting degree of conversion on temperature (defrosting curve, Fig. 2) allow a kinetic analysis of cellulose delignification by the polychronous kinetics method. The main concepts of the relevant theory, derivation of Eq. (2), and equations for calculations are given in [1–6].

$$n(t, T) = n_0 \int_{\ln K_{min}}^{\ln K_{max}} f(\ln K) G(K, t) d \ln K \approx n_0 \int_{\ln K_{min}}^{\ln K^*} f(\ln K) d \ln K, \quad (2)$$

where $n(t, T)$ is the amount of particles that mainly enter into the reaction within time *t* at a temperature *T*; $f(\ln K)$, the distribution function; $G(K, t)$, function describing the process kinetics in the isokinetic area, where $K \approx$ const; *E*, activation energy; K_0, preexponential factor; and $K(E) = K_0 \exp(-E/RT)$, rate constant. In the simplest case, *G* has the form $G_1 = \exp(-K_1 t)$ and $K^* = 1/t$.

The dependence $\theta = (1 - C/C_0)$–*T* is close to linear, which suggests a uniform (rectangular) distribution of ensembles of lignin macromolecules with respect to $\ln K$.

If the dependence $f(\ln K)$ has an almost rectangular shape in the range ($\ln K_{min}$, $\ln K_{max}$), then, under the condition of "strong polychronousness" (when $t \ll 1$, $tK_{max} \gg 1$, and the parameter of nonequivalence $S = \ln(K_{max}/K_{min}) > 1$ [2, 6]), we have

$$C(t, T)/C_0 = [\ln(K_{min}/K_{max})]^{-1} \ln K_{min} t. \quad (3)$$

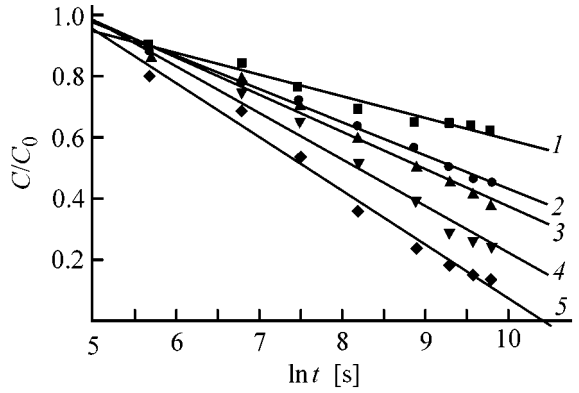

Fig. 3. Linearization of the kinetic curves of delignification of coniferous kraft cellulose in bleaching with hydrogen peroxide in the coordinates of the equation of polychromous kinetics.

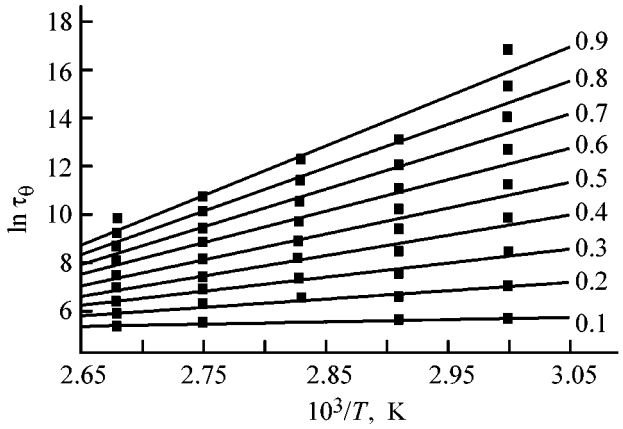

Fig. 4. Arrhenius plot of the characteristic time τ_θ for delignification of coniferous kraft cellulose with hydrogen peroxide at θ = 0.1–0.9.

The semilog plots of the delignification kinetics are shown in Fig. 3. It can be seen that most of experimental points are satisfactorily fitted by a straight line in the coordinates C/C_0–ln t.

With a horizontal section of the family of semilog plots in the coordinates C/C_0–ln t through the points corresponding to $C(t, T)/C_0 = \theta$, where θ is the lignin content corresponding to the considered portion of the kinetic curve, we obtain the temperature dependence ln τ_0–$1/T$ (Table 2).

Here, τ_0 is a characteristic time of the process in the given elementary group at a given degree of component removal θ; it is determined as an instant of time at which the kinetic curve for temperature T_i intercepts the axis $C/C_0 = \theta$.

A set of values of the characteristic time τ_θ, plotted in the Arrhenius coordinates ln τ_θ–$1/T$, allows us to obtain a set of activation energies $E(\theta)$ and preexponential factors $K_0(\theta)$ (Fig. 4, Table 2) for the spectrum of the rate constants of the process. From $E(\theta)$ and $K_0(\theta)$, we can obtain the inverse functions $\theta(E)$ and $\theta(\ln K)$, which are in fact joint integral distribution functions for the spectrum of kinetic constants of the process (Table 3).

The resulting spectra of effective activation energies E_{eff} and preexponential factors $\ln K^0_{\text{eff}}$ for delignification of coniferous kraft cellulose in bleaching with stabilized H_2O_2 are distributed in a wide range of values, which reflect a number of chemical and physical factors contributing to delignification and characterize the heterogeneity of properties of the lignocellulose matrix.

As shown previously [4–6], delignification is typically limited by the diffusion removal of the reaction products from the lignocellulose matrix. In this case, strongly overestimated values of E_{eff} and K^0_{eff} with the linear compensation dependence $\ln K^0_{\text{eff}}$–E_{eff}

Table 2. Values of characteristic time of conversion τ_θ

$10^3/T$, K^{-1}	ln τ_θ at θ				
	0.1	0.2	0.3	0.4	0.5
3.00	5.6	5.6	8.4	9.8	12.4

2.83	5.8	6.6	7.4	8.2	9.0
2.75	5.6	6.2	6.9	7.4	8.2
2.68	5.3	5.9	6.4	7.0	7.6

Table 3. Distribution of ensembles of residual lignin macromolecules with respect to activation energies and preexponential factors

θ	E_{eff}, kJ mol^{-1}	ln K^0_{eff}, s^{-1}
0.1	8.2 ± 5	–2.8 ± 2
0.2	28.7 ± 4	3.3 ± 1
0.3	48.9 ± 10	9.3 ± 2
0.4	70.3 ± 9	15.8 ± 3
0.5	89.8 ± 13	21.6 ± 4
0.6	110.1 ± 17	27.6 ± 6
0.7	130.6 ± 21	33.7 ± 7
0.8	154.6 ± 24	39.8 ± 8
0.9	171.2 ± 28	45.8 ± 10

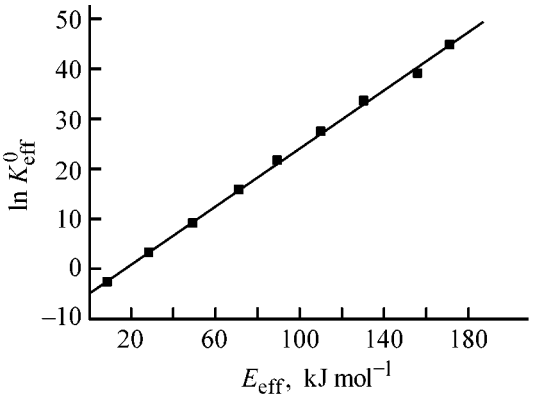

Fig. 5. Compensation dependence: (K^0_{eff}) preexponential factor and (E_{eff}) effective activation energy.

(Fig. 5) commonly originate from the so-called compensation effect in polymers at temperatures close to the softening point of the matrix [5], in particular, in transition of the lignocellulose matrix into the viscoelastic state, when the true values of activation energy E, governing the potential barriers for diffusion, begin to decrease with heating [$\partial E(T)/\partial T < 0$]. In this case, E and K_0 are determined according to the generalized Arrhenius–Voevodskii equation [12]:

$$E_{eff} = E - T(dE/dT),$$

$$\log K^0_{eff} = \log K_0 - (1/R)(dE/dT). \quad (4)$$

Thus, we made an adequate kinetic description of the process in wide time (60–18 000 s) and temperature (60–100°C) intervals in oxidative delignification of coniferous kraft cellulose with bleaching with stabilized H_2O_2 as bleaching agent. The experimental kinetic data and polychronous kinetic approaches allow a description and a forecast of delignification processes in microheterogeneous lignocellulose matrix. As can be seen from Fig. 1, the kinetic points evaluated from Eq. (3) are in good agreement with the experimental data.

CONCLUSIONS

(1) It was established in a study of oxidative delignification of kraft coniferous cellulose with hydrogen peroxide at 60–100°C that the process is polychronous and does not go to completion. Residual lignin macromolecules are kinetically nonuniform; they are characterized by a spectrum of activation energies and rate constants in the range from $\ln K_{min}$ (s^{-1}) equal to 48.3–171 to $\ln K_{max}$ (s^{-1}) equal to 4.6–8 (kJ mol)/RT. It was shown that $\ln K^0_{eff}$ and E_{eff} are related by a linear compensation dependence.

(2) It was foun that the kinetic nonequivalence of active centers, estimated from the parameter $S = \ln(K_{max}/K_{min})$ and E_{eff} value for all the ensembles of lignin macromolecules, decreases with increasing temperature. This suggests that there occurs a temperature rearrangement (defrosting) of the polymer lignocellulose matrix, accompanied by increase in the maximum degree of conversion, corresponding to kinetic termination of delignification of coniferous kraft cellulose in bleaching with hydrogen peroxide.

Abstract—Conditions were found for separating concomitant substances from cellulose in short flax fibers by treatment with surfactant and enzyme solutions. The chemical composition of the treated fibers was analyzed, and their structural organization was studied by IR Fourier spectroscopy.

The rise in production of linen textiles, observed in recent years, is accompanied by accumulation of wastes, such as short flax fibers and hardwood part of flax pedicels (boon). Short flax fibers can be used in textile industry instead of cotton fibers and in chemical industry as a raw material alternative to cotton linter.

There are two approaches to use of flax fibers in textile industry. The first approach is to develop appropriate equipment, which is very expensive. The second approach is to modify the properties of flax fibers (thickness, length, etc.) with the aim to process them on the existing equipment developed for cotton fibers.

One of the main problems that arises in utilization of flax fibers in chemical industry is their treatment to remove concomitant substances. Flax fibers differ from cotton fibers in the geometric parameters and chemical composition. Flax fibers, compared to cotton fibers, contain a considerably greater amount of fats, pectins, hemicelluloses, and lignin [1]. The concomitant substances can be removed by chemical, biochemical, and physicochemical methods.

Lignin can be removed from flax fibers by alkali treatment (by analogy with production of cellulose from wood). Pectin substances can be removed or recovered with aqueous solutions of mineral and organic acids, or of alkalis [2]. Fats and waxy substances are removed by treatment of fibers with organic solvents (ethanol, ethanol–benzene mixture) [3]. These compounds can also be removed by treatment of fibers with enzyme solutions. The latter procedure is preferable from the environmental viewpoint.

It is of scientific and practical interest to develop processes for treatment of bast fibers with the minimum use of organic solvents. In this study, we made a comparative analysis of biochemical and physicochemical procedures for removal of lignin, fats, and pectin substances from flax fibers with the aim to obtain purified fibers suitable for use in textile and chemical industries.

EXPERIMENTAL

As starting material we used short flax fibers with the degree of polymerization (DP) of cellulose equal to 1700, as determined viscometrically from the intrinsic viscosity [η] of cellulose in Cadoxen: $[\eta] = 7.0 \times 10^{-3}(DP)^{0.9}$ [4].

To separate concomitant substances from cellulose, we used Stearox nonionic surfactant and Celloviridin G2kh complex preparation (Promferment Ltd., preparation no. 1-67.2). Celloviridin is an ultraconcentrate of the culture medium of *Trichoderma reesei* fungus producing a complex of carbohydrases: cellullases, β-glucanases, xylanases, and pectinases. The CMCase (cellulase) activity of the preparation was 3000 units ml^{-1}; β-glucanase activity, 4100 units g^{-1}; xylanase activity, 2900 units g^{-1}; and polygalacturonase (pectinase) activity, 500 units g^{-1}. The activities were determined from the initial rate of hydrolysis of carboxymethyl cellulose (CMC), barley β-glucan,

Composition of the initial flax fibers before and after treatment with surfactant and Celloviridin G2kh solutions

Treatment	Component composition of fiber, wt %				
	cellulose	pectins	fats, waxes	other hemicelluloses	lignin
No treatment	68.8	5.4	5.2	11.1	9.5
0.1 M acetate buffer, pH 5.0	68.2	4.9	4.9	12.7	9.3
Celloviridin G2kh (1 ml/100 ml buffer)	67.8	3.5	4.6	15.5	8.6
Celloviridin G2kh (2 ml/100 ml buffer)	67.7	3.4	4.1	16.2	8.5
Celloviridin G2kh (4 ml/100 ml buffer)	66.9	3.2	4.3	17.3	8.3
Stearox surfactant	70.4	4.3	3.7	12.8	8.8

birch xylan, and polygalacturonic acid, respectively (according to the procedures described in [5]). The fibers with Celloviridin G2kh were treated at 50°C and pH 5.0 (0.1 M acetate buffer) for 1 h. Celloviridin G2kh was used as 1, 2, or 4 vol % aqueous solutions. The fibers were treated with a surfactant solution at the boiling point for 1 h.

The short fibers were preliminarily analyzed to determine the component composition (see table). The cellulose content was determined by the Kürschner–Hoffer method; lignin content, by the Komarov method [3]; fat and moisture content, according to [2, 3]; and pectin content, by the calcium pectate method [2]. After treatment of the fibers with surfactant and Celloviridin solutions, the fibers were washed with distilled water and dried at 105°C, and then the content of cellulose and residual impurities (lignin, pectins, fats, hemicelluloses) was determined.

The structural changes occurring in flax fibers upon treatment with surfactant and enzyme solutions were monitored by IR Fourier spectroscopy. The spectra of cotton fibers pelletized with KBr were recorded on a Bruker FS-88 spectrometer.

The chemical compositions of fibers after various treatments are listed in the table. Since Celloviridin G2kh was taken in a buffer solution, we also checked in a blank experiment whether treatment with a straight buffer solution (0.1 M acetate buffer) affects the component composition of the fibers; no significant changes were revealed upon such a treatment.

Treatment of the flax substrate with Celloviridin G2kh solutions makes higher the content of hemicelluloses, which is due to the capability of enzymes to break down not only components characteristic of the given enzyme but also cellulose and concomitant compounds. Treatment with a surfactant solution involves a minimum degradation of cellulose. Treatment of flax fibers with enzyme solutions results in a partial removal of lignins, pectins, and waxes. With increasing concentration of Celloviridin G2kh working solutions, the lignin content decreases insignificantly, whereas the content of hemicelluloses grows from 11.1 to 17.3 wt %. After treatment of the fibers with the 4 vol % enzyme solution, the DP of cellulose decreased from 1700 to 1320. The Celloviridin G2kh solutions are more effective in removal of pectins.

Treatment with a surfactant solution results in the most complete removal of fats; lignin and pectins are removed partially. The content of hemicelluloses slightly increases. The results of chemical analysis, indicating that treatment with the enzyme and surfactant solutions results in a partial removal of fats and pectins, are confirmed by IR spectroscopy.

Figure 1a shows the IR Fourier spectra of the initial flax fibers and those treated with Celloviridin G2kh solutions. The IR spectrum of purified (whitened) cotton linter is shown for comparison.

Purified cotton cellulose exhibits a broad absorption band in the range 3000–3700 cm^{-1} (free OH groups of the polymer and those involved in intra- and intermolecular hydrogen bonds) and a band at 2900 cm^{-1}, which belongs to the CH_2 and CH groups of the oligomers; in the spectrum of pure cellulose, the latter band is symmetrical [6].

The IR spectra of crude wood cellulose and cellulose from flax pedicels contain characteristic lignin absorption bands at 1600, 1500, and 850 cm^{-1} [6]. In the samples of flax fibers, only the band at 820–830 cm^{-1} is well defined. The absence of bands at 1600 and 1500 cm^{-1} may be caused by considerably lower content of lignin in flax fibers, compared to the hardwood part (boon), and also by differences in the chemical composition of lignin in wood celluloses of different origins. The IR spectra allow qualitative detection of impurities in cellulose.

The characteristic bands of pectins are those at 1740 (free COOH groups of polygalacturonic acid),

1615, and 1410 cm^{-1} (symmetric and antisymmetric stretching vibrations of ionized COO^- groups). In the range 2850–2950 cm^{-1}, pectins exhibit one or two broad bands associated with CH_2 and CH groups [7]. Figure 1b shows on the enlarged scale the characteristic fragments of the IR spectra (1500–1800 and 2800–3000 cm^{-1}).

The IR spectrum of crude flax fibers contains an absorption band at 1740 cm^{-1}, which suggests the presence of pectins, and bands at 2920 and 2850 cm^{-1}, assignable to pectins and fatty acids. The presence of lignins may be judged by comparison of the IR spectra of crude flax fibers and whitened cotton cellulose. In contrast to cotton, all samples of flax fibers have IR spectra that contain a band at 820–850 cm^{-1}, which suggests the presence of lignin.

Treatment of fibers with a surfactant solution (Figs. 1a, 1b, spectrum *3*) affects the shape of the band at 2900 cm^{-1} (it becomes more symmetrical); the bands at 1740 and 820 cm^{-1} are preserved, which suggests that pectins and lignin are removed incompletely. Pectin substances are present not only in intercellular laminas but also in the primary wall of a single fiber. Therefore, more severe conditions are required to remove pectins binding single fibers of flax into bundles. Such a treatment, however, may cause appreciable degradation of cellulose.

The IR spectra of fibers treated with Celloviridin G2kh solutions of various concentrations only slightly differ from that of the initial flax fibers. The decreased intensity of bands characteristic of lignin, pectins, and fats is due to partial removal of these substances. The increased content of cellulose in the fibers is suggested by a more symmetrical shape of the band at 2900 cm^{-1} (for purified cellulose, this band is almost symmetrical [6]).

From the IR data, we can calculate the so-called crystallinity index of cellulose I_{cr} as the intensity ratio of the bands at 1372 and 2900 cm^{-1}, I_{1372}/I_{2900} [8]. This ratio correlates with the degree of ordering (or cristallinity) evaluated by X-ray diffraction. Since the cellulose samples were prepared for IR measurements under standard conditions (pelletization with KBr), this procedure can be used to reveal changes in the structural ordering of cellulose macromolecules after treatment of the fibers with various agents.

To evaluate the contribution of pectin substances to the absorption at 2900 cm^{-1}, used for calculating I_{cr}, we measured the IR spectra of milled purified cotton cellulose, pectin, and a model blend of cotton cellulose with 5 wt % pectin (Fig. 2). The bands at 2915

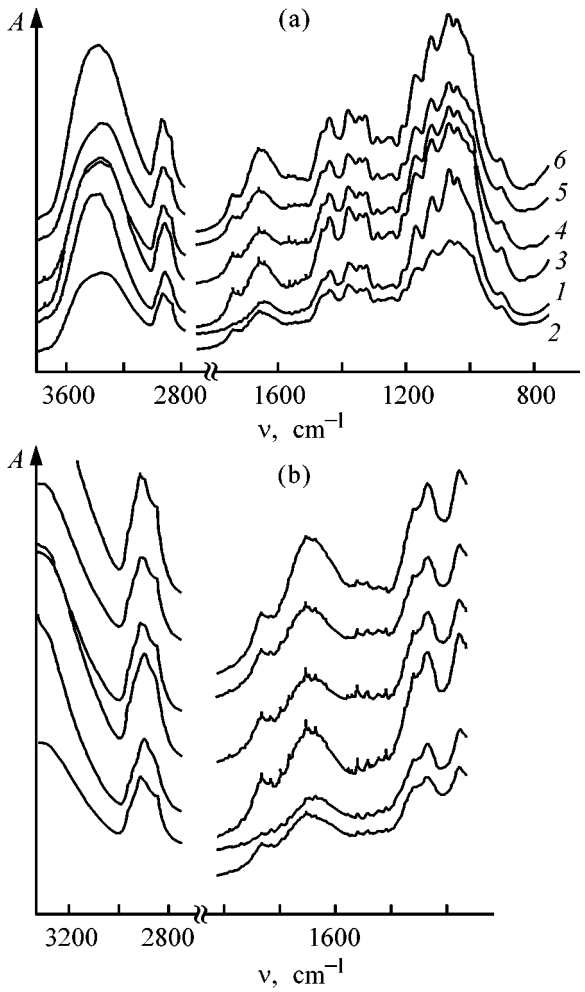

Fig. 1. IR Fourier spectra of (*1*) cotton linter fibers, (*2*) crude flax fibers, (*3*) flax fibers treated with Stearox surfactant, and (*4*–*6*) flax fibers treated with a solution of 1, 2, and 4 ml of Celloviridin G2kh, respectively, in 100 ml of 0.1 M acetate buffer (pH 5.0). (a) Total spectrum and (b) characteristic fragments (enlarged). (*A*) Absorption and (ν) wave number; the same for Fig. 2.

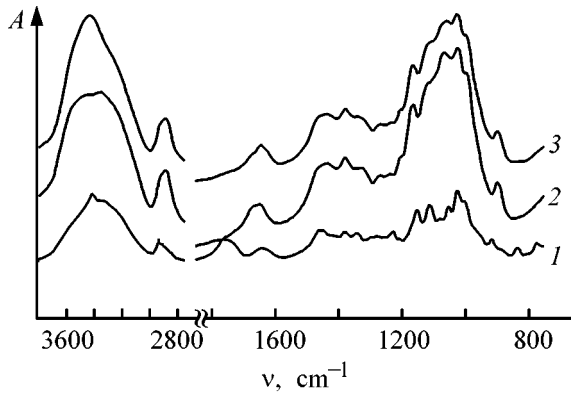

Fig. 2. IR Fourier spectra of (*1*) purified pectin, (*2*) cotton linter, and (*3*) a model blend of cotton linter with 5 wt % pectin.

and 2950 cm^{-1} observed in the IR spectrum of pectin do not make an appreciable contribution to the absorption at 2900 cm^{-1} in the spectrum of the blend. Indeed, the I_{cr} values calculated from the IR spectra of pure cellulose (0.44) and its blend with pectin (0.43) virtually coincide.

The crystallinity index of whitened cotton cellulose and crude flax fibers (Fig. 1a) is 0.64 and 0.54, respectively. After a treatment of the fibers with a surfactant solution, I_{cr} increased to 0.71. A treatment of the fibers with the enzyme solution (1 ml/100 ml buffer) increased I_{cr} to 0.83. However, as the enzyme concentration was raised further (2 and 4 ml/100 ml buffer), I_{cr} decreased to 0.64 and 0.60, respectively. The increase in I_{cr} upon treatment of flax fibers with surfactant and 1 vol % Celloviridin G2kh solutions and the decrease in I_{cr} upon treatment of the fibers with more concentrated enzyme solutions suggest that two processes occur. Partial removal of fats, pectins, and lignin results in that I_{cr} increases. However, further increase in the enzyme concentration accelerates the degradation of cellulose, which leads to disordering of the polymer macromolecules and formation of hemicelluloses having mainly amorphous structure. Thus, in treatment of flax fibers with surfactant and Celloviridin 2Kh solutions, it is necessary to find the optimal conditions under which the concomitant substances are partly removed from the fiber surface with minimum degradation and disordering of the cellulose macromolecules.

CONCLUSION

Treatment of short flax fibers with solutions of Stearox surfactant and Celloviridin G2kh complex enzyme preparation causes partial removal of concomitant substances (fats, pectins, lignin) from cellulose. However, treatment of fibers with Celloviridin G2kh solutions also causes an increase in the content of hemicelluloses and disordering of cellulose macromolecules.

Abstract—The activities and activity coefficients of the components of the system $NaNO_2$–$NaNO_3$, obtained from experimental saturated vapor pressures measured at 798, 823, and 848 K, were used to calculate the total and excess partial molar Gibbs energies $\Delta\overline{G}_i$, $\Delta\overline{G}_i^{ex}$, entropies $\Delta\overline{S}_i$, $\Delta\overline{S}_i^{ex}$, and total relative and excess thermodynamic properties ΔG, ΔG^{ex}, ΔS, ΔS^{ex} of the system.

Formation of a melt from pure components is accompanied by a change in the thermodynamic functions that characterize the given system. Of particular interest are changes in the Gibbs energy (ΔG), enthalpy (ΔH), and entropy of mixing (ΔS). If these quantities are known, the structure of the system and forces of ion–ion interaction between the components can be characterized.

The activities α_i and activity coefficients γ_i of the components of the system, determined by measuring the saturated vapor pressures [1–3], were used to calculate the total partial molar and excess partial molar Gibbs energies [4] for sodium nitrite and nitrate.

$$\Delta\overline{G}_i = 2.3RT \log \alpha_i,$$

$$\Delta\overline{G}_i^{ex} = 2.3RT \log \gamma_i.$$

The results of the calculation are listed in Table 1.

90	3.39	3.34	3.13	1.26	1.15	0.82	4.25	4.06	3.69	1.58	1.39	0.97

The resulting total and excess partial molar Gibbs energies were used to calculate the corresponding integral values

$$\Delta G = x_1\Delta\bar{G}_1 + x_2\Delta\bar{G}_2,$$

$$\Delta G^{ex} = x_1\Delta\overline{G_1^{ex}} + x_2\Delta\overline{G_2^{ex}},$$

where x_1 and x_2 are the mole fractions of $NaNO_2$ and $NaNO_3$ in the binary system.

The results of this calculation are listed in Table 2 and shown in Fig. 1a. The dashed line in Fig. 1a (curve *5*) represents the change in the integral molar Gibbs energy of the ideal system at a temperature of 798 K.

The partial molar total and excess entropies of mixing of $NaNO_2$ and $NaNO_3$ in their binary system were calculated [5]

$$\Delta\bar{S}_i = -2.3R\log\alpha_i,$$

$$\Delta\overline{S_i^{ex}} = -2.3R\log\gamma_i.$$

The results of this calculation are listed in Table 1.

These values of $\Delta\bar{S}_i$ and $\Delta\overline{S_i^{ex}}$ were used to calculate the integral molar total and excess entropies [5] for the system $NaNO_2$–$NaNO_3$

$$\Delta S = x_1\Delta\bar{S}_1 + x_2\Delta\bar{S}_2,$$

$$\Delta S^{ex} = x_1\Delta\overline{S_1^{ex}} + x_2\Delta\overline{S_2^{ex}}.$$

The results of this calculation are listed in Table 2.

Figure 1b shows the integral molar total and excess entropies for the system $NaNO_2$–$NaNO_3$. The dashed curve *5* shows how the integral entropy of mixing of the ideal system [5] varies at a temperature of 798 K.

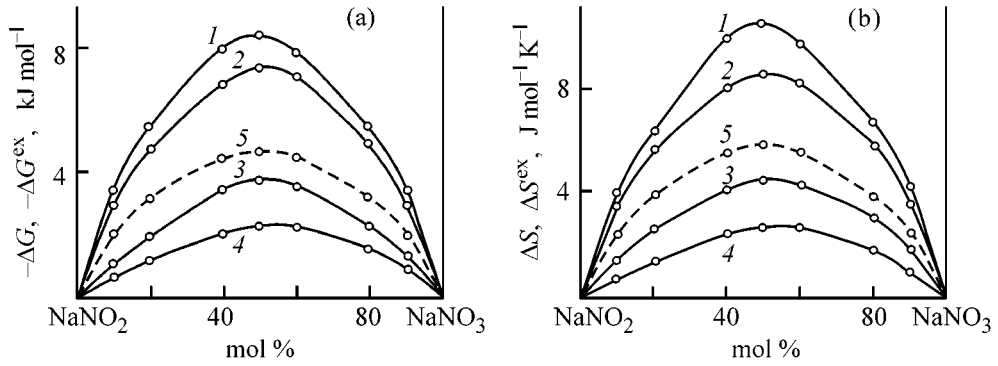

Fig. 1. (a) (*1*, *2*) Total and (*3*, *4*) excess integral molar Gibbs energies ΔG, ΔG^{ex} and (b) entropies of mixing ΔS, ΔS^{ex} for the system $NaNO_2$–$NaNO_3$. Curve *5*: (a) integral molar Gibbs energy and (b) entropy of mixing for the ideal system at 798 K. Temperature (K): (*1*, *3*) 798 and (*2*, *4*) 848.

As can be seen from Fig. 1a, the curves that represent the integral total and excess molar Gibbs energy exhibit negative deviations from the ideal behavior and a minimum at 50 mol %. The integral curves of the relative and excess molar entropies of mixing (Fig. 1b) exhibit positive deviations from the properties characteristic of the ideal system and a maximum at the same composition.

Such a behavior of the integral thermodynamic systems indicates that the arrangement of component species in the system under study is ordered to a certain extent.

The system $NaNO_2$–$NaNO_3$ shows larger negative deviations from ideality, compared with the previously studied system $NaNO_2$–KNO_3 [6]. Probably, this circumstance can be accounted for by the fact that the components $NaNO_2$ and $NaNO_3$ form a continuous series of solid solutions and a chemical compound, $2NaNO_2 \cdot 3NaNO_3$ [7], which does not decompose completely upon melting, but still exists in the form of complex ions [8].

BRIEF COMMUNICATIONS

Some Aspects of the Adhesion Compatibility of Hydrophobic and Hydrophilic Medicinal Materials

G. U. Ostrovidova, E. V. Zamyslov, and A. V. Makeev

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received March 31, 2004

Abstract—The hydrophilicity and hydrophobicity of surfaces was studied after their treatment with solutions of NaOH and polyethylene.

The initial stage in design of medicinal composite materials consists in solving the problem associated with ensuring the adhesion compatibility of their constituent ingredients having different structures and surface properties, e.g., polymer–polymer, polymer–carbon, polymer–metal [1, 2].

The aim of this study was to solve the problem of adhesion compatibility between the hydrophobic surface of the composite based on polysiloxane of medical purity ($PDMS_{med}$) and bulk-modified with graphite of S-1 brand [3] and the hydrophilic polyvinyl alcohol (PVC) film coating deposited on the surface of the composite in an electric field [4].

EXPERIMENTAL

In order to enhance the biocompatibility of the composite [3], a hydrogel PVC coating was formed on its surface in an ac electric field with ultralow frequency (meander-type signal) [4, 5]. A polyvinyl alcohol of medical purity [TU (Technical Specification) 605-05-26–75) was used for this purpose. As cross-linking agent served glutaric aldehyde (GA) and boric acid. Glycerol was introduced to ensure plasticity.

The coating was formed in an electric field with the simultaneous immobilization of biologically active (trypsin, a proteolytic enzyme), medicinal (heparin, an anticoagulant; various antibiotics), and other substances, which made it possible to extend considerably the range of medical-biological properties of the starting material [4, 5].

To improve the adhesion of the hydrophilic polymer film coating to the hydrophobic surface of the composite, it was preliminarily treated with 5 and 10 M aqueous solutions of NaOH (special-purity grade) at 60–70°C for 2 h or with a 0.1–0.5% aqueous solution of polyethylene imine (PEI). Then the samples were washed with distilled water and dried at room temperature for 24 h.

X-ray photoelectric spectra (XPS) of the composite were measured on an ESCA LAB-5 spectrophotometer with excitation by Al_{K_α} radiation (Mekhanobr Research-and-Production Association). The accuracy with which the peak positions were determined was ± 0.1 eV. The accuracy of quantitative analysis was 10%.

The adhesion of the hydrogel polymeric film coating to the surface of the composite was evaluated by the method of lattice cuts [6] [GOST (State Standard) 15140–78].

As revealed in a study of the adhesion, raising the concentration of the NaOH solution used to treat the surface of the composite to more than 5 M has no essential effect on the adhesion compatibility of the materials in question, even though this leads to a considerable increase in the number of reactive hydroxy groups on the surface and in their penetration into the material. In addition, use of a 10 M NaOH solution causes changes in the microprofile of the surface of the composite, i.e., makes more pronounced its roughness, which adversely affects the hemocompatibility of the material.

Table 1. Properties of the composite upon treatment of its surface with NaOH and PEI solutions (content of graphite 50 wt parts)

Material	Contact wetting, angle, deg	Electrical resistance, Ω m
Initial	72 ± 2	10^7
After treatment:		
with a 5 M NaOH solution	65 ± 2	10^6
with 0.5% PEI solution	70 ± 2	10^8

A preliminary treatment of the surface of the composite with PEI or NaOH solutions markedly raises the adhesion of the PVC film coating to the surface of the composite to 1 point.

The changes in some surface properties of the composite upon its treatment with NaOH or PEI solutions are illustrated by the data in Table 1. It can be seen that the electrical conductivity of the material increases by an order of magnitude upon its treatment with a 5 M NaOH solution, the wettability of the surface of the composite also grows. At the same time, treatment with a PEI solution makes higher its electrical resistance and changes its hydrophobicity only slightly. In this case, the adhesion of the hydrogel polymeric coating to the hydrophobic surface of the composite increases because of the hydrogen bonding and action of van der Waals forces [7, 8].

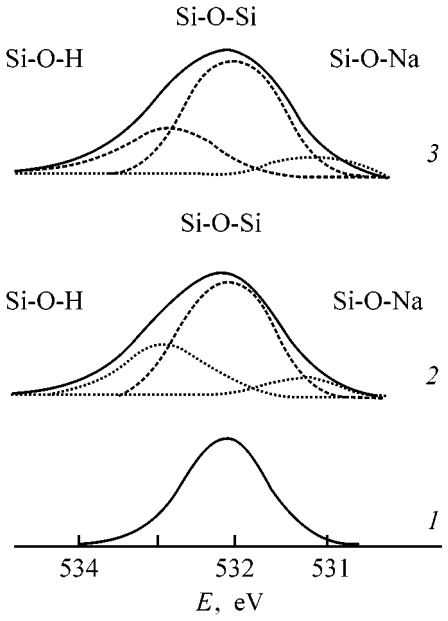
To reveal the reasons for the adhesion compatibility of the hydrophobic and hydrophilic surfaces, samples of the material were studied by XPS spectroscopy. XPS spectra of the surface of the composite, treated with a 5 M NaOH solution, are shown in the figure. For all of the samples, a peak at E = 532 eV is observed, which is related to the ≡Si–O–Si≡ bond (Figure, spectra *1–3*). Treatment with a NaOH solution gives rise to new peaks at E = 533 and 531 eV, which are associated with the ≡Si–OH and ≡Si–O–Na groups, respectively (see figure, spectrum *2*). In the course of a 2-h treatment of the composite, the following reactions occur on its surface [1]:

$$\equiv Si–O–Si\equiv + NaOH \rightarrow \equiv Si–OH + \equiv Si–O–Na, \quad (1)$$

$$\equiv Si–O–Na + H_2O \rightarrow \equiv Si–OH + NaOH. \quad (2)$$

The decrease in the intensity of the peak (E = 533 eV) associated with the ≡Si–OH group, observed upon deposition of a hydrogel layer on the surface of the composite (figure, spectrum *3*), suggests that polyvinyl alcohol chemically interacts, in the presence of glutaric anhydride, with hydroxy groups on the surface of the material, which appear upon treatment with a NaOH solution [9, 10].

The thus formed material was tested, as also were the starting components (composite and PVC film), for thromboresistance in *in vitro* experiments. The hemocompatibility of the surface of the materials obtained was evaluated by the method of activated partial thromboplastin time (APTT) [11]. A study of the thromboresistance of the resulting material by measuring the rate of coagulation of a plasma containing the basic coagulating proteins, brought in contact with various surfaces, demonstrated that materials with a hydrogel coating on a hydrophobic substrate do not activate thrombus formation (Table 2). The $PMDS_{med}$ shows an insignificant coagulation. The composite has better parameters, and the presence of a hydrophilic surface-type polymeric structure that is compatible with the hydrophobic surface of the composite makes this effect less pronounced, i.e., improves the hemocompatibility. This fact indicates that polymeric structures based on water-soluble polymers exert a positive influence on the interaction of blood with a foreign material. The hemocompatibility of the material can be considerably improved by introducing trypsin into



XPS spectra of composites. (*E*) Binding energy. (*1*) Before treatment, (*2*) after treatment with NaOH, and (*3*) with a PVC coating.

Table 2. Results of a study of a polysiloxane caoutchouc and the composite in combination with a hydrogel film coating (content of graphite 50 wt parts)

Material	APTT parameters, s	
	before incubation with the material	after incubation
$PDMS_{med}$, initial composite:	45	35
initial	45	44
treated with PEI, with a PVC+H_3BO_3 coating containing trypsin	45	55
treated with 5 M NaOH	45	>600
solution, with PVC coating containing heparin		
PVC film with heparin, formed in the electric field of a silicon wafer	45	>600

film coatings, and the effect exerted by the presence of heparin, an anticoagulanting agent, is apparent.

CONCLUSIONS

(1) It was established that the appearance of reactive hydroxy groups on the surface of the composite upon its preliminary treatment with a NaOH solution, and the resulting increase in hydrophilicity and electrical conductivity, make it possible to ensure the adhesion compatibility of the constituent ingredients of the composite obtained, which have different structural and surface properties, without changing the physicomechanical properties of the material.

(2) The compatibility of the hydrophilic and hydrophobic surfaces is provided by chemical bonding in the case of treatment of the latter with a NaOH solution in the presence of glutaric aldehyde in the polymeric coating and by van der Waals forces in treatment with a polyethylene imine solution.

(3) The materials obtained were tested in *in vitro* experiments and demonstrated a high level of thromboresistance.

ACKNOWLEDGMENTS

The authors thank A.V. Shchukarev and O.A. Bueva for assistance in certain experiments.

The study was supported by a Presidential Grant of the Russian Federation "Leading Scientific Schools of Russia," project NSh 2236.2003.3 "Chemistry of Highly Organized Substances."

BOOK REVIEWS

Kozin, L.F. and Volkov, S.V., *Khimiya i tekhnologiya vysokochistykh metallov i metalloidov* (Chemistry and Technology of High-Purity Metals and Metalloids), in 2 vols.: vol. 1, *Khimicheskie i elektrokhimicheskie metody glubokoi ochistki* (Chemical and Electrochemical Methods for Deep Purification, Kiev, Naukova dumka, 2002, 540 pp.; vol. 2, *Fiziko-khimicheskie i kristallizatsionnye metody glubokoi ochistki* (Physicochemical and Crystallization Methods for Deep Purification), Kiev: Naukova dumka, 2003, 350 pp.

The two-volume monograph devoted to methods for obtaining high-purity metals was written by professor L.F. Kozin and S.V. Volkov, an academician of the National Academy of Sciences of the Ukraine, who are well-known Ukrainia specialists in this field. High-purity metals and metalloids largely determine the development of quite a number of new fields of science and technology and branches of industry. The world's technological practice has produced a vast body of evidence concerning methods for obtaining high-purity metals and metalloids (with total impurity content of less than 1×10^{-5} wt %.

The first volume of the monograph comprises a foreword, introduction, three chapters, bibliographic list, and subject index. The foreword written by corresponding members of the National Academy of Sciences of the Ukraine, A.G. Belous and O.G. Zarubitskii, points to the importance of the problem under discussion. Rather stringent requirements to the purity of materials are imposed by nuclear and semiconductor industries: the total content of impurities should be on the order of 10^{-5}–10^{-6} and 10^{-7}–10^{-9} wt %, respectively. Of particular importance is the purity of metals for nanotechnologies, which are being developed all over the world. The brief introduction (pp. 5 and 6) outline the variety of elements whose deep purification is discussed in the first and second volumes of the monograph.

The first chapter of the first volume (pp. 7–33) presents a general information. It considers the main application fields of high-purity metals and metalloids, requirements imposed on their purity, accepted classifications of high-purity materials, and methods for analytical determination of their impurity content. Inversion voltammetry, whose theoretical foundations are being successfully developed in our country by A.G. Stromberg and his school, neutron-activation analysis, various spectral methods, and mass-spectrometry are discussed in the chapter. The second chapter (pp. 34–161) describes chemical methods for deep purification of metals and metalloids. These methods are based on chemical reactions in which substances are converted, with the accompanying impurities separated to give a high-purity main substance. A high separating capacity is characteristic of processes in which nonvolatile and volatile hydrides are formed, reactions of formation of organometallic compounds, and carbonyl processes. A considerable attention is given to halide processes; a hydrochemical technique for purification of simple and compound substances is considered. The theoretical foundations of all these methods are presented and particular examples are given.

The third chapter of the first volume (pp. 162–492) occupies in it the central position and contains evidence about the electrochemical methods for deep purification of metals and metalloids. The efficiency of deep purification by methods of this group primarily depends on the difference in the electrode potentials between the main component and the accompanying impurities. The same factor strongly affects the choice of an appropriate electrochemical refining technique. The authors analyze in detail the standard electrode potentials in aqueous solutions for a great number of electrochemical systems and discuss the influence exerted by various factors on the potentials. The kinetics of processes involving many-electron electrode reactions is described for specific examples. Anodic and cathodic processes involving bismuth, indium,

1070-4272/04/7710-1739 © 2004 MAIK "Nauka/Interperiodica"

gallium, tin, and iron and their ions in various states of oxidation are discussed in ample detail. The authors are mostly based on the results of their own studies. The fundamental aspects of electrodeposition and anodic dissolution of lead in various electrolytes and the electrochemical behavior of mercury have been described previously in special monographs [Kozin, L.F. and Morachevskii, A.G., *Fiziko-khimiya i metallurgiya vysokochistogo svintsa* (Physical Chemistry and Metallurgy of High-Purity Zinc), Moscow: Metallurgiya, 1991, 224 pp.; Kozin, L.F., *Fiziko-khimiya i metallurgiya vysokochistoi rtuti i ee splabvov* (Physical Chemistry and Metallurgy of High-Purity Mercury and Its Alloys), Kiev: Naukova dumka, 1992, 564 pp.] and are virtually not discussed in the book under consideration. The available published data on the kinetics and mechanism of discharge and ionization of zinc and on the electrochemical behavior of copper, silver, cadmium, palladium, rhodium, and gold are analyzed. It should be noted that the electrodeposition and dissolution of metals forming ions in various oxidation states have been the subject of a special monograph written by Kozin [Kozin, L.F., *Electroosazhdenie i rastvorenie mnogovalentnykh metallov* (Electrodeposition and dissolution of Polyvalent Metals), Kiev: Naukova dumka, 1989, 464 pp.]. The third chapter contains evidence about the kinetics and mechanism of the cathodic dissolution of metalloids: selenium, tellurium, arsenic, germanium, and antimony. In cathodic polarization of these elements in aqueous solutions, they are mostly reduced to hydrides. For example, selenium and its compounds can be reduced at the cathode in acid and alkaline media to give selenide ions Se^{2-}. The process of cathodic dissolution is strongly affected by the pH of the medium, material of the electrode, and potential of the cathode.

The same chapter (vol. 1, chapter 3) discusses the separation coefficients in purification of metals by electrochemical methods and, in particular, purification of metals by single-stage electrolysis with solid electrodes (zinc, cadmium, indium, thallium, silver, gold, palladium). To purify some metals, it is advisable to use singlestage electrolysis with liquid electrodes. Mercury is the most frequently used as a solvent for producing a liquid anode. This is a basis of the so-called "amalgam metallurgy." Also possible is use of gallium or low-melting formulations composed of a number of metals. Methods of the amalgam metallurgy can be used to purify zinc, cadmium, gallium, indium, and thallium to a rather high extent. In refining of tin, it is advisable to use the Wood alloy as a solvent for producing a liquid anode. The final part of the chapter is devoted to many-stage processes of deep purifica-tion of metals by electrolysis with liquid bipolar electrodes (zinc, cadmium, mercury, gallium, indium, thallium, tin, lead, bismuth). A special section of the chapter is concerned with deep purification of metals by reactive electrolysis. This technique is based on binding of impurities into electrochemically inactive compounds upon addition of some elements, as a rule, nonmetals. For example, introduction of sulfur, selenium, tellurium, or silicon into a metal being purified (lead, bismuth, cadmium, tin, indium, etc.) results in that the impurities contained in the metal form chalcogenides or silicides, being thus converted into an electrochemically inactive state. The impurities bound into chemical compounds are virtually not involved in the transfer of a metal being refined from the anode to the cathode.

Application of hydride electrochemical methods is discussed for the case of selenium, arsenic, and germanium.

The bibliographic lists (pp. 493–533) are composed separately for each of the three chapters. The total number of references in the first volume of the monograph is 1707. The volume ends with a subject index.

The second volume of the monograph has the same structure as the first volume: it comprises an introduction, two chapters, conclusion, bibliographic list, and subject index. The introduction (pp. 3 and 4) notes that the authors were the first to generalize and systematize the evidence concerning the theory and practice of deep refining of metals and metalloids by distillation, rectification, sublimation, and crystallization methods. In view of the involvement of metal systems in a liquid state in these processes, the authors found it appropriate to pay a considerable attention to a thermodynamic description of liquid alloys based on lead, cadmium, zinc, indium, tin, and antimony. The first chapter (pp. 5–210) is named "Physical methods for deep purification of metals and metalloids." Taking into account the existence of quite a number of monographs and spacious reviews devoted to the subject, Kozin and Volkov chose for consideration, among a great number of physicochemical methods, only techniques based on distillation, rectification, and sublimation. They described in detail the theory and technology of deep purification of zinc, cadmium, selenium, and tellurium by distillation and rectification; deep purification of arsenic by sublimation, distillation, and rectification; and purification of scandium, yttrium, and rare-earth metals by sublimation and distillation.

The second chapter of the second volume (pp. 211–320) is devoted to crystallization methods for separa-

tion and purification. These techniques are based on recrystallization of the starting component from melts (melt–solid) in a certain (optimal) temperature mode. The crystallization methods are mostly applied to metals and metalloids in the final stage of purification (finishing purification). The authors describe the theoretical and technological aspects of the crystallization purification; purification of lead, aluminum, gallium, indium, and noble metals; and crystallization purification of metalloids: sulfur, selenium, tellurium, arsenic, and antimony.

In the conclusion (pp. 321–323), the authors once again call attention to the complexity of processes used for obtaining high-purity metals and metalloids. It is commonly accepted that every subsequent decrease in the content of impurities in a high-purity material by an order of magnitude leads to an increase in its production cost by a factor of 2–5. The conclusion is also given in English (pp. 324–326). The bibliographic list for chapters of the second volume containes 808 references.

The monograph by Kozin and Volkov presents a detailed analysis of a wide variety of methods for obtaining high-purity metals and metalloids. In most detail are described the electrochemical behavior of metals in aqueous media and electrochemical refining techniques. At the same time, an impression is created, when reading the book, that part of the material presented could be excluded from the monograph without any noticeable sacrifice of understanding of the processes under consideration. Taking into account the earlier review and monographic publications of the authors, it would be appropriate to present in a considerably more concise form the section devoted to the kinetics and mechanism of electrode processes involving polyvalent metals (pp. 173–298) in the first volume. In the second volume, the thermodynamic evidence (pp. 7–93) given without any authors' concept are virtually unused in the subsequent presentation. These and some other curtailments would make the monograph more concise and closer to the technological practice.

After the year of 1991, the science experiences severe difficulties in all countries of the former Soviet Union, including the Ukraine. The major contribution by the authors in these not simple conditions deserves a deep appreciation. The book is of interest for a wide audience of specialists who deal with electrochemistry of aqueous solutions and production of high-purity metals and metalloids by various methods.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Pyrochemical Processing of Tungsten- and Cobalt-Containing Raw Materials

O. G. Zarubitskii, V. P. Orel, and B. F. Dmitruk

Vernadsky Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received June 30, 2004

Abstract—A method for processing of secondary tungsten- and cobalt-containing materials is suggested. The optimal parameters of the processes involved and the consumption of chemicals are determined.

Processing of secondary tungsten-containing raw materials, and primarily the recovery of tungsten and cobalt from worn-out drilling and cutting tools, is an urgent problem.

Hydrometalurgical, pyrometallurgical, physical, and electrochemical methods for processing of tungsten–cobalt alloys of the VK type are known [1–5]. These processes are low-intensive, have low selectivity, and involve discharge of noxious substances (nitrogen oxides, hydrogen fluoride) into the atmosphere. The existing techniques are mainly applicable to processing of lump scrap of cutting tools, but show low efficiency in recovery of tungsten and cobalt from worn-out roller drill bits used in mining and geological prospecting. Chemical and electrochemical methods performed in melts based on alkali metal hydroxides show promise for processing of raw materials of this kind [6–12].

Of particular interest is recovery of tungsten from a tungsten-containing alloy by oxidative calcination. It has been suggested to perform this procedure at 780–820°C with subsequent leaching-out of tungsten compounds [13]. A technique for recovery of tungsten from lumps of high-alloy materials has been patented [14]. This technique consists in heating of the starting product in air at 800–900°C for 48 h followed by treatment of the oxidized products with a solution of an alkali metal hydroxide in an autoclave at 140–195°C for 6–10 h. The total duration of the process is 54–64 h.

EXPERIMENTAL

The method suggested for processing of worn-out roller drill bits (drilling tools) is based on oxidation of a hard composite alloy (tungsten carbide with a cobalt binder) in an air flow, mechanical disintegration of the brittle oxidized product, and removal of its residual amounts from sockets in an alkali melt.

Samples of the same type, 200–250-g fragments of roller drill bits, were used in the experiments. Each sample contained two picks made of a WC–Co hard-alloy formulation. Part of the samples contained picks 12 mm in diameter, embedded to a depth of 10 mm, and part, picks 8 mm in diameter, embedded to a depth of 5 mm. The roller drill bit from which the samples were cut was completely worn out: the picks were completely worn virtually to the level of the steel base. The samples were treated in a muffle furnace with apertures for in- and outflow of air. Air was pumped with a compressor through the aperture in the furnace at a flow rate of 10–30 l h^{-1}. The hydroxide melt was fused in a corundum crucible.

Worn-out roller drill bits were heated to 950–1050°C and kept in the furnace for a time sufficient for oxidation of the hard-alloy picks. The components of the hard alloy are oxidized by the reactions

$$WC + 2.5O_2 = WO_3 + CO_2, \quad (1)$$

$$CO_2 + Co = CoO + CO. \quad (2)$$

The oxidation product is formed as a kind of "columns" or "flowers" growing from the sockets and occupies a volume exceeding by a factor of 6 that of the initial hard alloy (Fig. 1). The above temperature interval is the optimal. At lower temperatures, the oxidation rate markedly decreases. The same occurs as the temperature is raised from 1050 to 1100°C, and upon further increase in temperature, the oxidation of

(a)

(b)

Fig. 1. Roller drill bit (a) before and (b) after oxidative calcination at 1000°C.

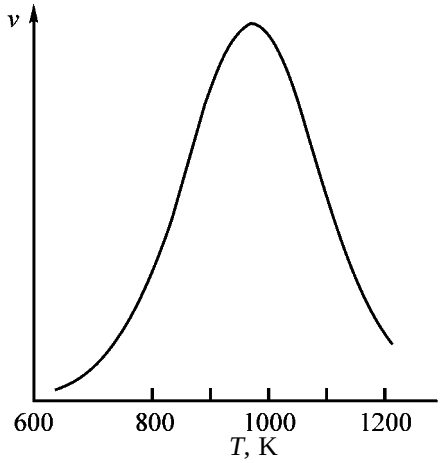

Fig. 2. Oxidation rate v of compact samples of the WC–Co alloy vs. temperature T.

the hard alloy is inhibited at all (Fig. 2). This is due to the formation on the pick surface of a thin dense layer of cobalt tungstate, preventing penetration of oxygen to the hard alloy. The tungstate is formed at approximately 1000°C by the reaction of tungsten(VI) and cobalt(II) oxides:

$$CoO + WO_3 \rightarrow CoWO_4$$

It was established experimentally that the rate of oxidation of VK alloys in air decreases at 1200°C by more than an order of magnitude, compared to 950–1050°C, with the reaction surface shielded by a layer of $CoWO_4$ (the salt was identified by X-ray phase analysis), in which the content of WO_3 is virtually zero.

The amount of oxygen theoretically necessary for oxidation of 1 kg of VK4, VK6, VK12, and VK15 alloys is 281, 279, 273, and 270 l, respectively. In terms of air, this amounts to 1.34–1.29 m^3. To ensure a high oxidation rate in practice, air is to be delivered at a 4–5-fold excess. For example, if oxygen is supplied at a fivefold excess, the volume V (m^3) of air, necessary for oxidation of hard-alloy picks in the roller drill bits, can be calculated by the formula

$$V = 66mc, \quad (4)$$

where m is the mass of roller drill bits (tons), and c is the average content of a hard alloy in the bits (%).

The rate of air delivery into the furnace, W ($m^3\ h^{-1}$), is given by

$$W = 66mc/\tau, \quad (5)$$

where τ is the duration of the stage of oxidation of hard-alloy picks (h).

The value of τ depends on the type of bits. In particular, picks inserted to a depth of 5 mm are completely oxidized in 4–5 h, and for those with insertion depth of 10 mm, the oxidation takes about 20 h.

Taking into account the consumption of atmospheric oxygen for oxidation of the hard alloy and, in part, for oxidation of the metal in the base of the roller drilling bits, it is desirable to maintain the content of O_2 in the outflowing air at about 12–16 vol %.

The mass of the oxidized product increases relative to that of the initial hard alloy by (%): 18.65 for VK4, 18.83 for VK6, 19.35 for VK12, and 19.63 for VK15. In calculating the heat balance of the furnace, it is necessary to take into account the fact that 5710–5950 kJ kg^{-1} is released as a result of chemical oxidation of the hard alloy alone.

After the oxidation of the hard-alloy picks is complete, the resulting oxidized product is disintegrated mechanically, for which purpose the roller drill bits

are subjected to one of the following types of treatment: barrel grinding, shot blasting, or water-jet treatment. The last two are preferable to barrel grinding. No less than 5/6 of the total mass of the oxidized product is disintegrated. The rest remains in the sockets.

The crushed mixture of tungsten and cobalt oxides with scale is subjected to magnetic separation. To diminish the capture of the oxides by the scale being separated, it is advisable to perform separation in an aqueous medium bubbled with air. This requires the subsequent settling, decanting, and drying of the finished product.

The oxidized product remaining in the sockets of roller drill bits is removed in a melt based on sodium hydroxide. To make lower the viscosity of the alkali melt, 4–8 wt % $NaNO_3$ and 1–3 wt % NaCl are introduced into the melt, so that it has the following composition (wt %): NaOH 89–95, $NaNO_3$ 4–8, and NaCl 1–3.

The drill bits are melt-treated at 450–550°C for 5–10 min. Tungsten(VI) vigorously reacts with the alkali by the reaction

$$WO_3 + 2NaOH = Na_2WO_4 + H_2O\uparrow. \quad (6)$$

The forming sodium tungstate has a high solubility in the melt. In processing of roller drill bits, the content of Na_2WO_4 is brought to 50–60 wt %, and after that the melt is discharged (cast into molds or iron drums). The solidified melt, which is an alkaline concentrate of sodium tungstate, is subjected to further processing [6]. In contrast to tungstic anhydride, cobalt oxide is only sparingly soluble in the alkali melt. Therefore, CoO precipitates in bath operation in the form of a slime, which is removed at regular interbals, together with the slime collector (pan), and directed to hydrometallurgical processing to give pure cobalt oxide [6].

CONCLUSIONS

(1) A method for processing of tungsten- and cobalt-containing secondary raw materials (roller drill bits) was suggested. This method includes the following main procedures: oxidative calcination at 950–1050°C and treatment in a NaOH–$NaNO_3$–NaCl melt at 450–550°C.

(2) An unusual effect of temperature on the oxidation rate of a hard-alloy formulation of the VK type (WC–Co) was observed. On heating the initial substance to 950–1050°C, the intensity of the process increases, but, on raising the temperature further, it falls dramatically because of formation on the sample surface of a dense layer of cobalt tungstate, which markedly hinders penetration of oxygen into the reaction zone.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Processing of Wastes from Manufacture of Cut Diamonds

O. G. Zarubitskii, B. F. Dmitruk, and N. M. Dyachenko

Vernadsky Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received June 23, 2004

Abstract—Test experiments on recovery and purification of diamonds in melts based on alkali metal hydroxides and ammonium hydrofluoride were carried out. A method for processing of diamond-containing materials is suggested and apparatus for implementing this technology is described.

Manufacture of cut diamonds from natural diamonds mainly involves their physical and mechanical treatments: cutting, grinding, and faceting. In the process, a significant part of the starting material is transformed into a waste in the form of fragments, chips, and dust. The existing process for recovery of diamonds from industrial waste consists in the following. Wastes collected from working places together with contaminants are subjected to magnetic separation and manual sorting. After that, the waste is burnt in special furnaces. The heavy and light fractions of the resulting ash are separated in bromoform ($CHBr_3$). The heavy fraction is processed in boiling solutions of acids: hydrochloric (1 : 1), nitric (1 : 1), and concentrated sulfuric. The total duration of such a treatment is 5–7 h. A dried residue is leached by fusing it with sodium hydroxide at 600°C and dissolving the fusion cake in hot water. The solid residue is again treated with HCl, washed, and dried, with undissolved impurities removed and diamonds divided into fractions manually. Thus, the existing process is low-intense and multistage and involves the use of boiling concentrated solutions of strong acids; moreover, more than 10% of the diamond material is lost through etching.

In this context, it seems appropriate to develop effective chemical solvents that would ensure dissolution of all foreign substances in the diamond-containing waste without etching of the diamonds themselves. Solvents of this kind were sought-for taking into account the properties of diamonds and the composition of industrial wastes from manufacture of cut diamonds.

It should be noted that the most difficultly soluble substances among the foreign impurities contained in the waste in question are carbon (graphite), corundum, carbides (e.g., SiC), quartz sand, and minerals [1]. Removal of metallic and organic components presents no special problems. Of certain interest in this context are data on purification of synthetic diamonds. Commonly, an agglomerate containing firmly bound graphite, diamonds, catalyst, carbides, and the material of the high-pressure container (aragonite, silicon dioxide, silicates) is removed from the reaction mixture in synthesis of diamonds [2]. The first stage of purification consists in dissolution of the catalyst and the carbide phase with acids or mixtures of these. In the second stage, graphite is selectively oxidized with various reagents. In the third stage, compounds that are insoluble in water, solutions of acids (with the exception of hydrofluoric acid), and alkalis are removed, if the content of these compounds exceeds 1% of the total mass [3].

It is known that acid solutions, suspensions, and melts of alkali metal hydroxides, nitrates, and carbonates can be used to separate graphite from diamonds [3, 4]. According to the available data, etching of diamonds in alkaline solutions becomes noticeable at about 600°C, although in some papers lower temperatures are indicated [5, 6]. Of the other molten media used for purification of diamonds, mention should be made of molten mixtures based on sodium tetrafluoroborate, sodium peroxide, and halides of alkali and alkaline-earth metals. The first of these melts ensures removal of silicates and alumina-containing wastes at 700–1000°C. However, the strength of diamonds decreases and their cracking is observed because of the high working temperature in this case. The second of the above melts is used to recover diamonds from diamond-containing wastes at glass works. Unfortunately, the quality of diamonds is also impaired upon a purification of this kind [7].

* In run nos. 1 and 2, the purification of diamonds is incomplete; in nos. 4–9, diamonds are etched; and in no. 3, diamonds are etched at incomplete purification.

EXPERIMENTAL

With account of the known data on the composition of solvents for processing of diamonds and diamond-containing mixtures, an attempt was made to use alkali and salt–alkali melts for recovery of diamonds from industrial wastes formed in manufacture of cut diamonds.

As additives to alkalis were used strong oxidizing agents: sodium and potassium nitrates, potassium persulfate and chromate, and sodium peroxide, as well as KCl and NaF. The range of working temperatures was 400–750°C. The results of selected experiments and conditions in which they were carried out are listed in Table 1. Similar results were obtained with molten potassium hydroxide and mixtures based on this compound. The treatment in melts was combined with that in an acid, hydrochloric or nitric. However, in no case could be simultaneously achieved the desired efficiency and quality of purification: at low temperatures, the process is insufficiently intensive, whereas at high temperatures and in the presence of an oxidizing agent, the quality of diamonds is impaired by their etching.

Having analyzed the possible solutions of the problem, we came to a conclusion that a low-temperature reaction medium is to be used in recovery of diamonds from wastes of jewel factories. As versatile solvent-reagent was taken ammonium hydrofluoride. The reactivities of aqueous solutions of NH_4HF_2 and of its melts were studied experimentally. It was established that ammonium hydrofluoride can vigorously react with metal oxides, including quartz, corundum, silicates, aluminosilicates, and, at elevated temperatures, even with carbon. The parameters of procedures used for treatment of diamond-containing wastes were chosen in solutions and melt of NH_4HF_2 at 100–200°C. Selected data are listed in Table 2. It can be seen that the intensity of impurity removal in a molten ammonium hydrofluoride grows as the temperature is raised. However, the volatility of the melt becomes noticeable at 175–180°C. Therefore, to preclude evaporation of NH_4HF_2, a new procedure was applied: its surface was covered with a layer of molten paraffin. It was established experimentally that effective purification of diamonds to remove foreign inclusions (impurities) should be performed at 140–200°C in the course of 1.5–3 h. No etching of the diamond surface occurs in this case.

Complete purification of diamonds also required an acid treatment in a boiling concentrated solution of HNO_3. The strongest effect was obtained upon direct dilution of the NH_4HF_2 melt (after the waste processing in this melt was complete) with hot (80–90°C) water taken in a 1 : 1 ratio. It was found that effective purification of diamonds is only achieved upon a combined treatment with the melt and the acid (Table 3). In this case, the duration of treatment in a solution of HNO_3 should be 1–1.5 h. The working capacity of the ammonium hydrofluoride melt was also determined experimentally. It was established that, for the process to be effective, the mass ratio of the melt and the raw material of process origin should be no less than 5 : 1.

The process developed in this study comprises the following steps: burning of the waste, separation of light fractions of the ash in bromobenzene, treatment of heavy fractions of the ash with molten ammonium hydrofluoride at 140–200°C for 1–3 h, dilution of the melt (fusion cake) with hot water taken in a 1 : 1 ratio, treatment of the dry residue with a boiling concen-

trated solution of HNO_3 for 1–1.5 h, washing, drying, and separation of diamonds into fractions.

The apparatus for performing this process includes a purification bath (electric furnace with a container for the melt and a unit for monitoring and maintaining the prescribed temperature) and baths with an acid and warm flowing water. To improve the purification efficiency, the bath with the melt is equipped with a device for rocking the wire basket in which the raw material to be processed is placed. The rocking is carried out at a frequency of 20–40 min^{-1} in the vertical direction. To collect slime, a pan with perforated side walls covered on the inside with a fine nickel mesh is placed on the bath bottom.

The process developed for recovery of diamonds from the waste formed in manufacture of cut diamonds is efficient, with virtually zero loss of the diamond material. This technique can be used to recover, together with other diamond fractions, diamond dust. In addition, the full process cycle is shortened, compared to that presently used in the industry, by a factor of approximately 2.

CONCLUSIONS

(1) An effective low-temperature melt based on ammonium hydrofluoride is suggested. This melt ensures removal of the most part of foreign inclusions present in diamond-containing wastes from manufac-

ture of cut diamonds. A procedure precluding evaporation of NH_4HF_2 from the melt surface was developed.

(2) A technique for obtaining pure diamonds from secondary raw materials, waste from manufacture of cut diamonds, was developed. The method suggested rules out any loss of the valuable material being recovered, with the duration of the process decreasing by a factor of approximately 2, compared to the existing industrial technique. An apparatus for performing the procedure is suggested.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Distribution Coefficients of Phenol between Water and Hydrocarbons at 283–328 K

I. E. Dobryakova and Yu. G. Dobryakov

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia

Received August 2, 2004

Abstract—Distribution of phenol between aqueous and organic phases at maximal dilution in the range 283–328 K was studied chromatographically. Ten systems containing saturated and aromatic hydrocarbons were examined.

The distribution coefficients of organic compounds in liquid–liquid systems are required for many purposes including development of extraction processes with organic solvents of various types and recovery, concentration, separation, and identification of substances. Distribution of a substance between immiscible solvents is determined by the difference in intermolecular interactions of this substance with the solvents. These interactions are studied by the solution theory. Ionization, hydration, and association constants [1–3] and activity coefficients [4] can be calculated form the distribution coefficients. Distribution coefficients in combination with gas chromatographic retention indices can be used to classify unknown organic compounds [5, 6]. Features of interphase distribution are extensively studied [7, 8]. The distribution coefficients are published in special handbooks [9, 10].

Phenol distribution in water–organic systems was extensively studied [11]. However, most of the distribution constants were measured at 20 ± 2°C. Data of different authors are sometimes inconsistent with each other. Many experiments were performed in acidified solutions and in solutions containing salt additives.

Improvement of procedures for determining distribution coefficients is also an urgent problem. Chromatographic analysis gives additional information on the presence of impurities, mutual solubility of the solvents, and occurrence of hydrolysis and other chemical reactions in the system [12].

The aim of this work was to develop a relatively simple and reliable chromatographic procedure for studying distribution of a low-volatile component between two phases and to determine the distribution coefficient of phenol between water and organic solvents at different temperatures. Saturated hydrocarbons (*n*-hexane, *n*-heptane, *n*-octane, and cyclohexane) and aromatic hydrocarbons (benzene, toluene, ethylbenzene, *o*-xylene, *p*-xylene, and *m*-xylene) were used as organic solvents. The distribution coefficients of phenol in 10 systems were measured at 10, 25, 40, and 55°C.

EXPERIMENTAL

The aqueous and organic phases were analyzed on a Multifract F-45 gas chromatograph (Perkin–Elmer, Germany) equipped with a flame ionization detector (FID). The samples were taken and injected in the chromatograph manually with the aid of a 10-μl Hamilton microsyringe. To keep the volume of injected liquid samples constant (2 μl), a special metal stop was fixed on the syringe rod.

The gas chromatographic analysis was performed under the following conditions: a 2-m metal column 3 mm in diameter was packed with Porapak P (50–80 mesh); flow rate of carrier gas (helium), hydrogen, and air was 25, 40, and 400 ml min^{-1}, respectively; the temperature of the column, detector, and injector was 200, 220, and 220°C, respectively; the detector sensitivity was 5×10^{-11} A; the analysis duration was 20 min. Under these conditions, the retention time of phenol is 13 min and its chromatographic peak is highly symmetrical. Each experiment was repeated at least four times. The electrical signal was treated with the aid of MultiChrom 1.5 for Windows software (Russia). The determination error of the peak area for the aqueous and organic samples was, on the average, 2 and 1.5%, respectively, and did not exceed 3%.

All organic solvents were distilled on a rotary distillation column with the 20 TP performance. The

1070-4272/04/7711-1750 © 2004 MAIK "Nauka/Interperiodica"

solvent purity was determined chromatographically. If the purity was insufficient, the solvent was distilled again. The main requirement to the solvent purity was low concentration of low-boiling impurities and the absence of compounds with the retention time close to that of phenol. Water was double-distilled from $KMnO_4$ on a 30-cm distillation column. Phenol was purchased from Merck (Germany) and used as received. The content of the main compound was 99.5%.

To determine the equilibrium distribution coefficients of phenol between the aqueous and organic phase at different temperatures, the phenol concentration in these phases was measured by gas chromatography [13]. The experiments were performed in a 100-ml glass cell (Fig. 1) whose temperature was controlled with a U-7c thermostat (Poland). The pipes were hermetically sealed with Teflon-coated silicon rubber seals and with screw stoppers. The cell had central and bottom lateral pipes to take upper (organic) and lower (aqueous) phases, respectively. The cell was equipped with a magnetic stirrer. To prevent emulsification, only the aqueous phase was vigorously stirred.

A stock 1% aqueous solution of phenol was prepared as follows. Solid phenol was melted (mp = 41°C). Liquid phenol (0.2 ml) was transferred with an automatic pipet into a 22.3-ml glass vessel and weighed. Double-distilled water (20 ml) was added, and the vessel was weighed again on an Ohaus Explorer electronic balance with an accuracy of 0.1 mg.

Double-distilled water (43 ml) was added into the cell with the aid of an automatic pipet. Then a 1% aqueous solution of phenol (2 ml) was added with a pipet, and the cell was loaded with organic solvent (45 ml). The resulting volume ratio of the phases was 1 : 1. The initial phenol concentration in the aqueous phase was about 5×10^{-3} M. At this concentration, phenol does not associate in the solution. The distribution coefficient of phenol between benzene and water at 25°C is almost independent of the phenol concentration up to 10^{-2} M [11]. In our experiments, the phenol concentration in the aqueous and organic phases was about 10^{-3} M. In this concentration range, the distribution coefficient is virtually constant and its determination error is lower than that in more dilute solutions.

The distribution coefficients were measured at 10, 25, 40, and 55°C. To attain the equilibrium, the system was kept for no less than 1 h. The cell was thermostatically controlled with an accuracy of ±0.05°C.

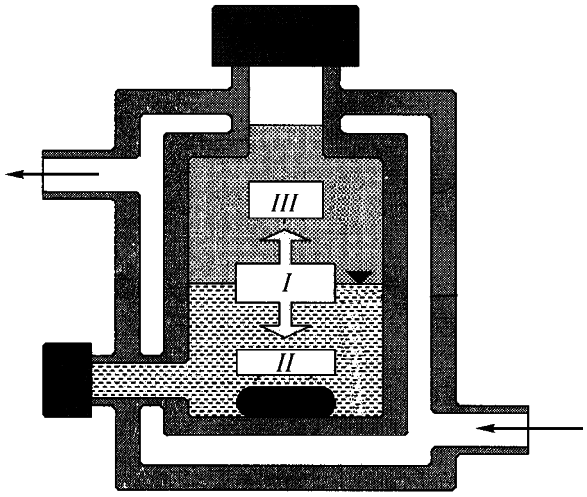

Fig. 1. Cell for study of (*I*) phenol distribution between (*II*) aqueous and (*III*) organic phases.

After the equilibrium was attained, the samples were taken with a microsyringe. Four to six samples of aqueous and then organic phases were analyzed chromatographically.

The phenol concentration in the aqueous and organic phases was determined from the peak area. Since the detector signal is proportional to the amount of the substance passed through the detector, the detector signal is proportional to the molar concentration of phenol in the sample. The ratio of the peak areas in the chromatograms of aqueous and organic phases will be equal to the distribution coefficient, if the detector works in the linear range and the sample volumes are the same:

$$S = kV_d c,$$

where S is the chromatographic peak area, V_d is the injected volume (ml), k is the coefficient, and c is the equilibrium concentration.

The molar distribution coefficient of phenol is calculated by the equation

$$K_d = \frac{c_{org}}{c_{aq}} \cong \frac{S_{org}}{S_{aq}}, \quad (1)$$

where c_{org} and c_{aq} are the equilibrium phenol concentrations in the organic and aqueous phases (M); S_{org} and S_{aq} are the peak areas of phenol in the chromatograms of the organic and aqueous phases.

The volume of injected samples was kept constant with the aid of a special metal stop fixed on the

m-Xylene	–	1.32 ± 0.02	1.47 ± 0.06	–
Ethylbenzene	0.89 ± 0.02	1.17 ± 0.02	1.34 ± 0.06	1.48 ± 0.02

syringe rod. The linearity of the concentration dependence of the detector signal in the range from 0.002 to 0.025 wt % was experimentally checked with five reference aqueous solutions of phenol.

It should be noted that, in this case, the distribution coefficient of phenol was determined without additional calibration of the chromatograph with external references and without taking the volume of the aqueous and organic phases into account, which made the determination more accurate [13].

The temperature dependence of the distribution coefficient of phenol in a water–benzene system is shown in Fig. 2 in comparison with the similar dependence determined in the aqueous HCl (pH 2)–benzene system by the photometric procedure. The phenol concentration ranged from 1×10^{-2} to 5×10^{-4} M. We used double-distilled water as the aqueous phase. The aqueous phenol solution was neutral. Since phenol is a weak acid ($K = 1.3 \times 10^{-3}$), its distribution coefficient should depend on the pH of the aqueous phase. However, calculations and the experimental data [11] show that only 0.1% of phenol molecules are dissociated at the phenol concentration of about

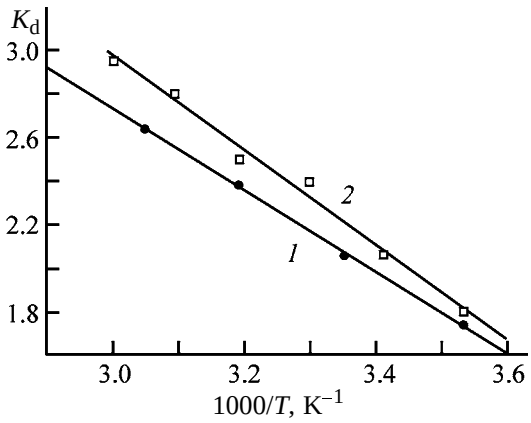

Fig. 2. Distribution coefficients of phenol in the benzene–water system, measured (*1*) in this work and (*2*) in [14]. (*T*) Temperature; the same for Fig. 3.

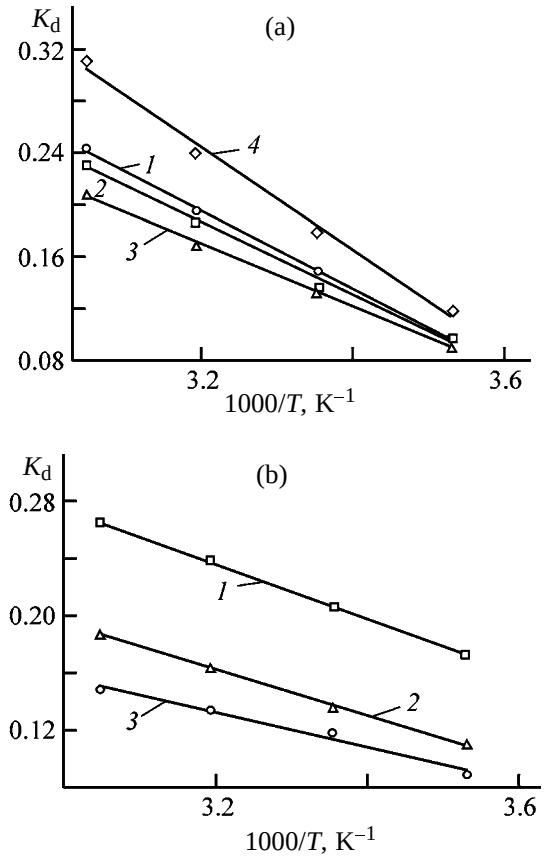

Fig. 3. Phenol distribution coefficient between aqueous phase and (a) alkanes [(*1*) hexane, (*2*) heptane, (*3*) octane, and (*4*) cyclohexane] and (b) aromatic hydrocarbons [(*1*) benzene, (*2*) toluene, and (*3*) ethylbenzene].

10^{-3} M and pH 7, which has virtually no effect on the distribution coefficient. Negligible discrepancy (7–8%) with the published data is likely due to the determination error and salting-out effect of hydrochloric acid.

The distribution coefficient of phenol in 10 systems at 10–55°C are summarized in the table.

The dependences of the distribution coefficient of phenol in water–alkane system and in water–aromatic hydrocarbon systems on the reciprocal temperature are shown in Fig. 3a and 3b, respectively. As seen from Fig. 3, the distribution coefficient decreases with an increase in the molecular weight or molar volume of the homologs.

It is known that the extracting power is determined by certain functional groups of the solvent. In the case of phenol extraction, this group is the aromatic ring. The distribution coefficients of phenol between saturated hydrocarbons and water are lower than 1 and decrease with an increase in the length of the hydrocarbon chain. In this case, the extraction depends on packing of phenol molecules in the solvent. The fact that the distribution coefficient of phenol in the cyclohexane-water system is higher than that in the *n*-hexane-water system is caused by this factor.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Gold(III) Ions from Hydrochloric Acid Solutions by Aminated Shungite

A. M. Akimbaeva and E. E. Ergozhin

Bekturov Institute of Chemical Sciences, Ministry of Education and Science of Kazakhstan Republic, Almaty, Kazakhstan

Received August 4, 2004

Abstract—Sorption of gold ions by aminated shungite from chloride solutions was studied. The effects of the solution pH and process duration on the degree of recovery were considered.

Sorption methods of concentrating precious metals (PM) using various materials occupy a prominent place in their analytical chemistry [1–3]. The use of known organopolymer sorbents with good sorption characteristics for PM recovery involves certain problems associated with their swelling, low rate of the process, and insufficient desorption of metal ions [1]. Widely used activated carbons are able to sorb quantitatively microamounts of platinum metal and gold ions from solutions; however, the equilibrium is attained within a rather long time, and the carbon regeneration involves problems [4].

Recently we initiated studies of the sorption of PM ions by modified shungites, which appeared to be effective sorbents [4–6].

The sorption technology involving expensive AM-2B anion exchanger is in wide use at enterprises of gold mining industry of the Kazakhstan Republic and CIS countries. Therefore, along with the problem of increasing gold mining, the search for new available and cheap sorbents is necessary. We developed anion exchangers based on modified epoxy and amino derivatives of shungites abundant in our region [4–6]. The results of recovering silver and platinum ions by aminated natural sorbents showed that surface-modified shungite rocks quantitatively recover precious metal ions within a short time [5, 6].

The study of sorption parameters of the new sorbent based on aminated shungite containing polyvinylpyridine in granules showed that functional groups with nitrogen donor atoms determine its chemical and analytical properties and its ability to extract precious metal ions.

The aim of this work was a study of the properties of aminated shungite as a sorbent for gold(III) ions from standard solutions and the subsequent analytical determination of these ions.

A shungite concentrate containing 80% carbon was prepared by demineralizing natural shungite (20% carbon) with subsequent granulation [6]. Aminated shungite was obtained by the polymerization of 2-methyl-5-vinylpyridine in shungite granules. According to the elemental analysis, the content of nitrogen in the aminated product was 27.16%; the weight gain of the sorbent after polymerization was 2.51%.

We prepared the starting solution of gold(III) by dissolving gold metal in a mixture of hydrochloric and nitric acids (3 : 1) with subsequent boiling down with concentrated HCl. Working solutions of gold(III) were prepared by dilution of the starting $H[AuCl_4]$ solution. The required acidity was created by adding HCl and NaOH and was monitored by an EV-74 pH-meter with an ESL-43-07 glass electrode. The sorption of gold(III) ions was studied under static conditions. To study the process kinetics, we brought 0.5 g of the sorbent into contact with 50 ml of Au(III) solution (c_{Au} = 10 mg l^{-1}). The mixture was stirred with a magnetic stirrer at a rate of 400–500 min^{-1} at room temperature. At certain time intervals, we took samples and determined the metal ion concentration by the atomic adsorption method on an AAS-3 spectrometer in a propane–butane–air flame. The analytical signal of gold was measured by the resonance line at 242.8 nm at the spectral aperture width of 0.25 nm and the current of a lamp with a hollow cathode of 5 mA. The degree of gold(III) recovery was determined from the difference between the starting metal ion concentration and its residual concentration in the solution after sorption.

1070-4272/04/7711-1754 © 2004 MAIK "Nauka/Interperiodica"

We studied the process kinetics at room temperature with the aim to find the optimal conditions for the recovery of gold(III) ions with aminated shungite. The study of the dependence of the degree of gold(III) recovery on the process duration showed that the nature of the surface groups on the samples determines distinctions between the kinetic parameters of the process. An equilibrium in the distribution of Au(III) ions between the sorbent and the solution under the suggested conditions (c_{Au} = 10 mg l^{-1}, m_s = 0.5 g, V_l = 50 ml) is attained in 4 h with the starting nonmodified shungite, the recovery of gold(III) ions being 80%. At the same time, with the aminated sample Au(III) is recovered from the solution almost completely within 2 h (Fig. 1). Its high kinetic parameters are determined by the presence of chemically active groups and by the selectivity to precious metal ions. We emphasize that the time of half-saturation with the natural shungite is about 2 h, and with the modified sample it is 15 min. We have found that a high degree of recovery R (99%) of gold(III) ions from chloride solutions with the Au concentration of 10 mg l^{-1} is achieved on the aminated shungite. Therefore, this material shows promise for recovering traces of precious metal ions.

The proportion of various forms of gold(III) ions in the solution is predominantly affected by its acidity. In chloride media, gold(III) ions are known to exist as $[AuCl_4]^-$, $[AuCl_3OH]^-$, and $[AuCl_2(OH)_2]^-$ anions [7], which can react with functional groups of the sorbent. At pH > 3, Au(III) chloride complexes are hydrolyzed, the content of Au(III) hydroxochloride complexes increases, and the absorption of gold(III) ions decreases. Therefore, we studied their sorption behavior in the range of pH 1–3 (Fig. 2). We found that the optimal pH of the solution lies in the range 0.5–2.0. The examination of the dependence of the degree of gold(III) extraction by aminated shungite on the HCl concentration (0.5–4.0 M) confirms high efficiency and completeness of the extraction (99.8%).

The study of the sorption activity of gold(III) ions as a function of the solution acidity suggests that they pass into the solid phase owing to the complexation with functional groups (carbonyl and pyridine), and the acidity of the medium does not affect the process. This fact suggests that in this case the nitrogen atom of the heterocycle takes part in the sorption, which makes the ion-exchange mechanism of the process improbable. The Au(III) ions are recovered owing to complexation with the pyridine groups of the macromolecular ligand. Thus, gold(III) ions are recovered by the modified shungite predominantly owing to their coordination by the nitrogen atom of the pyridine ring and by the active surface centers of the natural sorbent.

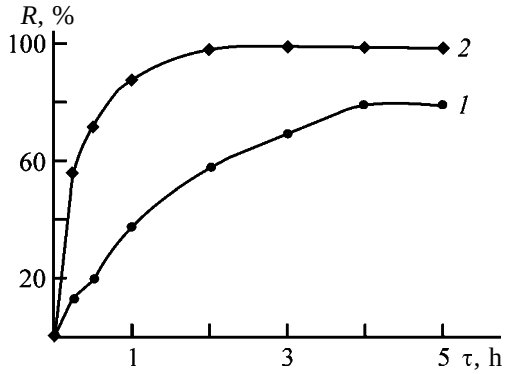

Fig. 1. Degree of Au(III) recovery R by shungites as a function of the process duration τ. c_{Au} = 10 mg l^{-1}, V_l = 50 ml, m_s = 0.5 g; the same for Fig. 4. Shungite: (*1*) natural and (*2*) modified.

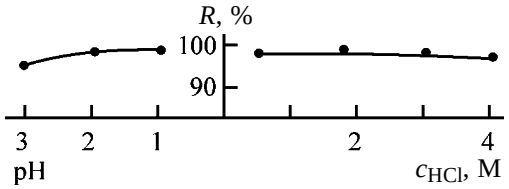

Fig. 2. Influence of the aqueous phase acidity on the degree of Au(III) extraction R by aminated shungite. c_{Au} = 10 mg l^{-1}, m_s = 0.5 g, τ = 24 h. c_{HCl} is the concentration of HCl solution (M).

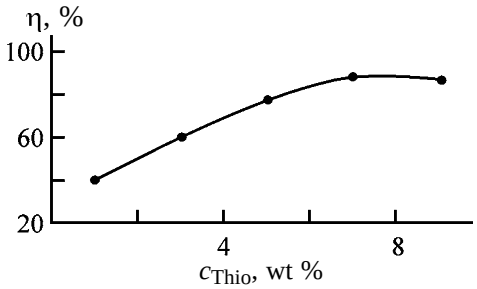

Fig. 3. Degree of Au(III) desorption η vs. thiourea concentration c_{Thio}. V_{el} = 50 ml, m_s = 0.5 g.

We examined the possibility of regeneration of aminated shungite for its multiple use and found that the sorbed gold(III) ions can be desorbed with a solution of thiourea in HCl. We have found that Au(III) is 90% desorbed with a thiourea solution (7 wt %) in 1 M HCl at room temperature (Fig. 3). An increase in the eluent volume by a factor of 2–3 results in complete desorption of gold ions (96–100%).

The pyridine group tends to form complex compounds via its nitrogen atom and shows a selectivity

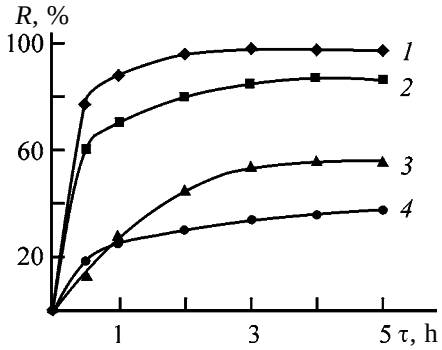

Fig. 4. Degree of Au(III) recovery R by aminated shungite vs. the process duration τ in the presence of concomitant metal ions: (*1*) Au(III), (*2*) Cu(II), (*3*) Co(II), and (*4*) Ni(II).

to transition metal ions. To determine the possibility of selectively recovering gold(III) ions on aminated shungite, we studied the kinetics of this process in the presence of copper(II), cobalt(II), and nickel(II) ions (the concentration of each metal ion was 10 mg l^{-1}) (Fig. 4). The comparison of the sorption curves shows that the selectivity of the sorbent under study varies in the order Au(III) > Cu(II) > Co(II) > Ni(II). Au(III) could be recovered completely, and the recovery of Cu(II), Co(II), and Ni(II) comprised 87, 56, and 38%, respectively. The sorbent is saturated with metal ions within 4–5 h.

It was shown in [3] that gold(III) ions can be quantitatively separated from transition metal ions [M(II)] in 0.5 M solution of HCl. Under the conditions of our experiments, the differences in the degree and rate of their sorption on the sorbent under study allow Au(III) to be determined in the presence of 10- and 50-fold amounts of M(II) (the table). The selectivity of the sorbent under study to the precious metal ions can be caused by the formation of an additional π-dative bond between Au(III) atoms and a π orbital of the pyridine ring. It has a positive effect on the recovery of Au(III) and allows us to separate the main body of the ions of concomitant elements.

Sorption of Au(III) on aminated shungite in the presence of concomitant metals. c_{Au} = 10 mg l^{-1}, m_s = 0.5 g, V_{el} = 50 ml, 0.5 M HCl

M(II)	M/Au	R(Au), %
Cu(II)	10	98.9 ± 1.1
	50	98.8 ± 1.2
Co(II)	10	98.9 ± 1.3
	50	98.9 ± 1.2
Ni(II)	10	98.9 ± 1.4
	50	98.9 ± 1.2

CONCLUSION

A shungite concentrate containing polyvinylpyridine in its granules efficiently sorbs gold(III) ions from chloride solutions. Its high selectivity makes it possible to concentrate gold(III) ions and to separate them from the concomitant elements Cu(II), Co(II), and Ni(II), even present in excess.

SORPTION AND ION-EXCHANGE PROCESSES

Separation of Cerium-Group Rare-Earth Elements on PAN–FOSPAN Fibrous Sorbent

L. N. Skvortsova and E. V. Selivanova

Tomsk State University, Tomsk, Russia

Received April 2, 2004

Abstract—The selectivity of sorption of cerium-group rare-earth elements on acid- and base-treated fibrous complexing PAN–FOSPAN ampholyte from aqueous solutions containing acetate and butyrate anions was studied as influenced by pH. The possibility of separating Nd^{3+} from Eu^{3+} by eluent chromatography on PAN–FOSPAN was studied. The conditions for concentrating the sum of rare-earth elements on the resin were found.

The separation and preconcentration of rare-earth elements (REE) is an important analytical problem which, as a rule, is solved by chromatographic and extraction techniques. The growing interest in ion-exchange chromatography is stimulated both by the simplicity of regenerating the sorbents and possibility of performing sorption separation under dynamic conditions. The most efficient ion-exchange separation and preconcentration of lanthanides is reached using fibrous oxygen-containing complexing sorbents. These sorbents are characterized by high selectivity to REE and fast attainment of the sorption equilibrium.

The advantage of using the fibrous PAN–FOSPAN ampholyte for separation and preconcentration of Nd^{3+} and Yb^{3+} was shown in [1, 2]. We found that, on treatment of this sorbent with aqueous acid, its selectivity to REE ions at pH 3.5–4.5 strongly increases due to favorable modification of the sorbing sites (Table 1). It was found that, on treatment with acid, the amino groups in the resin remain unprotonated. The IR studies showed that sorption of REE on PAN–FOSPAN is caused by coordination of its functional groups with REE ions. In this work we continued our studies on sorption of REE on PAN–FOSPAN fibrous ampholyte. The aim of our experiments was to elucidate the possibility of separating cerium-group REEs.

The selectivity of ion-exchange separation of metal ions can be optimized by varying the chemical composition of the aqueous phase. This procedure allows variation of both the metal ion speciation in solution and composition and complexing power of the ionic sorbing sites in the sorbent. To improve the selectivity of sorption separation of metals, new approaches are being developed, based on competing complexing reactions in the sorption system [3]. It was found that the sorption selectivity of the resin is improved after adding appropriate complexing agents in the aqueous phase and varying pH. In this work, the selectivity of fibrous PAN–FOSPAN ampholyte to REE was studied as influenced by low-molecular-weight competing ligands (acetate and butyrate) added into solution, pretreatment of the initial sorbent with acid or alkali, and pH of solution [4]. The acetate and butyrate competing ligands were used as their buffer solutions. The physicochemical characteristics of PAN–FOSPAN fibrous ampholyte and chemical composition of its sorbing sites before and after treatment of the sorbent with acid and alkali are presented in Table 1.

EXPERIMENTAL

The initial fibrous sorbent PAN–FOSPAN was converted to the acid form by treatment with 0.1 M

Table 2. Influence of acetate anions on the selectivity of REE sorption on PAN–FOSPAN ampholyte in the acid and base forms

REE ion	Acid form		Base form	
	$D_M \times 10^{-3}$, ml g^{-1} (without adding acetate)	$D_M \times 10^{-4}$, ml g^{-1} (on adding acetate)	$D_M \times 10^{-4}$, ml g^{-1} (without adding acetate)	$D_M \times 10^{-3}$, ml g^{-1} (on adding acetate)
Pr^{3+}	9.2 ± 0.3	4.10 ± 0.10	3.85 ± 0.20	4.9 ± 0.3
Nd^{3+}	9.9 ± 0.5	4.30 ± 0.15	3.40 ± 0.20	4.6 ± 0.4
Sm^{3+}	9.4 ± 0.4	3.20 ± 0.20	2.30 ± 0.16	5.0 ± 0.2
Eu^{3+}	9.5 ± 0.3	2.15 ± 0.12	2.10 ± 0.15	4.7 ± 0.2

HCl and then washed with 10^{-3} M HCl to pH 3. To convert the sorbent to the base form, the initial PAN–FOSPAN was treated with 0.1 M NaOH and then washed with distilled water to decolorization of phenolphthalein.

To elucidate the separation power of the fibrous sorbent with respect to REEs, the distribution factor of these metals between the sorbent and aqueous phase was determined under static conditions. In these experiments, a weighed portion of PAN–FOSPAN (0.05 g) was equilibrated with a 5×10^{-4} M aqueous REE chloride (10 ml) at pH 4.5. In studies of the effect of acetate and butyrate anions on REE sorption separation, the REE chloride solutions in the acetate and butyrate buffers were used. The content of acetic and butyric acids and their salts in the buffer solutions was 0.1 and 0.25 M, respectively. The resin sample suspended in an REE-containing buffer solution was kept until the sorption equilibrium was attained. The REE content in the equilibrium liquid phase was determined spectrophotometrically with Arsenazo III. The REE amount sorbed on the fibrous sorbent was determined as the difference between the initial and equilibrium REE concentrations in the aqueous phase. The REE distribution factor was calculated by the equation $D_M = [\overline{M}]/[M]$, where $[\overline{M}]$ and [M] are the equilibrium REE contents in the sorbent (mmol g^{-1}) and aqueous phase (M), respectively. The REE separation factors K were calculated from the corresponding distribution coefficients.

In our sorption experiments, a weighed portion of the sorbent preliminarily saturated with REE under static conditions was packed in a temperature-controlled glass column (10 cm high and 0.8 cm in diameter) and washed with distilled water. The elution rate of 1.5 ml min^{-1} was maintained with a peristaltic pump. The REE content in the eluate was monitored spectrophotometrically. The elution curves were processed with the Statistica 5.0 computer program (Basic Statistics language), and the REE distribution factors were calculated. The sorption preconcentration of REEs was carried out on a microcolumn (15 mm high and 0.3–0.4 mm in diameter) packed with PAN–FOSPAN fibrous sorbent (50 mg). In these experiments, 10 ml of the initial aqueous REE solution (2×10^{-4} M) was pumped through the column at the required velocity. REEs were desorbed from the column with 0.1 M HCl.

The effect of acetate anions on the selectivity of sorption of cerium-group REEs on fibrous PAN–FOSPAN ampholyte in the acid and base forms is demonstrated in Table 2.

This table shows that, on adding acetate anions to the aqueous phase, the selectivity of fibrous resin in the acid form to REEs is improved. On the contrary, the selectivity of the resin in the base form is deteriorated under these conditions. The improvement of the selectivity of the resin in the acid form to REEs can be caused by the following competing reactions: (1) dissociation of the hydrogen phosphate functional groups of the sorbent, (2) protonation of acetate anions, and (3) coordination of acetate anions with REE^{3+}:

$$\overline{H}_2R \rightleftarrows \overline{H}^+ + \overline{H}R^-, \quad (1)$$

$$L^- + H^+ \rightleftarrows HL, \quad (2)$$

$$M^{3+} + 2L^- \rightleftarrows [ML_2]^+. \quad (3)$$

These reactions show that the protonation of acetate anions by equilibrium (2) shifts equilibrium (1) towards formation of deprotonated hydrohen phosphate groups in the ampholyte, and also destroys metal acetate complexes. As a result, the acetate anions favor the sorption of REE on the ampholyte. The selectivity of REE sorption on the resin was found to decrease in the order $Pr^{3+} = Nd^{3+} > Sm^{3+} > Eu^{3+}$. It should be noted that the stability of acetate complexes of these metals increases in the same sequence. The sorption power of the resin in the base form decreases in the presence of acetate anions. This effect can be caused by the shift of reaction (3)

toward formation of weakly sorbable bis(acetate) complexes. The maximal selectivity of the resin in the acid form to REEs in the presence of acetate anions was observed in separation of Nd^{3+} from Eu^{3+}.

Reactions (1)–(3) show that pH affects the ion-exchange sorption of REEs by affecting both the free ligand concentration in the solution and protonation of the sorbing sites. Figure 1 shows how pH of the acetate and butyrate buffer solutions influences the selectivity of PAN–FOSPAN in the acid form to Nd^{3+} and Eu^{3+}.

The low sensitivity of the distribution factor D_M to acidity of solutions in the pH range 3.0 – 4.0 is caused by protonation of both the weakly acidic functional groups of the sorbent and complexing anions in the buffer solution. The most efficient separation of neodymium from europium (separation factor 2.0) is reached in their sorption from acetate buffer solution with pH 4.5.

The comparison of the kinetic curves of Eu^{3+} sorption on PAN–FOSPAN ampholyte in the acid and base forms (Fig. 2) shows that the resin in the base form predominantly sorbs Eu^{3+} by the ion-exchange mechanism (sorption equilibrium is attained in 30 min), whereas sorption of europium on the resin in the acid form is complicated by complexation (sorption equilibrium is attained in 6 h).

The efficiency of separation of Nd^{3+} from Eu^{3+} by eluent chromatography on PAN–FOSPAN was estimated from the elution curves. In elution experiments, the acetate and butyrate buffer solutions (pH 4.5) and dilute aqueous HCl (0.01 – 0.1 M) were used as eluents. The elution of REE with buffer solutions was found to be inefficient due to high REE distribution factor between the sorbent and the buffer solutions ($D_M = n \times 10^4$). The resolution of the elution bands of Nd^{3+} and Eu^{3+} was reached in eluting REEs with aqueous HCl of various concentrations (Fig. 3). We found that, although the sorption selectivity slightly increases with decreasing HCl concentration, the column performance noticeably decreases. As seen from Fig. 3e, in flowing 0.01 M HCl through the column at 20°C, REEs are not eluted. Although the REE distribution factors calculated by us from the elution curves (6–20) are considerably lower than those determined from the static sorption experiments ($n \times 10^4$), their values remain too large to ensure the efficient elution of the metals. Upon heating the column to 80°C (Figs. 3b, 3d, 3f), the efficiency of eluting Eu and Nd noticeably increases, but the separation factor, as before, remains too low to reach the good resolution of the Eu and Nd elution bands.

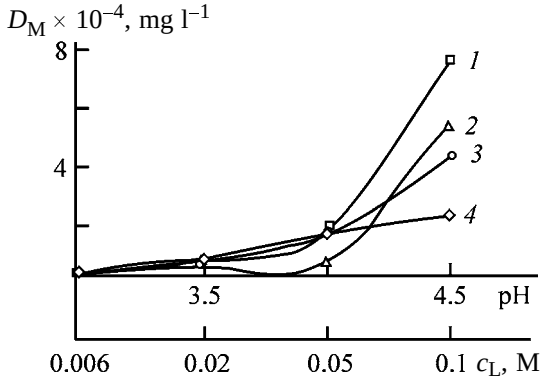

Fig. 1. Distribution factor D_M of (*1, 3*) neodymium and (*2, 4*) europium between PAN–FOSPAN in the acid form and buffer solution as functions of pH of (*1, 2*) butyrate and (*3, 4*) acetate buffer solutions and the butyrate and acetate concentration c_L.

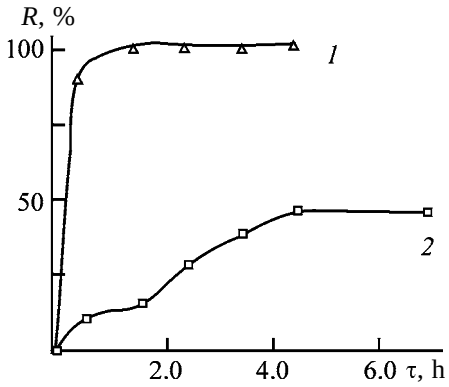

Fig. 2. Degree of europium sorption R on fibrous PAN–FOSPAN in the (*1*) base and (*2*) acid forms as a function of sorption time τ.

In order to improve resolution of chromatographic bands, we increased the sorbent bed height to 20 cm (Fig. 4). Under these conditions, the separation factor K increased to 2, which, however, was still insufficient for obtaining the resolution suitable for quantitative separation of Eu from Nd. From our experimental data, we calculated by the theory of the theoretical plates the resin bed height ensuring the acceptable degree of recovery of individual REE. For example, 99% of target REE can be recovered on a 60-cm column. To increase the degree of REE recovery to 99.95% , the resin bed height must be increased to 110 cm.

Table 2 shows that REEs can be concentrated by their sorption from acetate buffer solutions on PAN–FOSPAN ampholyte in both the base and acid forms. Figure 5 shows the degree of europium recovery vs. the filtration rate of europium-containing acetate buffer solution through the microcolumn packed with PAN–FOSPAN ampholyte. It is seen that the degree of europium recovery on the resin in the acid form is small even at very slow filtration. The inefficient

recovery of europium can be caused by slow europium sorption due to its complexation with acetate anions. On the contrary, the efficient preconcentration of REEs on the resin in the base form can be reached at relatively slow filtration.

CONCLUSIONS

The fibrous PAN–FOSPAN ampholyte in the acid form is a promising sorbent for separating cerium-group REEs in acetate buffer.solution. Nd^{3+} can be separated from Eu^{3+} by eluting them from the resin with 0.01 M HCl at 80°C. The fibrous ampholyte in the base form can be used for efficient preconcentration of the sum of rare-earth elements.

Abstract—Distribution in strength of the acid centers in sulfonic cation in the form of exchanger granules and fibers was studied by the novel modification of the thermal desorption method.

Previously [1–3], we studied the activity of sulfonic cation exchanger granules and fibers in the synthesis of methyl *tert*-alkyl ethers and found that FIBAN K-1 surpasses in the activity KU2-8 (gel structure) in the synthesis of methyl *tert*-butyl ether (MTBE) and Dowex msm 31 (macroporous structure) in the synthesis of methyl *tert*-amyl ether (MTAE).

The main advantage of fibrous sulfonic cation exchanger FIBAN K-1 is that the fiber diameter is by approximately an order of magnitude smaller than the diameter of KU-2-8 and Dowex msm 31 granules. This decreases intradiffusion inhibition and intensifies mass exchange.

The diameter of the Carbopon fiber can be estimated as 5–10 μm, which is substantially smaller than FIBAN K-1 fiber diameter. Hence, sulfonic cation exchanger supported on Carbopon, when used as a catalyst of acid–base reactions, can provide more intense mass exchange than FIBAN K-1.

The performance of sulfonic cation exchanger substantially depends on its acidity, i.e., concentration and strength of acid centers. The literature survey [4–6] shows that the most adequate method of its determination is ammonia thermal desorption. However, for organic ion exchangers with a low thermal stability, ammonia is acceptable only for determination of weak acid centers. To determine strong acid centers, another thermal desorption method is required.

In this work, we studied sorption and acid properties and catalytic activity (by an example of MTAE synthesis) of two samples of sulfonic cation exchanger supported on Carbopon (sample I with gel structure and sample II with macroporous structure) in comparison with their structural analogs, fibrous (FIBAN K-1) and granular (Dowex msm 31) sulfonic cation exchangers.

EXPERIMENTAL

The sorption of various liquids with the initial Carbopon, synthesized samples of the supported sulfonic cation exchanger, FIBAN K-1 fibrous sulfonic cation exchanger with gel structure, and Dowex msm 31 granular sulfonic cation exchanger with macroporous structure was evaluated gravimetrically. A cation exchanger sample (~0.5 g) dried to the constant weight at 90°C was introduced into a test tube, 10 ml of a liquid was added, and the mixture was stored for 3 h. The sample was centrifuged (4000 rpm) for 15 min, weighed, and dried to the constant weight at 90°C. The sorption value, G_l ($g_l\ g^{-1}$), was calculated as the ratio of the liquid weight to the weight of dry sample:

$$G = \frac{m_1 - m_2}{m_2},$$

where m_1 is the sample weight after centrifuging and m_2, sample weight after drying at 90°C.

The average value of three parallel experiments was used in calculations. Along with G_l, the volume sorption V_l ($cm_l^3\ g^{-1}$) was also calculated.

As seen from Table 1, sorption of water with Carbopon is 0.64 $g_l\ g^{-1}$, which is substantially larger than sorption of methanol and the other components of the reaction mixture of the MTAE synthesis, and of *n*-octane taken as a nonpolar liquid. The V_l values show a clear correlation with the molecular size of liquids [i.e., molecular-sieve effect characteristic for

n-Octane	0.19/0.27	0.16/0.23	0.15/0.21	0.14/0.20	0.08/0.11

finely porous sorbents (activated carbons, zeolites, silica gels) appears].

The effect of molecular size of liquid is preserved in samples of the sulfonic cation exchanger supported on Carbopon, and, in addition, the effect of the structure of the grafted copolymer can be observed.

Sample 1 (2% DVB, gel structure) sorbs more water (0.95 $g_l\ g^{-1}$) and the other polar components than does Carbopon. However, as expected, sample I sorbs nonpolar *n*-octane more weakly than does Carbopon. The fact that sample I is a weaker sorbent than its structural analog, fibrous FIBAN K-1, can be explained by lower exchange capacity (EC).

As compared to sample I and Carbopon, sample II (25% DVB, macroporous structure) sorbs water (0.44 $g_l\ g^{-1}$) and the other liquids substantially more weakly, probably due to a rigid cellular structure of the cation exchanger caused by the high degree of cross-linking of the polymer chains. The difference between the sorption properties of this sample and Dowex msm 31 can also be explained by differences in their EC (1.3 and 4.4 mg-equiv g^{-1}, respectively).

The novelty of the suggested method of the thermal desorption of bases consists in using a weak base, diethyl ether, as a desorbate to determine the concentration of strong acid centers. It is desorbed from the strongest acid centers of the dehydrated sulfonic cation exchangers at 120°C, i.e., under conditions of their thermal stability. In addition, diethyl ether is characterized by low adsorption power, due to small size of its molecule and low boiling point. Therefore, the sorbed ether is readily eliminated from the cation exchanger, which is important for obtaining correct results.

The concentration of weak acid centers is determined performed as follows. A cation exchanger (approximately 0.2 g) is charged into a glass reactor (70 mm long, 8 mm in diameter), and the reactor is attached to a carrier gas line in a chromatograph thermostat. Then the thermostat heating is switched on, and a sample is conditioned in a helium flow (30 ml min^{-1}) at 120°C for 2 h, cooled, and saturated with ammonia for 30 min at room temperature. Physically adsorbed ammonia is eliminated from the cation exchanger at room temperature in the helium flow. The course of desorption and its completion were monitored with a recorder. Then the stage of the thermal desorption of the chemisorbed ammonia begins. The temperature of the reactor is increased to 120°C, and the sample is kept for 1 h in a helium flow. The desorbed ammonia is trapped in a U-shaped glass condenser cooled with liquid nitrogen and, after heating at 90–95°C with hot water, is transported with helium flow to the katharometer, where it is monitored as a chromatographic peak. Using a calibration plot ammonia content–peak area, we determined the amount of ammonia desorbed and calculated from the weight of the ion exchanger sample and its EC the concentration (mmol g^{-1}) and percentage of weak acid centers in the sample.

To determine the concentration of strong acid centers, a cation exchanger sample is charged into a reactor arranged in the thermostat of a chromatograph, and the reactor is attached to an empty column functioning as a preheater of the carrier gas. After sample training in a dried helium flow (30 ml mim^{-1}) at 120°C for 2 h, the reactor is cooled to room temperature and detached from the column, and diethyl ether is added. After 1-h storage, excess ether is poured off, the reactor is attached to the column and flame-ionization detector, and the thermostat temperature is set at 75°C; the sample is kept in a helium flow until the recorder pen returns to the zero level, which indicates completion of ether desorption at this temperature. Then the temperature is sharply elevated to 100°C, and the peak of desorbed ether is recorded. After stabilization of the baseline, the temperature of the thermostat is elevated to 120°C, and the second desorption peak

Table 2. Acid properties of sulfonic cation exchangers

Sulfonic cation exchanger			Concentration and strength of acid centers							
sample	DVB, %	EC, mg-equiv g^{-1}	weak		medium		strong		very strong	
			mmol g^{-1}	%	mmol g^{-1}	%	mmol g^{-1}	%	mmol g^{-1}	%
I	2	1.7	0.27	16.3	1.16	69.2	0.16	9.4	0.09	5.1
II	25	1.3	0.17	13.3	0.97	74.8	0.10	7.9	0.05	4.0
FIBAN K-1	2	3.1	0.40	12.9	2.35	75.6	0.27	8.8	0.08	2.7
Dowex msm 31	25	4.4	0.86	19.5	3.32	75.4	0.18	4.1	0.04	1.0

is recorded. Then, using a calibration plot ether content–peak area, the amount of ether desorbed within the 75–100°C range is determined and the concentration and percentage of the strong acid centers in the sample are calculated from the sample weight and ion exchanger EC. Similarly, the amount of ether desorbed within the 100–120°C range is determined and the concentration of the very strong acid centers is calculated.

In accordance with the conventional classification, centers characterized by NH_3 desorption at temperatures of up to 120°C are weak acid centers, those characterized by diethyl ether desorption within the 75–100 and 100–120°C ranges are strong and very strong acid centers, respectively. The concentration of medium-strength acid centers was determined as the difference between the total amount the acid centers in the sulfonic cation exchanger (numerically equal to EC) and the sum of weak, strong, and very strong centers. It follows from Table 2 that the sum of the strong and very strong acid centers (strongly acidic centers) in sample I amounts to 0.25 and in sample II, to 0.15 mmol g^{-1}. In sulfonic cation exchangers FIBAN K-1 (gel structure) and Dowex msm 31 (macroporous structure), which are structural analogs of samples I and II, the concentration of strongly acidic centers responsible for the catalytic activity of the cation exchanger in the etherification reactions amounts to 0.35 and 0.22 mmol g^{-1}, respectively. Thus, the concentration of strong acid centers in samples with gel structure is higher than in macroporous samples. The content of strongly acidic centers in the cation exchangers considered decreases in the order FIBAN K-1 > sample I > Dowex msm 31 > sample II.

It is interesting to compare the acid characteristics of the sulfonic cation exchanger samples prepared with their catalytic activity. The experiments on MTAE synthesis were performed on a laboratory device of the flow type. The reaction unit of the device consisted of a catalytic reactor placed in a thermostat, a vessel for the starting compounds, a cooling system, and a product collector [2]. 1 g of fibrous sulfonic cation exchanger was loaded into the reactor, and the synthesis was performed under a pressure of 0.8 MPa to ensure the liquid state of the reaction system. In the case of granular sulfonic cation exchanger, the resin sample was mixed with ground glass of the same grain size to reach the volume of the compacted fibrous sample (1.4 ml). In the experiments, the process temperature was varied at a constant rate of raw material feeding, 4 g g_{ce}^{-1} h^{-1}, and CH_3OH : *i*-C_5H_{10} molar ratio of 1 : 1.

Methylbutenes were prepared by dehydration of isoamyl alcohol on γ-Al_2O_3 at 330°C. The mixture of isomers contained (%) 3-methyl-1-butene 45.8, 2-methyl-1-butene 19.4, and 2-methyl-2-butene 34.8.

The data on MTAE synthesis in the presence of sulfonic cation exchangers studied are listed in Table 3. The comparison of the sulfonic cation exchangers supported on Carbopon shows that sample I is more active: the maximal content of MTAE in the catalyzate reaches 42.4% at 80°C, while sample II gives 35.4% MTAE at 100°C. These results coincide with both the sorption properties of the samples and the concentration of strongly acidic centers. The decrease in the MTAE content as a result of the higher rate of the reverse reaction relative to the direct reaction rate on sample I is observed at 90°C. For FIBAN K-1 and Dowex msm 31, this decrease is observed at 100°C, and for sample II still higher temperature is required.

When the MTAE content in the catalyzate at 80°C is taken as a measure of the sulfonic cation exchanger activity, the following activity order is observed: sample I > FIBAN K-1 > Dowex msm 31 > sample II. As seen, the position of Dowex msm 31 and sample II in the catalytic activity series coincides with that in

Table 3. Synthesis of MTAE on sulfonic cation exchangers. Rate of raw material feeding 4 g g_{ce}^{-1} h^{-1}, molar ratio CH_3OH : *i*-C_5H_{10} = 1 : 1

Methylbutenes	45.1	42.2	41.5	44.9
Methanol	20.0	18.8	18.7	19.9
MTAE	34.9	39.0	39.8	35.2

the series of acid properties. FIBAN K-1 suprasses all the other cation exchangers studied in the content of strongly acidic centers; however, it is inferior in the activity to sample I. Probably, in this case a size factor (the diameter of the Carbonpon fibers is by an order of magnitude smaller than that of FIBAN K-1 fibers), and the nature of sulfonic cation exchanger support (carbon or polypropylene fiber), which can affect the structure of the matrix formed, can contribute to the catalyst activity.

Thus, sulfonic cation exchangers supported on Carbopon show much promise, opening prospects for development of the theory and practice of the catalysis with cation exchangers.

CONCLUSIONS

(1) Sorption properties of sulfonic cation exchangers supported on carbon fiber depend on the degree of cross-linking of the styrene–divinylbenzene matrix: sample I (gel structure) substantially better sorbs polar liquids than does sample II (macroporous structure), whereas sorption of a nonpolar liquid (*n*-octane) with these sorbents is virtually the same.

(2) The study of the acid properties of samples I and II by the modified method of the thermal desorption of bases showed that the concentration of strongly acidic centers in sample I is substantially higher than in sample II.

(3) By an example of the synthesis of methyl *tert*-amyl ether, it was shown that the catalytic activity of sulfonic cation exchangers in acid–base reactions depends on both the resin acid properties and the diffusion factors affecting the intensity of the mass exchange.

SORPTION AND ION-EXCHANGE PROCESSES

Choice of Optimal Conditions of Chromatomembrane Mass Exchange in the Liquid–Gas System for Saturation of Aqueous Solutions with Oxygen

L. N. Moskvin, G. L. Grigor'ev, O. V. Rodinkov, and K. Yu. Senchik

St. Petersburg State University, St. Petersburg, Russia
Pavlov State Medical University, St. Petersburg, Russia

Received July 23, 2004

Abstract—Fundamental aspects of the chromatomembrane mass exchange in the liquid–gas system are considered for the case of saturation with oxygen (oxygenation) of a physiological solution. The influence exerted by the geometrical dimensions and macroporous structure of a biporous matrix on the process efficiency is revealed.

At present, the membrane scheme of gas exchange is regarded as virtually the only possible way to remove gases from aqueous solutions and to saturate these solutions with gaseous components in flow-through analytical techniques [1] and as a unique principle of operation of blood oxygenators in medical practice [2–4]. However, this scheme has a common physicochemical disadvantage in all these cases, associated with the relatively low rate of molecular diffusion of oxygen across membranes. It is the limited rate of gas exchange across membranes that is responsible for the slow response of systems employed to monitor the composition of gases dissolved in water, for the need to use gas mixtures enriched in oxygen (compared with air) to saturate blood with oxygen, and for the insufficiently complete removal of carbon dioxide from blood in the course of oxygenation [4].

A scheme of mass-exchange processes in liquid–gas and liquid–liquid systems was suggested in the early 1990s as an alternative to diffusion membrane processes. This scheme was named the chromatomembrane mass-exchange (CMM) process [5]. It was demonstrated, already in the initial stage of investigations, that CMM can be, in principle, used for blood oxygenation [6, 7]. However, the problems associated with the efficiency of chromatomembrane oxygenation (CMO) and with the choice of optimal conditions of this process remained, on the whole, unsolved.

This study is concerned with fundamental aspects of the CMO process in model physiological solutions. Its goal is to determine the optimal porous structure of the mass-exchange bed and its geometrical dimensions and the best ratio of the flow rates of the liquid and gas phases.

EXPERIMENTAL

The scheme of the CMO process is shown in Fig. 1. The mass exchange between liquid and gas flows, which leads to saturation of the liquid with oxygen, occurs in a hydrophobic porous medium having the form of particles of porous polytetrafluoroethylene (PTFE), bound together in the course of repeated thermal annealing. Porous PTFE is formed in sintering of a PTFE powder formed in polymerization. Spaces between these particles constitute a system of open macropores along which moves an aqueous solution or, in the real oxygenation process, blood. The dimensions of these macropores can be arbitrarily varied by fractionation of particles of the porous PTFE obtained in the primary sintering. These particles contain open micro- and submicrometer pores comparable in size with particles of the polymerization powder. The micropores ensure the permeability of biporous matrices to air or gas mixtures. Biporous matrices are confined between the upper and lower microporous PTFE membranes impermeable to the liquid. The gas flow is fed into, and removed from, the microporous space of the matrices across these membranes.

The supply of the liquid into the micropores of the membranes and matrices is hindered by the capillary pressure arising because of the nonwettability of

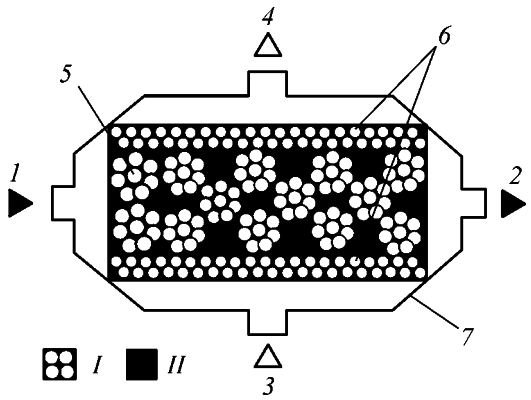

Fig. 1. Schematic of the chromatomembrane oxygenation process: (*1*, *2*) inlet and outlet of blood, (*3*, *4*) inlet and outlet of the air flow, (*5*) mass-exchange matrix, and (*6*) hydrophobic microporous membranes. (*I*) Microporous medium and (*II*) macropores.

PTFE with aqueous solutions and, in particular, with blood. In turn, the supply of the gas phase into macropores, in which the capillary pressure is negligible, is hindered by the pressure of the aqueous solution or blood filling the macropores. This pressure is maintained, according to the experimental conditions, at a higher level than the gas pressure. A more detailed information about the physicochemical principles and conditions under which chromatomembrane processes are performed can be found in [8].

The optimal conditions of the process, which would ensure the most effective saturation of the liquid phase with oxygen in CMM, were determined using the following physiological solution: 1 wt % NaCl + 4.5 wt % glucose. The physiological solution was passed through three in-series connected chromatomembrane cells (CMCs) with an independent feed of flows of the gas phase into each cell. The first CMC served for removing oxygen dissolved in the physiological solution with a flow of helium in order to determine the efficiency of the subsequent saturation of the solution with oxygen in the second CMC. It has been found previously that the CMO is more efficient than the conventional membrane scheme [6]. With account of these data, the physiological solution in the second cell was saturated with oxygen from the atmosphere, without its additional enrichment with oxygen. The third CMC was introduced into the hydraulic scheme to determine the degree of saturation of the physiological solution with oxygen in the second cell. For this purpose, a flow of helium was delivered into the third CMC through the line used to feed-in the gas phase. The flow of helium extracted dissolved oxygen from the physiological solution and then was directed into a gas chromatograph for analysis.

The results of a gas-chromatographic analysis were used to calculate, taking into account the fundamental aspects of CMM, the concentration c (mg l^{-1}) of oxygen dissolved in the physiological solution at the outlet of the CMC under study, using the formula

$$c = c_G W_L W_{G_0}, \quad (1)$$

where c_G is the concentration of oxygen in the flow of the extracting gas at the outlet of the third CMC according to gas-chromatographic data (mg l^{-1}); W_L, flow rate of the physiological solution through the chromatomembrane cells (ml min^{-1}); and W_{G_0}, flow rate of the extracting gas through the third CMC (ml min^{-1}).

The rates of gas flows through all the CMCs were varied with flow controllers and monitored using soap-film flow meters. The relative flow rate measurement error was ±1%. The flow rate of the physiological solution and blood through the CMC, W_L, was controlled with a peristaltic pump and measured with a measuring vessel and a stopwatch. The relative error in W_L measurements was ±1%.

The degree R of saturation of the liquid phase with atmospheric oxygen in the CMC under study was calculated by the formula

$$R = c/c_0, \quad (2)$$

where c_0 is the concentration of oxygen in water in equilibrium with air at a given temperature, known from reference data [9].

The biporous matrices of the CMC used in the study were in the form of parallelepipeds. The influence exerted on the efficiency of saturation with atmospheric oxygen by the ratio of the flow rates of the physiological solution and air through the CMC, by the dimensions of macropores in the biporous mass-exchange matrix, and by the length and height of this matrix was analyzed. The dimensions of the mass-exchange matrix in the directions of motion of the liquid phase and air and in that perpendicular to the first two were taken as length L, height H, and width, respectively.

The length and height of the matrices in the CMC under study, which are prototypes of chromatomembrane oxygenators, were varied from 20 to 100 mm and 10 to 30 mm, respectively, whereas the width remained constant (10 mm). The size of porous PTFE

particles constituting the matrix, which was taken as the macropore diameter, was varied in the range 0.25–1.5 mm.

The influence exerted by the ratio of the flow rates of air and physiological solution through the CMC on the degree of saturation of the latter with atmospheric oxygen is shown in Fig. 2. As expected, raising the flow rate of air through the CMC leads to an increase in the degree of saturation. In this case, the absolute values of the flow rates of air and the solution are unimportant and the degree of saturation depends only on their ratio. These data suggest that the maximum throughput of the CMC will be achieved at the maximum possible flow rates of the phases through the CMS, which are, in turn, determined by parameters of the porous structure of the biporous matrix. Degrees of saturation of the aqueous phase with atmospheric oxygen, equal to 95% and more, are easily obtained at a ratio of the flow rates of air and solution equal to 1 : 1 (and more).

The influence exerted by the length of the mass-exchange matrix on the efficiency of saturation of the aqueous solution with oxygen is illustrated by Fig. 3a. It can be seen that making the matrix and, accordingly, the CMC itself longer than 5 cm is virtually unfeasible because the degree of solution saturation changes in this case only slightly. The influence exerted by the height of the matrix is manifested in close association with that of its length. It was established that the height-to-length ratio of the mass-exchange bed, rather than the absolute value of the height, is of fundamental importance (Fig. 3b). It can be seen that the degree of saturation starts to decrease especially strongly when this ratio exceeds 0.5.

The size of macropores in the matrix affects the efficiency of saturation of the solution with oxygen only slightly (Fig. 4). By analogy with gas–liquid chromatography [10], this can be understood as follows: diffusion in the gas phase is the rate-determining stage of mass exchange. This circumstance makes reasonable use of CMC with coarse pores in chromatomembrane oxygenation to ensure high permeability of the mass-exchange bed to the liquid phase at minimum possible pressures, which rules out any damage to blood.

Thus, the optimal ratio of the flow rates of air and the liquid phase through the CMC is within the range 0.5–2. The height-to-length ratio of the matrix should not exceed 0.5; the sufficient length of the matrix is 50 mm; and, as shown previously [7], the width of the matrix affects the efficiency of mass exchange only slightly, and making it larger leads to a propor-

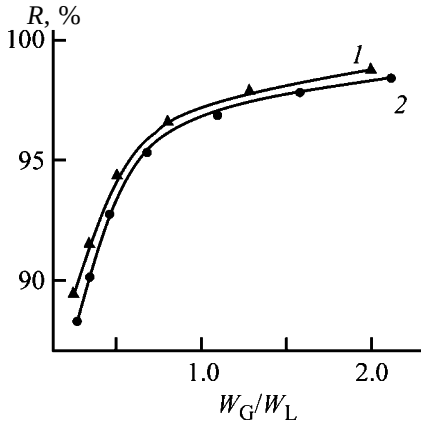

Fig. 2. Degree R of saturation of the physiological solution with atmospheric oxygen vs. the ratio of the flow rates of air and solution, W_G/W_L, through the CMC. tional increase in the output capacity of the CMM process.

The results of experiments performed with donor blood on the same CMC and at the same flow rate ratios of blood and atmospheric air confirmed that, as in the case of physiological solutions, the prototype chromatomembrane oxygenators ensure higher efficiency of oxygenation than that obtained with their membrane analogues.

CONCLUSION

The size of macropores in the biporous mass-exchange matrix has virtually no effect on the efficiency of chromatomembrane oxygenation. The optimal ratio of the flow rates of air and the liquid phase being oxygenated across the mass-exchange bed is within the range 0.5–2. The aqueous phase is saturated with oxygen to virtually the equilibrium extent if the dimension of the mass-exchange bed in the direction of its flow exceeds by a factor of at least 2 that in the direction of flow of the gas phase.

SORPTION AND ION-EXCHANGE PROCESSES

Solubilization Compositions for Template Synthesis of Mesoporous Sorbents

Abstract—The suitability of mixed solubilization compositions for template synthesis of mesoporous molecular sieves of various designations was demonstrated by analysis of published data and by the authors' experimental results.

Scientific approach and experimental methods in physical and colloid chemistry of surfactants are developed and improved mostly for individual substances, idealized models, and simple systems. In practice, it is more expedient, however, to use surfactant-based compositions, as, e.g., in production of detergents, flotation reagents, defoliants, emulsifiers, pharmaceuticals, and cosmetics [1–7].

The use of individual micelle-forming surfactants in template synthesis of mesoporous sorbents has been studied since 1992 [8, 9]. Beck *et al*. [8] and Huo *et al*. [9] suggested a number of basic schemes of interaction between a skeleton-forming inorganic reagent (I) and a micelle-forming surfactant (S), template. These authors assumed that the assembly (self-assembly) is controlled by electrostatic interaction of the ions in solution, namely, between charged polar groups of the surfactant and inorganic counterions. This interaction is the most efficient in the case of long-chain surfactants based on quaternary ammonium cations (S^+) and anionic silicate precursors (I^-), yielding hexagonal, cubic, of lamellar mesostructures. More recently, this concept was extended to include the views on the synthesis routes involving inversely charged reagents (S^-I^+), anionic surfactants such as sulfonates and phosphonates, as well as carboxylates and cations of inorganic precursors, buffer ions ($S^+X^-I^+$, $S^-M^+I^-$, where X is halogen, and M^+, alkali metal cation).

Irrespective of the scheme chosen, mesoporous sorbents are synthesized using insoluble/poorly soluble organic substances as auxiliary forming reagents. For example, Beck *et al*. [8] used trimethylbenzene (TMB) exerting a swelling (expanding) effect when added to a freshly synthesized template-containing mesophase: The diameter of the mesoporous molecular sieves (MMSs) increased from 4.0 to 6.5 nm. There is a good reason to assume that TMB is incorporated into the oil core of the micelle of the cationic surfactant.

Nonpolar aliphatic and aromatic hydrocarbons, for the most part, efficiently promote structure formation when introduced into freshly synthesized materials. Hydrocarbons with linear and branched radicals (C_5–C_{12}) yield an M41S phase mixture and/or cause the pore size to increase. At the same time, polar organic substances, in particular, alcohols, aldehydes, ketones, ethers, and esters, generally did not efficiently increase the pore size of the MCM-41 mesophase and, moreover, often yielded amorphous materials [10].

Kleitz *et al*. [11] prepared heat-resistant mesoporous oxides of transition metals (Ti and Zr) using binary organic additives, namely, 1-octanol as cosurfactant and toluene or TMB as swelling reagent. Both additives were introduced simultaneously with all the components (cetyltrimethylammonium bromide, CTMABr, acted as the basic template) into an acidic reaction mixture (RM). The ratio of the additives was varied and, since each additive was fixed at its specific place (cosurfactant was sorbed along the perimeter of the polar groups of the micelle, and TMB, codissolved in the CTMABr micelle core), these authors obtained composite mesostructures of Ti and Zr oxides with the pore diameter increased to 8.0 nm, while the degree of ordering of the hexagonal mesophase was not decreased. It was found that TMB increases the pore size more efficiently than toluene.

Kovalenko *et al*. [12] used organic hydrophobic cocondensing compounds in template synthesis for

preparing a diversity of functionalized MCM-41 materials. In hydrolysis of the ether groups of vinyl- or allyltriethoxysilane, the radicals formed were localized for the most part in the surface layer of the CTMABr micellar structures. This allowed preparation of a material with enhanced catalytic activity by sulfonation of the vinyl (or allyl) groups.

Miyake *et al*. [13] solubilzied phenol and some other organic compounds in an aqueous CTMABr solution to synthesize spherical mesoporous silica with the external diameter of particles of ca. 500 μm. The maximal degree of solubilization of phenol corresponded to the maximal specific surface area (according to BET) of calcined spherical silica.

In our previous work [14] we used a micellar solubilization solution (solubilized were monoethanolamides of medium and higher *n*-aliphatic acids EAC_m with m = 10, 12, 14, 16) to increase the degree of ordering of the spatial organization of the substance rather that the mesopore diameter. This proved to be feasible under mixed solubilization conditions.

We analyzed published data and found that only a few authors used preliminarily prepared solubilization solution in template synthesis. By now, extensive information has been accumulated about template synthesis of MMSs, which allows changing to a meaningful search for and use of solubilization template compositions both for laboratory purposes and for development of an accessible method (technology) of commercial production of nanoporous sorbents. This constitutes the long-term goal of our work.

EXPERIMENTAL

The synthesis conditions and properties were studied most comprehensively for siliceous MMSs, primary mesophases (and further, mesoporous materials) formed by the S^+I^- mechanism, owing to efficient interaction between the cationic surfactants and anionic silicon-containing reagent. As surfactants served alkylpyridinium halide homologs (C_nPyHal) with an even number of carbon atoms in the hydrophobic radical (n = 8–18). In C_{18}PyHal, the counterion was bromide, and in all other homologs, chloride.

The critical micellization concentrations (CMC) of aqueous and aqueous-salt solutions of the surfactants were determined conductometrically.

The synthesis (to be regarded as bitemplate synthesis) differed from that known for the S^+I^- scheme [8, 9] in that a preliminarily prepared micellar solubiliza-

* a_0 is the hexagonal unit cell parameter of MCM-41.

organization of the initial mesophases and derivatives of MMSs from not only the number, intensity, and resolution of the main reflections, but also from the *A*/*W* parameter [16], i.e., the ratio of the intensity to full width at half maximum of the first diffraction line (corresponding to the interplanar spacing d_{000}) (Table 1). Notably, structure formation of the mesophases continues when the samples are being dried. Figure 1 and Table 1 (samples with even numbers) present the X-ray diffraction patterns and selected X-ray phase analysis (XPA) results for the monotemplate-containing materials after keeping (aging) air-dry for 2 months.

Naturally, it could be suggested that creative interaction is possible under specific (in the limit, optimal) ratio between the inorganic reagent, each subsequent surfactant homolog, and water, whose role in template synthesis is not restricted to that of a solvent. Though the overwhelming majority of the publications is concerned with synthesis of MMSs specifically by the S^+I^- scheme [8, 9, 17], there are no clear concept and methodology of synthesis of mesophases and, consequently, MMSs, to determine the nature of the corresponding changes in the RM composition on going from one surfactant (template) homolog to another, which afford the optimal structure and sorption and other characteristics of the intermediate and end materials.

One of the approaches, partially implemented in [18], consists in introduction (preferentially dropwise) with stirring of a concentrated [in the region of stable existence of platelike micelles (concentration $c > CMC_3$)], solution of the surfactant into a dilute aqueous solution of Na_2SiO_3 (density ~1.02–1.03 g cm^{-3}). This affords optimal charge localization and distribution and size and shape of the complex anionic moieties. In a dilute Na_2SiO_3 solution, the surfactant concentration decreases to that intermediate between CMC_2 and CMC_3 (CMC_2 refers to cylindrical micelles), which results in spontaneous formation and packing of the hexagonal micellar structure. Table 2 shows that CMC_3 of aqueous AlkPyHal solutions significantly (15–20-fold) exceeds CMC_1. Evidently, this can be helpful for extrapolation of the initial concentration of the surfactant solutions, if CMC_2 and CMC_3 data for the given ionic strength of solution are lacking. Beck *et al*. [8] and Romannikov [17] took alkyl(C_{12}–C_{18})trimethylammonium bromides at a fixed molar ratio of the components for preparing mesophase materials with a hexagonal unit cell parameter a_0 varying from 3.53 to 4.61 nm, and HT-treated materials with a_0 varying from 3.95 to 4.82 nm. These authors concluded that, under these specific conditions, the main stages and the entire mechanism of formation of silica-micellar mesophases are weakly dependent on the alkyl chain length and are governed by polycondensation during the HT and thermal treatments.

Successive lengthening of the linear alkyl radical by two methylene groups (2.6 Å) implies a certain interrelation between the d_{000} and a_0 parameters of the mesophase materials. For example, a proportional increase in these parameters is observed for the major axis of the spheroidal micelles of individual surfactants with lengthening hydrocarbon radical, as well as with changing other parameters.

Table 1 summarizes the results of the syntheses of a number of mesophases with the hexagonal structure, attempted by us to further develop the synthesis concept suggested. Samples with odd numbers (1–11) are characterized by a maximum possible number of reflections for each homolog. Samples with even numbers (2–12) exhibit a proportionality between the first reflection intensity A, d_{000}, and a_0, but, unfortunately, they give a smaller number of reflections in the X-ray diffraction patterns. Notably, for both sample series the increment in d_{000} of the mesophases in going from the C_n to C_{n+2} template is much smaller than the length of two methylene groups of the two radicals whose ends meet at the center of the hydrophobic core ($0.26 \times 2 = 0.52$ nm). Probably, the hydrocarbon radicals get compressed in the oil core of the micelle and also undergo cross penetration and compaction.

Table 1 also shows that, upon lengthening of the template radical by two methylene groups, samples with odd numbers exhibit widely scattering differences between d_{000} (from 0.47 to 0.16 nm with an average of 0.30 nm) and, correspondingly, a_0 (from 0.55 to 0.19 nm, with an average of 0.36 nm). For the even sample series this scatter is much smaller, due, evidently, to a more perfect spatial organization of the substance (mesophase components).

We demonstrated earlier [14] that the perfection of alkylpyridinium-containing mesophases depends on the surfactant radical length. Materials with fairly perfect spatial organization can be prepared by templating $C_{16,18}$Py halides. After HT treatment for 72 h and calcination, the samples clearly exhibit four intense reflections in the X-day diffraction patterns (Fig. 2). Changes in the formation conditions, in particular, in the time of (co)mature, medium, and the HT and heat treatment temperature, markedly affect the perfection of the template-containing mesophases. We found that, for homologs with lower molecular weights, an efficient pathway lies in bitemplate synthesis based on mixed solubilization, when an insoluble/poorly soluble organic compound is solubilized in a solution of a typical micelle-forming surfactant. We listed the properties of the solubilizate and solubilizer, which afford mixed solubilization yielding mesophases with a fairly perfect three-dimensional structure.

To further develop this approach, we studied in more detail how the organoelemental solubilizate affects the perfection of the three-dimensional structure of the primary mesophases and MMSs thereof (Table 3). As organoelemental compounds served trialkylphosphine oxides $(H_{2n+1}C_n)PO$ with n = 8, 10, 12, 16. Their characteristic features affording mixed solubilization are as follows: a long linear radical; low water solubility (8–2 mg l^{-1} at 50°C for C_{10}–C_{16}); and a dipole moment of 2.66 D [19], which is responsible for dipole induction and formation of a stable polar shell of the micelle in interaction with the surfactant cation; the lack of substituents in the polar group and in hydrocarbon radicals, which could sterically hinder intermolecular interaction in the micelle; and the capability for hydrogen bonding with oxygen and hydroxy groups of the inorganic reagent. Trialkyl-

phosphine oxides also differ advantageously from aliphatic acid ethanolamides in enhanced thermal stability (because the C–P bond formed is stronger than C–C, and all the more than C–N) and in the specific stereochemical structure resembling a small shuttlecock, which favors expansion (increase in the volume) of the oil core of the micelle.

The organoelemental solubilizates with such properties, combined with a thermally stable surfactant (e.g., long-chain alkyltrimethylammonium bromide) as solubilizer, allow the temperature of HT treatment to be widely varied so as to reduce its time to 5–18 h. Table 3 shows that an organoelemental solubilizate with a relatively lower content in the micellar solubilization solution yields a mesoporous sorbent with improved structural characteristics.

The solubilization power and, thereby, the properties of the micellar structure, its interaction with inorganic reagents in the initial, ion-molecular stage of the mesophase formation can be controlled, in particular, by varying the composition of the medium and temperature. It is known that, with increasing solubilizate concentration in a solution of a neutral electrolyte, the specific solubilization S_{sp} of hydrocarbons and polar substances varies differently: With increasing concentration of a micellar surfactant S_{sp} tends to increase for hydrocarbons and decrease for polar solubilizates; with increasing amount of the neutral electrolyte S_{sp} also tends to decrease for polar solubilizates and increase for hydrocarbons [7]. In systems described by the relationships characteristic of mixed solubization, both trends in variation of the solubization power and several intermediate (transition) trends are observed, depending on the electrolyte and surfactant concentrations, the length of the hydrocarbon radical of the solubilizate and solubilizer, and some other factors [20].

Another approach to formulating solubilization compositions suitable for template synthesis of nanosorbents implies the use of close-cut surfactant fractions as both solubilizer and solubilizate. It should be noted that the use of wide fractions inevitably entails polytemplation and solubilization effect. Figure 3 illustrates how the solubilizate, with the example of monoethanolamide based on a low-molecular-weight fraction of C_{10}–C_{12} aliphatic acids, affects the structural characteristics of the end mesoporous sorbent, with decylpyridinium chloride serving as solubilizer. It is seen that, in the case of the solubilization bitemplate composition, the first reflection of the calcined sample grows in intensity manyfold compared to the freshly prepared sample. Compared to the calcined sample synthesized from the $C_{10}PyCl$ monotemplate, the reflection in the case of the solubilization bitemplate composition gets much more symmetrical and also grows in intensity (at the reagent molar ratio $C_{10}PyCl$: $EAC_{10–12}$: Na_2SiO_3 : H_2O = 1 : 0.5 : 1 : 1700; the mesophase was subjected to HT treatment in an aqueous medium at 80°C and calcined at 580°C).

The advantage of close-cut fractions of the solubilizate and solubilizer consists in that they form micelles with a more uniform surface (chemical nature, relief features, and curvature), characterized by a denser packing of the hydrocarbon radicals in the micelle core. Kryukova *et al*. [21] found that a significant portion of the radicals of an individual micelle-forming surfactant (40 – 60%, depending on its length) adjoins the polar group and contacts water. In the case of formation of a mixed two-component micelle ($C_{10}PyCl$ + $EAC_{10–12}$), the basic micelle-forming surfactant interacts with the surfactant fractions with shorter chains, i.e., water molecules are forced out of the hydrocarbon space. As a consequence, the micelle gets more "ideal." Once the optimal S_{sp} for several close-cut fractions of a specific solubilizate–solubilizer pair is determined, it is possible to formulate a series of solubilization composi-

tions for template synthesis of nanosorbents of various designations.

Thus, published data concerning the use of two- and multicomponent templates (mixtures of two micelle-forming surfactants and other versions) for synthesis of MMSs suggest the following. Cases of using preliminarily prepared and specially formulated solubilization solutions in the MMS synthesis were only few. The other researchers took advantage of one of the alternatives: codissolution of a hydrocarbon in the micellar core of the freshly formed mesophase [8, 10], introduction of a multicomponent template directly into the reaction [11], or utilization of cocondensing organic hydrophobic compounds in the synthesis [12]. In the latter case, localization of the hydrophobic–hydrophilic radicals in the surface layer of the micellar structures can be characterized as ad-solubilization. By this is meant, according to Esumi [22], formation of layers, adsorbed by surfactants, on hydrophobic particles, which favors incorporation of water-insoluble compounds into surfactant layers. The above-mentioned factors affecting the nature of ad-solubilization (surfactant structure, type of water-insoluble compounds, particle type) are generally close to those affording efficient solubilization, i.e., formation of a thermodynamically stable micellar solution of compounds insoluble in the given solvent. The suggested term "adsolubilization" implies cosorption of micelle-forming surfactants and water-insoluble compounds on the surface of hydrophobic particles.

On the whole, the use of solubilization compositions as templates seems to be an efficient and technologically sound method of preparation and, probably, production of a homologous series of organo–inorganic mesophases, micro- (template-containing) and mesoporous sorbents with regularly varying parameters of the spatial organization and pore structure, differing in the topography and nature of the sorption space surface, as well as of inclusion compounds and nanocomposites of various functional designations thereof.

CONCLUSIONS

(1) Solutions of micelle-forming surfactants in a specific for a certain homolog concentration range, corresponding to stable existence of plate-like micelles, are suitable for template synthesis of sorbents. The molar ratio of the reagents (surfactant : inorganic component) tends to increase on successively changing to a homolog with a higher molecular weight.

(2) The concept of bitemplate synthesis by mixed solubilization using solubilization solutions was further developed by studying how organoelemental solubilizate [trialkylphosphine oxide $(H_{2n+1}C_n)PO$ with n = 8, 10, 12, 16] affects the perfection of the structure of nanoporous silica sorbents.

(3) The close-cut fraction of carboxylic acid C_{10}–C_{12} monoethanolamides was tested as solubilizate for a bitemplate composition, and its influence on the structure formation of a low-molecular-weight (C_{10}PyCl) surfactant homolog and nanoporous materials thereof was elucidated.

(4) A technology of production of nanosorbents from bitemplate compositions comprised of a close-cut fraction of surfactants as solubilizer and a close-cut fraction of solubilizate was suggested and substantiated.

Abstract—The conditions of the joint electrolytic deposition of vanadium(V) and chromium(III) oxides from mixed sulfate solutions at different concentration ratios of the main components were studied.

Vanadium(V) oxide deposited on the anode from oxovanadium(IV) sulfate solutions in the presence of Mn(II) and Ni(II) ions has the higher specific characteristics compared to the bulk oxide [1, 2]. This is due to the formation of complex nonstoichiometric oxide systems having high electrochemical activity. Therefore, the oxide system formed by the joint electrolytic deposition of V_2O_5 and chromium(III) oxide from mixed salt solutions is of interest. Cr_2O_3 has the positive effect on the specific discharge characteristics of the complex oxide systems based on manganese oxide and other systems [3, 4]. The oxide system under consideration is also of interest, since, as a rule, Cr_2O_3 is not spontaneously deposited in electrolysis of aqueous solution. Data concerning the given problem are lacking.

We studied two-component solutions of oxovanadium(IV) and chromium(III) sulfates with a total concentration of 0.20 – 0.25 M and the ratio of component concentrations (hereinafter, V : Cr) varied from 15 : 1 to 3 : 1. To prepare the solutions, we used pure grade and analytically pure grade chemicals and distilled water. The electrolysis was performed in a 200-ml temperature-controlled glass cell. The temperature was similar in all the experiments, $85 \pm 3°C$, and the pH was varied within 1.8–2.0. These conditions were chosen on the basis of the preliminary study [5]. Compact coatings were deposited onto both sides of smooth platelike anodes ($10 \times 10 \times 0.3$ mm). The cathodes were smooth plates of VT-1 technical-grade titanium with the ratio $S_a : S_c = 1 : 5$. The efficiency of the anodic process was estimated from the conventional current efficiency CE_{con} (wt %) assuming that in the total anodic process all the efficient current is spent for V_2O_5 formation. This assumption was made because determination of the electrochemical equivalent q [g (A h)$^{-1}$] of the anodic deposits studied was virtually impossible. The phase composition of the deposits was studied by X-ray diffraction (DRON-2 diffractometer, CoK_α radiation). These data were used to calculate CE_{con} by vanadium(V) oxide in the total anodic process at various ratios of the $VOSO_4$ and $Cr_2(SO_4)_3$ concentrations in the solution. The volt–ampere characteristics of the total anodic processes were taken with a 12Cr18Ni9Ti steel anode (S = 1 cm^2) finished to V 7–8 class and cathodes made of VT-1 titanium at the above parameters of the electrolysis within i_a = 0.5–50 mA cm^{-2}. The potentials were measured relative to a silver chloride reference electrode (E = +0.225 V) using a Shch-4315 digital device. The CE_{con} values were also used for constructing partial polarization curves.

The conventional current efficiencies CE_{con} by the double V–Cr oxide as functions of the current density i_a at various concentration ratios of oxovanadium(IV) to chromium(III) sulfates (under equal other conditions) are presented in Fig. 1. The dependences have a steep ascending branch and a nearly symmetric descending branch in the range i_a = 5–12.5 mA cm^{-2}. At higher current densities, the right branch shifts regularly to a certain minimum. At V : Cr from 1 : 0 to 4 : 1, the curves pass through a well-defined maximum at i_a = 7.5 mA cm^{-2} (curves *1*–*3*), and at V : Cr = 3 : 1, at i_a = 10 mA cm^{-2} (curve *4*). Comparison of the dependences (Fig. 1) shows that Cr(III) ions strongly affect the character of the anodic processes. This is revealed as change in the rate of formation of the anodic deposit in the solution on adding Cr(III) ions. At relatively low $Cr_2(SO_4)_3$ concentration in the solution (V : Cr = 8 : 1), CE_{con} by the anodic deposit (Fig. 1, curve *1*) is considerably higher than in the solution without Cr(III) ions (Fig. 1, curve *2*). However, as the Cr(III) concentration is in-

6 : 1	35	3.5	33	1.15
4 : 1	32	3.2	37	1.18
3 : 1	28	2.8	40	1.13

* Data at i_a = 10 mA cm^{-2} and equal other electrolysis conditions.

creased further, CE_{con} considerably decreases and attains the critical value at V : Cr ≤ 3 : 1 (Fig. 1, curve *4*). This value agrees with the limiting content of Cr_2O_3 in the anodic deposit (Fig. 2, curve *3*). This trend is clearly seen when comparing CE_{con} by the anodic deposit and V_2O_5 as a function of the V : Cr ratio in the solution (Fig. 2, curves *1*, *2*). At V : Cr = 3 : 1, the corresponding values of CE_{con} are similar, which indicates that the total deposition rate and rate of V_2O_5 deposition become equal. Comparison of the CE_{con} values for various V : Cr ratios with the Cr_2O_3 content in the deposits (Fig. 2) shows that the specific mass of the doping component in the deposits remains virtually the same (see table).

The data presented (Fig. 1, 2) show that the V : Cr concentration ratio in the solution exerts a decisive effect on the kinetics of the anodic processes. This ratio determines the relative rate of the parallel reactions proceeding simultaneously at the anode: formation of the anodic deposit and O_2 evolution on the surface whose properties vary depending on the electrolysis conditions. The mutual influence of these reactions is complicated by redox processes of Cr(III) → Cr(VI) anodic oxidation and Cr(VI) → Cr(III) chemical reduction, which proceed simultaneously at the anode. The occurrence of these reactions is suggested, in particular, by the fact that the doping component in the anodic deposit is Cr_2O_3.

This conclusion is confirmed by the volt–ampere characteristics of the processes studied (Fig. 3). Their comparison shows that the curves of the total process and the partial curves of O_2 evolution are similar and have two ascending branches with a transition plateau between them (Fig. 3, curves *1*, *1*', and *4*, *4*'). Hence, it follows that the rate-determining reaction in the total process is O_2 evolution. The polarization is the lowest for the joint process of O_2 evolution and V_2O_5 deposition, and then it increases with decreasing Cr(III) content in a solution. For the curves of the total process and those of partial oxygen evolution, the current densities at the transition plateau decrease in the same order. On the surface with a preliminarily deposited layer, the polarization at the same V : Cr ratio in the solution is lower (Fig. 3, curve *4*''). In this case, clearly resolved inflections on the corresponding dependence are absent.

The partial curves of separation of the anodic deposit itself (Fig. 3, curves *1*'', *3*', *4*''') have sections which steeply ascend to certain limiting value and then pass a plateau. The limiting current densities decrease with increasing Cr(III) concentration in a solution. The exception is the partial curve of the V_2O_5

deposition with a steeper descending branch. The positions of extrema on the potential axis of the partial curves coincide with the analogous extrema in the total curves, which confirms similarity of the processes in each their section.

Analysis of the i_a–E_a curves presented here (Fig. 3) shows that their character is mainly determined by the relative rate of the joint anodic processes, which involves the formation of the anodic deposit, oxygen evolution, and probable redox reaction by the equations

$$2VO^{2+} + 3H_2O - 2e \rightarrow V_2O_5 + 6H^+, \quad E^0 = 1.1 \text{ V}; \quad (1)$$

$$2Cr^{3+} + 7H_2O - 6e \rightarrow Cr_2O_7^{2-} + 14H^+, \quad E^0 = 1.3 \text{ V}; \quad (2)$$

$$2H_2O + 2e \rightarrow O_2 + 4H^+, \quad E^0 = 1.23 \text{ V}; \quad (3)$$

$$18VO^{2+} + 2Cr_2O_7^{2-} + 19H_2O - 6e \rightarrow 9V_2O_5 + 2Cr_2O_3 + 38H^+. \quad (4)$$

The kinetic features of the anodic process consisting in that the anodic polarization in a solution containing small content of Cr(III) is lower than that in a pure oxovanadium(IV) solution are not fully understood. The same phenomenon was observed in anodic deposition of V_2O_5 from oxovanadium(IV) solution in the presence of Mn(II) ions [6]. This suggests that, at low concentration of Cr(III) ions (V : Cr = 8 : 1), the reaction (4) precedes reaction (2). Therefore, the forming Cr_2O_3 can block the anode surface and drastically decelerate the O_2 evolution; as a consequence, it can increase the anodic polarization. This corresponds to the extreme right position of the corresponding curves, i.e., total curve and partial curve of O_2 evolution (Fig. 3, curves *4*, *4*'). In the given case, the high O_2 overvoltage facilitates formation of the anodic deposit and exhaustion of the near-electrode space. For this reason, the limiting current density in the total curve is the lowest, and, on the contrary, that in the partial curve, the highest (Fig. 3, curves *4*, *4*'''). Apparently, this result is responsible for the fact that the limiting rate of formation of the anodic deposit is independent of E_a and that the relative rates of the anodic reactions, established correspondingly at each E_a value, are similar. Because the anode with a preliminarily deposited layer has the more developed surface, the blocking effect on it is lower and O_2 evolution occurs at lower polarization (Fig. 3, curve *4*'').

At higher concentrations of Cr(III) ions in a solution, consumption of dichromate ions by reaction (4) is delayed, and their excess amount appears in the near-surface layer of the anode. This may favor a decrease of the O_2 overvoltage by analogy with the effect observed in the course of the electrolysis of water [7]. Apparently, it can explain why with increasing Cr(III) concentration the limiting current densities increase and the total and partial curves shift to lower anode potentials (Fig. 3).

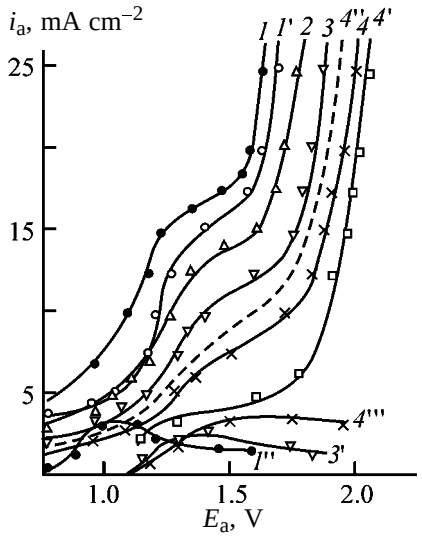

Fig. 3. i_a–E_a dependences taken in anodic deposition of (*1*) V_2O_5 and (*2*) V–Cr double oxide at different concentrations of the salts in a solution. V : Cr: (*2*) 3 : 1, (*3*) 4 : 1, (*4*) 8 : 1, and (*4*'') 8 : 1 (deposition onto the preliminarily formed film of the deposit). (*1*', *4*') Partial curves of the O_2 evolution with, respectively, vanadium(V) oxide and V–Cr double oxide (V : Cr = 8 : 1); (*1*'', *3*', *4*''') partial curves of the anodic deposit formation at V : Cr 1 : 0, 3 : 1, and 8 : 1, respectively.

The outward appearance and structure of the deposits studied directly depend on the electrolysis conditions. At the optimal values of the current densities (7.5–12.5 mA cm^{-2}) and V : Cr from 10 : 1 to 6 : 1, the deposits are characterized by the developed specific surface area having black color and amorphous structure typical of "pure" anodic deposits of V_2O_5.

At higher relative concentration of Cr(III) in the solution, the deposits become more compact and have clear crystalline structure. Increasing the current density above the limiting value makes the deposit surface nonuniform (i.e., results in appearance of regions of different color and roughness). This is manifested most clearly at V : Cr from 4 : 1 to 2 : 1 and is evidently associated with the increased concentration of Cr_2O_3 in the deposits. Also, this is manifested in the increased intensities of the reflections corresponding to the γ-Cr_2O_3 phase in the diffraction

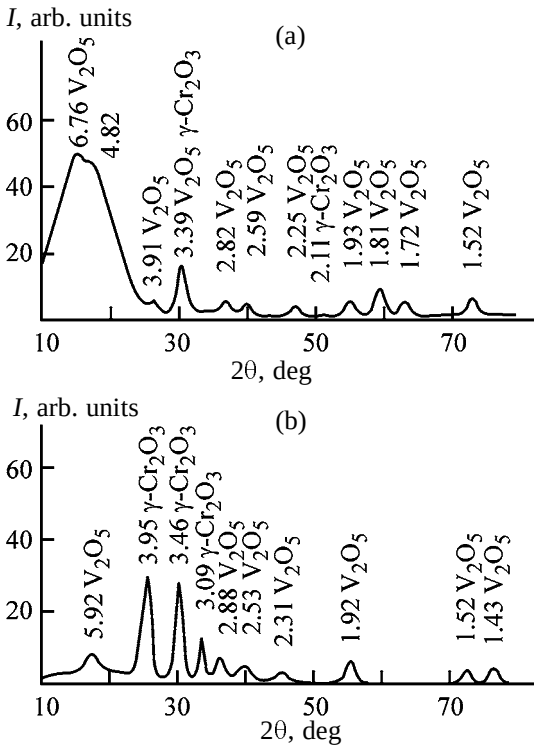

Fig. 4. Diffraction patterns of the V–Cr double deposits obtained at the V : Cr ratio in the solution of (a) 8 : 1 and (b) 4 : 1. (*I*) Relative intensity and (2θ) Bragg angle.

patterns of the precipitates obtained at higher concentration of Cr(III) ions in the solution (Fig. 4). According to the X-ray diffraction analysis, the deposits obtained under the conditions studied are two-phase systems V_2O_5–γ-Cr_2O_3, whose structure and phase composition are reasonably uniform for the given conditions of the electrolysis (Fig. 4). These data allow the materials studied to be classed with crystalline conglomerates whose constituting components enter into molecular interphase interaction.

CONCLUSIONS

The conditions for the formation of V–Cr double oxide materials from mixed sulfate solutions of the jointly deposited metals at the ratio of their concentrations V : Cr from 1 : 0 to 2 : 1 were studied. Reasonably compact coatings with the uniform structure can be deposited from the corresponding anode systems onto gauze and smooth platelike anodes made of 12Cr18Ni9Ti steel or aluminum with a current efficiency of 40–45 wt % in the course of the electrolysis from the above solutions at a total concentration of 0.2–0.25 M, concentration ratio V : Cr from 8 : 1 to 3 : 1, 80–85°C, pH 1.9–2.2, and the anodic current density of 7.5–12.5 mA cm^{-2}.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of Tin from Sulfate Electrolyte in the Presence of Syntanol, Formaldehyde, and Allyl Alcohol

G. I. Medvedev and N. A. Makrushin

Novomoskovsk Institute, Mendeleev Russian University of Chemical Engineering, Novomoskovsk, Tula oblast, Russia

Received April 23, 2004

Abstract—The elecrodeposition of tin from a sulfate solution containing $SnSO_4$, H_2SO_4, Syntanol, formaldehyde, and allyl alcohol was studied.

Organic substances ensuring formation of lustrous tin coatings can be chosen taking into account their first ionization potentials I [1]. It was established that obtaining lustrous tin coatings requires the presence of organic substances, luster-producing additives (LA), with I = 7.25 or 8.95–10.50 eV in an electrolyte containing Syntanol DS-10 and formaldehyde (37% solution).

We studied the influence exerted by allyl alcohol having I = 10.17 eV on the tin electrodeposition from a sulfate solution containing Syntanol and formaldehyde.

The study was performed in an electrolyte containing (g l^{-1}) $SnSO_4$ 10–50 and H_2SO_4 90–100. Organic substances were added into the electrolyte in the following amount: Syntanol DS-10 1–4 g l^{-1}, formaldehyde (37% solution) 1–10, and allyl alcohol 1–20 ml l^{-1}.

A 9–12-μm-thick tin layer was deposited onto copper samples. The polarization curves were taken with a P-5828 potentiostat. The degree of the coating luster was determined on an FB-2 photoelectric brightness-measuring device. The leveling power P of the electrolytes was determined by a direct method involving a profilographic measurement of the sample surface with a sine-shaped microprofile and calculation by the formula [2]

$$P = 2.3a/2\pi h_{av} \log (H_0/H_i),$$

where a is the amplitude of the wave of the sine-shaped microprofile; h_{av}, average thickness of the coatings (10 μm); H_0 and H_i, initial and final wave amplitudes of the sine-shaped profile, respectively.

The capacitance of an electrical double layer was measured in the course of electrolysis with a P-5021 ac bridge at a frequency of 30 kHz in a series equivalent chain.

The electrodeposition was performed at 18–25°C with and without agitation of electrolytes with a magnetic stirrer.

The influence exerted by organic additives on the outward appearance of the coatings was studied in an electrolyte containing (g l^{-1}) $SnSO_4$ 50 and H_2SO_4 100. It was found that the addition of Syntanol (1–4 g l^{-1}) to the electrolyte results in dull coatings. In the presence of formaldehyde (1–10 ml l^{-1}) or allyl alcohol (1–20 ml l^{-1}), or of both simultaneously, poor coatings are formed. The coatings with a considerably better outward appearance are formed in an electrolyte containing Syntanol (2–3 g l^{-1}), formaldehyde (6–8 ml l^{-1}), and allyl alcohol as additive. The influence of allyl alcohol is demonstrated in the table.

(*1, 7*) Electrolyte, (*2, 8*) *1* + 2 g l^{-1} Syntanol, 6 ml l^{-1} formaldehyde (37% solution), and 10 ml l^{-1} allyl alcohol; (*3, 4, 5, 6*) *2* at a rotation rate of the disk electrode (rpm) of 200, 500, 1000, and 2000, respectively.

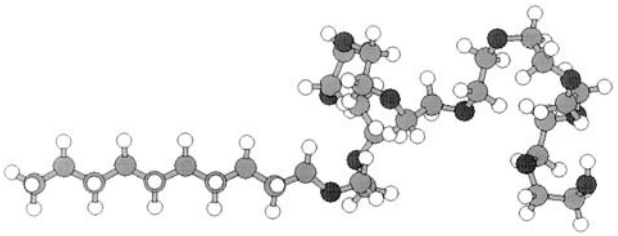

Fig. 2. Structure of Syntanol molecule according to quantum-chemical calculation. Hydrogen, carbon, and oxygen atoms are colored white, gray, and dark, respectively.

As seen, lustrous coatings can be obtained in the presence of allyl alcohol in certain modes of the electrolysis. The widest range (5–10 A dm^{-2}) of the current densities j_c ensuring formation of lustrous deposits is observed at an allyl alcohol concentration of 10–15 ml l^{-1}.

Deviations of the formaldehyde concentration from the above limit result in silvery coatings. At a Syntanol concentration below 1–2 g l^{-1}, the working interval ensuring formation of lustrous coatings is considerably narrower. At a Syntanol concentration above 3–4 g l^{-1}, the current density range in which lustrous coatings are obtained is the same, but foam formation in the electrolyte increases considerably, which complicates electrodeposition in the agitated electrolyte.

We studied the influence of the $SnSO_4$ concentration on the current density range ensuring formation of lustrous coatings. The study was performed in an electrolyte containing 2 g l^{-1} Syntanol, 6 ml l^{-1} formaldehyde, and 10 ml l^{-1} allyl alcohol. It was found that decreasing the $SnSO_4$ concentration makes j_c range ensuring formation of lustrous coatings narrower. For example, at a $SnSO_4$ concentration of 10–20 g l^{-1} lustrous coatings were formed in the current density range 2–4 A dm^{-2}, whereas at 30–60 g l^{-1}, they were formed in the 5–10 A dm^{-2} range. The H_2SO_4 concentration in the electrolyte must be within 90–100 g l^{-1}. Below 90 g l^{-1}, the electrolyte operation is instable, and the j_c range ensuring formation of lustrous coatings is narrower. At the H_2SO_4 concentration above 100 g l^{-1}, the range of the current densities ensuring formation of lustrous coatings does not vary.

It should be noted that high-quality lustrous coatings are obtained solely in an agitated electrolyte, and dull coatings are formed without agitation.

The current efficiency (CE) by tin in the electrolytes ensuring obtaining lustrous coatings decreases with increasing j_c and increases with increasing $SnSO_4$ concentration. At a $SnSO_4$ concentration varied within 10–20 g l^{-1} and at j_c = 2–4 A dm^{-2}, CE = 95–75%, and at the $SnSO_4$ concentration within 30–50 g l^{-1} and j_c = 5–10 A dm^{-2} CE = 95–90%.

The cathodic polarization curves on a rotating-disc electrode were obtained. As seen from Fig. 1, in the presence of organic substances, the cathodic polarization increases and the plateau of the limiting current appears on the cathodic polarization curve (curves *2, 3*). As the rate of rotation of the disc electrode increases, the limiting current density increases, whereas the cathodic polarization decreases (curves *2–6*). The limiting current in the polarization curves is due to adsorption of organic substances and formation of an adsorption layer on the cathode surface. This suggestion is confirmed by the results of measuring the capacitance of the electrical double layer. As seen from Fig. 1, curves *7* and *8*, the introduction of organic substances into the electrolyte results in the decrease of the double layer capacitance. In the potential range E from –0.3 to –0.4 V, the capacitance decreases from 32 to 11 μF cm^{-2}. At higher cathodic potentials, the organic substances desorb from the electrode surface, which makes the adsorption layer nonuniform and results in increased double layer capacitance.

To ascertain the nature of the adsorption layer formed on the cathode surface in electrochemical tin plating, we calculated the optimal structure of the

Syntanol molecule by the PM3 semiempirical quantum-chemical method [3, 4].

As seen from Fig. 2, the molecule consists of fibrillar hydrophobic nonpolar moiety (hydrocarbon radical $C_{10}H_{21}$) and hydrophilic moiety [globular oxyethylated fragment $(C_2H_4O)_{10}OH$]. The maximum size of the molecule lies within 2000 × 900 × 500 pm.

The surface of tin electrode was simulated by a rectangular cluster consisting of 48 tin atoms. The cluster was chosen as recommended in [5].

It was established that an adsorption layer on the tin surface is formed with planar orientation of the Syntanol molecule. In the process, formaldehyde, allyl alcohol, and Sn^{2+} ions are distributed in its globular moiety (Fig. 3). The calculation results show that, with the system Syntanol + allyl alcohol + Sn^{2+}, the interaction with the cluster surface is the strongest (E = 1009 kJ mol^{-1}). With formaldehyde introduced into this system, the interaction energy decreased by a factor of approximately 3 (E = 384 kJ mol^{-1}).

As known [6], formation of lustrous coatings is associated with the adsorption of organic substances on the electrode surface and with the complex physicochemical processes occurring in the near-cathode layer. The diffusion-hydrodynamic mode of delivery (removal) of ions changing the structure and properties of an adsorption layer on the cathode surface is also important [7]. The possibility of the electrochemical transformation of organic molecules must also be taken into account. In such a case, the products of transformation of the additive on the electrode, rather than the additive itself, can exert a luster-producing effect. Taking into account the experimental data obtained, the luster production in electrochemical tin plating can be explained by the adsorption–diffusion mechanism.

Unequal accessibility of different regions of the submicroprofile to LA is due to the adsorption film on the cathode [8]. The thickness of this film must be comparable with the size of ridges and pits, typical of lustrous surface.

As already noted, in a tin-plating electrolyte, the adsorption layer on the cathode is formed by Syntanol, formaldehyde, LA, and Sn^{2+}. Without agitation of the electrolyte, the thickness of the adsorption layer is large owing to polymolecular adsorption of organic substances (Fig. 4a). The layer formed in an agitated electrolyte has a smaller thickness, comparable with the size of ridges and pits (Fig. 4b). In this case, the adsorption layer plays the role of a diffusion layer in which a gradient of LA concentration is created. After

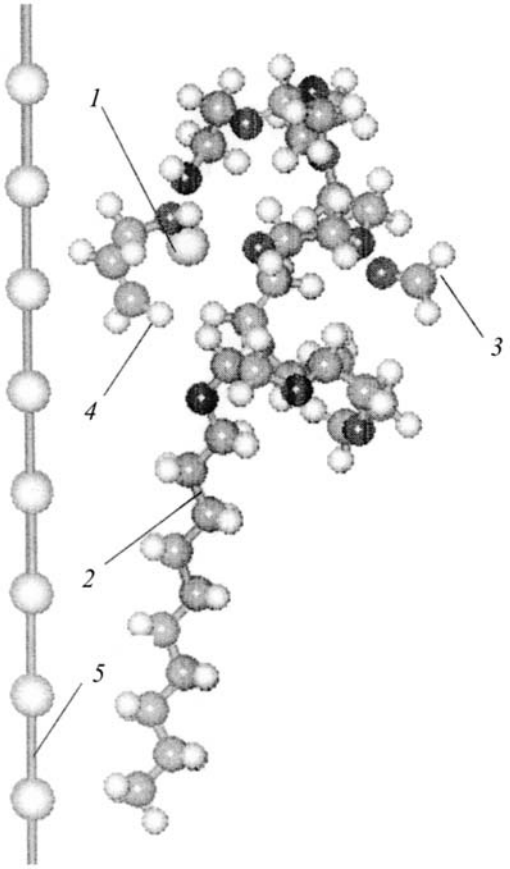

Fig. 3. System of (*1*) Sn^{2+}, (*2*) Syntanol, (*3*) formaldehyde, (*4*) allyl alcohol, and (*5*) Sn_{48} cluster. Planar orientation of the Syntanol molecule with respect to the cluster plane.

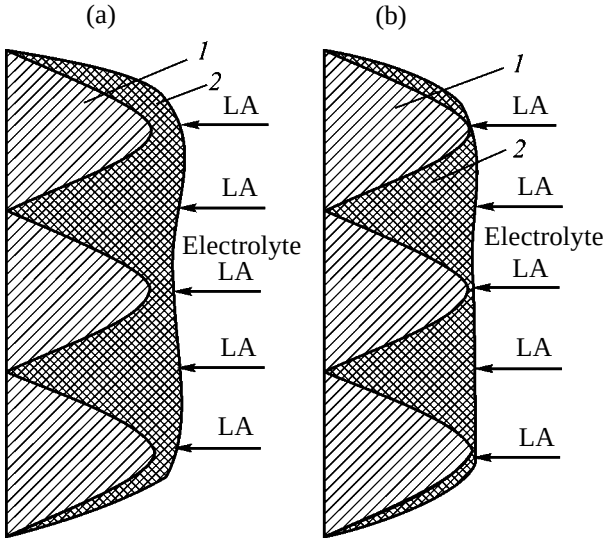

Fig. 4. Scheme of (*1*) ridges and pits of the submicroprofile in the presence of (*2*) adsorption layer (a) with and (b) without agitation of the electrolyte. Diffusion flow of LA is indicated by the arrows.

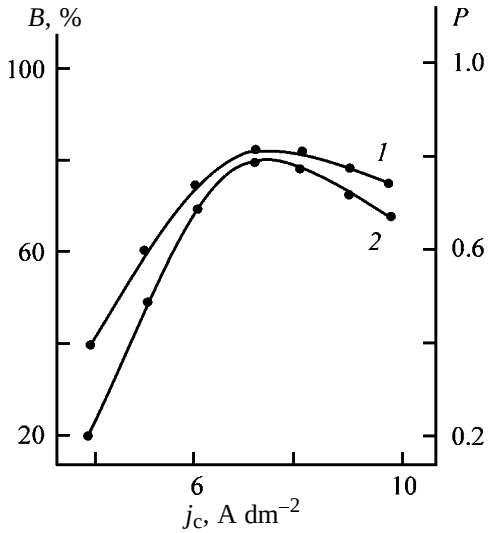

Fig. 5. (*1*) Degree of luster *B* and (*2*) leveling power *P* of the coatings vs. the cathodic current density j_c. Electrolyte: $SnSO_4$ 30 g l^{-1}, H_2SO_4 100 g l^{-1}, Syntanol 2 g l^{-1}, formaldehyde (37% solution) 6 ml l^{-1}, and allyl alcohol 7 ml l^{-1}; mechanical agitation.

the certain agitation rate is attained, the diffusion to the cathode will result in stronger adsorption of LA on ridges than in pits. As in adsorption–diffusion leveling theory [2], unequal accessibility of different regions of the microprofile is provided by consumption of LA in the diffusion-limited process, i.e., when the rate of LA consumption is equal to the limiting rate of its delivery to the cathode, with the consumption mechanism (incorporation of molecules into the deposit or their electrochemical reduction) insignificant. Since with increasing rotation rate of the disk electrode (and rate of the electrolyte agitation) the limiting current increases and the cathodic polarization decreases, it appears that inhibition on the ridges occurs to a lesser extent than in pits.

At the same time, despite the presence of the adsorption layer in them, a larger amount of tin will be deposited in pits than onto ridges (Fig. 4b). This is due to incorporation of tin ions Sn^{2+} into the adsorption film. Such redistribution of the metal makes the submicroprofile relief smoother and hence makes the surface lustrous.

We studied the leveling power of tin-plating electrolytes for obtaining lustrous coatings. It was found that they have the positive leveling power. The degree of luster and degree of leveling were studied in relation to the cathodic current density. Comparison of these parameters revealed their interrelation, i.e., the higher the degree of leveling, the higher the degree of luster (Fig. 5).

The phenomenon of leveling is associated with the luster of electrolytic coatings, since the luster production is also the process of the surface leveling. In the course of leveling, coarse microroughnesses, from 0.2 to 100 μm and larger, are removed. In the course of the formation of lustrous surface, very small submicroroughnesses, about 0.15 μm and smaller, are removed [9]. Thus, in a tin-plating electrolyte containing Syntanol, formaldehyde, and allyl alcohol, in the course of the tin electrodeposition the submicro- and microroughnesses of the cathode surface are smoothed.

Thus, we have developed a sulfuric acid tin-plating electrolyte of simple composition for obtaining lustrous coatings with a leveled surface. The electrolyte contains $SnSO_4$ 10–50 g l^{-1}, H_2SO_4 90–100 g l^{-1}, Syntanol (DS-10) 2–3 g l^{-1}, formaldehyde (37% solution) 6–8 ml l^{-1}, and allyl alcohol 10–15 ml l^{-1}. The process is performed with mechanic agitation of the electrolyte at the current density j_c = 2–10 A dm^{-2}. The current efficiency is 75–95% and the electrolyte temperature, 18–25°C. Above 25°C, the operation region of j_c in which lustrous coatings are obtained is narrower, the electrolyte becomes turbid wihtin a short time, and the deposit appears on the bath bottom. All the above impairs the quality of the coatings obtained. Anodes must be made of pure tin. To prevent the contamination of the electrolyte with sludge, it is necessary to place the anodes into jackets made of a polyvinyl chloride or polypropylene fabric.

The electrolyte should be adjusted with respect to $SnSO_4$, H_2SO_4, and formaldehyde on the basis of chemical analysis data [10]. The Syntanol amount in the electrolyte must be corrected after the amount of electricity of 100 A g^{-1} l^{-1} is passed; 1 g l^{-1} of Syntanol is added to the bath. The consumption of allyl alcohol is 0.02 ml A^{-1} h^{-1}.

CONCLUSIONS

(1) The study of the electrodeposition of tin from a sulfuric acid electrolyte containing organic additives showed that, when Syntanol, formaldehyde, and allyl alcohol are present simultaneously, the current densities at which lustrous coatings are formed vary within 2–10 A dm^{-2}, depending on the $SnSO_4$ concentration in the electrolyte.

(2) Lustrous coatings in tin electrodeposition are formed by the adsorption–diffusion mechanism.

(3) The leveling power of the sulfuric acid electrolyte containing organic additives was studied. It was

found that a tin-plating electrolyte containing Syntanol, formaldehyde, and allyl alcohol has the positive leveling power depending on j_c. It was shown that the degree of luster correlates with the leveling power: the higher the degree of luster, the higher the leveling power.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Mechanism of Electrochemical Synthesis of Copper(II) β-Diketonates

N. N. Kostyuk

Sevchenko Institute of Applied Physical Problems, Belarussian State University, Minsk, Belarus

Received July 28, 2004

Abstract—Formation of copper β-diketonates in electrolysis of a solution of acetylacetone in acetonitrile in the presence of oxygen, with tetraethylammonium bromide as supporting electrolyte, was studied.

In [1–3], we reported on electrochemical synthesis of copper(II) β-diketonates in acetonitrile solutions of β-diketones. When the electrolysis was performed in an inert atmosphere (Ar, He), the copper anode dissolved but copper β-diketonates were not formed in noticeable amounts. The major process was copper transfer from the anode to the cathode. Since copper(I) β-diketonates are unstable, it was suggested that the transfer of Cu(I) ions to the cathode and their reduction to metal occur faster than their anodic oxidation to the double-charged state. Therefore, it seems necessary to use an oxidizing atmosphere. Passage of a moderate flow of dry air through the electrochemical cell in the course of electrolysis resulted in the successful synthesis. The yield of copper(II) β-diketonates as a function of current in most cases exceeded 100% [1–3], reaching in some cases 130%. This fact suggests [2] that a considerable amount of β-diketonates is formed not electrochemically but by the direct reaction of copper with the β-diketone under oxidative conditions. With low-active compact copper anode, the reaction is weak [2, 3], but formation of relatively active refined copper at the cathode and powdered copper in the near-anode space [due to disproportionation of Cu(I) ions] promotes the reaction [5]. This is indirectly confirmed by the fact that the excessive (over 100%) yield of copper chelates as a function of current increases in going to more acidic β-diketones [1] and by the possibility of electrochemical preparation of active Cu powders [6, 7].

The above data give certain insight into reactions involved in synthesis of copper(II) β-diketonates. It is unclear, however, how the oxidative atmosphere of air favors an increase in the yield of copper(II) chelates, can the mechanism of anodic oxidation of copper in aqueous solutions [5, 8, 1]] be applied to aprotic solvents [1–3] (taking into account the fact that an important role in electrochemical processes is played by intermediate metastable compounds, specific for aqueous and nonaqueous electrolytes [8, 9, 11]), and what chemical equations describe the processes occurring in the electrochemical cell.

EXPERIMENTAL

The electrolysis conditions, chemicals, and procedures for their preparation are described in [2]. The IR spectra of acetonitrile solutions of the electrolyte [1 M solution of acetylacetone (HAA) in acetonitrile, supporting electrolyte 0.1 M tetraethylammonium bromide], taken in various steps of the electrochemical synthesis, were recorded on a Specord IR-75 spectrophotometer using liquid cells with NaCl windows and 0.126 mm layer thickness. The X-ray phase analysis of powders was performed on a DRON-2 diffractometer (Mo radiation).

On applying the electric current, the steady state of the electrochemical system changes. New phases are formed on the electrode surface, and sometimes also in the bulk of solution [8]. In the case of electrolysis of aqueous solutions, a metastable compound containing hydroxide is formed at the anode [8]. The processes occurring with a copper anode are described in detail in [9]. The sequence of transformations can be schematically represented as follows:

$$\mathrm{Cu} \rightarrow (\mathrm{CuOH})_{ads} \rightarrow (\mathrm{CuOH^+})_{ads} \rightarrow (\mathrm{Cu^{2+}})_{ads} \rightarrow [(\mathrm{Cu^{2+}})_{aq}]_0 \rightarrow \mathrm{Cu^{2+}_{aq}}. \quad (\mathrm{I})$$

The first two transformations are electrode reactions, and their rates depend on the electrode potential. Scheme (1) involves oxidation of Cu to the Cu(II)

1070-4272/04/7711-1786 © 2004 MAIK "Nauka/Interperiodica"

state directly on the electrode surface, followed by migration of the Cu^{2+} ion into the solution. If copper is also oxidized by another pathway, along with scheme (1), the current density should increase with formation of a brown-red deposit on the anode surface [9], suggesting formation of various copper oxides:

$$Cu(CuOH)_{ads} \rightarrow (Cu_2O)_{ads} \rightarrow Cu(CuO)_{ads}$$

$$\text{and } (CuOH^+)_{ads} \rightarrow (CuO)_{ads}. \quad \text{(II)}$$

In earlier papers [5, 10], a somewhat different mechanism of anodic dissolution of copper was suggested:

$$Cu \rightarrow Cu^+ + e \text{ (fast) and } Cu^+ \rightarrow Cu^{2+} + e \text{ (slow). (III)}$$

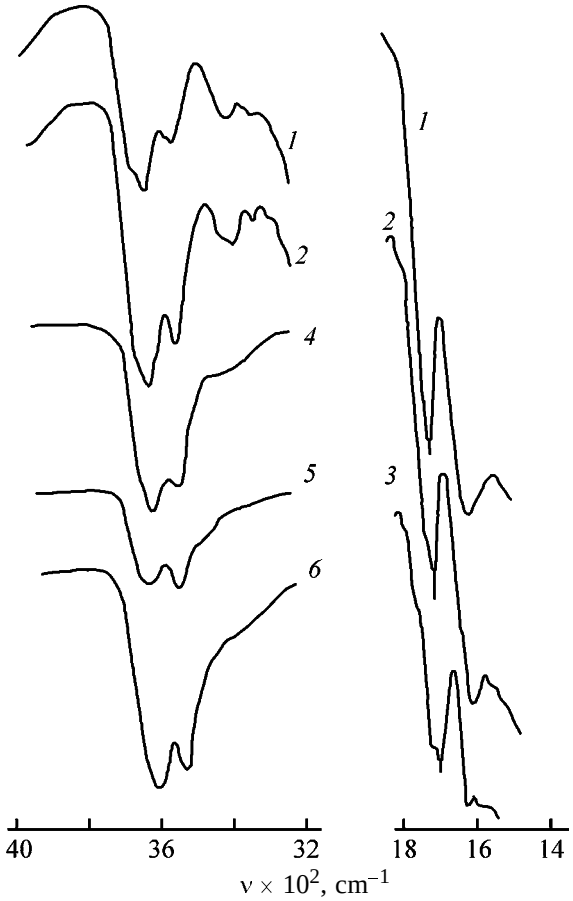
In anodic polarization, the fast step of formation of Cu^+ is followed by the slow step of oxidation to Cu^{2+}. Stable Cu^+ ions can partially diffuse into the bulk of solution from the anode surface. Beyond the layer surface, their concentration increases, and the disproportionation $2Cu^+ \rightarrow Cu + Cu^{2+}$ starts near the anode, yielding a copper powder [5].

The electrolysis of an acetylacetone solution with a copper anode under oxidative conditions results in precipitation of $Cu(AA)_2$ as blue crystals. After the electrolysis completion, an equal volume of water was added to the electrolyte, and the blue precipitate was filtered off, dried in air, and recrystallized from chloroform [1, 2]. In recrystallization of large amounts of copper(II) acetylacetonate (products from several experiments were combined), formation of a black powder on the beaker bottom was observed; this precipitate was filtered off, washed successively with chloroform and acetonitrile, and dried in air at room temperature. According to X-ray phase analysis, the isolated black precipitate is CuO. No traces of Cu_2O were detected. The electrolysis in an inert atmosphere resulted in copper refining and formation of a small amount of a finely dispersed copper precipitate [1–3].

These facts are better consistent with mechanism (III) of anodic dissolution of copper. Apparently, bubbling of dry air results in copper oxidation:

$$2Cu + O_2 = 2CuO \text{ and } 4Cu^+ + O_2 = 2CuO + 2Cu^{2+}.$$

Simultaneously, a brownish red film formed on the anode surface, suggesting the occurrence of some reactions in accordance with mechanism (II), which is possible only in the presence of water. Since the starting chemicals were thoroughly dried and the cell was protected from atmospheric moisture, the only source of H_2O could be a chemical reaction in the course of electrolysis.



Fragments of the IR spectra of the acetonitrile electrolyte. (ν) Wave number. (*1*) Initial solution (sample 1), (*2*) after electrolysis for 15 min (sample 2), (*3*) after electrolysis for 30 min (sample 3), (*4*) subtraction of the spectrum of sample 1 (reference channel) from that of sample 2, (*5*) subtraction of the spectrum of sample 2 (reference channel) from that of sample 3, and (*6*) subtraction of the spectrum of sample 1 (reference channel) from that of sample 3.

The release of water during the electrolysis was confirmed by the IR spectra of the electrolyte. Samples were taken from the initial solution (sample 1) and in 15 (sample 2) and 30 min (sample 3) after the start of the electrolysis. The figure shows the fragments of the IR spectra of the samples in the ranges of stretching vibrations of hydroxy groups (3700–3300 cm^{-1}) and bending vibrations of water (1700–1500 cm^{-1}). In the IR spectrum of the initial electrolyte solution (sample 1), there is fairly strong absorption in the range of stretching vibrations of OH groups. Since the electrolyte solution was prepared with thorough protection from atmospheric moisture,

this absorption should be assigned to the enol form of acetylacetone [12–14].

The absorption in the range 3700–3000 cm^{-1} noticeably increases in going from sample 1 to sample 2, suggesting generation of OH groups. Simultaneously, a shoulder belonging to bending vibrations of water appears at 1700–1500 cm^{-1} [13–15]. The manifestation of the bending vibrations of water confirms its generation in the course of electrolysis and indicates that the increased absorption in the IR spectrum of sample 2 in the range 3700–3300 cm^{-1} is not due to keto–enol transformations of acetylacetone (the OH groups of the enol form do not absorb in this range) [12–15]. Longer electrolysis (30 min) results in a further increase in the absorption in the range of water stretching vibrations, though less pronounced than in the first 15 min. The generation of water in the course of electrolysis is demonstrated more clearly by subtraction of the spectrum of the initial electrolyte (sample 1) from the spectrum of the electrolyte subjected to 15-min electrolysis (sample 2). To obtain the differential spectrum, we recorded the spectrum of sample 2 with sample 1 placed in the reference channel. The resulting spectrum (curve *4*) is due to stretching vibrations of water generated in the first 15 min of the electrolysis. By recording the spectrum of sample 3 (solution after electrolysis for 30 min) with sample 2 placed in the reference channel, we obtained the spectrum of the stretching vibrations of water formed in the last 15 min of the electrolysis. The intensity of this spectrum is appreciably lower. This fact is consistent with a decrease in the current density in the potentiostatic mode of the electrolysis and the corresponding deceleration of the synthesis in the second 15 min [1]. The total amount of water generated in 30 min is reflected by fragment *6* (sample 1 in the reference channel, sample 3 in the sample channel). The IR spectra in the range 3700–3300 cm^{-1} well correlate with the spectra in the range of bending vibrations of water, 1700–1500 cm^{-1}. In going from the initial sample 1 to samples 2 and 3, first a shoulder (fragment *2*) and than a band at 1610 cm^{-1} (fragment *3*), belonging to $\delta(H_2O)$ [13–15], appear in the IR spectrum.

Since generation of water under conditions of dry air bubbling is possible only in the presence of hydrogen, it should be associated with the cathodic elimination of proton from the γ-position of acetylacetone. Actually, this reaction is reduction of dissolved oxygen [5].

Summing up, we can conclude that electrochemical preparation of copper(II) acetylacetonate in an acetonitrile solution is a complex process described by the following sum of electrochemical and chemical transformations:

Anode:

$$Cu = Cu^+ + e \text{ (fast)}, \quad (1)$$

$$Cu^+ = Cu^{2+} + e \text{ (slow)}, \quad (2)$$

$$Cu(CuOH)_{ads} \rightarrow (Cu_2O)_{ads} \rightarrow Cu(CuO)_{ads} \quad (3)$$

$$(CuOH^+)_{ads} \rightarrow (CuO)_{ads}. \quad (4)$$

Reaction (2) makes no appreciable contribution to the yield of the target product [1–3]. The direct reaction of the compact anode material with acetylacetone does not occur either, as follows from data of [2, 3] and from the thermodynamic data: In the electrochemical series of metals, copper stands to the right of hydrogen. Reactions (3) and (4) occur at the anode surface as water is accumulated [9] and are also weakly pronounced, although in some cases they can cause passivation of the anode.

Cathode:

$$O_2 + 4HAA + 4e = 4AA^- + 2H_2O. \quad (5)$$

This cathodic reaction corresponds to that suggested in [5].

Solution:

$$Cu^{2+} + 2AA^- = Cu(AA)_2, \quad (6)$$

$$Cu_{disp} + 2HAA = Cu(AA)_2 + H_2, \quad (7)$$

$$4H + O_2 = 2H_2O, \quad (8)$$

$$2Cu + O_2 = 2CuO, \quad (9)$$

$$4Cu^+ + O_2 = 2CuO + 2Cu^{2+}. \quad (10)$$

Reactions (6) and (10) are, apparently, the main final reactions yielding the target product. Reaction (7) of finely dispersed copper with acetylacetone may make approximately 30% contribution to formation of $Cu(AA)_2$, as judged from the current efficiency reaching 130%, and its contribution will significantly depend on the β-diketone acidity. With fine particles having a strong curvature, the direct reaction of Cu with an acid, thermodynamically forbidden with compact metal, may become allowed [16], as a new term related to the particle curvature radius appears in the expression for the Gibbs energy:

$$\Delta G(r) = \Delta G - \Delta g, \quad \Delta g = 2\sigma M/\rho r,$$

where σ is the surface energy; M, molecular weight; ρ, density; and r, curvature radius.

Thus, at low r, the Gibbs energy decreases. Reaction (2) will make a noticeable contribution to the generation of water, in addition to the cathodic reduction of oxygen. Reactions (9) and (10) occur in the near-anode space [5].

CONCLUSIONS

(1) A pattern of electrochemical and chemical reactions involved in electrochemical synthesis of copper(II) chelates was suggested on the basis of published data on anodic oxidation of copper, features of electrochemical synthesis of copper(II) β-diketonates, IR spectra of the acetonitrile electrolyte solutions taken in the course of electrolysis, and analysis of the by-products formed.

(2) The overall process can be described by ten reaction equations.

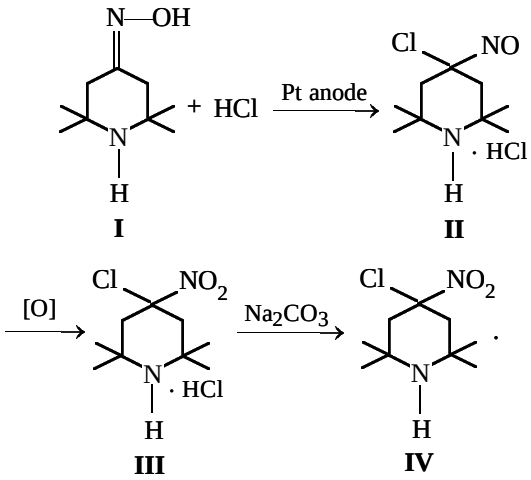
Abstract—Electrochemical chlorination and bromination of 4-hydroximino-2,2,6,6-tetramethylpiperidine were studied.

Halogenation of amines attracts researchers' attention as a route to the corresponding halo derivatives and products of their further transformations. Numerous papers concern this reaction [1–3]. *N*-Halo derivatives of aliphatic amines are widely used in organic synthesis [2]; therefore, search for new halogenating agents is an important problem of applied organic chemistry. It was shown previously that electrochemical halogenation of 2,2,6,6-tetramethylpiperidine and its derivatives at pH 5–10 yields *N*-halo compounds of this series [4, 5], which are relatively stable and can be used as oxidants and halogenating agents [6, 7].

We studied electrochemical halogenation of 4-hydroximino-2,2,6,6-tetramethylpiperidine **I**. We found that electrochemical chlorination of **I** in acidic solution yields 4-nitroso-4-chloro-2,2,6,6-tetramethylpiperidine hydrochloride **II**, which is readily oxidized to 4-nitro-4-chloro-2,2,6,6-tetramethylpiperidine hydrochloride **III**. Compound **III** on treatment with a saturated sodium carbonate solution transforms into the corresponding amine **IV**:



The electrolysis was performed at pH 4–5 at a platinum anode in a diaphragm electrolyzer in the presence of an organic solvent. After passing 2 F mol^{-1} of electricity, we isolated from the blue aqueous layer 4-nitroso-4-chloro-2,2,6,6-tetramethylpiperidine hydrochloride **II** in 70% yield based on **I**.

Apparently, the chlorinating agent in chlorination of **I** is 1-chloro-4-hydroximino-2,2,6,6-tetramethylpiperidine **V** formed by chlorination of **I** with molecular chlorine generated at the anode. Compound **V** is insoluble in water and passes into the organic phase. In the organic phase, apparently, compound **V** undergoes intramolecular chlorination or acts as a chlorinating agent with respect to substrate **I**. The resulting amine **II** passes into the aqueous phase from which it can be isolated as a salt. This reaction sequence is indirectly confirmed by cyclic voltammetry (CVA).

Chlorination of **I** in HCl solution could not be studied by CVA, because the process occurs in the potential range of discharge of the supporting electrolyte (1.0 V vs. silver chloride reference electrode). To study the process, we recorded the cyclic voltammograms of **I** in 1.5 M $HClO_4$. In this electrolyte, the oxidation wave of **I** was not observed (Fig. 1a). The background curve changed on adding a small amount of NaCl to the supporting electrolyte. In this case, the anodic current at 1.4 V increased, which is caused by the discharge of chloride ions (this peak grew with increasing concentration of Cl^- in the electrolyte), and a current wave appeared at 2 V. This wave is presumably related to oxidation of compound **V** formed by the reaction of chlorine with compound **I** added to the electrolyte earlier. Figure 1b shows the cyclic voltammograms of the solutions of **I** and 1-chloro-2,2,6,6-tetramethylpiperidine in the supporting electrolyte. Curve *2* in Fig. 1b, starting from 1.6 V, fully coin-

cides with curve *2* in Fig. 1a, which counts in favor of formation of **V** as an intermediate.

To prepare compound **III**, the blue acidic aqueous solution of **II** was evaporated to dryness on a water bath. In the process, compound **II** was oxidized with atmospheric oxygen to **III**. On treatment of **II** with hydrogen peroxide in alkaline solution, 4-nitro-4-chloro-2,2,6,6-tetramethylpiperidine **IV** formed immediately. The structures of **II** and **III** were confirmed by elemental analysis and ^{1}H NMR spectroscopy.

The electrochemical chlorination of **I** in neutral and weakly alkaline solutions in the two-phase system probably occurs with the formation of 1,4-dichloro-4-nitroso-2,2,6,6-tetramethylpiperidine, which, being a practically neutral compound, passes to the organic phase. 1,4-Dichloro-4-nitroso-2,2,6,6-tetramethylpiperidine appeared to be unstable, and we failed to isolate it pure.

Attempted electrochemical bromination of **I**, similar to chlorination in acidic solution, failed. In alkaline solution, bromination did not occur either. In both cases, the hydrolysis of **I**, yielding 4-oxo-2,2,6,6-tetramethylpiperidine (triacetonamine), prevailed.

We were able to perform bromination of **I** in a neutral solution at a constant pH of the electrolyte in a diaphragmless electrolyzer. As electrolyte we used a two-phase system consisting of an aqueous solution of hydrobromide of **I**, potassium bromide, and methylene chloride.

Similarly to chlorination in a neutral solution, bromination of **I** involves intermediate formation of 1,4-dibromo-4-nitroso-2,2,6,6-tetramethylpiperidine **VI**. This compound dissolves in the organic layer of the electrolyte, imparting to it green color; then, according to TLC, compound **VI** transforms into 4-bromo-4-nitroso-2,2,6,6-tetramethylpiperidine **VII**. We failed to isolate **VII** because of its rapid oxidation to 4-bromo-4-nitro-2,2,6,6-tetramethylpiperidine **VIII** with atmospheric oxygen. The structure of **VIII** was confirmed by elemental analysis and ^{1}H NMR spectroscopy.

EXPERIMENTAL

4-Nitroso-4-chloro-2,2,6,6-tetramethylpiperidine hydrochloride II. The electrolysis was performed in a 150-ml diaphragm electrolyzer with platinum electrodes (anode and cathode, 10 and 6 cm^2 plates, respectively) and a power-driven stirrer.

The anode compartment was charged with 1.7 g (0.01 mol) of **I**, 0.5 ml of HCl (ρ = 1.19 g ml^{-1}), 70 ml of water, and 30 ml of methylene chloride. The cathode compartment was charged with 30 ml of 10% HCl. The electrolysis was performed with vigorous stirring at 20°C, current density 0.05 A cm^{-2} (current 0.5 A), and completed after passing 2 F mol^{-1} (0.52 A h) of electricity. After the electrolysis completion, the organic layer was separated, and the aqueous layer was evaporated in a vacuum to 1/3 of the initial volume, until blue crystals precipitated; the crystals were filtered off. Yield of hydrochloride **II** 1.68 g (70%), mp >250°C (dec.). The compound was identified by IR, UV, and ^{1}H NMR spectroscopy (comparison with an authentic sample [8]).

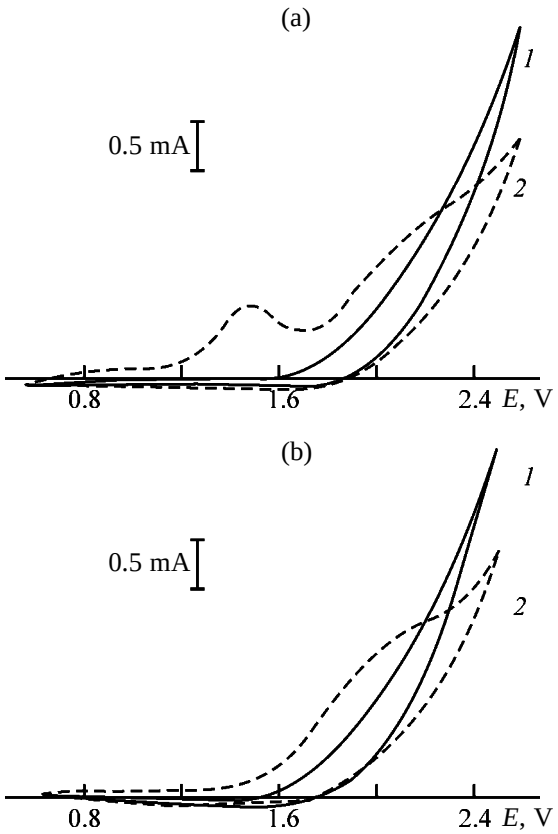

Fig. 1. Cyclic voltammograms of oxidation of **I**. (*E*) Potential. Pt anode; 20°C; potential sweep rate 0.2 V s^{-1}. (*1*) Supporting electrolyte (100 ml of 1.5 M $HClO_4$) + 2 × 10^{-4} M **I**; (*2*) the same + (a) 1 × 10^{-5} M NaCl and (b) 1 × 10^{-3} M 1-chloro-2,2,6,6-tetramethylpiperidine.

4-Nitro-4-chloro-2,2,6,6-tetramethylpiperidine hydrochloride III. An aqueous acidic solution (pH 4) of the electrolyte (70 ml), containing hydrochloride **II** (prepared as described above), was evaporated on a water bath to dryness; compound **III** was obtained as white crystals, yield 1.75 g (95%), mp 235°C (from ethanol). Mixing with an authentic sample gives no depression of the melting point [8].

4-Nitro-4-chloro-2,2,6,6-tetramethylpiperidine

IV. A suspension of 2.56 g (0.01 mol) of **III** in 30 ml of CH_2Cl_2 was treated with a concentrated Na_2CO_3 solution to pH 8–9. The organic layer was separated, and 40 ml of 30% H_2O_2 was added to it dropwise. After the blue color disappeared, the organic layer was separated, and the solvent was evaporated in a rotary evaporator; 2 g (94%) of **IV** was obtained, mp 45–46°C (from hexane). The ^{1}H NMR spectrum of the product coincides with that of an authentic sample [8].

4-Bromo-4-nitro-2,2,6,6-tetramethylpiperidine VIII. The electrolysis was performed in a 150-ml diaphragmless electrolyzer equipped with platinum electrodes (anode and cathode, 10 and 6 cm^2 plates, respectively) and a power-driven stirrer.

The electrolyzer was charged with 1.7 g (0.01 mol) of **I**, 1.5 ml of HBr (ρ = 1.39 g ml^{-1}), 2.4 g (0.02 mol) of KBr, 70 ml of water, and 30 ml of methylene chloride. The electrolysis was performed with vigorous stirring at 20°C, current density 0.05 A cm^{-2} (current 0.5 A), and completed after passing 2.5 F mol^{-1} (0.75 A h) of electricity. After the electrolysis completion, the organic layer was separated, washed with water (2 × 30 ml), and dried over sodium sulfate; the solvent was removed on a rotary evaporator. Compound **VIII** was obtained as white crystals; yield 1.35 g (60%), mp 106–108°C (from methanol).

Found, %: C 40.43; H 6.85; N 10.78.
$C_9H_{17}BrNO_2$. Calculated, %: C 40.8; H 6.45, N 10.55.

^{1}H NMR spectrum (CCl_4), δ, ppm: 1.09 s and 1.29 s (12H, MeC), 2.22 and 3.05 (4H, CH_2, *AB* pattern, J_{gem} 15 Hz, $\Delta\nu$ 63 Hz).

CONCLUSIONS

(1) Electrochemical chlorination of 4-hydroximino-2,2,6,6-tetramethylpiperidine in acidic solution (pH 4–5) yields 4-nitro-4-chloro-2,2,6,6-tetramethylpiperidine hydrochloride in 70% yield.

(2) 4-Nitroso-4-chloro-2,2,6,6-tetramethylpiperidine hydrochloride is oxidized with atmospheric oxygen to 4-nitro-4-chloro-2,2,6,6-tetramethylpiperidine hydrochloride; treatment of the latter with hydrogen peroxide in alkaline solution yields 4-nitro-4-chloro-2,2,6,6-tetramethylpiperidine.

(3) Electrochemical bromination of 4-hydroximino-2,2,6,6-tetramethylpiperidine in neutral solution yields 4-bromo-4-nitro-2,2,6,6-tetramethylpiperidine in 60% yield.

Abstract—The influence exerted by the porous structure of fibrous and granulated carbon materials on the nature of the charging process and depth of penetration of the electrochemical process was studied.

Fibrous carbon materials have a unique porous structure and find wide application in widely diverse processes of chemical technology [1]. Use of carbon materials as sorbents makes it possible to intensify and improve the efficiency of the separation and concentration of mixtures by sorption and the recovery of impurities in utilization of industrial solutions. Rather promising is application of carbon fibers as electrodes in power cells and high-sensitivity electrochemical methods of analysis [2]. Use of carbon fibers as sorbents in the adsorption recovery of organic compounds, noble metals, and other inorganic compounds from aqueous solutions has been reported [3, 4]. In this case, the efficiency of fibrous carbon materials is due not only to their large surface area and high rate of adsorption, but also to the possibility of carrying out the process at a prescribed surface potential.

The possibility of implementation of the liquid-phase adsorption technology using carbon materials under conditions of electrochemical polarization largely depends on the efficiency of the process of charging of porous carbon electrodes. This study is devoted to comparative analysis of the electrochemical properties of granulated activated carbon (GAC) and activated carbon fibers (ACF).

EXPERIMENTAL

The electrochemical properties of carbon materials were studied by measuring charging curves and potentiodynamic curves in a standard three-electrode electrochemical cell. As electrolyte served a deaerated 0.1 N solution of potassium sulfate. The samples studied were placed on a gold grid serving as an inert current lead. A saturated silver chloride electrode was used as reference, and a porous carbon rod, as an auxiliary electrode. The compartments for the working and auxiliary electrodes were separated by an MB-2 biporous membrane. The electrochemical parameters were set and recorded with a PI-50 potentiostat.

As carbon materials to be studied served ACF of varied texture: bundle (Aktilen of brands A and B: AUV-A and AUV-B, respectively), felt (AUV-2), fabric (AUV-7), and GAC with a uniform porous structure.[1] The GAC samples were composed of uniformly porous carbon materials obtained by treatment of transition metal carbides with chlorine at elevated temperatures. Removal of volatile reaction products yields a carbon matrix whose uniform porous structure is determined by the crystal lattice of the starting carbide [5]. The uniformity of the porous structure makes it possible to interpret more unambiguously the effect of the porous structure on the electrochemical properties of carbon materials.

The structural parameters of the carbon materials under study are listed in the table. It can be seen that the porous structure of the samples changes from mostly mesoporous (granulated carbon GAU-2, GAU-3) to pronouncedly microporous (granulated carbon GAU-7 and GAU-6, carbon fibers).

The course of charging of the surface of GAC and ACF can be judged from galvanostatic charging curves $\Delta E = f(Q)$ obtained in the double-layer region,

[1] The GAC samples were fabricated at St. Petersburg Technological Institute. Carbon fibers AUV-A and AUV-B are semicommercial samples supplied by Khimvolokno Production Association (St. Petersburg); the carbon felt AUV-2 and fabric AUV-7 are fibrous materials manufactured at the Institute of General and Inorganic Chemistry (Minsk, Belarus).

* V_{micro}, V_{meso} is the volume of micro- and mesopores, respectively; r_{eff}, effective pore radius; τ, characteristic charging time; and $\tilde{\rho}$, effective resistivity of the electrolyte in pores.

where Q is the quantity of electricity, and ΔE is the shift of the potential from the steady-state value (Fig. 1).

The nonlinear run of the dependence in the initial part of the curves corresponds to occurrence of transient processes and propagation of the "charging wave" across the thickness of the porous electrode [6]. The occurrence of pronounced transient processes in porous electrodes made of carbon sorbents results from nonuniform charging and is associated with the finite time of formation of an electrical double layer (EDL) in the pore space of the electrode. As a quantitative indication of the duration of these transient processes serves the characteristic charging time τ. The values of τ for the samples under study are listed in the table. At small radii of pores in the electrode, the hindrance to transport of ions in the interstitial space is significant, which makes the transient processes longer.

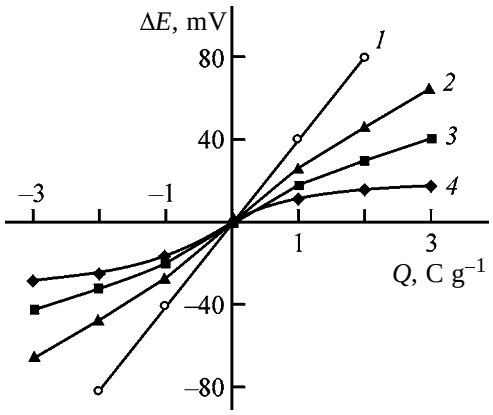

Fig. 1. Charging curves obtained on carbon fibers and activated carbon in 0.1 N K_2SO_4. (Q) Quantity of electricity and (ΔE) shift of the potential from the steady-state value. (*1*) GAU-3, (*2*) AUV-7, (*3*) AUV-2, and (*4*) GAU-7.

It can be seen from Fig. 1 that the dependence ΔE–Q is linear from virtually the very beginning for the mesoporous carbon GAU-3 (curve *1*) and carbon fiber AUV-3 (curve *2*). This indicates that the charging of the whole internal surface of the carbon samples is uniform, i.e., the rate at which the potential changes at any part of the internal surface of the porous electrode is comparable with the rate of EDL formation. The values of τ listed in the table for the given samples are comparatively short, as in the case of AUV-A and AUV-B fibers. Somewhat longer are transient processes on AUV-2 (Fig. 1, curve *3*). The nonlinear portion of the charging curve is very long for the microprous carbon GAU-7 (curve *4*), the small size of whose pores (r_{eff} = 1.1 nm) markedly limits the rate of transport of ions within the pore space and makes lower the rate at which the polarization is established across the thickness of the porous electrode.

The observed transient processes in charging of porous carbon materials are primarily due to the influence exerted by the porous structure on the rate and uniformity of the process of EDL charging and are independent of the degree of electrode impregnation with the electrolyte solution. The impregnation of the electrodes under study was complete because the electrodes were preliminarily kept in the electrolyte solution for a long time, and measurements were carried out 24 h after the electrodes were submerged in the electrolyte solution and a constant value of the stationary electrode potential was attained. After keeping the electrodes in the solution, the degree of impregnation reached a constant value and remained unchanged in the course of the experiment because the capacitance of EDL, determined for an electrode in different days, was the same.

All the carbon fibers under study have pores with small radii and would seemingly show a considerably longer duration of transient processes, comparable with that for a microporous sample GAU-7. However, this is not the case, which may be due to specific features of the pore structure of carbon fibers. Despite that the radius of micropores in carbon fibers is considerably smaller than that in activated carbon, the charging of fibers occurs more uniformly. This is favored by texture properties of ACF and, in particular, by the small thickness of threads and by the lability of the system of fibrils in the carbon fiber [6]. The effect of lability of the carbon fiber consists in that its porous structure changes in polarization because of the separation displacement of likely charged fibrils of the fiber and an increase in the dimensions of the transport pores. The manifestation of this effect favors a significant decrease in the hindering effect of the porous medium on the process of EDL formation and thereby leads to a faster establishment of a uniform polarization of the carbon fiber.

The relationship between the structure and nature of charging of ACF and GAC can be judged from the change in the capacitance of EDL in the electrode on raising the potential sweep rate. The capacitance of the EDL of the samples was determined by the method of potentiodynamic curves. Because of the increased ohmic resistance of the electrolyte in the pores, the rates of charging of the internal and external surfaces of the porous electrodes may differ. Beginning from certain small potential sweep rates, when the rate of EDL formation within the pore space starts to exceed the rate of polarization, the apparent capacitance of the carbon electrode corresponds to its whole internal surface area. As the polarization rate increases, the capacitance of the porous electrode decreases because the measured capacitance corresponds to only that part of the working surface which is involved in the electrochemical process and has enough time to be charged during the time of the potentiodynamic cycle.

Figure 2 shows that the capacitance of the EDL of the granulated carbon GAU-2 falls steeply and reaches rather small values as the polarization rate increases. This indicates that the charging process is displaced to the external surface. A considerably less pronounced decrease in the capacitance of the EDL is observed for AUV-7 and AUV-B, despite that the effective radius of pores in the fibers is severalfold smaller than that in carbon. The fact that high values of the capacitance of ACF are preserved in the whole range of potential sweep rates is a consequence of the lability of the

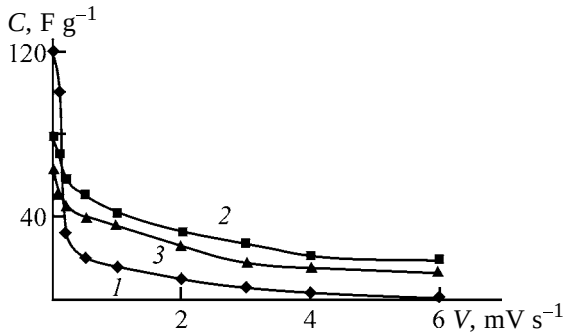

Fig. 2. Dependences of the capacitance C of the electrical double layer on the potential sweep rate V, obtained on carbon fibers (*1*) AUV-B and (*2*) AUV-A and (*3*) on activated carbon GAU-2.

structure of the fiber under polarization. The separation displacement of fibrils of a polarized carbon fiber and expansion of transport pores makes weaker the hindering influence of the porous medium and thus results in that rather high rates of current transport and mass exchange are preserved in polarized carbon fibers.

We calculated the parameters that make it possible to evaluate the efficiency of utilization of carbon materials under polarization. To these parameters belong the total resistance R and the effective resistivity $\tilde{\rho}$ of the electrolyte in the pores, the electrode capacitance C (F g^{-1}), and the characteristic time of charging ($\tau = RC$). The calculation was performed using a software that minimizes the deviation of experimental points from the theoretical curve describing the potentio-dynamic charging of a porous electrode in the double-layer range of potentials (range of ideal polarizability) [7]:

$$I = Cv\left\{1 - 2\pi^{-2}\sum_{k=1}(k + 0.5)^{-2}\exp\left[-\pi^2(k + 0.5)\frac{t}{RC}\right]\right\},$$

where I is the current (A g^{-1}); v, potential sweep rate (V s^{-1}); t, time; and k, summation index.

On calculating the values of C and R for each sample, $\tilde{\rho}$ was found by comparing the resistances R_i of the electrodes studied and that (R_0) of a model carbon adsorbent having sufficiently wide pores, which do not hinder the current transport and mass exchange. In this case, it can be assumed that $\tilde{\rho}$ of the model sample virtually coincides with the resistivity ρ_0 of the electrolyte in the solution bulk (found conductometrically). Then $\tilde{\rho}$ of the samples can be found using the relation

$$R_i/R_0 = \tilde{\rho} l_i S_0/(\rho_0 l_0 S_i),$$

where l and S are the thickness and cross-sectional area of the structural unit of the electrode (grains or fibers).

The calculated values of τ, R, and $\tilde{\rho}$ of the samples are listed in the table. It can be seen that the charging parameters found for the granulated carbons directly depend on the predominant pore radius. A decrease in the pore radius in carbons GAU-6, GAU-7, and GAU-1 leads to a steep increase in the effective resistivity $\tilde{\rho}$ of the solution in pores and in the characteristic time of EDL charging. At the same time, carbon fibers AUV-2, AUV-7, and AUV-B, which are sorbents with a clearly pronounced microporous structure in accordance with the values of the predominant pore radius, do not show so high values of $\tilde{\rho}$, which is presumably due to an increase in the size of transport pores in polarization of the fiber. Consequently, the structural lability of the fiber obviates ohmic limitations and allows a more uniform distribution of the polarization across the thickness of the porous electrode.

At strong polarizations (>0.1 V), at which Faraday processes occur in addition to the charging process, the effective depth λ of penetration of the electrochemical process was calculated for all the samples. This parameter characterizes the uniformity of distribution of the polarization across the thickness of the porous electrode [8]:

$$\lambda = (b/2\tilde{\rho} S i_0)^{1/2},$$

where b is the slope of the Tafel portion of the polarization curve (V); S, specific surface area of the electrode ($cm^2\ cm^{-3}$); and i_0, exchange current density ($A\ cm^{-2}$).

The value of λ and, consequently, the efficiency of polarization are determined by the size of structural units of the porous electrode and by the characteristics of the electrochemical process. The values of b and i_0 were found from cathodic polarization curves measured in a 0.1 N aqueous solution of K_2SO_4. Under the given conditions, the Faraday process is associated with discharge of water molecules. Comparison of the resulting values of λ (see table) shows that AFC are polarized considerably more efficiently than GAC. The better uniformity of AFC polarization in aqueous solutions, which is independent of the texture of fibers, is determined primarily by the very small thickness of carbon fibrils in the fibers, lability of their structure, and low exchange current densities, i.e., by the slow rate of water discharge on an energetically more uniform surface of carbon fibers.

Thus, fibrous carbon materials are rather promising for use as electrodes in various electrochemical processes, because they differ from granulated carbons in faster attainment of a prescribed polarization and in more uniform distribution of the polarization across the thickness of the carbon electrode.

CONCLUSIONS

(1) Comparison of the galvanostatic curves of charging of granulated carbons and carbon fibers shows that the time in which the equilibrium polarization is attained is shorter for carbon fibers.

(2) Analysis of the potentiodynamic curves reveals smaller hindrance to current transport and mass transfer in carbon fibers, compared to activated carbons.

(3) The calculated resistivity of the electrolyte in pores and the depth of penetration of the electrochemical process suggest that carbon fibers show more uniform distribution of the polarization across the thickness.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Zirconium, Calcium, and Barium on Corrosion-Electrochemical Behavior of Aluminum

I. N. Ganiev, R. O. Barotov, and M. B. Inoyatov

Nikitin Institute of Chemistry, Academy of Sciences of Tajikistan Republic, Dushanbe, Tajikistan

Received March 16, 2004

Abstract—The effect of zirconium, calcium, and barium on corrosion-electrochemical properties of aluminum was studied. A positive effect of alloying aluminum by these metals was revealed.

The dissolution of aluminum in neutral media is described by the following equations [1, 2]:

$$Al + 3OH^- = Al(OH)_3 + 3e, \quad (1)$$

$$Al(OH)_3 + OH^- = Al(OH)_4^-. \quad (2)$$

The process is limited by the transport rate of OH^- ions to an electrode surface. Oxygen is a depolarizer in neutral aerated solutions. Its reduction at the metal|solution interface follows the equation

$$O_2 + 2H_2O + 4e = 4OH^-. \quad (3)$$

The process is limited by the diffusion of oxygen dissolved in an electrolyte, which finally determines the metal corrosion rate. The intermediate product of the reaction of aluminum with OH^- ions is hydrated oxide of the general formula $Al_2O_3 \cdot nH_2O$. Various modifications of aluminum oxides and hydroxides are readily soluble in alkaline and acid media, but they are practically insoluble in neutral solutions. Therefore, aluminum and its alloys can be used only in near-neutral media. In such solutions, oxide films on aluminum show high protective properties, and the corrosion of aluminum and its alloys, as a rule, is minor and occurs at separate defects of oxide films [1, 2]. The pitting corrosion is the most dangerous type of corrosion degradation of aluminum and its alloys.

According to [3, 4], a corrosion process proceeds on aluminum in alkaline media at rather negative potentials (–1.5 to –1.75 V), and the corrosion mechanism can be expressed as a system of two conjugated stages:

$$Al + 2OH^- \rightarrow Al(OH)^{2+} + 3e, \quad (4)$$

$$H_2O + e \rightarrow OH^- + 1/2H_2. \quad (5)$$

In alkaline solutions, corrosion occurs virtually fully under the conditions of hydrogen depolarization. The addition of the first electron to a water molecule is the slowest stage.

Thus, the corrosion of aluminum in various media has been extensively studied, but this is not true for its alloys, especially for low alloys. This makes difficult the choice of alloying components and alloy compositions.

This problem is complicated by the lack of the theory for basic principles of corrosion-proof doping of metals and alloys. The existing assumptions consist in an increase in the thermodynamic stability of the system and a decrease in cathode or anode areas on the alloy surface [5].

The most efficient way of increasing the corrosion resistance of aluminum alloys is the retardation of anode processes, i.e., the passivation. From the viewpoint of corrosion, it is preferable that the strengthening structural phase of alloys should be anodic with respect to the main (cathodic) bulk of the alloy. In such cases, the alloys must have the smallest possible relative surface area of the anodic component. The reduction of the surface area of anodes is attained by obtaining an alloy with narrower uniform grain boundaries, for example, by increase in the alloy purity or by an appropriate thermal treatment. Doping of a metal or an alloy with a stronger inhibiting alloying element also enhances the capability of the alloy for anodic passivation [5, 6]. For this purpose, anodic dopants are often used. In this work we chose calcium and barium, and also zirconium as anodic dopants because of their lower electronegativity [7] and high oxygen affinity [8] compared to aluminum. They were chosen owing to the fact that zirconium as a transition metal positively affects the strength, plasticity, and

heat resistance of aluminum, whereas alkaline-earth metals act as refining and modifying agents and therefore positively affect physicomechanical properties and corrosion resistance of aluminum [9–12].

EXPERIMENTAL

The corrosion-electrochemical behavior of the synthesized aluminum alloys was studied according to [10, 11] in 0.01 and 0.1 N NaOH, 3% NaCl, and 0.01 N HCl using a PI-50–1 potentiostat operating at potential scan rates of 2 and 10 mV s^{-1}. A silver chloride electrode was used as a reference electrode, and all potential values were referenced to it. The corrosion rates of alloys were determined gravimetrically. The experimental data are shown in Tables 1 and 2.

It is known that the corrosion behavior of metals and alloys can be judged from various electrochemical parameters. The time dependence and steady-state value of the free corrosion potential can provide important data on the behavior of a metal in a corrosive medium. As a rule, a large shift of the corrosion potential to the positive region suggests that the anodic reaction rate can decrease owing to passivation. Such materials can be expected to be more corrosion-resistant under natural service conditions [13].

To select a corrosion medium, we first studied the behavior of Al in NaOH solutions of various concentrations.

Reduction of the NaOH concentration from 0.5 to 0.05 N results in decreasing corrosion current density, which suggests a decrease in the rate of aluminum corrosion. The sharpest decrease in the corrosion rate is observed in 0.05 N NaOH. If the sodium hydroxide concentration is less than 0.05 N, aluminum changes from an active state to a passive state owing to the accumulation of a film of aluminum hydroxide on the metal surface. These experimental data are in good agreement with the published data on aluminum behavior in KOH solutions [14, 15]. Taking these results into account, we carried out the further experiments in 0.1 N NaOH and in 3% NaCl.

The dynamics of free corrosion potential variation for low-alloyed aluminum alloys in 0.1 N NaOH solution (Table 1) indicates that a protective film on

their surface is formed slowly and the process is complete within 2–4 h and sometimes within a day. The alloys under study have a more positive free corrosion potential than the starting aluminum. The greatest positive shift of the potenial is observed within 5–30 min of the test in the corrosion medium.

Similar experiments were carried out in 0.01 N NaOH, 0.01 N HCl, and 0.5 N NaCl. In these media, free corrosion potentials of the alloys are also shifted to the positive region, the alloys showing more positive potential values than the pure metal (Table 2).

According to the experimental data, in particular, to the value of the steady-state free corrosion potential (Table 2), aluminum and its alloys have lower corrosion resistance in alkaline media than in acid media.

The results of the electrochemical study of aluminum alloys with various zirconium contents and constant barium and calcium contents in 3% NaCl are summarized in Table 3. The corrosion potentials of the alloys are shifted to the negative region as the zirconium content increases. Small amounts of zirconium scarcely affect the pitting formation potential E_{pf}, whereas the complete passivation potential E_{cp} somewhat decreases. With alloys, the passivation range is not reduced compared to aluminum. The alloys doped predominantly with 0.01–0.1% Zr have lower current densities of passivation onset i_{po} and of complete passivation i_{cp} than pure aluminum. Therefore, doping of aluminum with zirconium enhances the corrosion resistance of the alloys.

The modifying agents zirconium, calcium, and barium make alloy structures more finely dispersed and react with gases dissolved in aluminum. In the case of modified alloys, in contrast to nonmodified alloys, the intercrystallite corrosion is limited to the near-surface layer of the metal and is not developed significantly even after prolonged corrosion tests [16].

The role of zirconium as a dopant for aluminum alloys is not limited to its modifying action. It also sharply increases the recrystallization temperature of aluminum and its alloys after both hot and cold deformations, making it possible to obtain a non-recrystallized or partially non-recrystallized structure after thermal treatment and hence to enhance the corrosion resistance and mechanical properties. For example, the corrosion rate of the alloys of optimal composition under study after pressing (80% deformation) decreased from 0.0136 (initial state) to 0.0094 g m^{-2} h^{-1} after deformation.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Ozone on the Corrosion of Metals in an Acid Medium

G. O. Tatarchenko

Severodonetsk Technological Institute, Severodonetsk, Lugansk oblast, Ukraine

Received September 17, 2003; in final form, September 2004

Abstract—The corrosion-electrochemical behavior of steels and metals in sulfuric, hydrochloric, and acetic acids in the presence of ozone was studied.

In recent decades, one of directions of synthesis of oxygen-containing derivatives, oxidation of hydrocarbons and other organic compounds with ozone, which does not contaminate the products and the environment and makes it possible to improve the yield and quality of target products, has been developing successfully [1–3]. This poses an acute problem of the choice of structural materials and apparatus for organic synthesis in the presence of ozone. To fabricate the required equipment, it is necessary to use structural materials that would ensure prolonged and safe operation of the apparatus in chemical industries employing exceedingly corrosive media (sulfuric, hydrochloric, nitric, and acetic acids). Commonly, high-alloyed stainless steels (12Cr18Ni10Ti, 08Cr22Ni6Ti, and 06CrNi28MoCuTi), VT1-0 titanium and its alloys, and ADO aluminum and its alloys are used for this purpose. It is necessary to determine how such a strong oxidizing agent as ozone affects the corrosion resistance of these materials at different acid concentrations and temperatures and varied content of organic compounds, which may act both as corrosion inhibitors and as corrosion activators.

It should be noted that the materials mentioned above show different passivation mechanisms. The passivity of stainless steels is mostly due to chemisorption of the oxidizing agent on those parts of the surface which are enriched in chromium, whereas Ti and Al are passivated because of the formation of the oxides TiO_2 and Al_2O_3. The main factor that determines the rate of corrosion of the metals in nonoxidizing acids (H_2SO_4, HCl) is the hydrogen overvoltage on the cathodic areas of the metal. Ozone, which is an effective cathodic depolarizer, shifts the corrosion potential E_{cor} in the positive direction, with the result that the corrosion rate of a metal may increase if the metal remains in the region of active dissolution. At the same time, the facilitation of the cathodic process results in that the polarization of the anodic areas increases and may reach the critical current density and transfer the metal to the passive region.

The aim of this study was to determine how O_3, an exceedingly strong oxidizing agent, affects the corrosion-electrochemical behavior of steels, alloys, and metals in a corrosive acid medium.

EXPERIMENTAL

The following steels: 09Mn2Si, 08Cr17Ti, 12Cr·18Ni10Ti, 10Cr17Ni13Mo2Ti, and 06CrNi28MoCuTi, and metals: Ti, Ni, Cr, and Mo, were studied. As the acid media served hydrochloric, sulfuric, and acetic acids at 20–60°C. Polarization measurements were carried out in a three-electrode glass cell. The working electrodes were prepared using the standard procedure. The potential sweep rate was 1.44 V h^{-1}. Potentiometric and potentiodynamic curves were measured after the stationary corrosion potential E_{cor} was attained (10–15 min). The potentials are given relative to the standard hydrogen electrode. An ozone–air mixture was obtained in a laboratory glass ozonizer with a cooling water jacket from compressed cleaned and dried air. The concentration of O_3 in the mixture was varied by changing the feeding voltage with a laboratory one-coil transformer. The solutions were ozonized by bubbling with the ozone–air mixture at a rate of 0.07 m^3 h^{-1} during the entire time of experiment. The concentration of O_3 in the gas phase was 0.1 mol m^{-3}. The corrosion rate was found from the weight loss by samples kept in the solutions for 100 h.

The 06CrNi28MoCuTi alloy is corrosion-resistant in a 30% solution of H_2SO_4 at 80°C and an 80% solution of the same acid at 60°C. On the whole, introduction of O_3 into H_2SO_4 solutions improves the corrosion-electrochemical behavior of the alloy. However, the corrosion rate in a 70% solution of H_2SO_4 at 60°C

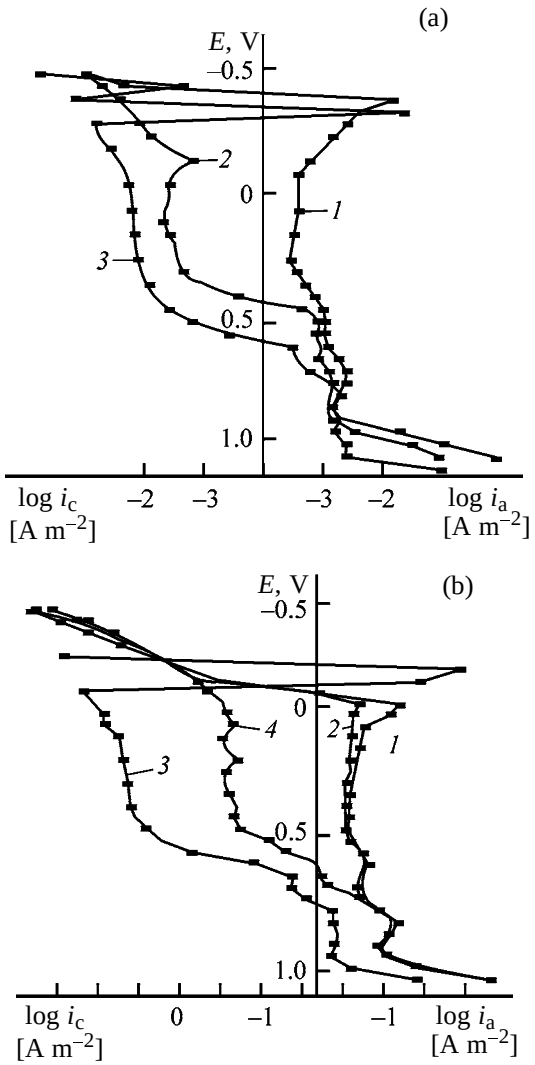

Fig. 1. Polarization curves for 12Cr18Ni10Ti steel in a 20% H_2SO_4 solution at 20°C. (i_c, i_a) Cathodic and anodic current densities and (E) potential; the same for Figs. 2–4. (a) H_2SO_4 solution: (*1*) subjected to aeration, (*2*) subjected to ozonation with agitation, and (*3*) subjected to ozonation. (b) Ozone concentration $c_0 \times 10^{-5}$ (M): (*1*) 1, (*2*) 4.8, (*3*) 25, and (*4*) 36.

increases from 0.07 to 0.49 g m^{-2} h^{-1} in the presence of O_3. The polarization curves show a noticeable increase in the width of the region of active dissolution, but the corrosion and repassivation potentials remain unchanged upon introduction of O_3 (E_{cor} = 0.4 V, E_p = 1.0 V) [4].

A study of the corrosion-electrochemical behavior of stainless steels in the medium subjected to ozonation revealed an ambiguous nature of the influence exerted by O_3. On the one hand, O_3, which is a strong depolarizer, transfers steels to the passive state; on the other hand, changes in the concentration of O_3, temperature, and pH of the medium can transfer the metal to the region of active dissolution, in which the rate of corrosion considerably exceeds that in an unozonized medium. For example, the 12Cr18Ni10Ti steel is in the region of active dissolution at 20°C in a 20% solution of H_2SO_4 and undergoes corrosion at a rate of 4.3 g m^{-2} h^{-1} (Fig. 1a, curve *1*). In a solution subjected to ozonation, the corrosion potential is shifted in the positive direction. However, a "cathodic loop" appears in the anodic curve, which is indicative of a state of unstable passivity (Fig. 1a, curve *3*). Agitation of a solution subjected to ozonation makes the cathodic reaction faster (the region of active dissolution disappears) and leads to a shift of E_{cor} into the passive region, but to a somewhat more negative value than that in an unagitated solution, with the rate of corrosion decreasing from 0.06 to 0.03 g m^{-2} h^{-1} (Fig. 1a, curve *2*). Agitation of solutions subjected to ozonation leads to an increase in the rate of cathodic processes; in the case of the 12Cr18Ni10Ti steel not only the cathodic, but also the anodic reactions become faster, with the rate of the anodic reaction increasing to a greater extent (Fig. 1a, curves *2*, *3*). However, as the current densities are low, the solution agitation affects the rate of corrosion significantly [5]. Raising the concentration of H_2SO_4 makes the influence exerted by O_3 weaker: the rate of corrosion in a 30% H_2SO_4 solution is half an order of magnitude lower than that in an unozonized solution, whereas in a 40% solution, the rates in ozonized and unozonized solutions are equal. Interestingly, the rate of corrosion of the 12Cr18Ni10Ti steel in a 70% H_2SO_4 solution is an order of magnitude lower than that in a 20% solution; however, the corrosion-electrochemical behavior in a medium subjected to ozonation is impaired.

Raising the concentration of O_3 from 10^{-5} to 3.6 × 10^{-4} M in a 20% H_2SO_4 solution leads to a gradual change of the anodic polarization curve (Fig. 1b). The range of concentrations at which the 12Cr18Ni10Ti steel is in the state of stable passivity is (0.10–3.6) × 10^{-4} M [5].

A study of the selectivity of dissolution of products formed in corrosion of the 12Cr18Ni10Ti steel demonstrated that the dissolution of Ni and Cr in ozonized solutions is lower in 30–40% H_2SO_4 solutions, compared to unozonized solutions, and that of Fe is lower in a 30% H_2SO_4 solution and higher in a 40% solution. However, the pattern changes in the 70% H_2SO_4 solution: with the total amount of dissolved products of corrosion of the 12Cr18Ni10Ti steel, the amount of Ni and Cr in ozonized media exceeds that in

unozonized solutions. In this case, the Fe : Cr : Ni ratio remains the same for virtually all the media, 1 : 0.08 : 0.02. Raising the temperature of the solutions makes the rate of steel corrosion considerably faster, the anodic polarization curves are shifted to higher currents.

The susceptibility of the stainless steels 12Cr18Ni·10Ti and 06CrNi28MoCuTi and their welded joints for intercrystallite corrosion (ICC) was studied in 20 and 40% H_2SO_4 solutions, respectively. Samples of the 12Cr18Ni10Ti steel were subjected to sensitization at 650°C for 6 h. The samples were tested for susceptibility to ICC in accordance with GOST (State Standard) 60-32.89. Sensitized samples exhibited no ICC after being kept in ozonized solutions for 100 h, but without O_3 ICC was observed [6]. Welded joints of steels did not undergo ICC in ozonized media, either.

The main alloying additives to stainless steels are Ni, Cr, and Mo; therefore, it was of interest to study the behavior of these metals in a medium subjected to ozonation.

Nickel is thermodynamically unstable in acid solutions; it may dissolve with formation of the Ni^{2+} ion and evolution of H_2. However, Ni is only slightly more electronegative in the electrochemical series with respect to the H^+/H_2 equilibrium. This means that the rate of dissolution of Ni in acid solutions will be low in the absence of oxidizing agents stronger than H^+. Indeed, the rate of Ni corrosion in 2–70% solutions of H_2SO_4 is low and virtually invariable, polarization potentiodynamic curves do not exhibit any significant differences either. As the concentration of H_2SO_4 increases, E_{cor} of Ni becomes more negative. The specific features of the electrochemical behavior of Ni are the dynamic instability, i.e., periodic oscillations of the current in a 2% solution of H_2SO_4 at potentials of 0.4–1.0 V, and anomalous phenomena in the dissolution of Ni, i.e., the absence of a Faraday correspondence between the quantity of electricity passed through Ni and the amount of dissolved metal. The corrosion rates calculated from the current differ by one or two orders of magnitude from those following from the weight loss, which can be attributed to the occurrence of an additional anodic process.

Introduction of O_3 shifts the corrosion potential in the positive direction by 0.1–0.15 V and leads to an increase in the density of the anodic dissolution current to 10 A m^{-2}. However, the rate of Ni dissolution cannot be determined from polarization curves, either. Comparison of polarization curves for Ni in a medium subjected to ozonation and that without O_3 does not show any significant difference in dissolution rates, whereas gravimetric analysis demonstrates that O_3 raises the corrosion rate by an order of magnitude and more.

The main reason for the decrease in the corrosion rate of Ni in an acid medium is adsorption of atomic hydrogen on atoms that occupy semicrystalline positions and block "active centers" on the surface [7]. At the same time, hydrogen dissolved in the metal partly dissociates into H^+ ions and electrons, and electrons can fill vacancies on the *d* level of Ni atoms. As a result, the metal loses its ability to chemisorb oxygen and hydrogenated Ni is activated in anodic polarization.

It was shown in [8] that, in corrosion of hydrogenated Ni with oxygen depolarization in the initial period of time, oxygen predominantly interacts with hydrogen that diffuses from the bulk of the electrode, and dissolution of Ni is hindered. Then binding of hydrogen and metal ions must occur at a higher rate in the presence of O_3, because atomic oxygen exists in the diffusion region in addition to molecular oxygen. The rate of variation of E_{cor} in solutions without O_3 in the first 10 min was 1 mV s^{-1} in the negative direction. In the presence of O_3, the rate of variation of E_{cor} was zero in a 2% solution of H_2SO_4, reached the highest value of 2 mV s^{-1} in the positive direction in a 20% solution, and again zero in a 70% H_2SO_4 solution [9]. In all probability, this is due to the following: In the 20% H_2SO_4 solution, the concentration of H^+ is sufficient for the reactions of O_3 reduction, with H^+ ions involved, and hydrogenation of the metal to occur simultaneously and for the rate of absorption of H^+ ions to be equal to the rate of diffusion supply of O_3 to the electrode surface. Ni samples preliminarily hydrogenated in a deaerated 5% H_2SO_4 solution were placed for 24 h in 5% H_2SO_4 solutions subjected to ozonation and aeration, and after that were analyzed by the vacuum method for the content of hydrogen. The volume of hydrogen in nickel was 20–30 cm^3 per kilogram of the metal in the presence of O_3, and 100 cm^3 without ozone, i.e., ozone diminishes the hydrogenation of Ni by a factor of 3–4, thereby making faster its dissolution [9].

Chromium belongs to metals that are easily passivated in an oxidizing medium, with the negative potential changing to positive relative to the standard hydrogen electrode; it has a higher electron deficiency of the *d* level (fraction of vacancies 0.8) than Ni (fraction of vacancies 0.6), and not only a chemisorbed layer, but also an oxide film can be formed on its sur-

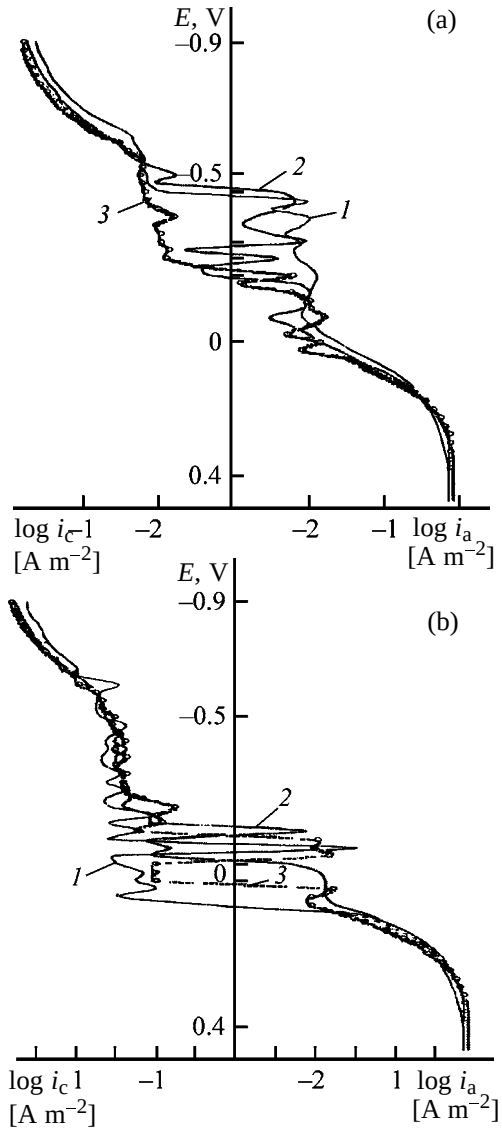

Fig. 2. Polarization curves for Mo in H_2SO_4 solutions subjected to (a) aeration and (b) ozonation at 20°C. Concentration of H_2SO_4 solutions (wt %): (*1*) 2, (*2*) 5, and (*3*) 10.

face. In the presence of oxygen-containing oxidizing agents (MnO_4^-, SeO_4^{2-}, H_2O_2) in a 0.05 M H_2SO_4 solution, the dissolution of Cr is accelerated because of the electroreduction of the oxidizing agent on the surface of chromium with formation of OH^- ions and discharge of H^+ ions [10, 11].

The polarization curves of Cr, obtained at different concentrations of H_2SO_4, exhibit a number of specific features. As the concentration of H_2SO_4 increases, the potentials of corrosion (E_{cor}) and repassivation (E_r) are shifted in the positive direction; the critical potential E_{cr} and the critical current density i_{cr} are virtually the same for all the concentrations (–0.5 V and 100 A m^{-2}), with the exception of the 70% H_2SO_4 solution: –0.35 V and i = 10 A m^{-2}. However, the region of active dissolution becomes in this case narrower and a cathodic loop appears in 5 and 10% solutions. The passive region lies within the range from –0.3 to 1.0 V. Introduction of O_3 into H_2SO_4 solutions does not change the E_{cor} of chromium, whereas i_{cr} decreases to 50 A m^{-2} for 2 and 5% H_2SO_4 solutions and remains unchanged for other concentrations. The cathodic loop becomes wider and the current densities in this region increase by an order of magnitude.

The best passivation characteristics are exhibited by Cr in a 20% H_2SO_4 solution subjected to ozonation. The corrosion rate of Cr in the presence of O_3 is lower than that in an unozonized medium, although Cr is stable in any of the solutions under study. The type of variation of E_{cor} with time demonstrated that the rate of electrochemical processes that occur on Cr is the highest during the first 10 min in a 70% H_2SO_4 solution and decreases as the acid concentration becomes lower. In the case of solutions subjected to ozonation, this dependence changes and the highest rate is observed in a 2% H_2SO_4 solution. The results obtained confirm the assumption that H^+ ions are actively involved in the cathodic reduction of O_3 [12].

In contrast to chromium, Mo has no region of active dissolution in the corresponding polarization curves. According to potentiodynamic data (Fig. 2), introduction of O_3 shifts the corrosion potential in the positive direction by 0.1–0.4 V. As the pH value is varied, E_{cor} remains virtually constant in the course of time for solutions subjected to ozonation (–0.2 V), being close to –0.5 V for solutions subjected to aeration. On introduction of O_3 into a solution (Fig. 2b), anomalous phenomena are manifested to a greater extent: the dissolution rate of the metal is independent of the potential in the region in which, obeying the laws of electrochemistry, the process would have been accelerated upon a shift of E in the positive direction (in accordance with the Tafel equation). For Mo in solutions subjected to ozonation, this region is observed at potentials from –0.6 to –0.3 V. It can be seen from Fig. 2 that, on the whole, the pH value of the solution exerts no influence on this effect. The corrosion potential of Mo in the presence of O_3 is more positive than that in solutions subjected to aeration, and the rate of the corrosion process in solutions subjected to ozonation exceeds by an order of magnitude that in solutions subjected to aeration. Ozone stimulates the corrosion process at the initial instant of time, with its subsequent deceleration, and then "shifts" Mo toward noble metals in the electrochemi-

cal series, acting as an agent passivating the corrosion process. In this case, the difference of the rates of variation of E_{cor} markedly decreases as the H_2SO_4 concentration increases, with the rates of variation of E_{cor} differing by a factor of only 2 in a 70% solution of the acid [13].

It would be appropriate to mention the effect of dynamic instability, observed at potentials in the range from –0.2 to 0.2 V. The frequency and amplitude of oscillations were different in different experiments, depending on their conditions (variation of the solution pH, presence or absence of O_3), but remained constant during each particular experiment. The data obtained suggest that, for solutions subjected to aeration, the amplitude of these oscillations increases with decreasing solution pH. The opposite tendency is observed for solutions subjected to ozonation, but ozonation makes wider the range of potentials at which the oscillations appear. Similar phenomena of dynamic instability, with oscillations of current or potential, have been described for iron [14]. However, no systematic experimental data on the conditions in which these oscillations appear are available at present, and no unambiguous explanation of this effect has been given, either.

According to reference data [15], Ti can be used as structural material in HCl solutions subjected to aeration at HCl concentrations of 10% at 35°C and up to 5% at 40°C. Analysis of the results obtained for stainless steels suggests that introduction of O_3 into HCl solutions will expand the region of the corrosion stability of Ti and its alloys. In the electromotive series, Ti is an active metal and is easily oxidized in the active state to pass into solution in the form of Ti^{3+} ions. The surface oxide film has properties of a semiconductor, which is mainly due to the presence of anionic oxygen vacancies and interstitial Ti^{3+} ions. They make the oxide an *n*-type semiconductor and, consequently, ensure its passive state. The disruption of the passivity of Ti is associated, on the one hand, with an increase in the activity of Cl^- ions, which penetrate into the chemisorbed layer through pores and defects more easily than O_2 or OH^- do and are adsorbed in competition with these ions. In this case, Cl^- ions, having reached the metal surface, favor hydration of metal ions and facilitate their transfer into solution, in contrast to the externally adsorbed oxygen. On the other hand, the solubilities of both O_2 and O_3, which provide the formation of the protective oxide film, decrease with increasing temperature. The decrease in the concentration of O_3 predetermines the diffusion control over electrochemical processes at potentials more positive than 0.1 V.

Bubbling of a 10% HCl solution with ozone at 20°C shifts the corrosion potential of VT1-0 titanium in the positive direction by 0.67 V, and that of the VT-5 and OT-4 alloys by 0.57 V, but all of them are passive at this temperature. However, the rate of corrosion in a 10% HCl solution at 40°C increases to 1.05 mm/year for VT1-0 and 1.85 mm/year for the alloys. The values of E_{cor} are –0.68 and –0.77 V, respectively, and the critical current densities i_{cr}, 0.76 and 2.10 A m^{-2}. On introduction of O_3 into the solution, the corrosion rate of Ti decreases to 0.06 mm/year (E_{cor} = 0.03 V), and the metal reaches the state of stable passivity. The electrochemical behavior of the alloys upon introduction of O_3 into solution exhibits a cathodic loop, which corresponds to the state of unstable passivity and to a lower rate of cathodic depolarization with ozone, compared to Ti [16]. The activity of Cl^- ions and the electrical conductivity of HCl reach the highest values at medium concentrations. Raising the concentration of HCl to 15–20% leads to a decrease in the corrosion resistance of Ti and its alloys, whereas in the presence of O_3 they remain in the passive state and can be used as structural materials. The presence of Al in Ti impairs its corrosion characteristics in solutions not subjected to ozonation, whereas in solutions subjected to ozonation at 20°C, there are no differences in the electrochemical behavior. At 40°C, the corrosion rate of VT1-0 is 2.56 mm/year, and that in the presence of O_3, 1.60 mm/year in a 15% HCl solution. A cathodic loop appears in the polarization curves, and the critical current densities of dissolution increase by an order of magnitude (Fig. 3).

Thus, presence of O_3 in HCl solutions favors passivation of Ti and its alloys and extends the limits of their applicability as structural materials.

It is known that steels of the 12Cr18Ni10Ti type are stable in acetic acid at any concentration up to 75°C; chromium stainless steels of the 08Cr17Ti type are stable only at low temperatures (30–40°C); St.3 and 09Mn2Si steels have low stability and are unstable in 5–10% solutions of acetic acid.

In a 5% CH_3COOH solution, the potentiodynamic polarization curve obtained for the 08Cr17Ti steel shows two peaks at E = –0.30 and 1.05 V at 20°C, i_{cr} = 1.22 A m^{-2}. Introduction of O_3 into the solution does not change the run of the polarization curve in the active dissolution region significantly. At more positive potentials, the anodic curve is abruptly shifted into the region of small current densities, with a cath-

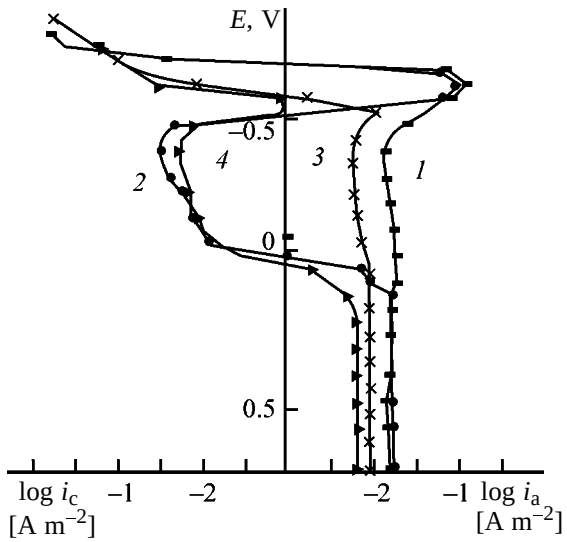

Fig. 3. Polarization curves for Ti in (*1, 2*) 15% HCl solution at 40°C and (*3, 4*) 20% HCl solution at 20°C. HCl solution: (*1, 3*) subjected to aeration and (*2, 4*) subjected to ozonation.

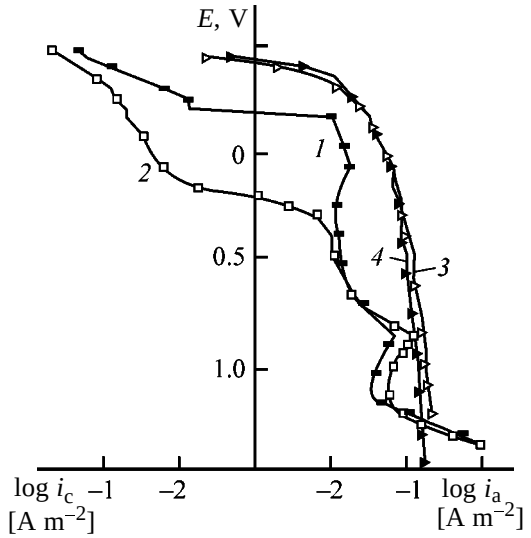

Fig. 4. Polarization curves of (*1, 2*) 08Cr17Ti and (*3, 4*) 09Mn2Si steels in an agitated 5% CH_3COOH solution at 25°C. CH_3COOH solution: (*1, 3*) aerated and (*2, 4*) ozonized.

odic loop formed both at 25°C and at 40°C. Vigorous agitation of a CH_3COOH solution subjected to ozonation makes it possible to eliminate the region of active dissolution because of the enhancement of the cathodic depolarization (Fig. 4). The corrosion rate of 08Cr17Ti steel in the presence of O_3 (0.009 g m^{-2} h^{-1}) somewhat exceeds that without O_3 at 25°C.

Low-carbon steels of the 09Mn2Si and St.3 types (Fig. 4) show a low stability in the presence of O_3, with their corrosion rate increasing by a factor of 2–3; consequently, they cannot be recommended for use in weakly acidic solutions subjected to ozonation. The differences in the corrosion rates of the 09Mn2Si and St.3 steels (100 h) and in the current densities in the polarization curves (1.5 h) are primarily determined by acceleration of the dissolution of the metals in the course of time because of the saturation of the near-electrode layer with ions of iron and manganese, which, being oxidized by ozone, are reduced on the metal and thereby enhance its corrosion.

Previously, a mechanism of reduction of O_3 in an acid medium to give H_2O_2 and OH^- ions in the near-electrode layer has been suggested [18]:

$$O_3 \longrightarrow O + O_2, \quad (1)$$

$$O + H^+ + 2e \longrightarrow OH^-, \quad (2)$$

$$OH^- + H^+ \longrightarrow H_2O, \quad (3)$$

$$O_2 + 2H^+ + 2e \longrightarrow H_2O_2, \quad (4)$$

$$H_2O_2 + 2e \longrightarrow 2OH^-. \quad (5)$$

The OH^- ions forming in the reaction zone favor transfer of the metal to the region of positive potentials, which leads to a decrease in the corrosion rate for metals that can be passivated, and to an increase in the corrosion rate for nonpassivated metals. In electroreduction of oxygen-containing oxidizing agents in acid solutions, the near-electrode concentration of H_3O^+ ions decreases, which leads to an increase in the pH value of the near-electrode layer.

CONCLUSIONS

(1) The action of ozone on metals and steels is determined by its high reactivity, as well as by the formation of not only molecular, but also atomic oxygen in the decomposition of O_3.

(2) The influence exerted by O_3 on the corrosion-electrochemical behavior of metals, steels, and alloys in an acid medium is determined by the concentration of O_3 in the medium, the pH value of the medium, the temperature of the medium, and diffusion into the double-layer region.

CATALYSIS

Hydride-Containing Silicas in Hydrosilylation of Olefin Monomers

Yu. N. Bol'bukh, V. V. Yanishpol'skii, and V. A. Tertykh

Received October 21, 2003; in final form, July 2004

Abstract—The kinetics of catalytic hydrosilylation of divinyltetramethyldisiloxane and 2-hydroxyethyl methacrylate with SiH groups fixed on the silica surface was studied. The influence exerted by the nature of the silica surface (initial and hydride-containing) on thermal and initiated [with a cobalt(II) acrylamide complex] polymerization of 2-hydroxyethyl methacrylate was examined.

Chemically modified finely dispersed oxides, in particular, those based on pyrogenic silicas containing active groups in the surface layer, are widely used for preparing filled polymer systems and nanocomposites with improved physicomechanical characteristics [1, 2]. Dispersed silicas with fixed ≡SiH groups (hydridosilicas) are studied in this respect insufficiently. At the same time, such modified silicas are of undoubted interest because of the possibility of hydrosilylation of various olefins with the surface ≡SiH groups under the action of catalysts, initiators, or temperature. Such an approach was used for immobilization on silicas of various functionalized olefins with the formation of hydrolytically stable surface compounds with a Si–C bond [3, 4]. The same type of the reactions can be used for formation of polymer–filler bonds (owing to direct reaction with the C=C bonds in polymeric macromolecules, or using appropriate bifunctional reagents for formation of cross-links). Participation of the ≡SiH groups fixed on the surface in chain termination and in polymerization of olefin monomers is also possible.

The behavior of silica fillers with the ≡SiH groups fixed on the surface in polymerization of olefin monomers is studied insufficiently. In particular, such examples of reaction systems hydridosilica–monomer were studied as catalytic hydrosilylation of styrene [5] and thermal addition of acrylic acid [6]. Previously we also initiated studies on reactions of hydridosilica with divinyltetramethyldisiloxane (DVTMDS) and 2-hydroxyethyl methacrylate (HEMA) in the presence of Speier catalyst [7, 8] and some reactive complexes of olefins with metal ions [9]. We used the cobalt(II) acrylamide complex, as it is catalytically active toward vinyl monomers in thermal polymerization [10] and tends to spontaneously polymerize by the radical mechanism with formation of highly rigid chains [11]. Recently the interest in silica–HEMA composites increased [12–14].

In this work we studied the kinetic features of solid-phase catalytic hydrosilylation of DVTMDS and HEMA. We also examined the effect exerted by silicon hydride groups present in the surface layer of silicas on thermal and initiated [with cobalt(II) acrylamide complex] polymerization of HEMA.

EXPERIMENTAL

The hydridosilica used in this study was prepared by chemical modification of nonporous finely dispersed silica (Aerosil, specific surface area 300 $m^2\ g^{-1}$, Oriana, Canada) with a solution of triethoxysilane (Kremniipolimer, Zaporozh'e) in ethanol at room temperature for 24 h, after which the solvent was removed by evaporation on a water bath. The content of silicon hydride groups grafted to the surface was controlled by the amount of the modifier added to the reaction medium. The concentration of the ≡SiH groups in the modified silicas was determined by titration. We prepared samples containing 0.25 and 0.64 $mmol\ g^{-1}$ silicon hydride groups. The degree of substitution of isolated silanol groups through which alkoxysilanes are mainly chemisorbed was about 30 and 80%, respectively. DVTMDS and HEMA (Fluka) were used without additional purification. DVTMDS can be considered as a model of bifunctional organisilicon compound with olefin groups. HEMA containing both hydrophilic and hydrophobic groups shows much promise in synthesis of nanocomposites with preset properties. The acrylamide (AAm) complex of cobalt(II) nitrate, $[Co(AAm)_4](NO_3)_2 \cdot 2H_2O$, was prepared in accordance with the recommendations of [11].

Catalytic hydrosilylation was performed in excess monomer (2–3 ml per 0.3–0.5 g of hydride-containing

1070-4272/04/7711-1808 © 2004 MAIK "Nauka/Interperiodica"

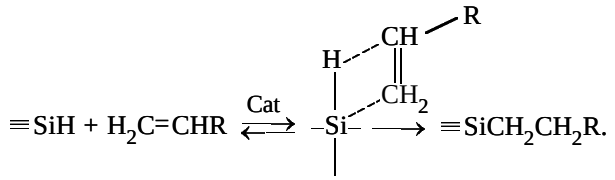
silica) in the presence of Speier catalyst (0.01 M $H_2PtCl_6 \cdot 6H_2O$ in isopropanol, 0.026 ml). The molar ratio of the catalyst to the amount of silicon hydride groups fixed on the Aerosil surface was 1 : 10000 [7]. The concentration of the ≡SiH groups fixed on the surface and the content of vinyl groups in the product were determined by bromide–bromate and iodometric titration [15]. Both methods are based on the reaction of an aqueous solution of a halogen with the surface functional groups, followed by titration of the unchanged reagent with $Na_2S_2O_3$ in the presence of starch. The choice of these methods was governed by their good reproducibility and sufficient sensitivity, especially in determination of low concentrations of fixed functional groups.

The volumetric method (treatment with alcoholic alkali and determination of the volume of the released H_2) gives less reproducible results and requires large amounts of the sample. It was shown [7] that the bromide–bromate method allows determination of the content of both vinyl and silicon hydride groups, and the iodometric method allows determination of the concentration of silicon hydride groups in the surface layer of modified silica at various reaction times after washing the product with ethanol and drying at 60°C. Since the monomer was taken in excess, the hydrosilylation can be considered as a pseudo-first-order reaction with respect to the concentration of the surface ≡SiH groups. The rate constants were calculated with the first-order equation by the least-squares method from the curves of the content of the surface silicon hydride groups vs. reaction time. The IR spectra of the starting compounds and modified silicas were recorded using KBr technique with a Nexus (Nicolet) IR Fourier spectrometer (diffuse reflection spectra) and a UR-20 spectrometer (absorption spectra, pellet weight 30 mg).

Taking into account the melting point and thermal stability limits of the cobalt(II) acrylamide complex [11], we performed the initiated polymerization of 2-hydroxyethyl methacrylate in air at 96–116°C and HEMA : $[Co(AAm)_4](NO_3)_2 \cdot 2H_2O$ weight ratio of 10 : 1. At certain intervals, we took 0.3-g samples, decanted the excess of the water-soluble monomer in the given volume of water, and determined the concentration of the C=C groups in solution by the bromide–bromate techniques [15]. The time of the sample setting (polymerization time) was extimated visually from the depth of indention of a glass rod into the final product.

Thermal and initiated [with cobalt(II) acrylamide complex] polymerization in the presence of the initial and SiH-modified Aerosil was performed at 106°C and 16 wt % filling. In initiated polymerization, the content of the cobalt(II) acrylamide complex was 10 wt % relative to the monomer. Prior to the reaction, the initiator and filler were thoroughly mixed in the required ratio and then added to the monomer. The reaction progress was monitored by determination of the content of the C=C bonds by the bromide–bromate method.

Catalytic hydrosilylation of olefins with the ≡SiH groups fixed on the silica surface follows the general scheme



innvolving nucleophilic addition to the surface silicon atom.

The IR spectrum of $(H_2C=CH)(CH_3)_2SiOSi \cdot (CH_3)_2(HC=CH_2)$ contains characteristic absorption bands at 3060–2968 cm^{-1} corresponding to the stretching vibrations of the C–H bonds in methyl and methylene groups of the monomer. The bands above 3000 cm^{-1} belong to the vinyl C–H bonds. The spectrum of the starting hydridosilica contains a strong band with the absorption maximum at 2260 cm^{-1}, corresponding to the stretching vibrations of the surface Si–H groups. In the course of hydrosilylation, the band at 2260 cm^{-1} decreases in intensity, which corresponds to consumption of the surface SiH groups, and new bands corresponding to the grafted monomer molecules appear at 3060–2968 cm^{-1}. The spectrum of the final product after the 5-h reaction contains no Si–H band.

According to chemical analysis, the kinetics of variation of the concentration of the surface ≡SiH groups is satisfactorily fitted by a first-order equation. In Fig. 1, the calculated concentrations of the surface ≡SiH groups are shown by solid lines. Calculation by the empirical equation [16]

$$n = 1 - \frac{\log(\tau_2/\tau_1) - 1}{\log a_1}, \qquad (1)$$

($a_1 = c_1/c_0$, $a_2 = c_2/c_0$ are the fractions of the ≡SiH groups that remained unchanged by the time τ_1 and τ_2, respectively, with $a_2 = a_1^2$) also gives the first order of the reaction. The data characterizing the reaction kinetics are given in Table 1.

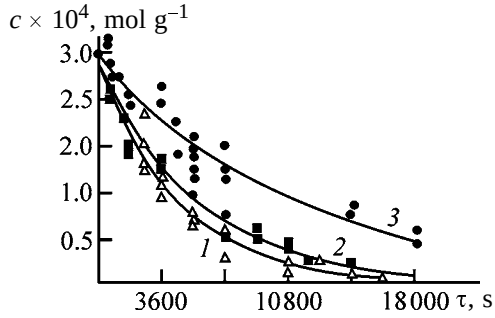


Fig. 1. Kinetic curves of hydrosilylation of DVTMDS with surface ≡SiH groups at (*1*) 80, (*2*) 60, and (*3*) 40°C. (*c*) Concentration of ≡SiH groups and (τ) time. Points are experimental concentrations of ≡SiH groups; solid lines are calculated by the equation $c = c_0 e^{-k\tau}$.

These data show that, as the reaction temperature is increased by 40°C, the rate of hydrosilylation of DVTMDS with the surface ≡SiH groups increases by a factor of slightly more than 2.

We found that, at a 0.25 mmol g^{-1} concentration of the surface ≡SiH groups in the initial hydridosilica, the content of grafter vinyl groups in the final product (the reaction for 5 h at 80°C) was also 0.25 mmol g^{-1}. These results, and also the IR data, indicate that all the surface ≡SiH groups were involved in the reaction. The surface immobilization of the vinyl groups in the amount equal to the content of the ≡SiH groups in the initial modified silica confirms that the hydrosilylation mainly follows the scheme

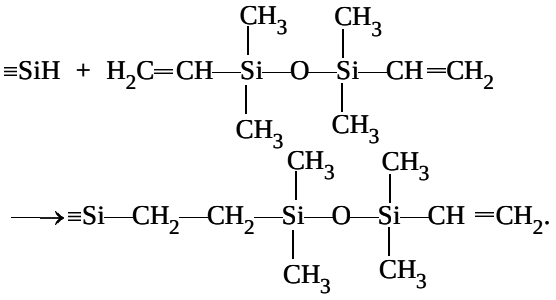

Table 1. Order *n*, rate constant *k*, and initial rate v_0 of hydrosilylation of DVTMDS with hydride-containing silica

T, °C	n_a^*	$k \times 10^4$, s^{-1}	$v_0 \times 10^8$, mol g^{-1} s^{-1}	
			$-\Delta c \Delta\tau^{-1}$, experiment	k/c_0, calculation
40	0.55–1	0.92 ± 0.076	3.33	2.30
60	1–0.83	1.77 ± 0.17	5.00	4.43
80	1.46–1	2.26 ± 0.24	7.50	5.65

* The reaction order was calculated by Eq. (1) at 36 and 60% conversion of the ≡SiH groups, respectively.

The activation energy of the hydrosilylation in the examined system, calculated from the temperature dependence (40–80°C) of the time corresponding to 20% conversion of the surface ≡SiH groups, is 72.2 ± 10.8 kJ mol^{-1}.

Catalytic hydrosilylation of HEMA with the ≡SiH groups fixed on silica is virtually complete in 0.5 h, and this time does not appreciably depend on the reaction temperature in the range 27–60°C [9]. The reaction rate measured at these temperatures 2–5 min after the start of the reaction is, on the average, (1.65 ± 0.18) × 10^{-7} mol l^{-1} s^{-1} (found from the equation $v = \Delta c \Delta\tau^{-1}$). At the same time, the maximal degree of conversion of the ≡SiH groups under these conditions does not exceed 90%. This is confirmed by the presence of a band at 2260 cm^{-1}, belonging to the residual ≡SiH groups, in the IR spectra of the final product. Also, the spectra contain bands at 1636 and 1717 cm^{-1} corresponding, respectively, to stretching vibrations of the C=C and C=O groups, which indirectly suggests the presence on the surface of both chemically fixed and physically adsorbed monomer molecules; the physical adsorption may involve hydrogen bonding with the residual silanol groups.

The chemical immobilization of the monomer molecules in the surface layer may also involve the reaction of the silanol groups with the hydroxy groups of HEMA. However, usually such reactions on the silica surface occur at higher temperatures or in the presence of bases [1]. In our case, because of mild hydrosilylation conditions, this reaction is improbable. Furthermore, the etherification will be hindered by relatively strong hydrogen bonds between the surface silanol groups and carbonyl groups of HEMA, formed in adsorption of HEMA on the silica surface. The complex mechanism of HEMA hydrosilylation is indicated by the reaction order calculated both in the $\log v = f(\log c)$ coordinates and with formula (1). Although the monomer, as in the previous case, was taken in excess, the reaction order *n* calculated by the two procedures was close to 2 (Table 2). The initial hydrosilylation rates given in Table 2 were determined from the *k* and *n* values found in the $\log v = f(\log c)$ coordinates. The high reaction rate in this system, compared to hydrosilylation of divinyltetramethyldisiloxane, may be due to the presence on the surface of a large amount of the adsorbed monomer and, correspondingly, to occurrence of the gel effect (increase in the reaction rate due to increase in the density of the medium [17]). Indeed, HEMA is adsorbed on the silica surface considerably more strongly than divinyl-

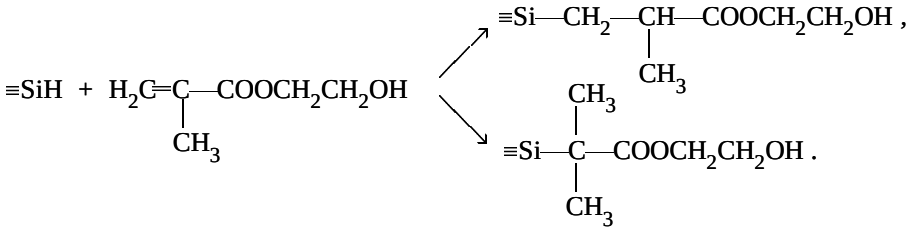
* (n_a) Reaction order calculated by Eq. (1).

tetramethyldisiloxane, which may result in increased density of the medium in the surface layer. Furthermore, the possibility of densification of the adsorption layer due to partial polymerization of the monomer on the surface cannot be ruled out. With increasing temperature, the role of the gel effect weakens; as a result, the reaction rate measured 2–5 min after the start of the reaction remains virtually unchanged in the examined temperature range. The initial rate of this reaction, as that of hydrosilylation of DVTMDS, increases with temperature in the range from 20 to 40°C and remains virtually unchanged in the range 40–60°C. Hydrosilylation of HEMA can be represented by the general scheme



Applying our results to filled polymer systems, we can expect that, with disperse hydride-containing silicas as fillers of olefin polymers, it will be possible to provide additinal chemical cross-linking of the composites by formation of hydrolytically stable Si–C bonds between the filler surface and macromolecules.

When studying the kinetics of thermal (106°C, air) polymerization of 2-hydroxyethyl methacrylate, we observed a large scatter of the content of the C=C groups (Fig. 2). By analogy with thermal polymerization of methyl methacrylate [17], this may be due to condensation of the monomer molecules with formation of various intermediate states, affecting the polymerization rate. We can distinguish in the kinetic curve two portions characteristic of polymerization of vinyl monomers and corresponding, respectively, to the induction and acceleration (gel effect) periods.

Figure 3 shows the kinetic curves of HEMA polymerization initiated with the cobalt(II) acrylamide complex. The scatter of the experimental points is low, suggesting stable course of the process. On adding the initiator, the initial polymerization rate appreciably increases. However, as the temperature of initiated polymerization is increased, a short portion corresponding to the induction period appears in the time dependence of the concentration of vinyl groups (Table 3). It is believed [17] that deceleration of the initiated polymerization followed by an increase in the reaction rate may be due to the "cage effect" and considerable influence of the viscosity of the medium on the process.

The rate constant of radical polymerization (with

116	60	145	240

respect to the monomer) can be calculated using a first-order kinetic equation [18]

$$k = \frac{2.303}{\tau}\log(c_0/c),$$

where c and c_0 are the initial and final concentrations of vinyl groups (M); τ is the polymerization time (s).

The rate constant calculated by this equation is 5.55×10^{-5} s^{-1}. When calculating the overall rate constant of initiated polymerization without determining the rate constants of individual reactions, it is appropriate to use the general equation [16] based on variation of the monomer conversion (variation of the concentration of the vinyl groups). The rate constant of HEMA polymerization in the presence of 10 wt % initiator, calculated by the equation

$$\frac{1}{1-n}[(a^{n-1})^{-1} - 1] = k c_0^{n-1}\tau,$$

($a = c/c_0$ is the fraction of unchanged vinyl groups; $n = 1.5$ [17, 18]), was $(7.94 \pm 0.92) \times 10^{-5}$ s^{-1}.

In thermal polymerization of HEMA at 106°C in the presence of 16 wt % Aerosil, we observed a considerable weight loss (~60%), which prevented formation of a uniform material. According to [19], this effect may be caused by strong adsorption interaction of the polymer with the filler, decelerating curing near the surface and preventing formation of a three-dimensional network. Complete curing was attained in 14 h (Fig. 4, curve *1*). With addition of hydridosilica into the monomer (Fig. 4, curves *2*, *3*), the weight loss was insignificant. The curing time of the composite at a 0.25 mmol g^{-1} concentration of surface ≡SiH groups was 14 h, and at their concentration of 0.64 mmol g^{-1} it decreased to 11 h. Thus, the ≡SiH groups present on the surface of the modified silica favor thermal polymerization of HEMA.

Published data on the effect of a filler on initiated radical polymerization of vinyl monomers are contradictory. For example, according to [20], introduction of Aerosil does not affect the degree of radical polymerization of methyl methacrylate initiated with benzoyl peroxide, and the presence of functional groups (methacryloyloxypropyl, aminopropyl, mercaptopropyl) grafted to the filler surface decelerates the overall process, though increasing the percentage of the monomer molecules grafted to the silica surface. Different data on the effect of Aerosil on initiated polymerization of methacrylic monomers were reported by Almazova *et al.* [21]. It follows from their conclusions that finely dispersed silica is an active

Table 4. Times of attainment of 20% (τ_{20}), 50% (τ_{50}), and maximal (τ) conversion of the monomer and degrees α of thermal and initiated [with the cobalt(II) acrylamide complex] polymerization of HEMA in the presence of silica fillers

Filler	c_{SiH}, mmol g^{-1}	τ_{20}	τ_{50}	τ	α, %
		min			
Hydridosilica	0.24	250	750	840	68
	0.64	40	200	660	85
Aerosil + initiator	–	90	325	390	71
Hydridosilica + initiator	0.24	75	250	330	75
	0.64	10	150	270	86

filler accelerating structure formation and ensuring more stable properties of the composite. According to our results, in polymerization of HEMA initiated with the cobalt(II) acrylamide complex, addition of Aerosil decreases the time of complete curing of the samples from 9 to 6.5 h compared to the initiated polymerization without a filler; the monomer conversion in the presence of Aerosil increases (Fig. 4b). Addition of hydridosilica into the monomer, along with an increase in the monomer conversion, results in a considerable increase in the initial polymerization rate, i.e., it accelerates initiation, thus shortening the reaction time (Table 4). Acceleration of the process in the presence of hydride-containing silicas may be caused by formation of additional reaction centers at the surface ≡SiH groups of the modified silica.

It is not improbable that the ≡SiH groups fixed on the filler surface participate in formation of the Si–C bonds directly in the course of HEMA polymerization. However, whereas in thermal polymerization the ≡SiH and C=C groups can react similarly to catalytic hydrosilylation, in the graft polymerization initiated with the cobalt(II) acrylamide complex the pathways of reaction of the polymer with the filler can be different, since the C=C bonds are present not only in the monomer but also in the initiator. Both addition of the cobalt(II) acrylamide complex to the hydridosilica surface, followed by the reaction with HEMA, and the direct addition of the monomer molecules to the filler surface are possible.

CONCLUSIONS

(1) Catalytic hydrosilylation of divinyltetramethyldisiloxane is a pseudo-first-order reaction with respect to the concentration of the ≡SiH groups. These groups are fully involved in the reaction within 5 h at 80°C.

(2) Solid-phase hydrosilylation of 2-hydroxyethyl methacrylate is satisfactorily described by a second-order kinetic equation, suggesting a more complex mechanism of processes in the surface layer.

(3) As compared to the unfilled systems, addition of finely dispersed silica somewhat decelerates thermal polymerization of 2-hydroxyethyl methacrylate and, on the contrary, accelerates the process initiated with the cobalt(II) acrylamide complex.

(4) The silicon hydride groups present on the surface of the modified filler accelerate both thermal and initiated polymerization of 2-hydroxyethyl methacrylate.

Abstract—The adsorption and ion-exchange properties of thermally expanded graphite with respect to hardness cations and SO_4^{2-} and Cl^- anions were studied.

Thermally expanded graphite (TEG) is a product formed in thermolysis of graphite intercalation compounds (GICs). Modification of carbon to give GICs makes it possible to create new materials with unique combinations of physicochemical properties. One of the properties of this kind is the ability of GICs to form foamed structures having a developed surface, which creates prerequisites for their use as sorption materials. The bulk density d_{TEG} of the best samples of TEG is $(1–2) \times 10^{-3}$ g cm^{-3} [1]. This value largely depends on the preparation conditions and may widely vary, from 1×10^{-3}–5×10^{-3} to 2×10^{-2}–1×10^{-1} [2–5]. The degree of thermal expansion depends on synthesis conditions and composition of the GIC obtained, as well as on the structure and particle size of the carbon raw materials used [6]. The surface properties of the starting graphite are mainly determined by its purity and purification technique. According to the classical concepts [7], oxygen is chemisorbed on the surface of graphite, which ensures a positive potential when this graphite is subsequently submerged in aqueous solutions. In anodic oxidation of graphite, oxygen-containing surface functional groups (SFGs) are accumulated on its surface. The composition and concentration of these groups is determined by the mode in which the anodic treatment is carried out [8]. The subsequent washing of GIC leads to partial or total substitution of ions and molecules of an acid contained in the intercalate by hydroxide ions and water. Fast heating of GIC during thermal treatment must lead to virtually complete removal of SFGs and the intercalate. Thus, the surface properties of TEG again approach those of the starting graphite, being different only in a manyfold increase in the surface area [9].

As is known, virtually all carbon materials have a high adsorption capacity for numerous organic substances [10–13] and, at the same time, can retain metal cations by the ion-exchange mechanism [14, 15]. It is known that carbon materials can be not only adsorbents, but also anion and cation exchangers [15]:

$$\geqslant C–OH + Ca^{2+} + 2OH^- \rightarrow \geqslant C–O–Ca–O + H_2O, \quad (1)$$

$$–COOH + Ca^{2+} + 2OH^- \rightarrow COOCaOH + H_2O, \quad (2)$$

$$\geqslant C–OH + Cl^- \rightarrow \geqslant C–Cl + OH^-. \quad (3)$$

In this context, we studied the sorption and ion-exchange properties of TEG with respect to hardness ions and anions of mineral acids.

EXPERIMENTAL

GICs were obtained electrochemically in 13.5 M HNO_3 by anodic oxidation of a GSM-1 dispersed carbon material with particle size of up to 200 μm [GOST (State Standard) 1891–78; ash content $A \leq 0.1\%$, moisture content $W \leq 1$ wt %, yield of volatiles $X \leq 0.2\%$) in the potentiostatic mode at a potential of 2.1 V [16, 17]. A silver chloride electrode served as reference in electrochemical measurements.

GIC samples were washed with distilled water at 15–18°C and dried to constant weight at 60–70°C. Thermally expanded graphite was obtained by rapid heating of the samples to 900°C. The bulk density of TEG was determined by the standard procedure [OST (Branch Standard) 16–0689.031–74]. The specific surface area of the carbon materials was determined on a Tsvet-20 chromatograph from the adsorption of argon.

The initial composition and requirements to the water used in the study are listed in Table 1.

1070-4272/04/7711-1815 © 2004 MAIK "Nauka/Interperiodica"

Table 1. Parameters of untreated and purified water

Parameter	Water	
	untreated	purified
Chloride ion, mg l^{-1}	38	26–28
Sulfate ion, mg l^{-1}	115	45–50
Total hardness	22.5	32–48
pH	9.5–10.5	8.5–8.8

To purify water to remove hardness ions, a weighed portion of TEG (0.8 g) was placed in a funnel on a filter paper and 100 ml of water was passed. After that, samples were taken and the concentration of hardness ions was found complexometrically (GOSTs 4151–72 and 4389–72). The sorption capacity c was calculated by the equation [18]

$$c = (c_{in} - c_{fin})V/m,$$

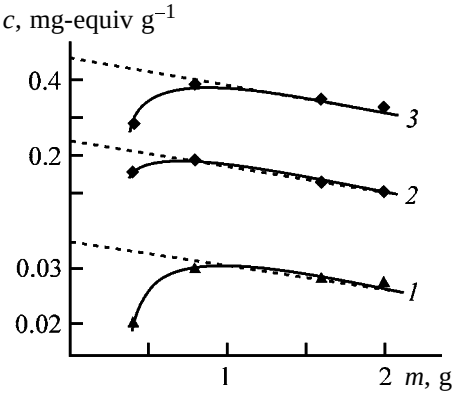
where c_{in} and c_{fin} are the initial and final concentrations of a contaminant; V, volume of the solution passed; and m, mass of the sorbent.

The degree of recovery (%) was calculated by the formula [18]:

$$R = \frac{c_{in} - c_{fin}}{c_{in}} \times 100.$$

As follows from Table 2, passing water across a TEG bed ensures the water treatment to the required purity.

According to published data [14, 15], the removal of SO_4^{2-} and Cl^- ions with TEG proceeds via substitution of OH^- ions in the outer "plate" of the electrical double layer by contaminating anions. In this case, ion exchange undoubtedly plays an important role in overcoming the potential barrier in electrostatic approach of an anion to the positively charged surface of graphite. In [11], direct ion-exchange interaction of sulfate and chloride ions with the surface of graphite was reported.



Sorption capacity c for different ions vs. mass m of TEG in the filter bed in passing 100 ml of water under study: (*1*) chloride ion, (*2*) sulfate ion, and (*3*) total hardness (Ca^{2+} + Mg^{2+}).

The dependences of the sorption capacity on the mass of TEG in the filter bed and on the filtration rate calculated in terms of the true surface area of the carbon material in passing a constant volume of water under study (100 ml) show that c first increases somewhat and then steadily decreases (see figure). Account should be taken of the fact that the filtration rate varies with the weight of TEG. Apparently, the recovery of contaminants and, accordingly, the value of c decrease because of the short time of contact between water and TEG at a small weighed portion of the carbon material (filtration rate is the highest). The further gradual decrease in the sorption capacity, observed for all the components (see figure), is due to an increase in the mass of TEG in the filter bed and to a decrease in the degree of saturation of the carbon surface with contaminants. Extrapolation of the linear portions of the curves in the figure to the ordinate axis makes it possible to approximately determine the limiting sorption capacity of TEG for SO_4^{2-} and Cl^- ions and hardness cations. The results of the graphical

Table 2. Change in the concentration of ions and pH upon filtration of water through TEG. d_{TEG} = 5 g dm^{-3}, S_{sp} = 43 m^2 g^{-1}

m_{TEG}, g l^{-1} of solution	Cl^- (c_{in} = 38 mg l^{-1})		SO_4^{2-} (c_{in} = 115 mg l^{-1})		Total hardness (c_{in} = 225 mg l^{-1})		pH
	c_{fin}, mg l^{-1}	R, %	c_{fin}, mg l^{-1}	R, %	c_{fin}, mg l^{-1}	R, %	
0.4	34.8	8.5	85.4	25.7	189	16.0	9.1
0.8	29.0	23.7	44.9	60.9	126	44.0	8.9
1.6	22.0	42.1	18.2	84.2	45.7	79.7	8.6
2.0	18.5	51.4	13.2	88.5	16.7	92.6	8.2

determination of the maximum sorption capacity for different ions in filtration of water across a TEG bed are presented below:

Ion	Chloride ion	Sulfate ion	Hardness cations
c_{max}, mg-equiv g^{-1}	0.033	0.23	0.42

According to the results obtained, the sorption capacity of TEG for hardness cations exceeds by a factor of more than 3 that of fibrous sorbents [19].

CONCLUSION

Thermally expanded graphite is an effective sorbent for removal of hardness cations. The sorption capacity for these cations is 0.42 mg-equiv g^{-1}, which allows use of thermally expanded graphite for practical purposes.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Radiolytic Gas Formation under γ-Irradiation of Oxalic Acid Solutions

N. N. Popova, Yu. V. Voronin, and I. I. Byvsheva

Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, Russia

Institute of Physical Chemistry, Russian Academy of Sciences, Moscow, Russia

Received May 11, 2004

Abstract—Radiolytic gas formation under γ-irradiation (10^4–10^6 Gy) of 10^{-2}-10^{-4} M aqueous solutions of oxalic acid at 25–60°C was studied.

Substantial volumes of radioactive waste solutions containing oxalic acid are accumulated in the radiochemical industry, as oxalate precipitation is one of the final steps of spent nuclear material reprocessing [1]. In safe management of liquid radioactive wastes, liberation of explosive radiolytic gases should be taken into consideration. The features of radiolytic gas formation necessary in organization of safe transportation, storage, and reprocessing of radioactive solutions containing oxalic acid are poorly understood. In addition, a study of radiolysis of oxalic acid is of interest for its use as a dosimetric substance.

Previously [2–4], we studied the composition and yield of gases formed upon γ-irradiation of nitrate–acetate solutions simulating liquid radioactive wastes.

Irradiation of oxygen-free oxalic acid solutions at comparatively large doses gives the following products: CO_2, H_2, H_2O_2, formic, glyoxylic, and dihydroxymalonic acids, formaldehyde, and glyoxal. In the presence of oxygen and at lower doses, only CO_2, H_2, and H_2O_2 are formed [5, 6].

In this work, we studied features of radiation-chemical decomposition of oxalic acid in aqueous solutions at high doses, when the radiolysis products appear not only in the liquid, but also in gas phase, and examined the effect of temperature on the radiolytic gas formation.

EXPERIMENTAL

A GUG-120 γ-irradiation source with a dose rate of 9–12 kGy h^{-1} was used. The required doses were accumulated for several days (4–5 h per day). The dosimetry was performed with a bichromate dosimeter [7]. The error in the determination of the radiation-chemical yield did not exceed 20% at the confidence level of 0.95.

A glass reactor connected to a reference manometer for measuring the pressure rise due to liberated gas was charged with 400 ml of the solution. The mixture was purged with helium for 1 h and then irradiated in a thermostat at 15°C. The working solutions were prepared with chemically pure grade oxalic acid and double-distilled water.

After the irradiation, the composition of the gas phase was determined gas-chromatographically on an LKh-72 chromatograph (helium as a carrier gas, katharometer as a detector, columns with Porapak-Q and 5A molecular sieves) and IR spectroscopically with a Specord-80 spectrometer. The analysis sensitivity with respect to hydrogen was 10^{-3} vol % and relative error, ±10%. The processes in the liquid phase were simulated with an U-12F linear electron accelerator at the average dose rate of 12.5 Gy s^{-1}, which allowed substantial shortening of the irradiation time. The experimental method was described in detail in [8].

The concentration of oxalic acid in the solutions was determined by the reaction with copper benzidine complex [9]. The pH of solutions was measured with an EV-74 universal ion meter using standard buffer solutions.

Radiolytic gas formation at the γ-irradiation of oxalic acid solutions was studied within the ranges of the acid concentration 10^{-2}–10^{-4} M, absorbed dose 10^4–10^6 Gy, and temperature 25–60°C. The parallel experiments with the same solutions were performed

1070-4272/04/7711-1818 © 2004 MAIK "Nauka/Interperiodica"

Table 1. Yield and composition of radiolysis products at a total γ-irradiation dose of 120 kGy and 10°C depending on the concentration of the initial solution of oxalic acid

$[H_2C_2O_4]$, M	Total yield of products, %	Radiation yield G, molecules per 100 eV			Composition of reaction products	
		total	H_2	CO_2	H_2	CO_2
5.0×10^{-2}	94.7	0.76	0.17	0.59	21.9	78.1
5.0×10^{-3}	60.1	0.48	0.17	0.31	34.9	65.1
5.0×10^{-4}	12.0	0.048	0.02	0.028	42.5	57.5

at heating without irradiation to determine the contribution of thermal decomposition of oxalic acid.

Typical curves of radiolytic gas formation under γ-irradiation of oxalic acid solutions are shown in Fig. 1. As seen, oxalic acid decomposition increases with increasing total absorbed dose, gradually leveling out. CO_2 and H_2 are the main components of the gas mixture. The amount of the gas liberated increases with increasing oxalic acid concentration (Table 1). The yield and composition of radiolysis products at the total γ-irradiation dose of 120 kGy as functions of the concentration of the initial oxalic acid solution are shown in Table 1 and Fig. 2. The acid amount and absorbed dose affect the relative content of H_2 and CO_2 (Fig. 3). With increasing acid concentration, the hydrogen fraction decreases, whereas the fraction of CO_2 in the gas phase increases. The increase in the absorbed dose increases the CO_2 fraction and decreases the H_2 fraction.

At the total dose of γ-irradiation of 120 kGy, the total radiation-chemical yield of gases increases by a factor of almost 2 as the temperature is increased from 10 to 60°C (Table 2, Fig. 4). This trend is due to increase in the CO_2 yield, whereas the yield of H_2

decreases. Here, the change in the solubility of gases in water with temperature was not taken into account (the content of gases in the reactor free volume was determined).

It is known that the gas solubility decreases with increasing temperature; in going from room temperature to 60°C, the solubilities of hydrogen and CO_2 decrease by a factor 1.08 and 1.8, respectively [10]. As seen from Table 2, at the acid concentration of 5×10^{-2} M, the $G_{60°}/G_{10°}$ ratio for CO_2 is larger than 1.8, while the hydrogen yield in all the cases decreases with increasing temperature. In addition, the dose used is relatively high, and therefore the amount of gas in the solution is substantially lower than that in the free volume over the solution. It is known that an increase in the temperature from room temperature to 60°C and even higher only weakly affects the yield of the primary products of water radiolysis [11, 12], which allows a conclusion that the main cause of the observed change in the yield of the gaseous radiolysis products is the radiolytic transformation of the solutions studied, namely, the secondary radiolysis of oxalic acid.

The processes occurring in the system under irradiation can be represented by the set of the reactions written in [8, 11, 13]. In the deaerated solutions, the hydrated electrons depending on pH convert into H atoms or react with oxalic acid molecules. Under these conditions, hydrated electrons, OH radicals, and H atoms can participate in the oxalic acid decomposition. It was shown in [8] that hydroxy radicals are substantially more active in oxalic acid decomposition than hydrogen atoms. In addition, in some works [9, 13], the reactions with hydrogen peroxide to form CO_2 are assumed to occur during radiolysis.

Simultaneously, the thermal decomposition of oxalic acid under the same conditions without irradiation was considered. The most concentrated initial solution of the acid (5.0×10^{-2} M) was taken in order to observe the gas liberation (Table 3). The results obtained show that the gas liberation does not exceed 1% even at 60°C in 30 h. This amount cannot affect the radiolysis process under consideration.

Table 3. Yield of the products of the oxalic acid decomposition under γ-irradiation at a dose of 0.06 MGy and under heating without irradiation

T, °C	τ, h	Yield of products, %	
		γ-irradiation	without irradiation
10	30	94.7	–
40	12	–	0.19
	24	–	0.32
60	17	69.0	–
	30	–	0.72

CONCLUSION

Gas formation in irradiated aqueous solutions of oxalic acid starts at comparatively high doses, but gradually decelerates and the gas accumulation curve flattens out. Hydrogen formed exists as a mixture with CO_2. Therefore, hydrogen explosion in storage of dilute solutions of oxalic acid is unlikely. The results obtained should be taken into the consideration in storage and reprocessing of various systems containing oxalic acid.

Abstract—The fundamental aspects of intensification of the mass transfer in gas–liquid flows in tubular turbulent apparatus are revealed, and dependences of the gas absorption rate on the reactor geometry and method of reagent introduction are considered for the example of dissolution of atmospheric oxygen in water.

The chemical technology includes a large number of processes that occur in liquid–gas systems. To these, in particular, belong halogenation, hydrohalogenation, and oxidation, in which the main difficulty is encountered in creating a reaction mixture with a developed phase-contact surface. Taking into account the diffusion limitations in transport of reactants across the phase boundary is particularly important at high rates of the occurring chemical reaction. In this case, the apparatus dimensions are to be diminished to become comparable with those of the reaction zone (intensive dispersion zone) to eliminate dead zones. In addition, the process is to be carried out in the jet mode with an as short as possible time of residence of reactants in the apparatus in order to make lower the probability of occurrence of slower side reactions.

These requirements are satisfied in the optimal way by small-size tubular turbulent apparatus of diffuser–confuser design [1], which are highly efficient in fast chemical and mass-exchange physical processes in liquid–gas systems and, in particular, chlorination of butyl rubber with molecular chlorine, preparation of a homogeneous gas–liquid mixture for obtaining ethylene–propylene rubbers, chlorination and hydrochlorination of ethylene, production of nitrogen fertilizers, etc. [2, 3]. An analysis of experimental data and results of numerical calculations performed in [4] yielded an analytical expression for calculating the mass-transfer coefficient in the liquid phase, averaged over the volume of the diffuser–confuser channel. This coefficient exceeds by a factor of 1.5–2 the linear mass-transfer coefficients in volume mixing apparatus. At the same time, scientifically substantiated application of tubular turbulent apparatus in gas–liquid processes requires consideration of possible ways to control the efficiency of mass transfer in liquid–gas systems.

The aim of this study is to examine the fundamental aspects of intensification of the mass transfer in gas–liquid flows in tubular turbulent apparatus and analyze the dependence of the gas absorption rate on the reactor geometry and method of reagent introduction for the example of oxygen dissolution in water.

The efficiency of mass transfer in gas–liquid flows was evaluated using the sulfite technique [5] based on catalytic oxidation of sodium sulfite with atmospheric oxygen:

$$Na_2SO_3 + 1/2O_2 \xrightarrow{CuSO_4} Na_2SO_4.$$

Under the experimental conditions, sodium sulfite reacts with atmospheric oxygen under conditions of the diffusion control, i.e., the rate of the process is completely determined by the stage of oxygen transfer from the gas phase into the liquid. In view of the low solubility of oxygen in water, the mass-transfer coefficient is totally determined by the mass-transfer coefficient in the liquid phase (by the stage of oxygen diffusion from the phase boundary into the bulk of the liquid). As a consequence, changes in the oxidation rate of sodium sulfite are associated with the intensification of the mass transfer in the liquid phase.

The experimental setup was shown schematically in [6], but this was done for the case of recycling of the liquid phase, with the flow returned to the inlet of the apparatus in preliminary separation of the gas. The variation of the concentration of sodium sulfite in the

1070-4272/04/7711-1822 © 2004 MAIK "Nauka/Interperiodica"

reaction mixture was determined experimentally by iodometric titration during the operation of the setup till the instant of complete conversion of sodium sulfite into sulfate. As reactors were used tubular units of diffuser–confuser (length of diffuser–confuser section $L_s = 2d_d$, number of sections N) and cylindrical designs. As optimization parameters served the ratio of diameters of the wide (diffuser) and narrow (confuser) parts of the reactor, d_d/d_c (1–3 at d_d = 24 mm), and also the diameters of the radial tube, d_2 (0.8–7 mm), and of the coaxial tube, d_1 (5–10 mm), for supply of the liquid phase.

As a quantity characterizing the intensity of gas dissolution in a gas–liquid reaction mixture flowing in the apparatus, we chose the "sulfite number of the reactor," i.e., the amount of oxygen taken up by unit reaction volume in unit time [5]:

$$\mathrm{SuR} = 0.127\frac{\Delta c_{Na_2SO_3}}{\Delta\tau}\frac{v_\Sigma}{v_r},$$

where v_r and v_Σ are the volumes of the reactor and the reaction mixture, respectively; and $\Delta c_{Na_2SO_3}$ is the change in the concentration of sodium sulfite in a time $\Delta\tau$.

Simultaneously with evaluating SuR, the size of gas bubbles was determined photographically, with the images obtained subjected to digital processing and the volume–surface diameter of particles of the dispersed phase (d_{32}) found [6].

When the ratio of the flow rates at which the gas and liquid phases are introduced, w_g/w_l (gas-to-liquid ratio of the dispersed system), in a tubular turbulent apparatus of diffuser–confuser design is raised to about 0.1, the sulfite number SuR of the reactor increases, as also, consequently, does the efficiency of mass transfer of oxygen from the gas phase into the liquid (Fig. 1). This is apparently due to an increase in the rate of oxygen supply to the reactor and to the resulting rise in its amount in the reaction mixture, which accelerates the oxidation process. It should be noted that, as indicated by visual inspection, the process occurs in this case in the bubble mode, and the oxidation rate increases, despite that the average size of gas bubbles, d_{32}, grows to 1.4 mm as the w_g/w_l ratio becomes larger. Further increase in the content of gas in the reaction mixture (gas flow rate w_g) does not lead to any change in the sulfite number of the reactor, which is due to the following: the flow of the two-phase mixture passes into a densely packed bubble (foam) mode, whereas the volume–surface

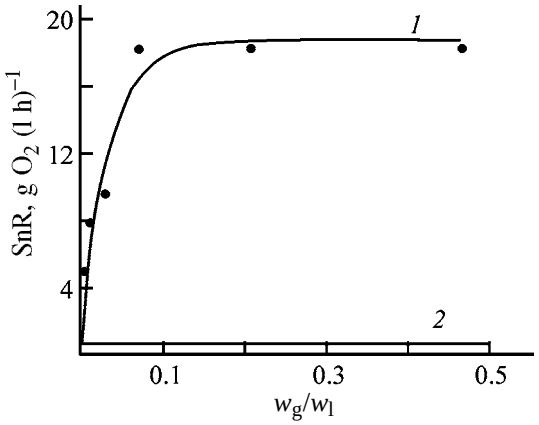

Fig. 1. Sulfite number of the reactor, SuR, vs. w_g/w_l in (*1*) tubular turbulent reactor ($w_l = 170 \pm 10$ cm^3 s^{-1}; N = 5; d_1 = 10, d_2 = 3, and d_c = 15 mm) and (*2*) volume mixing apparatus at a stirrer rotation rate of 1700 rpm (w_l/w_g = 3.3).

diameter of dispersed inclusions remains constant, $d_{32} \approx 1.4$ mm. It can be seen from the experimental data obtained that there exists the optimal ratio w_g/w_l, which apparently depends on the physical characteristics of the reacting components of the two-phase mixture, and there is no point in exceeding this value. This is especially important in working with aggressive gases, when the bypassing of the unreacted gas is impossible: in particular, in chlorination of butyl rubber with molecular chlorine in a hydrocarbon solvent [7].

The specific rate of uptake of atmospheric oxygen by water in a tubular turbulent reactor of the diffuser–confuser design (Fig. 1, curve *1*) exceeds by more than an order of magnitude that in a volume apparatus with a fast mechanical stirrer (~1700 rpm) (Fig. 1, curve 2). This is due to the following. In gas bubbling in a volume apparatus, including those with mechanical agitation, the zone of effective dispersion, which determines the rate of oxygen transfer, is considerably smaller than the reaction volume. In those parts of the apparatus which are remote from the zone of stirrer rotation in which effective dispersion occurs, gas bubbles coalesce and the area of the phase boundary decreases. In addition, zones of circulation of the two-phase mixture, which give rise to strong turbulent pulsations in the liquid phase, are absent in this case. As a consequence, tubular turbulent units of the diffuser–confuser design are distinguished by high values of the sulfite number of the reactor owing to the possibility of achieving a high-intensity dispersion throughout the reactor volume and to the presence of circulation zones in the diffuser–confuser sections.

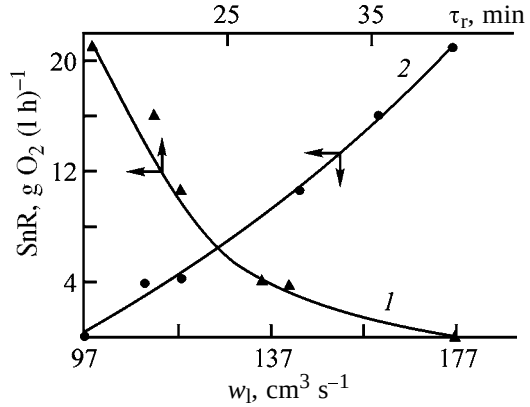

Fig. 2. Sulfite number SuR of the reactor vs. (*1*) residence time of the liquid in the reactor τ_r and (2) its flow rate w_l. w_l/w_g = 3.3; N = 5, d_1 = 10, d_2 = 3, and d_c = 15 mm.

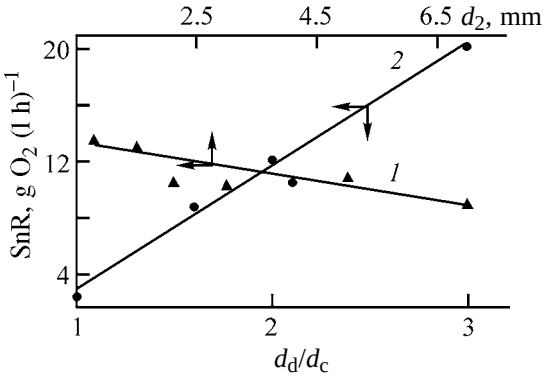

Fig. 3. Sulfite number SuR of the reactor vs. (*1*) diameter d_2 of the gas feed tube (d_d/d_c = 2) and (*2*) d_d/d_c (d_2 = 3 mm). w_l/w_g = 3.3, w_l = 140 cm^3 s^{-1}, N = 6, d_1 = 10 mm.

The small size of the tubular reactor ($v_r \approx 0.1$ l), compared to the volume mixing apparatus (v_r 4 l), allows metal saving and yields a higher (by a factor of more than 40) specific output capacity without a decrease in the time necessary for the oxidation to be complete.

The significant rise in SuR is observed when the flow rate of the reaction mixture increases at a constant content of gas in it (Fig. 2, curve *2*). In this case, the influence of shear deformation on gas bubbles is made stronger by the hydrodynamic energy of the flow, which leads to disintegration of particles of the dispersed phase in accordance with the exponential dependence and to an increase in the area of the phase-contact surface, as demonstrated for the example of emulsion formation [6]. In addition, gas uptake is virtually absent in the stratified mode of flow of the reaction mixture at low flow rates (<97 cm^3 s^{-1} in the given case), which is the lower limit to the output capacity of the reactor. At the same time, the maximum (plateau) in the SuR = $f(w_l)$ dependence is not reached at high w_l, i.e., there is no upper limit to the output capacity of the reactor. A characteristic feature of chemical and mass-exchange physical processes in tubular turbulent apparatus is that the rate of the process depends on the residence time of reactants in the reactor [2]. It can also be seen, for the example of dissolution of atmospheric oxygen in water, that SuR increases when the residence time of the reaction mixture in the reactor becomes shorter (Fig. 2, curve *1*). In this case, the reaction zone becomes "denser" as a result of diffusion control of the process.

As shown in [8], it is possible to effectively control the size of dispersion inclusions in liquid–liquid systems (specific area of the phase-contact surface) and, consequently, the efficiency of mass transfer by changing the method of reagent introduction. When gas–liquid flows move in tubular turbulent apparatus, raising the diameter of the gas feed tube results in that the sulfite number of the reactor diminishes only slightly (Fig. 3, curve *1*), which is determined by a decrease in the phase-contact area, because d_{32} increases by 15%. Similarly, when the diameter d_1 of the coaxial tube for supply of the liquid phase is reduced from 10 to 5 mm, SuR changes from 13.5 to 14 g O_2/(l h). Thus, the rate of oxidation of sodium sulfite by atmospheric oxygen in an aqueous solution is virtually independent of how the reagents are introduced. This is due to the fact that changing the method of introduction of the liquid and gas phases and, in particular, altering the diameters of feed tubes have no effect on the mass-transfer coefficient in the liquid phase.

In contrast to the method of reagent introduction, the geometry of the tubular turbulent apparatus and, in particular, the d_d/d_c ratio strongly affect the oxidation rate of sodium sulfite (Fig. 3, curve *2*). On passing from a cylindrical apparatus (d_d/d_c = 1) to that of a diffuser–confuser design with d_d/d_c = 3, the sulfite number of the reactor grows by nearly an order of magnitude. This is due to a rise in the mass-transfer coefficient in the liquid phase [4], which occurs because the coefficient of turbulent diffusion in the circulation zones of the diffuser–confuser sections grows as the depth of channel profile increases from d_d/d_c = 1 to d_d/d_c = 3 [3]. In addition, the size of dispersed inclusions decreases in this case by more than 70%. The rise in the efficiency of oxygen dissolution in water on passing from a cylindrical reactor to that of diffuser–confuser design is determined by the increase in the hydrodynamic energy of the flow. This is manifested in pronounced difference of the pressures at the apparatus ends (Fig. 4), which make higher the energy expenditure for a flow of the reaction mixture at the required linear velocity. However,

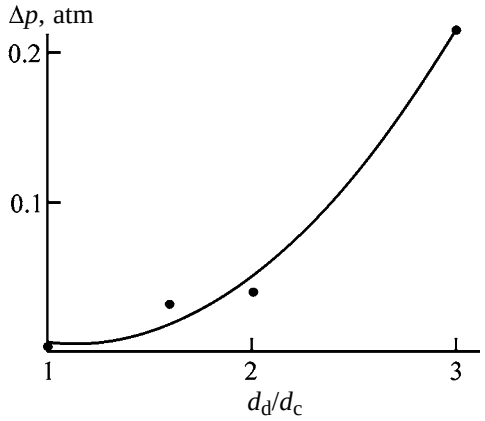

Fig. 4. Pressure difference across the ends of a tubular turbulent apparatus, Δp, vs. d_d/d_c (w_l = 140 $cm^3\ s^{-1}$).

the contribution of the expenditure for flow of the reaction mixture is insignificant owing to the small length of the tubular turbulent reactor, necessary for a fast chemical reaction to occur in high yield in the presence of a phase boundary, and to the high efficiency of mass transfer. Apparently, the best d_d/d_c ratio, from the standpoint of the efficiency of oxygen absorption in water (Fig. 3) and the optimal pressure difference across the ends of the apparatus (Fig. 4), is equal to 2.

Thus, tubular turbulent apparatus of diffuser–confuser design have a higher (by more than order of magnitude) specific rate of dissolution of atmospheric oxygen in water, compared to the volume mixing apparatus. An effective way to control the rate of oxygen absorption is to raise the flow rate of the two-phase reaction mixture (the output capacity of the reactor) and the depth of channel profile, expressed by the d_d/d_c ratio.

The results obtained in the study make it possible to recommend tubular turbulent apparatus for use in wastewater treatment by oxidation with atmospheric oxygen or ozone. In addition, the fundamental aspects of intensification of the mass exchange in liquid–gas systems, revealed in the study, enable effective use of tubular turbulent apparatus of diffuser–confuser design as reactors for fast chemical processes, as prereactors and external dispersion devices in order to make larger the area of the phase-contact surface in a two-phase reaction mixture, as internal circulation tubes in bubble-airlift (gas-lift) apparatus, as absorbers, etc.

CONCLUSIONS

(1) Tubular turbulent apparatus of diffuser–confuser design have a higher (by more than order of magnitude) specific rate of dissolution of atmospheric oxygen in water, compared to the volume mixing apparatus.

(2) Raising the flow rate of the reaction mixture leads to an increase in the sulfite number of the reactor, despite the decrease in the residence time of the reactants in the reaction zone, i.e., causes "densification" of the reaction zone.

(3) A decrease in the diameter of the radial tube for gas input by a factor of 9 and a threefold increase in the d_d/d_c ratio lead to a rise in the sulfite number of the reactor by factors of 1.5 and 9, respectively.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Model for Calculation of Reverse Osmosis Apparatus of the Roll Type

O. A. Abonosimov, S. I. Lazarev, and A. S. Gorbachev

Tambov State Technical University, Tambov, Russia

Received January 26, 2004; in final form, May 2004

Abstract—A model of reverse osmosis apparatus of the roll type is suggested. The model makes it possible to calculate the working area of the membrane, perform sectioning of the apparatus, determine the working pressure in separating units, and find the energy expenditure for the separation process.

Together with the conventional methods for separation of liquid systems, such as distillation, extraction, and evaporation, membrane processes find increasing use [1]. This is due to a number of advantages of membrane separation processes over the conventional techniques. Membrane processes are less energy-intensive and have a good economic feasibility; membrane installations are simple, space-saving, reliable in operation, and can be readily automated. The most promising is the method of reverse osmosis with the use of separating units of the roll type.

However, wide industrial implementation of membrane separation methods is hindered by insufficient understanding of the mechanism of the process and by the lack of reliable engineering procedures for calculation of membrane separation apparatus. The existing methods for calculation of processes and apparatus for membrane separation were considered in sufficient detail in [2–5]. An analysis of these calculation methods demonstrated that all the existing models are mostly of strictly specialized nature. Therefore, the aim of this study was to develop a sufficiently simple and reliable model for calculation of reverse-osmosis apparatus of the roll type.

The primary problem in calculating reverse-osmosis installations of the roll type consists in determining the basic parameters of a reverse-osmosis apparatus. To these parameters belong the working area of the membrane, the working pressure in the separating unit, and energy expenditure for separation.

Roll apparatus in reverse-osmosis installations are equipped with separating units (Fig. 1). Separating units of the roll type comprise a permeate collector *1* (perforated solution-removing tube) with several multilayer sheets wrapped around. Each sheet comprises two layers of planar semipermeable membranes *2* of rectangular shape. The surface of a permeate collector *3*, made of a synthetic fabric, is placed between the membranes. A spacer *4* for the flow of the starting solution (promoter of turbulence in the starting solution) is placed on the face surface of the membrane. The permeate-collecting surface and the membranes are attached at one end to the permeate collector, with the edges of their three other sides glued together hermetically. Each multilayer sheet wrapped around the perforated solution-removing tube forms a spiral channel for the flow of the solution being separated.

The main parameter in calculation of a separating roll unit is the total working surface area of the semipermeable membrane. We determined the area using the basic mass-transfer equation [1, 6]

$$F_M = M/(\Delta PK), \quad (1)$$

where M is the mass of the substance; ΔP, driving force of the reverse osmosis; and K, mass-transfer coefficient.

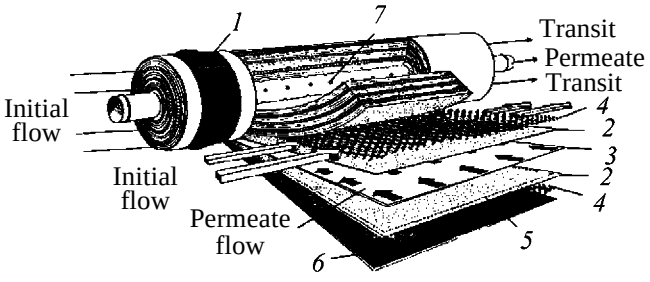

Fig. 1. Scheme of the roll-type separating unit: (*5*) adhesion line, (*6*) coating, and (*7*) seal; for the other designations, see text.

1070-4272/04/7711-1826 © 2004 MAIK "Nauka/Interperiodica"

We calculate the mass-transfer coefficient by the expression [6]:

$$K = \frac{1}{1/\beta + \delta/P_d}, \quad (2)$$

where β is the coefficient of mass transfer from the solution to the membrane surface; δ, membrane thickness; and P_d, the diffusion permeability coefficient of the membrane.

The diffusion permeability coefficients are calculated using approximating relations obtained in studies carried out on an industrial reverse-osmosis installation of the roll type [7, 8].

Experiments and calculations show that the kinetic characteristics of reverse osmosis depend on the longitudinal flow velocity in the intermembrane channel and on the pressure in the unit. The motion velocity and the flow mode of the solution in the intermembrane channel are taken into account in these calculations as usual, by means of the Reynolds number Re. The simplest way to take into account the pressure is to introduce the simplex

$$K_d = P_{work}/P_{st}, \quad (3)$$

where P_{st} is the standard pressure for which the rated throughput of the membranes is specified (P_{st} = 4 MPa).

More substantiated is use of the Euler number Eu

$$Eu = \Delta P/\rho w^2, \quad (4)$$

because Eu determines the forced transverse flow rate of the solvent and a number of other parameters.

However, simultaneous use of Re and Eu is inconvenient in processing of experimental data. Therefore, we used the following dimensionless combination instead of Eu:

$$K_{\Delta P} = Eu\,Re^2 = \Delta P \rho L^2/\mu^2. \quad (5)$$

Processing of calculated and analytical data on local mass-transfer coefficients made it possible to obtain rough approximating relations for the mass transfer coefficients averaged over the channel length. Having refined these relations on the basis of the experimental results, we obtained the calculation equation (error ±7%)

$$Nu = 1.84 \times 10^{-4} Re^{0.33} K_{\Delta P}^{0.18}. \quad (6)$$

Knowing the working area of a roll unit and taking into account the fact that the industrial reverse-osmosis apparatus consists of two units [9], we find the total number of apparatus in the membrane installation by the formula

$$n = F/2F_u, \quad (7)$$

where F_u is the working area of a single unit (m^2) (for the industrially used ERO-E-6.5/900A roll unit, this area is 6.5 m^2).

Further, we perform sectioning of the apparatus in the installation, based on the necessity for ensuring the same flow velocity of a solution being separated in each apparatus of each section and a constant decrease in the flow rate along the apparatus [6]:

$$L_i = (L_{in_i} + L_{fin_i})/2n_i = \text{const}, \quad (8)$$

$$q = L_{in_i}/L_{fin_i}, \quad (9)$$

where L_{in_i} and L_{fin_i} are the initial and final flow rates of the solution being separated in ith section; and n_i is the number of apparatus in ith section.

The value of q is chosen depending on the concentration coefficient k:

$$k = c_{fin}/c_{in}, \quad (10)$$

where c_{in} and c_{fin} are the initial and final concentrations of the solution being separated (the optimal value is q = 1.4).

The number of separation units in a section is calculated by the formula

$$n_i = \frac{L_{st}(1 - 1/q)}{q^{i-1}L_{per}}, \quad (11)$$

where L_{st} and L_{per} are the flow rates of the starting solution and the permeate in each apparatus.

To find the actual pressure in the reverse-osmosis apparatus, it is also necessary to calculate the loss of pressure for overcoming the hydraulic resistance constituted by the resistance of separating units, feed pipes, local resistances, etc. The major part of the pressure loss is accounted for by the hydraulic resistance of separating units, which can be calculated by the formula

$$\Delta P_\rho = \xi \rho w^2/2, \quad (12)$$

where ξ is a coefficient dependent on the design of a separating unit (type of the separating grid, drainage

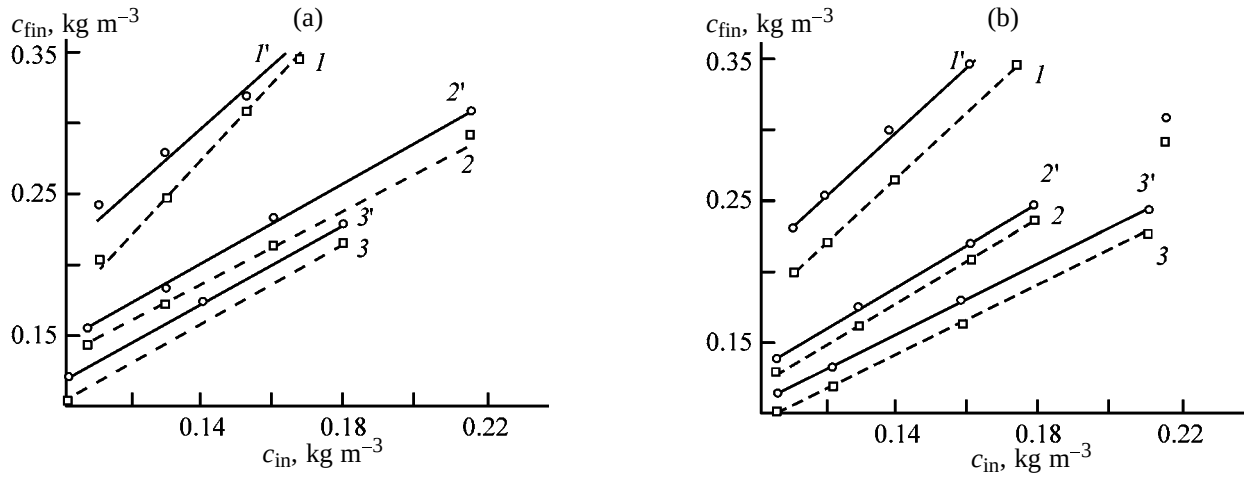

Fig. 2. Comparison of (*1*–*3*) calculated and (*1*'–*3*') experimental data for solutions of (a) $NiCl_2$ and (b) $NiCl_2$ + $K_2Cr_2O_7$. (c_{in}, c_{fin}) Initial and final concentrations of the solution being separated. Re: (*1*, *1*') 19, (*2*, *2*') 36, and (*3*, *3*') 55.

material, etc.); ρ, density of the solution being separated; and *w*, solution flow velocity in the intermembrane channel.

Knowing the actual pressure in the reverse-osmosis apparatus, we find the pump head:

$$H = \Delta P_{act}/\rho_{st} g, \quad (13)$$

were ρ_{st} the density of the initial solution.

The resulting data on the pressure and flow rate are used to select a pump for the reverse-osmosis installation.

The economical efficiency of the reverse-osmosis installation is evaluated by the total energy expenditure for separation, using the formula [10]

$$W_{eff} = VP/\varphi\eta, \quad (14)$$

where *V* is the volume of purified water; *P*, working pressure in a roll unit; φ, selectivity of retention; and η, efficiency of the pump unit.

The adequacy of the model for calculating reverse-osmosis apparatus of the roll type was assessed by comparing the experimental and calculated concentration dependences used in calculating the mass-transfer and diffusion permeability coefficients (Fig. 2). The calculated and experimental dependences for solutions of $NiCl_2$ and $NiCl_2$ + $K_2Cr_2O_7$ are shown in Fig. 2. It can be seen that the results are acceptable for engineering calculations.

Effect of Change of Phase Resistances on the Kinetics of Mass Transfer with a Chemical Reaction across Spherical Phase Boundary in the Interphase Instability Mode

S. A. Ermakov, A. A. Ermakov, and V. A. Stepanov

Ural State Technical University, Yekaterinburg, Russia

Received June 28, 2004

Abstract—The influence exerted by the concentration of the binder reagent on the ratio of phase resistances in mass exchange across a spherical phase boundary in the liquid–liquid system was studied.

As is known, the reciprocal of the mass-transfer coefficient characterizes the resistance to mass transfer in the phase. Hence follows that the phase resistance is affected by such physicochemical parameters as viscosity of interacting phases, diffusion coefficient, hydrodynamic situation in the phases, and ratio of initial concentrations of the substance being transferred and the binder reagent. Studies of the mass transfer in the liquid–liquid system have shown [1] that introduction of a binder into the receiving phase leads to redistribution of the diffusion resistance to mass transfer among the phases. As the concentration of the binder reagent increases, the reaction front is shifted from the bulk to the phase boundary; as a result, the diffusion resistance of the receiving phase is eliminated and a change of phase resistances occurs.

Studies of the mass transfer with a chemical reaction at the planar phase boundary in the liquid–liquid system [2] have shown that the change of phase resistances leads to loss of the hydrodynamic stability of the phase boundary, and thereby conditions are created in the system that give rise to a spontaneous interphase convection (SIC) or intensify the already existing convection process.

The change of phase resistances was evaluated, as it was done before for the case of mass transfer across the planar phase boundary, by the parameter [3]

$$L = c_A/c_{Bp}, \quad (1)$$

where c_A is the initial concentration of the substance being transferred (kmol m^{-3}), and c_{Bp} is the critical concentration of the binder reagent (kmol m^{-3}).

This study is concerned with the influence exerted by the change of phase resistances on the conditions of appearance and intensity of SIC in mass transfer with a chemical reaction across a spherical phase boundary in the liquid–liquid system.

EXPERIMENTAL

The mass transfer across the spherical phase boundary on a single drop was studied in temperature-controlled glass columns of diameter d = 0.055 m and height p = 0.5 m at a temperature of 20 ± 0.1°C. The phase being dispersed was fed with a precision feeder of volume 8 cm^3, equipped, in order to eliminate pulsations, with two special bellows operating simultaneously, one in compression and the other in expansion. The height of drop fall was varied with a mobile capillary, which yielded experimental data for short times of phase contact. A column with a discharge pipe in its lower part (Fig. 1) was used in the experiment. The drop catchers in which the dispersed phase was collected had a diameter d_c = 0.007 m (in order to diminish the mass transfer across the planar phase boundary at place of drop coagulation). The volume of liquid in drop catchers was maintained constant (2–3 drops) by continuously removing the dispersed phase. The drop diameter was varied by selecting capillaries of different diameters (0.19×10^{-3}–0.32×10^{-3} m). The volume of the continuous phase was V_{cp} = 1100 ml; that of the phase being dispersed, V_{dp} = 50 ml; and that of a sample, W_s = 2 ml.

The experiments were performed with organic solvents and transferred substances of chemically pure and analytically pure grades, preliminarily purified by distillation. As binder reagent served chemically pure grade sodium hydroxide. The purity of all the chemicals was judged from their refractive indices and boiling points.

Prior to an experiment, the organic and aqueous

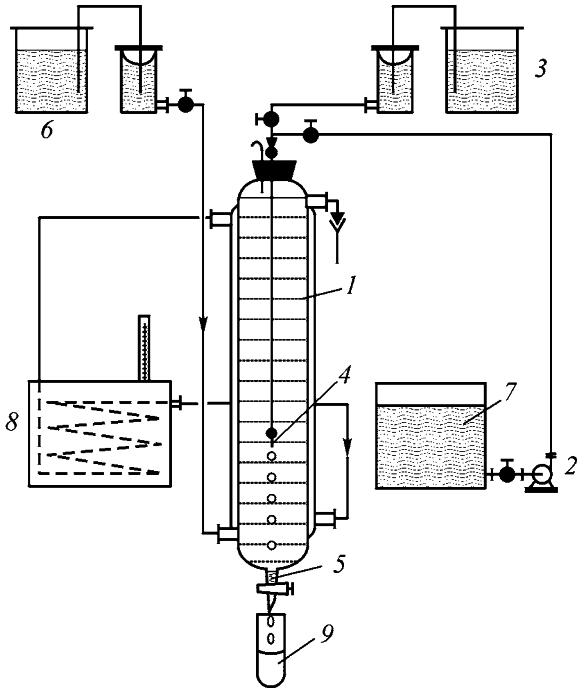

Fig. 1. Experimental setup for a study of the kinetics of mass transfer on a single falling drop. (*1*) Column, (*2*) precision feeder, (*3*) constant-level vessel for the dispersed phase, (*4*) capillary, (*5*) settler, (*6*) constant-level vessel for the continuous phase, (*7*) vessel for the starting solution of the dispersed phase, (*8*) thermostat, and (*9*) collector of the dispersed phase.

phases were mutually saturated (equal volumes of an organic solvent and distilled water were placed in a flask and kept there for 24 h) in order to eliminate the influence of mass exchange involving the solvents on the kinetic features of the mass exchange of the main substance being transferred. This substance was dissolved in the feeding (organic) phase, and the binder, in the aqueous phase. Before an experiment, the phases were thermostated for 30 min to eliminate the influence of the temperature factor.

The procedure used in the experiment on the laboratory setup consisted in the following: a certain height of ascent or fall of a drop (corresponding to a certain time of contact between the drop and the continuous medium) was set with a mobile capillary, and then the phase being dispersed was delivered into the capillary by a micropump, with separate drops formed in the continuous phase. After traveling a certain distance along the column height, the drop was caught with a drop catcher. The phase collected in the drop catcher was continuously discharged into the sampling device and analyzed. To determine the next point in the dependence of the concentration of the substance being transferred on the distance along the column height, the mobile capillary was moved into a new position and the procedure described above was repeated, with all the parameters (flow rate, time of drop formation, drop diameter, viscosity and density of phases) remaining unchanged. All the experiments were performed with the mass transfer directed from the drop into the continuous phase.

To determine the concentration of the substance being transferred, an aliquot (V_s = 1 ml) was taken from a weighing bottle with a pipet. The content of the substance in the aliquot was determined by potentiometric titration. The experimental error was found as root-mean-square error of the arithmetic mean to be $\leq$5%.

In a separate experiment, 100 to 200 drops were passed through the column, depending on the volume of the forming drops. The volume of a drop was 3–6 mm^3.

The time of drop formation, τ_{df}, was found as the total time in which the required number of drops was formed, divided by the number of drops formed.

The SIC was detected by three methods: visually, kinetically, and by the method of "strong surfactants."

As seen in Fig. 2a, the phase boundary is undisturbed in the case of mass transfer in the diffusion mode (diffusion-convective mechanism). In the case when the process occurs in the interphase-instability mode (Fig. 2b), waves are formed at the phase boundary, which is characteristic of SIC.

Figure 3 shows that interphase instability occurs in the presence of strong surfactants. It is known that some strong surfactants [polyvinyl alcohol (PVA) with 12.7% acetate groups, MW 47 800; Arkopol] can depress the interphase convection; however, mass exchange can proceed in this case in the diffusion mode [4]. As seen from Fig. 3, mass transfer occurs in the diffusion mode in the presence of polyvinyl alcohol (mass-transfer coefficient has a constant value); when mass transfer is performed in the same system without a surfactant, an increase in the mass-transfer coefficient is observed, which is characteristic of SIC.

In all the experiments, the kinetic method was used to detect the SIC [5]. This method consists in that the dependence $W = f(c)$ is plotted, where W is the rate of mass transfer and c is the driving force of mass transfer. A deviation from linear behavior points to occurrence of SIC (Fig. 4).

The experimental data obtained are presented in the form of kinetic dependences plotted in the c–h coordinates (c, concentration of the substance being transferred; h, distance along the height of column). With

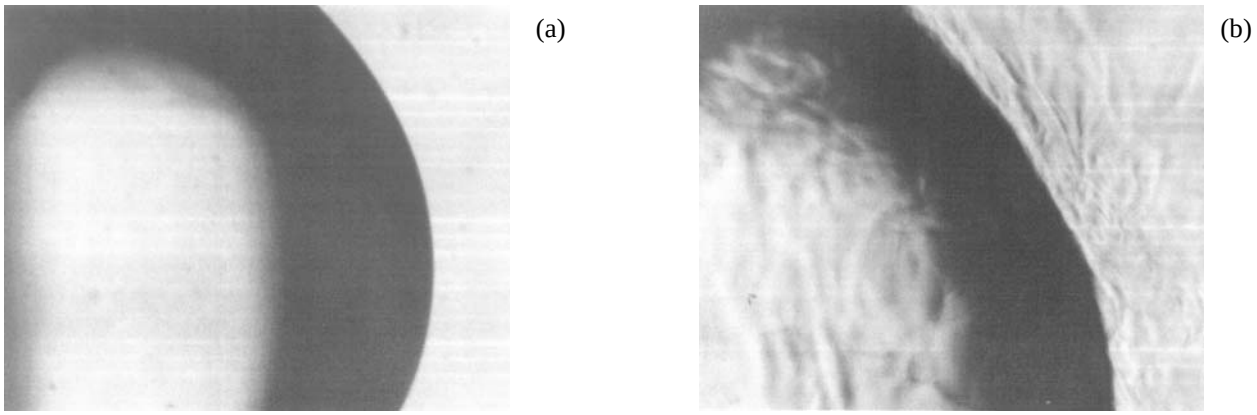

Fig. 2. Visual method for detecting SIC. Mass transfer of butyric acid (c_0 = 1 kmol m^{-3}) from CCl_4 to (a) water and (b) aqueous solution of NaOH (c_{NaOH} = 2 kmol m^{-3}).

the velocity of "free" motion of a single drop in the continuous phase and the distance traveled by the drop from the end of the capillary to the phase boundary known, the time of free motion of a single drop, τ_m, was calculated. The time of contact with the continuous medium was found by summing up the experimentally determined time of drop formation and the time of free motion of the drop:

$$\tau = \tau_f + \tau_m. \quad (2)$$

The experimental data were processed in the c–τ coordinates (c, as before; τ, process duration). The dependences obtained were approximated with a biexponential function by the least-squares method.

Further, using the resulting kinetic curve, we determined the averaged rates of the process and found the mass-transfer coefficients by the equation

$$-dc/d\tau = K_m S_{sp} c, \quad (3)$$

where K_m is the mass-transfer coefficient (m s^{-1}); S_{sp}, specific surface area of phase contact (m^2 m^{-3}); c, driving force of the mass-transfer process, equal to the concentration of the substance being transferred in the bulk of the feeding (limiting) phase [6] (kmol m^{-3}); and τ, process duration (s).

The specific surface area of phase contact was found as the ratio of the drop surface area to the drop volume by the formula

$$S_{sp} = 6/d_d, \quad (4)$$

where d_d is the average drop diameter.

The drop diameter was calculated on the following assumptions: the concentration of the substance in the continuous phase is constant during the experiment

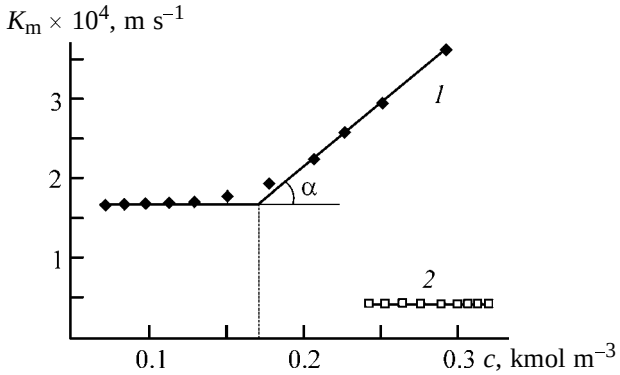

Fig. 3. Detection of SIC by the method of strong surfactants. (K_m) Mass-transfer coefficient and (c) concentration of the substance being transferred. Mass transfer of butyric acid (c_0 = 0.5 kmol m^{-3}) from CCl_4 into an aqueous solution of NaOH (c_{NaOH} = 2 kmol m^{-3}): (*1*) without surfactant and (*2*) in the presence of a surfactant (PVA, c_{surf} = 0.01 wt %).

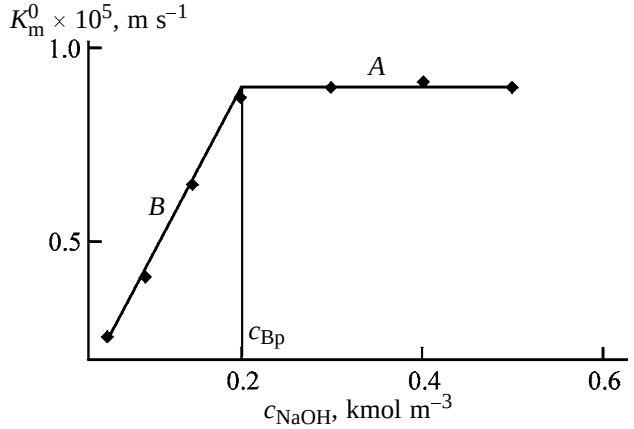

Fig. 5. Hatta curve: (K_m^0) initial mass-transfer coefficient and (c_{NaOH}) NaOH concentration; the same for Fig. 6. Mass transfer of benzoic acid (c_0 = 0.2 kmol m^{-3}) from toluene into aqueous NaOH (planar phase boundary): (*A*) diffusion region and (*B*) region of flows.

(the volume of the phase being dispersed was less than 4% of that of the continuous phase), the drop volume is constant during extraction (the drop density changed by less than 2%), and the phase boundary of the drop is spherical.

To determine the mass of drops dispersed in the column during an experiment, samples in weighing bottles were weighed on an analytical balance. The mass of the forming drop, m_d, was found by dividing the mass m_s of a sample taken by the number of drops that passed through the column during the time of drop formation. The mean arithmetic mass of a drop was found as the quotient of the total mass of drops in the experiments by the number of experiments. The error in determining the mean arithmetic mass of a drop was 2%.

With the average mass of a drop and its initial density known, the average drop diameter in an experiment was calculated by

$$d_d = (6m_d/\pi\rho_d)^{1/2}, \quad (5)$$

where ρ_d is the density of the drop (kg m^{-3}), and m_d, its mass.

The intensity of SIC and the conditions for appearance of an interphase instability were judged from the intensity coefficient ($K_{SIC} = \tan\alpha$, where α is the slope of the straight line plotted in the coordinates mass-transfer coefficient–driving force of the process) and the critical concentration c_{cr}, which are parameters of an empirical equation describing the process of mass transfer in the interphase-instability mode (Fig. 3) [7]:

$$J = \begin{cases} [K_D + K_{SIC}(c - c_{cr})] \text{ at } c > c_{cr}, \\ K_D c \text{ at } c \le c_{cr}, \end{cases} \quad (6)$$

where K_D is the coefficient of mass transfer in the diffusion mode (diffusion-convective mechanism) (m s^{-1}); K_{SIC}, coefficient taking into account the acceleration of the mass transfer in the interphase-instability mode (m^4 kmol^{-1} s^{-1}); c_{cr}, critical driving force (critical concentration) (kmol m^{-3}); c, driving force of the mass-transfer process (kmol m^{-3}); $K_D + K_{SIC}(c - c_{cr}) = K_m$, coefficient of mass transfer in the phase-instability mode (m s^{-1}).

In [8], it was suggested to evaluate the intensity of mass transfer in the phase-instability mode by the initial values of the mass-transfer coefficient, found graphically in the coordinates mass-transfer coefficient–driving force of the process at the point of intersection of the nonlinear portion of the curve for the mass-transfer coefficient with the driving force of the process at the initial instant of time.

In the present study, it is suggested to find the initial values of the mass-transfer coefficient, K_m^0 by extrapolating the function

$$K_m = -\frac{dc(\tau)}{d\tau}\frac{1}{S_{sp}c(\tau)}, \quad (7)$$

to the zero instant of time, which corresponds to the driving force of the process at the initial instant of time in the plot of the dependence of the mass-transfer coefficient on the driving force of the process.

The critical concentration of the binder component, c_{Bp}, was found from the plot of the dependence of the initial value of the mass-transfer coefficient on the initial concentration of the binder reagent, similar to the "Hatta curve" [1]. Two different portions can be seen in Fig. 5: portion *A*, parallel to the abscissa axis, corresponds to occurrence of a chemical interaction at the phase boundary, and sloping portion *B*, to the interaction of the reagent being transferred and the binder reagent in a certain volume of the extracting phase. The point of intersection of these portions corresponds to transition of the reaction front from some part of the volume of the receiving phase to the phase boundary. The critical concentration of the binder reagent, at which the change of phase resistances occurs, was found at the point of intersection of portions *A* and *B*.

Figure 6 shows a Hatta curve for mass transfer of carboxylic acids from a drop of carbon tetrachloride into an aqueous solution of NaOH. As seen from the

plot, raising the concentration of the binder reagent to the critical value for propionic and butyric acids leads to an increase in the initial values of the mass-transfer coefficient, which is accounted for by the appearance and development of SIC at approach of the front of the chemical reaction to the phase boundary. The decrease in the initial values of the mass-transfer coefficient under the conditions when the mass-transfer process is limited by the feeding phase (diffusion region) is due to hindrance to the turbulent motion of the liquid near the phase boundary. This hindrance is caused by the increase in the viscosity of the receiving phase. The quenching of the turbulization of the boundary layer diminishes the intensity of renewal of the contact surface by fresh portions of the binder reagent, which, in turn, makes less favorable the conditions of appearance and development of SIC. Accordingly, the intensities of interphase convection and mass transfer decrease.

The critical concentration of the binder reagent for the mass transfer of propionic acid (distribution coefficient $K_d = 4$) from CCl_4 into an aqueous solution of NaOH was $c_{Bp} = 0.7$ kmol m^{-3} (Fig. 6, curve *1*), i.e., the parameter L, which characterizes the change of phase resistances, is unity for propionic acid (initial concentration $c_0 = 0.7$ kmol m^{-3}). As seen in Fig. 6 (curve *2*), the change of phase resistances (transition of the limiting resistance from the receiving to feeding phase) for butyric acid (distribution coefficient $K_d = 1$) occurs at a critical concentration of the binder reagent, $c_{Bp} = 1.4$ kmol m^{-3}, i.e., at $L = 0.5$, as in the case of a planar phase boundary [2]. Comparison of the values of the parameter L for propionic and butyric acids shows that L decreases as the distribution coefficient of the substance being transferred becomes smaller, which coincides with the conclusions made in [3].

Now, the influence exerted by the change of phase resistances on the appearance conditions and intensity of SIC will be analyzed separately for substances being transferred, having different distribution coefficients.

As shown by the experiment (Fig. 7, curve *1*), the mass transfer of propionic acid in the absence of a binder reagent in the receiving phase or in its presence in low concentrations occurs under the SIC conditions, which is accounted for by the large distribution coefficient of the substance being transferred for the given system, i.e., the receiving phase does not hinder substantially the mass transfer of the main substance and thereby creates conditions under which SIC can appear and exist. At the critical concentration of the

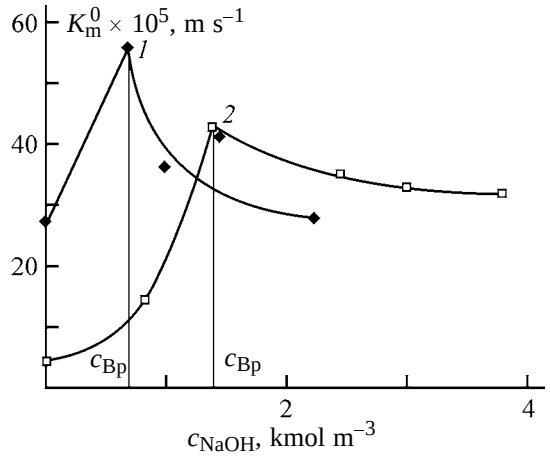

Fig. 6. Effect of the initial concentration of the binder reagent on the initial mass-transfer coefficient. Mass transfer from CCl_4 to aqueous NaOH: (*1*) propionic acid (c_0 = 0.7 kmol m^{-3}) and (*2*) butyric acid (c_0 = 0.7 kmol m^{-3}); the same for Fig. 7.

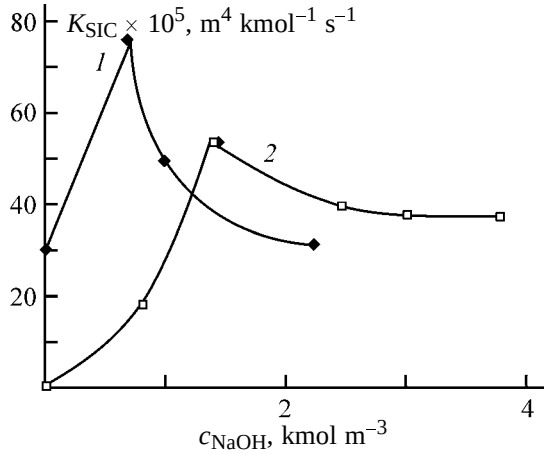

Fig. 7. Effect of the initial concentration of the binder reagent on the coefficient of SIC intensity, K_{SIC}. (c_{NaOH}) Concentration of NaOH.

binder reagent, $c_{Bp} = 0.7$ kmol m^{-3}, the maximum intensity of SIC is observed. As mentioned above, the decrease in the intensity of SIC is due to a rise in the viscosity of the receiving phase on raising the concentration of the binder reagent. The critical driving force, c_{cr}, i.e., the condition for appearance of SIC, is shifted to higher concentrations as the concentration of the binder reagent becomes higher (see table).

The mass transfer of butyric acid occurred in the absence of the binder reagent in the diffusion mode (diffusion-convective mechanism). Raising the concentration of the binder reagent from 0 to 3.8 kmol m^{-3} led to appearance of an interphase instability in the system and to intensification of mass transfer under the SIC conditions (Fig. 7, curve *2*). The absence of SIC in a system without a binder reagent is accounted

	3.79	2.45	32	37	0.02	0.5

for by the high diffusion resistance to mass transfer, exhibited by the receiving phase. Introduction of a binder reagent into the system results in that the process first occurs in the kinetic region. Then, at higher concentrations of the binder reagent, the reaction front is shifted to the phase boundary, and the process passes into the region of "flows" [3]. The occurrence of the mass-transfer process in this region creates conditions under which SIC can appear and develop. Raising the concentration of the binder reagent further leads to an increase in the coefficient of SIC intensity; at the critical concentration of the binder reagent, c_{Bp} = 1.4 kmol m^{-3}, there occurs a change of phase resistances (SIC has the maximum intensity) and the process passes into the diffusion region. As in the case of propionic acid, the decrease in the SIC intensity is due to an increase in the viscosity of the receiving phase on raising the concentration of the binder reagent. The critical driving force of the process decreases (see table).

CONCLUSIONS

(1) Raising the concentration of the binder reagent leads to transition of the limiting resistance from the receiving to feeding phase, i.e., to a change of phase resistances.

(2) The change of phase resistances in mass transfer of propionic acid leads to an increase in the intensity coefficient of spontaneous interphase convection. The conditions under which the spontaneous interphase convection can appear are shifted to higher concentrations.

(3) In mass transfer of butyric acid, the change of phase resistances creates conditions under which the spontaneous interphase convection can appear and the intensity of the already existing spontaneous interphase convection can considerably increase. The critical driving force of the process decreases.

(4) An increase in the initial concentration of the binder reagent in the diffusion region for propionic and butyric acids leads to a decrease in the intensity of spontaneous interphase convection, which is due to a rise in the viscosity of the receiving phase.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Chlorinated Polyimides

B. A. Zhubanov, V. D. Kravtsova, and R. F. Mukhamedova

Bekturov Institute of Chemical Sciences, Ministry of Education and Science of the Kazakhstan Republic, Almaty, Kazakhstan

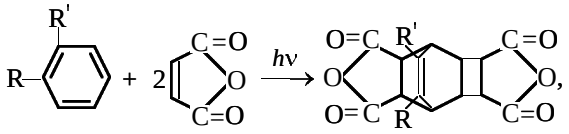
Received March 19, 2004

Abstract—Photoinitiated reaction of maleic anhydride with chlorobenzene and *o*-chlorotoluene in the presence of a sensitizer (benzophenone) was studied with the aim to prepare chlorinated tricyclodecenetetracarboxylic dianhydrides. New halogenated polyimides were prepared by the reactions of these products with various diamides in *N*-methyl-2-pyrrolidone in the presence of catalysts.

The chemistry of halogenated macromolecular compounds is a specific field of the polymer chemistry. It attracts researchers' attention because these compounds exhibit specific, often unique properties; this makes them indispensable in the modern engineering, medicine, and other fields. A particular place among such compounds is occupied by polyimides (PIs).

By now, the most studied are aromatic PIs. At the same time, certain studies show that alicyclic polyimides are also promising thanks to a favorable combination of chemical, physicomechanical, dielectric, and other properties [1, 2]. Some recent papers are devoted to fluorinated PIs; data on chlorinated PIs are virtually lacking.

The Diels–Alder reaction occurring upon sensitized UV irradiation of solutions of maleic anhydride (MA) in aromatic hydrocarbons yielded the corresponding chlorinated dianhydrides:



where R = H, Cl; R' = H, CH_3.

In this work we studied the specific features of preparation of chlorinated dianhydrides and PIs derived from them.

EXPERIMENTAL

The starting compounds and solvents were purified by standard procedures. The IR spectra were recorded on an IR-25 spectrometer; samples of the monomers were prepared as KBr pellets, and samples of the polymers, as 3–5-μm films. The ^{1}H NMR spectra were recorded on a Tesla BS-487B spectrometer in deuteroacetone (working frequency 80 MHz, internal reference hexamethyldisiloxane).

The reduced viscosities of 0.5% solutions of PI were measured in an Ubbelohde viscometer at 25°C in DMSO. Thermogravimetric analysis of the polymers was performed on a TGA SDTA Metler Toledo device at a heating rate of 8 deg min^{-1}. The temperatures of the onset of polymer degradation, $T_{o.d}$, were calculated from the TG curves.

The physicomechanical (tensile strength, relative elongation) and dielectric (dielectric loss tangent, dielectric permittivity) characteristics were studied under standard conditions [3, 4].

The dianhydrides were prepared by the Diels–Alder reaction upon irradiation of saturated solutions of MA in appropriate hydrocarbons in the presence of a sensitizer, benzophenone. 7-Chlorotricyclo[4.2.2.0^{2,5}]dec-7-ene-3,4,9,10-tetracarboxylic dianhydride [adduct of chlorobenzene (CB) and MA, ACB] was prepared in a temperature-controlled quartz glass reactor upon irradiation of a solution of MA (225.41 g, 2.30 mol) in 1000 ml of CB, containing 45.53 g (0.25 mol) of benzophenone, with a PRK-2M mercury quartz lamp (375 W) for 25 h. In the course of irradiation, a colorless crystalline precipitate formed, which was filtered off, recrystallized from acetic anhydride, washed with anhydrous diethyl ether, and dried in a vacuum at 80–90°C to constant weight; yield of ACB based on MA 74.2%.

7-Chloro-8-methyltricyclo[4.2.2.0$^{2.5}$]dec-7-ene-3,4,9,10-tetracarboxylic dianhydride [adduct of

o-chlorotoluene (CT) and MA, ACT] was prepared similarly, by irradiation of a solution of 186.01 g (2.00 mol) of MA in 1000 ml of CT, containing 36.42 g (0.20 mol) of benzophenone, for 30 h; yield of ACT based on MA 44.5%. Longer irradiation does not increase the yield of ACB and ACT.

Equivalent weight: ACB 154.43 (calculated 154.45), ACT 161.46 (calculated 161.47); mp: ACB 302–303, ACT 273–274°C.

Found, %: C 54.61; H 3.03; Cl 11.41.
$C_{14}H_9ClO_6$ (ACB).
Calculated, %: C 54.45; H 2.91; Cl 11.50.

Found, %: C 55.62, H 3.60, Cl 11.12.
$C_{15}H_{11}ClO_6$ (ACT).
Calculated, %: C 55.81; H 3.41; Cl 11.02.

IR spectra, ν, cm^{-1}: 1500 (benzene ring); 1775–1780, 1835–1840 (anhydride groups) [5]. ^1H NMR spectra, δ, ppm.: ACB 6.52 (1H), 2.82–3.61 (8H); ACT 1.97 (3H), 2.81–3.52 (8H).

The solvent, *N*-methyl-2-pyrrolidone (MP), was dried over 4 Å molecular sieves.

The polyimides were prepared in the presence of catalytic amounts of isonicotinic acid (INA) or triphenyl phosphate (TPP). Synthesis of PI derived from ACB and 4,4'-diaminodiphenyl ether (DADPE) was performed as follows. A three-necked flask equipped with a stirrer and a tube for feeding an inert gas was charged with 15.44 g (0.05 mol) of the dianhydride, 10.00 g (0.05 mol) of DADPE, and 1.52 g (5 wt % relative to the sum of the monomers) of INA, after which 76.3 ml of MP was added. The reaction flask was heated on an oil bath at 50°C for 15 min, after which the temperature was raised within 20 min to 160°C, and the mixture was heated at this temperature for 4.5 h. After cooling to room temperature, the PI was precipitated into acetone (chemically pure grade) and dried in a vacuum oven at 80–90°C to constant weight.

The elemental composition of the precipitated monomer corresponded to the theoretical calculation. The polyimide films were prepared by casting of solutions of the precipitated polyimides in MP (25 wt %) onto glass supports; to remove the solvent, the films were preliminarily dried in a vacuum oven at 80°C for 0.3 h and heated to constant weight at 150°C (1 h).

The polyimides derived from the other diamines in the presence of INA and TPP, and also the polyimides derived from ACT were prepared similarly; yield of the polymers 98.5–99.0%, degree of imidization about 100%.

Preparation of fluorinated alicyclic PIs from a an adduct formed by photochemical cycloaddition of MA to fluorobenzene was reported in [6]. Preparation of chlorinated dianhydrides of tricyclodecenetetracarboxylic acids has certain specific features. For example, synthesis of the photochemical adduct of CB and MA was attempted by other researchers [7], but they were not able to prepare ACB in a high yield; under the conditions used in [7], the yield of ACB did not exceed 5–7%, and the dianhydride derived from CT and MA was not obtained at all.

Photochemical synthesis of dianhydrides is two-step: First an unstable monoanhydride is formed (photochemical reaction), and then it is stabilized by addition of the second MA molecule (chemical step). In the initial period of the reaction (first 2.5–3 h), the rate constant in the temperature range 35–54°C is $(0.80–1.26) \times 10^{-5}$ s^{-1} for the CB + MA system and $(0.30–0.65) \times 10^{-5}$ s^{-1} for the CT + MA system. The activation energies are 53 and 79 kJ mol^{-1}, respectively. Such kinetic parameters are typical of reactions of MA with other aromatic hydrocarbons [2]. With CB, MA reacts at a higher rate; CT is less active, which may be due to the steric hindrance produced by the methyl group.

The conditions for preparing the adducts in the presence of two sensitizers, acetophenone and benzophenone, are listed in Table 1. As seen from Table 1, the yields of the process in the presence of benzophenone are 1.1–2.1 times higher, since the energy of the triplet state of this sensitizer (284 kJ mol^{-1}) is closer to the energy of the triplet level of the charge-transfer complex (CTC) between MA and aromatic hydrocarbons (280–284 kJ mol^{-1}). Furthermore, the spectrum of benzophenone covers the range of up to 420 nm, whereas acetophenone absorbs only up to 380 nm [8].

Examination of the influence of temperature on the reaction gave interesting results. As seen from Table 1, dianhydrides are formed virtually in the same, relatively narrow, temperature range. A decrease in the temperature to 30–35°C is accompanied by a decrease in the yield of the adducts; similar pattern is observed with increasing temperature to 60–65°C. A decreased yield of the dianhydrides at lower temperatures can be reasonably accounted for by the decreased solubility of the dienophile; in turn, too high temperatures may promote CTC decomposition, thus preventing the adduct formation. It should be noted

Table 1. Conditions for preparing chlorine-containing dianhydrides

Adduct	λ_{max}, nm	T, °C	c_{MA}, M	c_{sens}, M		Irradiation time, h	Adduct yield, %	
				acetophenone	benzophenone		acetophenone	benzophenone
ACB	280	45–50	2.30	0.30	0.25	25	64.2	74.2
ACT	284	50–55	2.00	0.30	0.20	30	20.6	44.5

that the CTC formed between the chosen addends is classed with so-called "contact" complexes, which are unstable and exist in solution virtually at the instant of contact of the donor and acceptor [9, 10]. If this time appears to be sufficient to receive the excitation energy from the sensitizer, formation of the monoadduct (and then bisadduct) becomes possible; if the CTC decomposes under the action of certain factors (increased temperature in our case), the yield of the final product decreases. We believe that these two factors are responsible for the narrow temperature range of the adduct formation.

Along with the direct influence on the CTC stability, the temperature exerts a still stronger influence on the second step of the process, stabilization of the monoadduct by addition of the second MA molecule. Heating causes the distances between the reacting species to increase, thus decreasing the probability and frequency of their contact. This fact is consistent with the previous data on the predominant influence of temperature on the second step of the process in photochemical synthesis of bisadducts of various structures [11].

A study of the reaction of MA with aromatic hydrocarbons showed that the MA conversion does not reach 100%. Along with the above factors, this is caused by side processes manifested in that the reaction mixtures turn yellow during prolonged irradiation (>35–40 h), and a tarry deposit (yellow to brown) is formed on the inner wall of the reactor. This product was identified as a low-molecular-weight product of photochemical polymerization of MA. Its yield is low (about 0.7–1 wt % relative to the final products), but it contaminates the dianhydrides, and their additional recrystallization from acetic anhydride becomes necessary.

Previously preparation of high-quality PIs from ACB and ACT was hampered by the lack of efficient synthesis procedures. However, in [6, 12] we showed that the polycondensation in polar aprotic amide solvents in the presence of catalytic amounts of INA allows preparation of PIs with high viscosity characteristics. In this paper, we consider the specific features of polymer preparation in the presence of INA and TPP. In the presence of TPP, acylation and cyclodehydration of the polyamido acids are accelerated, which may be due to the effect of the acidic ester formed by hydrolysis of the ester with water released in the cyclization [13]. The effect of the acidic ester is similar to that of the acid; the mechanism of polycondensation activation with carboxylic (in particular, pyridinecarboxylic) acids was discussed previously [13]. As solvent we chose MP in which PIs of the highest molecular weight are obtained (at 140–180°C) [12].

The optimal conditions of the synthesis of chlorinated PIs (CPIs) in the presence of INA and in the absence of a catalyst are listed in Table 2; the reduced viscosity of the PIs reaches 0.25–0.55 dl g^{-1}.

A study of the CPI formation showed that ACB is more active in polyacylation than ACT, due to higher electrophilicity of the anhydride groups. The CPIs prepared from ACB have higher viscosity characteristics. The reactivity of ACT decreases because of the presence of the alkyl group at the *endo*-ethylene bond.

In the presence of TPP, the polymers formed have a lower reduced viscosity (by 0.2–0.3 dl g^{-1}).

The compositions and structures of CPIs were proved by elemental analysis and IR spectroscopy. The IR spectra of CPIs contain absorption bands at about 1780 and 1720 (carbonyl groups of imide rings), 1360–1365 (–N<), 715–720 (imide ring), and 855 cm^{-1} (C–Cl). The absorption bands characteristic of the amido acid groups were lacking in the final polymers.

We have studied some properties of the new CPIs. We showed previously that the structural features of such halogenated PIs (presence of the fluorine atom) result in the lower glass transition point (T_g) compared to the nonfluorinated analog [6]. With the CPIs, the trend was similar (Table 3).

Relatively high reduced viscosities allowed us to cast films from the PI solutions and determine their main characteristics. The tensile strength of the CPI

* (DADPM) Diaminodiphenylmethane, (*p*-PDA) *p*-phenylenediamine, (*m*) *m*-phenylenediamine, (*p*-XDA) *p*-xylylenediamine, (HMDA) hexamethylenediamine, and (CDADPM) 3,3′-dichloro-4,4′-diaminodiphenylmethane.

films reaches 85–160 MPa depending on the diamine, and the relative elongation is 20–40%. The elastic modulus is within 2000–4100 MPa. We also determined some electrical characteristics: the dielectric loss tangent at 1 kHz and 25°C is 0.003–0.006, and the dielectric permittivity is 3.45–4.02.

It should also be noted that the samples prepared from the nonprecipitated polymers in the presence of TPP exhibit self-extinguishing properties. Furthermore, CPIs have lower oxygen index compared, e.g., to the fluorinated PI: The oxygen index of the PI derived from DADPE and the fluorinated dianhydride structurally related to ACB is 26; that of the PI derived from ACB, 0.30; and that of polymer no. 7, 0.40.

CONCLUSIONS

(1) Chlorinated dianhydrides of tricyclodecenetetracarboxylic acids were prepared by UV irradiation of solutions of maleic anhydride in chlorobenzene and *o*-chlorotoluene in the presence of benzophenone as sensitizer.

(2) New chlorinated polyimides exhibiting fairly high viscosity, thermal, physicomechanical, and dielectric characteristics were prepared by single-step polycondensation of the chlorinated dianhydrides with various diamines in *N*-methyl-2-pyrrolidone in the presence of catalytic amounts of isonicotinic acid or triphenyl phosphate.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Kinetics of Cleansing Action of Sodium Alkylbenzenesulfonate–Sodium Carbonate Binary Solutions

A. A. Kotomin, V. N. Naumov, and O. D. Yakimchuk

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received May 24, 2004

Abstract—Kinetics of cleansing action of sodium alkylbenzenesulfonate–sodium carbonate binary solutions, as the most widely used components of synthetic detergents, is studied using the procedure based on direct determination of the weight fraction of pollutants removed from the fabric. The effective kinetic parameters of the cleansing process are determined.

Cleansing is one of the most important and complex colloidal chemical and physicochemical mechanical processes. It is of great scientific interest and practical significance [1–3].

Up-to-date synthetic detergents (SDs) represent complex multicomponent systems containing both surfactants with high detergent power and mineral and organic additives promoting cleansing action. Household detergents also contain additives imparting to them the desired consumer's performance characteristics such as solubility, friability, color, and odor [4–9].

Cleansing involves a series of successive stages providing removal of pollutants and their emulsification in the aqueous phase [3, 7–9]: (1) wetting of the surface and displacement of pollutants, (2) dispersion of pollutants, (3) stabilization of various pollutants in the aqueous phase, (4) protection of the solid surface, (5) solubilization, (6) chemical decomposition of pollutants, and (7) foaming.

Although the nature of these elementary events is clear at the qualitative level, there are no analytical relationships for their simulation. Presently, detergent compositions are mostly formulated empirically, which is due to the fact that the theory of cleansing is now developed only as a very general concept. Physicochemical mechanisms of each elementary stage of cleansing remain to be understood. All these do not permit prediction of properties of detergent compositions. Numerous attempts to develop a quantitative theory of cleansing action using the thermodynamic approach proclaiming, as a key point, energy gain on transferring pollutants from the surface to be cleaned to the cleansing solution, failed. Cleansing is a nonequilibrium process. Its activation energy can be determined from the temperature dependence of the rate constant. Despite the fact that kinetic study of cleansing action provides information only on the effective parameters of this complex process, such experimental data could fix the rate-determining stages.

Previously we demonstrated [10] that, similarly to other kinetically controlled processes, the temperature dependence of the cleansing effect is an exponential curve. This type of relationship is characteristic of temperature dependences of such parameters of various processes as the chemical potential, rate constant, solute concentration, viscosity, etc. The temperature dependence of the cleansing action can be written as

$$M = Ae^{-E_a/RT}. \quad (1)$$

where A is the preexponential factor, and E_a has a sense of the activation energy of cleansing action.

Therefore, the goal of this work is to determine the effective kinetic parameters of cleansing action: the activation energy and preexponential factor.

The cleansing effect is mostly determined by comparing the whiteness of the fabric samples before and after laundering. However, it is known that home pollutions can consist of both strongly and weakly tinted spots. In this case, it is difficult to unambiguously judge the degrees of pollution and cleansing only from the change in the whiteness. Therefore, in the kinetic study, it was necessary to employ a more objective method based on direct determination of the weight fraction of a pollutant washed away from the fabric surface. In this work, the cleansing effect was

1070-4272/04/7711-1840 © 2004 MAIK "Nauka/Interperiodica"

determined gravimetrically according to GOST (State Standard) 22 567.15–95, as applied to laboratory conditions. The quality of laundering was tested by comparison of the weight of the laundered cotton fabric sample (5×5 cm) with that of the initial and contaminated ones. The contaminant composition included highly dispersed lampblack, Syntanol DS-10, oleic acid, sunflower-seed oil, nujol, casein, and ammonia. Before laundering, the contaminated samples were matured at 110°C for 1 h.

A polluted sample was fixed on a gate agitator and laundered in a beaker in 500 ml of fresh cleansing solution at fixed temperature for 0.5–20 min. High rotation rate (200 rpm) provided uniform laundering of the entire sample surface. After completion of laundering, the sample was thoroughly rinsed and then dried and ironed. Three parallel experiments were performed with each fabric sample. Before the experiment, fresh fabric samples were pretreated by boiling in a chlorine-containing bleaching solution to remove the dressing coating.

The cleansing action was characterized by the relative weight of the pollutants removed from the fabric surface.

$$M = \Delta m / m_i, \quad (2)$$

where Δm and m_i are the weights of the removed and initial pollution, respectively.

In the kinetic experiments we used a binary solution containing 30 wt % sodium alkylbenzenesulfonate [$C_{10-14}(C_6H_4)SO_3Na$] and 70 wt % sodium carbonate (Na_2CO_3) as a rather simple model system. Now sodium alkylbenzenesulfonate is the surfactant most widely spread in detergent production. It is characterized by high cleansing power [11], good performance characteristics, and relatively low cost. Soda reduces the water hardness, preventing formation of water-insoluble complexes of sodium alkylbenzenesulfonate with alkaline-earth metals. It also establishes alkalinity of the cleansing solution and saponifies fatty pollutants, providing their solubilization. Furthermore, soda, being an electrolyte, promotes realization of the maximal surface activity of the surfactant, thus reducing its consumption.

Kinetic experiments were carried out at 25, 40, 60, and 85°C at a fixed concentration of 5 g l^{-1}. The experimental kinetic curves are given in Fig. 1.

From the experimental curves we estimated the effective kinetic parameters of cleansing: the activation energy E_a and preexponential factor A. The activation energy was determined by the standard procedure from the temperature dependence of the cleansing effect plotted in the coordinates $\ln M$–$1/T$ [12]. It follows from the table that the mean effective activation energy of cleansing is 5.2 ± 0.3 kJ mol^{-1}.

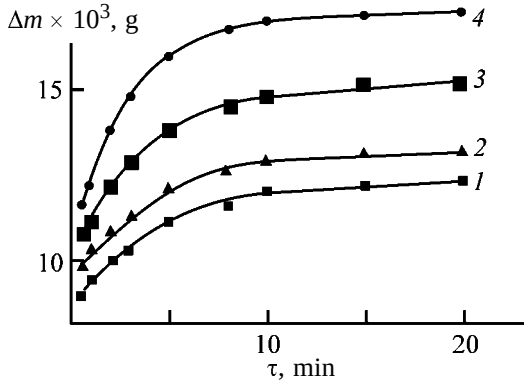

Fig. 1. Relative weight of pollutants removed Δm as a function of the time τ. Temperature (°C): (*1*) 25, (*2*) 40, (*3*) 60, and (*4*) 85.

As mentioned above, cleansing is a complex process involving a series of successive-parallel stages. Correspondingly, the activation energy is a function of all effective thermodynamic parameters controlling these stages. Determination of E_a allows fixation of the rate-determining stage of cleansing. We obtained E_a = 1–10 kJ mol^{-1}, which suggests that cleansing is a diffusion-controlled process. Previously [10], using the photometric method for determination of the whiteness of the fabric in the course of cleansing, we obtained the temperature dependence of the cleansing effect of sodium alkylbenzenesulfonate, its mixtures with sodium tripolyphosphate, and also of a complex composition based on sodium alkylbenzenesulfonate. This dependence is described by Eq. (3):

$$M^t_{max} = 8.65 M^{30}_{max} e^{-661.3/T}, \quad (3)$$

Estimated effective activation energy and preexponential factor at 298–358 K

τ, min	A	E_a, kJ mol^{-1}
0.5	2.35	4.87
1	2.75	5.15
2	2.82	5.03
3	3.03	5.37
5	3.36	5.21
8	3.49	5.14
10	3.65	5.15
15	3.71	5.20
20	3.68	5.19

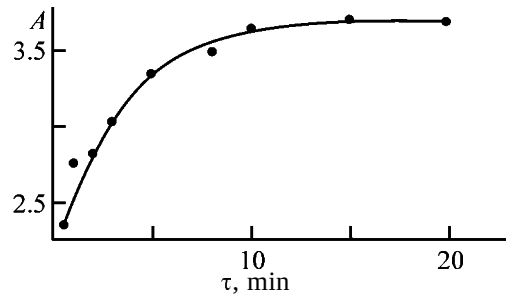

Fig. 2. Preexponential factor *A* as a function of the time of cleansing τ.

where M^{t}_{max} and M^{30}_{max} are the maximal cleansing effects of the substance at a fixed temperature and at 30°C, respectively, which practically correspond to its cleansing effect at a concentration above 50 g l^{-1}.

The activation energy of cleansing estimated by Eq. (3) for sodium alkylbenzenesulfonate and mixtures on its basis was found to be 5.8 kJ mol^{-1}. This value is consistent with that obtained in this work (5.2 ± 0.3 kJ mol^{-1}), also suggesting the significance of diffusion processes in cleansing.

Figure 2 shows the dependence of the preexponential factor *A* on the time of cleansing. As seen, *A* increases with time, but the growth decelerates starting from τ = 10 min, and the curve reaches saturation, suggesting that the process is unsteady in the initial stage (up to 10 min).

Nevolin [7] has demonstrated that, in all cases of laundering, mechanical activation is required to provide more uniform distribution of the cleansing solution and enhance wetting of the surface to be cleaned. The effect of agitation depends on the process time and natures of detergent and contaminated fabric. Generally, increasing agitation intensity accelerates removal of pollutants only in the first minutes of laundering, then having only slight effect. In parallel to desorption of pollutants, resorption occurs. Our results suggest that the preexponential factor *A* reflects the effect of mechanical activation. Furthermore, *A* can be affected by increasing viscosity of the cleansing solution as a result of formation of an emulsion and suspension of desorbed pollutants.

CONCLUSION

The estimated activation energy of cleansing (5.2 ± 0.3 kJ mol^{-1}) suggests that the process is diffusion-controlled. The value of the preexponential factor in Eq. (1) is a function of the intensity of mechanical activation and viscosity of the cleansing solution.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Colloid-Chemical Properties of 1,1-Dimethyl-1-Alkylhydrazinium Chlorides

M. G. Shcherban', A. V. Radushev, T. Yu. Nasretdinova, N. N. Teterina, and T. V. Bubyakina

Received August 8, 2004; in the final form, March 2004

Abstract—The colloid-chemical properties [surface tension, surface activity, and critical micellization concentration (CMC)] of aqueous 1,1-dimethyl-1-alkyl(R)hydrazinium chlorides (R = $C_{10}H_{21}$–$C_{18}H_{37}$) were studied.

1,1-Dimethyl-1-alkylhydrazinium chlorides (DMAHCs) are quaternary hydrazinium salts. Owing to colloid-chemical features and low toxicity, these compounds are used in petroleum production [1] and also as flotation agents [2], detergents, antistatics, and biocides [3, 4]. 1,1-Dimethyl-1-alkylhydrazinium chlorides are efficient surfactants. In spite of wide practical application of DMAHC, published data on their colloid-chemical characteristics are scarce [1–3, 5]. In this work we attempted to obtain more complete set of colloid-chemical characteristics of DMAHCs belonging to a single homologous series.

EXPERIMENTAL

1,1-Dimethyl-1-alkylhydrazinium chlorides $[R(CH_3)_2NNH_2]Cl$, where R is C_nH_{2n+1}, n = 10, 12, 14, 16, 18, and mixture (12 + 14), were prepared by quaternization of 1,1-dimethylhydrazine with chloroalkanes [6]. The crude product was purified by 2–3-fold recrystallization from acetone. The content of the main substance in the final product determined by the technique reported in [7] was no less than 96%.

The surface tension at the aqueous dimethylalkylhydrazinium chloride–air interface was determined stalagmometrically [8]. The surface tension was calculated by the equation

$$\sigma = \sigma_0 \frac{m_x n_0}{m_0 n_x}, \qquad (1)$$

where σ_x and σ_0 are the surface tensions of aqueous DMAHC and water (mJ m^{-2}); m_x and m_0 are the weights (g) of aqueous DMAHC and water discharged from a certain volume of a stalagmometer; and n_x and n_0 are the numbers of drops of aqueous DMAHC and water discharged from the same stalagmometer volume.

In calculating the surface tension by Eq. (1), we used the reference value of the surface tension at the water–air interface [9]. The average values of aqueous DMAHC surface tension were calculated from the results of four replicate measurements; the relative determination error did not exceed 2%.

The critical micellization concentration (CMC) was determined by the point of rupture in the plot of the specific electrolytic conductivity of aqueous DMAHC vs. DMAHC concentration.

Figure 1 shows the surface tension isotherms of aqueous DMAHC (R = $C_{14}H_{29}$, curve *1*) and R = $C_{12}H_{25}$ + $C_{14}H_{29}$ (curve *2*). The surface tension isotherms of aqueous DMAHC with R = $C_{10}H_{21}$, $C_{12}H_{25}$, and $C_{16}H_{33}$ are similar to those presented in Fig. 1, except for the system with R = $C_{18}H_{37}$ (curve *2*).

As seen from Fig. 1, in the range of dilute DMAHC solutions, the surface tension sharply decreases with increasing surfactant concentration, and its further trend becomes relatively flat. The first portion of the isotherm reflects the saturation of the liquid–air interface with DMAHC molecules due to their sorption. Further addition of surfactant molecules is accompanied by their micellization in the bulk of the aqueous phase. This process is manifested as a flat

C_{12}, C_{14}	34	2×10^{-2}
$C_{16}H_{33}$	34	2×10^{-3}
$C_{18}H_{37}$	66	1×10^{-4}

portion of the surface tension isotherm showing the insensitivity of the surface tension to micellization.

On further increasing the DMAHC concentration, the initial spherical micelles are apparently rearranged to nonspherical micelles influencing the state of the surface layer. This effect can be responsible for gradual decrease in the surface tension in the next portion of the isotherm.

Table 1 shows that, on adding DMAHC (R = $C_{10}H_{21}$, $C_{12}H_{25}$, $C_{14}H_{29}$, $C_{16}H_{33}$, and mixture R = $C_{12}H_{25}$ + $C_{14}H_{29}$] to water, the surface tension decreases to 35–40 mJ m^{-2}. This pronounced decrease in the surface tension shows that DMAHCs are active surfactants.

The surface tension isotherm of aqueous DMAHC (R = $C_{18}H_{37}$) (Fig. 1, curve *3*) has a small minimum at the surfactant concentration below CMC. We believe that this minimum is caused by the presence of impurity of a more active surfactant (presumably 1,1-dimethyl2-alkylhydrazine). It is known [8, 10] that the presence of even a trace of this foreign surfactant can significantly decrease the surface tension. After attainment of CMC, this impurity can be solubilized in the micelles. Therefore, σ slightly increases at DMAHC concentration exceeding CMC. Thus, the presence of a minimum in the surface tension isotherm of aqueous DMAHC suggests that the surfactant contains strongly surface-active impurities.

Each of the examined DMAHCs has two CMCs. The CMC_1 corresponds to formation of a monomolecular sorption layer filled with DMAHC molecules at the aqueous DMAHC–air interface. CMC_2 is manifested in the surface tension isotherms at DMAHC concentrations corresponding to formation of the nonspherical micelles. CMCs of aqueous DMAHC and the DMAHC concentrations corresponding to formation of the sorption layer at the aqueous DMAHC–air interface completely filled with DMAHC molecules are listed in Table 2. The published data show that the CMC values measured by various techniques differ [11]. For example, the CMC of aqueous DMAHC (R = $C_{12}H_{25}$ and $C_{16}H_{33}$) measured by the ring detachment technique is 9.4×10^{-3} M and 0.25×10^{-3} M, respectively. As seen from Table 2, these values considerably differ from the CMC values determined in this work stalagmometrically.

The surface activity of surfactants belonging to a single homologous series strongly increases with increasing number of carbon atoms in the hydrocarbon radical of the surfactant molecule [8]. Based on our

experimental data, we calculated the increment of the adsorption potential ΔW (contribution of the CH_2 group to the sorption work) for $\sigma_x = 68$ mJ m^{-2}. This value of the surface tension was chosen because it belongs to the linear portions of the surface tension isotherms of all the examined DMAHCs at $c_{DMAHC} \to 0$. The surface activity G can be calculated by the equation [8]

$$G = \lim_{c \to 0} (-d\sigma/dc) = RT\delta \exp[(W_0 + n\Delta W)/RT], \quad (2)$$

where δ is the adsorption layer thickness (m); W_0, work of adsorption of the polar groups of the surfactant molecule (J mol^{-1}); n, number of methylene groups; ΔW, contribution of one methylene group to the total work of sorption (J mol^{-1}); R, universal gas constant (J mol^{-1} K^{-1}); and T, temperature.

Equation (2) shows that, for the whole homologous series of surfactants, $\log c_{\Delta\sigma}$ is a linear function of n with the slope $\tan\alpha = \Delta W/RT$, where $c_{\Delta\sigma}$ is the surfactant concentration decreasing the surface tension by $\Delta\sigma$.

Figure 2 shows the plot of $\ln c_{\Delta\sigma}$ vs. n. The ΔW calculated from this plot is 2.1 kJ mol^{-1}, which is somewhat smaller than its theoretically calculated value (~2.7 kJ mol^{-1}) reported in [10]. We believe that this difference is caused by the fact that the surfactants used in our experiments (n = 10–18) have coarser molecules than the surfactant molecules used in the theoretical calculations (n = 3–6). The larger size of DMAHC molecules favors their sorption due to appearance of additional cohesion intermolecular interactions decreasing the sorption work.

In practice, surfactants are applied, as a rule, as their multicomponent mixtures. Owing to synergistic or antagonistic effects, the physicochemical characteristics of such mixtures can differ from the additive sum of characteristics of the individual surfactants. The multicomponent surfactants can exhibit higher micellization and solubilization power. Therefore, mixed surfactants often show enhanced performance. We studied as an example the surface tension of solution of commercial mixed DMAHC with $C_{12}H_{25}$ and $C_{14}H_{29}$ radicals. This multicomponent surfactant is used as flotation agent ChGS-1214 [2].

Figure 1 shows the surface tension isotherms of DMAHC (R = $C_{14}H_{29}$) and mixed commercial surfactant (R = $C_{12}H_{25}$ and $C_{14}H_{29}$). The comparison of these isotherms shows that the commercial surfactant has a high surface activity, which is governed by the contribution of the more active surfactant with R = $C_{14}H_{29}$. At a concentration of about 0.06 M, the surface tension isotherms of both the individual aqueous DMAHC and the commercial mixture become virtually indistinquishable. The commercial mixed surfactant decreases the water surface tension to 35 mJ m^{-2} at a concentration of 0.03 M, whereas with pure DMAHC (R = $C_{14}H_{29}$) this level of surface tension is reached at a concentration of about 0.06 M. The CMC of aqueous solution of mixed surfactant (R = $C_{12}H_{25}$ + $C_{14}H_{29}$) is lower than that of the individual DMAHCs, due to the higher micellization power of the mixed surfactant forming micelles of mixed kind.

Table 2. Critical micellization concentration of DMAHC and the aqueous DMAHC concentration corresponding to saturation of the sorption layer at the aqueous DMAHC–air interface with DMAHC molecules

Radical	CMC × 10^2, M		$c_1^{**} \times 10^2$, M

* Determined conductometrically.
** Determined from the surface tension isotherm.

CONCLUSIONS

(1) 1,1-Dimethyl-1-alkylhydrazinium chlorides are effective cationic surfactants. Their surface activity increases with increasing number of carbon atoms in the hydrocarbon radical. The increment of the adsorption potential is 2.1 kJ mol^{-1} per methylene group in the hydrocarbon radical.

(2) The critical micellization concentration of aqueous DMAHC corresponding to formation of the monomolecular adsorption layer at aqueous DMAHC–air interface was found. At DMAHC concentration exceeding CMC, the surface layer is rearranged due to formation of nonspherical micelles.

(3) With increasing number of carbon atoms in the DMAHC hydrocarbon radical, the micellization power of the surfactant increases.

(4) The surface activity of multicomponent commercial DMAHC (R = $C_{12}H_{25}$ + $C_{14}H_{29}$) exceeds that of the individual surfactants, which is mainly due

to the contribution of the more active surfactant, 1,1-dimethyl-1-tetradecylhydrazinium chloride.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Perfluoroalkanes by High-Temperature Reaction of Graphite with Fluorine in a Fluidized Bed

D. S. Pashkevich, G. G. Shelopin, D. A. Mukhortov, V. B. Petrov, Yu. I. Alekseev, and V. S. Asovich

Prikladnaya Khimiya Russian Scientific Center, St. Petersburg, Russia

Received July 23, 2004

Abstract—Synthesis of lower perfluoroalkanes (tetrafluoromethane, hexafluoroethane, octafluoropropane, decafluorobutane) by high-temperature reaction of graphite with fluorine in a fluidized bed was studied.

Tetrafluoromethane, hexafluoroethane, octafluoropropane, and decafluorobutane are widely used in the modern industry as ozone-friendly refrigerants, propellants, dielectrics, and gas-phase fluorine carriers for semiconductor industry [1]. The annual world consumption of these substances reaches several thousand tons; therefore, development of efficient processes for their production is an urgent problem.

There exist several procedures for preparing these compounds. Tetrafluoromethane is prepared from the elements in the inverse wave of filtration combustion of graphite in fluorine, using a fixed graphite bed [2]. The feasibility parameters of this process are high.

Hexafluoroethane can be prepared by catalytic fluorination of fluorochloroethanes with HF [3]. The raw materials for these process destroy the ozone layer, and their production should be stopped. The process has also other drawbacks: large amount of hydrogen chloride waste and the necessity of regeneration and utilization of the environmentally hazardous chromium magnesium fluoride catalyst.

Octafluoropropane is produced by fluorination of hexafluoropropylene with cobalt trifluoride [4]. The production of hexafluoropropene also involves ozone-decomposing substances [1]. Furthermore, processes involving cobalt trifluoride as fluorinating agent have low productive capacity.

Decafluorobutane can be prepared by electrochemical fluorination of tributylamine in an HF solution [5]. However, the yield and productive capacity of the process are poor.

At the same time, it is known that all the above perfluorocarbons and solid carbon polyfluoride $(CF_x)_n$ are formed by high-temperature reaction of carbon with fluorine:

$$C(s) + F_2(g) \rightarrow (CF_x)_n(s) + CF_4(g) + C_2F_6(g) + C_3F_8(g) + C_4F_{10}(g) + ... \quad (1)$$

The boiling points of tetrafluoromethane, hexafluoroethane, octafluoropropane, and decafluorobutane are –128, –78, –37, and –2°C, respectively. In industrial implementation of reaction (1), separation of the products by distillation seems to involve no serious problems. Thus, commercial mastering of carbon fluorination will allow several different processes to be combined in a single process involving simple and cheap raw materials, with an efficient distillation system.

Published data on the composition of gaseous products of carbon fluorination are contradictory. However, most of the authors indicate that the major product is tetrafluoromethane. As an efficient process for tetrafluoromethane production has been commercially mastered [2], development of the process based on carbon fluorination is appropriate only if higher fluoroalkanes will be obtained in a yield comparable with that of CF_4.

Moissan was the first to perform the reaction of carbon with fluorine [6]; he found that amorphous carbon forms ignite in fluorine even at room temperature, whereas graphite and diamond are resistant to fluorine at normal temperature. Ruff reported in 1934 [7] that at 420°C graphite reacts with fluorine to form a solid compound, carbon polyfluoride $(C_xF_y)_n$. He also found that at 460–700°C the reaction occurs with explosion, and at temperatures above 700°C graphite burns in fluorine to form fluorocarbons, mainly tetra-

Scheme of the reactor: (*1*) reactor body, (*2*) tube for feeding the fluorinating mixture, (*3*) chamber for separation of the gas and powder, (*4*) reactor lid, and (*5*) filter; (H_1, H_2) electric heaters, (T_1–T_5) thermocouples for the medium, and (Tc_1–Tc_2) thermocouples for the walls.

fluoromethane [8]. It was shown later [9] that the composition of carbon polyfluoride depends on the synthesis temperature and graphite particle size. Later, numerous papers concerning preparation of carbon polyfluoride were published; its composition, structure, properties, fluorination kinetics, and application fields were studied. Carbon polyfluoride found use as a solid lubricant and a cathodic material for lithium cells [10].

Thus, the majority of papers on fluorination of carbon were devoted to properties of carbon polyfluoride and procedures for its production; perfluoroalkanes were considered as by-products [11–13]. The available data are insufficient to determine the optimal conditions for preparing hexafluoroethane, octafluoropropane, and decafluorobutane from carbon and fluorine.

The goal of this study was to find conditions of carbon fluorination ensuring formation of a mixture of perfluoroalkanes containing tetrafluoromethane, hexafluoroethane, octafluoropropane, and decafluorobutane in commercially significant amounts.

The reaction of fluorine with carbon is strongly exothermic; in formation of CF_4, the thermal effect is 933 kJ mol^{-1}. The temperature of the reaction products in the adiabatic mode reaches several thousand degrees. Under these conditions, hexafluoroethane, octafluoropropane, and decafluoroethane decompose with the formation of other fluorocarbons, fluorine, and carbon.

To ensure the stability of the target products under the synthesis conditions, it is necessary to efficiently remove the released heat. This can be done by using dynamic (agitated) beds of powdered carbon.

Fluidization is one of the most advanced procedures for performing heterogeneous processes involving a solid phase. Systems fluidized with a gas flow are characterized by strong agitation inside the bed, provided by ascending gas "bubbles" [14]. Owing to the large surface area of solid particles, the heat exchange between them is very intense, and the difference between the temperatures of the fluidizing agent and solid particles is very small. To ensure stable fluidization, it is appropriate to use friable powders showing no tendency to sinter. Therefore, for laboratory tests we chose electrode graphite as a carbon material.

EXPERIMENTAL

For visual monitoring of the fluidization, experiments were performed in a model glass reactor. Stable fluidization without separation and removal of the particles is observed with the graphite fraction with the particle size less than 250 μm at a fluidizing gas velocity less than 15–20 cm s^{-1}. The contact time of the gas and powder varies from 0.5 to 3 s depending on the fixed bed height.

For fluorination experiments, we constructed a laboratory installation with a reactor containing a fluidized graphite bed. The reactor (Fig. 1) was a thick-walled pipe *1* from carbon steel of the following size: internal diameter 12 mm, external diameter 45 mm, and height 500 mm. The fluorinating mixture is fed through a porous insert *2* from pressed nickel powder, arranged in the bottom part of the pipe. In the top part, the pipe has an expansion *3* 28 mm in diameter for decreasing the gas velocity and separating the graphite particles. A filtering gauze is arranged at the reactor outlet.

To maintain the required temperature, two electric

heaters H_1 and H_2 are mounted on the reactor surface. The wall temperature is monitored with Chromel–Alumel thermocouples Tc_1 and Tc_2. The thermocouples in two-channel ceramic straws are arranged in wells 8 mm deep and 3 mm in diameter, so as to ensure reliable thermal contact between the thermocouple junction and well bottom.

The temperature of the reaction medium in the reactor volume is measured with Chromel–Alumel thermocouples T_1–T_5. The distance from the T_1 junction to the gas-feeding surface is 15 mm, and the distance between the junctions of the thermocouples, 115 mm.

As a fluidizing gas we used a mixture of fluorine and nitrogen, and as a carbon material, electrode graphite with the particle size less than 250 μm.

The expansion of the graphite powder bed was monitored with thermocouples T_1–T_5. If the bed expanded to occupy the whole channel height, the temperature became virtually equal throughout the reacting bed.

The experiment time was 25–30 min. In this time, the temperature of the reactor wall increased by no more than 15°C. Thus, fluorination of graphite was performed under approximately isothermal conditions.

Chromatographic analysis of the gaseous reaction products showed that the composition of the products changed during the first 5 min of the reaction. In the subsequent period, at constant feed rate and temperature, the composition of the gaseous products was stable and could be averaged.

The averaged (over the samples taken) composition of the gaseous products of the reaction of fluorine with graphite in the steady-state isothermal mode is given in Table 1 for various temperatures. At each temperature, we took three to five samples. When calculating the sample composition, we assumed the chromatographic correction coefficients to be unity for all the substances.

In Table 1 we also give the parameters $\Sigma S_{CF}/S_N$ characterizing the content of gaseous fluorocarbons in the gas flow. The parameter $\Sigma S_{CF}/S_N$ is the ratio of the total area of the fluorocarbon chromatographic peaks to the nitrogen peak area. The fluorine breakthrough was detected only at 410°C.

The dependence of the parameter $\Sigma S_{CF}/S_N$ on the fluorination temperature (contact time 3 s) is shown in Fig. 2.

Using the parameter $\Sigma S_{CF}/S_N$, we can qualitatively estimate the amount of fluorine consumed for formation of gaseous perfluorocarbons and solid carbon polyfluoride. This allows comparison of the rates of the synthesis and thermal decomposition of carbon polyfluoride and estimation of the accumulation of carbon polyfluoride in the reactor.

The molar ratio of fluorine and carbon in the gase-

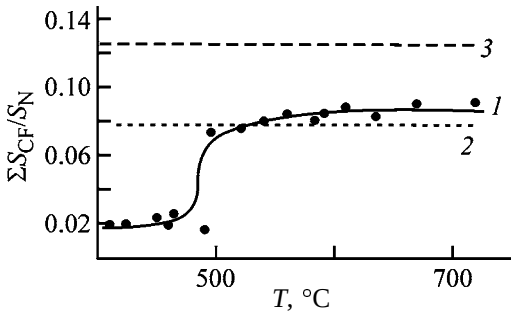

Fig. 2. Parameter $\Sigma S_{CF}/S_N$ as a function of temperature *T* at a gas–powder contact time of 3 s: (*1*) experimental dependence, (*2*) theoretical value corresponding to formation of $CF_{3.2}$ (which corresponds to the average composition of products obtained at 580–600°C), and (*3*) theoretical value corresponding to formation of CF_4.

ous reaction products at 550–600°C was 1 : 3.2 (Table 1).

Thus, the volume of gaseous fluorocarbons is by a factor of 3.2 smaller than the volume of fluorine consumed for their formation. The feed contained 20% fluorine, and the ratio of the volume of the gaseous reaction products to the volume of nitrogen, $\Sigma S_{CF}/S_N$, at a temperature close to 580°C should be

$$\frac{\Sigma S_{CF}}{S_N} = \frac{20/3.2}{80} = 0.078.$$

At 400–450°C, the theoretical value of $\Sigma S_{CF}/S_N$ is 0.083.

If the only fluorination product were tetrafluoromethane, the $\Sigma S_{CF}/S_N$ ratio would be the following:

$$\frac{\Sigma S_{CF}}{S_N} = \frac{20/2}{80} = 0.125.$$

At 400–450°C, the experimental value of $\Sigma S_{CF}/S_N$ is lower than the theoretical value by a factor of 4. This means that the fluorine fed into the reactor does not fully leave the reactor in the form of gaseous compounds. Hence, at this temperature the rate of formation of carbon polyfluoride is higher than the rate of its decomposition, and carbon polyfluoride accumulates in the reactor.

Table 2. Composition of gaseous products of the reaction of fluorine with graphite as influenced by temperature. Contact time 0.6 and 0.8 s

T, °C	CF_4	C_2F_6	C_2F_4	C_3F_8	C_3F_6	C_4F_{10}
	vol %					
565	59.2	20.9	1.6	11.8	1.3	5.2
590	62.3	17.9	–	13.3	1.0	5.4

At temperatures above 550°C, the experimental $\Sigma S_{CF}/S_N$ value agrees with the theoretical value; hence, the fluorine fed into the reactor fully leaves the reactor in the form of gaseous products. A slight increase in $\Sigma S_{CF}/S_N$ at temperatures exceeding 550°C is associated with an increase in the CF_4 content in the reaction products.

Thus, the gaseous products of graphite fluorination in a fluidized bed under the optimal conditions (550–600°C), when the CF_4 content is minimal and carbon polyfluoride does not accumulate, have the following composition (wt %): 40–45 CF_4, 20–25 C_2F_6, 20–25 C_3F_8, and 10–15 C_4F_{10}.

To estimate the minimal time of complete conversion of fluorine in a fluidized bed, we performed experiments with shorter contact times of the gas and powder: 0.6 and 0.8 s. The results are given in Table 2. No breakthrough of fluorine was observed. The composition of the gaseous products did not noticeably differ from that obtained at a contact time of 3 s.

Table 1 and Fig. 2 suggest that formation of gaseous perfluorocarbons involves intermediate formation of carbon polyfluoride, followed by its decomposition. To check this assumption, we performed experiments on synthesis and thermal decomposition of carbon polyfluoride. Carbon polyfluoride was prepared at 400–500°C in a fluidized bed for 35–40 min. The composition of carbon polyfluoride after the fluorination corresponded to the formula $(CF_{0.30–0.35})_n$.

Then we stopped the supply of gaseous fluorine and performed the decomposition at a higher temperature in a nitrogen flow ensuring fluidization and isothermal conditions. The decomposition of carbon polyfluoride was performed for approximately 10–100 min.

The composition of the gaseous products of thermal decomposition of carbon polyfluoride is given in Table 3.

These data confirm the assumption that perfluorocarbons containing more than one carbon atom are formed by synthesis and decomposition of carbon polyfluoride.

Tables 3 and 1 show that, as *x* in $(CF_x)_n$ decreases, the yield of tetrafluoromethane in decomposition of $(CF_x)_n$ increases. Also, the yield of tetrafluoromethane

is higher in decomposition of $(CF_x)_n$ prepared in advance (Table 3) than in synthesis–decomposition of $(CF_x)_n$ at the same temperature (Table 1). These facts suggest the following.

When a graphite particle reacts with fluorine, a film of carbon polyfluoride with high x is formed on the particle surface, whereas the internal region of the particle remains unchanged. The lowest yield of tetrafluoromethane was observed in thermal decomposition of the film with a high x. If the film does not decompose rapidly and the particle occurs for a long time at approximately 500°C, the fluorine inside the particle is redistributed, i.e., the two-layer distribution pattern with $x \to 1$ at the surface and $x \to 0$ inside the particle changed for a uniform distribution of fluorine with a constant x throughout the particle volume. In thermal decomposition of such a sample of carbon polyfluoride ($x \ll 1$), the yield of CF_4 is high.

Thus, to decrease the yield of CF_4, it is appropriate to perform the thermal decomposition of the synthesized carbon polyfluoride as quickly as possible, so as to avoid equalization of x throughout the particle volume.

We performed experiments on fluorination of graphite in a fluidized bed using a fluorinating mixture with an increased fluorine concentration. The results are listed in Table 4. The temperature measurements showed that the fluorination occurred in the isothermal mode; no fluorine breakthrough occurred.

Comparison of Tables 1 and 4 shows that, as the fluorine concentration in the fluorinating mixture is

Table 4. Composition of gaseous products of reaction of fluorine with graphite in the steady-state mode as influenced by temperature. Contact time 3 s, fluorinating mixture composition 40% F_2 + 60% N_2

T, °C	CF_4	C_2F_6	C_2F_4	C_3F_8	C_3F_6	C_4F_{10}
	vol %					
580	75.43	13.9	0.02	7.37	0.57	2.49
590	75.65	14.18	0.06	6.72	0.4	2.99

increased, the product composition changes: the amount of CF_4 increases, and that of the other fluorocarbons decreases.

This experimental fact can be explained as follows. Two reaction zones can be distinguished in the reaction unit: the zone of the fluorine uptake in which solid carbon polyfluoride is formed and the zone of the carbon polyfluoride decomposition yielding gaseous perfluorocarbons. In a reactor with a circulating fluidized bed, the zone of decomposition of carbon polyfluoride occupies the whole reactor volume, whereas the zone of formation of carbon polyfluoride occupies only its part. These zones overlap (Fig. 3), and thermal decomposition of carbon polyfluoride occurs in a medium containing gaseous fluorine.

As the fluorine concentration in the fluorinating mixture is increased, the height of the zone of the fluorine uptake increases. Apparently, under the experimental conditions the gaseous fluorocarbons react with fluorine to give lower-molecular-weight perfluoro compounds. Therefore, at increased fluorine content in the fluorinating mixture, the yield of CF_4 is higher.

Thus, to increase the yield of perfluorocarbons containing more than one carbon atom, it is appropriate to perform the decomposition of the synthesized polyfluoride in the absence of fluorine in the decomposition zone.

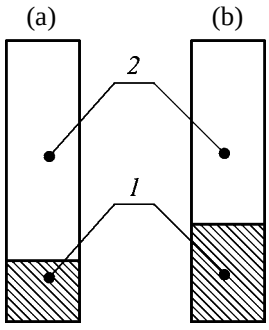

Fig. 3. Scheme of the distribution of the reaction zones in the reactor channel: (*1*) zone of fluorine uptake and (*2*) zone of decomposition of carbon polyfluoride. Fluorine concentration, %: (a) 20 and (b) 40.

CONCLUSIONS

(1) The major gaseous products of graphite fluorination are CF_4, C_2F_6, C_3F_8, and C_4F_{10}; the amounts of C_2F_4 and C_3F_6 do not exceed 2.0 wt %.

(2) At 550–600°C, the composition of the reaction products is as follows (wt %): 40–45 CF_4, 20–25 C_2F_6, 20–25 C_3F_8, and 10–15 C_4F_{10}.

(3) Synthesis of CF_4, C_2F_6, C_3F_8, and C_4F_{10} involves intermediate formation of $(CF_x)_n$ followed by its thermal decomposition.

(4) At temperatures above 550°C, solid carbon polyfluoride does not accumulate in the laboratory reactor.

(5) To increase the yield of perfluorocarbons containing more than one carbon atom, it is appropriate to perform the decomposition of $(CF_x)_n$ with $x \to 1$ under the isothermal conditions in the absence of fluorine.

Abstract—Reaction products of phosphorus(III) chloride and vanadium(V) oxychloride with low-density polyethylene were studied by chemical analysis and physicochemical (IR spectroscopy and atomic-force microscopy) methods. Thermaloxidative transformations of the initial and modified samples were studied by differential thermal analysis.

Modification of polymeric materials significantly expands their application field. The structure and properties of polymers can be modified in the desired direction either during synthesis or by introduction of fragments of different chemical nature into the macromolecules of final products. Since recently, special attention in development of polymeric materials with desired properties has been paid to modification of the polymer surface, because specifically the surface layer structure governs to a significant extent the behavior of polymers under exploitation [1]. Certain promise of enhancing the stability of polymers is offered by various methods of surface treatment, blocking the centers responsible for degradation of the material [2]. Among such methods is chemical gas-phase modification, in particular, molecular layer deposition (MLD) involving selective chemical reactions on the solid-phase matrix, which allow atom-by-atom assembly of fragments with the desired composition and structure [3].

Polyolefins, e.g., polyethylene, find wide commercial application due to their valuable properties such as good dielectric characteristics, chemical stability, frost resistance, strength, low specific weight, etc. The chemical activity of polyolefins is not very high. Among reactions by which various functional groups can be introduced into their macromolecules, halogenation, sulfochlorination, and phosphonation were studied in the most detail [4]. Modern physicochemical methods, e.g., atomic-force microscopy (AFM), allow not only examination of the surface layer structure [5] but also elucidation of the reactivity of the polymer with respect to low-molecular-weight compounds, as well as evaluation of the effect of modifying additives on the macroscopic, e.g., thermal oxidative, properties of the resulting products [6–8].

EXPERIMENTAL

In this work we studied chemical transformations of low-density polyethylene (LDPE) in reactions with phosphorus(III) chloride and vanadium(V) oxychloride vapors and elucidated how the thermal stability of the polymeric material is influenced by the inorganic structures synthesized. The choice of these specific modifiers was governed by the fact that phosphorus and vanadium compounds in various combinations are used for controlling the thermal oxidative properties of polymeric materials. Also, it was of interest to study the structure of the surface layer of polyethylene before and after its reactions with agents having different redox characteristics and to elucidate the interrelation between the chemical nature of the additives and the surface morphology, on the one hand, and the thermal oxidative characteristics of the products, on the other.

The element oxide groups were introduced in a flow-through reactor charged with the samples (40×20 mm films or specimens crushed to the particle size of ~4 mm). Gas-phase modification of the polymer was effected by phosphorus(III) chloride and vanadium(V) oxychloride vapors at 50°C in a stream of the carrier gas (air) dried to the dew point of –50 to –55°C. The degree of the chemical reaction between the low-molecular-weight modifiers and reactive groups of the polymeric material was estimated from

1070-4272/04/7711-1854 © 2004 MAIK "Nauka/Interperiodica"

the maximal concentration of the element in the modified samples. After modification, the polyethylene samples were treated with a stream of dried carrier gas until the initial chlorides and gaseous products formed were exhaustively removed from the reaction chamber. The chlorine-containing groups were replaced by hydroxyls via vapor-phase hydrolysis of the polymer matrix. The concentration of the nanoadditives in the material was determined on a PS-100 ICP spectrometer equipped with a computer accessory, upon preliminary degradation of the polymer in a solution of concentrated sulfuric and nitric acids in the microwave heating field (a Microdigest-301 instrument).

The IR spectra of the modified samples were recorded on an FSM-1201 Fourier IR spectrometer at 400–4000 cm^{-1}. The IR data and the results of chemical analysis furnished information about the composition and structure of grafted element-containing groups. The resistance of the initial and modified films to thermal oxidation was studied by differential thermal analysis (DTA) on an MOM (Hungary) instrument at 20–600°C at a heating rate of 5 deg min^{-1} in air. The AFM studies of the films were carried out on a Solver P47 Pro scanning probe microscope in the tapping mode, using a gold-plated silicon cantilever in two scanning modes: (1) topographic, to elucidate the surface morphology from the change in the frequency of the cantilever vibrations and (2) adhesive, to reveal the difference in the compositions of the sample surface segments from the changes in the slope of the cantilever to the surface under study, caused by adhesion interaction.

Chemical analysis[1] showed that, under the actual conditions, the total concentration of the elements in the samples attains a constant value within 15–20 min. The maximal content of phosphorus and vanadium in the polymer was estimated at 0.11 and 0.19 mmol g^{-1}, respectively.

Figure 1 shows the differential IR spectra of the films of the initial and modified polyethylene. The IR spectra of the polymer samples containing element oxide groups in the surface layer exhibit absorption bands near 1000 cm^{-1} due to stretching vibrations of the E–O bond in the E–O–Alk groups. Also, there are absorption bands with maxima at 1650 (stretching vibrations of the C=C bond upon introducing a new substituent) and 1455 cm^{-1} (bending vibrations of the C–H bond in substituted polyethylenes) [9], evidently,

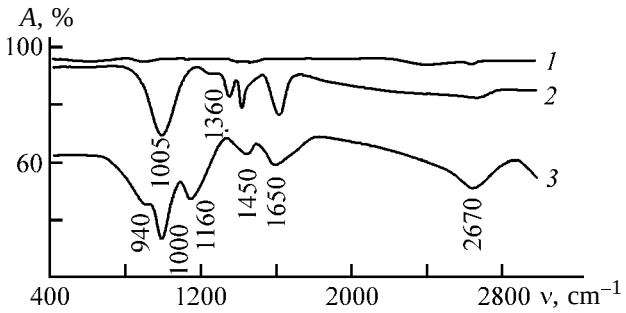

Fig. 1. Differential IR spectra of polyethylene. (*A*) Transmission and (*ν*) wave number. Sample: (*1*) initial, (*2*) vanadium-containing, and (*3*) phosphorus-containing; the same for Fig. 3.

due to the changes in the polymer matrix proper, caused by chemical modification (Fig, 1, curves *2*, *3*). Also, the spectra of phosphorus-containing polyethylene exhibit an absorption band near 1160 cm^{-1}, characteristic of phosphorus compounds (bending vibrations of the P=O bond). Vapor-phase hydrolysis of the modified films is responsible for appearance of the absorption bands due to vibrations of the OH groups at 2670 (stretching vibrations) and 940 cm^{-1} (out-of-plane bending vibrations) (Fig. 1, curve *3*).

The IR data evidence chemical grafting of the element oxide groups at the reactive centers of the polymer matrix. Our experimental results, together with published data, suggest that, for all the modified samples, element oxide groups are introduced via exchange reactions which can be represented as

$$[-CH_2-CH_2-CH_2-CH_2-]_n + ECl_m \longrightarrow [-CH_2-\underset{\displaystyle ECl_{n-m}}{\underset{|}{CH}}-CH_2-CH_2-]_n + (n-m)HCl, \quad (1)$$

$$[-\underset{|}{\overset{|}{C}}=\underset{|}{\overset{|}{C}}-]_n + ECl_m \longrightarrow [-\underset{\displaystyle Cl\ ECl_{m-1}}{\underset{|}{\overset{|}{C}}}-\underset{|}{\overset{|}{C}}-]_n. \quad (2)$$

Also, treatment of LDPE with a vapor of $VOCl_3$ (a modifier with a prominent oxidative power) causes partial oxidation of the reactive centers of the polymer, as evidenced by the presence in the IR spectra of an absorption band near 1360 cm^{-1} (symmetric stretching vibrations in the $CO-CH_3$ group) (Fig. 1, curve *2*).

When the modifying agents react with the polymer matrix by different mechanisms, they will, evidently, differently affect the structure of the surface layer of

[1] Chemical analysis was carried out at TsKP "Chemical Assembling of Nanomaterials", St. Petersburg State Technological Institute (TU).

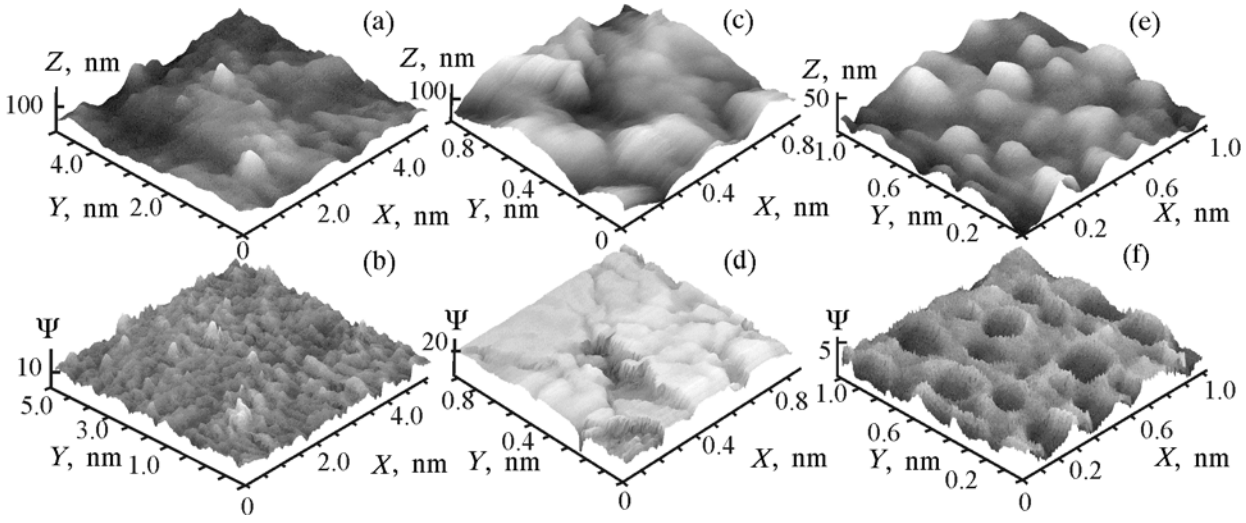

Fig. 2. AFM reconstruction of the surface of (a, b) initial and (c, d) vanadium- and (e, f) phosphorus-containing polyethylene. (a, c, e) Surface topography and (b, d, f) adhesion interaction pattern. (*X*, *Y*, *Z*) Axis coordinates and (Ψ) cantilever slope.

polyethylene as well. Redox reactions in synthesis of the vanadium oxide groups should, apparently, more profoundly transform the surface. Indeed, the AFM studies show that the initial film (Fig. 2a) is covered with projecting mutually fused crystallites; there are no profound relief defects and foreign inclusions affecting the adhesion interaction of polyethylene with the AFM probe (Fig. 2b). The surface roughness was estimated at 16–20 nm. Figure 2c suggests that, upon treatment with vanadium oxychloride, the surface exhibits clear intercrystallite boundaries; individual globules of modified polyethylene with a size of 200–250 nm are distinguishable. Also, up to 200 nm, deep caverns are observed, inside which the chemical composition sharply differs from that of the initial material, as suggested by a jumpwise variation of the slope of the cantilever to the surface at the cavern boundaries (Fig. 2d). These deep transformations of the structure of the surface layer are, evidently, due to the redox reactions with $VOCl_3$ vapor at the boundary separating the amorphous and crystalline areas in the initial matrix.

Chemical modification of the LDPE film with the PCl_3 vapor (Fig. 2e) yields on the surface spherically shaped islands 80–200 nm in diameter, in amount of 20–25 per quadratic micrometer. A sharp change in the slope of the cantilever when crossing the island boundary (Fig. 2f) also suggests the difference between the chemical compositions of the segments revealed and the surface of the initial polyethylene. Evidently, phosphorus-containing groups with a high hydrophilic power [10], when added to active centers of polyethylene, form a hydrate shell surrounding the grafted groups due to adsorption of water vapor from air. Since on the surface of the polymer matrix there are two fragments of different chemical compositions, which sharply differ in the strength and adhesion characteristics, it is fairly difficult to reveal the actual topography of the modified polyethylene surface from the AFM data. For example, the AFM reconstruction of the surface furnishes no information about the height of an individual phosphorus-containing island. However, it can be stated that, under the actual conditions, treatment of the material with the PCl_3 vapor does not cause degradation of the surface polymer layer, and phosphorus-containing groups add only to accessible active centers of the LDPE surface, which is in agreement with the results of chemical analysis.

The influence of the chemical modification on the heat resistance of the polymer was estimated both from the heat effects and from the change in the sample mass during thermal degradation. It should be noted that thermal oxidative degradation of polyethylene is a complex process due to the presence in its structure of amorphous and crystalline areas. It is known that first oxidized are amorphous areas of the material, which are more accessible for the oxygen molecule [11]. They act as a buffer protecting the crystalline areas from degradation.

The DTA curve for the initial polyethylene (Fig. 3, curve *1*) exhibits several segments corresponding to various degradation stages.

At 106°C, an endothermic melting peak is observed which is characteristic of LDPE [4]. The initial degradation stage due to low-temperature oxidation of

the material (exothermic effect with a maximum at 240°C) involves removal of the low-molecular-weight fraction contained in the polymer and degradation of weak bonds, which, in turn, initiates degradation of carbon–carbon fragments into free radicals. Upon further heating of the sample, the process acquires a more complicated multistage character, which is responsible for appearance in the DTA curve (Fig. 3, curve *1*) of a large number of exothermic (at 359, 392, 410, 435, and 452°C) and endothermic (at 425°C) peaks. These transformations are due to profound degradation of the skeleton and to removal of a wide spectrum of organic saturated and unsaturated volatile monomers. The third, final, stage involves complete (virtually 100%) degradation of polyethylene, and the corresponding exothermic peak is observed at 485°C.

Chemical modification of polyethylene with phosphorus(V) chloride causes virtually all the peaks due to thermal degradation of the polymer to shift by 20–90°C to higher temperatures (Fig. 3, curve *3*). The largest shift from 240 to 332°C, due, evidently, to decrease in the number of active centers of thermal oxidation [schemes (1) and (2)], is observed for the initial degradation stage. Upon further heating, the maxima of both exo- and endothermic effects in the DTA curve of the modified polymer (Fig. 3, curve *3*) shift by 20–40°C to higher temperatures. Also, exothermic peaks at 410 and 435°C disappear. These changes, together with the results of the previous studies, suggest active participation of phosphorus-containing additives in degradation processes both in the gas (deactivation of free radicals) and condensed (recombination of active centers at the gas–solid interface) phases [12].

The inhibiting action of the vanadium oxide fragments is manifested in the first and second stages of degradation of the polymeric material, as suggested by the following changes in the differential curve (Fig. 3, curve *2*). First, the exothermic peak shifts to higher temperatures from 240 (initial sample) to 280°C (vanadium-containing sample). This is evidently due to the preliminary partial oxidation of the polymer matrix and formation of more thermally stable fragments upon treatment of LDPE with $VOCl_3$ vapor. Second, the next degradation stage, similarly to the case of the phosphorus-containing sample, is characterized not only by shifts to higher temperatures of the exothermic (390, 430, 472°C) and endothermic (441°C) peaks but also by disappearance of the exothermic peaks with maxima at 392 and 435°C (Fig. 3, curve *2*). The influence of the modifying additive is, evidently, manifested in reactions with the oxidant

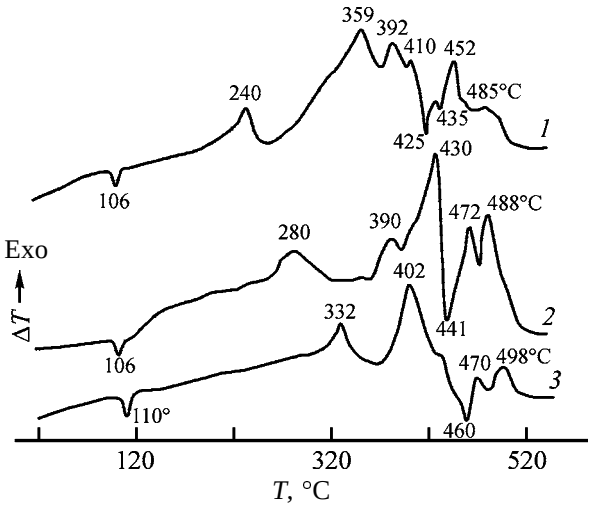

Fig. 3. DTA curves of polyethylene. (*T*) Temperature.

molecules, which, in turn, hinders formation of hydroperoxy radicals and degradation of the polymer chain.

Comparison of the derivatographic and AFM data for the modified polyethylene samples also revealed interrelation between their heat resistance and the surface layer structure, which is the most prominent in the initial degradation stage. For example, introduction of phosphorus-containing moieties is responsible for formation on the matrix surface of a uniform coating (Figs. 2e, 2f), which partially blocks the active centers of the degradation process. According to the DTA data, the temperature of the first exothermic effect significantly increases (by 92°C) relative to the initial polyethylene (Fig. 3, curve *3*). The AFM reconstruction for the vanadium-containing sample (Figs. 2c, 2d) clearly demonstrates etching of the polyethylene film surface, which can be responsible for the appearance of transport channels for atmospheric oxygen. This may be the reason for lowering of the temperature of the exothermic effect in the initial stage of degradation of this product relative to the phosphorus-containing sample (280 against 322°C) (Fig. 3, curves *2*, *3*). Partial degradation of the matrix surface on treatment with the $VOCl_3$ vapor, evidently, causes degradation of the internal layers of the polymeric material.

CONCLUSION

Chemical analysis and physicochemical studies of the reaction products of PCl_3 and $VOCl_3$ vapors with low-density polyethylene film samples suggest chemical grafting of the element oxide groups at the reactive centers of the polymer. Grafting proceeds both via

substitution reactions and, in the case of vanadium oxychloride, via redox transformations. Atomic-force microscopic studies reveal the difference in the morphologies of the initial and modified polymers and an interrelation between the chemical nature of the additive and the surface layer structure, on the one hand, and the thermal oxidative properties of polyethylene, on the other.

Abstract—The possibility of stabilization of some vinyl chloride polymers with elemental sulfur in their thermal and thermal oxidative degradation was studied.

Various sulfur compounds are widely used in chemical industry as initial components in synthesis of new products or as additives. In particular, to increase thermal and thermal oxidative stability of vinyl chloride (VC) polymers, some sulfur-containing compounds, dialkyl sulfides and sulfur-containing derivatives of dialkyltin [1, 2], are used as thermal stabilizing agents and antioxidants. Contrary to sulfur compounds, elemental sulfur is not used yet as an additive to polymers (only as vulcanizing agent for rubber [3]). There are published data on ability of sulfur to inhibit thermal oxidative degradation of polyethylene due to decomposition of hydroperoxides [4]. In this connection, it was appropriate to study the influence of elemental sulfur on thermal and thermal oxidative dehydrochlorination of hard and plasticized polyvinyl chloride (PVC) and some VC copolymers.

EXPERIMENTAL

Thermal and thermal oxidative dehydrochlorination of hard and plasticized PVCs were performed at 175°C in a bubbling-type reactor in nitrogen or air flow (3.3 $l\ h^{-1}$). The rate of dehydrochlorination and deacetylation was determined by the procedure described in [5]. Degradation of VC copolymer with 11.1 mol % vinyl acetate (VCVA-11.1) was estimated from the total rate of elimination of HCl and CH_3CO_2H. Titration of hydroperoxides was performed by the procedure described in [6]. Polymers of VC (PVC S-7059M, VCVA-11.1, and copolymer of VC with 28.8 mol % methyl acrylate VCMA-28.8) were washed with ethanol in a Soxhlet apparatus. Ester plasticizing agents, dioctyl phthalate (DOP) and dioctyl sebacate (DOC), were purified by filtration through a column packed with aluminum oxide. Elemental sulfur [GOST (State Standard) 127.1-93, content of main substance 99.98 wt %] and sulfur of ultrapure grade were not purified additionally.

Thermal oxidative degradation of PVC in the presence of sulfur may involve, along with dehydrochlorination and deacetylation, also formation of sulfur dioxide, which can affect the results of acid–base titration and thus can give overestimated rate of degradation of polymers. However, in a model experiment on oxidation of individual sulfur in air, the qualitative reaction on decolorization of $KMnO_4$ solution with products of sulfur oxidation at 175°C (at least in 80 min) gave negative result. The products of sulfur oxidation at 175°C, when bubbled through distilled water, did not change the color of the acid–base titration indicator (a mixture of Bromocresol Green and Methyl Red). The products of thermal oxidative decomposition of sulfur (175°C) did not also change the color of Congo Red indicator paper. Thus, we can conclude that, under the experimental conditions, sulfur dioxide is not formed and the resulting rates of PVC dehydrochlorination are correct.

Addition of sulfur to PVC results in an insignificant decrease in the rate of thermal dehydrochlorination of the polymer (Fig. 1); the kinetic curves for HCl elimination are linear. Using the indicator method with Congo Red, we showed that, under conditions of PVC degradation, sulfur has no accepting effect with respect to the released HCl.

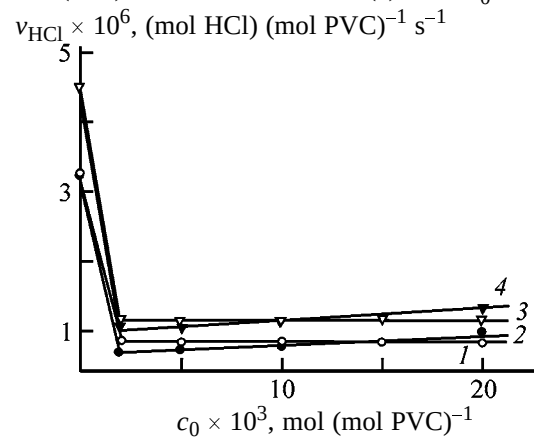

Fig. 2. Rate of thermal oxidative dehydrochlorination of PVC v_{HCl} plasticized (40 wt. parts per 100 wt. parts of PVC) with (*1, 2*) DOP and (*3, 4*) DOS as a function of the content of (*1, 3*) elemental sulfur and (*2, 4*) DPP c_0.

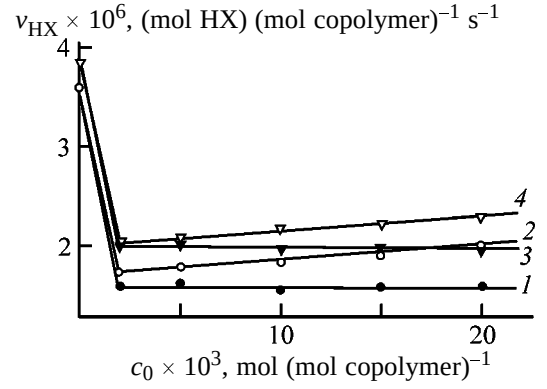

Fig. 3. Rate v_{HX} HX is HCl and CH_3COOH) of (*1, 2*) thermal oxidative dehydrochlorination of VCMA-28.8 and (*3, 4*) dehydrochlorination + deacethylation of VCVA-11.1 as a function of the content c_0 of (*1, 3*) elemental sulfur and (*2, 4*) DPP.

In thermal oxidative degradation of PVC, the stabilizing performance of sulfur noticeably increases and, in particular, exceeds the performance of a well-known antioxidant, diphenylolpropane (DPP) (Fig. 2). The kinetic dependences of thermal oxidative dehydrochlorination of PVC in the presence of sulfur remain linear.

The maximal decrease in the rate of PVC dehydrochlorination is observed at a sulfur content of 2 mmol per mole PVC and does not vary with a further increase in the sulfur content in the polymer. The dependence of the rate of thermal oxidative dehydrochlorination of PVC, v_{HCl}, on the sulfur content after reaching the minimum is linear, contrary to phenolic antioxidant DPP for which this dependence has an extremum. The rate of thermal oxidative dehydrochlorination of PVC decreases in the presence of sulfur practically to the values corresponding to the rate of thermal degradation of PVC, which is typical of antoxidants.

Stabilization of thermal oxidative degradation of VC copolymers with elemental sulfur is characterized by the same features as stabilization of PVC. However, the stabilizing performance of sulfur in VC copolymers is lower than that in PVC (Fig. 3). This is in agreement with the well-known fact that the inhibiting effect of stabilizers in VC copolymers is lower than that in PVC [7].

The problem of stabilization of plasticized PVCs in production of soft and semihard articles is mainly related to prevention of oxidative degradation of the plasticizer in polymer compounds by using antioxidants.

Introduction of elemental sulfur into PVC plasticized with ester plasticizers (DOP and DOS) results in an abrupt decrease in the rate of thermal oxidative dehydrochlorination of the polymer (Fig. 2). As in the case of degradation of nonplasticized PVC, the maximal decrease in the rate of dehydrochlorination of the plasticized polymer is observed at a sulfur content of 2 mmol per mole PVC. The stabilizing performance of sulfur in plasticized PVC materials is practically the same as the performance of DPP. It should be noted that the stabilizing effect is reached in introduction of sulfur into polymer composites in the range 0.02–0.05 wt % with respect to PVC, which is by an order of magnitude less than the weight concentration of the existing organic stabilizer-santioxidants for PVC. In this case, the stabilizing performance is independent of the sulfur origin (gas clumpy or natural clumpy).

The rate of thermal oxidative degradation of PVC decreases in the presence of elemental sulfur to substantially lower values corresponding to the rate of thermal oxidative degradation of nonplasticized PVC. It is evident that elemental sulfur efficiently prevents oxidation of the plasticizing agent (stabilizer-antioxi-

Fig. 4. ([ROOH]) concentration of hydroxoperoxides and (τ) process duration.

dant), which, in turn, enhances the thermal stability of PVC due to solvation stabilization (echo-stabilization of PVC [8]).

In stabilization of plasticized VC copolymers, the stabilization performance of elemental sulfur is also lower compared to plasticized PVC.

Iodometric titration of hydroperoxides formed in autooxidation of ester plasticizers, DOP and DOS, showed that introduction of sulfur into esters abruptly inhibits accumulation of hydroperoxides (Fig. 4). In the efficiency of inhibiting oxidation of ester plasticizers, elemental sulfur is comparable with the phenolic antioxidant 4-methyl-2,6-di-*tert*-butylphenol.

CONCLUSIONS

(1) Elemental sulfur has a high inhibiting effect in thermal oxidative degradation of hard and plasticized polyvinyl chloride, comparable with the inhibiting effect of phenolic antioxidants; it shows promise for practical use in production of polyvinyl chloride materials due to its availability and low coast.

(2) The stabilizing performance of elemental sulfur in polymer compounds based on copolymers of vinyl chloride is lower than that in stabilization of polyvinyl chloride.

Received July 28, 2004

Abstract—The effect of preparation conditions on the composition and properties of products of Fe(III) reaction with chitosan was studied. The reaction was carried out by partial neutralization of moderately concentrated $FeCl_3$ solutions with chitosan followed by precipitation in an organic precipitant.

Some neutral and anionic polysaccharides form water-soluble compounds with Fe(III), thus preventing the precipitation of Fe(III) hydroxide and retaining considerable amounts of Fe(III) in aqueous solutions at physiological pH values of 1–8. This caused wide application of such compounds as medicines for treatment of iron-deficiency anemia: Imferon (iron–dextran) and Blutal (iron–chondroitin sulfate) [1]. The content of Fe(III) in dextran complexes reaches 12–31% [2, 3]. According to [4, 5], the polyaminosaccharide chitosan (CTS) at pH ≤ 7 is a stabilizer for colloidal FeOOH particles which are formed when 1–10 mmol l^{-1} $FeCl_3$ solutions containing chitosan hydrochloride in the molar ratio Fe : [CTS] ≤2 ([CTS] is chitosan monomeric unit) are neutralized with an alkali. Since the reaction of Fe(III) with CTS is a simple and economic method for obtaining nanosize (5–10 nm) spherical FeOOH particles [4], and since chitosan, being a polybase, can serve as a mild neutralizing agent for weakly acidic aqueous solutions of $FeCl_3$, it was of interest to prepare of water-soluble iron–chitosan compounds with a high Fe(III) content by partial neutralization of $FeCl_3$ solutions with chitosan.

In this work we studied how the preparation conditions affect the composition and properties of water-soluble products formed in the reaction of Fe(III) with chitosan as a result of a partial neutralization of moderately concentrated $FeCl_3$ solutions with chitosan followed by the precipitation in an organic precipitant.

EXPERIMENTAL

Chitosan was obtained from pure-grade chitin of Far East crabs (ash content 2.1 %) and conditioned by the procedure from [6]. According to the elemental analysis, air-dry conditioned CTS is characterized by the absence of ash and Cl and contains 37.4 and 6.4% C and N, respectively. The degree of CTS deacetylation, as determined by potentiometric titration, was 87 ± 3%; its viscosity-average molecular weight was 150 000. The CTS fraction with the particle size of $0.025 < d < 0.0315$ cm was used in the work.

Iron(III) solutions (0.050 and 0.10 M) were prepared by dissolution of the corresponding weighed portions of $FeCl_3 \cdot 6H_2O$ (pure grade) in water. The concentration of Fe(III) in aqueous solutions was determined by the EDTA titration with sulfosalicylic acid, and that in solid products of the Fe(III) reaction with CTS, also by EDTA titration after wet combustion of a weighed portion of the product [7]. The relative error of Fe(III) determination in solid products did not exceed 1.3%. Methanol purified by the procedure from [8], ethanol (rectificate), acetone, and isopropyl alcohol (chemically pure grade) were used as precipitating agents. Chitosan hydrochloride (CTS · HCl) was precipitated in acetone [9], washed with acetone in a vacuum, dried in air, and triturated. According to the elemental analysis, it contained 5.4% N and 12.3% Cl.

The pH values of solutions were determined on an OR-211/1 laboratory digital pH meter with an OR-0808R combined glass electrode. The electronic absorption spectra of aqueous solutions of $FeCl_3$, CTS · HCl, and products of the reaction between CTS and Fe(III) were recorded on a Specord M40 spectrophotometer against water in 0.2-cm-thick quartz cells. The IR spectra of chitosan-containing substances were

1070-4272/04/7711-1862 © 2004 MAIK "Nauka/Interperiodica"

taken in Nujol on a Specord M80 spectrophotometer in the range 4000–200 cm^{-1}. The X-ray phase analysis of iron–chitosan products and CTS·HCl was carried out on a DRON-3M diffractometer with a graphite monochromator; CuK_α radiation, angle range 2θ = 10°–80°, scanning step 0.1°, voltage 40 kV, current 20 mA. The thermogravimetric analysis of the substances and CTS was carried out on a Q-1500D derivatograph (MOM, Hungary) in air under with heating from 17 to 1000°C at a rate of 5 deg min^{-1} with an Al_2O_3 reference.

The products of the reaction of CTS with Fe(III) were obtained as follows. A weighed portion of CTS was introduced into a beaker with a $FeCl_3$ solution in the molar ratios Fe : [CTS] 1 : 3, 1 : 2, 1 : 1, and 2 : 1 at 16±1°C with vigorous stirring (an MM 2A magnetic stirrer). The chitosan completely dissolved wihtin 1 h. The dissolution was accompanied by an increase in viscosity and changes in pH (Fig. 1) and in the solution color from yellow to red-brown. The solution was stirred for the time τ_s, which usually corresponded to flattening out of the curve pH = $f(\tau)$ and was about 4–5 h (Fig. 1). Compounds of CTS with Fe(III) were isolated from aqueous solutions by precipitating in an organic precipitant. In this case, the volume of the precipitant was 2.5–4 times larger than the volume required for the beginning of the quantitative precipitation of the chitosan fractions $V_{0(min)}$ (Table 1). An aqueous solution was added dropwise to a precipitant with stirring; the mixture with the precipitate was stirred for 30 min and left for τ_{pr} = 20–24 h in a closed vessel for the precipitation. The voluminous orange-brown fibrous precipitate was filtered off and washed with the precipitant in a vacuum on a Büchner funnel to the negative reaction of the filtrate for the Cl^- ions with $AgNO_3$ and for Fe(III) with KCNS; then it was dried in a Petri dish to constant weight. Air-dry red-brown products were triturated and analyzed. The yield of the products based on CTS, as estimated from the content of nitrogen in the starting CTS and in the product, was no less than 96%. The elemental analysis data for the products obtained under various conditions are given in Table 2.

The dependence of the solution pH on the synthesis time for various molar ratios of chitosan amino groups and Fe(III) (Fig. 1) is typical for partially neutralized Fe(III) solutions at the corresponding molar ratios of an inorganic base to Fe(III) (OH : Fe) [10]. The increase in pH in the initial parts of curves *1–3* reflects the protonation of free CTS amino groups and simultaneous neutralization of solutions with the

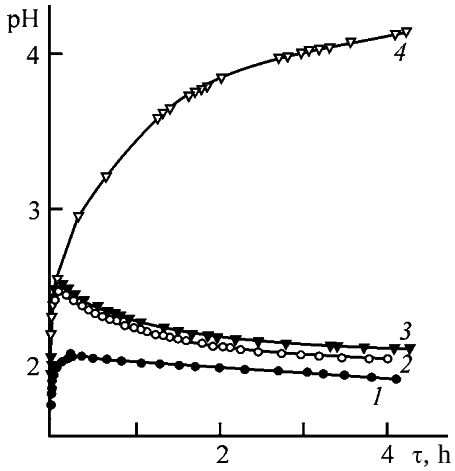

Fig. 1. Variation with time τ of pH of an $FeCl_3$ solution neutralized with chitosan. c_{Fe} (M): (*1*) 0.10 and (*2–4*) 0.05. Fe : [CTS]: (*1*) 2 : 1, (*2*) 1 : 1, (*3*) 1 : 2, and (*4*) 1 : 3. Mole ratio of chitosan amino groups to Fe(III): (*1*) 0.44, (*2*) 0.87, (*3*) 1.74, and (*4*) 2.61.

formation of nonequilibrium Fe(III) polynuclear hydrolysis products (PHP) imparting to the solution a red-brown color [10, 11]. The further pH decrease is caused by hydrolytic processes of aging of the partially neutralized $FeCl_3$ solutions. The maximal pH of solutions at Fe : [CTS] 2 : 1, 1 : 1, and 1 : 2 did not exceed 2.51 (Fig. 1), which corresponds to the degree of protonation of chitosan amino groups α = 1. The neutralization of the $FeCl_3$ solution by chitosan at the ratio Fe : [CTS] = 1 : 3 is accompanied by a monotonic increase in pH (curve *4*), as is the case with solutions neutralized with alkali at OH : Fe ≥ 2.5, and by the formation of a very viscous difficult-to-stir gelatinous solution. In this case, the pH of the solution obtained at τ_s ~4 days was 4.95, which corresponds to α ~0.96. Unlike solutions partially neutralized with alkali, the solutions partially neutralized with chitosan are stable against precipitation of Fe(III) hydroxide for a long time (no less than 3–6 months).

* Product no. 9: after stirring for 4 h at 17°C, the solution was heated on a water bath at 90°C for 5 min and cooled to room temperature before precipitation; product no. 13: polynuclear hydrolysis products precipitated with acetone from a $FeCl_3$ solution aged in storage for 1 month.

In the IR spectra of the iron–chitosan products (Table 2), as well as in the spectrum of CTS · HCl, two absorption bands of medium intensity $\delta_{as}(NH_3^+)$ = 1624–1632 and $\delta_s(NH_3^+)$ = 1510–1522 cm^{-1} of protonated amino groups appear [4, 12, 13] instead of the absorption band $\delta_s(NH_2)$ = 1595 cm^{-1} of free amino groups, which is present in the CTS spectrum. This confirms complete or considerable protonation of CTS amino groups in the products and is consistent with the data [4] for iron–chitosan products isolated from solutions with pH 4.6 (α = 1).

As the degree of neutralization of $FeCl_3$ solutions increases, medium-intensity bands appear at 1618 and 1534–1540 cm^{-1} in the IR spectra of the isolated products (nos. 11 and 12) in the range of bending vibrations of the protonated amino groups. Piron and Domard [14] assigned these bands to the coordination of CTS free amino groups to the transition metal ions Ag(I), Cu(II), and Al(III). Therefore, we may assume that in these iron–chitosan products a small part of CTS amino groups are in the deprotonated form and are coordinated to Fe(III) ions.

The increase in the CTS concentration in the course of the synthesis (Fe : [CTS] = 1 : 3, product no. 12) is accompanied by an increase in the concentration of deprotonated amino groups and by an essential increase in the solution viscosity. The latter factor prevents the complete and uniform formation of the salt form CTS · HCl and the formation of a dense ionic atmosphere around the polyion [9], and also considerably retards the diffusion of mononuclear products of the $[Fe(H_2O)_5OH]^{2+}$ and $[Fe(H_2O)_4(OH)_2]^+$ hydrolysis and, hence, prevents the condensation and polymerization processes of the PHP formation [11, 15]. Such conditions seem to favor the formation of a certain amount of intraloop and interchain cross-links as a result of the formation of coordination bischelate complexes with mononuclear Fe(III) cations, in which Fe(III) ions are coordinated with two monomeric CTS units via the atoms of amine nitrogen and ring hydroxyl oxygen [16]. The formation of coordination cross-links is indirectly confirmed by a considerable decrease in the solubility of iron–chitosan products in water with increasing degree of neutralization of $FeCl_3$ solution with chitosan: for the products obtained at Fe : [CTS] 2 : 1, 1 : 2, and 1 : 3, the solubility at 20°C is 14.3–15.4, 11.0, and 2.7%, respectively.

The conclusion that Fe(III) in the iron–chitosan products is in the PHP form [4] is confirmed by the presence of the following bands in their IR spectra: weak absorption bands at 388–394 and 830–860 cm^{-1}, which can be assigned to ν_s and ν_{as} (Fe–O–Fe), respectively, in oxo-bridging PHP fragments [17], a broad complex band of medium intensity in the range

400–500 cm^{-1} (with maximuma at 416–418, 432–440, 455–460, and 480 and a shoulder at 495–505 cm^{-1}) corresponding to ν(Fe–O) in hydroxides and water-soluble PHPs [18, 19], and also a band of medium intensity in the range 650–680 cm^{-1}, which is observed in the spectrum of β-FeOOH [20]. The intensity of these bands increases with increasing Fe(III) content in the product, whereas the frequencies and the ratio of intensities correspond to those observed in the IR spectrum of Fe(III) hydroxo species precipitated with acetone from the aged solution (Table 2, compound no. 13) and also in the spectrum of β-FeOOH [20], cm^{-1}: 380–390 w, 488 m, 688 vs, and 864 m.

According to [4], water-soluble products forming upon partial neutralization of a solution containing $FeCl_3$ and CTS·HCl to pH 6.4 ($\alpha \approx 0.5$) can be considered as a sol of Fe(III) hydroxide protected by chitosan hydrochloride and possessing properties of a reversible colloid. Therefore, the solubility of iron–chitosan products in aqueous and aqueous-organic media should be defined by properties of a protective polymer [15, 21], in particular, by the degree of protonation of the amino groups and the degree of electrolytic dissociation of the polyelectrolyte CTS·HCl. For example, 1 g of the products dissolves (Tables 1 and 2) at 20°C in 100 ml of aqueous solutions of HCl and NaOH with pH 1–8 and of 0.85% NaCl. The products are insoluble in NaOH aqueous solutions with pH ≥ 10 because of complete deprotonation of chitosan amino groups and in 1 M NaCl because of suppression of CTS·HCl electrolytic dissociation by a high concentration of chloride ions. The degree of electrolytic dissociation of polyelectrolytes decreases as the permittivity of an aqueous-organic solvent decreases [15]. Therefore, a decrease in the relative permittivity ε of a precipitant makes it possible to reduce the precipitant consumption $V_{0(min)}$ in the series MeOH > EtOH > *i*-PrOH ≈ acetone (Table 1).

It is known that a decrease in ε of an aqueous-organic medium results in an increase in the formation constants of hydroxo complexes of transition metals [22]. This can be a reason for the fact that the increase in the Fe(III) content in isolated products observed in the series of alcohols under study (Table 1) and also when EtOH is replaced wiht acetone (Table 2, product nos. 8, 10, 11 and 5, 1, 2) correlates with a decrease in ε and in the hydrophilicity [8] of the precipitant. The study of how the time of precipitation in acetone affects the composition of products of the CTS reaction with Fe(III) (Table 2, products 4–7) has shown that an increase in τ_{pr} results in a parallel increase in the Fe(III) content and in a decrease in the Cl content

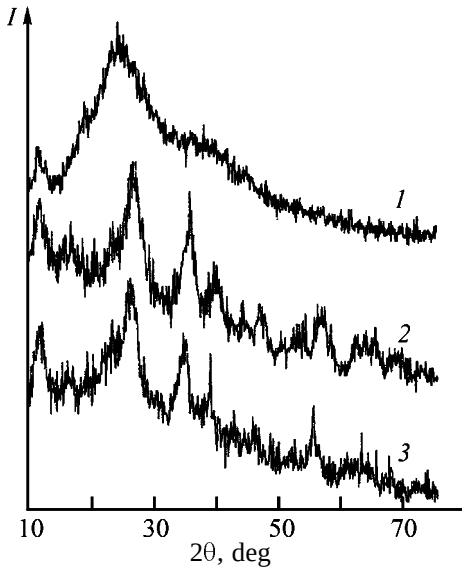

Fig. 2. X-ray patterns of (*1*) CTS·HCl powders and (*2, 3*) iron–chitosan product nos. 5 and 8, respectively. (*I*) Intensity and (2θ) Bragg angle.

at a constant molar ratio Fe : Cl_{exc} = 1 : (0.47–0.56) (Cl_{exc} is the superstoichiometric content of Cl relative to completely protonated amino groups).

According to [2], the presence of chlorine in the ratio Fe : Cl = 1 : (0.05–0.19) in water-soluble iron–dextran β-FeOOH-containing complexes obtained by the hydrolysis of $FeCl_3$ solutions is explained by a specific feature of the akaganeite structure. The increase in the content of Fe(III) in iron–chitosan products with increasing τ_{pr} seems to be caused by coprecipitation of hydrolyzed polymeric Fe(III) species forming in a aqueous acetone as a result of the decrease in ε of the solvent. Short heating of an iron–chitosan solution on a water bath at 90°C before precipitation increases the concentration and polynuclearity of PHP in aqueous solutions owing to acceleration of hydrolytic processes [10, 11] and makes it possible to precipitate water-soluble product no. 9 with a high Fe(III) content and a smaller Cl_{exc} content (Fe : Cl_{exc} = 1 : 0.20). The contents of Cl^- or NO_3^- anions, which are formed in partially neutralized Fe(III) solutions and compensate a high charge density in the nonequilibrium water-soluble PHPs of the composition $Fe_q(OH)_p^{(3p-q)+}$ ($p : q$ = 2.2–2.9), are known to decrease on aging of PHP solutions [10, 11].

According to the X-ray analysis (Fig. 2, Table 3), CTS·HCl is characterized by a noticeable crystallinity [23], and Fe(III) is present in the form of β-FeOOH in the products precipitated in acetone and ethanol. The higher relative intensity of β-FeOOH reflections at 2θ 12.0°–12.4° and 26.5°–26.7° for product

nos. 5 and 8, compared to the published data (Fig. 2, Table 3), is caused by overlapping with the reflections of CTS · HCl at 11.6° and 24.7°, respectively. The number of β-FeOOH reflections which are reliably identified in the X-ray pattern of product no. 8 is considerably less compared to product no. 5 (5 and 11 reflections, respectively), which is caused by a lower Fe(III) content and, probably, a smaller size of β-FeOOH crystallites in the product precipitated in ethanol, without significant coprecipitation of PHP from the aqueous-organic solution. The interplanar spacing corresponding to the first reflection for product no. 8 is less than that for β-FeOOH and CTS · HCl (Table 3), which seems to be due to a denser packing of CTS · HCl macromolecules [24] in iron–chitosan products as compared to CTS · HCl.

The TG and DTG curves of product nos. 5 and 8 are similar, which confirms the uniformity of their chemical and phase composition; at the same time, these curves essentially differ from the corresponding curves for CTS and CTS · HCl. The TG curves for CTS and CTS · HCl consist of three portions, and those for iron–chitosan products, of four portions, with different rates of weight loss. A broad endothermic effect in the DTA curves with a minimum at 83, 96 and 98–100°C corresponds, respectively, to the loss of physically bound water in the range 39–144°C for CTS (weight loss 11.2%), 30–156°C for CTS · HCl (17.5%), and (40–45)–188°C for product nos. 5 (16%) and 8 (11.3%). The increase in the weight loss with increasing Fe(III) content in product no. 5 (Table 2) suggests that in this temperature range, along with the physically bound water, the water forming by condensation of "ol" bridges in Fe(III) hydroxo species [25] is also removed. Intense decomposition of CTS and CTS · HCl starts at 200 and 170°C and comes to an end when they are completely burnt down at 530 and 541°C, respectively.

The features of the thermal oxidative degradation of CTS and CTS · HCl agree with the published data for CTS and its salt forms [26]. Intense exothermic degradation of product nos. 5 and 8 starts at 202–203 and comes to an end at 649 and 663°C, respectively. The weight of the residues is 21.7 and 14.2%, respectively, for product nos. 5 and 8. The content of Fe(III) in them is close to that in Fe_2O_3. Apparently, the residue of the decomposition products is hematite [20].

All the iron–chitosan products (Tables 1, 2) behave toward water as unrestrictedly swelling gels and form solutions stable against precipitation in storage for no less than 6 months. Saturated solutions of the products are very viscous and thick, they form films upon drying up. The viscosity of solutions considerably decreases on dilution by a factor of 2–3. Irrespective of the conditions of obtaining the products, their dilute aqueous solutions (0.5 g l^{-1}) have similar electronic absorption spectra and undergo equal changes with time and with changes in solvent pH in the range of physiological values.

Typical electronic absorption spectra of solutions of iron–chitosan products at various pH of a solvent (aqueous solutions of HCl, NaOH, and 0.1–0.15 M NaCl) are shown in Fig. 3. The spectra of solutions

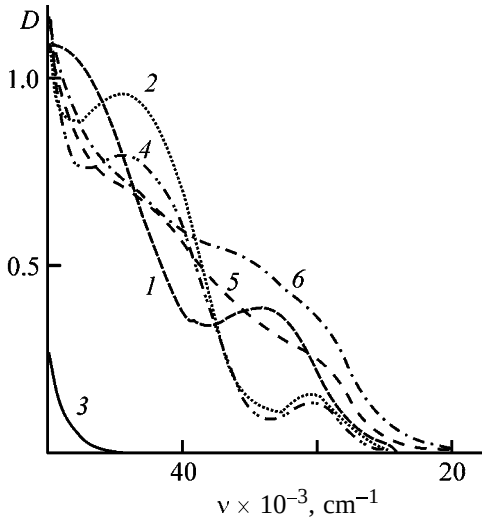

Fig. 3. Electron absorption spectra of solutions: (*1*, *2*) 1.04 M $FeCl_3$, (*3*) 0.5 g l^{-1} CTS·HCl, and (*4*–*6*) iron–chitosan product no. 8 in (*1*, *3*, *6*) water, (*2*, *4*) 0.1 M HCl, and (*5*) 0.01 M HCl. (*D*) Optical density and (ν) wave number. (*1*–*3*) Freshly prepared solutions and (*4*–*6*) 8 days after preparation (c_{Fe} = 8.4×10^{-4} M). pH: (*1*) 2.63, (*2*) 1.06, (*3*) 4.17, (*4*) 1.07, (*5*) 2.00, and (*6*) 3.87.

with the initial solvent pH of 4–7.7 resemble spectrum *6* and do not noticeably change with time (at least 20 days), which suggests that Fe(III) is present in the solutions in the PHP form [10, 27, 28]. The pH of these solutions decreases, compared to the pH of the solvents, to 3.8–4.1, which is caused by the hydrolysis of the CTS salt form (pH of the 0.5 g l^{-1} CTS·HCl aqueous solution is 4.17, which corresponds to the degree of salt hydrolysis about 4%), and also by the hydrolysis of Fe(III) PHPs isolated from acid solutions. These solutions do not show a qualitative reaction with KCNS for Fe^{3+} ions. The dialysis of the aqueous solution (initial pH of the solvent 6.1) of a product precipitated by acetone against water through a "100X" transparent cellophane film with the pore diameter of 2.0–3.5 nm has shown that chloride ions diffuse in water (test with $AgNO_3$) and low-molecular-weight Fe(III) species do not pass into water (test with KCNS in 0.1 M HCl). This confirms the hydrolysis of CTS·HCl and the absence of Fe(III) low-molecular-weight species in the solution of this product. At the initial solvent pH of 1–3, the pH values of solutions of iron–chitosan products correspond to those of the solvent and do not noticeably change with time. The electronic absorption spectra of such solutions suggest slow decomposition of PHPs as the solution acidity increases (Fig. 3, curves *4*, *5*). Within 3–4 h after preparation, the spectra of solutions of the products with pH 1 correspond to curve *5*, within 2 days they become more similar in shape of curve *4*, and within 8 days they become identical to curve *4* (molar extinction coefficients at ν 44400 and 30000 cm^{-1} are 4788 and 792, respectively) and to the spectrum of the $FeCl_3$ solution in 0.1 M HCl (curve *2*, molar extinction coefficients at ν 44480 and 29920 cm^{-1} are 4733 and 806, respectively), in which $FeCl_4^+$, $FeCl^{2+}$, and Fe^{3+} ions dominate [29]. Slow depolymerization of Fe(III) in the 0.1 M HCl solution indicates that PHPs in iron–chitosan products are considerably oxolated [11].

The high Fe(III) content in the iron–chitosan products studied, comparable to the content in commercial iron–dextran compounds (product no. 9), the solubility of products in aqueous solutions with physiological pH values, and the stability of their aqueous solutions on prolonged storage suggest that they are promising compounds for the use in medical and veterinary practice as drugs for treatment of iron deficiency anemia.

CONCLUSIONS

(1) Partial neutralization of moderately concentrated $FeCl_3$ solutions with chitosan results in formation of nonequilibrium polynuclear hydrolysis products stabilized in solutions by chitosan hydrochloride. Water-soluble iron–chitosan products with high Fe(III) content can be isolated by subsequent precipitation in an organic precipitant. The neutralization at the ratios Fe : [CTS] 2 : 1 and 1 : 1, a decrease in the precipitant permittivity, and short heating of the partially neutralized solutions before the precipitation result in a substantial increase in the Fe(III) content in the iron–chitosan products.

(2) The IR and X-ray phase analysis data show that a considerable part of chitosan amino groups in the isolated products is protonated, and Fe(III) is in the form of β-FeOOH.

(3) The dissolution of iron–chitosan products in aqueous solvents with physiological pH values is accompanied by slight aging of polynuclear hydrolysis products and by partial hydrolysis of the chitosan salt form in the range $4 \le pH \le 7.7$ and by slow depolymerization of polynuclear hydrolysis products in the range pH 1–3.

Received August 11, 2004

Abstract—Polymerization of methyl methacrylate in the presence of binary systems containing benzoyl peroxide and activators [4-(4-dimethylaminostyryl)pyridine, 4-(4-dimethylaminostyryl)pyridine *N*-oxide in chlorobenzene; triphenylbenzylphosphonium chloride, triphenylbenzylphosphonium bromide, tetraethylammonium chloride, tetraethylammonium bromide, tetraethylammonium benzoate in acetonitrile] at 303 K was studied. The rate constants of decomposition of benzoyl peroxide in the presence of activators, initial polymerization rates, initiation rates, and initiation efficiencies at 303 K were determined.

Binary systems consisting of peroxides and activators (amines, variable-valence metal compounds, phosphines, sulfides, onium salts) are widely used for initiation of radical-chain processes at temperatures close to room temperature.

Binary initiating systems containing peroxides are characterized by lower activation energies of radical generation (40–80 kJ mol^{-1}), compared to thermal decomposition of peroxides (120–170 kJ mol^{-1}), which allows fast polymerization at low temperatures. It was shown previously that quaternary ammonium salts and aminostyrylpyridines appreciably decrease the acrivation energy and temperature of decomposition of benzoyl peroxide (BP) and can be used as components of binary initiators [1–3].

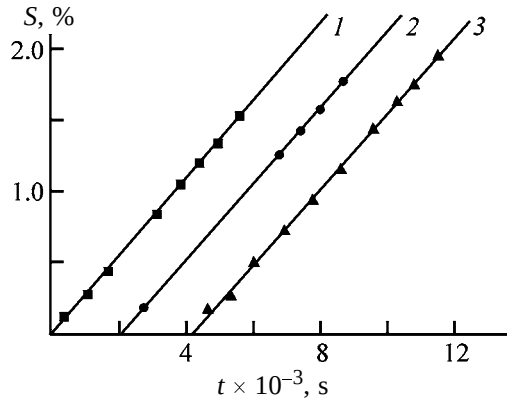
In this work we studied polymerization of methyl methacrylate in the presence of binary systems containing BP and activators [4-(4-dimethylaminostyryl)-pyridine (DASP), 4-(4-dimethylaminostyryl)pyridine *N*-oxide (DASPO) in chlorobenzene; triphenylbenzylphosphonium chloride (TPBPC), triphenylbenzylphosphonium bromide (TPBPB), tetraethylammonium chloride (TEAC), tetraethylammonium bromide (TEAB), tetraethylammonium benzoate (TEABenz) in acetonitrile] at 303 K.

EXPERIMENTAL

Benzoyl peroxide was recrystallized two times from ethanol. 4-(4-Dimethylaminostyryl)pyridine and its *N*-oxide were prepared by the procedure suggested in [4] and recrystallized from dimethyl sulfoxide and benzyl alcohol. TEAC and TEAB were purified by reprecipitation. TPBPC and TPBPB were prepared from triphenylphosphine and the corresponding benzyl halide. The onium salts were dried over P_2O_5 under reduced pressure at 333 K and were stored in a glove box over P_2O_5. Technical-grade methyl methacrylate was washed 2–3 times with 10–15% aqueous alkali for complete removal of the inhibitor. Then it was washed 2–3 times with distilled water, dried over anhydrous calcium chloride, and distilled three times in a nitrogen flow under reduced pressure; the fraction boiling at 22 ± 0.2°C (25 mm Hg) was collected. Freshly distilled methyl methacrylate was used. The kinetics of methyl methacrylate polymerization was monitored dilatometrically to 3% conversion of the monomer (see figure). The monomer content in the reaction mixture was 25 vol %. Polymerization of methyl methacrylate in the presence of BP and salts was performed in acetonitrile, and that in the presence of BP and aminostyrylpyridines, in chlorobenzene. The concentrations of BP and salt in the salt-containing initiating systems were 2.5×10^{-2} and 5×10^{-3} M, and the concentrations of BP and DASP or DASPO in the systems with the pyridine derivatives, 7.5×10^{-3}, 2.5×10^{-4}, and 2.2×10^{-4} M, respectively.

The kinetic studies of decomposition of BP activated with quaternary ammonium and phosphonium salts were performed under the conditions of the

1070-4272/04/7711-1869 © 2004 MAIK "Nauka/Interperiodica"



Inhibition of methyl methacrylate polymerization initiated with the system TEABenz–BP at 303 K. (*S*) Conversion and (*t*) time. [Inh], M: (*1*) 0, (*2*) 1×10^{-5}, and (*3*) 2×10^{-5}.

pseudo-first-order reaction with respect to the peroxide (291–313 K) at the initial BP concentration of 1.5×10^{-2} M. The initial concentrations of the salts were as follows (M): TEAC $(1.7–13) \times 10^{-2}$, TEAB $(2.6–10.34) \times 10^{-2}$, and TPBPC 9×10^{-3}. Triphenylbenzylphosphonium chloride is limitedly soluble in acetonitrile; therefore, the kinetic studies of BP decomposition in its presence were performed at a 1 : 1 concentration ratio of the peroxide and salt. The consumption of BP was monitored by a decrease in the intensity of the C=O absorption band (ν = 1764 cm^{-1}) in the IR spectrum (Specord 71-IR spectrophotometer, temperature-controlled 0.51-mm CaF_2 cells).

The kinetics of the reactions of BP with DASP and DASPO were monitored spectrophotometrically (Specord UV VIS) by consumption of DASP or DASPO (decrease in the absorption maximum: DASP, λ_{max} = 375 nm, $\varepsilon = 30\,000 \pm 600$ mol l^{-1} cm^{-1}; DASPO, λ_{max} = 395 nm, $\varepsilon = 32\,000 \pm 600$ mol l^{-1} cm^{-1}) in the presence of excess peroxide (0.01–0.4 M), at the initial amine concentration of 2.5×10^{-5} M.

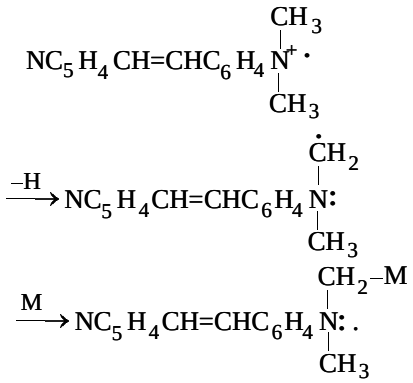
The polymerization initiation rate W_{in} was determined by the method of inhibitors. As inhibitor we used 2,2,6,6-tetramethylpiperidyl-1-oxyl, a radical stable under the experimental conditions (303 K). The facts that the induction period is proportional to the initial inhibitor concentration, the inhibition period is not followed by deceleration in the examined concentration range (1×10^{-5}–1×10^{-3} M, see figure), and the transition from the induction period to the linear reaction course is fast allow the calculation of the initiation rates by the formulas valid for effective inhibitors:

$$W_{inh} = \mu[\text{Inh}]/\tau, \quad (1)$$

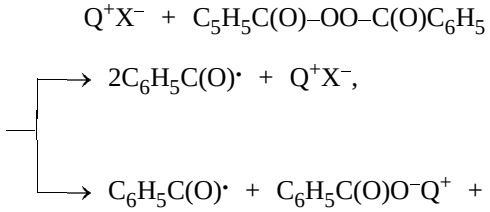
$$W_{inh} = nfW_d, \quad (2)$$

where τ is the induction period; W_d, initial rate of the initiatior decomposition; *f*, initiation efficiency; [Inh], inhibitor concentration; μ, stoichiometric coefficient equal to the number of chains terminated on one inhibitor molecule, μ = 1 in our case [5]; and *n*, number of radicals participating in the initiation.

The reaction of DASP and DASPO with BP yields two radicals capable to initiate polymerization of vinyl monomers. The amine radical cation generated in the process loses a proton, transforming into a radical which, along with the benzoyloxy radical, participates in the initiation [6]:



In decomposition of BP in the presence of quaternary salts, two pathways (catalytic and noncatalytic) are possible, both yielding two radicals:



The initiation efficiency was determined by the equation

$$f = W_{in}/2W_d. \quad (3)$$

The rate of BP decomposition W_d was calculated by the equation

$$W_d = k_D[\text{BP}][\text{Act}].$$

The kinetic parameters of methyl methacrylate polymerization in the presence of BP–activator initiating systems and the initiation efficiencies are given in Table 1.

The initial concentrations of the peroxide and salt were the same in all the experiments (2.5×10^{-2} and

5×10^{-3} M, respectively), which allowed comparison of the initiation rates. Table 1 shows that the initiation rate is the highest in the presence of tetraethylammonium chloride, decreasing in the order $Et_4N^+Cl^- > Et_4N^+Br > Ph_3(PhCH_2)P^+Br^- > Ph_3(PhCH_2)P^+Cl^-$. At the same time, the initiation efficiency decreases in the order $Et_4N^+Cl > Et_4N^+Br^- > Ph_3(PhCH_2)P^+Cl > Ph_3(PhCH_2)P^+Br^-$.

The initiation rates with the systems BP + DASP and BP + DASPO are approximately equal and comparable with those observed with the systems containing onium salts, but the concentrations of BP and amines are lower: 7.5×10^{-3} and 2.5×10^{-4} M, respectively. It should be noted that the efficiency of initiation of methyl methacrylate polymerization in the presence of BP and aminostyrylpyridines is considerably higher than in the presence of the peroxide–salt systems.

Decomposition of organic peroxides under the action of activators is a complex process involving decomposition of the peroxide bond with the formation of free radicals, ions, and molecules; the ratio of the species formed depends on the kind of activator and properties of the reaction medium. In particular, recombination of the radicals in a solvent "cage" significantly decreases the fraction of active radicals diffusing into the bulk and thus decreases the initiation efficiency. For example, according to [7], the recombination rate in thermal decomposition of diacyl peroxides $[RC(O)O]_2$ sharply decreases in the series of peroxides with $R = CH_3 > C_6H_5 > n\text{-}C_4H_7$, and the results given in [8] reflect the trend that the efficiency of escape of radicals into the bulk increases in going from linear aliphatic radicals to branched radicals.

As seen from Table 1, in the systems DASP–BP and DASPO–BP the initiation efficiency is higher than in other related peroxide–activator systems [9–11], which may be due to hindered recombination of the generated radicals. Generation of bulky radicals from the initiator is preferable for polymerization initiation [8], because the recombination rate depends

Table 2. Content *c* of residual monomer in poly(methyl methacrylate) prepared in the presence of benzoyl peroxide–activator initiating systems

Activator	*c*, %

$Ph_3(PhCH_2)P^+Cl^-$	0.89

on the accessibility of the active centers of the radical and on the diffusion rate. For radicals of simple structure, generated in the systems BP–onium salt [$C_6H_5 \cdot C(O)O^\bullet$, $Br^\bullet$, $Cl^\bullet$], the accessibility factor prevails, and the initiation efficiency appreciably decreases.

The main application field of peroxide–amine binary initiators is curing and vulcanization, since the reaction products formed in the system are, as a rule, colored. Peroxide–onium salt systems can be used for preparing transparent high-purity poly(methyl methacrylate). The polymers prepared in the presence of peroxide–quaternary ammonium salt initiators were analyzed for the residual monomer content. Test poly(methyl methacrylate) samples were prepared by polymerization of methyl methacrylate in the bulk, initiated with systems containing BP and quaternary ammonium and phosphonium salts. The polymerization was performed at 303–318 K for 24–48 h. The monomer conversion under these conditions was 85–97% (GLC data). Under these conditions, no gel effect was observed. Afterpolymerization was performed at 393 K for 48–72 h. The BP–onium salt initiating systems ensure preparation of the transparent polymer at 303–313 K. The residual monomer in poly(methyl methacrylate) was determined by gas–liquid chromatography after dissolution of the polymer in chloroform. The results are listed in Table 2.

CONCLUSION

Data on the efficiency of initiation of methyl methacrylate polymerization with the binary systems benzoyl peroxide–onium salt and benzoyl peroxide–aminostyrylpyridine show that the rate of the peroxide decomposition and the yield of the radicals can be varied in a wide range by varying the structure of the catalyst.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Structure and Characteristics of Copolyamides Based on ε-Caprolactam and Diisocyanates

Abstract—The main supramolecular characteristics and the processing and service characteristics of copolyamides based on ε-caprolactam and hexamethylene diisocyanate were studied. The relation between the comonomer composition and supramolecular structure of copolymers was established.

Among numerous procedures of production of polyamides (PAs), one of the simplest is anionic polymerization of ε-caprolactam (ε-CL), which allows realization of practically 100% conversion and production of the polymer with high strength characteristics [1–5]. The resulting polycaproamide can be subjected to only mechanical treatment and cannot be molded to form items by standard procedures of processing of thermoplastics, which significantly narrows possible fields of its application. Therefore, so-called copolymers of ε-CL with other monomers, such as adipate, amimoenanthic acid, pyrrolidone, piperidine, etc., are of great practical significance. These copolyamides (CPAs) have lower melting points, which facilitates their processing and in some cases extends the fields of their application (films, fibers, etc.) [6, 7].

A procedure of production of CPAs based on ε-CL and a series of aliphatic and aromatic diisocyanates [hexamethylene diisocyanate (HMDI), 2,4-toluylene diisocyanate (TDI), and 4,4'-diphenylmethane diisocyanate (MDI)] in the presence of alkali metal (Na and Li) lactamates was developed previously [8, 9]. It was shown that, by varying the structure of PA macromolecule by introducing isocyanate component, its thermal characteristics, in particular, softening point, can be varied over a wide range.

In this work we examined the influence of the comonomer composition on the thermal, supramolecular, and mechanical characteristics of the resulting copolymers.

EXPERIMENTAL

The supramolecular structure of CPA was studied by differential scanning calorimetry (DSC; a DSK-D unit, heating rate 4 deg min^{-1}), differential thermal analysis (DTA), and X-ray analysis. The TG and DTG curves were obtained on an MOM derivatograph (Hungary) at a heating rate of 3 deg min^{-1}. The sample weight was 0.2 g. The X-ray analysis was carried out on a DRON-2 equipment (CoK_α radiation). The effective size of crystallites L, degree of crystallinity χ_c, and first-kind G_1 and second-kind G_2 defects were determined by the procedure described in [10]. The relaxation time was determined on a pulse NMR relaxometer operating at 20 MHz. The measurements were performed by the Carr–Purcell–Meiboom–Gill method and the running sequence method at 25°C [11].

The activation energy of failure U_0 was found using the Gul' equation [12]

$$\sigma_d = K_1 V_1^n e^{U_0/RT},$$

where V_1 is the extension rate, and K_1 and n are the parameters determined by the material nature and the sample size and shape.

Taking the logarithm of this equation, we obtain

$$\ln \sigma_d = \ln K_1 V_1^n + U_0/RT.$$

The slope of the straight line plotted in the coordinates $\ln\sigma_d$–$1/T$ is U_0/R. Hence, $U_0 = R\tan\alpha$.

The samples for determination of physicochemical characteristics were cut from plates produced by hot pressing. The samples were kept under a pressure for 5 min per 1 mm of the sample thickness. The physicomechanical characteristics were determined on an RM 500-T tensile-testing machine. The velocity of the tensile-testing machine clamps was 100 mm min^{-1}.

15	39

The thermomechanical analysis was carried out with the samples 0.3 cm in diameter and 4 mm thick. The samples were cut from pressed plates and heated at a rate of 3 deg min^{-1}. The DTA and DTG curves were recorded at a periodical stress (period of stressing 0.25 min). The softening point was evaluated from the thermomechanical curves.

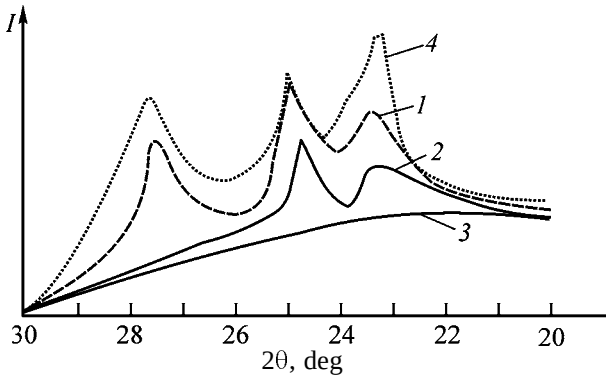

Fig. 1. Diffraction patterns (*1*–*3*) of copolymers based on ε-CL and HMDI at weight ratios of (*1*) 95 : 5, (*2*) 70 : 30, and (*3*) 50 : 50 and (*4*) of ε-CL homopolymer. (*I*) Intensity and (2θ) Bragg angle.

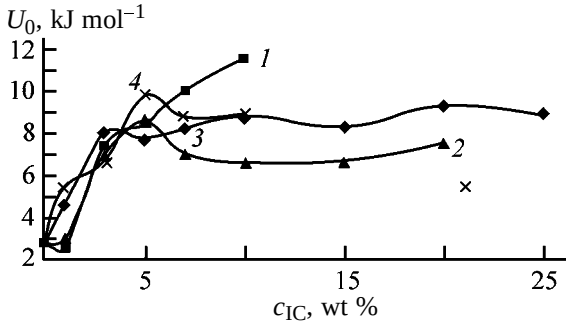

Fig. 2. Activation barrier of CPA failure as a function of content of ICs. (*1*) MDI, (*2*) SKU, (*3*) HMDI, and (*4*) TDI.

The synthesized CPAs are partially crystalline polymers. It was found that the degree of crystallinity of CPAs decreases with increasing content of isocyanates (ICs). This is apparently caused by growing steric hindrances appearing as a result of increasing branching of macromolecules, which is, in turn, determined by bifunctionality of the ICs used; this results in formation of polydisperse supramolecular structures. Thus, even at low content of HMDI in the initial monomer mixture, the heat of melting ΔH_m of the resulting CPAs significantly decreases; in this case, the temperature $T_{o.m}$ of the onset of melting and the equilibrium melting point T_m decrease and the melting diffuseness ΔT_m increases (Table 1). The similar variations are observed with an oligourethane SKU (the product of reaction of polyoxymethylene glycol and TDI) used as an isocyanate component (Table 2). The substantial changes in the supramolecular structure are evident from the diffraction patterns of the resulting polymers (Fig. 1). As seen, the copolymer of ε-CL with HMDI, similar to ε-CL hopolymer, has three reflections whose positions do not vary, only their intensities decrease.

With increasing fraction of ICs, χ_c of CPAs decreases, which, as mentioned above, can be caused by increase in branching of macromolecules. In parallel with decreasing fraction of crystallinity, the G_2 values caused by disordering in arrangement of the lattice points at long distances decrease and the G_1 values related, on the one hand, to displacement of the lattice points from the theoretical positions and, on the other hand, to nonuniformity in size remain practically the same (Table 3). The use of both sodium lactamate and lithium lactamate as a catalyst does not noticeably affect the trends in variation of the above characteristics.

An increase in the branching of macromolecules regularly hinders the conformation mobility. Thus, the spin–lattice relaxation time τ_1 of the synthesized CPAs in the temperature range in which they are in the hyperelastic state increases with increasing content of ICs in the initial monomer mixture (Table 4).

A decrease in the flexibility can be judged from a decrease in the activation barrier of CPA failure (Fig. 2). As seen, the copolymers prepared with all the ICs studied are characterized by increased U_0; in this case, the greatest increase occurs in the range of IC content in the initial monomer mixture from 1 to

Table 3. Data of X-ray analysis of CPA based on ε-CL and HMDI

HMDI content in initial monomer mixture, wt parts	G_1, %		G_2, %		χ_c, %	
	Na-CL	Li-CL	Na-CL	Li-CL	Na-CL	Li-CL
–	4.3	4.1	5.7	4.6	40	33
5	4.4	4.7	2.5	2.7	30	28
10	4.3	4.3	2.8	2.8	29	26
30	6.5	4.5	2.5	2.5	10	17

5 wt %. However, it is possible that the increase in U_0 is also caused by the increase in the cooperativity of deformation processes preceding the failure.

Changes occurring on the supramolecular level result in variation of the macroscopic characteristics. Thus, for CPAs with the HMDI content less than 20 wt parts, the shape of the stress–strain curves corresponds to crystalline polymers, while with increasing fraction of ICs it changes and becomes close to the shape typical of amorphous polymers (Fig. 3).

Table 4. Spin–spin relaxation time of CPA

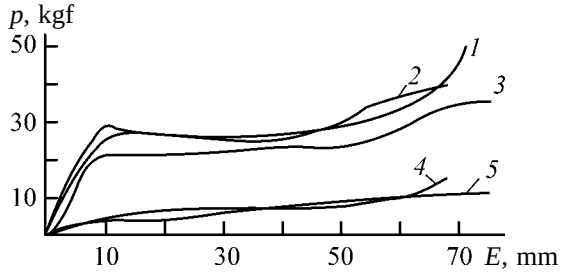

Fig. 3. Strain E–stress p curve of copolymers based on ε-CL and HMDI. HMDI content in the initial monomer mixture (wt parts): (*1*) 0, (*2*) 5, (*3*) 10, (*4*) 20, and (*5*) 30.

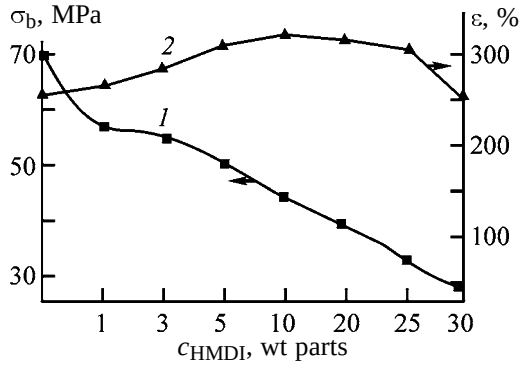

Fig. 4. (*1*) Breaking stress σ_b and (*2*) relative elongation ε of CPA as a function of HMDI content c_{HMDI} in the initial monomer mixture.

With increasing content of ICs, the softening point T_s determined from thermomechanical analysis monotonically decreases from 210°C for ε-CL homopolymer to 140°C on adding 20 wt parts HMDI. This decrease is apparently caused by variation in the structure of macromolecules. Introduction of IC into the polyamide chain results in appearance of bulky substituents with reactive NCO groups, which can cause branching of the macromolecule chain and, hence, decrease the intermolecular interaction in the resulting copolymer. This assumption is confirmed by the results of physicomechanical tests: the breaking stress σ_b decreases and the relative elongation ε slightly increases (Fig. 4).

CONCLUSIONS

(1) Copolymers with the supramolecular structure and characteristics varying in a wide range, depending on the ratio of the initial monomers, were prepared by anionic copolymerization of ε-caprolactam and diisocyanates.

(2) With increasing content of diisocyanates up to 30 wt parts, the crystalline polymers are formed. Further increase in the content of the isocyanate component results in complete disappearance of supramolecular formations.

Abstract—Mass-exchange characteristics of cellulose myristate or acetomyristate membranes in separating aqueous-organic, organic, or gas mixtures, particularly, in recovering aromatic hydrocarbons from binary mixtures with aliphatic alcohols, and also ethyl acetate from a mixture of esterification products, are studied.

There is a steady scientific and practical interest in cellulose-based membranes in recent six decades, which is caused by easy availability of cellulose raw material, and also by the possibility of directed synthesis of homologous series of various cellulose derivatives with desired physicochemical characteristics. Therefore, cellulose-based membranes with desired transport properties can be prepared as well. Microporous (diffusion) membranes are mostly formed on the basis of cellulose esters or mixed esters (diacetates, triacetates, acetobutyrates), regenerated cellulose, and chitosan [1–6]. Previously we demonstrated the possibility of using cellulose acetomyristate diffusion membranes for separating aromatic and aliphatic hydrocarbons using the pervaporation technique [7]. In this work we studied the transport properties of cellulose myristate (CM) and acetomyristate (CAM) membranes of different composition in separating gas, aqueous-organic, and organic mixtures.

EXPERIMENTAL

Cellulose myristate and acetomyristates were prepared according to the standard procedure [8]. Membranes as nonporous films of a fixed thickness were formed from chloroform solutions of the polymers on a cellophane support. The pervaporation experiments were carried out using a laboratory cell of the autonomous type (effective area of the membrane 12 cm^2) with stirring the mixtures over the membrane at a residual pressure under the membrane of 0.2 mbar. The permeate vapor (flow passed across the membrane) was condensed in a receiving vessel at the liquid nitrogen temperature and weighed, and the total flow $\prod$ ($kg\ m^{-2}\ h^{-1}$) was estimated. In the experiments we used binary mixtures ethanol–water, toluene–methanol, and benzene–ethanol of various compositions, and also a mixture of ethyl acetate, acetic acid, ethanol, and water. The compositions of permeates were analyzed on a refractometer or chromatographically using Porapak-Q or Reoplex columns. The partition factor α was estimated as

$$\alpha_{A/B} = (X_A/X_B)/(Y_A/Y_B),$$

where Y_A and Y_B are the concentrations of A and B in the initial binary mixture (wt %), and X_A and X_B, in the permeate (wt %).

The gas-permeability coefficient P and selectivity factor $\alpha_{A/B}$ of vapors were determined chromatographically using a column filled with 5A molecular sieve as a stationary phase at an excess pressure over the membrane of 10 mbar. The compositions of liquid permeates and gas-permeability coefficients were determined to within 5 and 10%, respectively.

To study the selectivity of CM membranes, we prepared a 1 m long chromatographic column with the CM stationary phase supported on Celite 22. The evolution of the chemical structure of cellulose esters on passing from cellulose diacetate to CM is accompanied by decreasing packing density of the polymer chains and increasing fraction of the free volume in the polymer matrix. This is caused by weakening of the network of the hydrogen bonds and disordering of the supramolecular structure, being reflected in a regular increase in the gas permeability with parallel decrease in the selectivity. These trends are illustrated

Table 1. Gas-selective characteristics of homogeneous cellulose acetomyristate membranes at 20°C

Parameter	CAM composition (acetate/myristate)

in Table 1 with an example of CAM membranes of various compositions. The results demonstrate the opposite tendencies in the behavior of the gas-permeability coefficients *P* of the individual gases and of the selectivity factor α for various pairs of gases with increasing myristate content in the CAM membranes.

The maximal *P* values and the corresponding minimal α values were obtained for the 10/290 CAM membrane. In this case, the transport parameters approach those of the membranes based on polymers with low glass transition temperature, for example, polydimethylsiloxane [9] or cellulose diacetate plasticized with polyethylene glycol oligomers [6].

It is known that, in pervaporation separation of aqueous-organic mixtures, the direction of selective mass transfer is controlled not only by the kinetic diameter of molecules diffusing across the membrane, but also by the difference in the affinity of the components of the mixture with respect to the film-forming polymer. One of the parameters characterizing such an affinity can be the equilibrium swellability of the membrane in individual components of the mixture to be separated. This parameter with respect to water and ethanol is considerably different for cellulose diacetate and CM (6.5 and 0.3 wt %, and 10.7 and 3.7 wt %, respectively). Therefore, it was interesting to study the transport properties of CAM membranes with various acetate to myristate group ratios.

Table 2 shows the results of pervaporation separation of aqueous-ethanol solutions of various compositions. In separating the concentrated solution of ethanol, all the CAM membranes studied demonstrate dehydrating properties, even though the maximal α_{H_2O} = 10.2 is considerably lower than that of the known highly selective membranes used for dehydration [10, 11]. The tendency of α_{H_2O} to decrease in this series from 10.2 to 1.5 correlates with the increase in the hydrophobicity of the corresponding CAM membranes. At the same time, in separating more dilute solutions of ethanol with 150/150 and 10/290 CAM membranes, the direction of selective mass transfer changes for the opposite, demonstrating the tendency to increase in α_{EtOH} from 4.0 to 11.1, depending on the composition of the initial mixture and content of the myristate component in the membrane. The maximal α_{EtOH} = 11.1, obtained for 10/290 CAM membrane in separating 10 wt % EtOH–H_2O mixture, is well comparable with that of the membrane based on hydrophobic polymethylsiloxane [12]. Therefore, even higher selectivity could be expected for the CM membrane. However, its permeability with respect to both ethanol and water appeared to be very low, which is consistent with data on the equilibrium swellability of CM in these solvents, suggesting no practical interest.

The results obtained evidence the necessity in optimization of the hydrophilic–hydrophobic balance for membranes of this purpose, to attain a reasonable relation between their permeability and selectivity. Therefore, 150/150 and 10/290 CAM membranes are more suitable to concentrate ethanol from dilute aque-

ous solutions. It should be pointed out that, with an example of CAM membranes having a unitypical chemical structure regardless of the composition, we have demonstrated the possibility of changing the direction of selective mass transfer in separating water–ethanol mixtures.

Furthermore, it was interesting to compare the known methods for separating aqueous-organic and organic mixtures, such as rectification and distillation, with the pervaporation technique. Like distillation, in pervaporation the permeate is removed as a vapor, allowing comparative evaluation of the expediency of using this technique. In this case, we can compare the pervaporation diagrams characterizing the dependence of the permeate composition on the composition of the feed mixture with the liquid–vapor diagram of the same system.

Such a comparative analysis of the diagrams appeared to be most indicative for azeotropic systems. High efficiency of pervaporation separation in such systems was repeatedly indicated in the literature. Furthermore, there are numerous examples of industrial applications of membrane separation of azeotropic mixtures [13]. As an illustration, Fig. 1 gives the comparison of the liquid–vapor diagram [14] and the experimental data obtained for CAM membranes of various compositions in separating ethanol–water mixtures. For the CAM membranes demonstrating dehydrating and organophilic properties, the dependences of the permeate composition on the composition of the initial mixture are arranged below (Fig. 1, curve *2*) and above (curves *3* and *4*) the liquid–vapor equilibrium curve (curve *1*).

Comparative analysis of data presented in Fig. 1 shows some advantage of the 150/150 and 10/290 organophilic CAM membranes in the selectivity of separation of more dilute solutions of ethanol (Fig. 1, curves *3* and *4*) over equilibrium open evaporation. It is known from the literature [12, 15] that close arrangement of the pervaporation curves with respect to the liquid–vapor equilibrium curve is typical of a series of ethanol-selective membranes. In Fig. 1 (curve *5*) this is illustrated by an example of the membrane fabricated from Silar block copolymer, which was previously studied in separating ethanol–water mixtures over a wide composition range [16]. Our results (Fig. 1, curve *2*) also demonstrate relatively small advantage of the dehydrating 290/10 CAM membrane in the selectivity as compared to open evaporation.

At the same time, the advantage of pervaporation could be more pronounced just in dehydration of

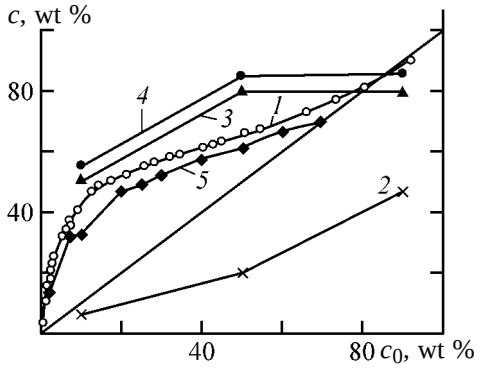

Fig. 1. Ethanol concentration c (*1*) in the vapor (liquid–vapor equilibrium in open evaporation) and in the permeate for membranes (*2*) 290/10 CAM, (*3*) 150/150 CAM, (*4*) 10/290 CAM, and (*5*) Silar as a function of the initial ethanol concentration c_0 in ethanol–water mixtures at 20°C.

water–ethanol mixtures. In this case, particularly in separating ethanol-rich mixtures close in their composition to the azeotropic mixture, the selectivity of membrane separation could be higher by 2–3 orders of magnitude than that in open evaporation. This is favored by the effect of diffusion mass transfer, i.e., by smaller kinetic diameter of the water molecules. From the practical standpoint, there is a wide spectrum of polymers and membranes on their basis [11, 17, 18] demonstrating strongly different affinity for water and ethanol, with the difference being considerably larger compared to dehydrating 290/10 CAM membrane (Table 2) and also to cellulose diacetate membrane [19].

Selection of binary systems showing more promise for pervaporation separation with the CM membrane was made using inverse gas chromatography (IGC). Roberts *et al.* [20] employed this technique using chromatographic columns with different polymeric stationary phases to predict the direction of selective mass transfer across the membranes fabricated from the same polymers in separating binary liquid mixtures. As a criterion they used the retention time (retention time of a component of the mixture on the column is in inverse proportion to its flow rate across the membrane). Therefore, we determined the retention times of a series of organic solvents on the CM column. The retention time increased in the order methanol < ethanol < benzene < toluene < ethyl acetate, being 105, 116, 126, 135, and 148 s, respectively. Knowing this parameter allowed prediction of the possibility of membrane separation of mixtures of toluene (or benzene) with methanol (or ethanol) with selective mass transfer directed in favor of the aromatic component, which was confirmed in the pervapora-

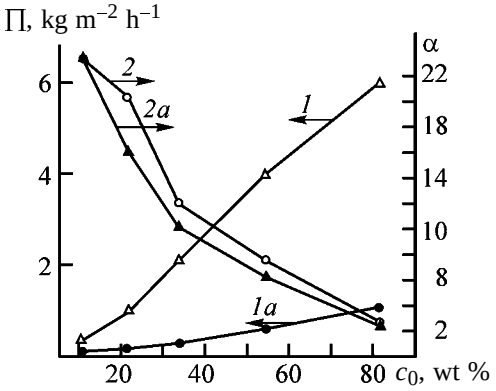

Fig. 2. (*1*, *1a*) Total flow ∏ and (*2*, *2a*) partition factor α in separating toluene–methanol mixture on the CM membrane as functions of the initial toluene concentration c_0 at 20°C. (*a*) For comments, see text.

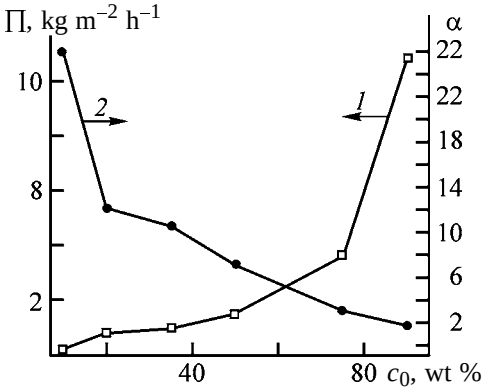

Fig. 3. (*1*) Total flow ∏ and (*2*) partition factor α in separating benzene–ethanol mixture on the CM membrane as functions of the initial benzene concentration c_0 at 20°C.

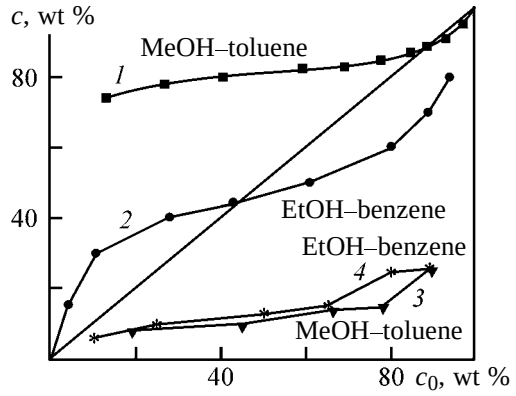

Fig. 4. (*1*, *3*) Methanol and (*2*, *4*) ethanol contents *c* in (*3*, *4*) permeate (CM membrane) and (*1*, *2*) vapor (liquid–vapor equilibrium in open evaporation) as functions of the initial methanol (or ethanol) concentration c_0 in mixtures with toluene and benzene, respectively, at 20°C.

tion experiments. Separation of such mixtures is of considerable scientific and practical interest, since these compounds form azeotropic systems and have similar boiling points (e.g., benzene and ethanol).

Figures 2 and 3 show the permselectivity α and total flow across the CM membrane ∏ as functions of the initial composition of the toluene–methanol and benzene–ethanol mixtures. As seen, over a wide concentration range, the CM membrane is selective with respect to the aromatic component of the mixture. Figure 2 demonstrates regular increase of the flow across the membrane (curve *1*) and parallel decrease in $\alpha_{toluene}$ (curve 2) with increasing toluene concentration in the initial mixture. Similar trend in the behavior of the transport parameters was observed also in separating the benzene–ethanol mixture (Fig. 3). It should be pointed out that, in separating the toluene–methanol mixture (Fig. 2), nearly the optimal relation between α and ∏ was obtained at the composition of the initial mixture close to the azeotropic composition (31 wt % toluene). For both systems, even at room temperature, 30–50 μm thick membranes allow sufficiently large flows in separating azeotropic mixtures, the attainable selectivity levels being well comparable with those of the membranes commonly used for this purpose [21].

Figure 2 (curves *1*, *2*) shows the dependences obtained in the pervaporation experiments on the same membrane with increasing toluene concentration in the initial mixture. Before passing to the next feed composition, the membrane cell was evacuated for a fixed time (10 min) to partially remove the solvents. Curves *1a* and *2a* were obtained at different evacuation time (1 h). As seen, longer drying of the membrane considerably affects the process characteristics, especially the flow ∏ (curve *1a*). The observed increase in the permeability at higher initial toluene concentration (Fig. 2, curve *1*) can be attributed to stepwise activation of the membrane structure at the supramolecular level with more penetrating component (toluene). Similar effect was observed previously [7] for CAM membranes in separating benzene–heptane mixtures.

In Fig. 4, the dependences of the permeate composition on the composition of the initial toluene–methanol (curve *3*) and benzene–ethanol (curve *4*) mixtures are presented along with the corresponding liquid–vapor diagrams obtained in the case of open equilibrium evaporation (curves *1*, *2*). A specific feature of pervaporation separation is that, over the entire feed composition range, the pervaporation curves are arranged considerably below the open evaporation curves, particularly, in separating the azeotropic mixtures. It should be pointed out that, in the frameworks of such comparative analysis, the pervaporation curves presented in Fig. 4 differ advantageously from those given in Fig. 2 for the system ethanol–water.

For the system toluene–methanol of the azeotropic compositions, we also studied the possibility of optimization of the transport properties with regard to the thickness of the CM membrane. The selectivity and flow across the membrane were determined at 20°C for 30-, 50-, and 690-μm thick membranes, and at 20 and 40°C for a 50-μm membrane. In each case, we determined the arbitrary production parameter as the product of ∏ and α. The maximal value of this parameter corresponds to the optimal relation between the flow across the membrane and the selectivity of separation. The production index appeared to be maximal for the 50-μm membrane (8.36 and 12.95 kg m^{-2} h^{-1} at 20 and 40°C, respectively).

In terms of the existing concept of the pervaporation mechanism, the immediate cause of the effect of the membrane thickness is associated with the penetrant concentration gradient across the membrane. In steady-state mass transfer, the penetrant concentration decreases in the direction to the permeate side of the membrane. Therefore, the surface of the membrane at the feed side occurs in the state maximally close to the condition of equilibrium swelling with regard to the components of the mixture. In this zone, the selectivity of separation is relatively low as a result of the plasticization of the surface layers of the membrane. In deeper layers, the degree of approaching the equilibrium swelling should decrease. As a result, "drier" layers at the permeate side are plasticized to a smaller extent, and the flexibility of the polymer chains or their segments in this zone is considerably lower, which should exert a positive effect on the separation selectivity. At the same time, with all other conditions being equal, with increasing concentration of more penetrable component in the mixture, the flow across the membrane increases. In this case, the concentration gradient and the thickness of the "dry" layer decrease, negatively affecting the selective properties.

This concept gives grounds to use the term "cross-membrane selectivity gradient." In each particular case of separation, the occurrence of such a gradient allows control of the transport characteristics of the membrane, including α. In this connection, it may be concluded that the use of the term "ideal partition factor" is incorrect with respect to pervaporation membranes as continuous nonporous films, since, with all other conditions being equal, α will increase with increasing thickness of the membrane.

To conclude, mixtures of aliphatic alcohols and aromatic hydrocarbons can be separated on pervaporation membranes in a single stage, to obtain the concentration of the aromatic component in permeate of up to 80–90 wt %. The resulting permeates can be then partitioned by, e.g., ordinary distillation. An alternative can be the use of methanol- or ethanol-selective pervaporation membranes in the second stage also. Furthermore, the IGC analysis revealed high affinity of CM for methyl acetate and ethyl acetate and low affinity for water and aliphatic alcohols. This difference could be of interest in view of the use of CM membranes in industrial processes in a series with a reactor, to shift the equilibrium of esterification and also to remove the target products from the reaction zone.

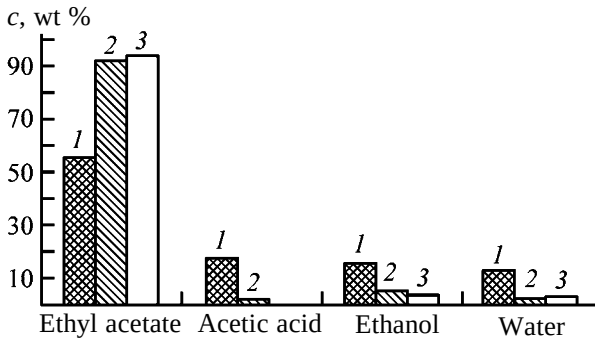

Fig. 5. Initial composition of the mixture ethyl acetate–acetic acid–ethanol–water compared to the compositions of permeates in separating the initial mixture in the pervaporation and evaporation modes with the CM membrane. (*c*) Component concentration. (*1*) Initial mixture; permeate composition: (*2*) pervaporation and (*3*) evaporation.

The histogram in Fig. 5 represents the results of separation of a four-component mixture whose composition models the esterification equilibrium realized in synthesis of ethyl acetate (55.0, 17.1, 15.4, and 12.5 wt % of ethyl acetate, acetic acid, ethanol, and water, respectively). The process was carried out at 20°C with direct contact of the simulated mixture with the surface of the CM membrane (pervaporation mode) or on a membrane in contact with vapor of this mixture (evaporation mode). In both cases, we observed considerable enrichment of permeate with ethyl acetate (from 55 to 91.6 and 93.8 wt %, respectively) with parallel significant decrease in the concentrations of acetic acid, ethanol, and water (1.5 and 0, 4.1 and 3.4, and 2.2 and 2.8 wt %, respectively). It is worth noting that the permeability of the membrane in the pervaporation and evaporation modes is considerably different (2 and 0.1 kg m^{-2} h^{-1}, respectively). Finally, our results are of interest in view of formation of composite CM membranes with higher permeability.

CONCLUSIONS

(1) The possibility of controlling the membrane permeability and selectivity with respect to some individual gases or their mixtures, as well as the direction of selective mass transfer in separating water–ethanol mixtures, was demonstrated with an example of cellulose acetomyristate membranes of various compositions.

(2) A comparative analysis is made of the selectivity of separation of binary organic and aqueous-alcoholic mixtures on cellulose myristate and acetomyristate membranes in the pervaporation and evaporation modes.

(3) The direction of selective mass transfer of components of organic mixtures across the cellulose myristate membrane can be predicted using the inverse gas chromatography.

(4) Cellulose myristate membranes are efficient for recovery of toluene and benzene from their mixtures with, respectively, methanol and ethanol, particularly from azeotropic mixtures.

(5) The separating properties of cellulose myristate membrane are studied with regard to a multicomponent mixture simulating the esterification equilibrium realized in synthesis of ethyl acetate. Ethyl acetate can be concentrated in permeate to 91.6–93.8 wt %.

Abstract—The composition and content of polysaccharides obtained from different samples of rice husk by successive treatment with water, ammonium oxalate (or oxalic acid), and alkali were studied. The chemical composition of the rice husk residues after the extraction was examined, and the possibility of their use for preparing amorphous silica or cellulose-containing products, depending on the hydrolysis conditions, was assessed.

Cleaning and polishing of rice grains involves formation of a large-tonnage waste, husk and dust, which is a valuable and renewable vegetable raw material for chemical industry [1–3]. It was shown previously that amorphous high-purity silica and xylitol can be prepared from rice husk [4], and phytin, from rice dust [5]. Rice husk and straw are also sources of polysaccharides [6]. Polysaccharides are widely used in various branches of industry, e.g., in production of fibers, films, adhesives, ethanol, and medicinals [6, 7]. Polysaccharides from higher herbs, including those from the Russian Far East, exhibit a broad spectrum of biological activity (immunomodulating, antiphlogistic, antiviral, antitumor, anticomplementary, wound-healing, etc.) [8, 9]. Data on the biological activity of polysaccharides recovered from vegetable waste, in particular, from rice husk, are virtually lacking.

This paper, continuing our studies on integrated processing of rice production wastes, concerns the chemical composition of rice husk polysaccharides recovered by various extraction proceduures and of the insoluble residues.

EXPERIMENTAL

We studied the composition and content of polysaccharides (PSs) in rice husk (RH-1, RH-2, RH-17) and dust (RD) samples taken in different years from the Primor'e and Krasnodar krais, and also of phytin recovered from rice dust without (phytin-1) and with (phytin-2) ultrafiltration by the method described in [5].

The RH samples usually contain an impurity of fine fractions of husk, grains, and dust (2–11 wt % depending on the equipment used). The husk particle size in our experiments was less than 2 mm. The RH samples were preliminarily washed with water and dried at 95°C in air to constant weight.

The RH and RD samples were treated successively with water, ammonium oxalate, an alkali. For this purpose, a sample was placed in water (weight ratio ~1 : 10) and heated on a water bath for 3 h. The solution was separated from the RH or RD residue by filtration and concentrated by evaporation on a rotary evaporator, after which the polysaccharides were precipitated with acetone (volume ratio of the solutions 1 : 4). The polysaccharide precipitate was separated by centrifugation, dissolved in water, and freeze-dried to obtain polysaccharides of aqueous extraction.

To the residue of RH and RD after treatment with water, we added a 0.5 N solution of ammonium oxalate (weight ratio ~1 : 10) and heated on a water bath for 3 h. The solution was separated from the undissolved residue by filtration and subjected to dialysis against running water (2–3 days) and then against distilled water (1 day). After that, the solution was concentrated, and a fourfold volume of acetone was added. The precipitate formed was separated by centrifugation, dissolved in water, and freeze-dried to obtain polysaccharides of oxalate extraction.

The solid residue of RH or RD after treatment with water and ammonium oxalate was suspended in 0.5 N NaOH and heated on a water bath for 2 h. The solution was separated by centrifugation (5000 rpm,

20 min) and worked up as described above, to obtain polysaccharides of base extraction.

The isolated polysaccharides were subjected to acid hydrolysis, performed by treatment with 1 N trifluoroacetic acid (TFAA) at 100°C for 4–5 h. The qualitative and quantitative monosaccharide composition of the products was determined by paper chromatography (PC), gas–liquid chromatography (GLC), and gas chromatography–mass spectrometry (GC–MS) after conversion of the polyols to acetates. The descending PC was performed on Filtrak FN-12 paper in the system 1-butanol–pyridine–water (6 : 4 : 3 by volume). Monosaccharides were detected with an alkaline solution of silver nitrate. Gas–liquid chromatography was performed with an Agilent 6850 chromatograph (the United States) equipped with a flame ionization detector. An HP 5MS capillary column (30 m × 250 μm × 0.25 μm), was coated with 5% methylphenylsiloxane. The column temperature schedule was as follows: 150°C, 1 min; heating to 230°C, 3 deg min^{-1}; 230°C, 10 min. The GC–MS analysis was performed with a Hewlett–Packard 6890 chromatograph (the United States). The capillary column and temperature schedule were the same as in the GLC analysis. The chromatograph was interfaced with a Hewlett–Packard 5973 mass spectrometer (the United States).

Data on the polysaccharides obtained by aqueous, oxalate, and base extraction of RH and RD samples are given in Table 1. All the polysaccharides of aqueous extraction consist essentially of glucans. The polysaccharide of oxalate extraction from RH-1 is also glucan, and that recovered from RH-2 contains, along with glucose, also xylose, arabinose, and galactose. The polysaccharide recovered by oxalate extraction from RD consists of gluconate with a minor impurity of galactose and mannose. The polysaccharides recovered by base treatment of RH contain the residues of arabinose, xylose, glucose, and galactose; the monosaccharide ratio is different depending on the source of the raw material (RH-1, RH-2). The polysaccharides from RD are mainly glucans irrespective of the extraction procedure.

To develop an integrated scheme of utilization of rice production wastes, it is necessary to know the content in them of water-soluble low-molecular-weight carbohydrates (free monosaccharides, FMs). Below are data on the composition and content of FMs in RH depending on the treatment procedure. We studied the RH-17 specimen, which is of the same origin as RH-1, and a phytin specimen. We prepared and analyzed six samples of RH-17 treated as follows.

Sample no. 1 (RH-17, H_2O, 1 h, 60–90°C). A 5-ml aliquot of the solution was treated with KU-2(H^+) resin. A half of the aliquot was reduced with sodium borohydride, and the remaining part was hydrolyzed with a 1 N solution of TFAA (4 h, 100°C). In both cases, the polyols were converted to acetates, which were analyzed by GLC and GLC–MS.

Sample no. 2 (RH-17, 0.1 N NaOH, 1 h, 60°C). A 5-ml aliquot of the solution was neutralized with HCl, treated with KU-2(H^+) resin, and worked up as described above.

Sample no. 3 (RH-17, 0.1 N $H_2C_2O_4$, 1 h, 60°C). A 5-ml aliquot of the solution was neutralized with concentrated ammonia and treated with KU-2(H^+) resin. A half of the solution was analyzed without hydrolysis, and the other half, after acid hydrolysis, as described above.

Table 2. Composition and content of FMs recovered from RH-17, phytin-1, and phytin-2 as influenced by the treatment of the raw material

Sample	Treatment	FM + PS*	Content of monosaccharides, mol %

* (FM) Without hydrolysis; (FM + PS) after hydrolysis.
** (Int) Inositol.

Sample no. 4 (RH-17, successive treatment with H_2O and 0.1 N $H_2C_2O_4$). The extract was treated similarly to sample no. 2; the aliquot was analyzed without hydrolysis by GLC and GC–MS.

Sample no. 5 (RH-17, successive treatment with H_2O and 0.1 N NaOH). The aliquot of the extract was treated similarly to sample no. 3. The monosaccharide analysis of the solution was performed both without hydrolysis and after acid hydrolysis.

Sample no. 6 (RH-17, successive treatment with H_2O, 0.1 N $H_2C_2O_4$, and 0.1 N NaOH). After neutralization of the solution and its treatment with KU-2 resin, the sample was analyzed without hydrolysis.

The results of analysis of the extracts for FMs are listed in Table 2. It is seen that low-molecular-weight carbohydrates are quantitatively recovered in the first extraction, irrespective of whether it was performed with water (sample no. 1), alkali solution (sample no. 2), or acid solution (sample no. 3). The monosaccharide composition only slightly depends on the RH-17 treatment procedure, but the quantitative ratios of the monosaccharides are different. In all the cases, polysaccharides are extracted together with FMs, as indicated by the difference in the quantitative ratio of FMs in the same RH-17 sample before and after hydrolysis.

In successive extraction of RH-17 with water and then with oxalic acid (sample no. 4), or alkali (sample no. 5), or with both acid and alkali (sample no. 6), FMs were detected only in extract no. 4. This can be accounted for by the fact that oxalic acid partially hydrolyzes polysaccharides present in the solution.

In the initial phytin samples (Table 2), inositol was detected by GLC in trace amounts, since it is present in the form of inositol phosphate. After acid hydrolysis, we identified in phytin-1 only inositol (100%), and in phytin-2, also mannose and glucose. Different composition of the phytin samples may be due to different procedures for their recovery from solution after acid hydrolysis of RD: phytin-1 was precipitated with ammonia from the crude hydrolyzate, and phytin-2, from the hydrolyzate purified by ultrafiltration. The hydrolyzate was purified by passing the solution, according to [5], through UAM-150 cellulose acetate membranes (pore diameter ~10–15 nm) permeable for molecules of a definite size. The molecular weights of inositol, mannose, and glucose detected in phytin-2 (Table 2) are equal (180). These data show that, to obtain a pure product from RD, ultrafiltration, giving a number of advantages in processing of the raw material [5], should be supplemented by washing of phytin to remove FMs.

Table 3. Yield of water-soluble substances from RH and content of inorganic elements in residues after different treatment procedures

Raw material	Treatment	Soluble substances	Residue	Ash residue from RH	SiO_2 content in ash	Content of elements in ash $c \times 10^3$, wt %						
		wt %				Fe	Al	Ca	Mg	Mn	Zn	Cu
RH-17	H_2O	12.5	87.5	14.0	96.7	51	46	620	85	26	25	0.1
	$H_2C_2O_4$	13.3	86.7	14.3	99.9	63	34	790	348	88	20	0.1
	NaOH	52.2	47.8	0.85	0.53	340	98	27 600	8220	2330	220	6.0
RH-1	H_2O, $(NH_4)_2C_2O_4$, NaOH	47.9	52.1	0.80	0.44	17	11	149	36	3	2	0.3
RH-2	H_2O, $(NH_4)_2C_2O_4$, NaOH	43.4	56.6	0.82	0.51	17	8	142	10	3	1	0.3

Comparison of our results with the data of [6, 10–12] shows that the chemical composition and content of water-soluble PSs and FMs in the rice production wastes depends on a number of factors: kind of the raw material (husk, straw, or dust), its origin (growth region; actually, apparently, the plant strain is concerned), and treatment procedure. In contrast to data from [6], uronic acids were detected only in trace amounts in some RH extracts.

The RH residues after extraction of water-soluble substances (cellolignin) are raw materials for production of amorphous silica [1–4] and, e.g., sorbents based on plant fibers [13–15]. Therefore, the RH residues after extractions were analyzed for the content of Si and metals by the procedures described previously [4] (Table 3).

The ash residue (oxidative calcination at 700–800°C [4]) from RH residue after aqueous or oxalate treatment is 10–12 wt % relative to the dry starting material. The content of amorphous silica in the ash is 96.7 wt % after aqueous extraction of RH and 98.3–99.9% after the oxalate treatment. The content of silica in ash of the RH residue after base hydrolysis does not exceed 0.6 wt %. The list of metals detected in the cellolignin ash and their contents are listed in Table 3.

CONCLUSIONS

(1) The chemical composition and content of water-soluble polysaccharides and low-molecular-weight carbohydrates in rice processing wastes depend on the kind of the raw material (husk, straw, dust), its origin (growth region, plant strain), and treatment conditions. Aqueous and oxalate polysaccharides mainly contain glucans.

(2) To obtain pure phytin from rice dust with ultrafiltration of the hydrolysis solution, it is necessary to include in the flowsheet the step of washing the product with water to remove free polysaccharides.

(3) High-purity amorphous silica can be prepared from rice husk after its pretreatment with water and acid. The content of the main substance, SiO_2, in the ash from the rice husk residue is 96.7–99.9 wt %, and the ash yield is 10–12 wt % relative to the dry starting material.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Acidifying Agent on Autophoretic Application of Polymeric Composite Coatings

Zh. I. Bespalova, L. G. Miroshnichenko, Yu. A. Lovpache, and Yu. D. Kudryavtsev

South Russian State Technical University (former Novocherkassk Polytechnic Institute), Novocherkassk, Rostov oblast, Russia

Received August 4, 2004

Abstract—The effect of acidifying agent on autophoretic application of a polymeric composite material and protective properties of the resulting coatings is studied.

Studies concerning intensification of the existing processes for applying polymeric coatings to metallic surfaces and improvement of these processes with regard to environmental problems are directed primarily at searching for novel cost-efficient solutions. Among such new developments is the autophoretic method of applying polymeric protective coatings (PPCs) [1–3].

In this context, combining the unique properties of Teflon (corrosion resistant, antifriction, and antiadhesive) with the advantages of autophoretic deposition (no loss of the applied material, possibility of full automation, uniform thickness of PPC on articles of complicated geometry, reduced power consumption owing to utilization of the energy of the chemical reaction) is a topical scientific and applied problem.

The autophoretic process is realized by immersing metallic articles in an acidic aqueous composition containing an organic coating-forming material in the dispersed form, dispersing and acidifying agents, and an oxidant [4, 5].

Acidifying agents are introduced to form concentration and electric fields [6] that arise from a redox reaction occurring on the metallic surface and cause motion of the particles in autophoresis [7]. The autophoretic formation of a gel-like PPC is similar to electrochemical corrosion. In the presence of an acidifying agent, anodic dissolution of a metal ($M \rightarrow M^{z+} + ze$) and cathodic reduction of an oxidant or oxygen contained in the system proceed [8].

Therefore, ionization of a metal takes place only in the presence of an acidifying agent, being inseparably linked with autodeposition from acidic solutions. This process results in oxidation of a metallic support, which induces the charge and distorts the stability of the composition.

In this work we developed a composite Teflon-based material and studied its applicability to autophoretic deposition with regard to the nature of acidifying agent.

PPCs were applied to pretreated surfaces of 08KP steel.

The autophoretic bath was made from Plexiglas. The process was carried out at 18–25°C. A sample was fixed on a mechanical agitator using a specially designed holder and immersed in the polymeric coating-forming dispersion. The rotation rate was 60 rpm.

pH of the composition was measured with a pH-340 laboratory pH meter. The thickness of PPCs was determined by the magnetic method using an MT-2 instrument [9]; PPC yield, gravimetrically; and electrokinetic potential of dispersed particles, by the method of electrophoresis in a parallel-sided cell; and PPC adhesion to the metallic surface, by the shear stress according to GOST (State Standard) 14759–69. The tribotechnical characteristics were determined on an end friction-testing machine. The continuity of PPCs was measured using an LOK-1M electric-contact defectoscope; the viscosity, with an Ostwald capillary viscometer; and corrosion resistance, by the weight loss in corrosive media.

The composition used was found to be stable by the dry residue, viscosity, aggregation state, and kinetic parameters. Such a stable state was obtained after optimization of the composition.

As coating-forming agents we used aqueous suspensions of Teflon F-4D and Teflon F-4MD and a solution of polymethylphenylsiloxane in toluene; as mineral additives, carbon black, titanium dioxide, mica, and Aerosil; and as organic solvents, xylene, butyl Cellosolve, and furfuryl alcohol.

1070-4272/04/7711-1888 © 2004 MAIK "Nauka/Interperiodica"

To attain better compatibility and wetting of the polymer phase, the mineral additives were dressed with some modifiers, particularly, heterocyclic compounds of the vinylpyrrolidone series and oxyethylated alkylphenol. The dry residue of the initial composition was 55 wt %; viscosity, 16 s (VZ-246 viscometer); and pH, 6.5. The parameters of autophoretic deposition of PPC were optimized with the composition selected on the basis of preliminary experiments. The optimal pH of the composition was found to be 3 (Fig. 1).

The optimal temperature (380°C) and time (30–40 min) of heat treatment of PPC were established on the basis of experimental data on the swelling of PPC in acetone vapor and 10% nitric acid. All further experiments were carried out at these process parameters.

We studied the effect exerted on autophoretic deposition by such acidifying agents as phosphoric, tetrafluoroboric, hydrofluoric, and sulfuric acids, and a mixture of phosphoric and boric acids. The acids were added in amount sufficient to attain pH 3.

Our results showed that the nature of acidifying agent influences the ζ-potential of dispersed polymeric particles:

Acid	ζ-Potential, mV
H_2SO_4	–27.9
$H_3PO_4 + H_3BO_3$	–39.4
HF	–46.0
HBF_4	–54.0
H_3PO_4	–62.0

The observed increase in the absolute value of the ζ-potential on passing from sulfuric to phosphoric acid can be attributed to the anion effect on the adsorption of macromolecules of the coating-forming agents on the surface of mineral additives. Formation of the adsorption layer is controlled essentially by the ion-electrostatic factor. Evidently, the presence of phosphoric acid promotes adsorption to a larger extent as compared to other acids. This conclusion is supported by data on the effect of anion on the yield of PPC (Fig. 2).

As seen, the specific weight of PPC increases with increasing ζ-potential. The optimal deposition time was found to be 5–10 min regardless of the acid added. With further increase in the deposition time, the PPC weight reaches some critical value and then decreases, which can be attributed to the fact that, after reaching certain thickness, the polymeric coating no longer grows, since the concentration of Fe^{2+} and Fe^{3+} ions under the coating decreases below the coagulation threshold, and, despite the fact that autophoretic transport of particles goes on then, they do not precipitate [1]. Furthermore, in this case, some part of the particles leaves the surface as a result of weakening of the cohesion interaction of the components in the coating.

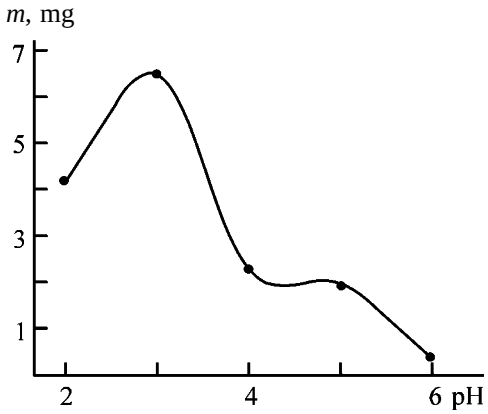

Fig. 1. Coating weight *m* as a function of pH of the composition at the optimal deposition time (5 min).

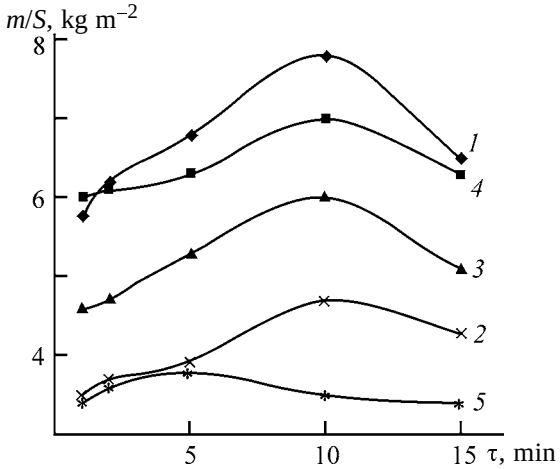

Fig. 2. Yield of the deposit *m*/*S* as a function of the time of deposition τ with various acidifying agents (acids): (*1*) H_3PO_4, (*2*) $H_3PO_4 + H_3BO_3$, (*3*) HF, (*4*) HBF_4, and (*5*) H_2SO_4; the same for Fig. 3.

The nature of the acidifying agent also affects the protective characteristics of PPC (Fig. 3). In the corrosion tests in 3 wt % HCl, the best protection characteristics were obtained for PPCs prepared with phosphoric acid. This is clear in view of the fact that phosphoric acid forms insoluble phosphates with metals, and phosphatization enhances the corrosion resistance and adhesion [10, 11]. Another reason is that, among the acids studied, phosphoric acid provides the highest yield of the deposit (Fig. 2).

The results of corrosion tests of the autophoretic coatings, prepared in the presence of phosphoric acid, in various corrosive media are given in Fig. 4.

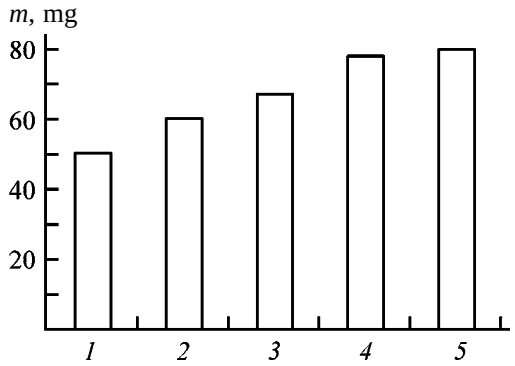

Fig. 3. Weight loss *m* in corrosion tests in 3 wt % HCl for coatings prepared in the presence of various acids.

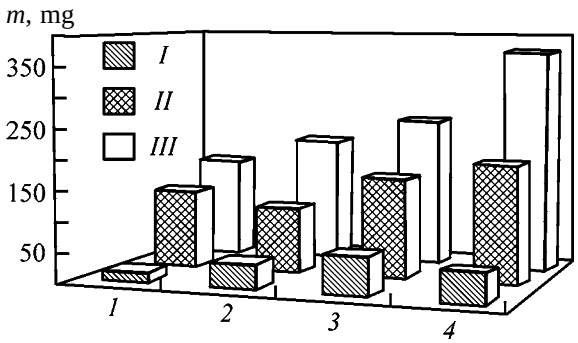

Fig. 4. Weight loss *m* in corrosion tests in (*1*) industrial atmosphere, (*2*) seawater, (*3*) 3 wt % NaCl, and (*4*) 3 wt % HCl. (*I*) PPC, (*II*) Teflon coating, and (*III*) uncoated steel.

As seen, the corrosion resistance of the polymeric composite coatings is higher by a factor of several tens as compared to uncoated steel, being several times higher than that of Teflon coatings prepared by immersing in aqueous suspensions of Teflon F-4D and F-4MD.

The adhesion tests of PPCs prepared with various acids also showed that phosphoric acid is the most effective acidifying agent. The adhesion of such coatings is rather high, ranging from 5.0 to 6.0 MPa:

Acid	Adhesion, MPa
H_3PO_4	5.9
H_3PO_4 + H_3BO_3	5.5
HF	5.0
HBF_4	4.9
H_2SO_4	4.5

CONCLUSIONS

(1) The nature of acidifying agent affects autophoretic deposition of polymeric composite coatings from compounded polymer dispersions, the effect being controlled by the adsorption characteristics of its anion.

(2) Among the acids studied, phosphoric acid is the most effective acidifying agent for applying coatings to 08KP steel, as providing the largest thickness of the coating and the highest adhesion and protective characteristics.

Abstract—Hydrolytic copolycondensation of ethyl silicate with copper salts in the presence of a base catalyst (NH_4OH) without organic solvent was studied.

Previously [1–3] we studied metal-containing (Cu, Co, Zn, Sn, Pb, etc.) siloxanes prepared by the sol–gel procedure involving homogeneous hydrolysis of ethyl silicate in 2-propanol in the presence of a base catalyst (NH_4OH) [1–3].

In practice, it is better to perform the sol–gel process without solvent. The advantage of the heterogeneous procedure is the absence of undesirable influence of the solvent impurities.

However, in the absence of solvent the reaction is substantially decelerated and the molecular uniformity of the products decreases. This is mainly due to phase segregation and emulsification.

Probably, a heterogeneous reaction can be promoted by choosing appropriate pH, temperature, and anion of the initial metal salt.

EXPERIMENTAL

The heterogeneous sol–gel process was simulated with commercial Etilsilikat-40 (partially hydrolyzed tetraethoxysilane) and copper salt crystal hydrates $CuSO_4 \cdot 5H_2O$, $CuCl_2 \cdot 2H_2O$, $Cu(NO_3)_2 \cdot 5H_2O$, and $Cu(OCOCH_3)_2 \cdot H_2O$.

As in our previous works, these salts were chosen because of formation of stable copper ammine complexes in a wide pH range. The preparation conditions were similar to those described in [3] except for the absence of the organic solvent. The products of hydrolytic copolycondenstaion were thoroughly washed by decanting and were dried at 120 ± 0.5°C to form xerogels. The xerogel was studied by thermal analysis in air (an MOM derivatograph, heating rate 10 deg min^{-1}) and by IR spectroscopy (a Specord IR-75 spectrophotometer, KBr pellets). To determine water absorption, the samples were kept at a 98% relative humidity for 72 h and then were weighed. The copper content in the xerogel was determined from that in the solution separated from the xerogel [4].

We found that the copper content in polycuprasiloxanes prepared by heterogeneous hydrolysis strongly depends on the anion of the initial salt, condensation temperature, and pH of the reaction mixture (Table 1). In the subsequent experiments we used polycupraethoxysiloxane prepared under the conditions (35°C, pH 12) that, on the average, proved to be the best.

The product of hydrolytic copolycondensation of ethyl silicate with copper salts in the presence of the base catalyst and in the absence of an organic solvent contains lattice and surface Si–O–Cu–O and Si–O–Si groups and minor amount of ethoxy groups. The presence of Si–O–Cu–O and Si–O–Si groups is indicated by the shift of the ν_{as}(Si–O) band (1093 cm^{-1}) with respect to this band in the spectra of silica xerogels free of copper. The shift depends on the anion of the initial copper salt (Table 2). The maximal shift of the ν_{as}(Si–O) band at 1093 cm^{-1} in the spectra of polycuprasiloxanes prepared from $CuSO_4$, $CuCl_2 \cdot 2H_2O$, $Cu(NO_3)_2$, and $Cu(OCOCH_3)_2$ is –13, –20, –29, and –13 cm^{-1}, respectively, and corresponds to the maximal copper content in the polycupraethoxysiloxanes (Tables 1, 2). The temperature dependence of the optical parameters of the ν_{as}(Si–O) band in the IR spectra of xerogels prepared at pH 12 correlates well with the copper content in these materials except for the xerogel prepared from $Cu(NO_3)_2$ (Tables 1, 2). In the latter case, the optical density of the ν_{as}(Si–O) band increases and its halfwidth $\Delta\nu_{1/2}$ decreases (Table 3). This is likely due to formation of cyclic fragments whose arrangement in the xerogel structure, unlike that of the other cross-linked structures, is three-dimensional or linear.

The structural transformations occurring mainly in the Si–O–Si groups are characterized by the optical parameters of the ν_s(Si–O) band at about 800 cm^{-1}. These data are consistent with the change in the optical parameters of the ν_{as}(Si–O) band (about 1093 cm^{-1}), i.e., the siloxane skeleton of the polymer changes simultaneously with the metallosiloxane structure and the changes depend on both the salt anion and the condensation conditions. The parameters of the ν_s(Si–O) band are presented in Tables 4 and 5.

Polycupraethoxysiloxane xerogels consists mainly of metal silicates. As determined by thermal analysis, the metal silicate content ranges from 80.7 to 92.1 wt %, depending on the anion of the initial copper salt. The weight loss at 200–450°C and the corresponding exoeffects in the DTA curves are due to the presence of residual ethoxy groups in the xerogels (Tables 6, 7).

The DTA curves of copper silicates prepared from copper nitrate and copper acetate contain a single exothermic peak at 300°C. Two exoeffcet in the range 290–320°C are observed in the DTA curves of xerogels prepared from copper chloride and copper sulfate. In all cases, these peaks are shifted to higher temperatures with increasing condensation temperature. The

Table 6. Weight loss Δm of polycupraethoxysiloxane xerogels at 200–450°C and the copper silicate content in the xerogels c

T, °C	Δm, wt %/c, wt %			
	$CuSO_4$	$CuCl_2$	$Cu(NO_3)_2$	$Cu(OCOCH_3)_2$

55	2.73/90.1	16.50/81.5	13.73/80.7	6.12/87.3

Table 7. Exothermic peak temperature T_{max} in the DTA curves of polycupraethoxysiloxane xerogels*

T, °C	T_{max}, °C			
	$CuSO_4$	$CuCl_2$	$Cu(NO_3)_2$	$Cu(OCOCH_3)_2$
25	290 s/330 s	300 s/320 m	300 s	300 s
55	300 s/340 s	360 s/550 w	320 s	335 s

* Intensity of the exothermic effect: s, strong; m, medium; w weak

xerogels, especially those prepared at 55°C, differ in the degree of condensation. The xerogels prepared at 55°C have a high degree of condensation and contain substantial amount of intraglobular alkoxy groups, which is indicated by the weight loss at 200–450°C (especially for copper silicates prepared from copper chloride and copper nitrate) and the shift of the exothermic peak to higher temperatures.

Thus, the structures of both siloxane skeleton and the Si–O–Cu–O–Si fragments of the polymers prepared at 25 and 55°C differ substantially. Either cross-linked or cyclolinear polymers are formed depending on the anion of the initial copper salt and the reaction conditions. The degree of copolycondensation (the copper content in the xerogel) depends on both the anion of the copper salt and the reaction conditions (temperature and pH of the reaction mixture).

Water sorption by the polycupraethoxysiloxanes depends on the anion of the copper salt. Xerogels prepared from $CuSO_4$, $CuCl_2$, $Cu(NO_3)_2$, and $Cu(OCOCH_3)_2$ adsorb 25.3, 21.7, 17.9, and 34.5 wt % water, respectively.

CONCLUSIONS

(1) The degree of hydrolytic copolycondensation of ethyl silicate with copper salts in the presence of a base catalyst (NH_4OH) without organic solvent and the composition and properties of the polycupraethoxysiloxanes are determined by the anion of the copper salt, temperature, and pH of the reaction mixture.

(2) Cuprasiloxanes prepared from $CuSO_4$, $CuCl_2$, and $Cu(OCOCH_3)_2$ have three-dimensional cross-linked structure. The structure of the polymers prepared from $Cu(NO_3)_2$ is cyclolinear.

BRIEF COMMUNICATIONS

Solubility in the NaCl–$(C_2H_5)_2NH$–H_2O System at 50°C

V. A. Panasenko and S. A. Mazunin

State Research and Planning Institute of Basic Chemistry, Kharkov, Ukraine
Perm State University, Perm, Russia

Received February 21, 2003; in final form, June 2004

Abstract—The solubility in the system NaCl–$(C_2H_5)_2NH$–H_2O at 50°C was studied. The shape of the solubility isotherm was analyzed.

The NaCl–$(C_2H_5)_2NH$–H_2O system at 50°C, which determines the preparation conditions of a saturated solution of sodium chloride (mass fraction of NaCl is 26% [1–3]) and diethylamine, has not been described in the literature. The phase equilibria in the NaCl–$(C_2H_5)_2NH$–H_2O system are known only for 10, 20, and 30°C [1, 2].

The main method of studying solubility is the modified method of residue [3–5]. In the modified method, we used the compositions of the saturated solution and initial reaction mixture, instead of residue, to calculate the composition of the equilibrium solid phase. The mass ratio of the components in the initial mixture samples was chosen so that the compositions were heterogeneous and the mass ratios of the solid to liquid phase did not exceed 2 : 5. When studying the monotectic region, in which two liquid phases and NaCl crystals coexist, we used the half-sum of the contents of the system components in the upper and lower liquid phases. Equilibration was judged by constancy in three measurements of the refractive index of the liquid phase, which is a physical property of a medium that can be determined readily and accurately. The measurements were performed on an RL1 refractometer in 30-min intervals. The measurements started after thermostating for 3 h at 50 ± 0.1°C.

The Na^+ ions were determined by the flame photometry on a Zeiss photometer and an F-30 digital recorder. Practically, the determination was performed as follows: Three different weighed portions, sampled after the thermostating, were placed into 0.1 dm^3 volumetric flasks, and distilled water was added to the mark. Then the flame intensity was determined with samples from all the three flasks. After that, the intensity of 3–5 reference solutions was measured. We used reference NaCl solutions of the concentrations from 0.0001 to 0.1 mol dm^{-3}, prepared from reference samples.

The concentration of the Na^+ ions was determined from the linear dependence of the flame intensity on the logarithm of the concentration.

The molal concentrations of the sodium ions (mol kg^{-1}) in the weighed portions were calculated by the formula:

$$[Na^+] = \frac{c_{Na^+} VR}{m}, \quad (1)$$

where c_{Na^+} is the molar concentration of a sodium cation in the volumetric flask, as determined by the linear interpolation (mol dm^{-3}); V, flask volume (ml); R, dilution of the solution; and m, mass of the weighed portion m (g). The unknown quantity was determined as the mean of the three obtained values.

The content of the chloride ions was determined by argentometric titration [4, 5]. The equivalent point was determined from the functional dependence of the silver electrode potential on the amount of the $AgNO_3$ solution added. A glass electrode was the reference. The test solution was acidified with an 85% H_3PO_4 solution (1 ml). The potential of the silver electrode in the course of the titration was measured with an EV-74 pH meter.

The molal concentration (mol kg^{-1}) of the chloride ions was calculated by the formula

$$[Cl^-] = \frac{V_{AgNO_3} c_{AgNO_3} K_{AgNO_3} R}{m}, \quad (2)$$

where V_{AgNO_3} is the volume of $AgNO_3$ solution spent for titration (ml); c_{AgNO_3}, concentration of $AgNO_3$

Solubility in the NaCl–$(C_2H_5)_2NH$–H_2O system at 50°C

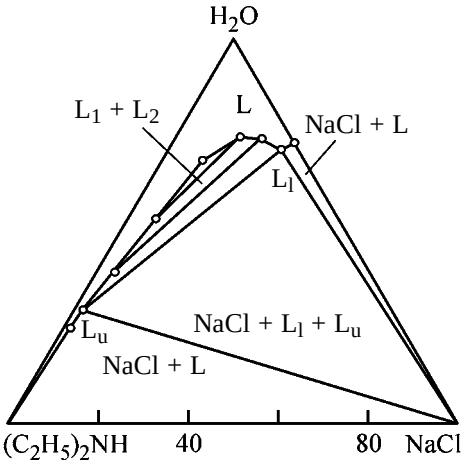
Component content in liquid phases, wt %			Solid phase
NaCl	$(C_2H_5)_2NH$	H_2O	
8.7	22.7	68.6	–
6.0/13.9*	40.6/11.1	53.4/75.0	–
3.6/19.1	56.6/6.4	39.8/74.5	–
1.65/25.0	68.9/3.5	29.45/71.5	NaCl
1.3	73.9	24.8	NaCl
26.9	–	73.1	NaCl

* Numerator, component content in the upper liquid phase L_u; denominator, that in the lower liquid phase L_l.

solution (for titration we used a 0.05 M solution); K_{AgNO_3}, correction coefficient of $AgNO_3$ solution; *R*, dilution (part of the weighed portion taken for the titration); and *m*, mass of the weighed portion (g).

The diethylamine content was determined by direct potentiometric acidometric titration [5]. The functional dependence of the pH of the titrated solution on the amount of the acid solution added has a single pH jump. The titration was done on a T-108 automated titrator by determining the volume of a 0.1 M HCl solution spent for the titration to the equivalent point. The pH value was measured on a pH-121 device.

We used chemically pure grade NaCl and pure grade diethylamine distilled at the boiling point (55.6°C).



Solubility in the NaCl–$(C_2H_5)_2NH$–H_2O system at 50°C.

The experimental solubility data are presented in the table and in the figure.

The solubility isotherm of the system is monotectic. The following areas were revealed: the area of the unsaturated solutions L, the area of the two-phase liquid equilibrium $L_1 + L_2$, the three-phase area in which NaCl crystals and two liquid phases NaCl + L_l + L_u coexist, and the area of the NaCl (NaCl + L) crystallization, broken by the monotectic area into two parts.

The composition of the liquid phases in monotectic equilibrium with the NaCl crystals is as follows (wt %): NaCl 1.65, $(C_2H_5)_2NH$ 68.9, H_2O 29.45 (point L_u); NaCl 25.0, $(C_2H_5)_2NH$ 3.5, and H_2O 71.5 (point L_l).

As seen from the phase diagram, the largest area is occupied by the fields of the NaCl crystallization and by the monotectic field of the three-phase equilibrium; the field of coexistence of two liquid phases and the field of unsaturated solutions occupy a smaller area.

CONCLUSIONS

(1) The solubility in the NaCl–$(C_2H_5)_2NH$–H_2O system at 50°C was studied.

(2) The solubility isotherm is monotectic. Diethylamine exerts the salting-out effect on NaCl and forms a system of two liquid phases with NaCl solutions at 50°C.

Abstract—Preparation of ultradispersed transition metals (20–100 nm) by reduction of metal complexes in molecular microreactors (cavities of immobilized calixarenes, polyelectrolytes) was studied.

Preparation and study of untradispersed metals and preparation of functional materials on their base are urgent problems of modern science [1]. It is known [2] that cross-linked polymers (polyelectrolytes) can be used as matrices for preparing ultradispersed metals. Cavities, complexes, and intercalated compounds contained in cross-linked polymers are immobilized microreactors providing certain spatial organization of molecules [3]. A study of processes occurring in immobilized microrecators gives insight into highly organized chemical transformations in supramolecular systems.

Previously [4] we prepared new cross-linked polymers with grafted *cis*-calix[4]resorcinolarene derivatives capable of forming intercalation compounds [5], i.e., having properties of a microreactor.

The aim of this work was to prepare ultradispersed transition metals in cross-linked polymers (polyelectrolytes), to study their catalytic activity in hydrogenation of organic nitro compounds, and to use *cis*-calix[4]resorcinolarenes immobilized in the polymeric matrix as microreactors for reduction and hydrogenation.

EXPERIMENTAL

Ultradispersed metals (Pd, Cu, and Ni) were prepared in pores of KU-2-12P and KU-23 sulfonic cation exchangers, AV-17 anion exchanger, and cross-linked polymer with immobilized *cis*-tetraphenylcalix[4]resorcinolarene groups. The Cu^{2+}, Ni^{2+}, and $[Pd(NH_3)_4]^{2+}$ cations were introduced in the sulfonic cation exchanger by the ion-exchange procedure. Reduction of palladium(II) tetraammine complex in the matrix yields 20–100-nm palladium particles. The X-ray pattern of KU-23 macroporous sulfonic cation exchanger containing palladium crystals is shown in Fig. 1.

The X-ray patterns were recorded on a DRON-2 diffractometer (copper radiation, voltage on the X-ray tube 30 kV, current 20 mA, scan rate 2 deg min^{-1}). The X-ray pattern contain reflections of crystalline palladium and a broad reflection of the amorphous polymer at 20°. The palladium content in the samples determined from the reflection intensity varies by an order of magnitude. The palladium dispersity calculated from the width of the reflection at 36° is 30–50 nm.

Pomogailo [2] showed that transition metal nanoparticles are formed by reduction of their cations in an ion-exchange matrix. When the dynamic ion-exchange capacity is completely saturated with transition metal amine complexes, the reduced metal particles form the metallic phase owing to short effective distance between the particles [2]. The catalytic activity of these materials is low. For the ultradisperse phase to be formed, palladium cations should occupy less than 0.2–0.3 of the total exchange capacity of KU-23 sulfonic resin. The catalytic activity at the palladium

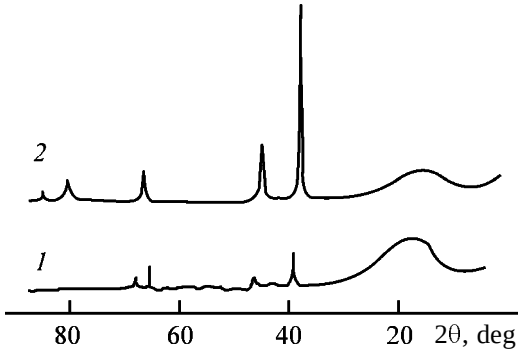

Fig. 1 .X-ray pattern of KU-23 30/100 macroporous sulfonic cation exchanger containing (*1*) 5.1 and (*2*) 34 g md^{-3} palladium(II). (2θ) Bragg angle.

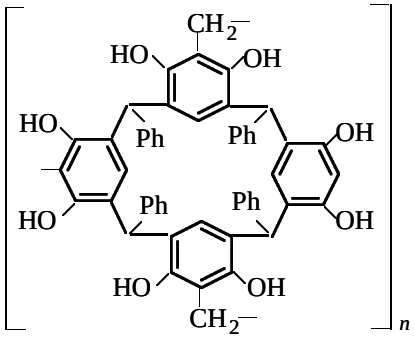
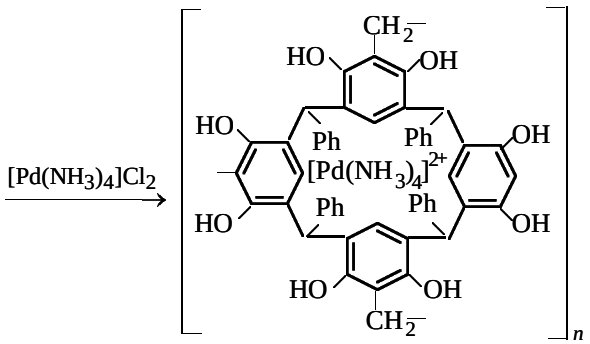
concentration corresponding to the total exchange capacity (65 g dm^{-3}) and at a low palladium concentration (<5 g dm^{-3}) is low.

We used KU-23 sulfonic cation exchanger containing Pd^0 as a heterogeneous catalyst for hydrogenation of nitro compounds that are intermediates in synthesis of dyes and pharmaceuticals (nitromethane, nitrobenzene, *p*-nitrobenzoic acid, and ethyl *p*-nitrobezoate). KU-23 30/100 sulfonic action exchanger containing 20–30 g dm^{-3} of 30–50-nm Pd^0 particles had the highest catalytic activity (2.6×10^{-3} mole H_2/min per gram of Pd^0).

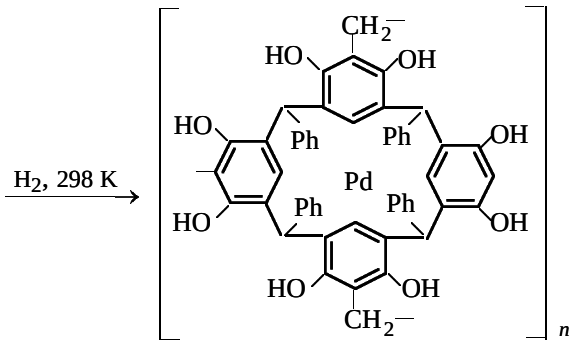
The reactions occurring in a microreactor based on *cis*-calix[4]resorcinolarene can be described by the following scheme:



(1)



(2)



(3)

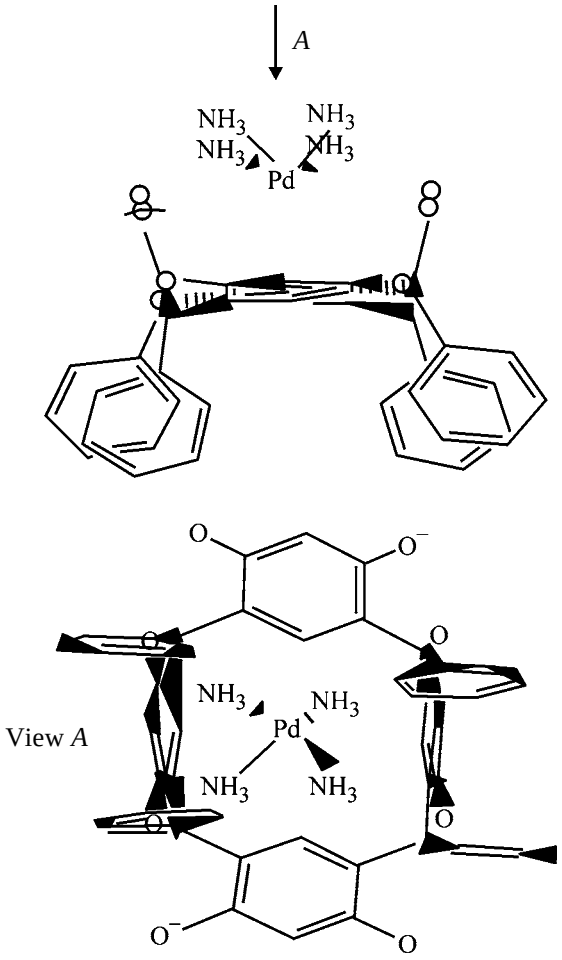


Fig. 2. Structure of the $[Pd(NH_3)_4]^{2+}$ complex with *cis*-tetraphenylcalix[4]resorcinolarene (MM2 calculation).

Three-dimensional cross-linked polymer (1) with grafted calixarene was prepared by polycondensation of *cis*-2,8,14,20-tetraphenyl-4,6,10,12,16,18,22,24-octahydroxycalix[4]arene with formaldehyde [4]. Metal ions were introduced in the polymer by sorption of Ni^{2+} and Pd^{2+} ammine complexes from aqueous solutions. The concentration of metal complexes in the solutions was chosen so as to provide the metal–polymer molar ratio of no more than 1. The structure of the $[Pd(NH_3)_4]^{2+}$ complex with *cis*-tetraphenylcalix[4]resorcinolarene, optimized by the MM2 method, is shown in Fig. 2.

Polymer (3) containing ultradispersed palladium is formed by hydrogenation of metal-containing polymer (2) at 298 K and 1 atm. Polymer (3) is hydrogenated at 600–650 K and 1 atm. The amount of consumed hydrogen, analysis of the thermolysis products, and the IR spectra of the polymers containing calix[4]resorcinolarene fragments [6] suggest formation of perhydroxanthene structures in the polymeric

matrix. These substances are new types of cavitands. Thus, palladium nanoparticles in polymer (3) catalyze hydrogenation of the surrounding benzene rings to form a new molecular reactor containing Pd^0 in the immobilized perhydroxanthene.

CONCLUSIONS

(1) Metal nanoparticles (20–100 nm) were prepared by reduction of transition metal (Pd^{2+}, Cu^{2+}, and Ni^{2+}) ammine complexes in the matrices of sulfonic cation exchnagers containing *cis*-calix[4]resorcinolarene fragments.

(2) KU-23 30/100 sulfonic cation exchanger containing 20–30 g dm^{-3} of 30–50-nm palladium(0) particles exhibits high catalytic activity in hydrogenation of nitro compounds.

Abstract—The heat effects of dissolution of two pairs of polyvinyl alcohols used as emulsifiers in suspension polymerization of vinyl chloride and the optical transmission of their stirred aqueous solutions as a function of time were determined.

One of the ways to improve the synthesis of suspension polyvinyl chloride (PVC) is the choice of emulsifying systems providing, in particular, production of a polymer with uniform grain size distribution with the minimal content or absence of so-called "fish eyes" having good ability to absorb the plasticizing agent. The following emulsifying systems are most frequently used: methyl cellulose derivatives [1], polyvinyl alcohols (PVAs) with various compositions and molecular weights [2–4], blends of PVAs with methyl cellulose derivatives [5–7], and blends of various PVAs [8].

In recent years, in synthesis of suspension PVC, preference is given to two-component emulsifying systems based on PVAs differing in the chemical structure and molecular weight. The component with a higher molecular weight, with the degree of hydrolysis of 70–80%, provides aggregative stability of the emulsion and polymer–monomer particles. The component with a lower molecular weight provides porosity of the polymer grain due to partial dissolution in drops of the polymerizing monomer. Here we attempted to find a criterion of choice of emulsifiers based on PVA by comparison of their characteristics with those of PVC to be synthesized. As the subjects of the study we used PVA of the Alcotex 72.5 and 552P brands (from here on, A-72.5 and A-552P) produced in the United Kingdom and of the L-9 and LM-20 brands produced in Japan. The first and the third are stabilizing agents for emulsion, and the second and the fourth are the modifying agents for morphology of the polymer grain. The characteristics of these products are given in the table.

EXPERIMENTAL

The enthalpy of solution was determined in a DAK-1A microcalorimeter of the Calvet type [9, 10]. The electric scheme of the measurement provides determination of heat release to no less than 98%. In each run, the calorimeter was calibrated by an electric current. The metrological characteristics were checked by measuring the standard enthalpy of solution of potassium chloride (chemically pure grade) in double-distilled water. The average determined from ten measurements was 17.7 ± 0.3 kJ mol^{-1} at 298.15 K. According to published data [11], this value is 17.58 ± 0.228 kJ mol^{-1}. The samples were prepared by grinding of PVA films prepared by casting. The films were dried in air to constant weight. The optical transmission of PVA solutions was determined on an FEK-3 photocolorimeter.

First and foremost, it was necessary to elucidate possible differences in the intensity of intermolecular

Characteristics of polyvinyl alcohols used in suspension polymerization of vinyl chloride

PVC	Color	Degree of hydrolysis, %	ΔH_{sol}, kJ g^{-1}

Optical transmission T as a function of time τ for aqueous solutions of PVC blends used as two-component emulsifying systems in suspension polymerization of vinyl chloride. (*1*) L-9 (0.18%)–LM-20 (0.06%) and (*2*) A-72.5 (0.15%)–A-552P (0.06%).

interaction between the components of two emulsifying systems and their solubility in the aqueous phase. It was assumed that both factors will affect the optical transmission of polymer solutions. The dependences of the optical transmission on time are shown in the figure. It is seen that the optical transmission of the solution of the blend of L-9 and LM-20 polymers abruptly decreases with time (with stirring of the solution), while for the blend of A-72.5 with A-552P the trend is inverse. These data suggest formation of associates of macromolecules in the first system and their degradation in the second system during stirring.

The enthalpies of solution of individual polymers and their blends are presented in the table. In their interpretation, account must be taken of the components of the total effect. According to published data [12], the energy of intermolecular interaction in PVA per hydroxy group is approximately 30 kJ mol^{-1}. The energy of hydrogen bonds of water molecules is 20–25 kJ mol^{-1}. Since dissolution of PVA is an exothermic process, it should be assumed that the strength of the hydrogen bonds formed by the hydroxy groups of this polymer with water is higher than the above values. Hence, we can conclude that, with increasing degree of hydrolysis of PVA, the exothermic effect of its dissolution in water increases. Indeed, PVAs of the L-9 and A-72.5 brands with a high degree of hydrolysis dissolve with a greater heat evolution as compared to PVAs of the LM-20 and A-552P types with an intermediate degree of hydrolysis.

The data listed in the table are in good agreement with this conclusion as applied to A-552P and LM-20. However, A-72.5 and L-9 have close degrees of hydrolysis and noticeably different enthalpies of solution. The deeper color of L-9 suggests higher degree of dehydration of this polymer compared to A-72.5. This change in color is equivalent to decreased degree of hydrolysis of PVA.

Thus, dissolution of PVA should be accompanied by energy evolution, which is the greater, the higher the degree of hydrolysis of PVA. These trends suggest an increase in the intensity of polymer–solvent interaction and a decrease in the polymer–polymer associative interactions (see figure). It is seen that the optical transmission of the stirred solution of the L-9 and L-20 blend decreases in time, while in the case of the polymer–polymer system the optical transmission increases. This suggests formation of aggregates of molecules in the first case and their degradation in the second case.

It was found that PVC prepared using a blend of L-9 with LM-20 does not meet the requirements of GOST (State Standard) imposed on granulometric composition, mainly due to the presence of a fraction of coarse particles, and also on the bulk density, which is equal to 0.39–0.45 g cm^{-1}, whereas the prescribed density is 0.45–0.55 g cm^{-1}. These deviations can be explained by a decrease in the relative amount of emulsifier macromolecules participating in stabilization of PVC drops, because of the tendency to polymer–polymer interaction caused by insufficient degree of hydrolysis. This follows from the calorimetric measurements and variation of the optical transmission of PVC solutions in stirring. The low degree of hydrolysis of the second component of this emulsifying mixture used as a modifying agent of PVC grain results in its increased affinity for the oil phase and, hence, in its increased content in PVC drops. As a result, the porosity of PVC particles increases.

Thus, we suggest a new approach to the choice of an optimal emulsifying system, based on determination of the enthalpy of solution and evaluation of polymer–polymer interactions of its components.

CONCLUSIONS

(1) A blend of polyvinyl alcohols of the A-72.5 and A-552 brands dissolves with a greater heat effect in comparison with a blend of L-9 and LM-20. For the first blend, the optical transmission of the stirred solutions increases with time, whereas for the second blend it decreases.

(2) Polyvinyl chloride prepared using the A-72.5 + A-552P blend meets all the requirements of GOST

(State Standard), while the polyvinyl chloride synthesized in the presence of a blend of L-9 and LM-20 does not meet the requirements imposed on the granulometric composition and bulk density, which is explained by the results of this work.

Influence of Various Additives on Base Hydrolysis of Chlorine-Containing Organic Impurities in Naphtha Fractions

A. F. Gogotov, Ya. N. Silinskaya, V. Yu. Kolotov, and V. P. Tomin

Angarsk Petrochemical Company, Joint-Stock Company, Angarsk, Irkutsk oblast, Russia

Received June 30, 2004

Abstract—Degree of dechlorination of chlorine-containing naphtha fractions in the course of their base hydrolysis in the presence of phase-transfer catalyst and other compounds was studied. The optimal type of the phase-transfer catalyst was determined.

Recently, many oil refineries faced with a problem of refining of oil containing more than 20×10^{-4} wt % organochlorine compounds (OCCs) [1]. These compounds seriously disturbed operation of main oil-refining apparatus and made the facilities inoperative owing to strong corrosion. Procedures for removing organochlorine impurities from naphtha are intensively developed. One of these methods of dechlorination of straight-run naphtha fractions is base hydrolysis to form inorganic chlorides which can be extracted into an aqueous phase and then separated in reflux vessels by distillation of oil under atmospheric pressure.

The aim of this work was to increase the degree of hydrolytic removal of organochlorine compounds from naphtha fractions.

EXPERIMENTAL

In our experiments, we added di- and trichloropropanes to naphtha fractions. Naphtha fractions containing $(9.8–72.8) \times 10^{-4}$ wt % OCCs and boiling in the range 80–180°C were dechlorinated for 0.5–4 h in an autoclave under the static conditions in the temperature range 20–250°C. Alcohols, dimethyl sulfoxide (DMSO) of pure grade, and polyethylene glycol (PEG) and polypropylene glycol (PPG) with different molecular weights were studied as additives catalyzing the hydrolysis. The chlorine content in organic compounds was determined by the coulometric procedure [2].

The degree of hydrolysis of OCCs present in straight-run naphtha depends on their nature. Chlorinated paraffins are hydrolyzed at room temperature. The content of these compounds in naphtha decreases by ~17–18% after contact with 10% aqueous NaOH solution (Table 1, run no. 1). At 180°C, the degree of dechlorination γ increases to approximately 60% (Table 1, run no. 3).

It is known that PEGs of various molecular weights catalyze hydrolytic processes, e.g., hydrolysis of polychlorinated diphenyls [3]. Indeed, in the presence of PEG the content of organic chlorine in chlorine-containing naphthas can be decreased by ~60% at lower temperature (Table 1, run nos. 4 and 5). We studied hydrolysis of OCCs at various temperatures in the presence of a phase-transfer catalyst (PTC). The highest degree of dechlorination (85%) was observed at 210°C.

PEG was considered as both alcohol and alkylating agent [3]. At the same time, PEGs and PPGs of various molecular weights are PTCs along with tetraethylammonium salts, crown ethers, and other compounds [4]. To determine the function of PEGs in hydrolysis of OCCs (3 h, 180°C), we estimated the degree of hydrolysis in the presence of various alcohols and DMSO (Table 2).

The degree of OCC hydrolysis in the presence of

28	37.6	PEG-Keres 2000	13.6	63.8
29	37.6	PEG-Keres 3000	12.7	66.2

* Weight 1.4 g.

alcohols is substantially lower than that in the presence of PEG. Butan-1-ol, its higher homologs, and glycerol do not catalyze the hydrolysis. On the contrary, the catalytic effect of DMSO (run no. 14) and TEA (run no. 16) is similar to that of PEG. It is known that PEG, DMSO, and TEA create "superbasic" effect in alkaline solutions, i.e., provide the best conditions for a base-catalyzed chemical reaction. As seen from Table 2, the degree of OCC hydrolysis in the presence of PEG-600, PEG-400, and PEG-300 is maximal; its is slightly lower in the presence of PEG-Polioks, PEG-Keres 3000, PEG-Keres 2000, PEG-4000, PEG-1500, PEG-20 000, and PEG-1540. Polypropylene glycol PPG-4251 (run no. 27) cannot be used as PTC. In the subsequent experiments we used PEG-600, PEG-400, and PEG-300 as PTCs. In the presence of PEG-600, about 91% of OCCs is hydrolyzed at 210°C in 3 h.

CONCLUSIONS

(1) The degree of hydrolysis of organochlorine compounds in straight-run naphtha with sodium hydroxide solutions at room temperature is 17%. The degree of hydrolysis increases with temperature.

(2) The most promising additives catayzing the hydrolysis are polyethylene glycols with molecular weight from 300 to 600, dimethyl sulfoxide, and triethanolamine. In the presence of these compounds (2 wt %), about 80 and 90% of organochlorine compounds can be hydrolyzed in 3 h at 180 and 210°C, respectively.

Oxidation of Propylene and Isobutylene in a Reactor with Barrier Discharge

S. V. Kudryashov, A. Yu. Ryabov, E. E. Sirotkina, and G. S. Shchegoleva

Institute of Petrochemistry, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received April 20, 2004

Abstract—The oxidation of propylene and isobutylene in barrier-discharge plasma in the presence of octane was studied. The possible reaction mechanism was considered.

Recently, the interest in organic synthesis in electric discharges has been increasing. However, development of new technologies based on electric discharges is hindered by the lack of a sufficiently large body of data on the mechanisms and kinetics of conversion of organic compounds in plasma, which is, as a rule, caused by the low selectivity of the occurring reactions, tarring, and deep degradation of organic molecules.

We have shown previously that oxidation of hydrocarbons belonging to various classes without formation of tars and products of complete oxidation is possible in a barrier discharge [1]. This is achieved by effective removal of reaction products from the zone of the barrier discharge with a hydrocarbon film formed by condensation of supersaturated vapor of a hydrocarbon on the cooled reactor walls. For example, oxidation of hexane, cyclohexane, and cumene mainly yields hydroxy and carbonyl compounds: alcohols, aldehydes, and ketones with the same number of carbon atoms as that in the starting compound. The product formed in oxidation of cyclohexene is epoxycyclohexane (62 wt %).

It was shown in [2] that the selectivity of cyclohexene oxidation can be, in principle, controlled. The maximum yield of cyclohexene oxide was ~72%. However, products of oxidation of light olefins are of greater importance for petrochemical synthesis.

In this work we studied oxidation of propylene (PR) and isobutylene (IB) in a reactor with a barrier discharge.

EXPERIMENTAL

PR and IB were oxidized in the presence of octane to create a hydrocarbon film in which reaction products are dissolved and are thereby removed from the zone of the barrier discharge. A flow-through gas-discharge reactor of coaxial design was used. The experimental setup has been described in detail previously [1].

The starting parameters of the process were as follows: flow rate of oxygen, olefin, and octane through the reactor 3.0, 0.6, and 6×10^{-3} l h^{-1}, respectively; temperature of the reactor walls 10°C; atmospheric pressure; amplitude of voltage pulses 12 kV; pulse repetition frequency 500 Hz; specific energy of the discharge 1.3 Wh l^{-1}.

The liquid reaction products were analyzed by gas chromatography: heat-conductivity detector in the isothermal mode at 120°C; 1.2-m-long packed column with an inner diameter of 3 mm; sorbent Porapak-Q; carrier gas helium.

The conversions and the composition of products formed in oxidation of PR and IB are listed in the table. It can be seen that the main reaction products are the corresponding epoxides. In contrast to the oxidation of cyclohexene, the oxidation of PR and IB is accompanied by degradation of the olefin molecule to give methanol and formaldehyde. At the same time, no CO, CO_2, acids, or tarring products were found in the reaction products, which constitutes a fundamental difference between the results of this study and those of previous studies of oxidation of light olefins in electric discharges [3–5].

It should be noted that octane is oxidized simultaneously with the olefins. The conversion of octane is ~0.5 wt % in both cases. As a result, hydroxy and carbonyl compounds characteristic of octane oxidation products are formed [6].

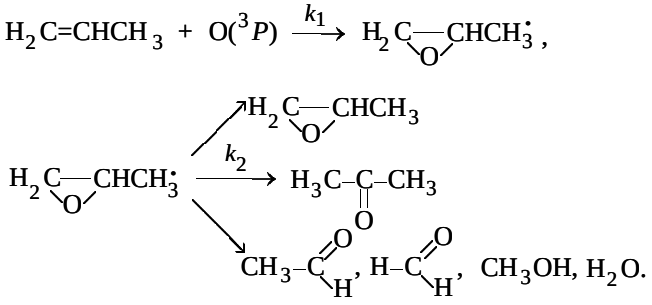
A possible mechanism of cyclohexene oxidation

1070-4272/04/7711-1904 © 2004 MAIK "Nauka/Interperiodica"

was suggested in [2]. In this mechanism, the reaction products are formed by two pathways. The first of them yields cyclohexene oxide, cyclohexanone, and cyclopentylmethanal, and the second, cyclohexenone, cyclohexenol, and bicyclohexenyl.

No unsaturated oxygen-containing compounds were found in oxidation products of PR and IB, which suggests that the reaction predominantly goes by the first pathway involving activation of oxygen molecules by electron impact. This can be attributed to the higher dissociation energies of PR and IB molecules, compared with those of cyclohexene and oxygen molecules [7].

By analogy with the previously suggested mechanism of cyclohexene oxidation, the possible mechanism of PR oxidation can be represented as



Acetaldehyde, formaldehyde, methanol, and water are formed by decomposition of a "hot" molecule of propylene oxide, with the resulting fragments subsequently involved in radical reactions. In the case of cyclohexene oxidation, the hot molecule of olefin oxide does not decompose [1, 2].

The validity of the suggested mechanism of PR and IB oxidation can be verified by simple calculations. For the oxidation of olefins, which occurs in a reactor with a steady flow mode, the following expression is valid:

$$w_1/w_2 = X_1/X_2, \quad (1)$$

where w_1, w_2, X_1, and X_2 are the oxidation rates and conversions of PR and IB, respectively.

In terms of the oxidation mechanism suggested, the following expression can be written for the oxidation rate of PR:

$$w_1 = \mathrm{d}[C_3H_5]/\mathrm{d}\tau = k_1[O(^3P)][C_3H_6]. \quad (2)$$

A similar expression can be written for w_2.

At a constant discharge power and all other experimental conditions being the same, the rates of generation of atomic oxygen in mixtures of oxygen with PR and IB will be the same, because their molecules have close cross sections of electron energy scattering. Therefore, the composition of the gas mixtures has no effect on the average electron energies. Hence, expression (1) can be written as

$$k_1'/k_1'' = X_1/X_2, \quad (3)$$

where k_1' and k_1'' are the rate constants of interaction of atomic oxygen with PR and IB, respectively. The results of calculation by expression (3) are given below:

$$\frac{k_1'}{k_1''} = \frac{2.2 \times 10^{12}\ \mathrm{cm^3\ mol^{-1}\ s^{-1}}}{2.2 \times 10^{13}\ \mathrm{cm^3\ mol^{-1}\ s^{-1}}} = 0.183\ [8],$$

$$X_1/X_2 = 1.56/6.74 = 0.231.$$

It can be seen that the calculation results reasonably agree with the experiment. The calculation error is 20.9%.

Conversions X and composition of products formed in oxidation of PR and IB*

Olefin	X, wt %	Oxidation products	Selectivity, wt %
Propylene	1.56	Propylene oxide	43.3
		Acetone	30.9
		Acetaldehyde	10.2
		Methanol	3.4
		Water + formaldehyde	12.2
Isobutylene	6.74	Isobutylene oxide	43.8
		2-Methylpropanal	23.9
		Acetone	19.2
		Methanol	4.6
		Water + formaldehyde	8.5

* Conversion obtained in a single pass of the starting mixture through the reactor at a time of contact with the discharge zone equal to ~10.5 s.

CONCLUSION

Oxidation of propylene and isobutylene by oxygen in the plasma of a barrier discharge allows synthesis of oxides of light olefins without formation of tars or complete oxidation.

INFORMATION

15th Annual BCC Conference on Flame Retardancy

The 15th Annual Conference on Flame Retardancy was held from June 6 to 9, 2004 in Stamford, Connecticut (the United States). The Conference was focused on recent advances in flame retardancy of polymeric materials (materials, applications, research and industrial developments, markets).

The conference started from performing the Intensive Short Course in Research, Production, and Marketing of Flame Retardancy of Polymeric Materials. The Course Director was Professor M. Lewin (the United States), and the Course Instructors were E.D. Weil, S. Levchik, and M.L. Janssens. The topics discussed in the Course were as follows:

(1) Principles of flammability and fire hazards: scheme of polymer combustion; energy balance; pyrolysis and structure of polymers; ignition and its sources; burn injury; spread of flame; smoke hazard.

(2) Flame retarding polymers: textile fabrics vs. plastics; processing systems; topical, reactive and nonreactive systems; flammability properties; other product properties.

(3) Review of flame-retardant chemicals based on: phosphorus, sulfur, halogens, antimony, nitrogen, boron, aluminum, magnesium, and others.

(4) Mechanisms of flame retardancy: gas-phase mechanism: radical scavenging in the flame; synergism in gas-phase systems: antimony trioxide, halogen blends; condensed-phase mechanism: reactions in the polymer phase, dehydration, char formation; intumescence and char properties, synergism in the condensed phase; mechanism based on physical effects in the gas phase; endothermic flame retardancy.

(5) Survey of flame retardancy of all significant plastics and textile fabrics: flame retardants in commercial use and some guidelines regarding their selection; problems of cost and effect on properties; unsolved or inadequately solved problems of interest for R&D.

(6) Discussion of material flammability, including effects of: heat and ignition sources; specimen size; shape and orientation.

(7) Standard-making and regulatory organizations: ASTM, ISO, ANSI, NFPA; Uniform building code; US Government, state regulatory; industry standards.

(8) Properties measured by fire tests: ignition; ease of extinction; flame spread; heat release rate; evolution of smoke and toxic or corrosive products.

(9) Fire test methods, grouped as: small scale, intermediate scale, full scale, and very large scale tests; research and development, regulatory, litigation.

The reports presented at the Conference were discussed in five sessions. Session I "General Mechanisms of Flame Retardancy" [chairmen: G.L. Nelson (the Unites States) and G. Camino (Italy)] included seven oral presentations. M. Nyden (the Unites States) in his lecture reported on the mechanism of the photolytic breakdown of decabromodiphenyl ether in plastics. Analysis of flammability of brominated epoxides was made in the lecture prepared by S. Stoliarov, R. Walters, S. Crowley, Q. Williams, and R. Lyon (the Unites States). The problems of charring and intumescence were discussed in the report of B. Schartel, M. Bartholmai, and U. Braun (Germany). The group of scientists (D. Price, T.R. Hull, G.J. Milnes, and L.K. Cunliffe) from the Center for Materials Research and Innovation (UK) reviewed current mechanistic and combustion product studies concerned with flame retardant systems. In his plenary lecture entitled Challenges in Flame Retardancy of Polymers, M. Lewin analyzed the future prospects in this field. Two last lectures of Section I were devoted to the problems of utilization of waste materials released in the course of intumescence [L.R.M. Estevro and R.S.V. Nascimento (Brazil); M. Le Bras, S. Bourbigot, and R. Delobel (France)] and of retardant release from materials [G.C. Stevens and J.L. Thomas (UK)].

Session II "Halogen- and Non-Halogen-Based FR Systems" [chairmen: G. Kirshenbaum and K. Shen (the Unites States) and T.R. Hull (UK)] included nine presentations. R.E. Lyon (the United States) reported on fire-smart chloral polymers, and the group of Hungarian researches (G. Marosi, A. Toldy, P. Anna, E. Zimonyi, S. Keszei, W. Krause, and S. Horold), on flame retardant mechanism and application of synergistic combinations of phosphinates. Flame retardant systems for textile back-coating applications were considered in the lecture prepared by R. Mazor, M. Peled, O. Ben-Vais, N. Zer-Zion, A. Shoshan, and I. Shalev (Israel). Yukihiro Kiuchi, Masatoshi Iji, and Makoto Soyama (Japan) reported on self-extinguishing

1070-4272/04/7711-1907 © 2004 MAIK "Nauka/Interperiodica"

epoxy resin compound and improvement of its flame resistance. The lecture prepared by the large German team (M. Doering, C. Kollann, M. Ahlmann, U. Dittrich, B.Just, H. Keller, V. Altstadt, H. Lengsfeld, R. Perez, D. Pospiech, and T. Hoffmann) was devoted to new phosphorous-containing flame retardants for epoxy resins. Reaction mechanisms of melamine-based flame retardants were discussed in the lecture prepared by N.J.J. Aelmans (Switzerland), N. Kaprinidis (the United States), and R. Kierkels and R. Steenbakkers (the Netherlands). R.L. Markezich (the United States) reported on low-smoke formulations for FR resins, and K.K. Shen and E. Olson (the United States), on the use of borates as fire retardants in halogen-free polymers. The last lecture of Session II [J. Kim (Korea)] was devoted to the effect of phenolic char former and oligomeric aryl phosphate mixtures on the flame retardance enhancement of ABS plastics.

Session III "Nano-Composites" [chairmen: D. Price (UK) and R. Kozlowski (Poland)] included six presentations. G. Camino (Italy) gave the lecture entitled Which Morphology for Nanocomposites FR C.A. Wilkie reported on advances in FR of polymer–clay nanocomposites. Researches from the United States (E.D. Weil, M. Lewin, K. Shen, and D. Rao) devoted their lecture to searching for interactive FR systems for EVA. The performance characteristics of PET/silica nanocomposites prepared via extrusion were considered in the lecture prepared by G.L. Nelson, Feng Yang, and C. Johnsrud (the United States).

The last two presentations of Session III were focused on the problems of evaluation of hydroxy double salts as fire retardant additives [J.M. Hossenlopp (the United States)] and flammability, degradation, and structural characterization of fiber-forming polypropylene nanocomposites [S. Zhang, A.R. Horrocks, T.R. Hull, B.K. Kandola, and D. Price (UK)].

Session IV "Consumer Focus/Industrial Products" [chairmen: C.A. Wilkie and S.V. Levchik (the United States)] included six presentations. Latest progress in rigid fire barriers was the subject of the lecture prepared by R. Kozlowski, B. Mieleniak, R. Gyrski, A. Przepiera, and K. Bujnowicz (Poland). T. Chen and T.J. Lynch (the United States) reported on the effect of surface treatment with magnesium hydroxide for flame-retardant wire and cable and TPO roofing compounds. C.Q. Yang, W. Wu, and H. Yang (the United States) considered applications of hydroxy-functional organophosphorus oligomers as a durable flame-retarding finishing agents for cotton and cotton/polyamide blends.

The next presentation was devoted to exploring issues surrounding flame retarded plastics used in electrical and electronic equipment [R.B. Dawson and S.D. Landry (the United States)]. S.V. Levchik reported on halogen-free printed wiring boards, O. Figovsky, V. Karchevsky, and D. Bellin (Israel) reviewed recent developments in waterborne compositions.

Finally, Section V "Testing/Standards/Methods" [chairmen J.S. Stimitz and M.M. Hirshler (the United States)] included eight presentation. R.H. White and M.A. Dietenberger (the United States) reported on cone calorimeter evaluation of wood products. G. Reznick, I. Finberg, A. Staimetz, Y. Bar Yaakov, and P. Georlette (Israel) discussed fire retardants for technopolymers of stricter fire safety and higher performance. Measurement of smoke production of low-smoke cables by means of present and future test methods was discussed in the lecture given by H. Breulet (Belgium). K. Battipaglia, J. Huczek, M. Janssens, and A. Sauceda (the United States) reported on using the cone calorimeter to predict FMVSS 302 performance of automotive materials. J.S. Stimitz and R.V. Wagner gave the lecture entitled Two New Test Methodologies To Evaluate Plastic Materials for Use in 42 Volt Auto Applications. The last two presentations of Session V were devoted to residential upholstered furniture hazards [M.M. Hirschler (the United States)] and to the regulatory status for flame retardants [R.B. Dawson, S.D. Landry, and V. Steukers (the United States)].

The poster presentations were made by researches from Germany, S. Korea, and the United States. Of particular interest was the presentation devoted to metal complexes of aromatic phosphinates as a newly developed class of fire retardants for engineering thermoplastics.

The Fifteenth Annual Conference on Recent Advances in Flame Retardancy of Polymeric Materials testifies to a continuous strong activity in various aspects of this field. It not only shows that the technical and commercial interest in flame retardancy is sustained but also indicates great vitality, as evidenced by the new and sometimes striking developments in the science and technology, and by the innovative applications, testing methods, and standards, presented and discussed at the conferences.

The next 16th Conference will be held in Stamford, Connecticut (the United States) early in June 2005.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Paul Sabatier (to 150th Anniversary of His Birthday)

A corecipient of the 1912 Nobel Prize in Chemistry, French scientist Paul Sabatier made an outstanding contribution to organic chemistry and heterogeneous catalysis, in particular, to studies of catalytic hydrogenation.

Sabatier was born in Carcassonne, in southern France, on November 5, 1854. His parents were farmers and, having lost their property, became merchants. He received his primary education at a lyceum in Carcassonne and went to a lyceum in Toulouse in 1868. He also attended there public lectures on physics and chemistry. Sabatier received higher education in Paris (Ecole Normale Supérieure, 1874–1877); he was the best student in his group and the first among the graduates in 1877. During the following year, Sabatier taught physics at a lyceum in Nice and then became an assistant of professor Marcellin Berthelot (1827–1907), an outstanding French chemist and statesman, at Collége de France. The first period of Sabatier's scientific activities (1879–1898) was associated with thermochemical and other studies of inorganic compounds. He earned his doctorate in 1880 for thermochemical studies of sulfur and metal sulfides. In 1881, Sabatier studied physics at the University of Bordeaux; he returned to Toulouse in 1882. In 1884, he became professor of chemistry at the University of Toulouse and occupied this position till his retirement in 1930. In 1905, he was appointed dean of a faculty.

In 1907, the French chemical sciences suffered a severe loss: H. Moissan (1852–1907, 1906 Nobel Prize in Chemistry) died on February 20, and M. Berthelot, on March 18. Both the scientists were members of the Paris Academy of Sciences and academies of many other countries and foreign corresponding members of the St. Petersburg Academy of Sciences; they were more than once elected Presidents of the French Chemical Society. Sabatier was invited to fill Moissan's position at Sorbonne or Berthelot's position at Collége de France. However, he preferred to remain in Toulouse. Sabatier's lectures enjoyed popularity. In 1901, he was elected a corresponding member, and in 1913, a full member of the Paris Academy of Sciences.

P. Sabatier

Sabatier's studies in the field of inorganic chemistry were widely diverse. He obtained pure hydrogen sulfide by vacuum distillation; studied sulfides, selenides, and nitrides of quite a number of metals, nitrogen oxides, and also nitrosodisulfonic acid and its salts. In 1895, Sabatier's attention was attracted by processes of recovery of metals by reduction of their oxides with hydrogen; he also obtained nickel carbonyl by direct action of carbon monoxide on finely dispersed nickel. However, Sabatier was made famous all over the world by his studies in the field of heterogeneous catalysis, which he and his co-worker J.B. Senderens (1856–1937) commenced in 1897 [1–3]. Initially, the studies involved only hydrogenation of unsaturated compounds, with various metals, and primarily nickel, used as catalysts. He obtained ethane from ethylene and the corresponding paraffins from a number of other olefins. He studied the condi-

1070-4272/04/7711-1909 © 2004 MAIK "Nauka/Interperiodica"

tions of catalytic hydrogenation of acetylene that ensured the maximum yield of ethylene. Of particular importance for organic synthesis were Sabatier's studies of hydrogenation of benzene and its homologs (1901); before that nobody could perform smooth hydrogenation. In 1902, the French scientist managed to reduce nitro compounds with the use of a nickel catalyst. In the same years, Sabatier and Senderens were the first to perform catalytic reduction of carbon monoxide to give methane. In 1902–1903, they found ways to reduce simplest aldehydes and ketones. Later, in 1907, Sabatier and co-workers studied in detail the ability of numerous oxides to catalyze dehydrogenation and dehydration processes.

Sabatier and his co-workers and disciples studied a large number of organic reactions and, as a rule, obtained target products in high yields. The experimental procedure they used was distinguished by its simplicity: It consisted in passing the vapor of a starting organic compound, mixed with hydrogen, through a tube containing a finely divided catalyst, mainly a metal, and heated to 100–190°C. For example, passing a mixture of benzene and hydrogen at 170–190°C over nickel ensured virtually 100% yield of cyclohexane.

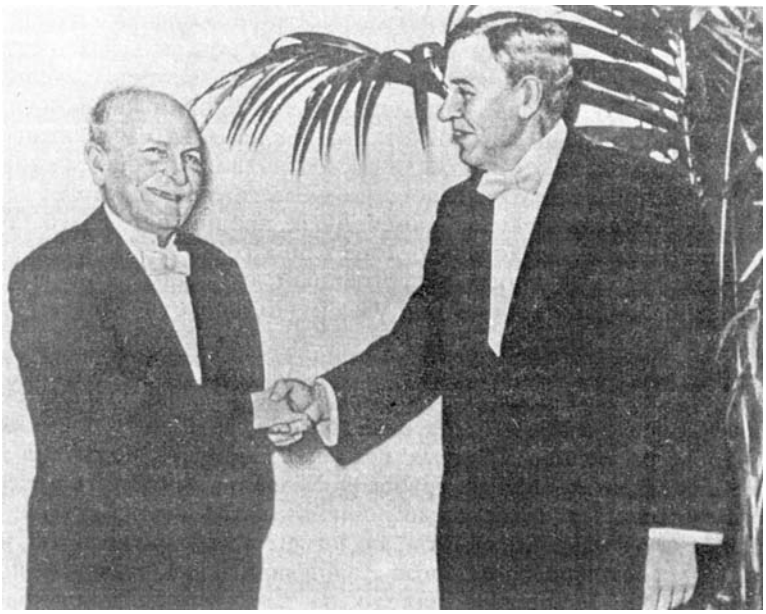
In 1907–1911, Sabatier carried out a set of investigations in the field of catalytic conversion of alcohols. He established that magnesium, cadmium, manganese, and their oxides cause dehydrogenation of alcohols, whereas aluminum, tungsten, silicon, and their oxides lead to their dehydration. In 1909, Sabatier performed a vapor-phase catalytic hydrogenation of unsaturated organic acids.

Already by 1907, Sabatier's investigations in the field of catalytic hydrogenation were highly appreciated by the scientific community, and he was nominated for a Nobel Prize in 1907, 1909, and 1911. In 1909, Sabatier's closest associate, Senderens, also was among nominees. In 1912, Sabatier was awarded a Nobel Prize "for his method of hydrogenating organic compounds in the presence of finely disintegrated metals whereby the progress of organic chemistry has been greatly advanced in recent years." His corecipient was another French chemist, Victor Grignard (1871–1935). The statement of the Nobel Committee said that he was awarded "for the discovery of the so-called Grignard reagent, which in recent years has greatly advanced the progress of organic chemistry." This is related to wide use of organomagnesium compounds in preparative organic chemistry. Sabatier said in his Nobel lecture: "For the past fifteen years this idea of mine on the mechanism of catalysis has never left me, and it is to the inferences drawn from it that I owe all my useful results" [4–6].

A year after he was awarded a Nobel Prize, Sabatier summarized the results of his studies in the field of catalysis in the monograph *La catalyse en chimie organique* (Paris, 1913). The second, supplemented edition of Sabatier's monograph was published in France in 1920. The book was published in England and Germany. Later, in 1932, the monograph was translated into Russian [7]. The concept of heterogeneous catalysis, developed by Sabatier, contradicted the theory put forward earlier by W. Ostwald (1853–1932, 1909 Nobel Prize in Chemistry). According to Ostwald, adsorption of gaseous reagents in micropores of the catalyst plays an important role. In Sabatier's opinion, heterogeneous catalysis in hydrogenation is associated with formation of intermediate compounds on the external surface of catalysts. Unstable compounds then decompose to give the end product. The main results of Sabatier's investigations in the field of catalytic reactions are contained in compact form in [8].

In 1900, investigations in the field of heterogeneous catalysis, as applied to reactions involving organic substances, were commenced by one of the most prominent chemists of the first half of the XX century, V.N. Ipat'ev (1867–1952, academician since 1916). The commonness of interests and scientific purposes unites Sabatier's and Ipat'ev's investigations, which complement each other [1–3, 9]. However, the approaches of these scientists to solution of the problem of catalytic hydrogenation were fundamentally different. Sabatier and his co-workers mostly solved problems of preparative organic synthesis, with only the catalyst being the main factor affecting the course of the process and temperature being of secondary importance. At the same time, Ipat'ev and his disciples regarded the pressure and temperature as most important factors affecting the course of the catalytic reaction. In their first experiments, aluminum oxide was the most frequently used catalyst. Later, Ipat'ev used complex formulations as catalysts and studied the influence of various additives enhancing the activity of catalysts. The history of chemical science has shown that catalytic hydrogenation processes could not be used under industrial conditions without high temperatures and high pressures.

Sabatier demonstrated the applicability of heterogeneous catalysis in reactions performed under comparatively mild conditions, which are typical of the classical organic synthesis. To Ipat'ev belongs proof of the successful applicability of heterogeneous catal-



P. Sabatier (left) and V.N. Ipat'ev (right) (Paris, 1936).

ysis at high pressures and temperatures, i.e., under extreme conditions from the standpoint of an organic chemist of that time. Hydrogenation catalysis under atmospheric pressure, discovered and developed in detail by Sabatier in the very end of the XIX century, gave place, already in the 1920s–1930s, to catalytic hydrogenation by Ipat'ev's method [9]. The main results of investigations performed by the Russian scientist were summarized in the monograph [10]. Ipat'ev was nominated for a Nobel Prize in 1941, 1948, 1949, and 1950. However, he was not awarded the prize he undoubtedly deserved. The possible reasons were analyzed in [11]. According to recently published materials [12], the scientist himself, who was awarded a large number of scientific prizes and honorary titles of many countries, took this historical injustice rather calmly.

Having retired in 1930, Sabatier continued delivering lectures till the end of his life. Academies and scientific societies of many countries elected him their foreign honorary member (England, Spain, Italy, Romania, etc.), he had a degree of doctor of *honoris causa* from quite a number of universities [13]. In 1897 and 1905, Sabatier was awarded medals of the Paris Academy of Sciences; in 1915, the London Royal Society awarded him a Davy medal; in 1933, he received a Franklin medal (the United States). The scientist was honored with highest state awards of France.

Paul Sabatier died on August 14, 1941, in Toulouse at the age of 86. Unfortunately, biographic evidence concerning Sabatier in publications open to general use is very scarce [4, 13–15]. The reference literature contains repeated annoying inaccuracies [5, 6, 16].

OBITUARIES

Armin Genrikhovich Stromberg

On September 18, 2004, at the age of 94, passed away Armin Genrikhovich Stromberg, the oldest Russian electrochemist, founder of the world's most prominent scientific school in the field of stripping voltammetry, honorary professor of the Tomsk Polytechnic Institute, Honored Chemist of the Russian Federation, honorary Soros professor, and doctor of chemical sciences.

A.G. Stromberg was born on September 16, 1910, and spent his early childhood in St. Petersburg. After his father, an army doctor and privatdocent of the Military Medical Academy in St. Petersburg, died in action at the frontline in 1914, Stromberg's family moved to his mother's homeland, Yekaterinburg. In 1927, Stromberg entered the chemical department of the Ural Polytechnic Institute and graduated therefrom in 1930 as chemist-engineer. The first period of Stromberg's scientific activities (before 1941) was devoted to original investigations in the filed of high-temperature electrochemistry. He was the first to study electrocapillary phenomena for liquid metals in ionic melts and determined the zero-charge points. In 1939, Stromberg defended his candidate's (chem.) dissertation.

The postwar period of Stromberg's scientific activities is distinguished by wide use of polarographic techniques for studies of various objects. Particularly important was scientist's contribution to the theory and practice of amalgam polarography and to examination of the polarographic behavior of organic compounds. In 1951, Stromberg defended the dissertation "Theory and Practice of Polarography, and Amalgam Polarography in Particular," and the degree of a doctor of chemistry was conferred on him.

In the prewar years, and also in 1944–1949, Stromberg worked at the Institute of Chemistry and Metallurgy, Ural Division, Academy of Sciences of the USSR, and in 1950–1955, at the chair of physical and colloid chemistry of the Ural State University. In 1956, he was elected head of the chair of physical and colloid chemistry at Tomsk Polytechnic Institute. It is at this chair and at the Basic Research Laboratory for Physicochemical Determination of Microimpurities in Semiconductors and High-Purity Materials, created at the chair by Stromberg's initiative, that his talent as not only a theoretician, experimenter, and pedagogue, but also a head and organizer of a large team of researchers, capable of solving exceedingly complicated scientific and applied problems, displayed itself in full measure. Stromberg himself headed the laboratory for 24 years and then remained there as scientific consultant. The goal of all the staff members of the laboratory was the same, to improve thoroughly the method of stripping voltammetry: to elaborate upon the theory, and develop new apparatus and practical procedures for determining microimpurities. During the 40 years of existence of the basic-research laboratory, tremendous success was achieved, summarized in the collection of works *Tomskoi electrokhimicheskoi shkole i problemnoi laboratorii mikroprimesei sorok let (1962–2002)* (Tomsk Electrochemical School and Basic-Research Laboratory of Microimpurities Is Forty (1962–2002)) (Tomsk, 2004). The presentation of the book was made on the scientist's birthday, on September 16, 2004, two days before his death. In the last months of his life, Stromberg suffered from cardiac insufficiency, but did not terminate his scientific activities and continued to consult his co-workers.

Armin Genrikhovich Stromberg was a man of astonishing working capacity and devotion to science, his motto was "The life is short, so be in a hurry." Under scientist's supervision, near 100 candidate dissertations were prepared and defended, a number of

1070-4272/04/7711-1913 © 2004 MAIK "Nauka/Interperiodica"

his disciples became doctors of science and headed scientific teams in various cities and towns of Russia. Stromberg wrote more than 430 scientific articles and the textbook *Fizicheskaya khimiya* (Physical Chemistry), which has already run into five editions. The last three of these (in 1999, 2001, and 2003) were supplemented by the author with important sections: "Introduction to the Theory of Self-Organization of Matter. Elements of Synergetics" and "Introduction to the Theory of Fractals." In 1999 was published an original textbook *Sinergetika: Primenenie v khimii* (Synergetics: Application to Chemistry). These supplements manifested another important principle of the scientist: to learn incessantly, to be at the frontline of research. An exceedingly talented and well-organized person, Stromberg always took a rest in performing Chopin preludes in strictly fixed hours of every day, in supplementing his home library with books and journal articles devoted to an exceedingly wide variety of topics, and in reading of memoirs.

In the person of Armin Genrikhovich Stromberg, we lost a prominent scientist and a true representative of Russia's intelligentsia of the early XX century. His friends and colleagues will ever thankfully keep his memory.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Study of the Reactivity of Copper Nanopowders in Their Reaction with Glacial Acetic Acid

E. V. Mikubaeva, N. S. Kobotaeva, and E. E. Sirotkina

Institute of Petrochemistry, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received August 11, 2004

Abstract—The reactivity of copper nanopowders obtained by mechanical treatment or electric explosion of a conductor was studied in their reaction with glacial acetic acid. Two parameters were used to evaluate the reactivity: heat effect of the reaction and the maximum rate of heat release.

Compared with compact substances, highly dispersed materials have an excess energy, and, therefore, they are frequently named energy-saturated systems or media [1, 2]. With the high energy content of dispersed particles, which is due, in particular, to the contribution of the surface energy, is associated a very important specific feature of ultradispersed media, i.e., their high reactivity.

Methods for preparing highly dispersed materials, including metal nanopowders, can be conventionally divided into physicochemical and mechanical techniques [3]. To the former belong processes in which powders are produced with a change in the chemical composition of the starting raw material or in its aggregative state, e.g., the method of electric explosion of a conductor (EEC). In mechanical techniques, the starting material is ground into a powder without any change in its chemical composition. The preparation technique used determines the size and morphology of particles, chemical composition, and physical and physicochemical properties of the powders obtained.

The electric explosion of a conductor consists in an abrupt change in the physical state of the metal because of the intensive release of energy in the conductor through which a pulsed current of high density is passed [4]. In the explosion stage, the metal is heated to above the melting point, with some part of the material of the wire evaporating and the rest flying apart in the form of liquid drops. The former phase yields, via condensation in a flow of a rapidly expanding gas, particles with exceedingly small size. Thus, the resulting particles are formed both via condensation (finer particles) and via dispersion (coarser particles). The relative amounts of these components depend on the type of disintegration of the conductor, which is determined by the process of energy introduction into the exploding conductor [5]. The energy introduced into the conductor is commonly characterized by the ratio of the density E of the energy introduced to the energy E_s of sublimation of the metal. This parameter, as well as the diameter of the wire being exploded, determines the specific surface area and size distribution of the resulting particles [5, 6]. The larger the ratio E/E_s, the greater the amount of finer particles (<30 nm) and the smaller that of coarse particles (≥100 nm). It should be noted that the particles formed in EEC have a regular spherical shape [5].

It is commonly believed that nanopowders produced by the EEC method have a very high excess energy [7], which exceeds severalfold the heat of melting of the same amount of substance in the bulk state. Such an excess of energy in nanopowders cannot be due to the contribution of only the surface energy. It is assumed, in particular, that the main component of the energy stored in electrically exploded powders is associated with charged structures [8], whose presence in the particles changes their electrochemical behavior.

Mechanical abrasion is the most productive method for obtaining powders of various materials in large amounts [4]. The grinding is commonly done with planetary, ball, and vibration mills. However, ordinary grinding is comparatively rarely used to obtain ultradispersed powders because of the existence of a certain limit of grindability [2, 9]. The grinding limit is an individual characteristic of a substance, which is commonly determined experimentally.

Cu-III	MT	–	″	$H(CF_2CF_2)_2CONH_2$	30
Cu-1	MT	–	″	$CuCl_2$	10
Cu-2	MT	–	″	$CuCl_2$	20
Cu-3	MT	–	″	$CuCl_2$	30

Two opposite processes compete in grinding of a solid: (i) decrease in particle size in the disintegration of the material and (ii) aggregation of particles as a result of plastic flow. When the treatment duration increases, the specific surface area may behave differently, depending on the relative rates of these processes. For example, if the contribution from the second process starts to grow in the course of dispersion and becomes predominant at a certain level of dispersity, the time dependence of the specific surface area will pass through a maximum. In the case when the rates of disintegration and aggregation become equal and remain in this state during a certain period of time, the specific surface area reaches the largest possible, under the given conditions, value and further grinding does not reduce the particle size [10].

The relative contributions of these processes can be affected by varying such dispersion conditions as temperature (change in the flowability limit, transition from the plastic to the brittle state at low temperature), medium, and grinding in the presence of surfactants making lower the surface energy and mechanical strength of particles [2, 10]. As surfactants can act both inorganic and organic polar compounds: organic acids, alcohols, amines, and high-molecular-weight compounds containing acid, alcoholic, amine, and other fragments. For example, mechanical treatment of copper powders in the presence of fluorine-containing organic surfactants (in particular, amide of perfluorovaleric acid) leads to an increase in the specific surface area to 5.2 $m^2 g^{-1}$, which is comparable with that in EEC-produced powders [11]. Most of particles formed under high-energy impact (including mechanical treatment) have an irregular shape [9].

In this study, the reactivity of copper nanopowders obtained in various conditions of EEC and those produced by mechanical treatment (MT) toward glacial acetic acid was examined by means of microcalorimetry.

EXPERIMENTAL

As objects of study served copper nanopowders obtained using two methods: electric explosion of a conductor in an inert atmosphere (nitrogen, argon, or xenon) and mechanical treatment in an AGO-2 centrifugal-planetary mill at a power introduced by the balls equal to 55 $W g^{-1}$ (40 g) in the presence of amide of perfluorovaleric acid $H(CF_2CF_2)_2CONH_2$ (10 wt %) or $CuCl_2$ (15 wt %) ($CuCl_2$ was washed with ethanol after MT).[1] The preparation conditions of the nanopowders are listed in Table 1.

To evaluate the reactivity of copper nanopowders and examine its dependence on the conditions under which these nanopowders were obtained and on the methods used for this purpose, the reaction of copper with glacial acetic acid in the presence of atmospheric oxygen was chosen [12]. This reaction proceeds by the scheme

$$2Cu + 2CH_3COOH + O_2 \rightarrow Cu(CH_3COO)_2 \cdot Cu(OH)_2.$$

The reaction was performed in an MKDP-2 microcalorimeter in special cells [13]: 2 mg of copper powder were placed in 1.5 cm^3 of glacial acetic acid at 50°C. For each powder, measurements were carried out in five replications and the averaged values were

[1] Electrically exploded copper nanopowders were produced at the Institute of High-Current Electronics, Siberian Division, Russian Academy of Sciences (Tomsk), and those mechanically treated, at the Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences (Novosibirsk).

* S_{sp}, specific surface area found by BET; d_s, average particle diameter, $d_s = 6/\rho S_{sp}$, where ρ is the theoretical density, g cm^{-3}; ΔH, heat effect of the reaction; and W_{max}, maximum rate of heat release.

further analyzed. In all the experiments, the time of thermostating and that during which heat-release curves were recorded were the same: 80 min each. After the reaction was carried out in the microcalorimeter, an electronic absorption spectrum of the reaction mixture was recorded on a Specord M40 spectrophotometer and the absorption band of copper acetate (683 nm) was used to monitor the completeness of the reaction. The total heat of the reaction was found by integration of the heat-release curves, and the heat effect of the reaction was calculated with account of the completeness of the reaction. As a parameter for comparison of the reactivities of the copper powders served, in addition to the heat effect of the reaction, the maximum rate of heat release. It is known [14] that the heat flux is proportional to the reaction rate, and, therefore, the kinetics of the process can be judged from the experimental curve of the heat flux. The experimental curve obtained in studying a fast reaction, when the whole amount of heat is released during a time comparable with the time constant of the calorimeter, is to be corrected. In the case in question, with the reaction duration considerably longer than the time constant of the calorimeter (the time constant of the MKDP-2 microcalorimeter does not exceed 180 s), kinetic parameters can be calculated directly from the experimental curve. The maximum rates of heat release were calculated by integrating experimental curves in the vicinity of the peak heat release.

The results obtained in studying the reactivity of copper nanopowders by means of microcalorimetry are listed in Table 2. The experimental data obtained were used to plot the dependences of the heat effects of the reaction and the maximum rates of heat release on the specific surface area of the powders (Figs. 1, 2). One curve represents the results obtained for copper powders obtained by an electric explosion in the atmosphere of argon (curve *1*); the heat effects

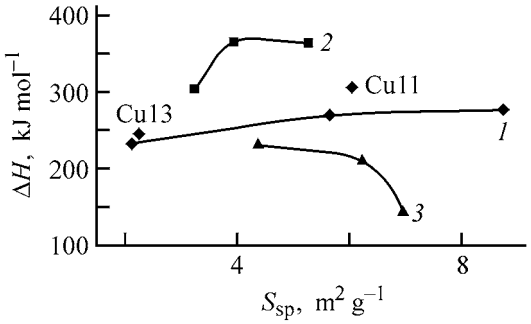

Fig. 1. Enthalpy of the reaction, ΔH, of copper nanopowders with glacial acetic acid at 50°C vs. specific surface area S_{sp}. Powder: (*1*) electrically exploded, (*2*) mechanically treated in the presence of amide of perfluorovaleric acid, and (*3*) mechanically treated in the presence of powdered $CuCl_2$; the same for Fig. 2.

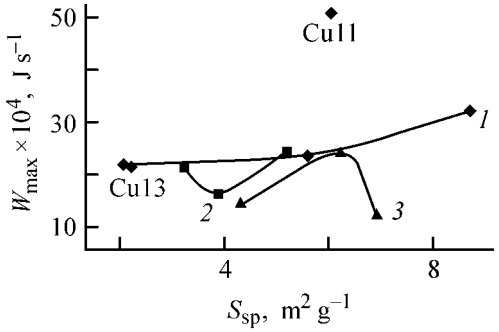

Fig. 2. Maximum rate of heat release, W_{max}, vs. the specific surface area S_{sp}.

of the reaction and the maximum rates of heat release for Cu-13 and Cu-11 powders prepared by an electric explosion in the atmospheres of argon and xenon, respectively, are plotted separately.

For the copper powders produced by electric explosion in the atmosphere of nitrogen, the heat effect of the reaction and the maximum rate of heat release grow as the specific surface area becomes larger (Figs. 1, 2; curves *1*). The values of the parameters ΔH and W_{max} for Cu-13 powder obtained in argon differ only slightly from the corresponding values for Cu-18 powder prepared by electric explosion in the atmosphere of nitrogen and having a specific surface area comparable with that of Cu-13. Thus, the reactivity of the copper powders produced by electric explosion in the atmosphere of nitrogen or argon grows with increasing specific surface area. An unexpectedly high reactivity is observed for Cu-11 powder obtained by electric explosion in the atmosphere of xenon. The highest heat effects of the reaction, fastest maximum rates of heat release, and highest yield of the product were obtained for this powder (Table 1).

It may be assumed that of decisive importance for the reactivity of electrically exploded powders with specific surface areas in the range studied and with the corresponding particle sizes (77 to 319 nm) is the medium in which the conductor is electrically exploded, rather than the specific surface area (or particle size), which is determined by the parameter E/E_s and by other conditions of the electric explosion [5, 6]. The highest reactivity is observed for Cu-11 copper powder produced by electric explosion in the atmosphere of xenon. Possibly, the electric explosion of a copper conductor in the atmosphere of xenon favors stabilization of metastable energy-saturated states to a greater extent than does the electric explosion in the atmosphere of other gases. It is also possible that presence of another type of impurities is important in this case. It was shown in [15], by means of radio-activation, chemical, and X-ray diffraction analyses and ESR and NMR spectroscopies that the particle of a powder produced by the EEC method is a metallic sphere of submicrometer size with a distorted crystal lattice, which also contains the amorphous phase of the metal and, in the bulk and on the surface, the gas in which the explosion was performed; air is adsorbed later, in storage. It is not improbable that powders produced by electric explosion in the atmosphere of xenon can be stored longer without loss of the initial properties.

Mechanically treated copper powders show a nonmonotonic variation of reactivity with increasing specific surface area of the powders (Figs. 1, 2; curves *2*, *3*). Among copper powders mechanically treated in the presence of amide of perfluorovaleric acid, the best combination of parameters is observed for Cu-III powder treated for 30 min and having the largest specific surface area. For copper powders produced by mechanical treatment in the presence of $CuCl_2$, the best results were obtained for Cu-2 powder treated for 20 min and not having the largest specific surface area among the three powders of this series.

Probably, the mechanical treatment of copper powders causes changes in their structure (e.g., accumulation of various kinds of defects and their subsequent relaxation [11, 16]), which lead, despite the continuing increase in the specific surface area, to a decrease in the reactivity of these copper powders. These changes are of cyclic nature, which is the reason for the nonmonotonic variation of the reactivity of the copper powders with increasing duration of mechanical treatment and, accordingly, with growing specific surface area of the powders. Although the highest reactivity is observed for Cu-III powder treated for 30 min in the presence of amide of perfluorovaleric acid, Cu-I powder treated for 10 min and having a considerably smaller specific surface area is inferior to Cu-III powder only in the heat effect of the reaction.

In addition, the mechanical treatment for 20 min in the presence of amide of perfluorovaleric acid leads to a decrease in the reactivity of Cu-II copper powder, as indicated by its maximum rate of heat release (the heat effect of the reaction is comparable with that obtained for Cu-III powder). At the same time, mechanical treatment for 20 min in the presence of $CuCl_2$, by contrast, causes an increase in the reactivity of the copper powder, because the resulting Cu-2 powder has the best reactivity as indicated by a combination of two parameters (ΔH and W_{max}). It may be assumed that the optimal duration of MT, yielding a copper powder with a high reactivity, depends on the type of additive in whose presence the copper powder is mechanically treated.

Comparison of the reactivities of copper powders obtained by different methods reveals the following specific features. As judged from the heat effects of the reaction of copper with glacial acetic acid, the reactivity is the highest for powders produced by mechanical treatment in the presence of amide of perfluorovaleric acid. However, as indicated by a combination of parameters chosen for evaluation of the reactivity, the most active are powders prepared by electric explosion: Cu-11 powder prepared by electric explosion in xenon and Cu-8 powder produced by

electric explosion in nitrogen and having the largest specific surface area.

CONCLUSIONS

(1) It is suggested to evaluate the reactivity of copper nanopowders toward glacial acetic acid by a combination of parameters determined by the microcalorimetric method: heat effect of the reaction and maximum rate of heat release.

(2) It is shown that the medium in which the electric explosion of a conductor occurs is of key importance for the reactivity of the resulting copper nanopowders. The highest reactivity is observed for a copper powder produced by electric explosion in the atmosphere of xenon. The reactivity of copper powders formed by electric explosion in the atmosphere of nitrogen or argon grows with increasing specific surface area of the powders.

(3) It is established that the reactivity of mechanically treated copper nanopowders varies nonmonotonically as the treatment duration becomes longer and, accordingly, the specific surface area of the powders grows. The optimal duration of mechanical treatment, necessary for obtaining the highest reactivity of a copper powder toward glacial acetic acid, depends on the type of additive in whose presence the copper powder is treated. As indicated by a combination of parameters, the reactivity is the highest for a copper powder produced by mechanical treatment for 30 min in the presence of amide of perfluorovaleric acid and that formed upon treatment for 20 min in the presence of $CuCl_2$.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Calorimetric Study of the Specific Heat of Cytisine and Enthalpies of Its Dissolution in Water and Ethanol

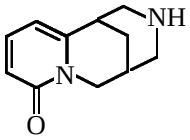
A. Zh. Abil'daeva, Sh. B. Kasenova, B. I. Tuleulov, S. M. Adekenov, and B. K. Kasenov

Institute of Phytochemistry, Ministry of Education and Science of the Republic of Kazakhstan, Karaganda, Kazakhstan

Received May 25, 2004

Abstract—The enthalpies of dissolution of an alkaloid cytisine at dilutions [mole of cytisine : moles of water; mole of cytisine : moles of 96% ethanol] equal to 1 : 9000, 1 : 18000, and 1 : 36000 were measured by means of calorimetry. The experimental data obtained were used to calculate the standard enthalpies of dissolution of cytisine in infinitely diluted (standard) aqueous and ethanolic solutions. The enthalpies of combustion, melting, and crystallization of cytisine were calculated. The method of dynamic calorimetry in the temperature range 198–298.15 K was applied to study the specific heat of the alkaloid, and an equation describing the dependence $C_p^\circ \sim f(T)$ was derived.

Quinolizidine alkaloids constitute a group of compounds with a broad spectrum of physiological proprties. The interest in this type of vegetable bases is due to the originality of their structure and existence of a large number of conformational and optical isoers [1]. A theoretically and practically important comound belonging to this class of substances is cytisine. Cytisine $C_{11}H_{14}N_2O$ is a secondary-tertiary acid base:



Numerous derivatives of cytisine have been studied in sufficient detail by PMR, IR, and UV spectroscopies [1]. However, no systematic thermochemical and thermodynamic studies of both cytisine itself and its derivatives have been reported in the literature.

In view of the aforesaid, the aim of this study was to make a calorimetric analysis of the specific heat and enthalpy of dissolution of cytisine in water and 96% ethanol and to evaluate its thermodynamic parameters.

The enthalpies of cytisine dissolution in water and 96% ethanol were studied on a DAK-I-IA calorimeter. The theory and practice of calorimetric investigations have been described in detail [2–5]. The main technical parameters of the calorimeter are as follows: range of working temperatures 25–200°C, ampule volume 8 cm^3, time of attainment of the steady state 5 h, sensitivity in the mode of direct measurement of the thermoelectric voltage no less than 0.12 $\mu V\,\mu W^{-1}$, sensitivity in the mode of automatic compensation of the thermoelectric voltage no less than 0.012 $\mu V\,\mu W^{-1}$, error in measurement of heat effects not exceeding 2%. The heat effects were recorded with a KSP-4 recorder and, in parallel, with an IP-4 precision integrator. The time of preliminary thermostating was 2 h.

The operation of the device was tested by measuring the ΔH of dissolution of thrice recrystallized KCl at dilutions of 1 : 1600, 1 : 2400, and 1 : 3200 (mole of salt : moles of water). The resulting ΔH of KCl dissolution (at 25°C), equal to 17860 ± 283 kJ mol^{-1}, is in a good agreement with the values obtained in [6, 7].

The experimental errors and the homogeneity of their variance were calculated using Student's and Barthlett's criteria [8].

The enthalpies of cytisine dissolution in water and 96% ethanol were determined experimentally at dilutions of 1 : 9000, 1 : 18000, and 1 : 36000 [mole of alkaloid : moles of water (ethanol)]. Table 1 lists the results of a calorimetric determination of

the heat of cytisine dissolution at different dilutions.

The values of ΔH^m_{dissol} obtained for $C_{11}H_{14}N_2O$ at different dilutions (Table 1) were extrapolated to infinite dilution. Using the data reported in [9], the enthalpy of cytisine dissolution was calculated, using the equation $\Delta H^m_{dissol} = a + b\sqrt{m}$ (m is the molal concentration) in relation to the concentration of cytisine in water and ethanol (kJ mol^{-1}):

$$\Delta H^m_{dissol}(C_{11}H_{14}N_2O) = -(0.65 \pm 0.01) - (99.48 \pm 1.49)\sqrt{m}, \quad (1)$$

$$\Delta H^m_{dissol}(C_{11}H_{14}N_2O) = (36.13 \pm 0.47) - (311.83 \pm 4.05)\sqrt{m}. \quad (2)$$

Relations (1) and (2) were used to calculate the enthalpies of dissolution of cytisine in standard (infinitely diluted) solutions of water and 96% ethanol to be -0.65 ± 0.01 and 36.13 ± 0.47 kJ mol^{-1}, respectively.

The specific heat of cytisine was studied at 198–298.15 K on an IT-S-400 calorimeter. The duration of measurements in the whole temperature range, with processing of the experimental data, was about 2.5 h. The device was calibrated by determining the heat conductivity of the heat flow meter, K_{hfm} [10, 11]. For this purpose, several experiments were carried out with a copper sample and empty ampule. The heat conductivity was found using the formula

$$K_{hfm} = \frac{C_{Cu\ sample}}{\bar{\tau}_{hfm\ Cu} - \bar{\tau}^0_{hfm}}, \quad (3)$$

where $C_{Cu\ sample}$ is the total specific heat of the copper sample (J mol^{-1} K^{-1}); $\bar{\tau}_{hfm\ Cu}$, average time lag of the heat flow meter in experiments with the copper sample; and $\bar{\tau}^0_{hfm}$, the average time.

Table 2 lists the results obtained in determining the specific heat of cytisine. The rated error of the device in measuring the specific heat was ≤ to ±10% [11]. The device was tested by measuring $C^\circ_p(298.15)$

Table 2. Experimental values of the specific heat of $C_{11}H_{14}N_2O$

T, K	$C_p \pm \bar{\delta}$, J K^{-1} g^{-1}	$C_p^\circ \pm \Delta$, J mol^{-1} K^{-1}
198	0.7570 ± 0.0155	144 ± 8
223	0.9265 ± 0.0240	176 ± 13
248	1.0305 ± 0.0173	196 ± 9
273	1.1216 ± 0.0122	213 ± 6
298	1.1476 ± 0.0277	218 ± 15

of α-Al_2O_3. The experimental value of $C_p^\circ(298.15)$ of α-Al_2O_3, equal to 76.0 J mol^{-1} K^{-1}, is in a satisfactory agreement with the reference value of 79.0 J mol^{-1} K^{-1} [12].

The data in Table 2 were used to obtain the equation $C_p^\circ = f(T)$, which has the following form for cytisine at 198–298.15 K (J mol^{-1} K^{-1}):

$$C_p^\circ = (372.8 \pm 20.4) - (253.9 \pm 13.9) \times 10^{-3} T - (70.0 \pm 3.8) \times 10^5 T^{-2}. \quad (4)$$

To calculate $\Delta_f H^\circ$ (298.15) of $C_{11}H_{14}N_2O$, its standard heat of combustion was evaluated using the Karas and Frost methods [13], which are the most appropriate for taking into account the contributions of various groups to the heat of combustion. The results obtained were averaged to give a value of –6144 ± 232 kJ mol^{-1} for the heat of combustion of $C_{11}H_{14}N_2O$. Using the ΔH° of combustion by the Hess cycle for the reaction

$$C_{11}H_{14}N_2O_{(l)} + 14O_{2(g)} = 11CO_{2(g)} + 7H_2O_{(l)} + N_{2(g)}, \quad (5)$$

the standard enthalpy of formation of liquid $C_{11}H_{14}N_2O$ was calculated to be –189.7 kJ mol^{-1}. It is known that the Karas and Frost methods are applicable only to calculation of ΔH° of combustion of liquid hydrocarbons [13]. The data necessary for calculating $\Delta_f H^\circ(298.15)$ of $C_{11}H_{14}N_2O_{(l)}$ by Eq. (5), were taken, with the exception of ΔH° of combustion, from [14].

In view of the fact that cytisine is in the crystalline state at 298.15 K, $\Delta_f H^\circ(298.15)$ of solid cytisine was calculated. For this purpose ΔH°_{melt} of $C_{11}H_{14}N_2O$ was evaluated using the Gambill equation [15]:

$$\Delta H^\circ_{melt}/T_{melt} = 20.72 \times 10^{0.00324M}. \quad (6)$$

The value of ΔH°_{melt}, found for $C_{11}H_{14}N_2O$ by Eq. (6), is 36.6 kJ mol^{-1}. The equation

$$\Delta H^\circ(298.15)\, C_{11}H_{14}N_2O_{(s)} = \Delta_f H^\circ(298.15)\, C_{11}H_{14}N_2O_{(l)} - \Delta H^\circ_{melt} \quad (7)$$

was used to calculate the standard enthalpy of formation of crystalline cytisine, equal to –226.3 kJ mol^{-1}.

CONCLUSIONS

(1) The enthalpies of cytisine dissolution in water and ethanolic solution at different dilutions were determined experimentally and the corresponding values for the same solutions at an infinite dilution (standard solutions) were calculated. The standard enthalpies of formation of liquid and crystalline $C_{11}H_{14}N_2O$ and its heats of combustion and melting were also calculated.

(2) The method of dynamic calorimetry at 198–298.15 K was used to study the specific heat of cytisine, and an equation describing the dependence $C_p^\circ \sim f(T)$ was derived.

(3) The results obtained can be used in directed synthesis of biologically active compounds existing in the nature, for standardization and certification of preparations based on these compounds, and for loading of the data obtained into databases of fundamental constants and thermodynamic reference books.

Abstract—The solubility of components and critical phenomena in a ternary system constituted by potassium nitrate, water, and isopropyl alcohol were studied by the visual-polythermic method in the temperature range 25–90°C. The formation temperature of the critical node of the monotectic equilibrium (critical solution–solid phase) and the solution compositions corresponding to the critical solubility points at different temperatures were determined. Isothermal solubility diagrams of the system were constructed, the previously suggested scheme of the topological transformation of the phase diagrams of ternary stratifying systems constituted by a salt and a binary solvent was confirmed, and the distribution coefficients of isopropyl alcohol at different temperatures were calculated.

Published evidence concerning the solubility of the components in the system KNO_3–H_2O–*i*-C_3H_7OH are scarce. A study has been reported [1] in which the solubility and density of mixtures of the components of this system were analyzed and it was suggested to use the system to obtain KNO_3. The onset temperature of the stratification of the system was determined. However, the pattern of the topological transformation of the solubility diagram of this system was not elucidated completely and no influence of temperature on the salting-out effect of KNO_3 was revealed.

EXPERIMENTAL

The polythermic study of phase equilibria in the ternary system constituted by potassium nitrate, water, and isopropyl alcohol was performed using the visual-polythermic method [2]. The experimental procedure consisted in the following. Mixtures of the three components were prepared by weighing on an analytical balance in 6-ml ampules made of a heat-resistant glass in such a way that the compositions of these mixtures varied along the chosen sections of the concentration triangle. The ampules with the mixtures were sealed and, by turns, placed in a 800-ml thermostated chemical vessel. Water was used as a heat-carrying agent. The temperatures of phase transitions were determined by successive heating and cooling of each mixture, with ampules shaken at regular intervals of time and the formation or disappearance of a liquid or solid phase fixed visually. Each value of the phase transition temperature, found with an accuracy of ±0.1°C, was an averaged result of several replicate measurements. The equilibrium in a heterogeneous mixture was considered to be attained when the results of measurements of the phase transition temperature became reproducible.

The results obtained in measurements for each section were used to plot the phase transition temperatures against the content of a component in mixtures of all the components of the system (polytherms). Using the resulting polytherms of phase states, the mixture compositions corresponding to phase transitions at chosen temperatures were found by graphical interpolation and isothermal phase diagrams of the ternary system were constructed. The relative error in determining these compositions was ±0.5–1.0%. The solution compositions corresponding to the critical solubility points were found by the method of phase volume ratios [3]. A mixture of the components, with a critical opalescence and equal volumes of the liquid phases in the vicinity (±0.1°C) of the phase transition temperature, was chosen. The solutions with a critical opalescence were studied in graduated ampules; the error in measuring the phase volumes was about 5%.

KNO_3 of analytically pure grade, additionally recrystallized, finely ground, and dried to constant weight in a vacuum over phosphorus(V) oxide at 100°C, was used in the study. The absence of moisture was

1070-4272/04/7712-1924 © 2004 MAIK "Nauka/Interperiodica"

verified by a thermogravimetric analysis. A salt sample prepared for study was stored over calcined $CaCl_2$ in a desiccator. A sample of chemically pure isopropyl alcohol (content of the main substance >99.8%) was dried over calcined K_2CO_3 for 24 h, separated from the precipitate by decantation, distilled on an installation with a rod-and-disk type fractionating column of height 0.3 m, and the fraction with a boiling point of 82.2–82.4°C was selected. The purified alcohol was stored over 4-Å molecular sieves. Water was obtained on a DEM-20 MERA-POLNA bidistiller. The solvents used were identified by their boiling points, refractive indices, and densities. The physical constants of isopropyl alcohol and water were in a good agreement with reference data [4].

The compositions of the component mixtures were varied along twelve sections of the concentration triangle of the system under study. The component mixtures belonging to sections *I–X* had a varying content of KNO_3 and constant mass ratios of isopropyl alcohol and water: 5 : 95 (*I*), 10 : 90 (*II*), 20 : 80 (*III*), 28 : 72 (*IV*), 36 : 64 (*V*), 50 : 50 (*VI*), 60 : 40 (*VII*), 70 : 30 (*VIII*), 80 : 20 (*IX*), and 90 : 10 (*X*). The component mixtures belonging to section *XI* had a varying content of the alcohol and a constant mass ratio of the salt and water (40 : 60), whereas the mixtures belonging to section *XII*, had a constant content of the salt (50.0 wt %) and a varying mass ratio of water to isopropyl alcohol.

For all the sections, polytherms of the phase states of the system were plotted. The polytherms of sections *XI* and *XII* made it possible to determine the temperature at which the critical node of the monotectic equilibrium (critical solution–solid phase) is formed, which corresponds to the onset of stratification in the system. The polytherms of the phase states of sections *I–IX* are similar.

Figure 1 shows as an example the polytherm of section *XII*. It comprises four curves that converge to a common point and delimit four fields of phase states, those of unsaturated solutions (*l*), saturated solutions ($l + S$), stratification ($l_1 + l_2$), and monotectic equilibrium ($l_1 + l_2 + S$). The solid phase has a composition KNO_3. In going from the saturated state ($l + S$) into the region of a monotectic equilibrium ($l_1 + l_2 + S$), critical phenomena in the system of two liquid phases were observed. The region of critical points corresponding to the compositions of the solutions with a critical opalescence is encircled with a dashed line, and the critical point corresponding to a mixture with equal volumes of liquid phases is denoted by a large circle and letter *K*. Apparently, point *K* corresponds to a mixture composition corresponding to

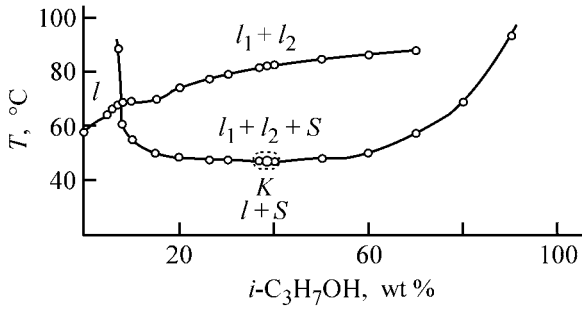

Fig. 1. Polytherm of the phase states of the system constituted by potassium nitrate, water, and isopropyl alcohol in mixtures of the components along section *XII* of the composition triangle. (*T*) Temperature and (i-C_3H_7OH) content.

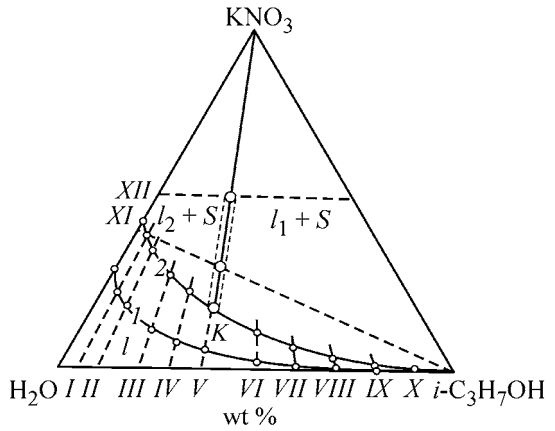

Fig. 2. Isotherms of phase states of the system constituted by potassium nitrate, water, and isopropyl alcohol at (*1*) 25.0 and (*2*) 47.2°C.

the critical node *KS* (critical solution–solid phase), which appears in the field of saturated solutions at 47.2°C.

The temperature dependence of the solution composition corresponding to the critical solubility point was found. For this purpose, component mixtures belonging to additional sections and having a varying content of the salt and a constant mass ratio of water to the alcohol were studied. It was established that the composition of the critical solution changes only slightly when the temperature is raised (see Table 1).

The polytherms and the temperature dependences of the composition of the critical solution were used to plot isothermal phase diagrams of the system at 25.0, 47.2, 50.0, 60.0, 70.0, 80.0, and 90.0°C. At temperatures in the range from 25.0 to 47.2°C, a simple solubility of potassium nitrate in mixtures of water and isopropyl alcohol is observed. For example, there is a field of homogeneous solutions (*l*), separated by a smooth curve *1* from the field of saturated solutions ($l + S$), in the isotherm at 25.0°C (Fig. 2).

* Composition of the liquid phase of the critical node of the monotectic equilibrium (critical solution–solid phase).

At 47.2°C, a critical point *K* appears on the solubility line *2* (Fig. 2). This point corresponds to a mixture in which two liquid phases, alcoholic (l_1) and aqueous (l_2), have identical compositions and properties. As the critical liquid phase *K* is in equilibrium with the solid phase *S* (KNO_3), there appears a critical node *KS* of the monotectic equilibrium. The composition of the critical phase *K* of node *KS* was determined graphically in the concentration triangle from the point of intersection of the critical node with the solubility line *2* for 47.2°C. This temperature is the onset temperature of stratification in the given system, and it coincides with that reported in [1].

As the temperature is raised, the critical node is transformed, as can be seen from the isotherm at 50.0°C (Fig. 3), into a monotectic triangle ($l_1 + l_2 + S$) with the adjacent fields of stratification ($l_1 + l_2$) and of saturated solutions ($l_2 + S$ and $l_1 + S$). As the temperature is raised further, the isotherms of phase states, measured at 60.0, 70.0, 80.0, and 90.0°C, do not change significantly, but the fields of the monotectic state and stratification increase in size, and those of saturated solutions become narrower (Fig. 4, isotherm at 90.0°C).

The results obtained in determining the solubility of the components of the system are listed in Table 1. Data on the solubility of KNO_3 were taken from a reference book [5]. The compositions of the liquid phases of the monotectic equilibrium (Table 2) were found graphically by plotting triangles of the monotectic equilibrium on the plane of the concentration triangle at different temperatures (Fig. 5). The dashed line *aKb* (Fig. 5), which reflects the variation of the compositions of the equilibrium liquid phases of the monotectic with temperature comprises two branches. The composition of the aqueous phase (l_2) varies along branch *Ka*, and that of the organic phase (l_1) along branch *Kb*. As the temperature increases, the aqueous phase is enriched with the salt and depleted of the alcohol, and the organic phase is enriched with the alcohol and depleted of water and the salt.

The distribution coefficient K_d of the alcohol was calculated as the ratio of the concentrations of the alcohol in the organic and aqueous phases of the monotectic equilibrium (Table 2). The fact that the distribution coefficient grows with increasing temperature indicates that the effect of salting-out of the alcohol with potassium nitrate from aqueous solutions is enhanced. Apparently, this is due to decomposition of alcohol hydrates [6, 7] and to a significant increase in the concentration of KNO_3 in the aqueous phase. A comparative analysis of the results of the poly-

thermic study of phase equilibria in the system constituted by potassium nitrate, water, and isopropyl alcohol and in the previously studied ternary systems constituted by potassium chloride (bromide), water, and isopropyl alcohol [8] revealed an analogy between the topological transformations of their phase diagrams upon a change in temperature and confirmed the scheme suggested by Mertslin and Nikurashina [9] for ternary systems that are constituted by a salt and a binary solvent and exhibit salting-out. According to this scheme, the binary liquid system does not stratify in the entire temperature range of its liquid state. The difference is in the onset temperatures of stratification: 24.4°C in the system with KCl, 32.9°C in the system with KBr, and 47.2°C in that with KNO_3. Presumably, with the cation in the salts being the same, the energy of their hydration decreases in order of increasing radius of the anions, Cl–Br–NO_3^- [10], which leads to an increase in the onset temperature of stratification.

The values obtained for the distribution coefficients of isopropyl alcohol in the systems studied suggest that, at equal high temperatures (60–80°C), the salting-out of the alcohol with KNO_3 is stronger, and at equal low temperatures (50°C), weaker than that with KCl and KBr (Table 3). Apparently, this can be attributed to a higher temperature coefficient of the solubility of KNO_3 in aqueous-alcoholic mixtures, compared with that for KCl and KBr. Therefore, use of KNO_3 for salting-out of isopropyl alcohol from aqueous solutions is preferable at higher temperatures.

CONCLUSIONS

(1) The phase equilibria in mixtures of components along twelve sections in the composition triangle of the ternary system constituted by potassium nitrate, water, and isopropyl alcohol was studied in the temperature range 25–90°C by the visual-polythermic method and the temperature corresponding to the onset of stratification in the system was determined to be 47.2°C.

(2) The previously suggested scheme of the topological transformation of the phase diagrams of ternary systems that are constituted by a salt and a binary solvent and exhibit salting-out was confirmed. According to this scheme, the binary liquid system does not stratify in the entire temperature range of its liquid state.

(3) It was established that at 60–80°C the effect of salting-out of isopropyl alcohol from aqueous solutions with potassium nitrate is stronger than that with potassium chloride or bromide. Therefore, potassium nitrate can be effectively used to salt-out isopropyl alcohol from aqueous solutions only at high temperatures.

Received March 10, 2004

Abstract—The kinetics of the heterogeneous reaction of metallic molybdenum with elementary fluorine under conditions close to those used in actual technological practice at a concentration of fluorine in the gas mixture equal to 20–50 vol % was studied. The kinetic parameters were evaluated using the Arrhenius equation. A regression equation was obtained using the statistical method of experimental design for practical calculations of the rate of fluorination of metallic molybdenum with elementary fluorine. This equation makes it possible to calculate the fluorination rate at any point of the factor space, at fluorine concentrations of 30–50 vol % and initial temperatures of 250–350°C.

A study of the kinetics of the heterogeneous reaction of metallic molybdenum with elementary fluorine to give gaseous molybdenum hexafluoride MoF_6 is of profound practical interest. Molybdenum hexafluoride is widely used in various fields of the national economy: for deposition of high-temperature- and corrosion-resistant Mo films of prescribed thickness on metallic articles, for obtaining ultrapure metallic powders, and as a fluorinating agent in synthesis of organofluorine substances.

In [1], the kinetics of fluorination of metallic Mo with elementary F_2 was studied at its concentration of 4 to 13 vol %. The kinetic parameters of the reaction (activation energy, reaction order) were determined. At a F_2 content in argon equal to 4–13 vol %, the concentration of MoF_6 in the gas flow is too low. This may present difficulties in the subsequent stages of isolation of molybdenum hexafluoride from the gas flow.

The goal of our study was to examine the kinetics of the heterogeneous reaction of powdered metallic Mo with elementary F_2 at real technological parameters of the fluorination process: concentration of fluorine in argon in the range 20–50 vol % and initial temperature of 250–350°C, by the classical and statistical methods.

EXPERIMENTAL

We performed the experiments aimed to study the kinetics of fluorination of metallic Mo with elementary F_2 on a "continuous weighing" setup shown schematically in Fig. 1.

The setup comprises a VLA-200M analytical balance *1*, induction transducer *2*, thermocouple *3*, reaction boat *4* with a sample *5*, furnace *6*, and table *7* for

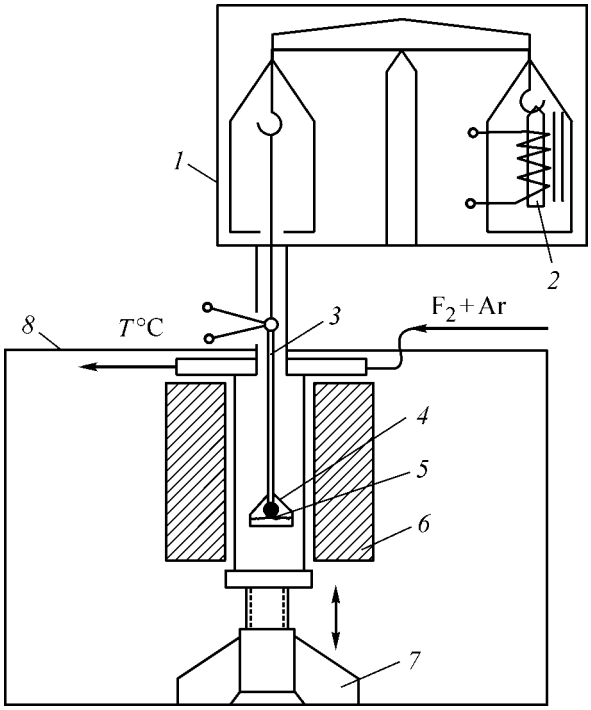

Fig. 1. Schematic of the continuous-weighing setup for studying the kinetics of the heterogeneous reaction of metallic molybdenum with elementary fluorine. (*8*) Exhaust hood; for other explanations, see text.

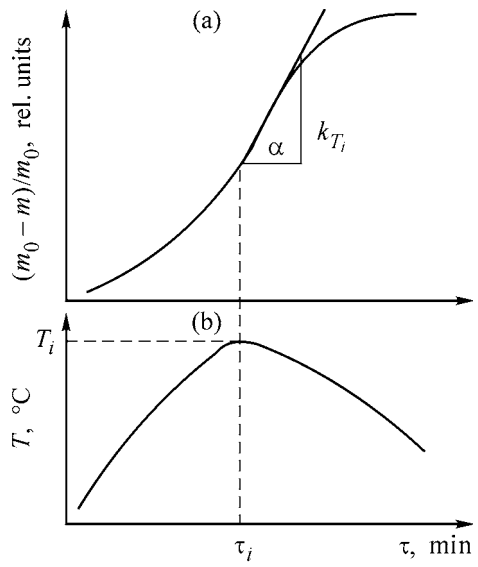

Fig. 2. Variation of the sample mass, $(m_0 - m)/m_0$, and of temperature T in the reaction between metallic molybdenum and elementary fluorine with time τ.

moving the reactor up and down in the furnace. The iron core of the induction transducer *2* is suspended on the right arm of the balance, and the thermocouple *3* and the reaction boat *4*, on the left arm.

The unbalance of the balance leads to motion of the iron core in the induction coil *2*, which gives rise to an induction voltage proportional to the change in the mass of the sample as a result of the reaction of metallic Mo with elementary F_2. The induction transducer *2* is connected into an arm of the differential-transformer circuit of a DSR-35 instrument. The linear portion of the plot of the change in mass against the induction voltage corresponded to variation of the sample mass in the range 0–500 mg. The conversion of the metallic Mo was determined from the loss of mass by the sample as a result of the formation of gaseous MoF_6. The variation of the mass of a sample of metallic Mo was continuously monitored with a secondary DSR-35 instrument. The completion of the reaction was judged from termination of variation of the sample mass.

A weighed portion (~400 mg) of powdered metallic molybdenum (particle size 20–50 μm) was charged into a cylindrical nickel boat 15 mm in diameter and 3 mm high. The boat with the sample was attached with a special clamp to the suspended Chromel–Alumel (ChA) thermocouple so that the thermojunction was close to the sample surface.

After that the fluorination reactor was hermetically sealed and heated to a required temperature in a flow of argon. The variation of temperature in the course of time was recorded with the ChA thermocouple and a secondary EPP-09 potentiometer. Then the zero level was set and the loss of mass by the sample in the course of fluorination was monitored. Fluorine with the content of the main component of 92–96 vol % was used in the study; argon of A brand served to dilute fluorine.

Before the experiments, we passivated the setup at a temperature of 300–400°C and F_2 concentration in argon of about 30 vol % until a stable fluoride film was formed on the surface. The ChA thermocouple was placed within a corundum "straw," with only its junction contacting with the fluorine–argon mixture. The error in weighing in the range 0–500 mg did not exceed 1–2%.

The heterogeneous reaction between metallic Mo and elementary F_2 occurs in accordance with the following overall equation

$$Mo + 3F_2 \rightarrow MoF_6.$$

At the technological parameters used in actual practice, the reaction of fluorination is strongly exothermic and, therefore, certain difficulties were encountered in experimental data processing. The results obtained using the procedure we suggested are shown in Fig. 2: after a stable temperature T_i was reached at an instant of time τ_i, the derivative of the curve describing the variation of the sample mass with time was found graphically at τ_i [2]. This derivative is numerically equal to the rate constant of fluorination, k_{T_i}, at a temperature T_i. The rate constants were determined at two temperatures and the apparent activation energy (kJ mol^{-1}) of the heterogeneous reaction between powdered Mo and elementary F_2 was calculated using the equation

$$E = \frac{19.1479 T_2 T_1}{T_2 - T_1} \log \frac{k_{T_2}}{k_{T_1}}. \quad (1)$$

We carried out more than 40 experiments, and typical S-shaped curves describing the variation of the mass of metallic Mo in the course of fluorination were obtained. During the first 2 min, there is no reaction, i.e., an induction period is observed. Further, the sample mass somewhat increases because of the formation of solid molybdenum fluorides MoF_5 and MoF_4. Then volatile MoF_6 starts to be formed, which leads to a decrease in the sample mass.

We processed the results of the experiments on the kinetics of fluorination of metallic Mo with

elementary F_2, using the Arrhenius equation [3–5]. The averaged values of the kinetic parameters are listed in Table 1.

The kinetic equation of the heterogeneous reaction of metallic Mo with elementary F_2 can be written in the general case as

$$k = k_0 e^{-E/RT}. \quad (2)$$

At technological parameters used in the actual practice, the reaction between metallic Mo and elementary fluorine proceeds with a considerable heat release, and reproducibility could not be achieved in parallel experiments. As a result, the error in determining the numerical values of the kinetic parameters was 35% at 20 vol % F_2 in the reaction mixture and about 60% at a concentration of 40–50 vol %.

In accordance with the values of the apparent activation energy (Table 1), the process is limited by diffusion of F_2 into a layer of metallic Mo. The reaction order with respect to F_2 is close to unity. Raising the concentration of F_2 in the gas mixture leads to a considerable exothermic effect.

Practical calculations of the rate of fluorination of metallic Mo with elementary F_2 require simpler and more precise relations. We solved this problem by using the experimental-statistical method of experiment design [6, 7], orthogonal central composite design (CCD). The necesary number of experiments can be calculated by the formula

$$N = 2^n + 2n + 1, \quad (3)$$

where n is the number of factors constituting a complete factorial experiment; $2n$, number of star points;

and 1 corresponds to an experiment at the center of design (at the point with zero level of the factors).

As independent parameters of the fluorination process were taken the concentration of F_2 in argon (c_{F_2}, vol %), X_1, and the initial temperature in the fluorination zone (°C), X_2. The rate of fluorination of metallic Mo, Y (kg h^{-1} m^{-2}), was chosen as the response function (output parameter).

It was established experimentally that the fluorination occurs on the outer surface of the sample, equal to the area of the reaction boat. This is also confirmed by the fact that, if the weighed portion (layer thickness) of metallic Mo is lowered by a factor of 2–4 (200, 100 mg) at initial temperatures of 250–350°C and F_2 concentration of 20–50 vol %, the fluorination rates remain virtually unchanged. The specific surface area of the metallic powder is apparently larger than the outer surface area of the sample, and, therefore, the calculated rates are underestimated. No quantitative estimates were performed.

The center of the design (zero level) corresponded to a F_2 concentration in argon of 40 vol % and the initial temperature in the reaction zone equal to 300°C; the range of variation of the independent parameters was taken to be 10 vol % for the concentration of F_2 and 50°C for temperature.

The regression equation obtained in this case with the use of an orthogonal CCD is as follows:

$$Y = b_0 + b_1X_1 + b_2X_2 + b_{12}X_1X_2 + b_{11}X_1^2 + b_{22}X_2^2. \quad (4)$$

The experimental conditions and the results obtained are listed in Table 2.

Each experiment in the design matrix was carried out no less than three times. The results of parallel experiments performed to study of the rate of fluorination of metallic Mo with elementary F_2 are listed in Table 3. Table 2 lists the averaged values of the rate Y [kg Mo/(h m^2)], calculated from the experimental data in Table 3. A statistical processing of the results obtained made it possible to calculate the rms deviation of the output response function to be σ_y^2 = 0.583, at a variance of the average, σ_y^2/n = 0.583/3 = 0.1943.

The reproducibility of the results of experiments is commonly verified by finding the ratio of the largest estimated variance to the sum of all estimates of variances (Cochrane criterion):

$$G_{calc} = \frac{\max \sigma_j^2}{\Sigma \sigma_j^2} = \frac{1.5621}{6.2467} = 0.29.$$

For the confidence probability P = 0.95, f = 3 – 1 = 2 and N = 9, G_{tab} = 0.478, and the experiments are considered to reproducible, and the estimates of the variance, to be uniform, because $G_{calc} \le G_{tab}$ (0.29 < 0.478).

The regression coefficients were calculated by the formulas

$$b_0 = 1/N \sum_{j=1}^{N} y_j, \quad (5)$$

$$b_0 = \frac{9.3373 + 15.6238 + 9.0984 + 13.7215 + 8.6850 + 14.0453 + 13.1831 + 11.5654 + 12.3613}{9} = 12.4386,$$

$$b_i = \sum_1^N x_{ij}y_j / \sum_1^N (x_{ij}), \quad (6)$$

$$b_1 = \frac{-9.3373 + 15.6239 - 0.0984 + 13.7215 - 8.685 + 14.0493}{6} = 2.7117,$$

$$b_2 = \frac{-9.3373 - 15.6238 + 9.0984 + 13.7215 - 13.1831 + 11.5654}{6} = -0.6265,$$

$$b_{ik} = \sum_1^N x_{ij}x_{ik}y_j / \sum_1^N x_{ij}x_{ik}, \quad (7)$$

$$b_{12} = \frac{9.3373 - 15.6238 - 9.0984 + 13.7215}{4} = 0.4159,$$

$$b_{ii} = \sum_1^N x_{ij}y_j / \sum_1^N (x_{ij})^2, \quad (8)$$

$$b_{11} = \frac{0.33(9.3373 + 15.6238 + 0.0984 + 13.7215 + 8.6850 + 14.0453) - 0.67(13.1831 + 11.5654 + 12.3613)}{0.33^2 \times 6 + (-0.67)^2 \times 3} = -0.7975,$$

$$b_{22} = \frac{0.33(0.3373 + 15.6238 + 0.0984 + 13.7215 + 13.1831 + 11.5654) - 0.67(8.685 + 14.0453 + 12.3613)}{0.33^2 \times 6 + 0.67^2 \times 3} = 0.2117.$$

To determine the significance of the coefficients obtained, we calculated their variances

$$\sigma_{bi}^2 = \sigma_{\text{av}}^2/N = 0.1943/6 = 0.0324,$$

$$\sigma_{bix}^2 = 0.1943/4 = 0.0483,$$

$$\sigma_{bii}^2 = 0.1943/[0.33 \times 6 + (-0.67)^2 \times 3] = 0.0971,$$

$$\sigma_{b0}^2 = 0.2549.$$

It is commonly believed that a regression coefficient is significant if the following condition is satisfied

$$|b| \geq \sigma_b t, \quad (9)$$

where t is the value of Student's criterion.

In the given case, for the confidence probability $P = 0.95$: $f = 9 - 1 = 8$, $t = 2.31$, $\sigma_{b0}t = 1.167$, $\sigma_{bi}t = 0.416$, $\sigma_{bik}t = 0.508$, $\sigma_{bij}t = 0.720$; $|b_0| = 12.3486 > 1.167$, $|b_1| = 2.7117 > 0.416$, $|b_2| = 0.6265 > 0.416$, $|b_{11}| = 0.7975 > 0.720$; $|b_{22}| = 0.2117 < 0.720$, $|b_{12}| = 0.4159 < 0.508$.

Thus, the regression coefficients b_{22} and b_{12} are nonsignificant and should be excluded from the regression equation.

The equation for the rate of fluorination of metallic Mo is written in the code variables as

$$Y = 12.3484 + 2.7117X_1 - 0.6265X_2 - 0.7975X_1^2. \quad (10)$$

Let us pass from the code variables to technological parameters:

$$X_1 = (c_{F_2} - 40)/10 = (0.1c_{F_2} - 4), \quad (11)$$

$$X_2 = (T - 300)/50 = (0.02T - 6). \quad (12)$$

Substituting the values of X_1 and X_2 in the code equation and simplifying it, we have

$$Y = 0.9092c_{F_2} - 0.0125T - 0.7975 \times 10^{-2}c_{F_2}^2 - 7.4992, \quad (13)$$

$$c_{F_2} = 30\text{–}50 \text{ vol \%}, \quad T = 250\text{–}350^\circ\text{C}.$$

Substituting the values of the independent parameters into this equation, we obtain the calculated fluorination rates (Table 4).

The adequacy of the equation was assessed by the Fisher criterion for a confidence probability of 0.95:

$$F_{\text{calc}} = 0.2549/0.1943 = 1.312.$$

Table 4. Calculated values of the fluorination rate

no.	$Y_{i\text{calc}}$	$Y_{i\text{exp}}$	$Y_{i\text{calc}} - Y_{i\text{exp}}$	$(Y_{\text{calc}} - Y_{\text{exp}})^2$
1	9.4743	9.3373	0.137	0.0188
2	15.4383	15.6238	–0.186	0.0344
3	8.2243	9.0984	–0.874	0.7640
4	13.6483	13.7215	–0.073	0.0054
5	8.8493	8.6850	0.164	0.0270
6	14.2733	14.0453	0.228	0.0520
7	12.9838	12.1831	0.801	0.6411
8	11.7338	11.5654	0.168	0.0284
9	12.3588	12.3613	–0.003	0.0001
				Σ 2.0392*

* $\sigma^2 = \sum_1^N 2.0392/(N-1) = 0.2549$.

At $f = 2$ and $N = 9$, the tabulated values of the Fisher criterion $F_{\text{tab}} = 4.26$ and, therefore, $F_{\text{calc}} \le F_{\text{tab}}$ ($1.312 \le 4.26$). Hence follows that the regression equation obtained is adequate to the experimental results. This equation can be used for calculating the numerical value of the rate of fluorination of metallic Mo ($\text{kg h}^{-1}\,\text{m}^{-2}$) at any point of the factor space: c_{F_2} = 30–50 vol % and T = 250–350°C.

CONCLUSIONS

(1) The kinetics of the heterogeneous reaction of metallic molybdenum with elementary fluorine was studied experimentally. The results obtained make it possible to calculate, using the Arrhenius equation, averaged values of the kinetic parameters (rate constant, apparent activation energy) for conditions close to those used in actual technological practice of fluorination. It was found that, as the concentration of F_2 in the gas mixture is raised from 20 to 50 vol %, the error in determining the kinetic parameters increases from 35 to 60%.

(2) A regression equation (13) for practical calculations was derived using the statistical method of experiment design. This equation relates the rate of fluorination of metallic Mo to temperature and concentration of fluorine. It can be used to calculate the rate of fluorination of metallic Mo at any point of the factor space at F_2 concentrations of 30–50 vol % and temperatures of 250–350°C.

SORPTION AND ION-EXCHANGE PROCESSES

Surface Chemistry of Ultradispersed Diamonds

A. N. Eremenko, O. A. Besedina, and I. I. Obraztsova

Kemerovo Branch of the Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Kemerovo, Russia

Received August 18, 2004

Abstract—The type and amount of functional groups on the surface of ultradispersed diamonds were determined. The adsorption of potential-determining ions was studied in relation to various factors, and the surface charge density was evaluated. The influence exerted by thermal treatment in argon and hydrogen on the functional composition of the surface was analyzed.

A new research area, "nano: -particles, -materials, and -technologies," has formed and has been generally accepted as a priority field of world's science.

By the term "nanotechnology" is understood creation and use of materials, devices, and systems whose structure is controlled on the nanometer scale. The primary goal is to reveal the principles governing the physicochemical properties of such materials and methods for their fabrication and to thereby master the prognostication of, and control over the properties of the objects obtained.

The specificity of the properties of the substances in question and the associated new physical phenomena are determined by the fact that the characteristic dimensions of the structural elements of nanoobjects are within the range 10^{-9}–10^{-7} m, which is comparable with the size of atoms and molecules in ordinary materials. Novel functional characteristics, markedly differing from those of ordinary materials, can be imparted to nanomaterials by controlling the dimensions and shape of nanostructures.

In the authors' opinion, ultradispersed diamonds (UDD) are the most interesting objects of study among all kinds of nanomaterials: they possess a unique combination of markedly anomalous chemical, physicochemical, and mechanical properties.

Ordinary (natural) diamonds are, as a rule, used only as abrasive and cutting materials or substrates in microelectronics. At the same time, the application field of UDD is rather wide. By chemical, barometric, or thermal treatment, various surface properties can be imparted to UDD. In this context, the attention of researchers is focused on a detailed study of parameters and properties of diamonds and on a search for new areas of their application. It is believed that the main application fields of UDD have not been found yet, and their wide use in future high-tech projects is expected [1].

Many physicochemical properties of diamonds strongly depend on the composition and properties of their surface, which is formed in synthesis and chemical treatment of the material. In a number of cases, this is the key issue in obtaining new diamond-containing composites with prescribed characteristics. The electrokinetic, ion-exchange, and sorption properties of diamonds are primarily determined by the nature and amount of surface functional groups. Despite the existence of numerous methods for studying the surface of detonation-produced diamonds (spectral, thermographic, potentiometric, polarographic), the available information about its chemical composition is of mostly qualitative nature [1].

In view of the importance of the surface chemistry of UDD for various applications, some quantitative characteristics of the chemical composition of the UDD surface were determined in the present study.

UDD with particle size of 3–5 nm were used; the method for their recovery from the detonation-produced diamond-carbon stock and subsequent purification has been developed previously [2, 3].

The type and amount of acid groups were found by reverse acid–base titration by selective neutralization with sodium hydroxide, hydrocarbonate, and carbonate by the Boem method [4] developed for carbon

Table 1. Amount of protonogenic groups on the UDD surface, determined by the Boem method

Alkaline agent	NN, mg-equiv g^{-1}
KOH	0.55 ± 0.02
NaOH	0.67 ± 0.03
Na_2CO_3	0.34 ± 0.01
$NaHCO_3$	0.12 ± 0.01

Table 2. Effect of UDD treatment on the functional composition of the surface

Neutralizing agent	NN, mg-equiv g^{-1} at indicated *T*, °C			
	–	400	600	800
		Ar		
NaOH	0.67	0.28	0.04	0.04
$NaHCO_3$	0.18	0.05	0.03	0.00
NH_2OH	2.70	1.40	0.80	0.06
		H_2		
NaOH	0.67	0.25	0.07	0.06
$NaHCO_3$	0.18	0.05	0.03	0.00
NH_2OH	2.70	1.10	0.76	0.04

materials. It is assumed that sodium hydrocarbonate neutralizes stronger carboxy groups, and sodium carbonate, the same groups and weakly acidic carboxyls of lactone groups. Under the action of Na_2CO_3, the lactone ring is opened with a rearrangement and formation of an oxy and a carboxy groups. This accounts for the different acidities of surface carboxy groups. Sodium hydroxide neutralizes virtually all protonogenic groups. The difference of the neutralization numbers (NN) in neutralization with sodium hydroxide and carbonate, $NN_{NaOH} - NN_{Na_2CO_3}$, gives the amount of phenol groups.

It was revealed experimentally that 3 h is sufficient for equilibrium to be established after neutralization with sodium carbonate and hydrocarbonate, and 24 h, in the case of sodium hydroxide. The centrifuge effluent was titrated with a 0.1 N solution of HCl. The difference between the amounts of alkali in the starting solution and in the effluent was used to find the amount of neutralized surface groups, the neutralization number (mg-equiv g^{-1} UDD).

A comparison of the NN for surface groups in neutralization with the alkalis KOH and NaOH demonstrated that the neutralization with potassium hydroxide is weaker, in an agreement with the results [5] obtained for UDD purified to remove nondiamond carbon by liquid-phase oxidation with nitric acid and gas-phase oxidation. The results of experiments on reverse titration are listed in Table 1.

The data obtained were used to evaluate the amount of protonogenic groups (± 0.01 mg-equiv g^{-1}): carboxy 0.12, phenol 0.33, and lactone 0.22. The total neutralization number for NaOH is 0.67 mg-equiv g^{-1}.

The content of carbonyl groups was determined by the oximation method [6]. The analysis was based on the action of free hydroxylamine in an aqueous medium. Free hydroxylamine was obtained by neutralization of hydroxylamine hydrochloride with a strong base, NaOH. After the oximation was complete, the decrease in the alkalinity of the reaction medium was determined by titration with an acid, with Bromcresol Blue as indicator. The results of the analysis show that UDD has a considerable amount of surface carbonyl groups, 2.7 ± 0.02 mg-equiv g^{-1}, which is an order of magnitude higher that that of any of the previously determined groups.

The content of peroxy groups on the UDD surface (–O–O–) was determined by iodometric titration [7]. It was found that these groups are present on the surface of UDD in an insignificant amount, 0.034 ± 0.002 mg-equiv g^{-1}.

It is known that thermal treatment removes chemisorbed oxygen from the surface of UDD in the form of CO_2 (200–550°C) and CO (620–750°C). Carboxy groups, saturated with oxygen to the greatest extent are responsible for the evolution of CO_2 in thermal desorption, and carbonyl, hydroxy, and ester groups, for the evolution of CO [8].

A study of the influence exerted by thermal treatment of UDD in an atmosphere of oxygen, hydrogen, or argon on the amount of surface acid groups demonstrated that, in all cases, the total amount of protonogenic groups on the surface decreases. The NN in neutralization with sodium hydroxide at 400°C is as follows (mg-equiv g^{-1}): 0.28 in argon, 0.25 in hydrogen, and 0.30 in oxygen; strongly acidic carboxy groups (neutralization with sodium hydrocarbonate) are virtually absent.

For a more detailed study of the effect of thermal treatment on UDD, samples were calcined in a flow of argon or hydrogen at different temperatures. The results obtained are listed in Table 2.

It can be seen from Table 2 that thermal treatment in the atmosphere of argon or hydrogen at 800°C

leads to a virtually complete (>95%) removal of surface groups, which opens up a way to obtaining UDD with a monofunctional surface composition. This is very important for development of selective catalysts, sorbents, and composites on its base.

In addition to determining the types and amounts of functional groups on the UDD surface, some general characteristics used to assess the properties of carbon materials were studied.

In particular, potentiometric titration was used to study the adsorption of potential-determining ions $\Gamma_{OH^-H^+}$ (henceforth Γ) and evaluate the surface charge density on UDD [9], depending on the ionic strength of the electrolyte solution, pH value, and method used for pretreatment of UDD.

The specific adsorption of ions, Γ, was found using the formula

$$\Gamma = cV/m, \quad (1)$$

where c is the concentration of the alkali (KOH) solution; V, difference of volumes of KOH solutions added, in order to adjust pH to the prescribed value, to the dispersion and supporting electrolyte; and m, mass of a UDD portion.

The data obtained were used to evaluate the surface charge density σ_0:

$$\sigma_0 = \Gamma F/S, \quad (2)$$

where F is the Faraday number, and S, the specific surface area of the UDD powder (300 $m^2 g^{-1}$).

As shown above, thermal treatment of UDD leads to a significant change in the composition of surface groups, which is reflected on the specific adsorption and pH values of the suspensions studied (Table 3).

Table 3. Effect of thermal treatment on the specific adsorption Γ and pH of suspensions

Type of treatment	Γ (pH 8) mg-equiv g^{-1}	pH_{in}
No treatment	0.81	3.60
T = 400°C:		
Ar	0.20	7.18
H_2	0.10	7.32
T = 800°C:		
Ar	0.08	7.20
H_2	0.05	7.30

Table 4. Surface charge density on UDD, σ_0, in relation to the ionic strength of the solution, I_{KCl}, ultrasonic dispersion of the suspension, and temperature of the thermal treatment of UDD

UDD	I_{KCl}	σ_0, C m^{-2}	
		pH 7	pH 8
Suspension:			
after preparation	10^{-1}	0.24	0.34
24 h after preparation	10^{-1}	0.20	0.51
	10^{-2}	0.14	0.31
	10^{-3}	0.13	0.29
after ultrasonic dispersion	10^{-1}	0.27	0.56
	10^{-2}	0.19	0.34
	10^{-3}	0.12	0.25
Thermal treatment			
400°C, Ar	10^{-3}		0.064
400°C, H_2	10^{-3}		0.035
800°C, Ar	10^{-3}		0.026
800°C, H_2	10^{-3}		0.016

It can be seen from Table 3 that thermal treatment of UDD leads to a decrease in the adsorption capacity: the specific adsorption decreases by an order of magnitude, with a more complete reduction of active groups occurring in hydrogen.

It was found using potentiometric titration that, as the ionic strength of the electrolyte (KCl) or the solution pH increases, the specific adsorption becomes higher. In the first case, this is accounted for by an increase in the degree of exchange of hydrogen ions from the surface layer for K^+ ions with the concentration of the latter in solution, in an agreement with the results of similar experiments in which the adsorption capacity of natural diamond was studied [9]. In the second case, the dependence is accounted for by the increase in the degree of dissociation of surface groups having acid properties.

The data obtained were used to evaluate the surface charge density on UDD at pH 7 and 8. The results obtained are listed in Table 4.

Analysis of the results obtained shows that the surface of UDD in an aqueous suspension is strongly charged. The amount of charge is close to that for oxidized synthetic diamonds, 0.3 C m^{-2} at pH 8.6 [9]. The rise in the charge on a particle with increasing pH is apparently due to ionization of surface protonogenic groups.

With account of the fact that the 1% suspension of UDD has a pH 3.6, a calculation performed on the as-

sumption that the particle size is 2.5 nm and the density is equal to 3.5 g cm^{-3} indicated that there are 36 H^+ groups per a single UDD particle.

CONCLUSIONS

(1) The types and amount of functional groups on the surface of ultradispersed diamonds were determined.

(2) It was established that thermal treatment of ultradispersed diamonds in a flow of hydrogen or argon leads to significant changes in the composition and amount of surface groups, which is reflected on the specific adsorption and pH of the suspensions.

(3) It was shown that the surface of ultradispersed diamonds in an aqueous suspension is strongly charged, and the surface charge density depends on the ionic strength of the electrolyte, pH value, and method of preliminary treatment.

(4) It was found that thermal treatment of ultradispersed diamonds at 800°C leads to a virtually complete removal of surface groups, which opens up a way to obtaining ultradispersed diamonds with a monofunctional composition of the surface.

SORPTION AND ION-EXCHANGE PROCESSES

Natural Zeolites as Dehydrating Agents for Some Organic Solvents Used in Liquid Chromatography

T. G. Andronikashvili, L. G. Eprikashvili, and T. N. Kordzakhiya

Melikishvili Institute of Physical and Organic Chemistry, Georgian Academy of Sciences, Tbilisi, Georgia

Received July 15, 2004

Abstract—Possibility and conditions of dehydration of organic solvents [*N*,*N*'-dimethylformamide (DMF), tetrahydrofuran (THF), 1,4-dioxane, acetonitrile, ethyl acetate, and methyl ethyl ketone] with natural zeolites (analcite, laumontite, clinoptilolite, mordenite, and phillipsite) were studied.

The role of a mobile phase (solvent) in high-performance liquid chromatography, unlike gas chromatography, is multifunctional. The solvent not only transports substances, but also is actively involved in their separation [1]. Chromatographic separation is sometimes very sensitive to the composition of the mobile phase. Even insignificant variations in the water content of the solvent may noticeably change the capacity coefficient K^{I} and the degree of chromatographic separation [2]. Liquid, gaseous, and solid substances are exhaustively dried by different chemical and physical methods [3]. However, the most acceptable is the adsorption method which can be used for dehydration of solvents under both static and dynamic conditions [4]. The important advantage of this method is that the sorbents can be readily regenerated and repeatedly used as dehydrating agents.

Silica gels, zeolites, and, occasionally, alumina are currently used for drying [4]. Zeolites can sorb moisture at its low content in the sample, and their sorption capacity is substantially higher than that of other sorbents. Zeolites exhibit a molecular-sieve effect, i.e., they selectively sorb molecules whose diameter is smaller than their pore size [4–7]. Usually solvents used in liquid chromatography as the mobile phase are exhaustively dried. Synthetic zeolites, like NaA and especially KA [2, 6] activated by calcination at 420–450°C in a muffle furnace [2], are the best dehydrating agents for solvents. At the same time, natural zeolites of sediment origin also effectively dry various gaseous and liquid systems [8–10]. Sediment zeolites are naturally abundant and their industrial deposits are situated in Russia and countries of Former Soviet Union, including Georgia [8–12].

The aim of this study was to demonstrate the possibility and advisability of using natural zeolites of sediment origin from Georgian deposits to dehydrate some organic solvents used as the mobile phase in high performance liquid chromatography.

EXPERIMENTAL

We studied dehydration of the following solvents: dimethylformamide (bp 153°C, Snyder selectivity group III), tetrahydrofuran (bp 66°C, Snyder selectivity group III), 1,4-dioxane (bp 101°C, Snyder selectivity group VI), acetonitrile (bp 82°C, Snyder selectivity group VI), ethyl acetate (bp 77°C, Snyder selectivity group VI), and methyl ethyl ketone (bp 80°C, Snyder selectivity group VI). These solvents belong to different classes and have different molecular structures [2]. The water content in the initial solvents was 3.2–3.4%.

We studied the following zeolite-containing rocks abundant in Georgia [12]: (1) analcite containing rock of Kutaisi-Gelati region (western Georgia) with a 70–80% analcite content and prevalence of sodium in the cationic composition; (2) laumontite-containing rock from Tbilisi region (eastern Georgia) with a 60–70% laumontite content and prevalence of calcium in the cationic composition; (3) heulandite, clinoptilolite-containing rock from Tedzami deposit of Kaspi region (eastern Georgia) with a 70–90% clinoptilolite content and prevalence of calcium and sodium in the cationic composition; (4) mordenite-containing rock from Bolnisi-Ratevani region (easten Georgia) with a 60–80% mordenite content and prevalence of calcium and sodium in the cationic composition; and (5) phillipsite-containing rock from region of Shukhuti village

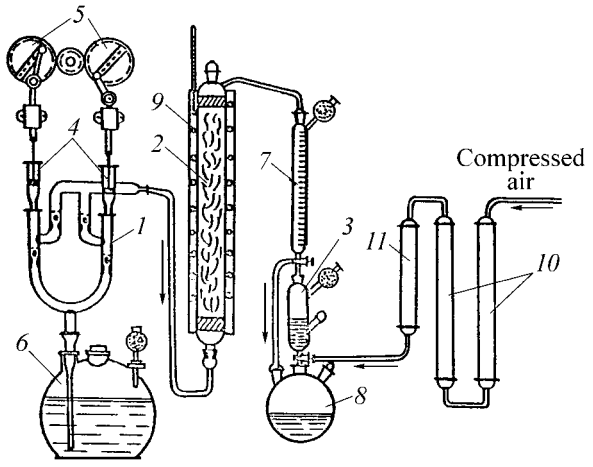
Table 1. Physical properties of natural zeolites

Zeolite	Chemical composition	Channel size, nm	Free volume, %	Structure of channel system	Kinetic diameter, nm
Analcite	$Na_{16}(Al_{16}Si_{32}O_{96})\cdot 16H_2O$	0.26	18	Unidimensional	0.26
Laumontite	$Ca_4Al_8Si_{32}O_{48})\cdot 16H_2O$	0.46 × 0.63	0.35	″	0.23
Clinoptilolite	$(K_2Na_2Ca)_3Al_6Si_{30}O_{72}\cdot 22H_2O$	0.39 × 0.54	0.34	Two-dimensional	0.35
Mordenite	$Na_3KCa_2(Al_8Si_{40}O_{96})\cdot 28H_2O$	0.29 × 0.57	0.26	″	0.39
Phillipsite	$(K_2C`)_3(Al_6Si_{10}O_{32})\cdot 12H_2O$	0.28 × 0.49	0.30	Three-dimensional	0.26
NaA	$Na_{12}(Al_{12}Si_{12}O_{48})\cdot 27H_2O$	0.42	47	″	0.40

(westen Georgia) with a 60–90% phillipsite content and prevalence of calcium in the cationic composition.

The typical chemical composition of these zeolites and synthetic NaA zeolite and some physical parameters of these materials [5, 8, 10] are listed in Table 1.

We studied dehydration of model solvent–water (3.4%) systems in a special flow unit (see figure) [13] under dynamic conditions. The unit consists of three main parts: (*1*) dosing pump, (*2*) sorption column, and (*3*) sampler. The pump was made from 1-ml medical syringes *4*. Two plunger pumps were phase-shifted by half a period to smooth the pulsation. The pump was driven with an RD-09 electric motor via a system of pinions and a crank mechanism *5* built in a pinion. A solvent was fed by dosing pump from vessel *6* to adsorber *2* and passed from the bottom to the top of the sorbent bed. To determine the feed rate of the solvent, the dried solvent was fed into a graduated receiver *7*. To prevent penetration of atmospheric moisture into the system, it was equipped with drying tubes packed with $CaCl_2$.



Scheme of the lab unit: (*1*) dosing pump, (*2*) sorption column, (*3*) sampler, (*4*) medical syringe, (*5*) crank mechanism, (*6*) vessel for solvent, (*7*) graduated receiver, (*8*) collector, (*9*) electrical furnace, (*10*) drying filters, and (*11*) color indicator.

The water content of the dried solvents was determined on an LKhM-8MD chromatograph [1.5-m column 3 mm in diameter, Porapak *Q* adsorbent (80–100 mesh), katharometer, carrier gas helium]. The column temperature and the flow rate of the carrier gas were set depending on the molecular weight and boiling point of the solvent. The water content in the dried solvents was 0.05%; 0.02% water passed through the sorbent.

The absorption column 1.0 cm in diameter was packed with a crushed zeolite (0.5–1.0-mm particles). The height of the sorbent bed was 24 cm. The zeolite was activated by heating at 300°C for 3 h in a flow of dry nitrogen. The solvent was passed through the sorbent bed at a rate of 1.3 ml min^{-1}. The column was isothermally heated in the range 25–100°C. Elution curves were plotted in the c/c_0–τ coordinates, where c is the concentration and τ is time. The experiment was continued to complete saturation of the sorbent, i.e., until the water concentration in the eluate became equal to that in the initial solvent c_0.

We determined the following interrelated parameters of adsorption dehydration of organic liquids: equilibrium (a_e, g/100 g) and dynamic (a_d, g/100 g) adsorption capacities of the column, height of the sorption layer H_s (cm), and degree of utilization of the active part of the sorbent bed η (%). The equilibrium adsorption capacity of the zeolite was calculated by the equation [14]

$$a_e = [w\tau_{bt}c_0 + w(\tau_s - \tau_{bt})c_0\varphi]v,$$

where w is the flow rate of the solvent (cm^3 min^{-1}); τ_{bt}, sorption time to breakthrough (min); τ_s, time to complete saturation of the sorbent (min); c_0, initial water concentration (wt %); v, sorbent weight (g); and φ, utilized fraction of the sorbent bed (symmetry coefficient) [4].

The dynamic sorption capacity of the sorbent bed is determined by the amount of substance absorbed

Table 2. Dynamic a_d and equilibrium a_e sorption capacity of zeolite bed for water in organic solvent–water systems at 25°C

Zeolite	Ethyl acetate	Butan-2-one	Acetonitrile	DMF	THF	1,4-Dioxane
Dynamic capacity, a_d, g/100 g						
NaA	13.32	14.61	13.00	18.56	21.75	20.05
Phillipsite	13.11	14.34	12.73	9.81	10.74	11.84
Mordenite	12.03	13.14	8.64	8.97	9.61	10.73

Laumontite	2.34	2.42	1.98	2.04	2.31	2.09
Analcite	0.90	0.98	1.02	0.93	1.05	0.80
Equilibrium capacity, a_e, g/100 g						
NaA	14.20	15.55	14.82	20.05	23.10	21.05
Phillipsite	13.81	15.11	13.71	12.03	13.05	12.31
Mordenite	13.77	15.06	11.81	11.31	10.44	11.97
Clinoptilolite	11.20	12.00	12.10	9.94	8.19	10.38
Laumontite	4.20	4.31	3.17	4.01	3.40	3.74
Analcite	3.00	3.20	2.07	2.07	2.10	2.67

to breakthrough and is calculated using the equation [15].

$$a_d = a_e(1 - L_0/L),$$

where L is the height of the sorbent bed (cm), and L_0, height of the sorption zone (cm).

The height of the sorption zone, so-called height of the working bed, L_0, was calculated by the Michaels Treybal equation [4]

$$L_0 = L\frac{\Delta\tau}{\tau_s - (1-\varphi)\Delta\tau},$$

where $\Delta\tau$ is the time interval from the breakthrough (τ_{bt}) to saturation of the sorbent (τ_s).

The degree of utilization of the sorbent bed η (%) was calculated by the equation [4]

$$\eta = \frac{a_d}{a_e} \times 100.$$

To found the most effective desiccant for the organic solvents examined and to determine the best conditions of water adsorption, we considered the following parameters: type of a natural zeolite, type and molecular structure of a solvent, content of the main mineral in the rock, cationic composition of the zeolite, and column temperature. The dehydration efficiency of a zeolite depends on the spatial structure of the network of its channels and on the free volume and size of water-permeable pores of the sorbent.

Zeolites with a three-dimensional (3*D*) system of channels, large free pore volume, and, which is of particular importance, pore size allowing penetration of only water molecules (molecular-sieve effect) have the best dehydration properties.

However, the zeolites examined exhibit these properties incompletely. Zeolite A and phillipsite have a 3*D* system of channels. Zeolite A has relatively large free pore volume, and the size of its pores is larger than that in phillipsite (Table 1). Hence, zeolite NaA can adsorb not only water but also hydrocarbons with a linear chain structure. In this case, the competing sorption deteriorates the dehydration properties of the sorbent.

Phillipsite, unlike NaA zeolite, selectively sorbs water molecules (molecular-sieve effect). The dynamic and equilibrium sorption capacity of phillipsite for water in solvents with a linear molecular structure is similar to that of NaA (Table 2). However, the dynamic and equilibrium sorption capacities of NaA for water in the solvents with a cyclic or branched molecular structure (THF, 1,4-dioxane, DMF) are substantially higher than those of phillipsite. This is due to the fact that NaA zeolite selectively adsorbs water molecules (molecular-sieve effect) and its free pore volume is 50% larger than that of phillipsite.

Mordenite and clinoptilolite-containing rocks have a 2*D* system of channels. Unlike phillipsite, these zeolites have a more open pore structure (Table 1) and hence lower dynamic and equilibrium sorption capacity for water. This effect is more pronounced for clinoptilolite. In this case, both the competing sorption and the molecular-sieve effect are observed, depending on the molecular structure of the solvent.

Table 3. Equilibrium (a_e) and dynamic (a_d) sorption capacities of NaA zeolite and phillipsite for water

Zeolite	a_d	a_e	η	L_0	τ*
Ethyl acetate–water					
NaA	13.32	14.20	94	3.1	80
Phillipsite	13.11	13.81	95	3.2	75
THF–water

Table 4. Dependence of the dynamic sorption capacity of the sorbent bed, a_d, for water in acetonitrile on the zeolite content in rock

Clinoptilolite		Phillipsite	
Content in rock, wt %	a_d	Content in rock, wt %	a_d
80–90	9.80	>85	12.85
70–80	9.70	70–80	12.73
60–70	9.12	60–70	12.10
50–60	7.20	50–60	11.21
40–50	3.12	40–50	5.20

Laumontite and analcite have a 1*D* system of channels, and their sorption capacity for water is low [16]. As can be seen from Table 2, these zeolites are unsuitable for dehydration of solvents. Although the size of their water-permeable pores is close to that of phillipsite, the free pore volume of the zeolites is very low (Table 1).

The parameters of water sorption on NaA zeolite and phillipsite from the ethyl acetate–water (competing sorption) and THF–water (molecular-sieve effect) systems are listed in Table 3. The parameters of dehydration by the competing sorption on NaA zeolite are close to those on phillipsite. Unlike synthetic zeolites in which the content of the crystalline phase is higher than 90%, the zeolite content of rocks varies widely, which undoubtedly affects the dehydration power. We determined to what extent the zeolite concentration in rocks can be decreased without affecting the performance in dehydration of organic solvents.

We determined the dynamic sorption capacity for water in acetonitrile of rocks with varied content of clinoptilolite and phillipsite.

As can be seen from Table 4, the dehydration efficiency of rocks with a 60–90% zeolite content is almost the same. However, in both cases, the dynamic sorption capacity sharply decreases at lower zeolite content. The sorption properties of a zeolite depend not only on its type but also on its cationic composition. Enrichment of clinoptilolite with various cations can increase its sorption capacity for water by 40–50% [17].

Since natural clinoptilolite contains potassium, sodium, calcium, and barium cations, we examined in this study clinoptilolites enriched with these cations.

To enrich clinoptilolite with the above-indicated cations, 0.5–1.0-mm zeolite granules were treated several times with a 0.1 N solution of appropriate metal chloride to maximum saturation with preservation of the zeolite lattice [18]. The composition of initial and modified zeolites based on 36 oxygen atoms, determined by chemical analysis [19, 20], is as follows: $Clin_{in}$ $C_{1.06}Mg_{0.36}Na_{1.10}K_{0.54}$, NaClin $Ca_{0.04}Mg_{0.05}Na_{1.52}K_{0.48}$, KClin $Ca_{0.04}Mg_{0.04}Na_{0.01}K_{3.58}$, CaClin $Ca_{4.93}Mg_{0.16}Na_{0.09}K_{0.05}$, and BaClin $Ca_{0.08}Mg_{0.07}Na_{0.1}K_{0.51}Ba_{1.31}$.

As can be seen from Table 5, the dynamic and equilibrium sorption capacity for water in organic solvents depends on the metal cation prevailing in the modified clinoptilolite. Based on these data, the zeolites can be ranked with respect to the selectivity of water sorption depending on the metal cation prevalent in their structure.

With the majority of the solvents examined (ethyl acetate, butan-2-one, 1,4-dioxane, THF, DMF), the selectivity of water sorption (dehydration efficiency) decreases in the following order: KClin > BaClin > CaClin > NaClin > $Clin_{in}$. With acetonitrile, this order in inverse: $Clin_{in}$ > NaClin > CaClin > BaClin > KClin.

In the first case, the enrichment of clinoptilolite with a specific metal cation improves the dehydration efficiency, with this effect being the strongest with potassium cations. The dynamic sorption capacity of the sorbent bed enriched with potassium increases, compared to the initial zeolite, by 39, 41, 22, 22, and 23% with ethyl acetate, butan-2-one, DMF, THF, and 1,4-dioxane, respectively. This positive effect is difficult to explain. We can only suggest the following. Only sodium and calcium (magnesium) cations can be exchanged with equimolar amounts of other cations [19, 20]. The position of a large portion of potassium atoms in the zeolite skeleton differs from those of Ca^{2+} and Na^{+}. In the course of ion exchange, potassium cations are localized deep in the channel *C* near the center of eight-membered rings, thus enlarging the free pore volume of the zeolite [21] and the kinetic diameter of zeolite pores.

Table 5. Dynamic (a_d) and equilibrium (a_e) sorption capacities of zeolite bed for cation-modified clinoptilolite in the system organic solvent–water

Zeolite	Ethyl acetate	Butan-2-one	Acetonitrile	DMF	THF	1,4-Dioxane
			Dynamic capacity, a_d, g/100 g			
Initial $Clin_{in}$	13.32	14.61	13.00	18.56	21.75	20.05
NaClin	9.60	10.50	8.90	7.32	7.88	7.77
KClin	11.80	12.94	7.32	8.33	8.91	8.77
CaClin	10.10	11.01	8.60	7.61	7.18	7.83
BaClin	0.63	10.74	8.42	7.80	8.50	8.25
			Equilibrium capacity, a_e, g/100 g			
Initial $Clin_{in}$	14.20	15.55	14.82	20.05	23.10	21.05
NaClin	10.90	11.90	11.90	10.31	10.45	11.89
KClin	14.31	15.61	9.00	11.31	10.92	12.54
CaClin	11.00	12.03	14.40	10.50	10.60	12.00
BaClin	11.70	12.2	10.20	11.0	10.80	12.64

Table 6. Increase (as compared to experiments at 25°C) in the dynamic sorption capacity of a bed of natural zeolites and synthetic NaA zeolite for water at the best column temperature T_{best}

Solvent	T_{best}, °C	Increase, a_d, %			
		NaA	clinoptilolite	mordenite	phillipsite
Butan-2-one	65	17.9	17.2	17.9	14.8
Ethyl acetate	65	15.6	15.2	14.7	13.9
Acetonitrile	65	13.1	12.6	12.2	14.1
1,4-Dioxane	70	11.4	10.9	11.0	11.7
DMF	90	8.6	14.3	10.0	10.2

It is also difficult to explain the fact that features of dehydration of acetonitrile with substituted clinoptilolites differ from those observed with the other solvents. Probably acetonitrile molecules specifically interact with cations present in clinoptilolite. As a result, water sorption on clinoptilolites enriched with potassium and barium cations is lower than that on the initial clinoptilolite.

In some cases, dehydration of solvents is accelerated with increasing temperature [22]. It is known that many organic compounds form associates with water. At elevated temperatures, water is redistributed between water–water and water–solvent associates; also, these associates partially decompose. Temperature affects the sorption rate in two ways. The limiting sorption of the absorbate decreases, and the sorption selectivity becomes worse with increasing temperature in the case of competing sorption. At the same time, the diffusion coefficient increases, the mass transfer is intensified, and the mass-transfer zone is shortened, and hence the dynamic sorption capacity of the sorbent increases. Hence, the temperature oppositely affects the equilibrium and dynamic sorption properties. The temperature effect is the most pronounced with high-boiling solvents. The viscosity of *N*,*N*'-dimethylformamide (bp 153°C) decreases by a factor of 3 upon heating to 90°C. As a result, the diffusion coefficient of water in this solvent increases and intramolecular and intermolecular hydrogen bonds are rearranged, thus improving the parameters of dynamic sorption dehydration.

To determine the maximum dynamic sorption capacity of a sorbent bed, the temperature dependence of its sorption properties should be studied. In the case of the solvents examined, the best sorption temperature is in the range 65–90°C (Table 6).

Since the boiling point of THF is low (66°C), we did not study the temperature dependences in this solvent.

As can be seen from Table 6, the increase in the dynamic sorption capacity for water of the examined zeolites at the best column temperature is almost the same.

The increase in the sorption capacity after modification of clinoptilolite tuffs with metal cations and the increase in the sorption capacity at the best column temperature are presented in Table 7. As can be seen from

Table 7. Change in the dynamic sorption capacity a_d in water–solvent systems of the initial and modified natural clinoptilolite at the best column temperature

Solvent	Increase in a_d as compared to the initial zeolite, %				T_{best}, °C	Increase in a_d at the best temperature, %				
	BaClin	KClin	CaClin	NaClin		$Clin_{in}$	KClin	CaClin	NaClin	BaClin
Ethyl acetate	25.06	38.70	17.50	12.80	65	13.9	18.38	15.60	14.40	12.61
Butan-2-one	19.54	40.20	16.61	14.00	65	14.77	17.43	14.80	15.24	12.61
1,4-Dioxane	15.21	22.5	9.40	8.50	70	10.30	10.26	10.34	9.65	13.3
DMF	13.8	21.6	11.1	6.90	90	9.6	18.0	21.0	20.6	21.9
Acetonitrile	–13.2	–7.2	–11.3	–8.2	65	14.1	23.3	10.3	14.7	13.3

Table 7, modification of the initial zeolite with sodium, calcium, barium, and especially potassium cations improves the efficiency of dehydration of all the solvents except acetonitrile. In acetonitrile, the sorption capacity of the modified zeolites is lower than that of the initial clinoptilolite. Thus, dehydration of solvents with natural clinoptilolite can be, in most cases, substantially improved by its modification with metal cations and by variation of the column temperature.

CONCLUSIONS

1. Dehydration properties of phillipsite are similar to those of synthetic NaA zeolite in the case of a competing sorption mechanism.

2. The efficiency of solvent dehydration with clinoptilolite can be substantially improved by modifying the zeolite with metal cations and performing sorption at the best temperature. The parameters of sorption performed under these conditions are similar to those obtained with synthetic zeolites.

Abstract—Data on elemental and phase composition, morphology, and electrocatalytic behavior in dilute chloride solutions of ruthenium-titanium oxide anodes subjected to preliminary plasma-electrolytic treatment are presented.

The properties, including electrocatalytic ones, of ruthenium-titanium oxide anodes (RTOA), adhesion of an active layer, and oxidation of titanium at the interface between the active layer and titanium are determined by the ratio of titanium to ruthenium oxides [1–3], method of preliminary treatment of a titanium support [4], and conditions of electrolysis (concentrated or dilute sodium chloride solutions).

Corrosion-resistant oxide layers having different chemical compositions and good adherence to the substrate can be obtained on the surface of valve metals, including titanium, by means of the plasma-electrolytic deposition (PED) [5–7].

The first applications of PED showed that it can be used both to improve the adhesion of the active paste to the titanium support and decrease the oxidation of titanium [8] and to directly form electrodes with properties close to those of RTOA [9].

As shown previously [10], films formed by PED on titanium in a borate aqueous electrolyte contain only the rutile modification of TiO_2. Ruthenium oxides RuO_2 are isomorphic to the rutile modification of titanium oxide TiO_2, which is a prerequisite for further formation of coatings with electrocatalytic and catalytic properties.

In this study, we examined the composition, morphology, and electrocatalytic properties of electrodes obtained by depositing pure ruthenium hydroxo chloride or its mixture with titanium chloride onto oxide layers formed by PED on titanium in a tetraborate electrolyte.

EXPERIMENTAL

Samples of VT1-0 titanium ($2.5 \times 0.5 \times 1$ cm) were mechanically ground, chemically polished in a mixture of concentrated acids ($HF : HNO_3 = 3 : 1$) at 60–80°C for 2–3 s to remove the surface layer and standardize the surface, washed with distilled water, and dried in air.

Oxide films were formed on titanium by PED in a 0.1 M aqueous solution of sodium tetraborate in the galvanostatic mode at $i = 0.2$ A cm^{-2} and an oxidation time of 1–10 min. As current supply served a TEP4-100 : 46OH thyristor transducer with unipolar pulsed current. The process was performed in a 500-ml vessel made of a heat-resistant glass. As a cathode served a spiral tube made of Kr18Ni9Ti stainless steel and cooled with tap water. The temperature of the electrolyte was maintained within the range 10–50°C. The oxidized samples were washed with distilled water and dried in air.

An active layer was deposited onto oxidized titanium by means of thermal decomposition of ruthenium hydroxo chloride (RTOA1) or a mixture of ruthenium hydroxo chloride and titanium chloride taken in a molar ratio Ru : Ti = 30 : 70 (RTOA2) [4].

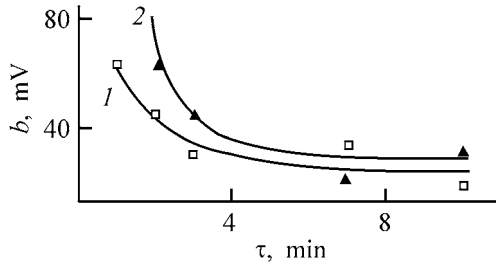

Fig. 4. Coefficient *b* vs. the time of formation of the oxide sublayer, τ, for (*1*) RTOA1 and (*2*) RTOA2.

The phase composition of the coatings was studied on a DRON-2.0 X-ray diffractometer (Cu_{K_α} radiation). The relative content of the crystalline phases was estimated from the ratio of the intensities of the strongest reflections present in the X-ray diffraction patterns of the samples being analyzed to the intensities of the same reflections in the X-ray diffraction patterns of the samples obtained on titanium oxidized for 1 min. The amount (wt %) of titanium and ruthenium in the surface layer was measured with a JXA-5A X-ray fluorescence microanalyzer. The atomic content of the elements was calculated on the assumption that the coatings contained oxygen, in addition to titanium and ruthenium.

An electron microscopic study was done on an LEO 430 scanning electron microscope.

Electrochemical measurements were performed in a 3% NaCl solution modeling sea water in a YaSE-1 standard electrochemical cell with a P-5827 potentiostat. An EVL-1M silver chloride electrode served as reference. The current efficiency (CE) by active chlorine was determined at a current density of 0.15 A cm^{-2} by iodometric titration.

The influence exerted by the time τ of PED pretreatment of a titanium support on the phase and elemental compositions of RTOA1 and RTOA2 is illustrated in Fig. 1.

In the case of RTOA1, an increase in τ, corresponding to a rise in the thickness of the original oxide layer, leads to a higher rutile content and lower anatase content, but does not affect the content of crystalline RuO_2 (Fig. 1a). In this case, the content of titanium, ruthenium, and oxygen (~76 at.%) in the analyzed layer remains virtually unchanged (Fig. 1b).

In the case of RTOA2, making longer the time of formation of an oxide sublayer has no effect on the phase composition (Fig 1c). At the same time, it should be noted that the elemental compositions of RTOA2 on the supports treated for less than 3 and more than 5 min are different (Fig. 1d). The content of titanium, ruthenium, and oxygen changes from 13 to 18, 7 to 5, and 80 to 77 at.%, respectively. At $\tau > 5$ min, the elemental composition of RTOA2 is close to that of RTOA1.

The current efficiency (CE) by active chlorine in electrolysis from a dilute chloride solution is independent of the time of oxidation of the titanium support for RTOA1, and markedly increases at $\tau > 5$ min for RTOA2 (Fig. 2). The current efficiency in deposition of a standard RTOA onto a titanium support

without a preliminarily formed oxide layer was 65–67% in the experiments described. Thus, pretreatment of the support by means of the PED method in a borate electrolyte at $\tau > 5$ min raises the selectivity of the chloride reaction by 6–8%.

The general run of the polarization curves obtained on the anodes under study (Fig. 3) corresponds to that the curves measured on standard RTOA under these conditions. As the time of formation of the oxide sublayer is made longer, i.e., the sublayer thickness increases, the coefficients b in the Tafel equation $E = a + b\log i$ decrease to become constant at $\tau > 5$ min (Fig. 4). In this case, they are equal to 0.03–0.04 V and correspond to the coefficients b for standard RTOA in dilute chloride solutions [10].

Figure 5 shows electron micrographs of PED coatings formed on titanium in a borate electrolyte at an oxidation time of 2 and 10 min, as well as those of samples with RTOA1 and RTOA2 deposited on the above sublayers. The surface of the oxide sublayer formed in 2 min is constituted by alternating projections and depressions (Fig. 5a). The difference of heights on the surface is as large as 0.5 μm. Pores, which are, in all probability, channels of electric breakdowns, open onto the surface. The distribution of pores over the surface is rather uniform, and their mouths are seen both on top of projections and on side slopes of depressions. The surface of the coatings formed in $\tau > 5$ min, which are thicker, has another profile (Fig. 5b). In this case, rather uniform areas of the surface, onto which pores open, also have microdepressions with pores seen on their bottom.

At a formation time of 2 and 10 min, the thickness of the coatings studied is 2–3 and 8–10 μm, respec-

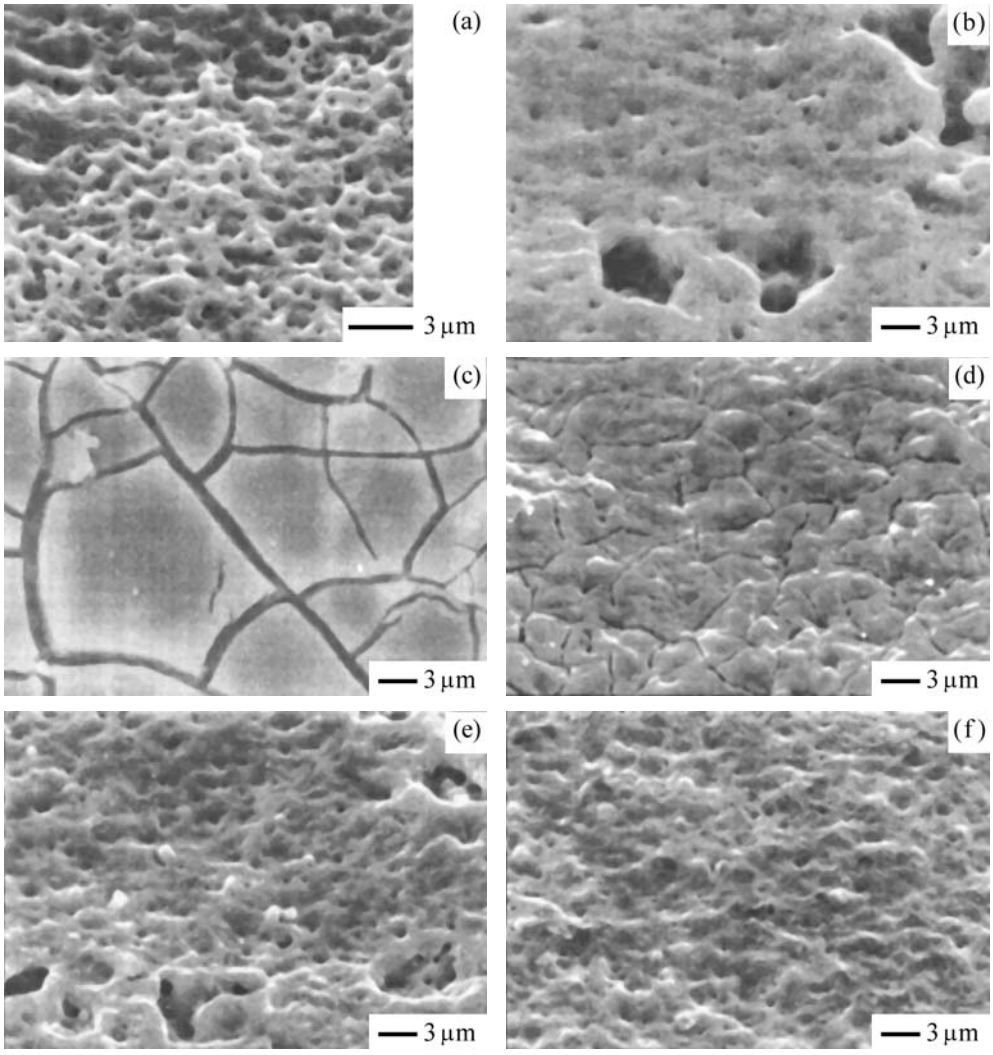

Fig. 5. SEM micrographs of the surface of (a, b) oxide sublayer, (c) standard RTOA, (e) RTOA1, and (d, f) RTOA2. Time of formation of the oxide sublayer (min): (a, d) 2 and (b, e, f) 10.

Results of an analysis of the SEM micrographs of the surface of titanium oxide and ruthenium-titanium oxide anodes subjected to PED

Parameter	Treatment time, min

* TOA, titanium oxide anode.

tively. In both cases, the coating material resembles a partly molten glassy formation.

The results of an analysis of the electron micrographs are listed in the table. The calculated surface porosity of the oxide layers obtained is low, i.e., these layers should have satisfactory protective properties. If the formation time is made longer, not only the oxide layer thickness increases, but also the pore diameters grow, whereas the pore density (ratio of their total number to the micrograph area) and the surface porosity (ratio of the sum of the pore areas to the micrograph area) decrease. In this case, microdepressions ("hollows" or "large pores") are present on the surface of the anodic deposits formed at $\tau > 5$.

The deposition of the catalytically active material results in a change in the surface morphology of the oxide layers. As in the case of standard RTOA (Fig. 5c), isolated areas separated by cracks constitute the surface of both RTOA1 and RTOA2 at a time of formation of the oxide sublayer, $\tau < 5$ min (Fig. 5d). Under magnification, small pores can be seen on the bottom of cracks. On the surface of RTOA1 and RTOA2, the cracks are no more visible when the time of formation of the oxide layer exceeds 5 min (Fig. 5e, 5f). In these cases, the density of the most probable pores on the surface increases, whereas their diameter decreases, compared with the corresponding parameters of the oxide sublayer (see table), with the pore sizes and densities being the same for RTOA1 and RTOA2. When RTOA1 is deposited onto the oxide layers formed at $\tau > 5$ min, the depth and size of the hollows (large pores) decrease by about 1 μm. No hollows are observed on the surface of RTOA2 under these conditions.

In the general case, the oxide layer formed on titanium in an aqueous electrolyte under the action of electric breakdowns consists of a dense barrier layer with a thickness of no less than 1 μm, which is adjacent to the metal, and an outer layer transformed by breakdowns and pierced with pores, which contains titanium oxides with inclusions of compounds based on, or mainly composed of the solution components. The layers obtained on titanium by PED in the tetraborate electrolyte studied contain a rutile modification of TiO_2 [11]. As follows from the results obtained, pores open onto the surface of these layers. With increasing time of layer formation, the diameter of the most probable pores increases, whereas their number per unit surface decreases. Such oxide layers have a low electrical conductivity both in air and in a 3% NaCl solution, with the electrical resistance of the structures indicated not affected by annealing in air at 450°C for 1 h.

The deposition onto the given structures of both ruthenium hydroxo chloride and its mixture with titanium chloride (30 mol % RuO_2 and 70 mol % TiO_2), with the subsequent annealing for 1 h, results in a sharp decrease in the electrical resistance to values typical of the standard RTOA. The electrochemical parameters of the electrodes obtained are also close to those of the standard RTOA. This means that either the structures considered become electrically conduct-

ing throughout their bulk, or interconnected current-conducting regions or channels are formed in their structure. Apparently, these current-conducting regions are localized in pores (cracks) of the oxide sublayer and are associated with the presence of ruthenium oxide or with the formation of a TiO_2–RuO_2 solid solution both in voids and on the walls and bottom of pores (cracks). This assumption is confirmed by the observed correlation between the morphology of the oxide sublayer preliminarily formed in a tetraborate electrolyte and the properties of the anodes obtained. Probably, the conducting regions are formed in the barrier layer adjacent to titanium, owing to thermal diffusion of ruthenium ions into this layer in the course of the oxidative annealing at 400–450°C.

Both RTOA1 and RTOA2 compositions contain crystalline phases of TiO_2 in the rutile and anatase modifications and RuO_2 (Fig. 1). Presumably, the anatase modification is a product of oxidative annealing of the titanium support in air. In this case, the decrease in the amount of anatase, observed for RTOA1 when the formation time (thickness) of the oxide sublayer increases, indicates that its protective properties are improved. At the same time, the appearance of anatase may result from crystallization in the course of annealing of the amorphous phase in the oxide sublayer. It is noteworthy that the anatase phase is also recorded in the X-ray diffraction patterns of an annealed PED coating.

For RTOA1, the elemental composition (Fig. 1) and the current efficiency (Fig. 2) are virtually independent of the parameters and morphology of the oxide sublayer, despite the change in the phase composition. For RTOA2 at $\tau > 5$ min, the current efficiency increases from 65–67 to 72–75%. The change in the elemental composition, i.e., a decrease in the content of ruthenium in the surface layer and an increase in that of titanium (Fig. 1), and the morphological transformations, i.e., the appearance of large pores (hollows) on the surface of the oxide sublayer (Fig. 5b), correlate with these results. Presumably, the change in the macrostructure facilitates penetration of ruthenium into the oxide layer.

Calculations show that, in the RTOA1 surface layer analyzed, the Ru/Ti ratio (in at.%) is 0.23 on the average. For RTOA2, this ratio is 0.54 at $\tau < 5$ min and 0.28 at $\tau > 5$ min. When a mixture of ruthenium hydroxo chloride and titanium chloride is deposited to give a standard RTOA, this ratio is 0.43. The close electrocatalytic properties of the RTOA1 and RTOA2 electrodes, standard RTOA on titanium, and electrodes with a decreased content of Ru (e.g., at a Ru/Ti ratio of 0.23–0.28) possibly indicate that only certain parts of the electrode surface are active in the reaction of chlorine evolution.

An analysis of the SEM images shows that the morphologies of the RTOA1 and RTOA2 surfaces are, on the whole, similar (see table and Fig. 5). At $\tau < 5$ min, their surface, as also the surface of the standard RTOA, is covered with a network of cracks. At $\tau > 5$ min, the cracks are absent, but pore mouths emerge to the surface of RTOA1 and RTOA2.

The estimated pore sizes for the samples studied are listed in the table. Presumably, small pores on the oxide sublayer are craters of electric spark breakdowns, and larger pores, of micrometer size, are craters formed by arc discharges of higher power. As the number of pores per unit surface is two orders of magnitude larger on RTOA1 and RTOA2 and the sizes of these pores are smaller than those on the oxide sublayer, the pores on RTOA1 and RTOA2 are not associated with channels of electric breakdowns present on the oxide sublayer. In all probability, the pores on the surface of RTOA1 and RTOA2 result from evolution of gases (water vapor, chlorine, or HCl vapor) in the thermal treatment of the deposited aqueous solutions of ruthenium hydroxo chlorides or a mixture of ruthenium hydroxo chloride and titanium chloride. The change in the depth of large hollows upon deposition of the active paste was used to estimate the thickness of the deposited outer layer to be about 1 μm for RTOA1 and about 3 μm for RTOA2. These estimates agree with published data [12].

Cracking of RTOA (Fig. 5c), RTOA1, and RTOA2 on the thin, micrometer-thick oxide layers (Fig. 5d) is due to the drying of a wet layer, which tends to contract on a less contractible support. The absence of cracking in RTOA1 and RTOA2 deposited on relatively thick (8–10 μm) oxide sublayers means that the properties of these structures vary to a lesser extent. As a consequence, it would be expected that the adhesion of the active paste to the substrate should be higher in this case.

CONCLUSIONS

(1) Preliminary treatment of titanium in a tetraborate electrolyte by the method of plasma-electrolytic deposition does not deteriorate the electrochemical parameters of ruthenium-titanium oxide anodes in dilute chloride solutions.

(2) The surface structure of the oxide sublayer and the electrochemical characteristics of the ruthenium-titanium oxide anodes correlate.

(3) The results obtained suggest that an additional plasma-electrolytic treatment can be a promising method for improving the adhesion of the active paste and depressing the oxidation of a titanium support.

Received May 12, 2004

Abstract—The electrochemical behavior of methanol on graphite electrodes modified with a coating composed of (III) hexacyanoferrate and ruthenium(III) hexacyanoferrate(II) and hexacyanoruthenate(II) was studied. A method for electrochemical determination of ethanol on a carbon-paste electrode modified with a coating composed of ruthenium(III) hexacyanoruthenate(II) under stationary and flow-injection conditions was suggested.

Ethanol is commonly determined using a variety of techniques [1–3]: classical and modern physicochemical, including electrochemical methods. Direct voltammetry on metallic and graphite electrodes is not used to determine ethanol because of the oxidation overvoltage of this compound. Modifying the surface of solid electrodes with redox mediators markedly expands the analytical capacity of voltammetry. Various mediators are used for determining aliphatic alcohols: metals [3–6], metal complexes [7], or electron-conducting polymeric materials [8].

In the last years, a considerable attention has been given to electrodes modified with hexacyanometallates (HCM) [9–15]. Electrodes with a coating composed of ferric ferrocyanide [$KFe^{II}Fe^{III}(CN)_6$] are used as detectors or transducers in biosensors [9] The properties of these chemically modified electrodes (CME) are changed because of the alteration of the nature of metal ions in both the inner and outer coordination spheres. It has been established that the catalytic activity of HCM also changes because of the cross-linking of HCM species by ions of platinum-group metals [15, 16]. For example, introduction of ruthenium ions into the composition of a coating improves the catalytic activity of CME and makes their electrochemical response more stable [10–16].

The present study is concerned with the electrocatalytic properties of a carbon-paste (CPE) or a glassy carbon (GC) electrode with an electrodeposited coating composed of ruthenium(III) hexacyanoferrate(II) and hexacyanoruthenate(II) in oxidation of ethanol and with the possibility of using these electrodes to determine ethanol under stationary and flow-through conditions.

The electrochemical properties of hexacyanometallates deposited on the surface of GC, such as iron(III) hexacyanoferrate $KFe^{II}Fe^{III}(CN)_6$ (FeO–FeCN), ruthenium(III) hexacyanoferrate(II) $Ru_4[Fe(CN)_6]_3$ (RuO–FeCN), and ruthenium(III) hexacyanoruthenate(II) $Ru_4[Ru(CN)_6]_3$ (RuO–RuCN). A study of the electrochemical properties of ruthenium(III) hexacyanometallates established that ruthenium(III) oxidizes to oxidation states higher than 3+, with oxygen bridges formed between metal ions, such as Ru–O–Fe or Ru–O–Ru [15, 16]. Therefore, ruthenium ions in higher oxidation states are designated as oxo groups, e.g., –Ru(VI)O or –Ru(IV)O, and the designations RuO–FeCN or RuO–RuCN are commonly accepted for HCM coatings.

As can be seen in Fig. 1, the voltammetric curves obtained on HCM-modified electrodes are different. The voltammogram of an electrode with a FeO–Fe–CN coating contains two pairs of anodic and cathodic peaks (Fig. 1, curve *1*). The peak at E = 0.2 V is commonly attributed [17] to oxidation of a complex iron(II) ion, i.e., to the redox pair $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ (E^0 = 0.36 V [18]), and the peak at E = 1.2 V is associated with oxidation of an outer-sphere ion of iron and is related to the redox pair Fe^{3+}/Fe^{2+} (E^0 = 0.77 V [18]).

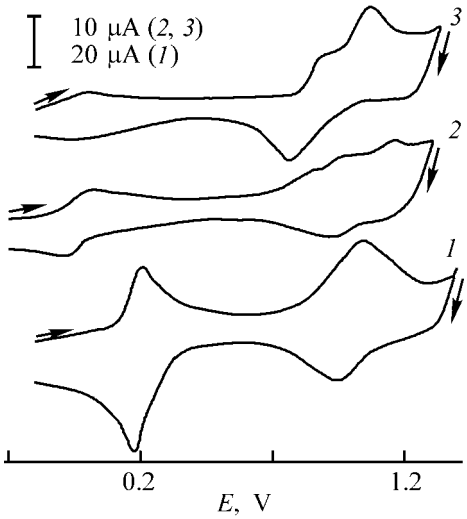

Fig. 1. Voltammograms obtained on GC with coatings composed of (*1*) $KFe^{II}Fe^{III}(CN)_6$, (*2*) RuO–FeCN, and (*3*) RuO–RuCN on the background of a 0.1 M solution of K_2SO_4 in the presence of 0.01 M H_2SO_4. (*E*) Potential; the same for Figs. 3, 4.

Introduction of ruthenium ions into the composition of an inorganic coating leads to an increase in the number of anodic and cathodic peaks in the cyclic voltammogram (Fig. 1; curves *2*, *3*). The voltammogram of an electrode with a RuO–RuCN coating contains three well pronounced anodic and reverse-cathodic peaks at potentials in the range from –0.2 to 1.5 V. Although data that could be used to assign each peak to a particular redox pair are still lacking, the electrochemical reactions occurring at a potential of 0.05 V are commonly attributed to the redox pair Ru(III/II), and peaks at 0.80 and 1.10 V, to oxidation of mixed-charge ruthenium ions bound to oxo and cyano groups to higher oxidation states. For example, it was assumed in [10, 13] that electron transfer occurs at E = 0.80 V, and Ru(IV) is oxidized to Ru(VI) at E = 1.05 V. An assumption was made in [11, 14] that the two current peaks observed at potentials of 0.6 to 1.2 V are associated with electrochemical transformations of the redox pairs Ru(III)/Ru(IV) and $Ru(II)(CN)_6/Ru(III)(CN)_6$. If account is taken of the similarity between the shapes of the voltammograms obtained on electrodes modified with Ru and RuO_2 species [19] and with a RuO–RuCN coating and published data obtained in studying these coatings by X-ray photoelectron spectroscopy [20] are analyzed, it may be concluded that the peaks observed in the curves are to be attributed to the following electrochemical reactions:

$$Ru(II) \rightleftarrows Ru(III) + e, \quad E = 0.05 \text{ V}; \qquad (1)$$

$$Ru(III) \rightleftarrows Ru(IV) + e, \quad E = 0.80 \text{ V}; \qquad (2)$$

$$Ru(IV) \rightleftarrows Ru(VI) + 2e, \quad E = 1.05 \text{ V}. \qquad (3)$$

The anodic and cathodic peaks recorded on GC modified with a RuO–FeCN coating (Fig. 1, curve *2*) are probably also associated with electrochemical reactions (1)–(3). The peak recorded at E = 0.2 V in the voltammogram of the electrode with a $KFe^{II}Fe^{III}(CN)_6$ coating (Fig. 1, curve *1*) and associated with oxidation of $Fe(CN)_6^{3-}$ ions is not observed in the voltammogram of the electrode with a RuO–FeCN coating. Possibly, the electrochemical reaction $Fe(CN)_6^{4-} \rightarrow Fe(CN)_6^{3-}$ occurs at potentials that are characteristic of the redox pair Ru(III)/Ru(II), which leads to a certain increase in the height and width of the peak at E = 0.05 V, compared with the peak observed on GC with a RuO–RuCN coating.

An HCM coating was deposited onto the surface of graphite electrodes electrochemically. The $KFe^{II}Fe^{III}(CN)_6$ coating was obtained using the procedure suggested in [17], and the RuO–FeCN coating, by the method described in [21].

The RuO–RuCN coating was deposited in two ways: potential sweeping in a fixed range or potentiostatic electrodeposition (Table 1). The voltammetric curves were compared by the peak observed at E = 1.05 V. When the first method was used, the potential was varied in a cyclic way in the range –0.2…+1.1 V. This is the optimal range of potentials. If the starting potential of sweeping was shifted into the anodic region, the current of the peak decreased at E = 1.05 V (Table 1). Using the potentiostatic electrodeposition instead of potential sweeping did not lead to any increase in the intensity of the peaks observed

Table 1. Conditions of electrodeposition of coatings composed of ruthenium(III) hexacyanoruthenate(II) on the surface of GC

Potential sweep		Potentiostatic electrodeposition	
potential, V	i_p, μA	potential, V	i_p, μA
+0.35…+1.1	7	+0.50	6
+0.20…+1.1	8	+0.70	9
+0.10…+1.1	10	+0.80	10

* E_{mod} and i_{mod}, potential and current of the oxidation peak of the modifier; E_{cat} and i_{cat}, potential and current of catalytic oxidation of ethanol on CME.

(Table 1). However, as can be seen in Fig. 2, this made it possible to shorten the time in which an inorganic coating was obtained by a factor of 2.

The coating is stable only in an acid medium. Figure 3 shows as an example voltammograms obtained on CME with a RuO–RuCN coating at different pH values. Making the pH higher impaired the shape of the peaks, with the anodic peaks becoming lower and the cathodic peaks even disappearing at all. In alkaline solutions, the coating disintegrates and repeated recording yields only the background curve characteristic of the unmodified GC.

A comparison of the properties of the coatings in question revealed that reproducible results are obtained on the electrode coated with FeO–FeCN when voltammograms are recorded in a narrow range of potentials: –0.5 to 0.5 V. In polarization of the electrode, the film disintegrates beginning at $E > 0.5$ V, which distorts the shape of the voltammogram and leads to a decrease in the intensity of the signal. Chemically modified electrodes with films containing oxo compounds of ruthenium can be used in a wider range of electrode polarizations, up to $E = 1.3$ V. The fabrication methods and the electrochemical and working properties of electrodes coated with RuO–FeCN and RuO–RuCN are similar in many respects. However, RuO–RuCN coatings are distinguished by a higher chemical and electrochemical stability. For example, the RuO–FeCN coating is stable during several days, and the RuO–RuCN coating, during several months, which is indicated by the good reproducibility of cyclic voltammograms obtained on the background of a 0.01 M H_2SO_4 solution. In addition, higher anodic and cathodic peaks are recorded on the electrode with this coating (Fig. 1).

Ethanol is not oxidized at potentials in the range from –0.2 to 1.4 V (Fig. 4, curve *1*) although the equilibrium potential of the redox system CH_3CHO/C_2H_5OH is 0.19 V [18]. A study of the electrooxidation of ethanol on electrodes coated with the HCM in question (Table 2) demonstrated that ethanol is not oxidized

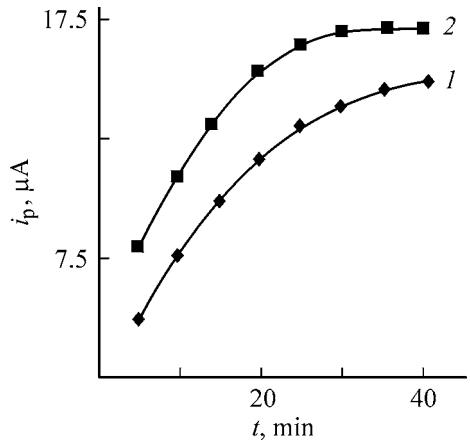

Fig. 2. Oxidation current i_p of the modifier at E_p = 1.05 V vs. the time t of electrodeposition (*1*) with potential sweeping in the interval –0.2…1.1 V and (*2*) in the potentiostatic mode at E_e = 1.05 V.

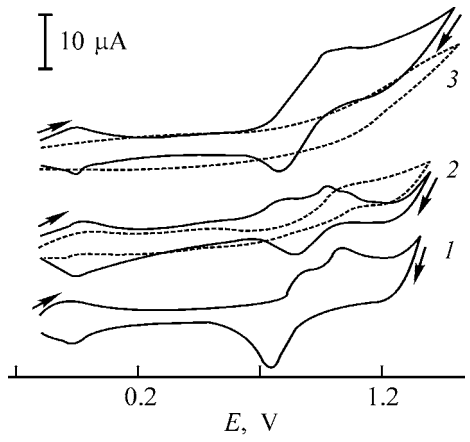

Fig. 3. Voltammograms obtained on GC with a RuO–RuCN coating on the background of (*1*) 0.1 M H_2SO_4 solution, (*2*) 0.1 M K_2SO_4 solution, and (*3*) borate buffer solution with pH 9.0. *Dashed line*: repeated sweep.

Table 3. Analytical parameters obtained in determining ethanol on GC modified with HCM coatings in stationary and FIA conditions [regression equation $i = a + bc$ (i, μA; c, M)]

Electrode	c, M	$a \pm \Delta a$	$(b \pm \Delta b) \times 10^4$	R
		Stationary conditions		
RuO–FeCN	1×10^{-3}–5×10^{-2}	4.03 ± 0.03	76 ± 0.2	0.997
RuO–RuCN	1×10^{-4}–5×10^{-2}	8.89 ± 0.02	19 ± 0.9	0.999
		FIA conditions		
RuO–RuCN	1×10^{-5}–5×10^{-2}	0.70 ± 0.06	2.1 ± 0.3	0.998

on CME coated with $KFe^{II}Fe^{III}(CN)_6$ and, therefore, the shape of the background voltammogram is not changed in the presence of the substrate. In oxidation of ethanol on CME with a RuO–FeCN or RuO–RuCN coating, a considerable increase in current is observed in the same range of potentials.

Figure 4 shows cyclic voltammograms obtained in the absence (curve *2*) and in the presence (curve *3*) of ethanol on an electrode modified with a RuO–RuCN coating. It can be clearly seen that electrocatalytic oxidation of ethanol occurs on CME. In this case, an increase in the peak current is observed at $E_p = 1.05$ V. At the same potential, the blank curve (Fig. 4, curve *2*) shows a current peak characteristic of the transition –Ru(IV)O → –Ru(VI)O, i.e., the substrate is oxidized in the oxidation region of this modifier. The peak

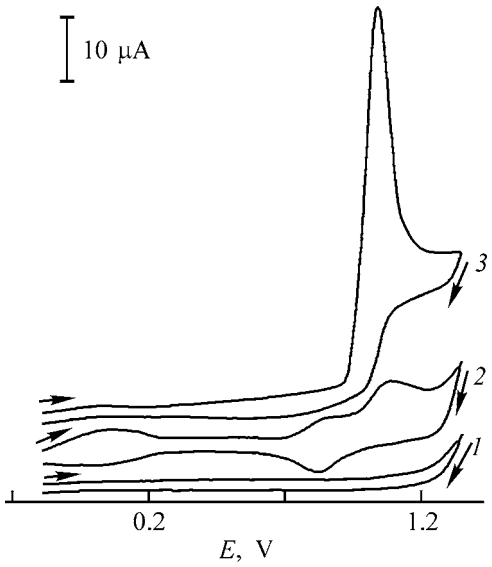

Fig. 4. Voltammograms of ethanol oxidation on (*1*) GC and (*3*) GC with a RuO–RuCN coating on the background of a 0.1 M H_2SO_4 solution. Ethanol concentration 5×10^{-2} M; the same for Fig. 5. (*2*) Blank curve obtained on GC with a RuO–RuCN coating.

current linearly depends on the ethanol concentration. The manyfold increase in the current, decrease in the overvoltage of substrate oxidation, and the value of the Semerano coefficient $\Delta\log i/\Delta\log v$ [22], equal to 0.3, suggest that the electrochemical process is of a catalytic nature.

The mechanism of ethanol electrooxidation is complicated and depends on the range of potentials in which the voltammograms are recorded [23]. In the first stage, ethanol oxidizes to an aldehyde, but deeper oxidation of the substrate to acetic acid is also possible. The scheme of the electrochemical reaction can be represented as

$$\text{–Ru(IV)O} \rightleftarrows \text{–Ru(VI)O} + 2e, \quad (4)$$

$$C_2H_5O + \text{–Ru(VI)O} \begin{cases} \rightarrow CH_3CHO + \text{–Ru(IV)O} + 2H^+, \\ \rightarrow CH_3COOH + \text{–Ru(IV)O} + 2H^+. \end{cases} \quad (5)$$

It should be noted that the catalytic effect, defined as the difference of the catalytic current i_{cat} and the peak current of modifier oxidation, i_{mod}, which is recorded in the background curve at $E = 1.05$ V, divided by i_{mod}, is observed on CME with RuO–FeCN and RuO–RuCN coatings (Table 2). However, the RuO–RuCN coating has a higher catalytic current, which makes the sensitivity of ethanol determination higher and the range of determinable ethanol concentrations wider.

A linear dependence of the catalytic current on the ethanol concentration is observed in the range 1×10^{-3}–5×10^{-2} M for RuO–FeCN and 1×10^{-4}–5×10^{-2} M for RuO–RuCN (Table 3). Moreover, the RuO–RuCN coating is more stable. Therefore, it is more appropriate to use CME with this type of coating for analytical purposes.

A chemically modified electrode based on ruthenium(III) hexacyanoruthenate(II) was used to determine

ethanol under conditions of a flow-injection analysis (FIA).

The FIA signal was recorded in the potentiostatic mode. Preliminarily, the influence exerted by hydrodynamic parameters on the magnitude of the FIA signal was studied. The maximum FIA signal is observed at a volume V of a sample injected equal to 0.6 ml (Fig. 5, curve *1*) and a flow rate u of 3.5 ml min^{-1} (Fig. 5, curve *2*).

The dependence of the current on the voltage applied to a CME with an electrodeposited RuO–RuCN coating was studied under these hydrodynamic conditions. The maximum current was observed at E = 1.05 V (Fig. 5, curve *3*). The data obtained were used to establish the working conditions of recording of a FIA signal on CME: u = 3.5 ml min^{-1}, V = 0.6 ml, E = 1.05 V.

The analytical parameters of the amperometric FIA determination of ethanol on a CPE modified with a RuO–RuCN coating are listed in Table 3. The magnitude of the FIA signal is a linear function of the substrate concentration in the range 5×10^{-2}–1×10^{-5} M, which is an order of magnitude wider than that under stationary conditions. The detection limit calculated using the 3s-criterion [24] is 8×10^{-6} M.

In assessing the metrological characteristics of different electrodes, the reproducibility of results of FIA determinations was analyzed. It was established that, in prolonged use (for 8 h) of a CME in a flow-through cell without renewal of the surface, the magnitude of the FIA signal remains virtually unchanged. The S_r calculated for the oxidation current in the case of ethanol (c = 0.05 M) does not exceed 3% (at n = 20).

Thus, graphite electrodes with a coating composed of ruthenium(III) hexacyanoruthenate(II) can be used for voltammetric determination and amperometric detection of ethanol under FIA conditions without preliminary sample preparation.

The method of voltammetric determination of ethanol on a graphite electrode coated with ruthenium(III) hexacyanoruthenate(II) was tested on ethanol-containing solutions. It was established that matrix components do not hinder the determination of ethanol. Most part of organic compounds present in solutions (carbohydrates, polyphenols, volatile organic acids, and mineral salts) exhibit no electrochemical activity and, therefore, have no effect on the results obtained when determining ethanol. Presence of alcohols (propanol, butanol, amyl alcohol), polyalcohols (sorbitol, mannitol, glycerol), aldehydes (e.g., acetaldehyde), oxy acids (tartaric, malic, and sorbic), and vitamins of groups B and C, which are all oxidized on the CME suggested does not affect the determination of ethanol without preliminary sample preparation, either, because the content of these components is considerably lower than that of ethanol.

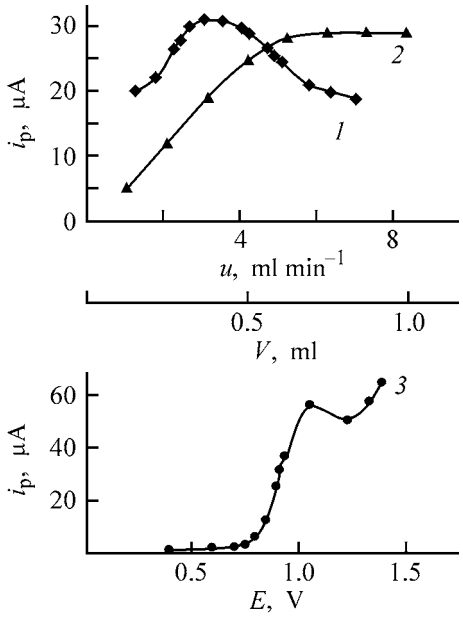

Fig. 5. FIA signal produced in ethanol oxidation on CPE modified with a RuO–RuCN coating vs. (*1*) flow rate u, (*2*) volume V of a sample injected, and (*3*) applied potential E on the background of a H_2SO_4 solution with pH 2.0. (i_p) Peak current.

The procedures developed for determining ethanol on CME with catalytic properties are distinguished by simplicity, high sensitivity, and short time of analysis (10 min); moreover, the necessary sample volume is small (V = 0.5 ml).

EXPERIMENTAL

A PU-1 polarograph and a PI-50-1.1 potentiostat were used to record dc voltammograms with linear and triangular potential sweep in a three-electrode cell. As indicator electrodes served GC and CPE with working surface areas of 0.1 and 0.09 cm^2, respectively, and CME. A silver chloride electrode served as reference, and a platinum wire, as an anode. The procedure used to fabricate the CPE was described in [19]. GC and CPE were used as supports in fabricating a film CME. By analogy with that described in [21], the method employed for this purpose consists in the following: first, the surface of a graphite electrode is polished on filter paper; then, the electrode is rinsed with distilled water and introduced into an el-

ectrochemical cell containing a freshly prepared solution: 1×10^{-3} M $RuCl_3$, 1×10^{-3} M $K_4[Ru(CN)_6]$ {or $K_4[Fe(CN)_6]$}, and 0.01 M H_2SO_4, and the potential is varied by means of sweeping in the range from –0.2 to 1.1 V at a rate of 100 mV s^{-1} for 40 min. Then the electrode is removed from the cell, rinsed with distilled water, and dried.

The FIA was performed on a setup comprising a peristaltic pump, injector, flow-through electrochemical cell, and recording unit [25]. The solutions used were delivered and discharged via flow-through lines made of silicone tubes with an inner diameter of 2.0 mm. The injection was performed with a microsyringe through a sealing membrane.

The standard ethanol solution (c = 1.0 M) was prepared from 96% ethanol. Solutions with lower concentrations were obtained by successive dilution of the standard solution.

To make the solutions electrically conducting, 0.1 M aqueous solutions of H_2SO_4, KOH, and K_2SO_4, and a borate buffer solution were used. The pH value was monitored with a pH-150 pH-meter.

CONCLUSIONS

(1) It was found that ruthenium(III) hexacyanoferrate(II) and hexacyanoruthenate(II) electrodeposited onto the surface of a graphite electrode exhibit a catalytic activity in oxidation of ethanol. A catalytic peak was observed at E = 1.0 V in the region of Ru(IV) oxidation. The conditions in which a chemically modified electrode with an inorganic coating composed of hexacyanometallates can be fabricated and the maximum catalytic current of ethanol oxidation on this electrode were determined.

(2) A method for voltammetric determination of ethanol on an electrode modified with a coating composed of ruthenium(III) hexacyanoruthenate(II) was developed. A procedure for amperometric detection of ethanol on this electrode under conditions of a flow-injection analysis was suggested. The electrochemical and hydrodynamic conditions for signal recording were established. A linear dependence of the catalytic current on the concentration of ethanol was observed in the range 1×10^{-4}–5×10^{-2} M under stationary conditions and 1×10^{-5}–5×10^{-2} M under conditions of a flow-injection analysis.

(3) It was established that the matrix components of ethanol-containing solutions do not hinder the determination of ethanol. The method suggested for determining ethanol is distinguished by simplicity, high sensitivity, good precision, short analysis duration, and use of samples with small volume.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Carbon Nanostructures as Hydrogen Sorbent for Anode of a Chemical Power Cell

M. O. Danilov and A. V. Melezhik

Received June 24, 2004

Abstract—Carbon nanofibers with a porous structure and a specific surface area of 300–475 $m^2 g^{-1}$ were synthesized by pyrolysis of acetylene on iron-containing catalysts. The possibility of using the carbon nanostructures synthesized as hydrogen sorbents to replace hydride-forming metal alloys in chemical power cells was analyzed.

Further development of electronics is impossible without use of power cells. Among them, alkaline batteries occupy an important place. In the European Community, the manufacture and use of nickel–cadmium and mercury-containing batteries has been prohibited since 1991. Therefore, rechargeable electrochemical systems with nontoxic electrodes and electrolytes are being intensively studied everywhere. The cells in which a cadmium electrode is replaced with a metal hydride electrode have a number of advantages over the conventional nickel–cadmium cells. These are, in addition to the similar technology of manufacture, the higher power and energy density and lower sensitivity to overcharging. Presently, metal hy- dride cells based on rare-earth metal alloys with AB_5 additives are produced with a capacity of 290–320 A h g^{-1}, and those based on Ti–Zr–Ni alloys with AB_2 additives, with a capacity of 385 to 450 A h g^{-1}. At the same time, all these alloys are complicated in preparation and have their own disadvantages.

Therefore, the search for the materials that can adsorb hydrogen electrochemically is being continued. The new structural modifications of carbon, developed in recent decades (Carbyne, fullerenes, nanotubes, and nanofibers), have received much attention of researchers as promising hydrogen accumulators in negatively polarized carbon electrodes in alkaline solutions [1–3]. It is known that, for activated carbon, the amount of adsorbed hydrogen grows with increasing specific surface area [2]. It has also been shown that carbon nanofibers (CNF) and nanotubes sorb a considerable amount of hydrogen at room temperature [3]. CNFs that can retain 10–13 wt % hydrogen at a pressure of 8–11 MPa [4] and 15 wt % [5] have been synthesized, which considerably exceeds the amount of hydrogen accumulated by such metallic alloys as $LaNi_5$.

Also, new carbon nanostructures, porous CNFs, have been described in the literature [6]. In principle, structures of this kind should be good hydrogen sorbents.

The type of a catalyst is known to determine the structure of carbon nanofibers formed by vapor pyrolysis of hydrocarbons. Classical carbon nanotubes, in which graphene layers are oriented along the axis, and CNFs with a crow-shaped and normal orientation of the carbon layers with respect to the fiber axis can be grown by choosing the composition and structure of a catalyst. According to the available data, it is the last two types of carbon nanostructures that are the most efficient hydrogen accumulators. It is assumed that hydrogen is incorporated into nanocavities between the graphene layers.

The aforesaid suggests that carbon nanostructures can be used as a hydrogen electrode in nickel–metal hydride power cells instead of metal alloys. The large specific surface area of nanoparticles and the high porosity and low apparent density of the electrode materials based on them suggest that carbon nanostructures are more efficient hydrogen accumulators than metal alloys.

The aim of this study was to develop methods for synthesis of carbon nanostructures promising as hy-

1070-4272/04/7712-1958 © 2004 MAIK "Nauka/Interperiodica"

drogen accumulators and to analyze the possibility of their use, instead of metal alloys, as electrode materials that can accumulate and store hydrogen in charging of a prototype chemical power cell.

EXPERIMENTAL

CNFs obtained by catalytic vapor deposition were chosen for study. Acetylene served as the source of carbon. It was found that pyrolysis of acetylene on catalysts with carbon and iron clusters on the surface of particles of finely dispersed pyrogenic silica yields porous CNFs. The catalysts were produced by pyrolysis of organometal compounds mechanochemically deposited on aerosil or aluminoaerosil. A thoroughly developed method for preparation of catalysts and the conditions of CNF deposition have been described previously [7]. The selectivity and output capacity of the process are reasonably high. For example, 75–100 g of CNFs at a virtually 100% conversion of acetylene into carbon were obtained in a lab reactor (2 l volume) at 620°C in 3–4 h. Admixtures of metals and silicon dioxide were removed from these materials by treatment in an alkali solution and then in hydrochloric acid. The resulting purified CNFs had a specific surface area of 300–475 $m^2 g^{-1}$ at a fiber diameter of 50–200 nm. The electrical resistivity of compacted powders was 0.08–0.4 Ω cm.

An electron micrograph of a typical nanostructure formed under the given conditions is shown in Fig. 1, and a thermogravimetric curve of a purified CNF sample with a specific surface area of 330 $m^2 g^{-1}$, obtained using a Fe/C/Al_2O_3–SiO_2 catalyst, in Fig. 2. It can be seen that the CNF sample heated in air starts to lose mass above 500°C. The inflections in the thermogravimetric curve are probably due to the presence of different nanostructural forms of carbon in the sample. However, no "amorphous" carbon, which is commonly rather rapidly oxidized by atmospheric oxygen beginning at 350–400°C, is present in the sample. The X-ray diffraction pattern of this sample is virtually identical to that of the CNF sample with a specific surface area of 460 $m^2 g^{-1}$ (Fig. 3, curve *1*) and contains a broadened band with the peak position corresponding to an interplanar spacing of 3.44 Å, which can be probably assigned to the 002 reflections of packages of turbostratified disordered graphene layers, and a wide halo peaked at around 5 Å. Possibly, these bands belong to different structural modifications of carbon, since nanofibers with X-ray diffraction patterns containing only the halo at around 5 Å were obtained on some catalysts (Fe–Sn/C/Al_2O_3–SiO_2).

The specific surface area of multilayer carbon nanotubes can be considerably increased, to 877–1184 $m^2 g^{-1}$, by activation with a KOH melt at 800°C and subsequent washing-out of potassium hydroxide [8]. It was assumed that activated nanotubes of this kind, with a well-developed surface, are promising

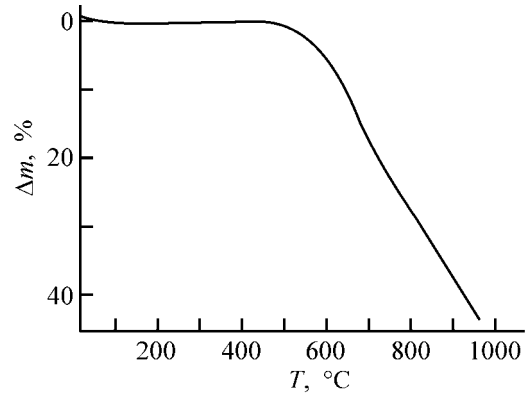

Fig. 2. Thermogravimetric curve of purified CNFs (specific surface area 330 $m^2 g^{-1}$). (Δ*m*) Loss of mass and (*T*) temperature.

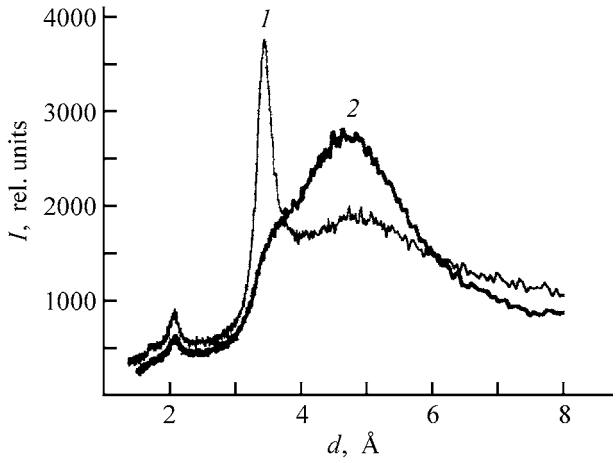

Fig. 3. X-ray diffraction patterns of a CNF sample (*1*) before and (*2*) after activation with a KOH melt. (*I*) Intensity and (*d*) interplanar spacing. Specific surface area ($m^2 g^{-1}$): (*1*) 460 and (*2*) 1700.

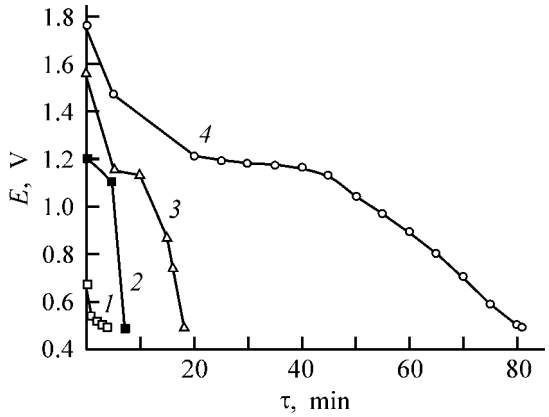

Fig. 4. Discharge curves measured on a prototype power cell with an anode made of carbon materials. (*E*) Potential and (τ) time; the same for Fig. 5. (*1*) Acetylene black, (*2*) activated carbon felt with a specific surface area of 1000 $m^2 g^{-1}$, (*3*) CNF with a specific surface area of 330 $m^2 g^{-1}$, and (*4*) activated CNFs with a specific surface area of 1700 $m^2 g^{-1}$.

electrode materials. The mechanism of activation remains unclear. Probably, carbon layers partly unfold to form nanocavities. We attempted to apply this method to obtain a more developed surface in CNF synthesized by the technique described above.

An X-ray diffraction pattern of CNF obtained by pyrolysis of acetylene on the $Fe/C/SiO_2$ catalyst (curve *1*) and that of the same carbon material activated with a KOH melt at 750°C in the atmosphere of argon (curve *2*) are shown in Fig. 3. It can be seen that the band at 3.44 Å virtually completely disappears upon activation, and the wide halo at around 5 Å becomes more pronounced. At the same time, the band at around 2.12 Å remains unchanged. Probably, the last band can be assigned to the 001 reflections from the graphene layers. Interestingly, the specific surface area of the material increases from 460 (starting CNFs) to 1700 $m^2 g^{-1}$, whereas the electrical resistivity of a compacted powder decreases from 0.4 to 0.05 Ω cm. These data indicate that activation with a KOH melt disrupts the parallel orientation of the graphene layers, which probably results in the formation of nanocavities between these layers. In the process, the layers themselves remain highly ordered, which is confirmed by the high electrical conductivity of the activated sample. The rise in the electrical conductivity of the sample upon activation is probably due to burning-out of a low-ordered carbon.

The nanocarbon electrodes were tested in a prototype Ni–MH battery in the galvanostatic mode. As a counter electrode served nickel oxide electrode with large area and capacity. As the electrolyte was used a 5 M potassium hydroxide solution containing 1 M lithium hydroxide. The test electrode was in the form of a tablet 30 mm in diameter, obtained by compaction at a pressure of 10 MPa on a nickel mesh. For this purpose, an emulsion of F-4D fluoroplastic was added as a binder to the CNF sample (5% fluoroplastic relative to the mass of CNF). All the potentials are given relative to a silver chloride reference electrode.

After fabrication, the electrode being tested was kept in the prototype battery for 1 h without loading. The cycle of study started from charging with a 50 mA g^{-1} current. All the charging cycles were 3 h long. After the charging was complete, the prototype remained unloaded for 5 min. Then, the discharge cycle was performed until the voltage on the prototype became 0.5 V, after which the charging was started. The discharge current (50 mA g^{-1}) was equal to the charging current.

The self-discharge of the hydrogen-sorbing electrode materials in the prototype battery was studied as follows. First, the prototype was charged with a current of 50 mA g^{-1} to a charging capacity of 450 A h g^{-1}. Then, the dc supply was switched off and the potential of the hydrogen electrode and the open-circuit voltage were measured. The prototype was stored for 24 h or a week, and after that the electrode potential and the open-circuit voltage were measured again. Then, the power supply was connected and the prototype was discharged with a current of 20 mA g^{-1}. After that, the discharge capacity of a prototype after storage was compared with that obtained directly after charging.

It is known from the literature that hydrogen is formed under these conditions of charging on the carbon electrode through reduction of water, and this hydrogen easily penetrates into nanopores present in the carbon material [1].

Hydrogen-sorbing electrodes made of acetylene black (AB), activated carbon felt (ACF, 1000 $m^2 g^{-1}$), CNF (330 $m^2 g^{-1}$), and activated CNFs (ACNF, 1700 $m^2 g^{-1}$) were fabricated and studied. Figure 4 shows the discharge curves measured on a prototype battery with electrodes made of AC (curve *1*), ACF (curve *2*), CNF (curve *3*), and ACNF (curve *4*). It can be seen that the hydrogen capacity of the traditional carbon materials (curves *1* and *2*) is very small, 3.2 and 9.2 mA h g^{-1} for carbon black and felt, respectively.

The electrical capacity was 16.7 for CNFs and 135 mA h g^{-1} for activated CNFs. The shape of the discharge and charging curves with a plateau and the potential in this region relative to that of the reference electrode show that there occurs an electrochemical reaction of oxidation–reduction of hydrogen.

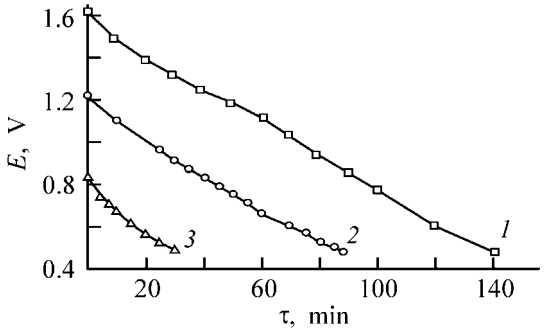

Fig. 5. Influence of the storage time on the self-discharge of the electrode made of activated CNFs with a specific surface area of 1700 $m^2 g^{-1}$ (discharge current 20 mA g^{-1}). Discharge curve: (*1*) measured immediately after discharge, (*2*) after 24 h of storage of a charged prototype, and (*3*) after 1 week of storage of a charged prototype.

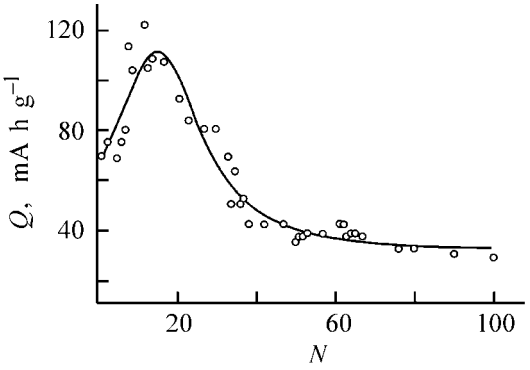

Fig. 6. Variation of the discharge capacity *Q* of a prototype power cell during cycling to complete discharge of the electrode made of activated CNFs with a specific surface area of 1700 $m^2 g^{-1}$ with the number of cycles, *N*.

As can be seen from Fig. 4, the CNFs have a considerably higher capacity, compared with carbon black and felt, despite that their specific surface area is smaller. The activation of CNF leads to a dramatic increase in the electrical capacity. For hydrogen electrodes based on carbon black and felt, the self-discharge was 100% in 24 h. For CNFs with a specific surface area of 330 $m^2 g^{-1}$, the residual capacity after 24 h was 3% of the initial value. It should be noted that the experiments were performed without hermetically sealing the prototype, so that the self-discharge is probably caused by diffusion of hydrogen from the electrode.

Figure 5 shows the results of a study of the self-discharge of a prototype power cell based on ACNF with a specific surface area of 1700 $m^2 g^{-1}$. As can be seen, the electrical capacity is 56% after 24 h of storage and 24% of the initial capacity after a week of storage.

The results obtained in a study of the self-discharge of the hydrogen electrodes made of CNFs show that, as the specific surface area of CNF increases (as a result of activation), the ability of the electrodes to store electrochemically accumulated hydrogen is improved.

Figure 6 shows how the electrical capacity of a prototype battery based on activated CNF with a specific surface area of 1700 $m^2 g^{-1}$ varies with the number of charging–discharge cycles. It can be seen that, after 100 cycles with a 100% discharge, the electrical capacity decreases by 25% of the initial value. In the process, the electrode crumbled, which is apparently due to the nonoptimal amount of binder in the hydride electrode.

It should be noted that the experiments described here were performed in an unsealed prototype power cell under atmospheric pressure. Probably, if charged under elevated pressure, the CNF electrodes could retain a considerably larger amount of electrochemically accumulated hydrogen.

CONCLUSIONS

(1) Pyrolysis of acetylene on catalysts containing carbon and iron compounds as clusters on supports made of finely dispersed pyrogenic silica yields carbon nanofibers with a porous structure.

(2) When the carbon nanofibers obtained are activated with a potassium hydroxide melt, the orientation of graphene layers changes, the specific surface area and electrical conductivity considerably increase, and the electrochemical parameters are improved.

(3) The resulting carbon nanofibers can be used as hydrogen sorbents in chemical power cells instead of a metal hydride anode.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Electrochemical Polymerization of Complexes [Ni(Salpn-1,3)] and [Cu(Salpn-1,3)]

L. P. Ardasheva, G. V. Vovk, L. G. Pchelova, and G. A. Shagisultanova

Hertzen Russian State Pedagogical University, St. Petersburg, Russia

Received July 9, 2004

Abstract—New experimental data characterizing the conditions of electrochemical synthesis of stable electrically conducting electrochromic polymeric film systems based on the complexes [Ni(Salpn-1,3)] and [Cu(Salpn-1,3)] [Salpn-1,3 is *N,N'*-propylenebis(salicylidenimine)] in a 0.1 M Bu_4NClO_4/CH_2Cl_2 solution are presented. The redox conductivity of the new polymers is characterized by the charge diffusion coefficient. The electrochemical stability of the polymeric films is analyzed in relation to the potential and time of accumulation, and also to the range of potential sweeping.

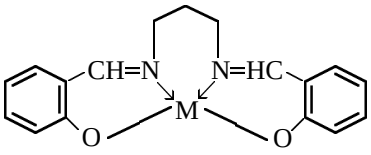
Studies of thin electrically conducting electrochromic metal-containing polymeric films on solid supports are of current interest because of the possibility of creating electro- and photocatalysts, sensors, and solid-phase galvanic cells for conversion of the energy of light on their basis [1, 2].

In the last fifteen years, polymeric film systems based on complex compounds of transition metals with macrocyclic ligands of varied composition and structure have been synthesized and rather extensively studied, including *N,N'*-ethylenebis(salicylidenes) [3–10], porphyrins [11], phthalocyanines [12], etc. Complexes with ligands of this kind are of the utmost interest to a researcher, because they are models and (or) analogues of most important natural organometallic compounds.

However, despite that a considerably body of experimental data has been obtained, the optimization of the synthesis conditions and analysis of the structure, stability, and functional features of organometallic polymers, including the best-studied compounds of copper(II) and nickel(II), remains a matter of current interest.

The present communication reports original results characterizing the synthesis conditions of polymeric systems based on the complexes [Cu(Salpn-1,3)] and [Ni(Salpn-1,3)], where Salpn-1,3 is *N,N'*-propylenebis(salicylidenimine)], in a solution of methylene chloride. It should be noted that the ability of the complex [Cu(Salpn-1,3)] to form, as a result of oxidation at the electrode, photosensitive electrically conducting polymers has been revealed previously [10], whereas the possibility, in principle, of polymerization of [Ni(Salpn-1,3)] is established for the first time.

The complexes [Ni(Salpn-1,3)] and [Cu(Salpn-1,3)]



M = Ni(II), Cu(II)

were synthesized by the known methods [10]. The complexes were identified by electronic absorption spectroscopy in the visible and near-UV spectral ranges and by X-ray photoelectron spectroscopy (XPS). XPS spectra were obtained on an Axis Ultra electronic spectrometer (Kratos Analytical, UK) under excitation with monochromatic Al_{K_α} radiation (1486.6 eV).[1] During the experiments, the initial vacuum in the spectrometer was 5×10^{-7} Pa. The spectra obtained were processed with a Vision software package (Kratos Analytical). The scale of binding energies was calibrated against the C1s line of aliphatic carbon (E_b = 285.0 eV). The binding energies of photoelectrons and the atomic concentrations of selected components of the photoelectron spectra for the ligand H_2Salpn-1,3

[1] The XPS spectra were measured by A.V. Shchukarev (St. Petersburg State University)

Table 1. Binding energies of photoelectrons and atomic concentrations of selected components of the XPS spectra of the starting compounds

Line	H_2Salpn-1,3		[Cu(Sapn-1,3)]		[Ni(Sapn-1,3)]	
	E_b, eV	atomic concentration, at.%	E_b, eV	atomic concentration, at.%	E_b, eV	atomic concentration, at.%
C1*s*	285.0	51.7	285.0	51.9	285.0	49.6
	286.4	28.5	286.4	28.6	286.5	22.4
					288.7	2.4
O11*s*			529.6	0.1		
	531.1	1.8	531.2	7.0	531.6	11.7
	533.0	7.9	532.1	0.5	533.0	1.5
N1*s*	399.1	7.1	399.5	7.2	399.5	6.0
	399.9	1.8				
	401.3	0.6	401.8	0.3	401.3	0.4
	402.9	0.6	403.5	0.6	403.5	0.6
Cu2*p*			934.7	3.7		
			936.7	0.1		
Ni2*p*					855.4	5.4

and the complexes [Cu(Salpn-1,3)] and [Ni(Salpn-1,3)] are listed in Table 1.

The presence of two components with binding energies of 531.1 and 533.3 eV in the spectra of O1*s* and two highest-intensity components with binding energies of 399.1 and 399.9 in the spectra of N1*s* for a free protonated ligand and H_2Salpn-1,3 can presumably be accounted for by the equilibrium transfer of a proton from an oxygen atom to a nitrogen, with the equilibrium shifted toward formation of hydroxy groups. The component with a binding energy of 402.9 eV in the spectra of N1*s* can be attributed to and electronically excited state of the π–π^* type, and the component with a binding energy of 401.3 eV is, in all probability, due to presence of trace amounts of the solvent used in synthesis.

The formation of the complexes [Cu(Salpn-1,3)] and [Ni(Salpn-1,3)] is accompanied by a change in the binding energies of the highest-intensity components in the spectra of O1*s* and N1*s*, compared with the case of a free ligand. For example, the binding energy of the N1*s* electron increases for both the complexes from 399.1 to 399.5 eV and that of the O1*s* electron decreases from 533.0 to 51.2 and 531.6 eV for [Cu(Salpn-1,3)] and [Ni(Salpn-1,3)], respectively.

Nickel has in the complex a binding energy of 2*p*-electrons equal to 855.4 eV, which corresponds to Ni(II) [11].

It follows from the spectrum of the [Cu(Salpn-1,3)] complex that copper is present in the starting compound in two different chemical states with binding energies of the Cu2*p* line equal to 934.7 and 936.7 eV. The main line with E_b = 934.7 eV can be attributed to the Cu(II) ion [11]. The line with a low intensity of the component with E_b = 936.7 eV is probably due to the presence of dimeric structures of the type Cu–O–Cu [12, 13].

The electrochemical measurements were performed with a PI-50-1 pulsed potentiostat with a PR-8 programming unit in the potentiostatic and potentiodynamic modes with a linear potential sweeping at sweep rate in the range 0.01–0.5 V s^{-1} in a three-electrode with separated spaces. A platinum wire (99.99% Pt) embedded in glass, with a surface area of 0.25 cm^2, was used as a working electrode, and a platinum wire, as an auxiliary electrode. All the potentials are given relative to a silver chloride glass electrode filled with a saturated solution of NaCl.

The concentration of the monomeric complex in the working solution was 1 mM. A 0.1 M solution of tetrabutylammonium perchlorate (Bu_4NClO_4) in methylene chloride (CH_2Cl_2), deaerated with high-purity argon, served as a supporting electrolyte.

Figures 1a and 1b show typical cyclic voltammograms reflecting the first 10 cycles of anodic polarization of the complexes [Cu(Salpn-1,3)] and [Ni(Salpn-1,3)], respectively, at potentials in the range 0.0 … +1.5 V. In the first cycle, two anodic processes with peaks at $E_{ap}(1) \approx +1.12$ V and $E_{ap}(2) \approx +1.25$ V and one cathodic process with a process at $E_{cp}(1) \approx$

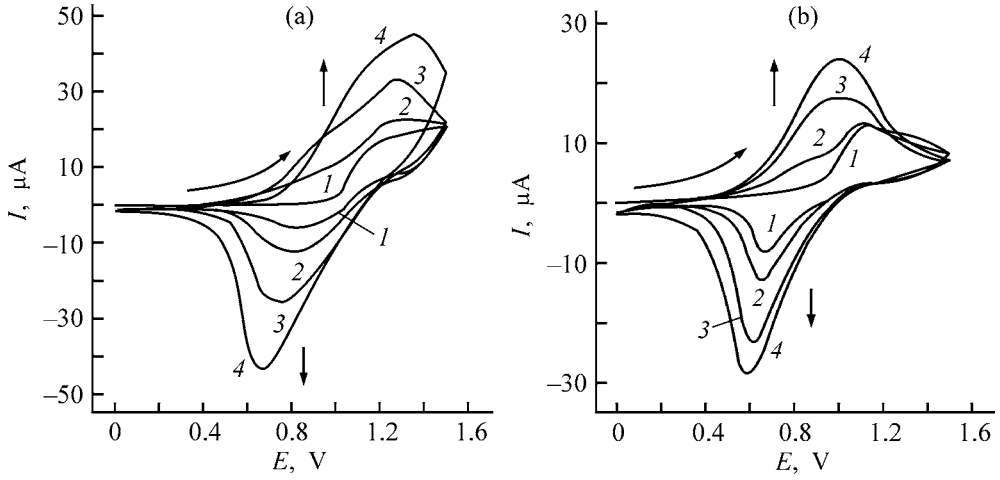

Fig. 1. Cyclic voltammograms reflecting the anodic polymerization of the complex (a) [Cu(Salpn-1,3)] and (b) [Ni(Salpn-1,3)] in potentiodynamic mode in a 0.1 M solution of Bu_4NClO_4 in CH_2Cl_2. $c_{complex} = 1 \times 10^{-3}$ M, $v_{sw} = 0.05$ V s^{-1}. (*I*) Current and (*E*) potential. Cycle of potential sweeping; (*1*) first, (*2*) second, (*3*) fifth, and (*4*) tenth.

+0.75 V are observed for [Cu(Salpn-1,3)] and one anodic and one cathodic peaks at $E_{ap} \approx +1.13$ V and $E_{cp} \approx +0.67$ V, respectively, for [Ni(Salpn-1,3)]. Further potential sweeping results in that a new broad wave at +0.6…+0.95 V without any clearly pronounced peaks appears in the anodic branch of the cyclic voltammogram and the intensities of all the current peaks observed in the first cycle increase. This effect indicates that a new solid substance is formed on the surface of an electrically conducting substrate. Visual inspection confirms the presence of a brightly colored film on the electrode surface. The color of the film is independent of the oxidation state of the substance on the electrode. For example, oxidized forms of poly[Cu(Salpn-1,3)] and poly[Ni(Salpn-1,3)] have a dark green and brown-yellow color, respectively, and the reduced forms are light green and pale yellow.

However, the rise in the peak currents virtually terminates for poly[Ni(Salpn-1,3)] by the tenth cycle, and the currents start to decrease. In the cyclic voltammograms reflecting the polymerization of [Cu(Salpn-1,3)], the anodic wave at $E = +0.7$ V is shifted, beginning with the fifth cycle of potential sweeping, to more positive potentials. Both the effects observed are probably due to a decrease in the redox activity of the polymeric film on the electrode surface, which is caused by an irreversible oxidation of the ligand or by passivation of the polymeric material. Nevertheless, films of poly[Ni(Salpn-1,3)] were found to be more stable than poly[Cu(Salpn-1,3)] at potentials in the range 0.0…+1.5 V. This is, in all probability, due to the role of the central metal atom. Comparison of the potentials at which the peaks of anodic currents of the first and subsequent cycles of polymerization are observed suggests that oxidation processes with the highest intensity (highest current strength) in poly[Cu(Salpn-1,3)] occur at more positive potentials than those in poly[Ni(Salpn-1,3)]. Apparently, the probability of overoxidation of the ligand environment decreases in the last case, and thereby the electrochemical stability of the polymer formed increases. Also to a decrease in the probability of overoxidation of the organic component of both the complexes can be attributed the fact that, as the range of potential sweeping is narrowed to 0.0…+1.3 V, electrochemically more stable films can be obtained in a larger (no less than 30) number of cycles than in the case of the 0.0…+1.5 V range.

The polymers were synthesized under potentiostatic conditions in a prescribed time at the experimentally established potentials with account of the potentials of the anodic peaks in the cyclic voltammograms of the first cycles. The presence of two peaks in the curve of a single cycling of [Cu(Salpn-1,3)] resulted in that two accumulation potentials, $E = +1.25$ and +1.1 V, were used in synthesis. As demonstrated by experiments, thick electrochemically active films cannot be obtained at $E = +1.25$ V. Already by the fifth minute of synthesis at this potential, the cyclic voltammogram of film-type poly[Cu(Salpn-1,3)] shows a significant decrease in the currents of the anodic and cathodic peaks and acquires a shape characteristic of a cyclic voltammogram recorded on a clean platinum electrode in a supporting electrolyte that does not contain the complex under study. At the same time, the accumulation potential of +1.1 V ensures accumulation of electrochemically stable polymeric systems based on both [Cu(Salpn-1,3)] and [Ni(Salpn-1,3)].

* The range of potential sweeping corresponds to that in which the polymer was synthesized.

To determine the electrochemical parameters characterizing the individual substances poly[Cu(Salpn-1,3)] and poly[Ni(Salpn-1,3)], electrodes with the corresponding polymers synthesized were transferred into a solution of a pure supporting electrolyte and then cyclic voltammograms reflecting redox processes in the solid phase were recorded.

An analysis of the cyclic voltammograms obtained at different potential sweep rates on an electrode coated with poly[Ni(Salpn-1,3)] or poly[Cu(Salpn-1,3)] yielded the potentials of anodic and cathodic current peaks, which characterize the redox process in the polymers under study (Table 2). The data in Table 2 indicate that, as the potential sweep rate increases, the peaks of anodic currents are strongly shifted to more positive values, and the cathodic peaks, to negative values. This points to a considerable overvoltage of redox processes occurring in the solid phase of both polymers. This results from hindrance to motion in the polymer of ions of the supporting electrolyte, whose motion velocity is the rate-determining stage of charge transport in polymeric systems of this kind [14].

The thicknesses h of the polymers studied were calculated from the data obtained by integrating the areas of the anodic branch of the cyclic voltammograms by the known procedure [1] using the formula

$$h = NM/Sd = QM/FSd,$$

where Q is the amount of electricity consumed for the reduction, found by integrating the area under the anodic branch of the cyclic voltammogram; M, molecular weight of a fragment; F, Faraday number; S, surface area of the electrode; and d, density of the polymer (~1 g cm^{-3}).

For poly[Cu(Salpn-1,3)] and poly[Ni(Salpn-1,3)] with different thicknesses, the charge diffusion coefficient in the polymeric phase, D_{ct}, was calculated. This coefficient reflects the rate of charge transfer and is a characteristic of the redox conductivity of the polymers [1]. The value of D_{ct} depends on the polymer thickness, nature of the supporting electrolyte, and type of solvent [15].

The values of D_{ct} were calculated using data obtained in an analysis of cyclic voltammograms recorded at high potential sweep rates ($\geq$0.1 V s^{-1}), at which the film is not oxidized or reduced completely. In this case, the redox processes in the polymer occur in the semi-infinite-diffusion mode. In this mode, the peak currents in the voltammograms depend linearly on $v_p^{1/2}$, and it can be used to calculate D_{ct}. This calculation was done for both the anodic and the cathodic peaks by means of the Rendls–Shevchik equation [1]

$$I = 2.69 \times 10^{-5} n^{3/2} S D_{ct}^{1/2} v_{sw}^{1/2} c_0,$$

where I is the current of a cathodic (anodic) peak (A); n, number of electrons transferred in an elementary event; S, electrode surface area (cm^2); v_{sw}, potential sweep rate (V s^{-1}); and c_0, concentration of electrochemically active centers in the polymeric film (M).

The values calculated show that, for poly[Cu(Salpn-1,30] of thickness 0.05 and 0.12 μm, the values of

D_{ct} were 6.5×10^{-13} and 5.3×10^{-12} $cm^2\ s^{-1}$, respectively, for the anodic process, and 1.2×10^{-12} and 4.5×10^{-12} $cm^2\ s^{-1}$ for the cathodic process. Similarly, for [Ni(Salpn-1,3)] with h = 0.03 and 0.10 μm, the values of anodic D_{ct} were 3.3×1^{-13} and 3.5×10^{-12} $cm^2\ s^{-1}$, respectively, and those of the cathodic D_{ct}, 1.6×10^{-12} and 6.0×1^{-12} $cm^2\ s^{-1}$. Further increase in the polymer thickness leads to a decrease in the redox conductivity of the polymeric systems, because high potential sweep rates, at which D_{ct} is to be calculated, do not ensure oxidation of the polymeric phase. This is due to a pronounced hindrance to motion of ions of the supporting electrolyte in such a comparatively viscous solvent as methylene chloride.

CONCLUSIONS

(1) It was established that electrochemical synthesis of thin-film electrically conducting polymers based on the complex [Ni(Salpn-1,3)] is, in principle, possible.

(2) A study of the conditions of electrochemical synthesis of polymeric compounds based on the complexes [Ni(Salpn-1,3)] and [Cu(Salpn-1,3)] in the potentiostatic accumulation mode demonstrated that the optimal accumulation potential, at which polymeric films with the thickest electrically active layer are formed in unit time, is $+1.1 \pm 0.5$ V.

(3) It was established that the anodic and cathodic processes in poly[Cu(Salpn-1,3)] in a pure supporting electrolyte occur at more positive potentials than the processes in poly[Ni(Salpn-1,3)] synthesized in the same number of cycles.

(4) The rate of charge transport in poly[Cu(Salpn-1,3)] and poly[Ni(Salpn-1,3)] grows as the thickness of the polymeric phase increases.

(5) Poly[Cu(Salpn-1,3)] is electrochemically stable in a wider (up to +1.5 V) range of potentials than poly[Ni(Salpn-1,3)].

Abstract—Purification of ammonium-chloride-bromide cobalt-containing electrolyte to remove ions of impurity metals with an adsorbent containing complexing organic reagents immobilized on the surface of synthetic activated carbon was studied.

Purification of solutions of cobalt(II) salts to remove impurities is an important technological process in manufacture of metallic cobalt and its compounds. The value of both metallic cobalt and its compounds is the better, the higher their purity. Therefore, methods for purification of cobalt-containing solutions, from which the target products are obtained, are being continuously improved [1]. Impurities are removed from electrolytes used in electrochemical production of cobalt by various methods based on the difference between the physicochemical properties of cobalt(II) ions or their compounds and those of ions of accompanying impurities or their compounds (recrystallization and precipitation, hydrolytic and sulfide purification, cementation and preliminary electrolysis, extraction and ion exchange). These methods have a limited capacity as regards both the amount of impurities extracted and the possible degree of extraction. As a rule, deep purification to remove all impurities from the electrolyte requires a combination of several complementary techniques.

In electrochemical recovery of cobalt from solutions of its salts, presence of impurity metal ions discharging at cathodes simultaneously with cobalt ions [Cu(II), Fe(II), Ni(II), Cd(II), Zn(II), etc.] in the electrolyte is undesirable for the electrolysis process and purity of cobalt obtained. A promising method for purification of cobalt electrolytes to remove impurities of this kind is their extraction from solution by selective sorbents. This study is concerned with purification of a cobalt-containing chloride-bromide-ammonium electrolyte (0.5 M $CoCl_2 \cdot 6H_2O$ + 2.0 M NH_4Br, pH 4.8 ± 0.1) to remove ions of some impurity metals with the help of organic reagents immobilized on the surface of synthetic activated carbon. As reagents of this kind served sodium dithiocarbamate, 8-oxiquinoline, 1,10-phenanthroline, and Xylene Orange. As a support for these reagents was used SKNP-2 synthetic activated carbon.

The organic reagents used form with metal ions stable (as a rule) chelate complex compounds, which is indicated by their high stability constants [2, 3]. According to published data on the stability constants of chelate complexes and to the stability series of complex compounds formed by doubly charged cations of transition metals with chelate-forming organic reagents (Irving–Williams series), the most stable complexes are formed by copper(II) ions: Mn(II) < Fe(II) < Co(II) < Ni(II) < Cu(II) > Zn(II) [4]. Consequently, it would be expected that a cobalt-containing electrolyte can be selectively and deeply purified with these reagents to remove Cu(II) even at a high background concentration of Co(II) cations.

However, the complexation involving chelate-forming organic reagents strongly depends on the solution pH, because reagents of this kind are weak acids or weak bases. Cu(II) ions form intracomplex compounds with sodium diethyldithiocarbamate at pH 4–11 [5, 6], 8-oxiquinoline at pH 5.33–14.55, and Xylene Orange

1070-4272/04/7712-1967 © 2004 MAIK "Nauka/Interperiodica"

at pH 5.4–5.8 [7]. Consequently, a weakly acidic cobalt-containing electrolyte can, indeed, be thoroughly purified to remove C(II) ions with the help of the organic reagents mentioned above. It is important that complexes of Co(II) cations with, e.g., sodium diethyldithiocarbamate and 8-oxiquinoline are formed at pH > 7 [8], and, therefore, Co(II) cations must not hinder the complexation of impurity metal cations with these reagents. As a result, it becomes possible to recover from a cobalt-containing electrolyte not only Cu(II) ions, but also ions of other impurity metals. For example, Zn(II) ions form a chelate complex with 8-oxiquinoline even at pH > 4 [4, 8, 9], and, for precipitation of Cd(II) ions with 8-oxiquinoline, it is recommended to acidify the solution with acetic acid (0.5% CH_3COOH) [10]. The complexation of 1,10-phenanthroline and Xylene Orange with cations of many impurity metals also occurs in the weakly acidic medium [4, 6, 9, 10].

The simultaneous use of several reagents makes it possible to recover a wider variety of impurity metals from electrolytes and creates prerequisites for occurrence of a synergetic effect in the process because of the mutual influence of the reagents. Apparently, organic reagents of this kind, immobilized on activated carbon, can be used to recover metal ions forming with the reagents both sparingly soluble and soluble, but little-dissociating compounds from solutions.

EXPERIMENTAL

SKN activated carbons [TU VV (Technical Specification) of the Ukrainian Soviet Socialist Republic 211.003.009–85] are spherical carbonates produced by carbonization of nitrogen-containing polymeric resins with the subsequent activation in a water vapor or in CO_2. These carbons have a high chemical resistance, mechanical strength, and adsorption capacity for a number of organic molecules of various sizes [11]. The immobilization of organic reagents on the surface of the SKNP-2 activated carbon consisted in adsorption of the reagents by the carbon from their saturated solutions. For this purpose, saturated solutions of the reagents in the following solvents were preliminarily prepared: water for sodium diethyldithiocarbamate; ethanol for 8-oxiquinoline; a 2 : 1.5 : 1 (by volume) mixture of $CHCl_3$, C_2H_5OH, and H_2O for 1,10-phenanthroline; and a 4 : 1 (by volume) mixture of H_2O and C_2H_5OH for Xylene Orange. The procedure used to prepare the carbon and to immobilize organic reagents on its surface has been described in detail previously [12]. Prior to sorption purification of a cobalt-containing electrolyte to remove impurities, modified activated carbons were mixed in such a way that the content of each organic reagent in the mixture was 2 wt %. The resulting mixture of carbons can be regarded as a modified carbon adsorbent with a variety adsorption centers.

The electrolyte was prepared using analytically pure $CoCl_2 \cdot 6H_2O$, chemically pure NH_4Br, and water twice distilled in a quartz apparatus. Solutions with a single impurity contained a $CuCl_2$ additive in amounts ranging from 1 to 55 mM. In multiple-impurity solutions, the following concentration of impurity cations were created (mM): Mn(II) 0.29, Cu(II) 0.3, Zn(II), 0.48, and Cd(II) 0.33. A weighed portion of a mixture of carbons and a certain volume of a solution to be purified were placed in a thermostated cell with a stirrer (180 rpm) and the purification was performed under static conditions. When studying the sorption kinetics, identical fresh portions of the solution being purified and the sorbent were used in each run. The content of impurities in untreated solutions and those after sorption purification was determined by means of atomic-adsorption analysis. The solution pH was measured with an EV-74 pH-meter.

The analytical data obtained were used to calculate the following sorption parameters: coefficient of sorption purification, η_{sr} (%); distribution coefficient of impurities, K_d; and adsorption by Gibbs, Γ:

$$\eta_{sr} = \frac{c_{in} - c_{eq}}{c_{in}} \times 100, \quad (1)$$

$$K_d = \frac{(c_{in} - c_\tau)V}{c_\tau m}, \quad (2)$$

$$\Gamma = \frac{(c_{in} - c_{eq})V}{m}, \quad (3)$$

where c_{in} and c_{eq} are the initial and equilibrium concentrations of impurity metal ions in solution (mM); c_τ, concentration of an impurity metal ion in solution at an instant of time τ (mM); V, solution volume (ml or l); and m, weighed portion of the adsorbent (g).

The adsorption by Gibbs [13] is equal to the excess of a component being sorbed (mol) in a certain solution volume near the adsorbent surface over that in the equal solution volume at a sufficient distance from the adsorbent surface.

To determine the optimal ratio between the weighed portion of the adsorbent and the volume of the solution to be purified, the dependence of the coefficient of sorption purification of a cobalt-containing electrolyte in the presence of 10 mM of Cu(II) on the V/m ratio was analyzed. The duration of purification under

static conditions at 298 K was 30 min. Figure 1 shows the η_{sr}–V/m dependence obtained in purification of the electrolyte to remove Cu(II) ions. It can be seen that the coefficient of sorption purification exceeds 95% at V/m less than 12.5 ml g^{-1}. Further experiments were performed at $V/m \leq 10$ ml g^{-1}.

To study the kinetic features of adsorption of impurity metals from a cobalt-containing electrolyte on the sorbent prepared, the dependences of the impurity concentrations in solution on the adsorption time τ were determined. This made it possible to calculate the impurity distribution coefficients at different instants of time. Figure 2 shows how the distribution coefficients of the ions Cu(II), Zn(II), Cd(II), and Mn(II) depend on the time of adsorption.

The initial concentrations of the four controlled impurities in the electrolyte solution are given above. The solution temperature was 298 K. The ratio between the volume of the electrolyte and the amount of the adsorbent was 3 ml g^{-1}. It can be seen from Fig. 2 that the distribution coefficients of Cu(II), Zn(II), and Cd(II) ions rapidly increase during the first 10–20 min of purification and then become constant (292, 129, and 50 ml g^{-1}, respectively). The content of Mn(II) in the electrolyte does not change significantly during 100 min of purification. This is, apparently, due to the fact that chelate complexes with Mn(II) are commonly formed at pH values exceeding that of the electrolyte being purified. For example, Mn(II) ions form complexes with sodium diethyldithiocarbamate at pH 6–8 [4–6] and with 8-oxiquinoline at pH 7.2–12.5 [14]. Making the pH values of the electrolyte higher will lead to hydrolysis of Co(II) ions and precipitation of basic salts of cobalt and Co(II) hydroxide [3]. Therefore, extraction of Mn(II) ions from a cobalt-containing electrolyte requires that other reagents, selective toward MN(II) ions in this electrolyte, should be used. These results indicate that the modified carbon adsorbent developed can be successfully used to purify solutions of Mn(II) salts to remove impurity metals. In the electrolyte under study, Mn(II) is not an interfering impurity because the standard electrode potential of manganese ($E^0_{Mn^{2+}/Mn^0} = -1.18$ V) is considerably more negative than the standard electrode potential of cobalt ($E^0_{Co^{2+}/Co^0} = -0.277$ V) [15].

The limiting values of the impurity distribution coefficients, which are reached upon a prolonged sorption purification of a cobalt-containing electrolyte and are equilibrium values, are in an agreement with the Irving–Williams series and with published data on the stability constants of chelate complexes with metal ions. The largest distribution coefficients were ob-

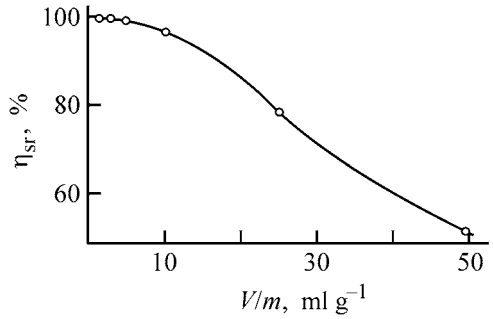

Fig. 1. Coefficient of sorption purification of a cobalt-containing electrolyte with a single impurity to remove Cu(II) ions, η_{sr}, vs. the ratio of the volume of the solution being purified to the sorbent mass, V/m. c_{in} = 10 mM, T = 298 K, τ = 30 min.

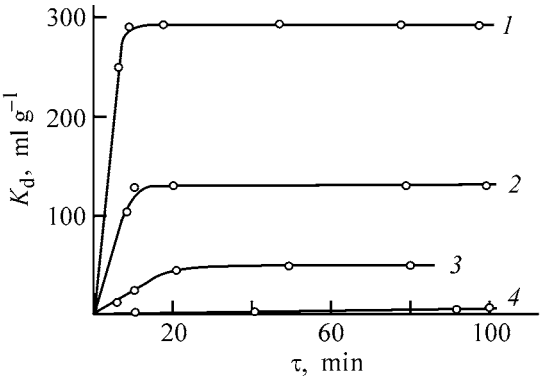

Fig. 2. Distribution coefficients K_d of (*1*) Cu(II), (*2*) Zn(II), (*3*) Cd(II), and (*4*) Mn(II) ions vs. the adsorption time τ in purification of a cobalt-containing electrolyte. T = 298 K, V/m = 3 ml g^{-1}.

tained in extraction of Cu(II) ions. These results can be regarded as a confirmation that it is chemical reactions of complexation of metal ions with organic reagents immobilized on the surface of activated carbon that are responsible for the binding of impurity metal ions with the sorbent developed.

A dependence similar to that in Fig. 2 was also obtained in purification of a cobalt-containing electrolyte solution with an initial concentration of Cu(II) ions equal to 10.3 mM. The equilibrium distribution coefficient for Cu(II) in purification of such a solution was 2027 ml g^{-1}, and 20 min were required to reach this value.

Figure 3 shows the experimental dependence of the concentration of Cu(II) ions in an electrolyte solution on the adsorption time, and also the dependence of $\ln c_\tau$ on τ. It can be seen that, in the initial stage of sorption purification of the solution to remove Cu(II) ions, their concentration in solution rapidly decreases; however, at an adsorption time exceeding 4 min, this

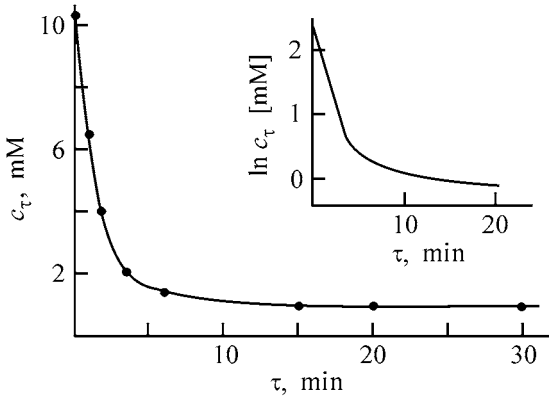

Fig. 3. Concentration c_τ of Cu(II) ions in a cobalt-containing electrolyte with a single impurity vs. the adsorption time τ. c_{in} = 10.3 mM, T = 298 K, V/m = 10 ml g^{-1}.

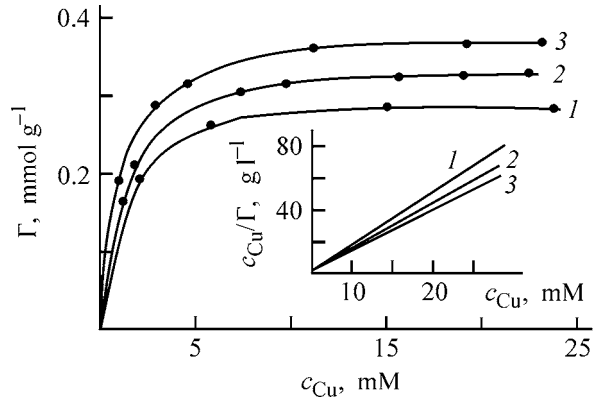

Fig. 4. Isotherms of Cu(II) adsorption Γ from a cobalt-containing electrolyte with a single impurity and the dependence of c_{Cu}/Γ on c_{Cu}. c_{in} = 1–55 mM, V/m = 10 ml g^{-1}. Adsorption temperature (K): (*1*) 283, (*2*) 298, and (*3*) 313.

decrease slows down and a constant value of c_τ is reached at τ > 20 min. As noted above, the adsorption of impurity metals on the adsorbent developed is based on reactions of their complexation. It is reasonable to conclude that it is these reactions that determine the rate of the purification process. At τ ≥ 4 min, the solution is depleted of Cu(II) ions, on the one hand, and the surface concentration of organic reagents on activated carbon decreases, on the other. As a result, there appears a transport hindrance associated with the deceleration of the delivery of Cu(II) ions to free active centers of the adsorbent. At τ > 20 min, the adsorbent is saturated with Cu(II) ions.

The initial portion (τ < 4 min) of the kinetic curve plotted in the ln c_τ–τ coordinates is linear (Fig. 3), and, consequently, this portion of the curve is described by a kinetic equation of a first-order chemical reaction [16]

$$\ln c_\tau = \ln c_{in} - k\tau, \quad (4)$$

where k is the rate constant.

The rate constant was found graphically as the slope ratio of the initial linear part of the dependence of lnc_τ on τ, and also was calculated using the equation

$$k = \frac{2.303}{\tau} \log \frac{c_{in}}{c_\tau}. \quad (5)$$

The calculation was done using the concentrations of Cu(II) ions in solution 1, 2, and 3.5 min after the beginning of adsorption. The resulting average calculated rate constant coincided with its graphically found value (0.46 min^{-1}), which points to a high rate of adsorption of Cu(II) ions in the initial stage of purification of a halide cobalt-containing electrolyte to remove these ions.

To obtain thermodynamic data on adsorption of Cu(II) ions from a cobalt-containing electrolyte on the adsorbent developed, the Gibbs adsorption of Cu(II) from the electrolyte under equilibrium conditions at 283, 298, and 313 K was determined. The initial concentrations of Cu(II) ions were in the range 1–55 mM, the V/m ratio was equal to 10 ml g^{-1}. The resulting values of adsorption were plotted against the equilibrium concentrations of Cu(II) ions in the electrolyte to give adsorption isotherms at the above temperatures (Fig. 4). These isotherms have a shape of type-I isotherms according to the classification of adsorption isotherms by Brunauer [17]. Isotherms of this kind can be described using the Langmuir equation. To make certain that this is the case, the isotherms were linearized in accordance with the Langmuir equation transformed to

$$\frac{c_{Cu}}{\Gamma} = \frac{1}{b\Gamma_m} + \frac{1}{\Gamma_m} c_{Cu},$$

where c_{Cu} is the equilibrium concentration of Cu(II) ions in solution; Γ_m, limiting adsorption; and b, adsorption coefficient.

The resulting plots of c_{Cu}/Γ against c_{Cu} are shown in the inset in Fig. 4. It can be seen that these dependences are linear and, consequently, the isotherms of Cu(II) adsorption can be described using the Langmuir equation. Below are given values of Γ_m, calculated from the slope ratios of the dependences of c_{Cu}/Γ on c_{Cu}, and values of the coefficient b, calculated from the intercept on the ordinate axis at a known Γ_m:

T, K	Γ_m, mM	b, mM^{-1}
283	0.300	0.667
298	0.325	1.538
313	0.387	1.290

As can be seen from Fig. 4 and from the data presented above, the adsorption of Cu(II) ions grows as temperature increases, which indicates that the adsorption process has a chemical nature. The adsorption isotherms obtained at several temperatures of the electrolyte make it possible to determine the isosteric heat of adsorption [13, 18] of Cu(II) ions, q_{st}:

$$q_{st} = RT^2(\partial \ln c_{Cu}/\partial T)_\Gamma, \quad (7)$$

where R is the universal gas constant, and T is the absolute temperature.

Because the temperature dependence of q_{st} can be disregarded in the case of a narrow temperature interval, the result of integration of Eq. (7) can be represented as

$$\ln c_{Cu} = \frac{q_{st}}{TR} + B, \quad (8)$$

where B is a constant.

It can be seen from Eq. (8) that the slope ratio $\tan\alpha$ of the dependence of $\ln c_{Cu}$ on $1/T$ is $-q_{st}/R$. Therefore, with $\tan\alpha$ determined, the isosteric heat of adsorption can be calculated by the equation

$$q_{st} = -R\tan\alpha. \quad (9)$$

Using the adsorption isotherms shown in Fig. 4, isosters of Cu(II) adsorption on the adsorbent developed were plotted for several values of adsorption (Fig. 5). These isosters are linear and their slope grows from 2100 to 3600 as the adsorption increases from 0.1 to 0.275 mmol g^{-1}. On substituting the values of $\tan\alpha$ in Eq. (8), the isosteric heats of adsorption of Cu(II) ions were calculated at the chosen amounts of adsorption. Figure 6 shows the resulting dependence of q_{st} on Γ. It can be seen that q_{st} varies from –17.459 kJ mol^{-1} at Γ = 0.1 mmol g^{-1} to –29.93 kJ mol^{-1} at Γ = 0.275 mmol g^{-1}, which indicates that the adsorption of Cu(II) ions occurs with an exothermic effect, which is the larger, the higher the amount of adsorption.

Thus, use of a carbon adsorbent modified with the organic reagents studied makes it possible to purify a cobalt-containing electrolyte to remove Cu(II), Zn(II), and Cd(II) ions. This adsorbent can also be successfully used to purify manganese-containing

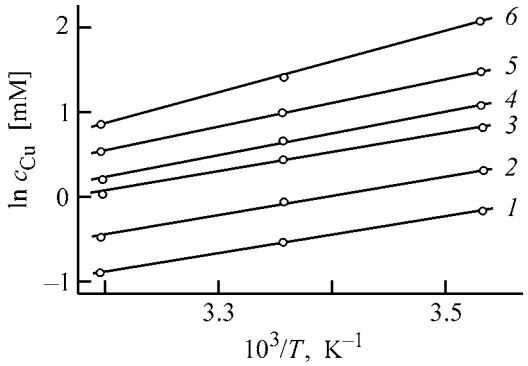

Fig. 5. Isosters of Cu(II) adsorption at different values of their adsorption by Gibbs. (c_{Cu}) Concentration of Cu(II) and (T) temperature. Amount of adsorption (mmol g^{-1}): (*1*) 0.100, (*2*) 0.150, (*3*) 0.200, (*4*) 0.225, (*5*) 0.250, and (*6*) 0.275.

solutions to remove impurity metal ions. The results obtained indicate that an adequate choice of reagents can yield selective sorbents for extraction of interfering impurities from electrolyte solutions used to obtain high-purity metals or their compounds.

CONCLUSIONS

(1) Extraction of impurity metals from a cobalt-containing electrolyte with complex-forming organic reagents immobilized on the surface of a synthetic activated carbon is a promising method for purification of electrolytes to remove ions of this kind.

(2) Adsorption of Cu(II) ions on a carbon sorbent modified with sodium diethyldithiocarbamate, 8-oxiquinoline, 1,10-phenanthroline, and Xylene Orange is a chemisorption process whose initial rate is described by the kinetic equation of a chemical reaction of first order with respect to these ions.

(3) The isosteric heat of Cu(II) adsorption is negative, and its magnitude is the higher, the larger the amount of adsorption, which indicates that the adsorption process is exothermic.

Abstract—The influence of aluminum content in the zeolite matrix of Pentasil on its acid and catalytic properties in conjugate conversion of lower alkanes and methanol was studied.

Studies of the conversion of lower alkanes and methanol on Pentasils into olefins and aromatic hydrocarbons have shown that their activity and selectivity are primarily determined by the structure of zeolite skeletons and the reaction conditions [1, 2]. The conjugate conversion of lower alkanes and methanol on Pentasil-containing catalysts allows the reaction to be performed under conditions of thermal neutrality and at lower temperatures owing to the formation of highly reactive intermediates from methanol, which initiate conversion of lower C_2–C_4 alkanes into C_2–C_4 alkenes, isoalkenes, and aromatic hydrocarbons [3–5]. The content of aluminum in the zeolite skeleton can be changed in the stage of the zeolite synthesis [6] or by thermal modification (high-temperature treatment of zeolite with air or steam) [7]. However, as applied to the above process, this possibility has virtually not been examined at all.

In this study, we examined the influence of the aluminum content in the matrix of the zeolite on its acid and catalytic properties in conjugate conversion of lower alkanes and methanol into hydrocarbons.

EXPERIMENTAL

High-silica zeolites (HSZ) with silica ratios (SiO_2/Al_2O_3) of 30, 50, 70, and 90 (HSZ-30, -50, -70, -90) were synthesized from alkaline aluminosilica gels, using an organic template by the method described in [6]. The Na-form of HSZ was transformed into the H-HSZ form by decationization with a 25% solution of ammonium chloride at 90°C for 2 h. Then the zeolite in the NH_4^+ form was dried at 110°C and calcined for 6 h at 600°C. The residual content of Na_2O in all the samples did not exceed 0.05 wt %, and that in the zeolite subjected to high-temperature steam treatment, 0.18 wt %. In accordance with data of X-ray diffraction analysis (Mo anode, Ni filter) and IR spectroscopy, the HSZs obtained were zeolites of the ZSM-5 type [8]. The degree of crystallinity of HSZ, found from the ratio of intensities of the absorption bands at 550 to 460 cm^{-1}, assigned to bending vibrations of SiO_4 and AlO_4 tetrahedrons, was no less than 90%.

The high-temperature steam treatment (HTST) of an HHSZ-30 sample was performed in a quartz reactor at 600°C in a flow of 100 wt % steam (space velocity of water supply 2 h^{-1}) for 4, 8, and 12 h (HHSZ-30-4, HHSZ-30-8, HHSZ-30-12). The Al fraction eliminated from the zeolite with steam into the steam condensate during HTST was determined colorimetrically on a KFK type photoelectrical colorimeter by the standard procedure. The acid properties of HSZ were studied by the thermal desorption of ammonia. HSZ samples (0.7 g) were charged into a quartz reactor and heated in a He flow (130 $cm^3\ min^{-1}$) at 600°C to eliminate volatile impurities from the sample surface. Then the reactor was cooled to 100°C, and NH_3 was sorbed to saturation of HSZ, with the subsequent removal of free ammonia. The thermal desorption of ammonia from HSZ was performed in a helium flow (130 $cm^3\ min^{-1}$) at a linear heating rate of 10 deg min^{-1}.

The conjugate conversion of lower alkanes and methanol in a flow unit consisting of a quartz reactor with a fixed catalyst bed (3 cm^3) was studied under the atmospheric pressure within the 500–650°C range.

Table 1. Acid characteristics of HSZ with various silicate ratios

Catalyst	T_{max}, °C		Amount of acid centers, mmol g^{-1}			Fraction of strongly acidic centers, %
	form (I)	form (II)	form (I)	form (II)	sum	
HHSZ-30	208	411	0.683	0.532	1.215	44
HHSZ-50	208	420	0.585	0.529	1.114	47
HHSZ-70	206	415	0.439	0.445	0.885	50
HHSZ-90	203	391	0.353	0.363	0.716	51

The space velocity of methanol supply was 2 h^{-1}, and that of propane–butane fraction (PBF) with the composition (wt %): ethane 0.9, propane 58.3, isobutene 5.5, and *n*-butane 35.3, 200 h^{-1}. Under these temperature conditions, methanol is completely converted on HSZ into hydrocarbons, water, CO, and H_2. The PBF and reaction products were analyzed gas-chromatographically. Before studying the acid and catalytic properties, all the HSZ samples were activated in an air flow at 560°C for 2 h. The error of gas-chromatographic determination of the composition of PBF, products of PBF and methanol conversion, and the concentration of acid centers in the catalysts was 2.5%.

The TG and TGA curves of coked HSZ samples were recorded on an MOM-1500 (Hungary) derivatograph in a porcelain crucible in air within the 25–750°C range at a heating rate of 10 deg min^{-1}.

Influence of silicate module. A study of acid properties of HSZ with various silicate modules by the method of thermal desorption (TD) of ammonia showed that the TD spectra of all the samples contain mainly two peaks of NH_3 desorption. The low-temperature peak at 300°C is caused by ammonia desorption from weakly acidic centers (form I), which are mainly triple-coordinated aluminum atoms and residual sodium cations. The high-temperature NH_3 peak at temperatures above 300°C is caused by ammonia desorption from strongly acidic HSZ centers, including strong Broensted (B) and Lewis (L)-centers (form II) [9].

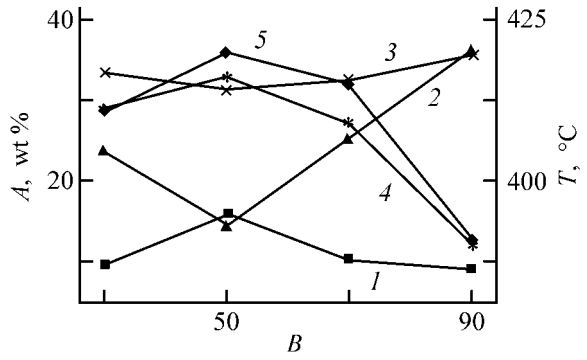

Fig. 1. Yield of products *A* of PBF and methanol conjugate conversion vs. silicate ratio *B*. (*T*) Temperature. (*1*) Methane, (*2*) Propane and butanes, (*3*) C_2–C_4 alkenes; and (*4*) arenes; (*5*) T_{max} of peaks of form II in the TD spectra.

Analysis of the concentration distribution of acid centers (Table 1) shows that, as the SiO_2/Al_2O_3 ratio in the zeolite is increased from 30 to 90, both the total acidity of the zeolites and the concentration of the acid centers corresponding to forms I and II of adsorbed ammonia decrease. This trend in the variation of the concentrations of the acid centers is caused by an increase in the content of the skeleton Al responsible for the formation of zeolite acid centers [8, 9]. All the zeolites synthesized, irrespective of the silicate ratio, are strongly acidic, because they contain a high fraction of strongly acidic centers; with increasing silicate ratio, this fraction also grows (Table 1).

The strength of the acid centers can also be estimated from the T_{max} values in the TD spectrum. T_{max} of the low-temperature peak of form I of NH_3 desorption shifts to lower temperatures with increasing HSZ silicate ratio, which indicates a decrease in the strength of the weakly acidic centers. HSZ with a silicate ratio of 50 has the highest strength of strongly acidic centers corresponding to form II of ammonia desorption (T_{max} = 420°C).

The results of the study of the HSZ activity in the conjugate conversion of PBF and methanol (600°C, space velocity of methanol supply 2 h^{-1}, and that of PBF supply, 200 h^{-1}) are shown in Fig. 1. It can be seen that the residual content of propane and butane in the reaction mixture passes through a minimum as the silicate ratio increases, i.e., changes in the opposite direction with respect to the strength of the acid centers of form II. A sample with SiO_2/Al_2O_3 = 50, which has strongest acid centers, is the most active among the zeolites studied in the propane and butane conversion. As the silicate ratio increase from 30 to 50, the yield of C_2–C_4 alkenes decreases from 33.4 to 31.3,

Table 2. Influence of high-temperature steam treatment on HSZ acid characteristics

Catalyst	T_{max}, °C		Content of acid centers, mmol g^{-1}			Fraction of strongly acidic centers, %
	form (I)	form (II)	form (I)	form (II)	sum	
HHSZ-30	194	367	0.841	0.325	1.166	28
HHSZ-30-4	174	338	0.369	0.128	0.496	26
HHSZ-30-8	174	333	0.364	0.136	0.499	27
HHSZ-30-12	169	300	0.236	0.109	0.345	32

and then increases from 31.3 to 35.7% at the silicate ratio increases from 50 to 90. The highest yield of lower alkenes is observed on a zeolite with SiO_2/Al_2O_3 = 90. The yield of arenes and methane varies in parallel with the strength of the strongly acidic centers (form II of ammonia desorption) and passes through a maximum for the sample a with silicate ratio of 50.

It should be noted that the influence of the silicate ratio on the yield of reaction products increases with temperature. The dependences of the yield of the main products of the conjugate process on the silicate ratio at the lowest and highest temperatures in the range examined are shown in Fig. 2. The yield of C_2–C_4 alkenes, C_3–C_4 alkanes, and arenes at 500°C on HSZs with a silicate ratio of 30, 50, and 70 changes insignificantly with increasing SiO_2/Al_2O_3. Raising the reaction temperature to 650°C favors activation of cracking reaction and hydrogen redistribution first of all for the HSZ sample with a silicate ratio of 50 containing the strongest acid centers, i.e., the rise in temperature activates just these centers.

A comparison of the acid characteristics of zeolites with their catalytic properties showed that the HSZ activity and selectivity (especially with respect to formation of aromatic hydrocarbons) in the conjugate process are largely governed by the strength of the acid centers, rather than by their concentration. On the whole, we can conclude that a decrease in the Al concentration in the zeolite skeleton in the stage of HSZ synthesis decreases the activity of the zeolite catalysts in the cracking and hydrogen redistribution reactions.

Influence of HSZ thermal-vapor treatment. The effect of thermal-vapor treatment (TVT) of HSZ is of interest as regards the possibility of controlling the Al content in the zeolite matrix (and thereby varying the zeolite acidity) and the change in the catalyst selectivity in conversion of hydrocarbon and methanol under the action of water formed in the reaction [10]. Determination of the content of aluminum transferred into the condensate during HTST under the above conditions showed that virtually the whole amount of Al remains in the zeolite. Only an insignificant, virtually the same for all the samples, part of Al (amounting to no more than 0.03 wt % Al in the HSZ sample studied) is carried away by steam.

Data on the acid properties of steam-treated HHSZ-30 zeolite are shown in Table 2 and Fig. 3. The TD spectra of ammonia (Fig. 3) for all HSZ samples con-

tain two poorly resoved peaks because of the rather high residual content of sodium in the initial zeolite (0.18 wt %). The shape of the spectrum remains unchanged on going to more severe conditions of HSZ steam treatment. Hence, HTST does not affect the exchanging sodium cations in HSZ [11].

The temperatures T_{max} of ammonia desorption peaks and calculated amounts of acid centers of both forms are listed in Table 2. Their strength, qualitatively characterized by T_{max}, decreases during HTST. The longer the HTST time, the stronger the shift of T_{max} to lower temperatures and hence the higher the strength of acid centers. Our results also show that HTST of HSZ for 4 h sharply decreases the total amount of acid centers and the concentration of acid centers of both types. An increase in the time of HTST of HSZ gradually decreases the concentration of weakly acidic centers. However, after a 8-h steam treatment of HSZ, the concentration of strongly acid centers and the total acidity slightly increase as compared to the concentration of strongly acidic centers after a 4-h HTST. It is known [8] that HTST of HSZ first of all eliminates nonskeleton Al from the cationic sites and transfers it into the Al_2O_3 phase. Under definite conditions, HTST of HSZ can form centers with enhanced activity (EAC), including bridging OH groups and Al atoms whose bonds with the crystal lattice of the zeolite are partially (or completely) decomposed under HTST [11]. Probably, in our case, treatment of HSZ (HHSZ-30-8 sample) with steam for 8 h, similar strong centers leads to additional formation of and, as a result, their concentration somewhat increases.

The steam treatment at a higher temperature and for a longer time results in a further decrease in the zeolite acidity due to dealumination of the zeolite skeleton [13]. Indeed, an increase in the HTST duration to 12 h decreases the amount of strongly and weakly acidic centers and weakens their strength. The change in HSZ acid properties under HTST at a high temperature should change the zeolite activity and selectivity in the process studied. Data on the catalytic properties of the initial HHSZ-30 zeolite and its steam-treated samples are listed in Table 3.

As seen, the yield of products of the conjugate PBF conversion on HHSZ-30 and on HHSZ-30 after HTST correlates with the acid properties of the catalyst. Already with an HHSZ-30-4 sample, the yield of olefins sharply increases, and the yield of arenes and naphthalenes decreases within the entire temperature interval. The content of propane and butane (initial

Table 4. Derivatographic analysis of coked HSZ samples

Total weight loss	16.5	11.5	12.0	9.5

components of the reaction mixture) changes insignificantly and fluctuates. Such a variation of the composition of the reaction products is probably caused by an increase in the concentration of B centers (due to dealumination of the zeolite skeleton) and strong L centers (aluminum at the cationic sites) responsible for olefin aromatization. However, in spite of a decrease in the total concentration of the acid centers in the zeolite, the fraction of strongly acidic centers increases (Table 2), and the residual amount of strongly acidic centers is sufficient for cracking of C_3–C_4 alkanes. Therefore, their yield remains virtually unchanged at varied HTST duration. The yield of methane and ethane on steam-treated HSZ samples substantially decreases as compared to the initial HHSZ-30, especially at $T \leq 600$°C.

Such a change in the product composition shows that HTST of the zeolite catalyst suppresses reactions of redistribution to lower alkanes and arenes on the strongly acidic centers [14]. It is interesting that, after a high-temperature steam treatment of a zeolite and with an increase in its duration, the fraction of heavy hydrocarbons increases in both liquid and gas phases of the catalyzate. For instance, on the background of general decrease in the content of C_{4+} alkanes among the reaction products, the amount of methane and ethane falls especially sharply. At the same time, on the background of general increase in the amount of C_2–C_4 alkenes, the amounts of propylene and butenes increase faster. A similar trend is observed for the liquid products. Among the aromatic hydrocarbons, the benzene content decreases faster. The contents of C_{5+} alkanes and C_{5+} alkenes increase with time of treatment within the entire temperature interval. Preliminary HTST of a zeolite catalyst changes not only its activity and selectivity but also stability, which is manifested in the character and degree of catalyst coking. The data obtained in DTA analysis of coked zeolite samples are listed in Table 4.

The pronounced exothermic effect at $T > 600$°C, corresponding to coke burning, is observed in the DTA curves of all the HSZ samples. Zeolite samples (excluding HHSZ-30-12) contain adsorbed water, and their DTA curves show an endothermic effect at 80–100°C. The decrease in the T_{min} of this effect for samples subjected to HTST, compared to the initial HHSZ-30, and the absence of such an effect for HHSZ-30-12 suggest an increase in the sample hydrophobicity because of dealumination of the zeolite skeleton.

The stages of the weight loss during calcination within the 25–750°C range were recorded for each HSZ sample. Stage I corresponds to loss of water and weakly sorbed reaction products. Features of the reaction course and the presence of methanol in the reaction mixture cause irregular deactivation of the catalyst along the bed. Three zones of methanol conversion on the zeolite catalysts can be distinguished: (A) zone of a spent catalyst, (B) zone of predominant conversion of methanol and dimethyl ether, and (C) zone of reactions of hydrogen redistribution [15]. Hence, the weight loss in stage II can be assigned to burning of the nonaromatic coke formed as a product of olefin oligomerization in zone C. With regard to high T_{max} of the exothermic effect, the weight loss in stage III corresponds to burning of the condensed aromatic coke formed in the zone of a spent catalyst (A).

The temperature of the completion of nonaromatic coke burning gradually decreases with increasing time of HTST. This can be connected with a decrease in the amount of B centers responsible for olefin oligomerization [12] because of a decrease in the aluminum amount in the zeolite skeleton. Although the amount of nonaromatic coke on all the zeolite samples remains constant, its condensation decreases with increasing time of HTST. The maximum amount of high-condensed coke was observed on HHSZ-30; it

decreases with increasing time of HTST. The total weight loss in calcination changes in parallel with the concentration of the strongly acidic centers (Tables 2, 4). Along with a decrease in the amount of B centers under HTST, their strength should increase in accordance with quantummechanical calculations [16]. Then, as noted above, formation of EAC is possible. In this case, the T_{max} of coke burning does not decrease smoothly with increasing time of HTST, but passes through a maximum (for HHSZ-30-8 sample). The subsequent decrease in the T_{max} of coke burning for HHSZ-30-12 confirms the suggestion [10] that these centers are unstable and decompose under the more severe conditions of TVT.

Thus, rather clear correlations between their acid and catalytic properties are observed for steam-treated HSZ samples. The selected catalytic properties of zeolites as functions of their acid characteristics change in the following order:

HHSZ-30-12 > HHSZ-30-4 > HHSZ-30-8 > HHSZ-30 →

Increase in total acidity of zeolites

In this series, the yield of C_2–C_4 alkenes at T = 500°C decreases, the yield of arenes at T = 500°C increases, and the total loss in calcination of the coked samples increases;

HHSZ-30-12 > HHSZ-30-8 > HHSZ-30-4 > HHSZ-30 →

Increase in the strength of acid centers of form II

In this series, the yield of C_2–C_4 alkenes at T > 500°C decreases, and the yields of arenes at T > 500°C and the yield of aromatic coke increase.

CONCLUSION

The activity of zeolites at low temperatures is controlled by the total concentration of the acid centers. With an increase in temperature (>500°C), the yield of the main products is controlled by the strength of acid centers. Similar trends are observed for samples with different silicate ratios, i.e., different contents of aluminum set in the stage of the zeolite synthesis.

Abstract—A mathematical model of a multistage process of thermocatalytic decomposition of 1-methylcyclohexyl hydroperoxide in the presence of sodium stearate is developed. A procedure for calculating the unknown rate and equilibrium constants of the elementary and overall reaction stages is described. It is based on an analysis of the kinetic relationships in consumption of the initial products and accumulation of the intermediate and final products of thermocatalytic decomposition, with account of the known constants for individual stages.

Simulation in studies of the kinetics of chemical transformations involves solution of the forward and reverse problems of chemical kinetics. The forward problem consists in calculating the current concentrations of the components from their known initial concentrations and the known rate constants of the chemical reactions for all the elementary stages. The reverse problem consists in determining the unknown constants for selected stages from the known constants for the remaining stages and the experimentally estimated compositions of the multicomponent mixture at selected moments.

Let us formulate and analyze the forward problem. Let the dynamics of the component concentrations be described by the equations

$$db_1/d\tau = f_1(b_1, \ldots, b_n, k_1, \ldots, k_s),\ b_1\big|_{\tau = 0} = b_1^{in},$$

$$db_n/d\tau = f_n(b_1, \ldots, b_n, k_1, \ldots, k_s),\ b_n\big|_{\tau = 0} = b_n^{in}, \quad \text{(I)}$$

where $b_1, \ldots, b_n$ are unknown current concentrations; $b_1^{in}, \ldots, b_n^{in}$, known initial concentrations; $k_1, \ldots, k_s$, known constants; τ, time; and $f_1, \ldots, f_n$, preset kinetic functions.

A theoretical calculation of the current concentrations is confined to numerical integration of a system of ordinary equations (I), e.g., by the Euler method:

$$b_1/\tau = j\Delta\tau \equiv b_1^{(j)}, \ldots, b_n\big|_{\tau = j\Delta\tau} \equiv b_n^{(j)},$$

$$b_1^{(0)} = b_1^{in}, \ldots, b_n^{(0)} = b_n^{in};\ j = 1, 2, \ldots,$$

$$b_1^{(j)} = b_1^{(j-1)} + \Delta\tau f_1(b_1^{(j-1)}, \ldots, b_n^{(j-1)}, k_1, \ldots, k_s),$$

$$\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots$$

$$b_n^{(j)} = b_n^{(j-1)} + \Delta\tau f_n(b_1^{(j-1)}, \ldots, b_n^{(j-1)}, k_1, \ldots, k_s), \quad \text{(II)}$$

where $\Delta\tau$ is the integration step.

However, this approach is practically unacceptable, since system (I) is typically a "rigid" system: It is characterized by a wide scatter of the matrix eigenvalues df_1/db_j. Thus, to obtain a stable numerical solution for (II), we have to use an extremely small step, namely, the time range of interest reduced by 6–10 orders of magnitude. Physically, this is due to the simultaneous occurrence of "slow" and "very fast" reactions with incomparable durations of 10^3 against 10^{-7} s, as well as to the need to coordinate the integration step with the smallest of these time periods.

One way to overcome these difficulties lies in the use of the method of steady-state concentrations, which consists in a physically valid simplification of the system (I) with the aim to eliminate the singularity. The method implies classifying all the components into unstable (free radicals, etc.) and stable. Next, it is assumed that, after a small induction period (10^{-2}–10^{-6} s), the system is characterized by the dy-

1070-4272/04/7712-1979 © 2004 MAIK "Nauka/Interperiodica"

namic equilibrium of the concentrations of the unstable components, when the rates of formation and consumption of these components are equal. The corresponding equilibrium concentrations depend on the current concentrations of the stable components and slowly vary in time with them.

Under the assumptions made, system (I) is transformed into

$$dc_1/d\tau = \varphi_1(c_1, \ldots, c_m, x_1, \ldots, x_k, k_1, \ldots, k_s),\ c_1\big|_{\tau=0} = c_1^{in},$$
$$\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots$$
$$dc_m/d\tau = \varphi_m(c_1, \ldots, c_m, x_1, \ldots, x_k, k_1, \ldots, k_s),\ c_m\big|_{\tau=0} = c_m^{in},$$
$$dx_1/d\tau = 0 = \Psi_1(c_1, \ldots, c_m, x_1, \ldots, x_k, k_1, \ldots, k_s),$$
$$\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots$$
$$dx_k/d\tau = 0 = \Psi_k(c_1, \ldots, c_m, x_1, \ldots, x_k, k_1, \ldots, k_s), \quad \text{(III)}$$

where $c_1, \ldots, c_m$, and $x_1, \ldots, x_k$ are the current concentrations of the stable and unstable components, respectively.

We will express the concentrations $x_1, \ldots, x_k$ from the second group of equations in system (III) as

$$x_1 = x_1(c_1, \ldots, c_m, k_1, \ldots, k_s),$$
$$x_k = x_k(c_1, \ldots, c_m, k_1, \ldots, k_s) \quad \text{(IV)}$$

and substitute them into the first groups of equations in system (III), which will yield eventually

$$dc_1/d\tau = \alpha_1(c_1, \ldots, c_m, k_1, \ldots, k_s),\ c_1\big|_{\tau=0} = c_1^{in},$$
$$dc_m/d\tau = \alpha_m(c_1, \ldots, c_m, k_1, \ldots, k_s),\ c_m\big|_{\tau=0} = c_m^{in}, \quad \text{(V)}$$

where $\alpha_1, \ldots, \alpha_m$ are the resultant kinetic functions.

System (V) is not rigid any more and can be integrated without difficulties by the Euler method with a fairly large step of 1–100 s. Physically, this transformation consists in changing from very fast to "infinitely fast" reactions, which allows us, via the limiting transition, to exclude from consideration small time scales and to remove the corresponding restrictions imposed on the integration step.

For the overwhelming majority of real problems of chemical kinetics, the dependences (IV) of the quasi-equilibrium concentrations on the currents concentrations of the stable components can be obtained analytically. Specifically this method should be preferred, since it not only significantly reduces the time required to solve the problem, but also makes it possible to reveal certain relationships.

By way of example, let us consider the mechanism of thermocatalytic decomposition of tertiary 1-methyl-1-cyclohexyl hydroperoxide (MCHP). The figure presents the kinetic curves of decomposition of MCHP and accumulation of the products formed. Based on the kinetic data, the composition of the MCHP decomposition products, and isotope analysis results, the MCHP decomposition mechanism can be represented by a set of 47 reactions [1–6] (Table 1).

Along with monomolecular thermal decomposition, MCHP undergoes bimolecular decomposition with a solvent involved, as well as catalytic decomposition in the ROOH · NaSt and 2ROOH · NaSt complexes [1–4]. Also, the MCHP dimers, $(ROOH)_2$, are involved in the decomposition. Oxygen-containing products (alcohols, acids) form inactive dimers $(ROH)_2$ and $(RCOOH)_2$ and complexes with MCHP (ROOH · RCOOH or ROOH · ROH). Alcohols and acids are incorporated into the coordination spheres of the initially formed complexes ROOH · NaSt to form ternary complexes ROOH · NaSt · RCOOH or ROOH · NaSt · ROH [2–6].

To simplify further calculations, we introduce the designations for stable and short-lived species (Table 2).

The rate constants of mono- and bimolecular decomposition of MCHP have been determined earlier [4, 5].

The rate constants $k_{17} = 10^6$ and $k_{20} = 1.6 \times 10^6$ l mol^{-1} s^{-1} of recombination of the secondary and tertiary peroxy radicals were calculated using the known partial oxidizabilities of methylcyclohexane $k_2/\sqrt{k_6}$ and independently determined chain propagation constants k_2 [1].

The estimated constants $k_{16} = 10^9$, $k_{19} = 2.5 \times 10^7$, and $k_{29} = 3 \times 10^2$, l mol^{-1} s^{-1}, were taken from [7]. We determined more precisely the constants k_{13}, k_{14}, k_{17}, k_{19}, k_{21}, and k_{24} later, when comparing the calculated and experimental rates of accumulation of the corresponding products of MCHP decomposition during the process.

The calculated kinetic curves of accumulation of the MCHP decomposition products at low conversions (up to 10–15%) coincide with the experimental data [the MCHP decomposition mechanism is described by reactions (1)–(29)].

Further calculations should take into account the influence of the reaction products [the MCHP decomposition mechanism in the developed process is supplemented by reactions (30)–(47)]. This affords an adequate description of the thermocatalytic decompo-

Table 1. Mechanism of thermocatalytic decomposition of MCHP (T = 130°C, $[NaSt]_0 = 4.7 \times 10^{-3}$ M, $[ROOH]_0$ = 0.3 M)

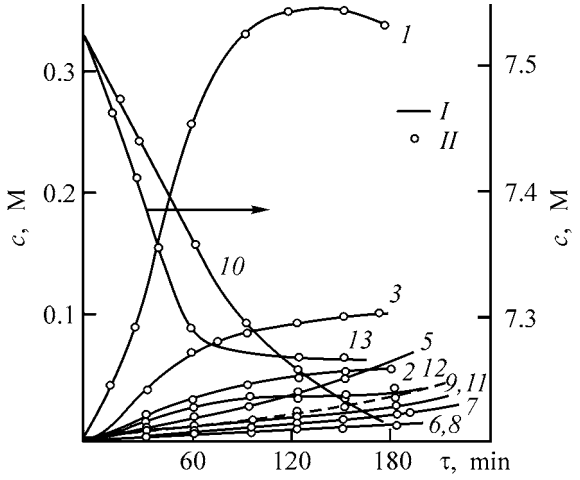
sition of tertiary hydroperoxide until exhaustive conversion (see figure).

With increasing content of MCHP (0.1–0.35 M), when the NaSt content is varied within (4.72–236) × 10^{-4} M, the yields of alcohols grow relative to the uncatalyzed reaction (Table 3).



Kinetic curves of accumulation of the MCHP decomposition products. T = 130°C, [NaSt] = 4.7×10^{-3} M. (c) Concentration, and (τ) time. (*1*) Methylcyclohexanol, (*2*) secondary isomeric methylcyclohexanols, (*3*) 2-heptanone, (*4*) isomeric methylcyclohexanones, (*5*) water, (*6*) acetic acid, (*7*) valeric acid, (*8*) methane, (*9*) carbon dioxide, (*10*) MCHP, (*11*) 1-methylcyclohexyl acetate, (*12*) 1-methylcyclohexene, and (*13*) consumption of methylcyclohexane. (*I*) Experiment and (*II*) calculation.

An increase in the effective rate constant of MCHP decomposition in the presence of sodium stearate at 55–60% conversions is certainly due to formation and transformations of MCHP · ROH and MCHP · RCOOH associates and ROOH · NaSt · ROH and ROOH · NaSt · RCOOH complexes. The ratio of the radical and molecular routes in MCHP decomposition (and, consequently, the ratio of the main reaction products, 1-methylcyclohexanol : 2-heptanone) for these associates and complexes may differ from those for thermal and thermocatalytic process occurring at the initial moments of the reaction, when the influence of oxygen-containing reaction products can be neglected. Therefore, we carried out a series of experiments on catalytic decomposition of MCHP in the presence of 1-methylcyclohexanol and valeric acid. We estimated the limiting constants of the molecular and radical decomposition of 1-MCHP in the presence of these compounds: $k_{31} = 3 \times 10^{-5}$, $k_{32} = 2.7 \times 10^{-4}$, $k_{34} = 1.16 \times 10^{-4}$, and $k_{35} = 2.09 \times 10^{-4}$ s^{-1}.

Using the portions of the plot of W_Σ vs. the concentration of the monomeric form of acetic acid $[RCOOH]_m$, in which W_Σ grows with increasing concentration of the free (monomeric) acid, we estimated K_{30} at 21.0 ± 1.1 l mol^{-1}.

The rates of the radical and overall decomposition of MCHP without NaSt proved to be lower than those with NaSt. For example, at 130°C, [ROOH] = [RCOOH] = 6.5×10^{-2} M, and [NaSt] = 4.7×10^{-3} M, the limiting rate constants of the radical and overall decomposition of MCHP exceed by a factor of 3.2 those for decomposition of ROOH under identical conditions without NaSt. To understand why the rate of radical (overall) decomposition of MCHP in the presence of NaSt and RCOOH is independent of the hydroperoxide concentrations at high $[ROOH]_0$, we have to assume formation of mixed complexes NaSt · ROOH · RCOOH. In this case, the catalytic decomposition of MCHP in the presence of NaSt and ROOH is described by the scheme

$$ROOH_{free} + NaSt \overset{K_7}{\rightleftarrows} [NaSt \cdot ROOH]$$
$$\xrightarrow{k_8 + k_9} \text{free radicals and molecular products,} \quad (48)$$

$$[NaSt \cdot ROOH] + ROOH_{free} \overset{K_{10}}{\rightleftarrows} [NaSt \cdot 2ROOH]$$
$$\xrightarrow{k_{11} + k_{12}} \text{free radicals and molecular products,} \quad (49)$$

$$ROOH_{free} + RCOOH_{products} \overset{K_{30}}{\rightleftarrows} [ROOH \cdot RCOOH]$$
$$\xrightarrow{k_{31} + k_{33}} \text{free radicals and molecular products,} \quad (50)$$

$$ROOH_{free} + NaSt_{free} + RCOOH_{products}$$
$$\overset{K_{36}}{\rightleftarrows} [ROOH \cdot NaSt \cdot RCOOH] \xrightarrow{k_{37} + k_{38}} \text{products,} \quad (51)$$

$$RCOOH_{products} + NaSt_{free} \overset{K_{42}}{\rightleftarrows} NaSt \cdot RCOOH. \quad (52)$$

The constants K_7, K_{10}, k_8, k_9, k_{11}, and k_{12} were determined earlier.

The rate of the overall decomposition of MCHP is equal to

$$W_\Sigma = \frac{[NaSt]_0 [ROOH]_0 K_7(k_8 + k_9) + K_7K_{10}(k_{11} + k_{12})[ROOH]_0 + K_{36}[RCOOH]_{free}(k_{37} + k_{38})}{1 + K_7[ROOH]_0 + K_7K_{10}[ROOH]_0^2 + K_{36}[ROOH]_0[RCOOH]_{products} + K_{42}[RCOOH]_{free}}$$
$$+ K_{30}[ROOH]_0[RCOOH]_{free}(k_{31} + k_{32}). \quad (VI)$$

Using the plot of (VII) describing the catalytic decomposition of hydroperoxide, at known K_7, K_{10}, k_8, k_9, k_{11}, and k_{12}, under conditions (VIII), we obtained $K_{36} = 8.8 \pm 0.8$ l^2 mol^{-2}, and then, using the dependence of W_Σ on $[ROOH]_0$ in the presence of acids, all other constants being known ([NaSt] = 4.7×10^{-3} M), we obtained $K_{42} = 28 \pm 1.5$ l mol^{-1}:

$$W_\Sigma - K_{30}[ROOH]_0[RCOOH]_{products}(k_{31} + k_{32}) = f[RCOOH]_{free}, \quad (VII)$$

$$1 + K_7[ROOH]_0 + K_7K_{10}[ROOH]_0^2$$
$$+ K_{36}[ROOH]_0[RCOOH]_{products} \gg K_{42}[RCOOH]_{free}. \quad (VIII)$$

Likewise, we obtained $K_{33} = 21 \pm 1.1$ and $K_{43} = 21.4 \pm 1.2$ l mol^{-1} and $K_{39} = 5.1 \pm 0.3$ l^2 mol^{-2}.

The dimerization constants for acetic acid and 1-methylcyclohexanol were reported in [7]. The constants for the radical and molecular routes of decomposition of ternary complexes k_{37}, k_{38}, k_{40}, and k_{41} were determined experimentally.

We write the expression for the elementary rates of irreversible reactions in the mathematical model (the rates R_i and the rate constants k_i of the reaction are numbered in accordance with the numbers of the reaction equations in the model).

Rates of the elementary reactions of MCHP decomposition (IX)

$R_1 = k_1 c_{1s}$	$R_9 = k_9 c_4$	$R_{17} = k_{17} x_3^2$	$R_{29} = k_{29} c_{1s} x_1$	$R_{38} = k_{38} c_{21}$
$R_2 = k_2 c_{1s} c_2$	$R_{11} = k_{11} c_5$	$R_{18} = k_{18} c_2 x_2$	$R_{31} = k_{31} c_{19}$	$R_{40} = k_{40} c_{22}$
$R_3 = k_3 c_{1s} c_2$	$R_{12} = k_{12} c_5$	$R_{19} = k_{19} c_8 x_1$	$R_{32} = k_{32} c_{19}$	$R_{41} = k_{41} c_{22}$
$R_5 = k_5 c_3$	$R_{13} = k_{13} c_2 c_5$	$R_{20} = k_{20} x_5^2$	$R_{34} = k_{34} c_{20}$	$R_{46} = k_{46} c_{6s}$
$R_6 = k_6 c_3$	$R_{14} = k_{14} x_2$	$R_{21} = k_{21} c_{1s} c_7$	$R_{35} = k_{35} c_{20}$	$R_{47} = k_{47} c_{6s} c_{10s}$
$R_8 = k_8 c_4$	$R_{16} = k_{16} x_1$	$R_{24} = k_{24} c_7 x_1$	$R_{37} = k_{37} c_{21}$	

Note. k_{47} is the rate constant of accumulation of *tert*-methylcyclohexyl acetate.

It is seen that the expressions for R_{15}, R_{22}, R_{23}, and R_{25}–R_{28} are lacking; the rate constants of the corresponding reactions are unknown. We show below that, when the current concentrations of the radicals involved in the process are steady-state, there is no need to precisely know the absolute values of the rates of these reactions. They can be derived from the other, known rates of reactions describing the MCHP decomposition mechanism.

The initial concentrations are known: $[ROOH]_0$ = 0.3, $[RH]_0$ = 7.5, and $[NaSt]_0 = 4.72 \times 10^{-3}$ M. The concentration of the dissolved oxygen in solution was estimated experimentally at $(1 \pm 0.1) \times 10^{-4}$ M. The oxygen evolving during the process leaves the reaction zone.

We have to establish the dependences to be used for calculating for any moment the concentrations c_3–c_5, c_{19}–c_{26} for the complexes formed by equilibrium reactions. Also, we have to calculate the concentrations of free reactants (c_{1s}, c_{6s}, c_{10s}, c_{16s}, c_{18s}) at any moment.

We assume that the concentrations of the above-listed complexes are steady-state, and the reactions in which the complexes are consumed do not affect the equilibrium reaction of their accumulation. Then, the concentrations of the complexes can be expressed as

$$c_3 = K_4 c_{1s2},\ c_4 = K_7 c_{1s} c_{16s},$$
$$c_5 = K_{10} c_{1s} c_4,\ c_{19} = K_{30} c_{1s} c_{18s},$$
$$c_{20} = K_{33} c_{1s} c_{6s},\ c_{21} = K_{36} c_{1s} c_{16s} c_{18s},$$
$$c_{22} = K_{39} c_{1s} c_{16s} c_{6s},\ c_{23} = K_{42} c_{18s} c_{16s},$$
$$c_{24} = K_{43} c_{6s} c_{16s},\ c_{25} = K_{44} c_{218s},$$
$$c_{26} = K_{45} c_{26s}. \quad \text{(X)}$$

Next we determine the concentrations of free hydroperoxide, *tert*-methylcyclohexanol, acetic acid, and catalyst and also the sum of the concentrations of acetic and valeric acids (RCOOH) by the balance equations

$$c_1 = c_{1s} + c_3 + c_4 + c_5 + c_{19} + c_{20} + c_{21} + c_{22},$$
$$c_6 = c_{6s} + c_{20} + c_{22} + c_{24} + c_{26},$$
$$c_{10} = c_{10s} + c_{19} + c_{21} + c_{23} + c_{25},$$
$$c_{16} = c_{16s} + c_4 + c_5 + c_{21} + c_{22} + c_{23} + c_{24},$$
$$c_{18} = c_{18s} + c_{19} + c_{21} + c_{23} + c_{25}. \quad \text{(XI)}$$

We introduce a number of simplifications, namely, $c_4 + c_5 + c_{21} + c_{22} < c_{16} = 4.72 \times 10^{-3}$ M ($\tau = 0$), and the dimer concentration c_3 does not exceed 7.2×10^{-3} M, since it is equal to $K_4[ROOH]_2$, where $K_4 = 0.081$ l mol^{-1}. Then $c_{1s} \approx c_1 - c_{19} - c_{20}$ holds.

Analysis of K_{44} and K_{45} shows that the concentrations of the dimers c_{25} and c_{26} are low, and, hence, $c_{21} + c_{22} + c_{23} + c_{24} = 4.72 \times 10^{-3}$ M. This gives

$$c_{6s} \approx c_6 - c_{20},\ c_{10s} \approx c_{10} - c_{19},\ c_{18s} \approx c_{18} - c_{19}. \quad \text{(XII)}$$

Since $K_{30} = K_{33}$, we obtain

$$c_1 = c_{1s}(1 + K_{30} c_{18s} + K_{33} c_{6s}),\ c_6 = c_{6s} + K_{33} c_{6s} c_{1s},$$
$$c_{10} = c_{10s} + K_{30} c_{10s} c_{1s},\ c_{18} = c_{18s} + K_{30} c_{18s} c_{1s}, \quad \text{(XIII)}$$

or

$$c_{6s} = c_6/(1 + K_{33} c_{1s}),\ c_{10s} = c_{10}/(1 + K_{30} c_{1s}),$$
$$c_{18s} = c_{18}/(1 + K_{30} c_{1s}),$$
$$c_1 = c_{1s}[1 + K_{30} c_{18}/(1 + K_{30} c_{1s}) + K_{33} c_6/(1 + K_{33} c_{1s})]. \quad \text{(XIV)}$$

Hence,

$$c_1 = c_{1s}[1 + 21(c_{1s} + c_6 + c_{18})]/(1 + 21 c_{1s}). \quad \text{(XV)}$$

We obtain, eventually

$$c_{1s} = \sqrt{(D^2 + 84 c_1 - D)/42}, \quad \text{(XVI)}$$

where $D = 1 - 21(c_1 - c_6 - c_{18})$.

From the balance in the catalyst we obtain

$$c_{16s} = 4.72 \times 10^{-3}/(1 + K_7 c_{1s} + K_7 K_{10} c_{21s}$$
$$+ K_{36} c_{1s} c_{18s} + K_{39} c_{1s} c_{6s} + K_{42} c_{18s} + K_{43} c_{6s}). \quad \text{(XVII)}$$

All the assumptions suggest that, at the moment $\tau = 0$, when $c_6 = c_{6s} = c_{10} = c_{10s} = c_{1s} = c_{18s} = 0$ M, $c_{1s} = c_1 = 0.3$ M, which is not a very rigorous value.

We obtain a more rigorous value of c_1 by solving a transcendent equation ($\tau = 0$).

$$c_{1s} = c_1 - c_3 - c_4 - c_5,\ c_{16s} = c_{16} - c_4 - c_5,$$
$$c_3 = K_4 c_{1s2},\ c_4 = K_7 c_{1s} c_{16s},$$
$$c_1 = 0.3 \text{ mol dm}^{-3},\ c_{16} = 4.72 \times 10^{-3} \text{ M}. \quad \text{(XVIII)}$$

With $K_4 = 0.081$, $K_7 = 15.7$, and $K_{10} = 51$ l mol^{-1}, simple transformations give

$$c_{1s} + 0.081 c_{1s}^2 - 4.72 \times 10^{-3}/(1 + 15.7 c_{1s} + 791.28 c_{1s}^2)$$
$$- 0.29528 = 0. \quad \text{(IXX)}$$

We solve this equation and find $c_{1s} = 0.2887$ M $\approx c_1$, $\tau = 0$. Thus, the inaccuracy due to the assumptions made is very small and decreases with increasing reaction time τ.

The condition of steady state for the concentrations of the radicals x_i (i = 1, …, 12) gives

$$\left.\begin{aligned}
dx_1/d\tau &= R_2 + R_{13} + R_{14} + R_{18} + R_{21} - R_{16} - R_{19} - R_{29} = 0,\\
dx_2/d\tau &= R_1 + R_2 + R_5 + R_8 + R_{11} + 2R_{17} + R_{21} + R_{29} + R_{31} + R_{40} + R_{34} + R_{37} - R_{14} - R_{18} = 0,\\
dx_3/d\tau &= R_5 + R_6 + R_{11} + R_{13} - 2R_{17} + 0.75R_{19} = 0,\\
dx_4/d\tau &= R_1 + R_5 + R_8 + R_{31} + R_{34} + R_{37} + R_{40} - R_{16} = 0,\\
dx_5/d\tau &= 0.25R_{19} - 2R_{20} = 0,\\
dx_6/d\tau &= R_{14} - R_{15} = 0,\\
dx_7/d\tau &= R_{21} - R_{22} = 0,\\
dx_8/d\tau &= R_{22} - R_{23} = 0,\\
dx_9/d\tau &= R_{24} - R_{25} = 0,\\
dx_{10}/d\tau &= R_{25} - R_{26} = 0,\\
dx_{11}/d\tau &= R_{26} - R_{27} = 0,\\
dx_{12}/d\tau &= R_{26} - R_{28} = 0.
\end{aligned}\right\} \quad \text{(XX)}$$

Simple transformations yield

$$\left.\begin{aligned}
x_1 &= 8(R_2 + 0.5R_6 + R_{11} + R_{13} + R_{21})/K_{19}c_8,\\
x_2 &= (R_1 + R_2 + 2R_5 + R_8 + 2R_{11} + R_6 + R_{13} + 0.75K_{19}c_8x_1 + R_{21} + K_{29}c_1x_1 + R_{31} + R_{34} + R_{37} + R_{40})/(K_{14} + K_{18}c_2),\\
x_3 &= \sqrt{(R_5 + R_6 + R_{11} + R_{13} + 0.75K_{19}c_8x_1)/2k_{17}},\\
x_4 &= (R_1 + R_5 + R_8 + R_{31} + R_{34} + R_{37} + R_{40})/k_{16}x_1,\\
x_5 &= \sqrt{k_{19}x_1c_8/8k_{20}}.
\end{aligned}\right\} \quad \text{(XXI)}$$

Thus, knowing the concentrations of the molecular products and radicals x_i (i = 1, …, 5), we can obtain the desired R_i values.

We now write a system of differential equations describing the thermocatalytic decomposition of MCHP in the presence of sodium stearate in a methylcyclohexane solution under the starting conditions $c_{i(0)}$ at $\tau = 0$ $dc_n/d\tau$ (c_n is the current concentration of ith product, mM):

$$\left.\begin{aligned}
dc_1/d\tau &= -R_1 - R_2 - R_3 - R_5 - R_6 - R_8 - R_9 - R_{11} - R_{12} - R_{13} - R_{21} - R_{29} - R_{31} - R_{32} - R_{34} - R_{35} - R_{37} - R_{38} - R_{40} - R_{41},\\
&c_{1(0)} = 0.3 \text{ M};\\
dc_2/d\tau &= -R_2 - R_3 - R_{13} - R_{15} - R_{18} - R_{23} + R_{24} - R_{28};\\
&c_{2(0)} = 7.5 \text{ M};\\
dc_6/d\tau &= 2R_3 + R_6 + R_9 + 2R_{12} + 0.75R_{16} + R_{18} + 0.75R_{29} + R_{32} + R_{35} + R_{38} + R_{41} - R_{46} - R_{47},\\
&c_{6(0)} = 0,\\
dc_7/d\tau &= R_{13} + R_{15} - R_{21};\\
&c_{7(0)} = 0;\\
dc_8/d\tau &= 0;\\
&c_{8(0)} = 1 \times 10^{-4} \text{ M};\\
dc_9/d\tau &= R_2 + R_5 + R_{11} + R_{13} + R_{46} + R_{47};\\
&c_{9(0)} = 0;\\
dc_{10}/d\tau &= R_{22} - R_{47},\\
&c_{10(0)} = 0;\\
dc_{11}/d\tau &= R_{27},\\
&c_{11(0)} = 0;\\
dc_{12}/d\tau &= R_{28},\\
&c_{12(0)} = 0;\\
dc_{13}/d\tau &= R_{28},\\
&c_{13(0)} = 0;\\
dc_{14}/d\tau &= 0.25R_{16} + R_{20} + 0.25R_{29},\\
&c_{14(0)} = 0;\\
&c_{15(0)} = 0;\\
dc_{16}/d\tau &= 0,\\
&c_{16(0)} = 4.72 \times 10^{-3} \text{ M};\\
dc_{17}/d\tau &= R_{23},\\
&c_{17(0)} = 0;\\
dc_{27}/d\tau &= R_{46},\\
&c_{27(0)} = 0;\\
dc_{28}/d\tau &= R_{47},\\
&c_{28(0)} = 0;\\
c_{18(0)} &= c_{10} + c_{11} \text{ (at any moment).}
\end{aligned}\right\} \quad \text{(XXII)}$$

Thus, the set of equations (XXII) constitutes the mathematical model of MCHP decomposition in the presence of sodium stearate. Table 1 lists the reaction rate constants (determined experimentally and partially found in the literature).

To verify the adequacy of the mathematic model with a real process, it is necessary to solve the system of differential and nonlinear equations (XIV), (XVIII), (XX), (XXII) and compare the calculated concentrations of the reagents with the experimental data (see figure and Table 3). We solved the system on a PC. The solution was optimized in accordance with the criterion of the best agreement of the experimental and calculated data by more precisely determining the constants whose precise numerical values were unknown. The system of differential equations was solved by the Euler method:

$$c_i^{j+1} = c_i^j + (\mathrm{d}c_i/\mathrm{d}\tau)^j h \qquad \text{(XXIII)}$$

with a constant step h of 25 s for the time range 0–3 h.

For all the products yielded by MCHP decomposition, the calculated and experimental kinetic curve agree within 5% (see figure). Using the data obtained, we calculated the contributions from the radical F_R and chain F_C routes in the MCHP decomposition over the time range of interest:

$$F_R = -(R_1 + R_2 + R_5 + R_6 + R_8 + R_{11} + R_{13} + R_{29} + R_{31} + R_{34} + R_{37} + R_{40})/(\mathrm{d}c_1/\mathrm{d}\tau), \qquad \text{(XXIV)}$$

$$F_C = -R_{29}/(\mathrm{d}c_1/\mathrm{d}\tau). \qquad \text{(XXV)}$$

Our calculation showed that F_C asymptotically approaches zero, and F_R tends to 0.368 in the course of time, which is close to the experimental data.

CONCLUSION

A mathematical model of a multistage thermocatalytic process of decomposition of 1-methylcyclohexyl hydroperoxide in the presence of sodium stearate was developed, which adequately describes the experimentally observed relationships. A procedure for searching for the unknown rate and equilibrium constants of the elementary and overall reaction stages was also developed. The procedure utilizes the steady-state concentrations of the unstable components and kinetic relationships for analytical determination of the stable components (initial, intermediate, and final reaction products), using the known constants for selected elementary stages of the process of interest.

CATALYSIS

Complex Formation of Carbonyls, Carboxylates, and Acetylacetonates of Main-Group and Transition Metals with Hydroperoxides and Alcohols

A. M. Syroezhko and V. A. Proskuryakov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 2, 2004

Abstract—The thermodynamic and structural parameters of complexes formed by secondary and tertiary alcohols and hydroperoxides with carbonyls, carboxylates, and acetylacetonates of variable-valence metals were determined. The complexes of *s* and 3*d* elements with hydroperoxides have different structures.

The controlling role of 3*d*-element carboxylates and acetylacetonates in oxidation of *n*-alkanes and cycloalkanes is manifested in the stage of catalytic decomposition of hydroperoxides and in competitive reactions of $RO_2^{\cdot}$ radicals with the catalyst, initial substrate, and intermediates formed in oxidation [1]. The difference in the stability and lability of the resulting complexes is the key factor responsible for the specific controlling effect of these catalysts.

The aim of this study was to examine the reaction of transition metal carbonyls, carboxylates, and acetylacetonates with secondary and tertiary alcohols and hydroperoxides and to compare the catalytic activities of *s* and 3*d* elements in decomposition of tertiary hydroperoxides.

EXPERIMENTAL

The objects of study (ligands) were 1-methylcyclohexyl hydroperoxide (1-MCHP), cyclohexyl hydroperoxide (CHP), cyclohexanol (CH), and 1-methyl- and 4-methylcyclohexanol (1- and 4-MCH). Main-group and transition metal [Li(I), Co(II), Cr(III), Ni(II), Cu(II)] stearates and acetylacetonates, and also metal carbonyls $Cr(CO)_6$ and $Mo(CO)_6$ were used as complexing agents.

The ^{1}H NMR spectra of hydroperoxides in CCl_4 and *n*-heptane (0.625–2.0 M) were recorded on RYa-2310 and Tesla BS-497 spectrometers operating at 100 MHz in the temperature range from –50°C to 22°C; the ^{1}H NMR spectra of alcohols were taken at 15–50°C.

The broadening and shifts of signals in the ^{1}H NMR spectra of HO and HOO groups of alcohols and hydroperoxides dissolving the catalyst suggest the presence of labile paramagnetic complexes (Figs. 1–3). The position and linewidth of the NMR signals of hydroperoxide and alcohol molecules in complexes

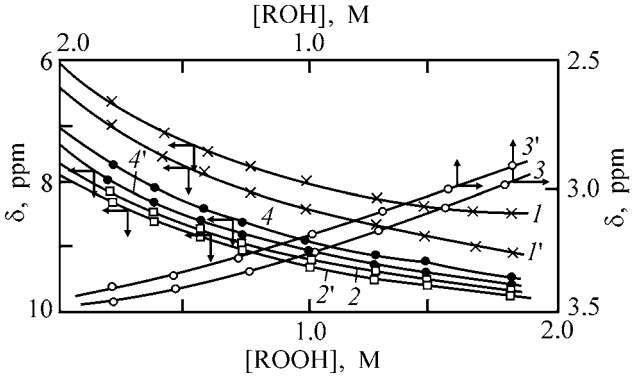

Fig. 1. Chemical shift δ of HO and HOO groups in the ^{1}H NMR spectra of alcohols and hydroperoxides vs. their concentrations [ROH] and [ROOH] in heptane at (*1*, *1*') –20, (*2*, *2*', *4*, *4*') –10, and (*3*, *3*') 23°C. Group: (*1*, *1*', *2*, *2*') OOH in 1-MCHP, (*3*, *3*') OH in 1-MCH, and (*4*, *4*') OOH in CHP; (*1*'–*4*') in the presence of 2×10^{-3} M $Mo(CO)_6$.

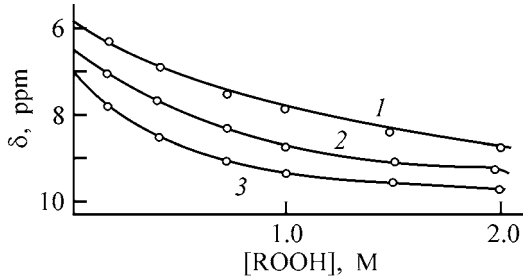

Fig. 2. Chemical shift δ of the HOO group in the ^{1}H NMR spectra of CHP vs. its concentration [ROOH] in heptane at -20°C (*1*) in the absence of a catalyst and in the presence of 2×10^{-2} M (*2*) $Mo(CO)_6$ and (*3*) $Co(acac)_2$.

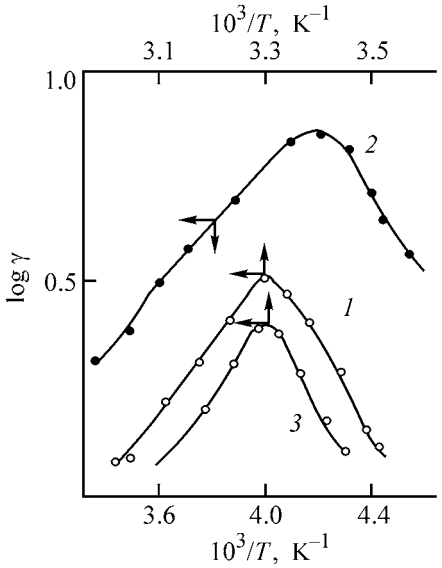

Fig. 3. Temperature dependence of signal broadening $\log\gamma$ in the ^{1}H NMR spectra of 1-MCHP and 1-MCH ([ROOH] = [ROH] = 0.25 M) in heptane in the presence of 2×10^{-2} M (*1*, *3*) $Mo(CO)_6$ and (*2*) $Co(acac)_2$.

are governed by the temperature and concentrations of the initial substrates.

The linewidths and shifts of signals in the ^{1}H NMR spectra are described by the Swift–Connick equations [2]. Consideration of special cases [3] under conditions of slow and fast exchange of ligands allows determination of the thermodynamic and structural parameters of complex formation in the systems: equilibrium constants K; enthalpy of complex formation, ΔH; lifetime of ligands in the coordination sphere of the metal, τ_1; activation energy of ligand elimination from the coordination sphere, E_a; and distances between the electron donor and acceptor in the complex, l.

The slow and fast ligand exchange can be distinguished by the temperature dependence of the linewidths of the ^{1}H NMR signals analyzed. In the first case, the linewidth increases with temperature, and in the second, it decreases. From the equation describing the complex formation

$$ML_n + XOH = ML_n \cdot XOH \quad (1)$$

[ML_n is a compound of a variable-valence metal, XOH is free hydroperoxide (ROOH) or alcohol (ROH), $ML_n \cdot XOH$ is paramagnetic labile complex], we can obtains provided that ML_n << [XOH], the complex concentration:

$$[ML_n \cdot XOH] = [ML_n]_0[XOH]_0/(1 + K[XOH]_0), \quad (2)$$

where $[XOH]_0$ and $[ML_n]_0$ are the initial concentrations of the ligand (hydroperoxide or alcohol, respectively) and variable-valence metal.

At a long lifetime of the ligand in the coordination sphere formed by the central atom ($\tau_1 >> \tau_{21}$, where τ_1 is the lifetime of ligand in the coordination sphere of the metal and τ_{21} is the transverse relaxation time of the ligand in the coordination sphere), the Swift-Connick equation for broadening τ_1/T_{2p} has a simple form

$$\tau_1/T_{2p} = P_1\tau_1^{-1}, \quad (3)$$

where P_1 is the mole fraction of ligands and τ_1/T_{2p} is paramagnetic broadening.

At a short lifetime of ligand in the coordination sphere of an ion ($\delta_{21} >> \tau_1$), the paramagnetic broadening and paramagnetic shifts (ppm) are given by expressions (4) and (5), respectively:

$$\tau_1/T_{2p} = P_1 2\pi(D + C), \quad (4)$$

$$\delta = -P_1\alpha a, \quad (5)$$

$$T_{2p} = 0.5(2\pi\Delta\gamma) = \pi\Delta\gamma, \quad (6)$$

where D is the contribution of the dipole-dipole electron-nuclear interaction in the complex of a transition metal with the ligand; C, the contribution of contact (isotropic) hyperfine interaction caused by delocalization of the unpaired electron of metal to the ligand; α, a coefficient; and $\Delta\gamma$, the line broadening measured at half-maximum (Hz).

From expressions (4) and (5) we obtain expressions (7) and (8) [4] allowing determination of the required thermodynamic and structural parameters of the complexes:

$$\delta^{-1}[ML_n]_0 = [-1/(\alpha a)](1/K + [ROOH]_0), \quad (7)$$

$$[ML_n]_0/\Delta\gamma = 1/2(D + C)(1/K + [ROOH]_0). \quad (8)$$

The dependences of the shifts $\Delta\delta$ and broadenings $\Delta\gamma$ on the concentration of alcohol or hydroperoxide, typical of the complexes studied, are shown in Figs. 1–4. The different directions of paramagnetic shifts of the ^{1}H NMR signals in complex formation with $Mo(CO)_6$ (downfield shift for ROOH and upfield shift for ROH) and the opposite signs of the signal shifts in complex formation of ROOH and ROH with $Co(acac)_2$ suggest different mechanisms of delocalization of the spin density from the metal to the ligand.

The distance between the oxygen atoms in ROOH is 0.1475 nm, and the O–H bond length is 0.095 nm. The quantum-chemical calculations by the extended Hückel method give the electronic structure of the ROOH molecule: the charge on the oxygen atoms is –0.59 (C–O) and –0.67 (O–H), and the charge on the hydrogen atom, +0.64.

The charge on atoms, the bond orders, and population of the –O–O bond vary only slightly with the structure of radical R•; however, introduction of polar substituents into radical R• has a noticeable effect. The electronic structure of ROOH is mainly characterized by two unshared pairs localized on the $2p_yO_\alpha$ and $2p_zO_\beta$ orbitals of oxygen atoms, which play an important part in the formation of the H–X bonds and in the weakening of the O–O bond in complexation with electron donors and acceptors. The lowest unoccupied molecular orbital is antibonding with respect to the O–O bond (it has a node located between the oxygen atoms), while the highest occupied molecular orbital is nonbonding and is close to the oxygen atomic orbital occupied by the unshared electron pair. The lower the energy level of the lowest unoccupied molecular orbital, the easier the reaction of the O–O group in ROOH with nucleophilic reagents. It would be expected that the associates of ROOH formed by H-bonds with bases should be preferentially formed along the 1*s* atomic orbital of hydroperoxide hydrogen and the $2p_z$ orbitals of the base heteroatom, and those with acids, along the $2p_yO_\alpha$ orbital of ROOH.

Applying Eqs. (7) and (8) to analysis of the ranges of fast exchange, we obtain the enthalpies of complex formation $H + E$ (E is the activation energy of electronic relaxation, equal to 4.2 kJ mol^{-1}). The hyperfine coupling constant a was determined from the dependence $[ML_n]/\delta = f[ROOH]$ (Fig. 4). From the concentration dependence of broadening under conditions of fast exchange (Fig. 5), we determine by Eq. (8) the sum (D + C), i.e., the dipolar and scalar contributions. In complexes with alcohols [5] under conditions of fast exchange, the scalar contribution ($S = 0.25a^2\tau$) can be neglected, and for complexes with ROOH (larger broadening in comparison with the shifts), all the observed broadenings in the ^{1}H NMR spectrum can be accounted for by the dipolar contribution D. Applying Eq. (3) to analysis of the ranges of slow exchange, we calculate the lifetime of ligands in the coordination sphere and the activation energy of ligand elimination from the coordination sphere.

In the complexes $Mo(CO)_6$–ROOH (CHP and 1-MCHP), $Co(acac)_3$–1-MCH, $Co(acac)_3$–4-MCH,

* Evaluation by Eq. (7) is correct for complexes with an equimolar stoichiometric ratio.

and $Co(acac)_2$–1-MCH (downfield shift), the hyperfine coupling constant is positive. In complex formation of ROH and ROOH with acetylacetonates, the most probable is delocalization of the spin density along the conjugation system [4, 5]. In complexes of Co and Cu carboxylates with ROOH (Table 1), the spin density is delocalized by the polarization mechanism (parameter *a* is negative). The hyperfine coupling constant is affected by the steric hindrance in complex formation and also by the electron-donor power of the initial ligands. Of no small importance is the shielding of the coordinated 3d transition metal, which is evident from a comparison of the parameter *a* for metal carboxylates and acetylacetonates with the same ligands (Table 1).

Table 2. Thermodynamic parameters of complex formation of ROOH and ROH with carbonyls, carboxylates, and acetylacetonates of variable-valence metals

Complex	E_a, kJ × mol^{-1}	ΔH, kJ × mol^{-1}	$\tau_1 \times 10^4$, s (*T*, °C)
$Co(acac)_2$–1-MCHP	31.6	24.4	4.8 (–40)
$Co(acac)_2$–CHP	32.2	26.5	5.1 (–40)

$Cu(acac)_2$–1-MCHP	33.5	29.2	–
$Ni(acac)_2$–1-MCH	34.5	30.3	–

With account of the fact that, for the complexes studied, the dipolar interaction makes the main contribution to the linewidth of the ^1H NMR signal (D >> C) [5], the distance between the metal and the ligand nucleus in the complex (*l*) can be determined with a sufficient accuracy:

$$D = 4/3S(S + 1)(\gamma_e^2\gamma_n^2h^2/l^6)\tau_c, \quad (9)$$

where γ_e and γ_n are gyromagnetic ratios of electron and the nucleus, respectively; *h* is the Planck constant; τ is the correlation time of dipolar interaction varied in the range 10^{-11}–10^{-12} s [in calculations, τ_c and *S* (spin quantum number) are taken to be 10^{-12} s and 0.5, respectively].

From these data we calculated the structural parameters of the complexes studied (Table 1). From the temperature dependences of broadening of the ^1H NMR signals for HO and HOO groups of alcohols and hydroperoxides (Fig. 3), we evaluated the thermodynamic and kinetic parameters of the complexes (Table 2).

In the temperature range studied the hydroperoxides enter into a slow ligand exchange at low temperatures and into fast exchange at a higher temperature. The sum of dipolar and scalar contributions to the

signal broadening is greater for ROOH than that for structurally related ROH. The equatorial and axial stereoisomers of secondary alcohol (4-MCH) form with $Co(acac)_3$ complexes of varied stability. Complex formation with the sterically nonhindered equatorial *cis* isomer proceeds more easily (Table 1).

The activation energy of ROOH and ROH elimination from the coordination sphere of $Cr(CO)_6$ and $Mo(CO)_6$ is 19.6–21.0 kJ mol^{-1}. These values are typical of the energy of hydrogen bonds of metal cabonyls with hydroperoxides.

The lifetime of ROOH or ROH molecules in the solvation shell of $Mo(CO)_6$ is significantly longer than that of diffusion pairs in liquids. Since the lifetime of ligand in the coordination sphere of metal is nine orders of magnitude longer than the characteristic time of elemental events in chemical processes, it would be expected that the orientation of molecules due to outer-sphere complex formation should promote the catalysis.

The enthalpy of complex formation of ROOH and ROH with Co(II), Cr(III), Cu(II), and Ni(II) stearates and acetylacetonates is higher than that for similar complexes of $Mo(CO)_6$, and the distance between the donor and acceptor is shorter. All these characteristics are typical of "anisotropic" complexes intermediate between inner-sphere and outer-sphere complexes. The activation energy of ligand elimination from the coordination sphere of Co(II), Cr(III), Cu(II), and Ni(II) exceeds the energy of H-bond; however, this does not allow an unambiguous conclusion that of only a coordination bond exists. The thermodynamic parameters of complexes of 1-MCHP and CHP with the same catalyst are virtually the same. The data obtained (Table 2) show that there is a clear correspondence between the capability of a transition metal ion for complex formation and its catalytic activity in oxidation of alkanes and cycloalkanes and also decomposition of ROOH [1]. The activation energy of ROOH elimination from the coordination sphere of Cr(III) is lower, compared to the Co(II), Cu(II), and Ni(II) complexes. This can account for the enhanced activity of Cr(III) in catalytic decomposition of ROOH.

The presence of vacant *d*-electron levels in variable-valence metals determines their capability for complex formation with oxidation products of various hydrocarbons (saturated, olefin, and aromatic). With increasing electronegativity of 3*d* transition metals, the stability of complexes of their acetylacetonates with ROOH and ROH grows, compared to acetylacetonates of 3*d* transition metals with a small number of *d* electrons. The presence of various oxidation states (from 2 to 6) is typical of metals with a small number of *d* electrons (V and Cr). Delocalization of π electrons of the enol form of acetylacetonate and *d* electrons of the metal over the chelate ring is typical of inner-sphere coordination compounds [Mn(III), Fe(III), Co(III), and Cu(II) acetylacetonates], and delocalization of only π electrons over the chelate ring is more probable for Ni(II), Co(II), and Zn(II) acetylacetonates. Data on the mechanism of delocalization of the spin density in complexes of alcohols and hydroperoxides with compounds of 3*d* transition metals are contradictory [4–7].

The chemical shift is only a qualitative indication of changes in the electron density in formation of chemical bonds, since the local paramagnetic contribution arises from the anisotropy of electron density distribution at the atom for which the chemical shift is measured. The contact shift in octahedral complexes of 3*d* transition metal acetylacetonates is caused by delocalization of the electron density from the metal to ligand or from the ligand to metal. The charge transfer from the metal to ligand should give rise to delocalization of the positive spin. The charge transfer from the ligand to metal should give rise to delocalization of the positive spin for the d^5–d^9 configuration and delocalization of the negative spin for the d^1–d^4 configuration [7]. The more probable is the delocalization of the electron from the metal to ligand, involving π orbitals of the ligand, which only slightly differ in the energy from the nonbonding *d* orbitals of the metal, rather than σ orbitals.

The acetylacetonate anion and carbon monoxide are ligands in which the donor atom contains a pair of electrons capable of formation of σ bond and low-energy vacant π antibonding orbital which can accept an electron pair from a metal atom to form a dative bond. The acetylacetonate anion is a "hard" base, which is caused by the planar structure of the ring and conjugation due to strong π electron interaction along the ring. In the complex ROOH–catalyst, the ROOH anion is activated and decomposes homolytically, and the oxidation state of the transition metal ion changes by the mechanism of single-electron transfer.

In this reaction, *s* and 3*d* transition metal carboxylates are more active than the corresponding chelates, which is caused by the difference in the electron density at the central coordinating atom of the catalyst in these compounds and at the oxygen atom of the ROOH group (Table 1). The IR spectra of 1-MHCP [1], measured in the presence of Li(I), Co(II), and

Cu(II) carboxylates, show, in combination with the ^{1}H NMR data, that, in the presence of the above catalysts, the hydrogen bond in ROOH self-associates is replaced by hydrogen bonds of ROOH with oxygen atoms of the carboxylate. At the same time, the observed chemical shift of the OH group (upfield shift) suggests formation of a coordination bond between the metal ion (*s* and 3*d*) and the oxygen atom of the OOH group in ROOH. In complexes of *s* and 3*d* transition metal carboxylates with ROOH, the electron density on the oxygen atom of the OOH group of 1-MCHP increases.

In complex formation of lithium stearate with 1-MCHP, the shift of the electron density to the oxygen atom of the OOH group in ROOH [8] can be understood with account of the electrostatic effect of Li^+ ion, local polarity of the carboxylate anion, and polarizability of 1-MHCP as a result of formation of H-bond. In complexation of 3*d* transition metal stearates, this explanation is probably incorrect since the shifts of the ^{1}H NMR signals of OOH are significant. It is most likely that both donor and the acceptor properties of ROOH are manifested in complex formation.

The acceptor properties of hydroperoxides are manifested as a result of transfer of the electron density from the metal ion to the free antibonding orbital (nonbonding valence orbital) of the peroxide bond. In ROOH, this orbital has predominantly the $2p^*$ character. In this interaction, the occupied orbital of the donor overlaps with the vacant orbital of the acceptor. The efficiency of interaction is governed by the overlap integral. The overlapping orbitals should correspond to each other in symmetry. For ions of metals in the lower oxidation states [Cr(II), Fe(II), Cu(I), Co(II), and oxovanadium VO(IV)] in the reaction with H_2O_2, the overlap of the orbitals in the transition state ($d \rightarrow p^*_\sigma$) results in the formation of a π complex [9]. The probability of formation of this bond grows with increasing number of *d* electrons of the metal. Formation of π^* bonds with organic reagents is typical of Cu(I), Cr(II), Fe(II), and Co(II) ions [10]. It should be noted that we used the concept of σ and π bond by convention with account of the local symmetry of the O–O bond. "Hard" Lewis acids [Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ti(IV), etc] form no π bonds.

The appearance of electrons on the antibonding orbital of ROOH results in weakening of the O–O bond. As a result of its decomposition, a radical or a radical ion of the peroxy compound and an oxidized metal ion (M^{n+1}) are formed.

The donor properties of ROOH are related to the possibility of electron density transfer by the acceptor from the 2*p* nonbonding orbitals of the hydroperoxides. The population of oxygen *p* orbitals in ROOH, on which the unshared pair is localized [9], is close to that of pure atomic orbitals. In this case, the orbitals overlap at the electron transfer $p \rightarrow d$ from the nonbonding *p* orbital of ROOH to the vacant orbital of the 3*d* transition metal ion. This type of bonding is typical of 3*d* transition metals Cu(II), Mn(III), Fe(III), and Co(III). In these reactions, a one-electron reduction of metal is very probable. The data obtained show that the mechanism of donor–acceptor interaction is influenced by the geometry of 3*d* transition metal compound (acetylacetonate or carboxylate) and by the splitting of the central atom levels and the number of electrons on the valence orbitals. When σ bonds between ROOH and metal ion Co(II), Cu(II), Ni(II), or Mn(III) in high-spin octahedral complexes are formed, only decomposition of ROOH is observed. The π-bonding between the central atom of the catalyst and ROOH molecule in the case of Mo, W, V, and Cr compounds activates the ROOH molecule for its reaction with an olefin to form the epoxide. The ROOH molecule is activated by interaction of its π^* orbital with the t_{2g} orbital of the metal ion.

In complexation of Mo and Cr carbonyls, only the outer-sphere coordination of ROOH is possible. For example, in $Cr(CO)_6$ chromium atom uses six d^2sp^3 hybrid orbitals and forms a σ bond with six carbon atoms of CO groups octahedrally arranged around this atom. The filled *d* orbitals of chromium d_{xy}, d_{xz}, and d_{yz} have the same arrangement (symmetry) as the antibonding π^*_x and π^*_y orbitals of CO. The back donation of *d* electrons from the metal to the antibonding orbitals of CO ligands decreases the π bonding between the C and O atoms, so that the carbon-oxygen bond in the carbonyl is not triple. The ligands are strongly bound to the metal [11]. The M–C and C–O bond lengths in $Cr(CO)_6$ are 0.19 and 0.11 nm, and in $Mo(CO)_6$, 0.2 and 0.11 nm, respectively.

In the complexes studied, the distance between the central atom and ligand (ROOH and ROH) is 0.38–0.40 nm (Table 1). The structural parameters and energy characteristics obtained correspond to outer-sphere coordination, probably caused by H bonding. The structural parameters of the other complexes correspond to an intermediate state between inner- and outer-sphere complexes (Table 1). For example, the Co–O bond length in $Co(acac)_2$ is 0.205 nm, and that in $Co(acac)_2$–1-MCHP and $Co(acac)_2$–CHP, 0.29–0.28 nm, respectively. Cobalt(II) stearate coordinates 1-MCHP more strongly (l = 0.26 nm) than $Co(acac)_2$, which decreases the energy barrier of the reaction.

These results are in a good agreement with published data [7, 8, 12–14]. The products formed in decomposition of ROOH (alcohol and water) will competitively coordinate to the catalyst, which inhibits the reaction.

The shift of the electron density from the oxygen atom of ROOH to the metal in complex formation with $Co(acac)_2$ cannot be explained, since the charge on the α-atom of the OOH group should increase in this case [4]. In the complexes of $Co(acac)_2$ with ROOH, the pseudocontact interaction resulting in significant shift of the signal in the ^1H NMR spectrum plays an important role. In complexes of acetylacetonates with ROH, formation of an H bond is not ruled out [7].

The abnormal catalytic activity of chromium compounds [$Cr(ac)_3$, $CrSt_3$ (where ac is acetate and St is stearate anion), $Cr(acac)_3$, and $Cr(CO)_6$] can also be caused by the possible competitive formation of ROOH complexes with coordination through α- or β-oxygen atom [5]. It seems likely that, in the systems ROOH–catalyst, complexes of both types are formed and their ratio depends on the nature of metal and ROOH. The mobility of unshared electron pairs, i.e., the electron-donor power of both oxygen atoms in the hydroperoxide molecule, is virtually the same. The acceptor power of oxygen atoms of hydroperoxides varies: the energy level of the O_α atom is higher than that of the O_β atom. To compounds of metals with larger atomic numbers (Fe, Co, and Cu), ROOH should predominantly coordinate through the O_α atom, while with Mo(0), VO^{2+}, Cr(VI), and in part Cr(III) the coordination through the O_β atom is possible.

It is likely that the differences in the structure of the complexes studied and complexes of 3*d* transition metal acetylacetonates with methanol [4] are caused by the geometric structure and spatial arrangement of bulky compared to methanol, molecules of cyclic alcohols and hydroperoxides. A small molecule of coordinated methanol can approach the metal ion by 0.13–0.18 nm and enter into the inner coordination sphere. Bulky molecules of cyclic alcohol or hydroperoxide are situated at a significantly longer distance (0.24–0.30 nm). Contrary to published data [4] concerning the existence of two coordination spheres in the complexes $Co(acac)_2$–*tert*-butyl hydroperoxide and $Co(acac)_2$–*tert*-amyl hydroperoxide, for the cyclic alcohols and hydroperoxides studied here in the temperature interval examined we did not observed complete exchange of ligands between the inner and outer spheres.

CONCLUSIONS

(1) Acetylacetonates and stearates of 3*d* transition metals form anisotropic complexes with cyclohexanol and cyclohexyl hydroperoxide and their methyl-substituted derivatives, intermediate between inner- and outer-sphere complexes; molybdenum and chromium hexacarbonyls form labile outer-sphere complexes.

(2) In complex formation of hydroperoxides with carboxylates or acetylacetonates of 3*d* transition metals, both donor and acceptor properties of hydroperoxides are manifested, depending on the number of electrons on the *d* level of metal and its oxidation state. This results in different mechanisms of delocalization of the electron density.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Kinetic Relationships in Synthesis of Dimethoxymethane

S. M. Danov, V. A. Kolesnikov, and I. V. Logutov

Dzerzhinsk Branch, Nizhni Novgorod State Technical University, Dzerzhinsk, Nizhni Novgorod oblast, Russia

Received July 15, 2004

Abstract—The kinetics of formation of dimethoxymethane by acetalization of formaldehyde with methanol, catalyzed by silicotungstic heteropoly acid, were studied.

Dimethoxymethane (DMM) is a colorless solvent with a low boiling point, low viscosity, and an excellent dissolving power. It finds application in organic and pharmaceutical syntheses, paint and varnish industry, as a washing solvent, as component of cleaning and degreasing solvents, in production of adhesives and plastics, as a fuel additive, and as a component of in technical aerosols and in household chemistry articles.

The starting reagents for preparation of DMM are formaldehyde (FA) and methanol (M). These are readily accessible and cheap chemicals, which, combined with their acceptable production costs, affords a cheap commercial DMM. The overall reaction of DMM formation can be represented schematically as

$$2CH_3OH + HCHO \overset{Cat.}{\rightleftarrows} CH_2(OCH_3)_2 + H_2O.$$

Since recently, commercial plants have been using as catalysts ion-exchange resins, which afford DMM in high yields but degrade during the reaction into small particles clogging the column, lose their activity under exploitation, and need either regeneration or replacement [1]. Also, inorganic acids such as sulfuric acid have been tested as catalysts, but they cause many nuisances like corrosion activity, environmental pollution, the need for neutralization of wastewater, and irreversible loss of the acid [2].

We believe that tungstic heteropoly acids and, in particular, silicotungstic heteropoly acid $H_4SiW_{12}O_{40}$ (STA), are suitable as catalysts. The trials on laboratory batch and continuous-operation units showed that tungstic heteropoly acids can be successfully applied as catalysts in synthesis of DMM.

In the context of development of the optimal procedure for isolation and purification of DMM, it is necessary to analyze the kinetic aspects of its synthesis, which constituted the aim of this study.

EXPERIMENTAL

In experiments, we used a water-methanol solution of formalin containing 37 wt % FA; the amount of FA was determined by the sodium sulfate technique, and that of M, by gas chromatography. We used M purified by distillation; gas chromatographic analysis showed that it contained residual water only. Analytically pure silicotungstic heteroply acid was dried by calcination at 250°C for 3 h.

The kinetic relationships were experimentally studied in a glass reactor (V = 100 ml) equipped with a water jacket, two ground-glass joints connecting the reactor with a reflux condenser and a thermometer, and a sampler. To exclude hot spots, the reaction mixture was stirred with a magnetic stirrer. A constant temperature in the reactor was maintained by water circulating between the thermostat and the reactor jacket, with the temperature monitored within the latter. A water thermostat connected to the reactor case was operated in the forced-circulation mode.

The reaction mixture was prepared by mixing M, FA, and water to achieve the desired ratio of the reactants, whereupon the required amount of the resulting mixture was sampled, weighed on an analytical balance, and placed in the reactor. When the desired temperature was established in the reactor, the required amount of STA was added, from which moment the time of the process was measured. Samples (0.2 ml) were taken at regular intervals; a sample was added to 5 ml of aqueous NaOH of the concentration required for neutralizing the acid contained in the taken volume of the reaction mixture, and the mixture contained in the test tube was thoroughly stirred.

All the samples were analyzed chromatographically on a Tsvet 500 gas chromatograph with a flame-

1070-4272/04/7712-1994 © 2004 MAIK "Nauka/Interperiodica"

ionization detector and a 2000 × 3 mm steel column packed with Polysorb (0.16–0.2 mm grains). The carrier gas was nitrogen; the flow rate of nitrogen and hydrogen was 30, and that of air, 300 $cm^3\ min^{-1}$. The temperatures of the column, detector, and vaporizer were 150°C. The relative error of analysis was 3%.

As mentioned above, DMM is formed by a two-stage reaction between M and FA:

$$HCHO + CH_3OH \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} HOCH_2OCH_3, \quad (1)$$

$$HOCH_2OCH_3 + CH_3OH \underset{k_{-2}}{\overset{k_1}{\rightleftarrows}} CH_2(OCH_3)_2 + H_2O. \quad (2)$$

The rate of formation of hemiacetal (HA) is very high [3], with the equilibrium strongly shifted toward its formation [4]. Since M was taken in excess in all the experiments, we assumed that the whole amount of FA was in the form of HA. Thus, we developed a kinetic model taking into account reaction (2) only. We described the DMM formation rate of by the differential equation

$$dc_{DMM}/d\tau = k_2' c_{PA} c_M - k_{-2}' c_{DMM} c_{H_2O},$$

where k_2' and k_{-2}' are the effective rate constants, $l\ min^{-1}\ mol^{-1}$; c_{PA}, c_M, c_{DMM}, and c_{H_2O}, concentrations (M) of PA, M, DMM, and water, respectively.

This equation was solved by the Runge-Kutta method. The rate constants were calculated by the least-squares method. Figure 1 shows the typical kinetic curves of DMM formation.

The dependence of the effective rate constants k_2' and k_{-2}' on the catalyst concentration was described by the equation

$$k_2' = k_2 c_{cat}^n, \quad k_{-2}' = k_{-2} c_{cat}^m,$$

where k_2 and k_{-2} are true rate constants, $l^2\ min^{-1}\ mol^{-2}$; c_{cat}, catalyst concentration, M; and n and m, reaction orders with respect to the catalyst.

Figure 2 shows that the logarithm of the effective rate constants linearly varies with the logarithm of the catalyst concentration. The orders with respect to the catalyst are identical for the constants k_2' and k_{-2}', namely, 1.43.

The constants k_2 and k_{-2} were calculated by the equations

$$k_2 = k_2'/c_{cat}^{1.43}, \quad k_{-2} = k_{-2}'/c_{cat}^{1.43}.$$

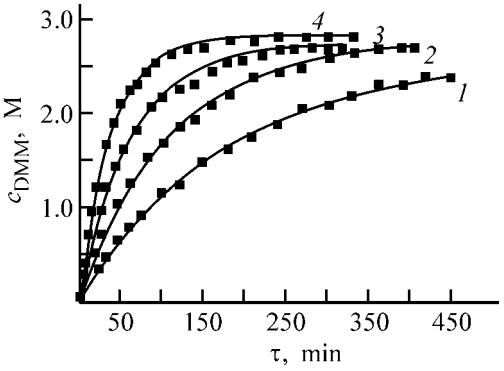

Fig. 1. Kinetic curves of DMM formation at (*1*) 303, (*2*) 308.3, (*3*) 313.3, and (*4*) 318.3 K. M : FA molar ratio 2 : 1. (c_{DMM}) DMM concentration, and (τ) time. (*Solid line*) Calculated values and (*black squares*) experimental values at c_{cat} = 0.1298 M.

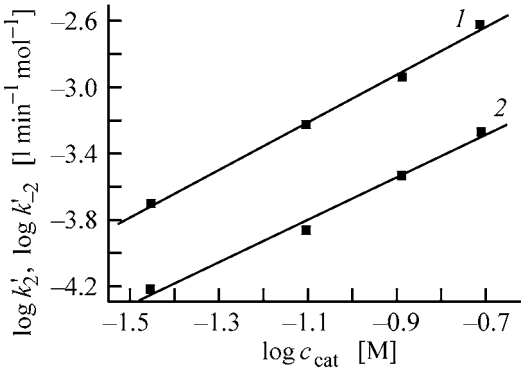

Fig. 2. Variation of the effective rate constants (*1*) k_2' and (*2*) k_{-2}', of DMM formation with the catalyst concentration c_{cat} at 313.3 K.

The temperature dependence of the rate constant is described by the Arrhenius equation (see table), and it was used for determining the expressions for $k_2 = f(T)$ and $k_{-2} = f(T)$ (activation energy, J mol^{-1}; temperature, K):

$$k_2 = 1.478 \times 10^{13} e^{-88\,800/RT},$$

$$k_{-2} = 6.798 \times 10^{11} e^{-84\,690/RT}.$$

Rate constants k_2 and k_{-2} at different temperatures

T, K	k_2	k_{-2}
	$l^2\ min^{-1}\ mol^{-2}$	
303	0.007421	0.001855
308.3	0.01318	0.002784
313.3	0.02226	0.005566
318.3	0.03897	0.008165
323.1	0.06679	0.01484

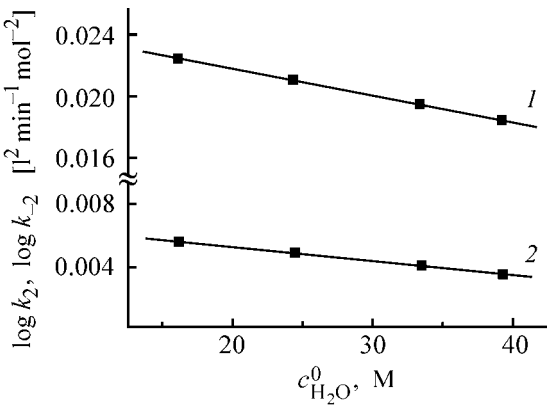

Fig. 3. Variation of the rate constants (*1*) k_2' and (*2*) k_{-2}', of DMM formation with the initial water concentration c^0_{H2O} at 313.3 K.

Using the dependences of k_2 and k_{-2} (T = 313.3 K) on the initial concentration of water in the system (Fig. 3), we derived the expressions

$$k_2 = 0.02493 - 0.000161c^0_{H_2O},$$
$$k_{-2} = 0.0069 - 0.00008454c^0_{H_2O}.$$

These dependences suggest that the rate constants k_2 and k_{-2} are weakly dependent both on the initial water concentration in the system and, evidently, on the composition of the reaction mixture as a whole.

CONCLUSION

A kinetic model was developed for synthesis of dimethoxymethane from methanol and formaldehyde, catalyzed by silicotungstic heteropoly acid $H_4SiW_{12}O_{40}$. The dependences of the rate constants of the process on the temperature and composition of the medium were obtained.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Nucleophilic Substitution of Chlorine with Hydrazine and Methylhydrazine in Chlorinated Pyridazines and Pyridazones

A. B. Baranov, V. G. Tsypin, A. S. Malin, and B. M. Laskin

Prikladnaya Khimiya Russian Scientific Center, St. Petersburg, Russia

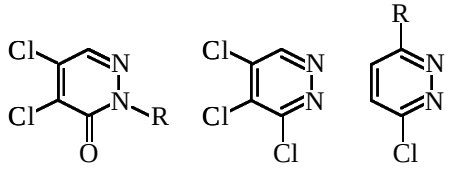
Received August 18, 2004

Abstract—The reactions of methylhydrazine and hydrazine hydrate with chlorinated pyridazines and pyridazones were studied.

The reactivity of hydrazine and methylhydrazine toward aliphatic and aromatic compounds has been well studied [1, 2]. However, data on reactions of hydrazine and methylhydrazine with heterocycles and, in particular, with pyridazines are scarce. The interest in the chemistry of hydrazine is determined by its diverse applications in science and technology. In particular, hydrazine derivatives are widely used in medicine as physiologically active compounds exhibiting antitubercular, anticancer, radiation-protective, and other effects; in agriculture, as plant growth regulators and stimulants, as insecticides, fungicides, and hebricides; and in industry, for preparing synthetic fibers, films, and coatings [3, 4].

In this study we examined the reactions of hydrazine hydrate and methylhydrazine with some chlorinated pyridazines and pyridazones.

In the pyridazine series, available substrates for nucleophilic substitution are 4,5-dichloro-6-pyridazone **I**, 1-methyl-4,5-dichloro-6-pyridazone **II**, 3,4,5-trichloropyridazine **III**, 3,6-dichloropyridazine **IV**, and 3-methyl-6-chloropyridazine **V** [5–8]:



I, **II** **III** **IV**, **V**

where R = H (**I**), Me (**II**, **V**), Cl (**IV**).

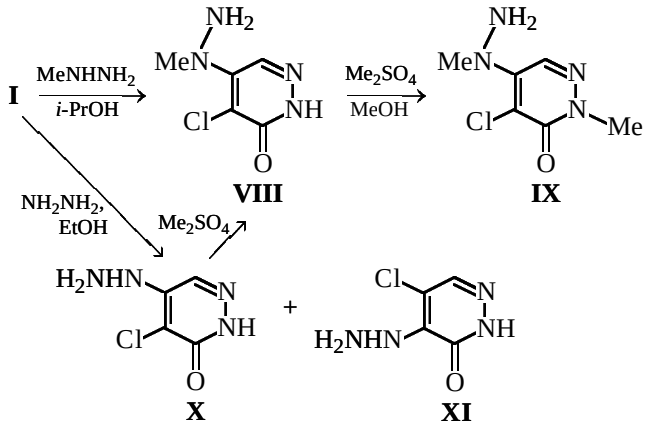
It is known that pyridazone **I** reacts with ammonia [9], alkylamines [10], and hydrazine [11] selectively with chlorine substitution at the 4-position of the pyridazine ring. This is due to the activating effect of the keto group on the 4-position in **I** [10, 12]. However, it has been reported [13, 14] that the reaction of **I** with ammonia yields a mixture of 4-amino-5-chloro-6-pyridazone **VI** and 5-amino-4-chloro-6-pyridazone **VII**.

Our experiments showed that pyridazone **I** reacts with methylhydrazine in 2-propanol strictly specifically to give 4-(1-methylhydrazino)-5-chloro-6-pyridazone **VIII** in 95% yield. In methylation of **VIII** with dimethyl sulfate in methanol in the presence of sodium, the reaction occurs selectively at the 1-position of the pyridazine ring, giving 1-methyl-4-(1-methylhydrazino)-5-chloro-6-pyridazone **IX** in 37% yield.

It is known [11] that the reaction of **I** with 95% hydrazine in methanol yields exclusively 4-hydrazino-5-chloro-6-pyridazone **X**. Its structure was determined by hydrogenation (Pd/C) and independent synthesis of the dechlorination products. However, under the experimental conditions, the reaction of **I** with 100% hydrazine hydrate in ethanol yields a mixture of pyridazone **X** and 5-hydrazino-4-chloro-6-pyridazone **XI** in 29 and 48% yields, respectively, which is confirmed by the ^{1}H NMR and TLC data, and also by depression of the melting point, observed on mixing **X** and **XI**.

Then we performed methylation of **X** with dimethyl sulfate. The reaction was performed in the system 10% aqueous NaOH solution–$CHCl_3$ in the presence of Et_4NI. The reaction occurs selectively at the N^1 atom of the hydrazine moiety, yielding pyridazone **VIII**:

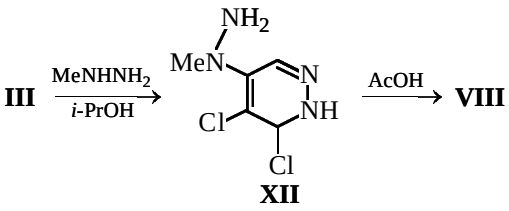
1070-4272/04/7712-1997 © 2004 MAIK "Nauka/Interperiodica"



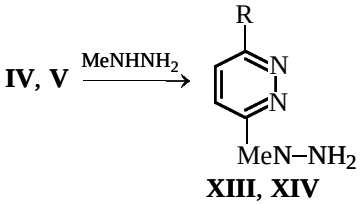
It is known that the reaction of pyridazone **II** with various amines occurs selectively with the substitution of chlorine at the 4-position of the pyridazine ring [10]. We also studied the reactions of pyridazone **II** with methylhydrazine and hydrazine hydrate. Pyridazone **II** does not react with methylhydrazine in refluxing alcohols (methanol, 56°C, 30 h; ethanol, 78°C, 30 h; 2-propanol, 86°C, 30°C; 1-butanol, 110°C, 30 h) and is recovered unchanged from the reaction mixture. The attempted reaction of **II** with 100% hydrazine hydrate in ethanol and 2-propanol results in tarring.

It is known that pyridazine **III** is synthesized by the reaction of **I** with $POCl_3$ [6]; acidolysis of **III** in glacial acetic acid eliminates chlorine from the 3-position of the pyridazine ring to give tion of **I**.

Our experiments showed that pyridazine **III** reacts with methylhydrazine in 2-propanol at 45°C selectively with substitution of the 5-Cl atom to give 5-(1-methylhydrazino)-3,4-dichloropyridazine **XII** in 40% yield. Acidolysis of **XII** in glacial acetic acid at 60°C gives pyridazone **VIII** in 10% yield:



The starting substrates **IV** and **V** were prepared by the procedures described in [7, 8, 15]. We found that pyridazine **IV** in ethanol at 78°C reacts with methylhydrazine selectively with substitution of one chlorine atom to give 3-(1-methylhydrazino)-6-chloropyridazine **XIII** in 55% yield. The reaction of **V** with methylhydrazine in 1-butanol at 110°C gives 3-methyl-6-(1-methylhydrazino)pyridazine **XIV** in 32% yield:



where R = Cl (**XIII**), Me (**XIV**).

EXPERIMENTAL

The ^1H NMR spectra were measured on a DPX-300 spectrometer (300 MHz), solvent DMSO-d_6, internal reference TMS. The elemental analysis was performed on a Hewlett–Packard automatic C, H, N analyzer. The melting points were determined on a PTP device. The TLC analysis was performed on Silufol UV-254 plates (eluent 90 vol % $CHCl_3$–10 vol % MeOH), development with UV light and iodine vapor.

4,5-Dichloro-6-pyridazone **I** and 1-methyl-4,5-dichloro-6-pyridazone **II** were prepared by the procedure described in [5].

3,4,5-Trichloropyridazine III. To 10 ml of $POCl_3$ we added with stirring 3 g of **I**. The mixture was stirred at 70°C for 6 h, after which excess $POCl_3$ was distilled off. The residue was cooled to 0–2°C and carefully neutralized with 5% aqueous NaOH. The precipitate of **III** was filtered off and dried in air; yield 1.45 g (43%), mp 56–58°C.

Found, %: C 26.10, H 0.01, N 15.20.
$C_4HCl_3N_2$.
Calculated, %: C 26.16, H 0.01, N 15.26.

4-(1-Methylhydrazino)-5-chloro-6-pyridazone VIII. (a) A 5-g portion of **I** was dissolved in 85 ml of 2-propanol, and a solution of 2.9 g of methylhydrazine in 15 ml of 2-propanol was added. The mixture was refluxed with stirring for 2 h, after which it was cooled and kept for 12 h at 0°C. The precipitate of **VIII** was filtered off and dried in air; yield 5.04 g (95%), mp 144–146°C (dec.). ^1H NMR spectrum, δ, ppm: 12.40 s (1H, NH in heterocycle), 8.19 d (1H, CH), 4.77 s (2H, NH_2), 3.40 s (3H, Me).

Found, %: C 34.31, H 0.04, N 32.05.
$C_5H_7ClN_4O$.
Calculated, %: C 34.38, H 0.04, N 32.09.

(b) A 2-g portion of **X** was dissolved in 20 ml of 10% aqueous NaOH, and 3.25 g of Et_4NI was added.

The mixture was heated with stirring to 30°C, and 2.1 ml of dimethyl sulfate in 20 ml of chloroform was added. The resulting mixture was stirred at 40°C for 10 h, cooled, and settled. The aqueous layer was treated with a 20-ml portion of chloroform. The extract was combined with the organic phase, the solvent was distilled off, and the precipitate of **VIII** was dried in air and recrystallized from ethanol; yield 0.21 g (10%).

(c) A 2-g portion of **XII** was dissolved in 50 ml of glacial acetic acid. The mixture was stirred at 60°C for 12 h, cooled, and kept at 0–5°C for 12 h. The precipitate of **VIII** was filtered off, dried in air, and recrystallized from ethanol; yield 0.19 g (10%).

1-Methyl-4-(1-methylhydrazino)-5-chloro-6-pyridazone IX. A 2-g portion of Na was dissolved in 30 ml of methanol, 3 g of **VIII** was added, the mixture was heated to 35–40°C, and a solution of 3 ml of dimethyl sulfate in 5 ml of methanol was slowly added with stirring. The mixture was stirred at 35–40°C for an additional 14 h and cooled; excess methanol was distilled off. The residue was mixed with 20 ml of 10% aqueous NaOH and treated with 50 ml of chloroform. Excess chloroform was distilled off, and the precipitate of **IX** was filtered off and dried in air; yield 1.22 g (38%), mp 136–137°C. ^{1}H NMR spectrum, δ, ppm: 8.19 s (1H, CH), 4.82 s (2H, NH_2), 3.57 s (3H, CH_3 in heterocycle), 3.38 s (3H, Me).

Found, %: C 38.15, H 4.72, N 29.68.
$C_6H_9ClN_4O$.
Calculated, %: C 38.19, H 4.77, N 29.71.

4-Hydrazino-5-chloro-6-pyridazone X and 5-hydrazino-4-chloro-6-pyridazone XI. A 3.3-g portion of **I** was dissolved in 60 ml of ethanol. This solution was heated to 70–75°C, and 3 g of 100% hydrazine hydrate in 10 ml of ethanol was added. The mixture was stirred at 70–75°C for 4 h and cooled; the precipitate containing a mixture of **X** and **XI** was filtered off and dried in air. To separate **X** and **XI**, the mixture was boiled in 50 ml of water and filtered while hot to separate difficultly soluble pyridazone **XI**. The mother liquor was cooled, and the precipitate of **X** was filtered off and dried; yield 0.95 g (30%), mp 195°C. ^{1}H NMR spectrum, δ, ppm: 12.30 s (1H, CH), 8.07 s (1H, NH in heterocycle), 7.63 s (1H, NH), 4.62 s (2H, NH_2).

Found, %: C 29.83, H 3.09, N 34.80.
$C_4H_5ClN_4O$.
Calculated, %: C 29.91, H 3.11, N 34.89.

For 5-hydrazino-4-chloro-6-pyridazone **XI**: yield 1.55 g (48%), mp 189°C. ^{1}H NMR spectrum, δ, ppm: 12.29 s (1H, CH), 8.07 s (1H, NH in heterocycle), 7.60 s (1H, NH), 4.50 s (2H, NH_2).

Found, %: C 29.90, H 3.10, N 34.85.
$C_4H_5ClN_4O$.
Calculated, %: C 29.91, H 3.11, N 34.89.

Mixing of **X** (R_f 0.11) and **XI** (R_f 0.35) showed 20°C depression of the melting point.

5-(1-Methylhydrazino)-3,4-dichloropyridazine XII. A 3-g portion of **III** was dissolved in 30 ml of 2-propanol. The solution was heated with stirring to 40°C, a solution of 1.87 g of methylhydrazine in 5 ml of 2-propanol was added, and the mixture was stirred at 45°C for 10 h, cooled, and kept at 0–2°C for 12 h. The precipitate of **XII** was filtered off and dried in air; yield 1.27 g (40%), mp 116–117°C. ^{1}H NMR spectrum, δ, ppm: 9.11 s (1H, CH), 4.99 s (2H, NH_2), 3.40 s (3H, Me).

Found, %: C 30.98, H 3.10, N 28.95.
$C_5H_6Cl_2N_4$.
Calculated, %: C 31.09, H 3.11, N 29.01.

3-(1-Methylhydrazino)-6-chloropyridazine XIII. A 30-g portion of **IV** was dissolved with stirring in 200 ml of ethanol, a solution of 19.4 g of methylhydrazine in 40 ml of ethanol was added, the mixture was stirred at 70–80°C for 1 h, and the solvent was distilled off. The residue was stirred with 200 ml of water at 50–60°C until it completely dissolved. The resulting mixture was cooled, and the precipitate of **XIII** was filtered off, dried in air, and crystallized from water or benzene; yield 17.5 g (55%), mp 110–111°C. ^{1}H NMR spectrum, δ, ppm: 3.33 s (3H, Me), 4.61 s (2H, NH_2), 7.23 d (1H, CH in heterocycle), 7.53 d (1H, CH in heterocycle).

Found, %: C 37.3, H 4.3, N 34.9.
$C_5H_7ClN_4$.
Calculated, %: C 37.9, H 4.4, N 35.1.

3-Methyl-6-(1-methylhydrazino)pyridazine XIV. A solution of 2.24 g of methylhydrazine in 10 ml of 1-butanol was added with stirring to a solution of 2.5 g of **V** in 25 ml of 1-butanol. The mixture was stirred at 108–111°C for 1 h, and excess solvent was distilled off. The residue was dissolved in 25 ml of water and treated with 50 ml of chloroform. Excess chloroform was distilled off, and the precipitate of

XIV was filtered off, dried in air, and recrystallized from CCl_4; yield 0.91 g (32%), mp 73–75°C. ^1H NMR spectrum, δ, ppm: 3.30 s (3H, Me), 4.38 s (2H, NH_2), 7.06 d (1H, CH in heterocycle), 7.39 d (1H, CH in heterocycle).

Found, %: C 52.3, H 7.1, N 40.4.
$C_6H_{10}N_4$.
Calculated, %: C 52.2, H 7.2, N 40.6.

CONCLUSIONS

(1) In the reaction of 4,5-dichloro-6-pyridazone with methylhydrazine, the nucleophilic substitution of chlorine occurs selectively at the 4-position of the ring to give 4-(1-methylhydrazino)-5-chloro-6-pyridazone (yield 95%), whereas the reaction of 4,5-dichloro-6-pyridazone with hydrazine hydrate gives a mixture of products of chlorine substitution at the 4-and 5-positions (yield 30 and 48%, respectively).

(2) 3,4,5-Trichloropyridazine reacts with methylhydrazine in 2-propanol selectively with substitution of the 5-Cl atom to give 5-(1-methylhydrazino)-3,4-dichloropyridazine in 40% yield. Acidolysis of 5-(1-methylhydrazino)-3,4-dichloropyridazione in glacial acetic acid gives 4-(1-methylhydrazino)-5-chloro-6-pyridazone (yield 10%).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Cleaning Action and Surfactant Properties of Alkyl Glucosides

O. D. Yakimchuk, A. A. Kotomin, M. B. Petel'skii, and V. N. Naumov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received September 24, 2004

Abstract—Cleaning action and surfactant properties of a series of alkyl glucosides, having high detergent power, emulsifying capacity, and biodegradability and low foaming capacity, were studied. The effects of various factors on the cleaning action of the surfactants and compositions on them were investigated, allowing prediction of the cleaning effect on the basis of data on physicochemical characteristics of the solutions and process parameters.

Today there is a tendency to reduce the use of certain classes of surfactants polluting the environment and to change them for new ones [1–3]. Accordingly, efforts are being made to develop new classes of surfactants with reduced foaming capacity and mild action, which operate at a lower temperature, with synergistic action of their components [3–6]. Such new surfactants should be environmental friendly and cost efficient.

Alkyl glucosides only recently started to be used in production of detergents, and, therefore, their properties are little studied. Some of them demonstrate very good surfactant properties [7–9]. These surfactants are stable in alkaline and acidic solutions and show careful action with respect to color retention. The use of this class of surfactants for production of detergents shows promise not only from the efficiency standpoint, but also in view of the environmental protection. Alkyl glucosides are characterized by high biodegradability, as being manufactured from natural raw materials. At the same time, these are mild, low-toxic surfactants providing no skin irritation. Large-scale application of alkyl glucosides was previously limited by their high cost. However, in recent years, the cost demonstrates a steady tendency to decrease.

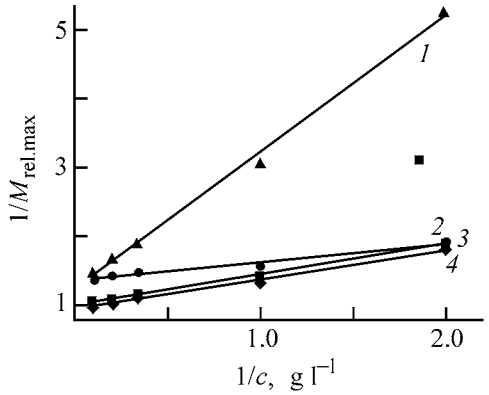
Till now researchers mostly focused on long-chain alkyl glucosides with a broad distribution of the number of carbon atoms in the chain (C_{10}–C_{18}) [8, 9]. Short-chain compounds virtually have not been studied. However, such alkyl glucosides are of interest in view of the fact that they may have low foaming and good emulsifying properties.

In this study, we examined the relationships between the physicochemical characteristics of alkyl glucosides $C_6H_{11}O_5$–O–C_nH_{2n+1} and their cleaning properties. The results were then compared with those obtained for the known anionic and nonionic surfactants: linear sodium alkylbenzenesulfonate [SABS, C_{10-14}–(C_6H_4)–SO_3Na], sodium alkylsulfonate (C_{12-18}–SO_3Na), Syntanol DS-10 [C_{10-18}–$O(C_2H_4O)_{10}H$], Syntanol ALM-10 [C_{12-14}– $O(C_2H_4O)_{10}H$], and Neonol AF_9-12 [C_9H_{12}–C_6H_4–$O(C_2H_4O)_{12}H$]. We also studied the effect of the length of the hydrocarbon chain on the cleaning action and surfactant properties in the homologous series of alkyl glucosides with short (C_6, C_8, and C_{8-10}) and long (C_{8-16} and C_{12-14}) chains. It should be pointed out that the short-chain alkyl glucosides studied are new compounds, and their cleaning action and surfactant properties have not been investigated yet.

The cleaning action was determined from the whiteness of laundered cotton fabric samples [10]. Then the cleaning action in the test solutions was compared with that obtained in a reference solution, M_{ref}, under similar conditions. The reference solutions contained linear sodium alkylbenzenesulfonate (1 g l^{-1}) and sodium tripolyphosphate (2 g l^{-1}) in accordance with GOST (State Standard) 22 567.15–95. To eliminate some side effects, we used the relative cleaning action of a compound $M_{rel} = M/M_{ref}$ as a basic parameter in analysis of the results.

It follows from the concentration dependences of the relative cleaning action of alkyl glucosides (Table 1) that the cleaning effect increases as the hydrocarbon chain becomes longer. Short-chain alkyl glucosides (C_6 and C_8) demonstrate low cleaning action, while that of alkyl glucoside C_{8-10} is higher as compared to SABS and sodium alkylsulfonate

1070-4272/04/7712-2001 © 2004 MAIK "Nauka/Interperiodica"



Cleaning effect of surfactants, $M_{rel.max}$, vs. their concentration c: (*1*) SABS, (*2*) Neonol AF_9-12, (*3*) alkyl glucoside $C_{8–16}$, and (*4*) alkyl glucoside $C_{12–14}$.

(Volgonate). Alkyl glucosides $C_{8–16}$ and $C_{12–14}$ demonstrated very high cleaning effect, which exceeded that of all the previously studied surfactants. The cleaning effect of alkyl glucoside $C_{12–14}$ was found to be slightly higher then that of $C_{8–16}$.

Previously, we have shown [10, 11] that, for surfactants and detergents, the dependence of the relative cleaning action M_{rel} on their concentration c in aqueous solutions, being plotted in the reciprocal coordinates, is a linear function expressed by Eq. (1).

$$M_{rel} = \frac{M_{rel.max}}{\alpha + c}, \quad (1)$$

where $M_{rel.max}$ and α are the parameters suggested as quantitative characteristics of the cleaning power of detergents.

Data on the cleaning effect of alkyl glucosides show that Eq. (1) is valid for this class of surfactants. The figure demonstrates the dependence of the reciprocal of $M_{rel.max}$ on the reciprocal of c for alkyl glucosides SABS and Neonol AF_9-12. As seen, the cleaning effect of alkyl glucosides $C_{12–14}$ and $C_{8–16}$ is higher.

The cleaning effect of the conventional anionic and nonionic surfactants (Table 1) depends on their structure and physicochemical characteristics, such as the work of adsorption W_a, limiting adsorption Γ_m, critical micelle concentration CMC, and work of micelle formation W_m. In this study, we examined whether the general structure-property relationships are valid for alkyl glucosides.

Table 1 summarizes the physicochemical characteristics of alkyl glucosides, determined from the experimental surface tension isotherms. The results reveal that the work of adsorption increases with increasing length of the alkyl chain of surfactants. Since the work of adsorption is a measure of the surface activity, which, in turn, controls the cleaning effect, it may be suggested that an increase in the work of adsorption causes to a significant extent an increase in the cleaning effect in the series of alkyl glucosides and formulations based on them.

The cleaning action is also associated with the critical micelle concentration. Cleaning requires a certain amount of a surfactant for wetting of the surface to be cleaned, emulsification of liquid pollutants and suspension of solid pollutants, foaming, and protection

* (Γ_m) Limiting adsorption, (W_a) work of adsorption, (CMC) critical micelle concentration, and (W_m) work of micelle formation.

from resorption. After establishment of the critical micelle concentration, the fatty and solid pollutants are additionally stabilized in the surfactant micelles. With increasing surfactant concentration in the solution, the solubilization increases, as new coarser micellar structures are formed, providing an additional potential for retention of pollutants. Table 1 shows that, with increasing length of the hydrocarbon chain in the alkyl glucoside molecules, their CMC decreases and work of adsorption increases. Therefore, these factors can also enhance the cleaning effect with increasing length of the chain.

The limiting adsorption is controlled in our case by the chemical nature of the polar fragment of a surfactant, which is the same in all the alkyl glucosides studied. Therefore, the limiting adsorption should be constant throughout the homologous series (Table 1), being about 2.9 mol m^{-2}.

The hydrophilic–lipophilic balance (HLB) for the alkyl glucosides is as follows: C_6 17, C_8 16, C_{8-10} 14–12, C_{12-14} 14–12, and C_{8-16} 16–14, suggesting that these surfactants are direct-emulsion emulsifiers.

Alkyl glucosides C_{8-16} and C_{12-14} demonstrate a higher cleaning effect as compared to nonionic surfactants examined in this study (Table 1). Accordingly, they have a higher work of adsorption and lower CMC.

The cleaning effect of alkyl glucoside C_{8-10} is slightly higher than that of SABS. Correspondingly, this glucoside has a higher work of adsorption and lower limiting adsorption and CMC (Table 1).

Thus, the general structure–property relationships typical of the conventional nonionic and anionic surfactants are valid for alkyl glucosides too.

We also studied the cleaning effect of 1 : 1 (by weight) surfactant–soda binary mixtures. Table 2 shows that, for alkyl glucosides C_{8-10} and C_{12-14}, the cleaning effect of such mixtures is considerably higher over the entire experimental concentration range as compared to SABS–soda mixtures.

The foaming capacity of the alkyl glucosides was determined by the Ross–Miles method, which is accepted as a standard procedure in many countries. The measurements were carried out at a constant concentration (0.5 g l^{-1}) and temperature (20°C) (Table 3). As seen, short-chain glucosides demonstrate very low foaming capacity, allowing their use in those cases when foaming is undesirable. The foaming capacity of alkyl glucosides C_{8-10}, C_{12-14}, and C_{8-16} is lower than that of SABS, making it possible to use them instead of SABS in low-foam detergents. Alkyl glucoside C_{12-14} has a higher cleaning effect and lower foaming capacity as compared to C_{8-16}, which makes it preferable to use the former surfactant in production of detergents.

Table 2. Relative cleaning effect M_{rel} of 1 : 1 surfactant–soda binary mixtures

Surfactant	M_{rel} at indicated c, g l^{-1}				
	0.5	1.0	3.0	5.0	10.0

	0	3	5
Alkyl glucoside:			
C_6	2	0	0
C_8	4	0	0
C_{8-10}	90	79	78
C_{12-14}	98	86	83
C_{8-16}	109	96	94
SABS	118	105	100

We studied the cleaning effect of alkyl glucosides C_{8-10}, C_{12-14}, and C_{8-16} at 30°C (Table 4). The results show that the difference in the cleaning effect of the alkyl glucosides and SABS at lower temperature (30°C) becomes even stronger than that at 80°C. Therefore, these surfactants are preferable in production of low-temperature detergents.

Alkyl glucosides C_{8-10}, C_{12-14}, and C_{8-16} and mixtures based on them can be used as components of detergent formulations intended for strongly polluted surfaces, i.e., in those cases when highly concentrated detergents are needed. The high cleaning power of the alkyl glucosides and mixtures on their basis allows considerable improvement of the quality of formulations with the total amount of an active compound remaining unchanged. Furthermore, the use of alkyl glucosides allows reduction in the total surfactant

Process conditions	Addition of alkali salt (surfactant/salt weight ratio)	25/75–75/25	50/50
	Temperature	30–85°C	$M^t_{max} = 8.65 M^{30}_{max} e^{-661/T}$
	Concentration	0.5–50.0 g l^{-1}	$M_{rel} = M_{rel.max} c/(\alpha + c)$
	Mechanical activation (agitation rate)	50–200 rpm	↑

* Increase (↑) or decrease (↓) in the factor value results in increasing cleaning capacity; (σ_{wo}, σ_{ws}, σ_{os}) surface tension at the aqueous surfactant solution–nonpolar pollutant, surfactant solution–solid surface, and pollutant–solid surface interfaces, respectively.

content with the quality of the formulation remaining unchanged. This is important not only from the standpoint of economy, but also in view of the environmental protection demands (discharge of organics to the environment decreases).

Short-chain alkyl glucosides C_6 and C_8 can be used as components facilitating dissolution of surfactants and various additives in water, i.e., as hydrotropes. The estimated HLB values suggest that short-chain alkyl glucosides can be effective emulsifiers of the first kind. As known, recently a need arose in development of low-foam surfactants [2]. Since the cleaning effect of short-chain alkyl glucosides considerably increases in the presence of mineral salts, they can be used in emulsifying low-foam detergents.

Based on data on the cleaning effect and surfactant properties of various classes of surfactants and formulations, we obtained the dependences of the cleaning capacity on various factors. The basic physicochemical characteristics, factors of influence, and conditions necessary to enhance the cleaning effect are summarized in Table 5. These results allow prediction of the cleaning power of surfactants and formulations based on them.

It can be seen that in the concentration range practically significant for laundering of fabric (0.5–5.0 g l^{-1}), the maximum cleaning effect and, accordingly, high $M_{rel.max}$ and low α [Eq. (1)] are demonstrated by surfactants having the following physicochemical characteristics: W_a = 38–

41 kJ mol^{-1}, $\Gamma_m = (2.6–2.9) \times 10^{-6}$ mol m^{-2}, and CMC = 0.01–0.06 g l^{-1}.

Addition of alkali salts (soda, sodium metasilicate, and sodium tripolyphosphate) enhances the cleaning effect of the mixtures by 30–100% as compared to the individual surfactants.

CONCLUSIONS

(1) A study of the cleaning effect and surfactant properties of a series of alkyl glucosides, C_6, C_8, $C_{8–10}$, $C_{8–16}$, and $C_{12–14}$ revealed that, with increasing length of the hydrocarbon chain, the critical micelle concentration of the alkyl glucosides decreases, the work of adsorption increases, and the limiting adsorption remains approximately constant. Accordingly, the cleaning effect increases. The surfactants studied demonstrate good cleaning and emulsifying properties and low foam. Recommendations are made on practical use of the alkyl glucosides in detergent formulations.

(2) Systematization is made of the basic factors controlling the cleaning properties of surfactants and formulations and also of conditions necessary to enhance the cleaning effect.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Variation of pH in Reaction of Sodium Sulfide with Carbonyl Compounds

A. M. Ivanov, O. S. Altukhova, and I. A. Ivanov

Kursk State Technical University, Kursk, Russia

Research Institute of Leather, Kursk, Russia

Received November 26, 2003; in final form, July 2004

Abstract—The results of an experimental study of how pH varies in the course of a reaction between sodium sulfite and carbonyl compounds are presented.

It is commonly believed that, of all carbonyl compounds, only formaldehyde can react with sodium sulfite with a nearly quantitative yield [1]. However, this is far from being the case. A similar reaction proceeds to a large extent with acetaldehyde, too [2], even though at lower rates and smaller maximum conversion. If the HA acid is introduced dropwise, following a certain program, the process occurs quantitatively with numerous carbonyl compounds. [2–4]. As this process is used industrially, in particular, in manufacture of greasing and emulsifying formulations for leather and fur [5–7], it was of interest to study it in more detail.

The experiment was carried out as follows. A reactor with a mechanical or magnetic stirrer and electrodes for pH measurements was charged with a certain amount of a preliminarily prepared solution of Na_2SO_3 (commonly 100 ml of a 0.5–1.3 M solution) and agitation was switched on. After that, a calculated amount of a carbonyl compound (most frequently, also in the form of a preliminarily prepared solution) was introduced and the variation of the pH values was monitored. Commonly, these values increased rather rapidly. At some instant of this rise, a 5–10 N solution of a mineral or carboxylic HA acid started to be introduced in an amount equivalent to the content of Na_2SO_3 in the starting reaction mixture. The acid was introduced for 10–150 min. High concentrations of the HA acid were chosen in order to avoid a strong dilution of the reaction mixture and the inevitably resulting distortion of the results obtained. After about 90% of the calculated amount of the acid was introduced, the rate of its introduction was considerably lowered or a more diluted acid was used. This was done in order not to pass through the point corresponding to the 100% conversion of the carbonyl compound (see table). Simultaneously, the reaction mixture was sampled to determine the content of the carbonyl compound and the sum of Na_2SO_3 and $NaHSO_3$.

In those cases when the solubility of a carbonyl compound in water was insufficient, attempts were

Effect of the nature of a carbonyl compound on the pH value reached by the end of the 2nd minute after the introduction of this compound into a Na_2SO_3 solution (pH_1) and by the time of its nearly complete consumption (pH_2) (equimolecular amounts of the reagents)

made to raise the solubility by introducing 5–30 vol % water-soluble alcohols into the reaction mixture. When these attempts failed, the carbonyl compound was preliminarily dissolved in an appropriate organic solvent and the resulting solution was introduced, together with a Na_2SO_3 solution in a 1 : (1–1.5) ratio by volume, into the reactor, with the emulsion maintained by means of agitation in a state uniform throughout the volume. In some cases, in particular, when the densities of the aqueous and organic phases differed by a factor of 1.5 and more, the process under consideration was performed in a bead mill with occasional monitoring of the pH value of the aqueous phase outside the working zone of the reactor.

Figure 1 shows how the pH values in the systems Na_2SO_3–acetaldehyde and Na_2SO_3–acetone vary with the amount of acid introduced and the corresponding variation of the concentrations of carbonyl compounds. A significant change in behavior on passing from an aldehyde to a ketone is well seen. In the case of the aldehyde, the initial pH value is considerably higher and falls as the amount of the acid introduced increases at a substantially slower rate, whereas the concentration of the carbonyl compound, contrariwise, decreases faster. This behavior is observed until the conversion of the carbonyl compound exceeds 80–85%, and after that the dependences for the aldehyde and ketone are described by virtually the same curve.

In an aqueous solution of Na_2SO_3, there exists the equilibrium

$$Na_2SO_3 + H_2O \rightleftarrows NaHSO_3 + NaOH. \quad (I)$$

If a carbonyl compound is introduced into such a solution, the following reaction occurs:

$$\rangle C{=}O + NaHSO_3 \xrightarrow{k_2} \rangle C(OH)SO_3Na. \quad (II)$$

This reaction results in that the equilibrium of reaction (I) is shifted to the right, and this predetermines a rise in the pH value of the reaction mixture. For aldehydes with high reactivity in reaction(II), the rise in the pH value is rather significant. In particular, at the initial concentrations of acetaldehyde and Na_2SO_3 equal to 1 M, the pH value changes from 9.4 at $\tau = 0$ to 13.5 during the first 37 min and, further, to 13.7 at $\tau = 1500$ min. Such a variation of the pH value with time [the function $pH = f(\tau)$ was recorded automatically] can be easily recalculated to a kinetic curve of NaOH accumulation (for the case in question, this is the range 3×10^{-5}–~0.5 M),

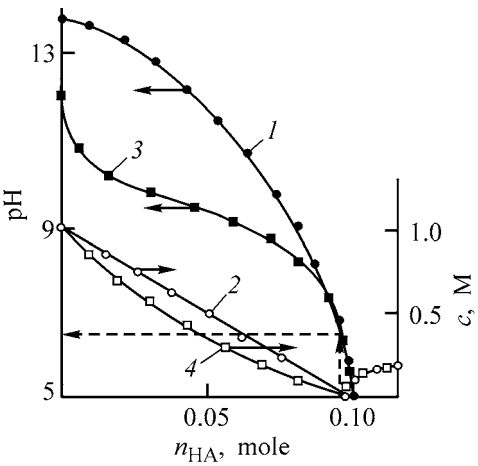

Fig. 1. (*1, 3*) pH value and (*2, 4*) the corresponding concentrations of carbonyl compounds vs. the amount n_{HA} of HCl introduced into the systems (*1, 2*) Na_2SO_3–acetaldehyde and (*3, 4*) Na_2SO_3–acetone. Dosage of each reagent 0.098 M; temperature 23°C, agitation with a magnetic stirrer.

which can be graphically differentiated to obtain values of $dc_{NaOH}/d\tau$.

Summation of the stoichiometric equations (I) and (II) yields the reaction equation

$$\rangle C{=}O + Na_2SO_3 + H_2O \rightarrow \rangle C(OH)SO_3Na + NaOH, \quad (III)$$

according to which the rate of NaOH accumulation must be equal to the consumption rates of both Na_2SO_3 and the carbonyl compound. This makes it possible to express the rate of reaction (II) in terms of the rate of NaOH accumulation:

$$\frac{dc_{NaOH}}{d\tau} = \frac{dc_{\rangle C=O}}{d\tau} = k_2 c_{NaHSO_3} c_{\rangle C=O}. \quad (1)$$

The concentrations of reagents in Eq. (1) are related to the concentration c_{NaOH} by the following expressions

$$c_{\rangle C=O} = c^0_{\rangle C=O} - c_{NaOH}, \quad (2)$$

$$c_{NaHSO_3} = \frac{6.3 \times 10^{-8}(c^0_{NaHSO_3} - c_{NaOH})}{c_{NaOH}}. \quad (3)$$

Substitution of Eqs. (2) and (3) into (1) gives the formula for evaluation of k_2. The value of k_2 for acetaldehyde was approximately 40 000 M^{-1}.

The value of k_2, estimated for acetone in a similar way, is approximately three orders of magnitude smaller. Therefore, the maximum conversion of a carbonyl compound by Eq. (III), α_{max}, is only several percent, against 40% and more for acetaldehyde. As $(0.7–0.8)\alpha_{max}$ is reached during the first several

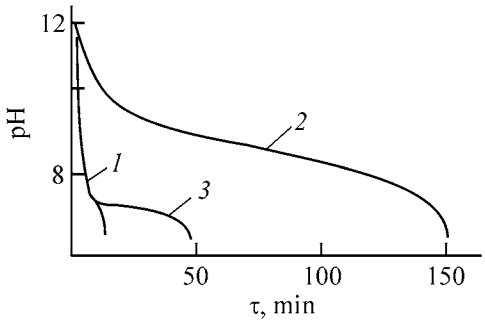

Fig. 2. Automatically recorded variation of the pH value with time τ at different concentrations of sulfuric acid introduced in the course of the reaction between acetone and Na_2SO_3 at 17°C. Dosage of each reagent 0.10 mole. H_2SO_4 concentration (equiv l^{-1}): (*1*) 8.6 and (*2, 3*) 1.05.

minutes, the corresponding rise in the pH value can be used for a rough estimate of the reactivity of a carbonyl compound under the chosen conditions (see table).

To raise the rate of the reaction between Na_2SO_3 and carbonyl compounds and make this reaction virtually quantitative, it is necessary to take the HA acid instead of water in the stoichiometric equation (III). This leads to the reliably practically substantiated stoichiometric equation

$$\rangle C{=}O + Na_2SO_3 + HA \rightarrow \rangle C(OH)SO_3Na + NaA. \quad (IV)$$

In accordance with this equation, for 1 mol of a carbonyl compound to be converted into a hydrosulfite derivative, it is necessary to introduce 1 mol of HA acid (1 mol-equiv for polybasic acids), in a good agreement with the data in Fig. 1.

Equation (IV) can be obtained by summing up the stoichiometric equations (I), (II), and (V):

$$NaOH + HA \rightarrow NaA + H_2O. \quad (V)$$

In this case, the role of the acid consists only in neutralization of the alkali accumulated in accordance with Eq. (III). However, such a function of the acid cannot be accepted as the only one, because it was established experimentally that reaction (IV) may occur quantitatively and at a comparable rate in a virtually anhydrous medium, i.e., between solutions of carbonyl compounds in organic solvents and solid Na_2SO_3 (with a bead mill as a reactor). As for the aqueous medium, reaction (V) accelerates reaction (II), and does so the more strongly, the larger the value of k_2. However, as shown by the experiment, the system of reactions (I) + (II) + (V) [or (III) + (V)] cannot ensure a quantitative extent of reaction (IV) by itself even at very large values of k_2. This occurs if the stoichiometric equation (IV) is represented as a sequence of reactions (II) and (VI):

$$Na_2SO_3 + HA \rightarrow NaHSO_3 + NaA. \quad (VI)$$

Most part of a carbonyl compound whose reactivity is comparable with, or is significantly lower than that of acetone is consumed in accordance with this scheme. Also by this scheme occur the final stages of reactions involving more reactive aldehydes (after curves *1* and *3* in Fig. 1 merge).

As mentioned in [8], more than 80–90% of the initial amount of Na_2SO_3 is selectively converted into $NaHSO_3$ under model conditions in the case of hydrochloric or nitric acids. The competitive capacity of reaction (VI) is high as compared with the reactions in which H_2SO_3 ($SO_{2(d)} + H_2O$ is formed from $NaHSO_3$ and spherical nickel hydroxide, or other mineral or carboxylic acids are used. This offers a clear view of why even high rates of introduction of the HA acid, $dn_{HA}/d\tau$, in systems with $c_{Na_2SO_3} > 0.2$ mol kg^{-1} do not lead to decomposition of the hydrosulfite derivative even in local zones formed immediately after the introduction of a drop of concentrated acid into the reaction mixture. And only at very low residual concentrations of Na_2SO_3 it is appropriate to make lower the rate of introduction of the HA acid, which can be most easily done by taking 0.5–1 N solutions instead of 5–10 N solutions and by maintaining a nearly constant rate of introduction of the solution itself. Naturally, the latter rate can be lowered too, which has no effect on the function $pH = \varphi(n_{HA})$, as demonstrated by a direct experiment.

The rate of introduction of the HA acid fully predetermines not only the process duration, but also the function $pH = f(\tau)$, as can be well seen in Fig. 2. One and the same process can be completed quantitatively in periods of time that differ by a factor of 10 and more. At a high rate $dn_{HA}/d\tau$, it is possible to pass, in the final stages, the point at which $c_{\rangle C=O} \approx 0$, with the concentration of the carbonyl compound increased because of the decomposition of the hydrosulfite derivative (Fig. 1). At low rate, the process duration may become too long. At the same time, it is possible to obtain a more acceptable (if not the optimal) variant by considerably lowering $dn_{HA}/d\tau$. Hence follows that process (IV) under consideration occurs in a clearly pronounced diffusion mode, with the mechanical introduction of the HA acid into the system being the rate-determining stage.

It was established that the quantitative characteristics of the function $pH = \varphi(n_{HA})$ are virtually in-

dependent of the nature of an HA acid (confirmed for hydrochloric, hydrobromic, formic, acetic, chloroacetic, trichloroacetic, sulfuric, oxalic, malonic, orthophosphoric, and citric acids; the differences in pK_a values between the first and subsequent stages of dissociation of polybasic acids are of no fundamental importance). Also unimportant is the presence in solution in amounts of up to 20 wt % of water-soluble organic substances (e.g., propanol-2, ethyl cellosolve). However, these characteristics strongly depend on the ratio of the initial concentrations of the carbonyl compound and Na_2SO_3. This is readily illustrated by the data in Fig. 3, in which the ratio between the number of mol-equiv of the acid introduced and the initial concentration of the reagent taken in deficiency is plotted along the abscissa axis. It was confirmed experimentally that, with the data presented in this form, it is the ratio of the initial concentrations of Na_2SO_3 and the carbonyl compound that is important. At different initial concentrations of these reagents, but equal ratios of these concentrations, the dependence in the coordinates of Fig. 3 will be represented by actually a single curve.

Curves describing how the pH value varies upon introduction of the acid in the case of reaction (VI) occurring under model conditions with the use of HCl and a number of other acids are plotted in Fig. 3 as auxiliary lines. For these curves, the quantity chosen to be plotted along the abscissa axis is also $n_{HA}/n^0_{Na_2SO_3}$. This is done to facilitate the interpretation of how the pH value varies in the case when the carbonyl compound and Na_2SO_3 are taken in excess in carrying out the main process.

As can be seen from a comparison of curves *1* and *2* in Fig. 3, the excess of acetone leads to higher pH values over virtually the entire range of variation of the molar ratio of the amounts of acid and a reagent taken in deficiency. The only exception are the values close or equal to unity, when the curves under consideration converge to a point. This circumstance is quite understandable, because such an excess will favor a decrease in the running concentrations of Na_2SO_3 and will shift the equilibrium of reaction (I) to the right; and the higher the reactivity of a carbonyl compound and its concentration, in the more alkaline medium will the process develop (Fig. 1).

In the case of an excess of Na_2SO_3, the amount of the acid introduced will be constituted by the amount consumed for a quantitative conversion of the carbonyl compound by reaction (IV) and for partial conversion of the excess amount of Na_2SO_3 into $NaHSO_3$ on reaching pH 6.3–6.5, which corresponds to the instant (denoted by the horizontal line) when the residual amount of the reacting carbonyl compound will approach to zero (see table).

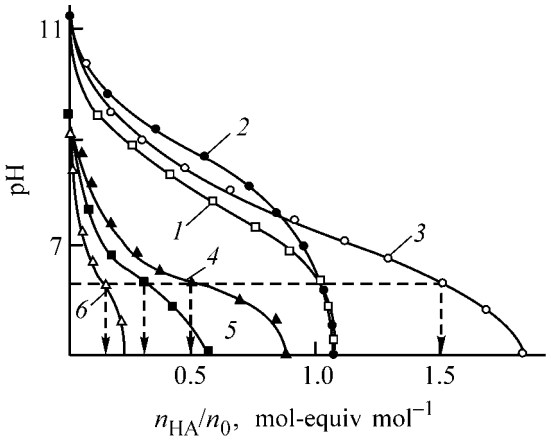

Fig. 3. Variation of the pH value in the course of (*1–3*) process (IV) and (*4–6*) its stage (VI) under model conditions with the relative amount of the acid introduced, n_{HA}/n_0 (n_0, amount of the reagent taken in deficiency). Temperature 23°C, agitation with a magnetic stirrer. Dosage (mole): Na_2SO_3: (*1, 2*) 0.05 and (*3, 6*) 0.10; acetone: (*1, 3*) 0.05 and (*2*) 0.10. Acid: (*1–4*) hydrochloric, (*5*) monochloroacetic, and (*6*) *para*-toluenesulfonic acid.

As can be seen in Fig. 3 (curves *4–6*), the fraction of Na_2SO_3 consumed in reaction (VI) by the instant of time when this pH value is reached depends on the nature of an HA acid used. It is about 50% for HCl, 40% for HNO_3, 33–35% for $NaHSO_4$ and $ClCH_2COOH$, 17% for *para*-$CH_3C_6H_4SO_3H$, etc. If the fractions corresponding to the above percentages are denoted by ε, the following formula can be suggested for calculating the number of moles (mol-equiv) of the acid to be introduced for reaching pH ~6.3–6.5 in the case of an excess amount of Na_2SO_3:

$$n_{HA} = n^0_{\rangle C=O} + \varepsilon(n^0_{Na_2SO_3} - n^0_{\rangle C=O}). \qquad (4)$$

Equation (4) is highly important for several reasons. First, the quantity n_{HA} is one of the most easily, rapidly, and accurately determinable in a kinetic experiment. At the same time, simultaneous monitoring of pH and n_{HA} can furnish a sufficient information about the course of the process in such an experiment. Second, the lower the reactivity of a carbonyl compound, the larger excess of Na_2SO_3 is necessary to faster obtaining a hydrosulfite derivative in a quantitative yield. In this case, not only the value of $n_{HA}/n^0_{Na_2SO_3}$ is important, but also that of ε. Naturally, the choice should ensure the highest value of ε. Third, Eq. (4) shows how the instant of completion of the target process can be determined if there are no other

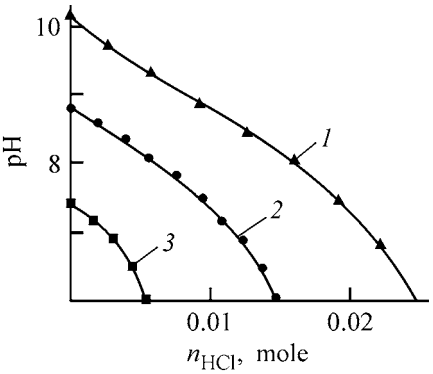

Fig. 4. pH value vs. the amount of hydrochloric acid, n_{HCl}, introduced in the course of reaction between *para*-oxybenzaldehyde with Na_2SO_3 at different amounts of *para*-oxybenzoic acid introduced with the aldehyde. *para*-Oxybenzoic acid impurity (mole): (*1*) virtually absent, (*2*) 0.010, and (*3*) 0.018.

reliable methods that can be used for this purpose: It is necessary to introduce a calculated amount of the acid in such a way that the intermediate pH value is not lower than 6.3–6.5.

A number of long-stored carbonyl compounds, especially aldehydes, contain as impurities products of their oxidation by atmospheric oxygen, which, in particular, include acids. As the strength of an acid in performing process (IV) is of no importance in a rather wide range of its values, acid impurities in aldehydes do not interfere with the process under consideration. The amount of a mineral or carboxylic acid to be introduced to ensure a quantitative conversion of a carbonyl compound into a hydrosulfite derivative is simply decreased by the number of mol-equiv of the acid coming as impurity with the aldehyde (Fig. 4).

CONCLUSIONS

(1) The variation of the pH value with time upon introduction of a water-soluble reactive aldehyde into a Na_2SO_3 solution makes it possible to estimate the rate constant of an exceedingly fast reaction of this aldehyde with $NaHSO_3$.

(2) In the case of a dropwise introduction of a mineral or carboxylic acid into the system constituted by sodium sulfite and a carbonyl compound, there exist two pathways of intermediate conversion of Na_2SO_3 into $NaHSO_3$. The competitive capacity of these pathways depends on the nature and reactivity of a carbonyl compound, Na_2SO_3 concentration (especially in the range ≤ 0.2 M), presence and amount of water in the system, but is virtually independent of the nature of an acid being added.

(3) Quantitative conversion of a carbonyl compound into a hydrosulfite derivative not only in a virtually anhydrous medium, but also in aqueous and aqueous-organic media, is provided by a fast reaction of Na_2SO_3 with an acid to give $NaHSO_3$ and a salt of the acid.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Binding of Protein to Polystyrene Particles in the Presence of Polyvinylpyrrolidone in the Surface Layer

Abstract—Adsorption and chemisorption of bovine serum albumin on polystyrene particles obtained by dispersion polymerization and containing graft polystyrene/polyvinylpyrrolidone copolymers and carboxy groups of the initiator in the surface layer were studied.

Binding of immunochemicals to the surface of micrometer polymer particles facilitates observation of immunochemical reactions, allows modeling of the behavior of biological objects and, in particular, bacteria or elements of blood, and improves the performance of diagnostic tests [1]. Such monodisperse polystyrene (PS)-based particles with a modified structure of the surface layer were obtained by dispersion polymerization of styrene in alcoholic solutions in the presence of polyvinylpyrrolidone (PVP) and 4,4'-azobis(4-cyanoisovaleric acid) (CVA) as an initiator [2]. The surface layer of these particles is composed by *in situ* formed graft PS/PVP copolymers, which, being diphilic, better stabilize the dispersion than the initial PVP. The carboxy groups of the initiator are localized at the ends of the side chains of PS, and, being ionized, impart a surface charge to the particles, thus providing their additional stabilization by virtue of the electrostatic factor. Hydrophilization of the particles through the effect of the PVP blocks of the graft copolymers can reduce the probability of nonspecific hydrophobic interactions in the surface layer in the course of immunochemical reactions.

Previously, we have shown [2] that the size of monodisperse PS particles, as well the concentration of the carboxy groups on their surface, can be controlled in the course of synthesis by varying the reagent concentrations, composition of the dispersion medium, and polymerization temperature. At the same time, it was found that these factors also influence the structure of the resulting graft copolymers. The structure of the surface of the resulting PS particles may determine their capacity for adsorption and covalent binding of proteins, and, therefore, their effectiveness as carriers for immunochemicals. Therefore, in order to obtain particles in which the structure of the surface layer would be optimal for binding of bioligands, we examined this study the effect of the graft copolymers on these characteristics.

EXPERIMENTAL

Polystyrene latexes were obtained by CVA-initiated dispersion polymerization of styrene at 351 ±1 K in ethanol containing 7 wt % double-distilled water. As an initial steric stabilizer we used medical grade PVP with MW 35 000 ± 5000 (Farmakon Joint-Stock Company, St. Petersburg, Russia). Synthesis, purification, and analysis of the resulting PS particles for their dispersity and surface functionality, and also the methods for partial extraction of the graft copolymers from the surface layer of the particles and of an IR spectroscopic and conductometric study of their structure and composition are described in detail in [2]. Table 1 listed the compositions of the reaction mixtures and characteristics of the resulting PS particles used to their capacity to bind protein.

As an adsorbate we employed bovine serum albumin (BSA), which is widely used in immunoassay as a carrier for small antigens and also as a blocking agent for protection of a hydrophobic surface from nonspecific interactions with proteins from the sample to be analyzed. Purification and analysis of BSA are described elsewhere [3]. Covalent binding of BSA to the surface of PS microspheres was carried out after preactivation of the surface carboxy groups with wa-

ter-soluble 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (Sigma) in the presence of *N*-hydroxybenzotriazole (Sigma), which were taken in the equimolar proportion relative to the surface carboxy groups [4]. The process was carried out at 0°C in 10^{-2} M 2-(*N*-morpholino)ethanesulfonic acid (MESA, Reanal) (pH 5.5) for 15 min. Then these reagents were removed by centrifugation; the PS particles were redispersed in the MES solution; 0.05–1.50 mg ml^{-1} BSA solution in the same buffer was added; and the system was allowed to stand for 24 h at 20°C.

When the activation and covalent binding stages are performed separately, the carboxy groups of the protein are not activated and not involved in the chemical interaction leading to cross-linking of the protein globules and distortion of their native conformation. Adsorption was performed under the same conditions, but without preactivation of the carboxy groups. The protein concentration before and after the interaction with the particles was determined by high-performance monolithic chromatography (HPMC) on a CIMR DEAE anion-exchange membrane (BIA Separations, Ljubljana, Slovenia) [5, 6]. The BSA-modified particles were redispersed for storage in the phosphate buffer (pH 7.4) and then used for studying their surface electrical properties.

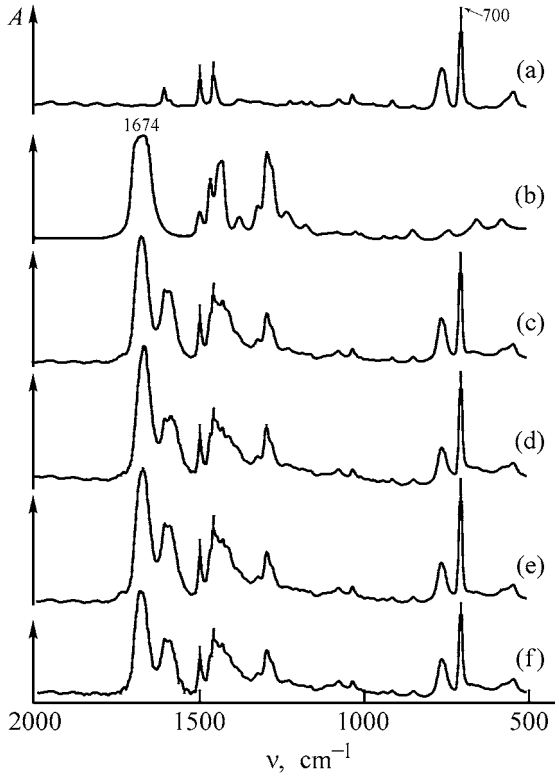

Fig. 1. IR spectra: (a) PS, (b) PVP, and alcoholic extracts from the surface of the latex sample nos. (c) 1, (d) 2, (e) 3, and (f) 4. (*A*) Absorbance and (ν) wave number.

The ζ potentials of the resulting particles before and after modification with BSA were determined by the standard microelectrophoresis method at a NaCl concentration of 10^{-3} and 10^{-2} M over the pH range 2.0–10.9. Calculation was performed by the Helmholtz–Smoluchowski equation [7]. In carrying out the microelectrophoresis, we used double distilled water with a conductivity of 1.2×10^{-4} Ω^{-1} m^{-1} and reference solutions of HCl, NaOH, and NaCl. Before the study, the latexes were equilibrated for 24 h with a NaCl solution of a given concentration and pH.

The interaction of the surface of the particles with the protein was studied with samples differing in the structure of PS/PVP graft copolymers in the surface layer (Table 1). Sample nos. 1 and 2 were prepared at a low styrene concentration and a sufficiently high PVP content in the reaction mixture, to obtain a structure with a large amount of grafted short PS chains [2, 8]. With increasing styrene concentration, the average length of the grafted PS chains grows (sample no. 2). With increasing PVP content in the reaction mixture (sample nos. 3 and 4), the grafting number decreases because of the decrease in the initiator/PVP ratio. Nevertheless, the weight percentage of the PVP and PS units in the graft copolymers extracted from the surface of the samples, determined from the IR

spectra (Fig. 1), falls in a narrow range, only slightly deviating from the 1 : 1 ratio (Table 2).

Vigorous washing of the PS particles does not provide complete removal of the graft copolymers containing the PVP units from the surface layer, as demonstrated by the inversion of the sign of the ζ potential of the samples studied over the pH range 2.0–2.3 (Fig. 2, curves *1*, *2*). Note that such an inversion is not typical of the PS particles obtained by CVA-initiated polymerization, but in the absence of the steric stabilizer [10]. The lactam groups of PVP units on the surface are capable of protonation in strongly acidic solutions [11], which gives rise to a positive charge on the surface of the particles.

At the same time, preliminary washing of the particles before adsorption or chemisorption of the protein prevented washout of weakly bound copolymer chains from the surface and of their binding to BSA in solution, which was observed when the particles were washed only with water. This is supported by the lack in the HPMC chromatograms of the peaks of conjugates with a retention time longer than that of the initial BSA (Fig. 3).

Modification of the surface of the particles with the protein resulted in a drift of IEP of all the samples studied from pH 2.0–2.3 to 3.6–5.0. As the surface was covered with BSA, IEP changed, taking values mostly lower than IEP of the native protein (4.8–5.2) [12].

To elucidate the contribution of the graft copolymers of the surface layer to sorption, it was advisable to compare the chemisorption and adsorption isotherms of BSA (Fig. 4) and also the isoelectric points for various samples (Table 3).The limiting adsorption increases in the series of sample nos. 1–4 from 1.6 to 2.7 mg m^{-2}. For sample nos. 1 and 2, the chemisorption continues to increase over the entire experimental range of BSA concentration. The noticeable excess of the chemisorption over the adsorption at high BSA concentrations, observed for these samples (Figs. 4a and 4b, curves *1*, *2*), can be attributed to loosening of the surface of the particles in the course of activation of their carboxy groups and further interaction with BSA. Such a loosening is promoted by vigorous washing of the particles with hot alkaline alcohol, to extract graft copolymers weakly bound to the surface. In the case of sample no. 1, the extraction is facilitated by the presence of carboxylate anions at the ends of relatively short grafted PS chains (Table 2). The grafted chains of sample no. 2 are longer and are more tightly bound to the surface, and, therefore, the surface loosens to a lesser extent in this case. As a result, the difference between the chemisorption and adsorption decreases.

Sample nos. 3 and 4 show a knee in the initial section of the isotherm, suggesting hindered sorption at low protein concentration in solution (Figs. 4c and 4d, curves *1*, *2*). Insertion of small amounts of the protein into the surface layer may be unfavorable because

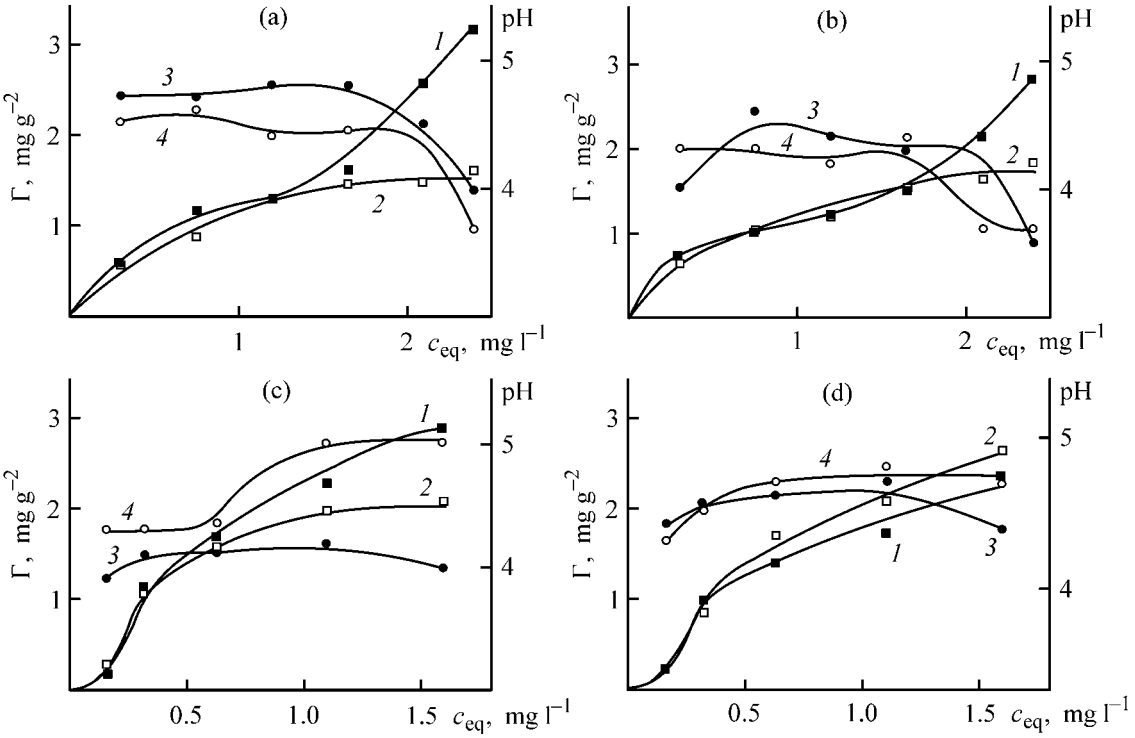

Fig. 4. Isotherms of (*1*) chemisorption and (*2*) physisorption Γ, and pH of isoelectric point of particles of latex sample nos. (a) 1, (b) 2, (c) 3, and (d) 4 after (*3*) chemisorption and (*4*) physical adsorption of BSA. (c_{eq}) Equilibrium concentration of BSA.

of the decreasing contribution of the entropy to the energy of the system as a result of a decrease in the flexibility of the hydrophilic segments of PVP graft copolymers. However, with increasing BSA concentration in solution, the amount of bound protein increases, and at the maximum chemisorption (2.9 mg m^{-2}, sample no. 3) and adsorption (2.7 mg m^{-2}, sample no. 4), 1 μm^2 of the surface contains as much as 2.3×10^4 and 2.5×10^4 BSA globules, respectively. These values reach the maximum amount of adsorption on the surface of the hydrophobic PS particles containing no graft copolymers in the surface layer (2.5×10^4 BSA globules per 1 μm^2 [12–14], suggesting a dense packing of the protein globules on the surface of the resulting particles. Thus, hydrophilization of the surface of the particles by virtue of PVP units of the graft copolymers does not hinder the effective binding of the protein. It should be pointed out that adsorption, i.e., concentration of the protein globules in the surface layer, is the first stage of interaction in covalent binding of the protein also. Therefore, the observed close values of the chemisorption and adsorption suggest that the conformation of BSA is preserved in the course of its binding by the standard carbodiimide method, since, in this case, the area occupied by one BSA globule in the surface layer remains unchanged and the size of the globule corresponds to the hydrodynamic radius of BSA (3.6 nm) [13].

The isoelectric point of sample no. 1, equal to 4.7–4.8 at the minimal chemisorption (Fig. 4a), falls in the IEP range characteristic of native BSA, suggesting that the surface is totally shielded by the protein. However, with the surface concentration of BSA increasing to 3.2 mg m^{-2}, 2.8×10^4 protein molecules per 1 μm^2 of the surface, IEP unexpectedly decreases to 4.0. This indicates that the effective specific surface area of sample no. 1 increases because of its loosening; the decrease in IEP suggests the formation of a loose mosaic structure, which permits both PS/PVP copolymers and BSA globules to move toward the slip boundary. For sample no. 2, the decrease in IEP with increasing chemisorption is slightly less pronounced (Fig. 4b), which is caused by the higher stability of the surface structure. The evolution of the IEP in sample nos. 1 and 2 with increasing adsorption of BSA is similar to that occurring in the case of chemisorption.

The isoelectric points of the samples modified by chemisorbed BSA may fall beyond the IEP range of native BSA for several reasons. Even in the case of full shielding of the substrate surface by the protein, this can be a result of chemical interaction of its amino groups with the carboxy groups of the surface. For example, in the case of sample no. 3, IEP is not higher than 4.1, being considerably lower than that of native BSA. At the same time, after the protein was adsorbed on this sample, IEP increased to 5.0 (Fig. 4c). However, for sample nos. 1 and 2, IEP decreased not only in the case of chemisorption, but also in adsorption, suggesting a noticeable effect on IEP of PS/PVP copolymers, which do not permit BSA to fully shield the surface of the particles. Only for sample no. 4, the constancy of high IEP values at any coverage of the surface with BSA and any type of binding suggests that BSA is well exposed at the slip boundary (Fig. 4d). It is obvious that the surface of the particles of this sample has the most stable structure, which was formed with participation of the grafted PS chains with the minimum amount of the longest grafted PS chains among all the samples studied (two chains 100 monomer units long, on the average [2]). The lack of surface loosening in the case of sample no 4 is also supported by the low difference between the adsorption and chemisorption throughout the isotherms. Since the graft copolymers have in this sample the minimum amount of grafted PS chains, free segments of the PVP backbone can interact additionally with the amino groups of BSA through coordination to the lactam groups. As a result, the adsorption of BSA is the highest for this sample.

The effects of the binding mode and BSA concentration in the surface layer of the particles (Table 3) on their ζ potential are shown in Fig. 2. As the sorption of BSA increases, the ζ potential of the particles decreases in absolute value for all the samples (Fig. 2, curves *3–6*), suggesting that the insertion of the protein globules into the surface layer of the particles causes a shift of the slip boundary toward the bulk of the solution. However, after chemisorption of a small amount of BSA, the negative ζ potential of the particles in the alkaline range appeared to be slightly higher in absolute value than after adsorption of the same amount of the protein (Figs. 2a, 2c, 2e, 2g). It may be suggested that, thanks to the spacer function of the PVP backbone, BSA globules chemically bound to the side PS chains of the graft copolymers via the terminal carboxy groups are more mobile. As pH increases, they can move toward the slip boundary with increasing negative charge of both the surface of the particle and the BSA globules. Quite the contrary, at high coverage of the surface of sample nos. 1 and 2 with BSA, the pH dependences of ζ potential, obtained for different binding modes, are virtually coincident (Figs. 2b, 2d), regardless of the large chemisorption. With the densest packing of BSA globules on the surface of sample nos. 3 and 4, the high neg-

ative ζ potentials are reached in the case of adsorption binding of the protein (Figs. 2f, 2h). These facts reveal the limited conformational flexibility in the surface layer, as it is saturated with the protein.

CONCLUSIONS

(1) Adsorption and chemisorption of bovine serum albumin on polystyrene particles allow reaching the adsorption capacity corresponding to the limiting adsorption. Therefore, hydrophilization of the surface through introduction of the steric stabilizer in the surface layer does not hinder the protein binding.

(2) The structure of the graft polystyrene/polyvinylpyrrolidone copolymer has a considerable effect on the stability of the surface structure of the particles and, accordingly, on the adsorption and chemisorption isotherms, and also on the surface electrical properties of the particles after the protein was bound.

(3) The most stable surface structure of the particles is formed when a small amount of long polystyrene chains is grafted to the polyvinylpyrrolidone chain. In this case, the resulting particles can effectively bind the protein through both chemical interaction of the amino groups of BSA with the surface carboxy groups and coordination interaction in physisorption. As a result, the adsorption and chemisorption isotherms are virtually coincident. The isoelectric points of the particles modified with BSA approach that of native BSA already at a low surface concentration of the protein and maintain their values until the complete coverage of the surface. This suggests that the protein globules are exposed at the slip boundary and, therefore, are accessible further immunochemical reactions.

Abstract—The efficiency of treatment of paper prepared from 100% sulfite cellulose with basic agents (solutions of magnesium alkoxides or methoxycarbonate in alcohols or in supercritical carbon dioxide) to neutralize acid was studied, as influenced by the following factors: concentration of a basic agent in the neutralizing solutions, repetition of impregnation of paper with a neutralizing solution and hydrolysis of the neutralizing agent after each impregnation cycle, temperature and pressure of supercritical carbon dioxide, mixing of a neutralizing agent with supercritical CO_2, and conditions (dynamic or static) the paper treatment with a neutralizing solution.

Numerous libraries all over the world, including Russia, have accumulated a great number of decrepit and damaged documents. It is known that paper is destroyed due to hydrolytic breakdown of cellulose catalyzed with acids. Acids of various origins are present in paper: auxiliary acid additives (bleaches, sizing compounds) used in paper making, acid inc, paints, and pigments. A paper can be acidified with atmospheric sulfur, carbon, and nitrogen oxides, its acidity can increase on heating, moistening, and illumination. In order to weaken the negative effect of acids accumulated in paper, we must not only increase its pH to 8, but also provide a sufficiently large excess bacisity (henceforth the base stock) (no less than 300 mg-equiv kg^{-1}) to decelerate paper aging and destruction in prolonged storage [1].

The modern high-performance technique must ensure large-scale treatment of stitched paper documents [2–5]. The simplest solution of this problem is to treat books and paper documents with a neutralizing agent in organic solvents. However, in large-scale treatment, this technique consumes a very large volume of an organic solvent. Furthermore, organic solvents destroy and deform covers, smear inc, and distort the color pattern.

Analysis of domestic and foreign data on large-scale conservation of paper documents by their treatment with various basic agents to neutralize acid [1, 2–11] shows that, in solution of this problem, the most promising neutralizing agents are alkaline-earth alkoxides and, in particular, magnesium alkoxides and their carbonate derivatives, in a supercritical carbon dioxide fluid. These compounds are the most effective and widely approved basic agents. In their use, the pH of the initial acid paper and the base stock can be raised to 8–10 and 200 mg-equiv kg^{-1}, respectively, depending on the kind and state of paper (age, pH), treatment procedures and also kind and concentration of alkaline-earth alkoxides [4–6, 8, 10].

The processing of paper with alkaline-earth alkoxides in supercritical carbon dioxide (SC CO_2) ensures its highly efficient, safe, and wasteless conservation. These advantages are governed by the specific properties of supercritical CO_2 as solvent [12]: (1) SC CO_2 dissolves the most effective basic agents suitable for neutralizing paper under controllable conditions; (2) the solubility of basic agent can be varied by varying the thermodynamic parameters (T, P) of supercritical CO_2 or introducing an additional organic solvent; (3) owing to low surface tension and high dif-

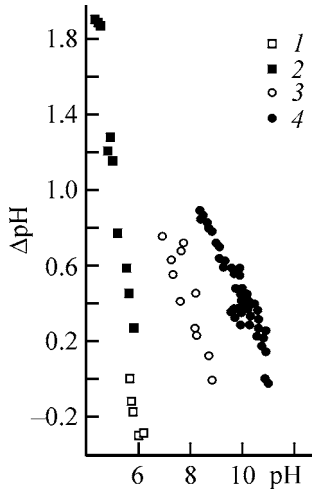

Fig. 1. Sign and value of the surface electrical charge of paper prepared from 100% sulfite cellulose (ΔpH) vs. pH of paper. (*1*) initial SFI paper, (*2*) treatment with water and alcohol, (*3*) treatment with NH_4COONH_2 in aqueous alcohol and (*4*) treatment with alcoholic solutions of $Mg(CH_3O)_2$ and $Mg(CH_3O)_2 \cdot nCO_2$ n = (0.6–1.0).

fusion coefficient of SC CO_2 molecules, the neutralizing agent in SC CO_2 quickly penetrates into pores and paper fibers and uniformly impregnates the paper; and (4) the basic agents in SC CO_2 can be easily regenerated and reused. Owing to these features of SC CO_2, the time-consumption of paper treatment considerably decreases and paper documents can be neutralized in the stitched state.

Carbon dioxide has low critical parameters (T = 31°C, P = 7.3 MPa) suitable for treatment of paper. The supercritical CO_2 fluid is chemically inert, nontoxic, odorless, fire and explosion safe, and commercially available.

The use of supercritical CO_2 in combination with other organic solvents instead of aqueous and organic solutions commonly used for neutralizing paper allows minimization of the negative effect of solvents on the color intensity and tint of inc, paints, and pigments and on the state of sizing compounds.

Although supercritical gases have come into use for treatment of paper documents in some countries; in Russia, supercritical gases are not applied in large-scale treatment of paper document in spite of a certain progress in this direction.

EXPERIMENTAL

In our experiments we used samples of paper prepared from 100% medium-porous sulfite cellulose (SFI) with pH 5.5–6.3.

Magnesium alkoxides (methoxide and ethoxide) and magnesium methoxycarbonate (MMC) were used as neutralizing basic agents.

The main characteristics of paper (pH, base stock, value and sign of the surface electric charge, physicomechanical parameters, reflection coefficient) were determined before and after processing the paper by standard techniques. It was reported in [1, 2, 11, 13] that there is a correlation between the pH of paper and its main characteristics (folding endurance, tensile strength, reflection coefficient). In our experiments, pH was determined in aqueous extracts from paper and directly on the surface of paper. The pH measured on the surface of paper characterizes the uniformity of impregnation of paper with the basic agent. The value and sign of the surface electric charge of paper were determined by the method of the suspension effect. The base stock in paper was determined either by titration with acid or by determination of magnesium content by atomic absorption spectroscopy. The same characteristics were also determined for paper samples subjected to artificial aging in a TABAI climatic chamber at 80°C and 65% relative humidity under conditions simulating a 75-year aging.

In separate experiments, we elucidated how basic agents are accumulated in paper and determined the amount of basic agent ensuring both the prescribed base stock and stability of paper in long-term storage. In the first experiments, paper samples were treated with methanolic and ethanolic solutions of magnesium alkoxides. For comparison, alcoholic solutions of ammonium carbamate were also tested. In these experiments, a standard sample of paper was immersed into a solution containing 0.1–5.0 wt % of basic agent and allowed to stand for 15–40 min. Our results are shown in Figs. 1 and 2.

Figure 1 shows that treatment of paper with basic agent changes the sign of the surface electric charge. Under these conditions, the zero-charge point shifts to the basic region. For both the initial paper and paper treated with water and alcohol the zero-charge point is observed at pH_{zcp} ~ 6. After processing of paper with alcoholic solutions of ammonium carbamate and magnesium alkoxide, the zero-charge point shifts to pH_{zcp} ~9 and ~11, respectively. Figure 1 shows a correlation between the surface electric charge of paper and its pH for different kinds of basic agents used for paper treatment. With the Mg^{2+} content in the paper increasing to 0.15–0.28 wt % , the pH of paper increases to 10–10.5, and the base stock, to 150–220 mg-equiv kg^{-1}. Further accumulation of

a basic agent in the paper does not affect the pH but leads to a steady increase in the base stock (Fig. 2).

The table shows how treatment of SFI paper (initial and artificially aged) with alcoholic solutions of magnesium methoxycarbonate (1.0, 2.5 and 5.5 wt %) affects its main characteristics. Similar effects were observed for paper treated with alcoholic solutions of magnesium methoxide and magnesium ethoxide of the same concentration.

We found that, after a single treatment of paper with alcoholic solutions of magnesium methoxycarbonate ($C \geq 2.5$ wt %), its pH exceeds 10 and the base stock becomes larger than 300 mg-equiv kg^{-1}. Testing of this paper sample showed that the single treatment of paper provides its stability during 75-year storage under common conditions.

In treatment of paper with dilute alcoholic solutions of magnesium methoxycarbonate (0.1–1.0 wt %), the base stock of ~300 mg-equiv kg^{-1} is reached only after repeated treatments with intermediate hydrolysis of the applied basic agent after each treatment cycle. Thus, the total base stock in paper is formed due to gradual accumulation of hydrolysis products of basic agent. We found that fivefold treatment of paper by the above-described procedures increases the base stock by an order of magnitude as compared to single treatment. These results were used in developing a technique for paper treatment with basic agent in supercritical carbon dioxide.

Figure 3 shows the scheme of our experimental device for paper treatment with a basic agent in supercritical carbon dioxide.

A supercritical carbon dioxide solution of a basic agent was prepared in a mixer *1* (350 cm^3) equipped with a magnetic stirrer. The treatment of paper with a basic agent in supercritical carbon dioxide was carried out in a reactor *2* (350 cm^3). The temperature was monitored with a TSP thermistor thermometer, and the pressure, with MTI-0.6 standard pressure gages and LKh-412 pressure sensors (grade of accuracy 0.6). All the parameters were recorded with a PC.

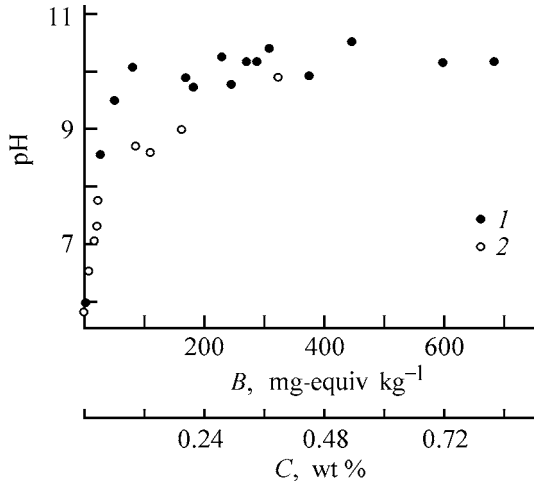

Fig. 2. pH of paper vs. base stock B and magnesium concentration C in paper. Basic agent: (*1*) alcoholic solutions of $Mg(CH_3O)_2$ and $Mg(CH_3O)_2 \cdot nCO_2$ (n = 0.6–1.0) and (*2*) $Mg(CH_3O)_2 \cdot nCO_2$ in super-critical CO_2 (n = 1.0–2.0).

In our experiments, the pressure was varied from 7 to 20 MPa; temperature, from 30 to 60°C; and the content of a basic agent in SC CO_2, from 8 to 30 wt %.

We tested various procedures for preparing supercritical carbon dioxide solutions of a basic agent: (1) a weighing bottle containing an alcoholic solution of the basic agent was placed in the mixing chamber; (2) an alcoholic solution of the basic agent applied to

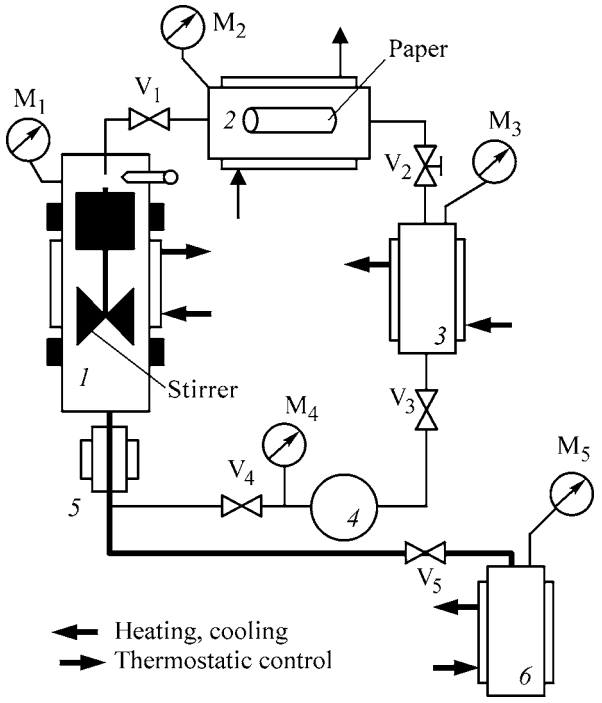

Fig. 3. Scheme of an experimental device for paper treatment with a basic agent in supercritical carbon dioxide to neutralize acid: (*1*) mixer, (*2*) reactor, (*3*) regenerator, (*4*) high-pressure pump, (*5*) heater, (*6*) thermocompressor, (V_1–V_5) shutoff valves, and (M_1–M_5) pressure gages.

a porous support was placed in a mixing chamber; and (3) an alcoholic solution of a basic agent was introduced in portions into the mixing chamber during pumping of CO_2. The introduced alcoholic solution of a basic agent was mixed with supercritical CO_2 fluid with a magnetic stirrer. Both static and dynamic procedures for application of alcoholic solution of a basic agent to paper were tested. The content of the basic agent in supercritical CO_2 was determined by gravimetric, atomic-absorption spectroscopic, chromatographic, and spectroscopic techniques.

We found that the maximum solubility of the basic agents under consideration in supercritical CO_2 containing 20% methanol or ethanol does not exceed 0.1 wt % even at the highest *T* and *P*. Therefore, after a single, even prolonged (8 h) processing of paper with the basic agent in SC CO_2, the base stock in the paper was relatively small (~100 mg-equiv kg^{-1}).

In order to increase the base stock, we used repeated impregnation of paper with a basic agent in SC CO_2, followed by hydrolysis of the basic agent after each impregnation stage. Such a procedure was preliminarily tested for treatment of paper with dilute alcoholic solutions of a basic agent. Under these conditions, the base stock increases to 300 mg-equiv kg^{-1} and more, depending on the treatment parameters.

In the course of our experiments, we optimized the separate process stages. We found that the largest base stock is reached in paper treatment under dynamic conditions, in pumping of CO_2 through a reactor at a rate of 300 $cm^3\ min^{-1}$ (temperature 38–40°C, pressure 11–13 MPa). To improve mixing of alcoholic solutions of a basic agent with SC CO_2, the mixing chamber was equipped with a magnetic stirrer.

The paper treatment with a basic agent in SC CO_2 was carried out in three stages: (1) treatment of paper with SC CO_2 containing approximately 1 wt % methanol to remove the soluble products of cellulose degradation; (2) treatment of the paper with a basic agent in SC CO_2, and (3) treatment of paper with pure SC CO_2. Each of these stages was carried out for no more than 0.5 h. The second and third stages were repeated 4–5 times, with intermediate pressure relief to atmospheric pressure and exposure of the paper to air for 1 h.

A methanolic solution of magnesium metoxycarbonate (up to 8 wt %) is recommended as the neutralizing agent solution. The tests of our technique for paper treatment showed its high efficiency: in a set of experiments, we obtained paper with pH 10.5 and the base stock of 300 mg-equiv kg^{-1}.

CONCLUSIONS

(1) The effective neutralization of paper (pH > 8, base stock 300 mg-equiv kg^{-1}) is reached by its repeated impregnation with dilute (<0.1 wt %) alcoholic or supercritical CO_2 solutions of a basic agent (magnesium methoxide or magnesium methoxycarbonate), with hydrolysis of the applied basic agent after each treatment stage.

(2) An experimental device for paper treatment with a basic agent in supercritical CO_2 to neutralize acid was constructed and the optimal conditions of neutralization of paper prepared from 100% sulfite cellulose were found: the use of magnesium methoxide or methoxycarbonate as basic agents, temperature 38–40°C, pressure 11–13 MPa, and CO_2 pumping rate 300 $cm^3\ min^{-1}$.

(3) The tretment of paper with a basic agent in supercritical CO_2 decreases the consumption of organic solutions of basic agents by almost two order of magnitudes; it decreases the detrimental environmental effect of the organic solvents and the cost of paper conservation. This technique shows much prom-

ise for developing a semicommercial installation for large-scale treatment of books and other paper documents.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Inhibiting Effect of Fullerenes C_{60} and C_{70} on High-Temperature Oxidative Degradation of Copolymers of Methyl Methacrylate with Methacrylic Acid and Methacrylamide

B. B. Troitskii, L. V. Khokhlova, A. N. Konev, V. N. Denisova, and M. A. Novikova

Razuvaev Institute of Organometallic Chemistry, Russian Academy of Sciences, Nizhni Novgorod, Russia

Received June 24, 2004

Abstract—The inhibiting effect of fullerenes on thermal oxidative degradation of copolymers of methyl methacrylate with methacrylic acid and methacrylamide at 340°C was studied.

Fullerenes C_{60} and C_{70} are heat-resistant inorganic compounds consisting of 60 and 70 carbon atoms arranged on the surface of a sphere and an ellipsoid, respectively [1–9]. Both C_{60} and C_{70} inhibit radical chain reactions of anaerobic thermal decomposition of poly(methyl methacrylate) (PMMA) and polystyrene (PS), as well as branched chain reactions of thermal oxidative (in an oxygen atmosphere) degradation of PMMA, PS, and methyl methacrylate (MMA) copolymers.

The inhibiting effect of fullerenes on chain reactions of polymer degradation is due to reactions of C_{60} and C_{70} with macroradicals to form thermally stable diamagnetic compounds [7]. It has been shown that fullerenes C_{60} and C_{70} inhibit thermal oxidative degradation of PMMA only up to 320°C. This is the limit above which fullerenes are not effective as inhibitors of thermal oxidative degradation of PMMA [3, 4].

At high temperatures (290–320°C), C_{60} and C_{70} are more effective antioxidants in thermal oxidative degradation of PMMA than the known organic antioxidants: sterically hindered amines, phenols, and sulfur- and phosphorus-containing compounds [3–8]. Organic antioxidants inhibit the thermal oxidative degradation of polymers only up to 280–290°C [10, 11].

Experiments on thermal oxidative degradation of PMMA and of MMA copolymers with various comonomers at 304°C have shown [12, 13] that MMA copolymers with methacrylic acid (MAAc) and methacrylamide (MAAm) are more heat-resistant than PMMA.

Therefore, it seems appropriate to study the effect of C_{60} and C_{70} on thermal oxidative degradation of MMA–MAAc and MMA–MAAm copolymers at temperatures above 320°C.

EXPERIMENTAL

A procedure for preparing and purifying C_{60} and C_{70} has been described elsewhere [14, 15]. The purity of C_{60} was 99.9%, and that of C_{70}, 98%. The crude mixture contained about 80% C_{60} and 20% C_{70}.

Copolymers of MMA were prepared similarly to PMMA according to [1]. MMA and MAAc were separated from the inhibitors and distilled under reduced pressure; MAAm (commercial product) was used without additional purification.

Transparent films of polymers with and without C_{60} and C_{70} additives were prepared from polymer solutions by casting onto a glass surface, after which they were dried in a vacuum at 60–80°C; the film thickness was about 100 μm.

The oxidation of C_{60} and C_{70} was studied by differential scanning calorimetry (DSC) with a Perkin–Elmer DSK-7 device in the range 100–500°C at an oxygen flow rate of 40 ml min^{-1} and a heating rate of 5 deg min^{-1}. The thermal oxidative degradation of the copolymers was studied by thermal gravimetric analysis at 340°C and oxygen pressure of 200 mm Hg.

Figures 1a and 1b show the DSC curves characterizing the oxidation of C_{60} and C_{70}, respectively. It is seen that an appreciable oxidation of C_{70} starts

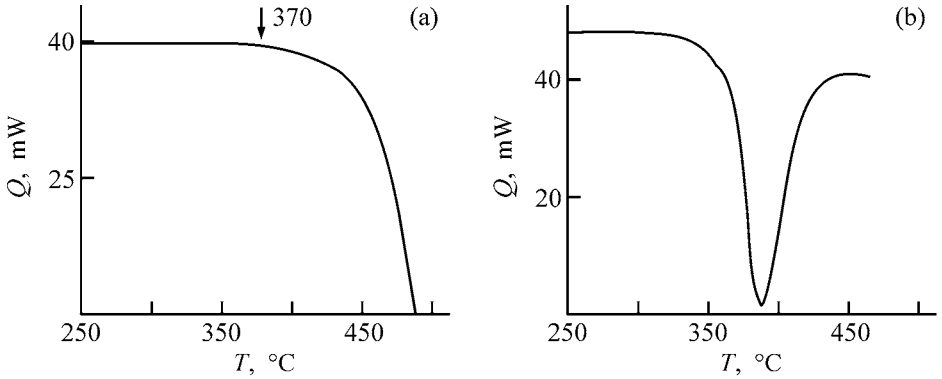

Fig. 1. DSC curves of (a) C_{60} and (b) C_{70} in oxygen: (Q) thermal flow and (T) temperature.

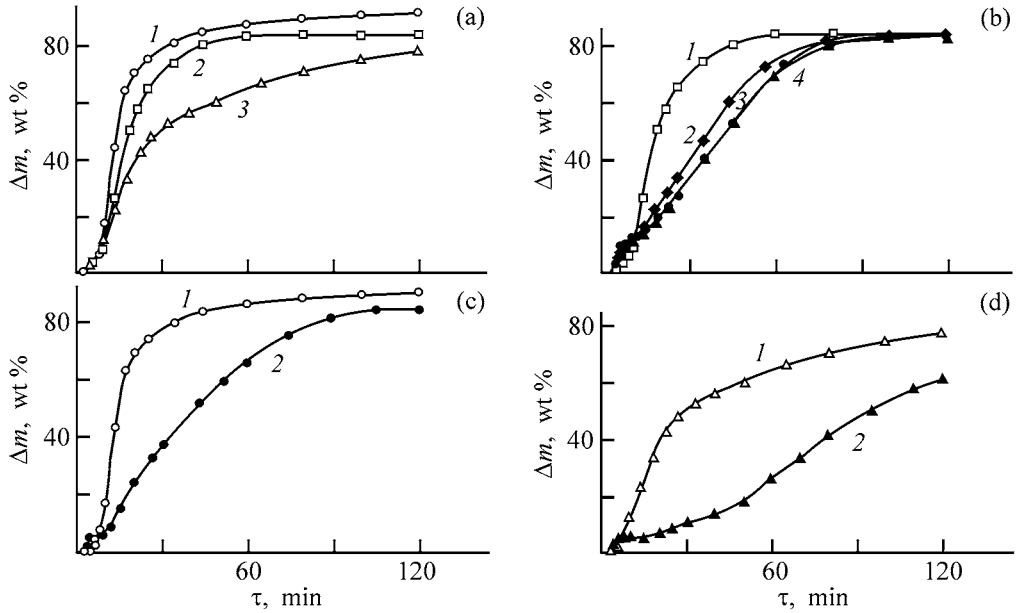

Fig. 2. Curves of the weight loss Δm in thermal oxidative degradation of copolymers. T = 340°C, p_{O_2} = 200 mm Hg. (τ) Time. (a) Copolymer of MMA with (*1*) 5 and (*3*) 10 mol % MAAm or (*2*) 15 mol % MAAc, no additives; (b) copolymer of MMA with 15 mol % MAAx (*1*) without additives and (*2–4*) with addition of fullerenes (mol kg^{-1}, $\times 10^3$): (*2*) C_{70} 8.3, (*3*) mixture of C_{60} with C_{70} 7.8, and (*4*) C_{60} 7.8; (c) copolymer of MMA with 5 mol % MAAm (*1*) without additives and (*2*) with addition of 11×10^{-3} mol kg^{-1} C_{60}; (d) copolymer of MMA with 10 mol % MAAm (*1*) without additives and (*2*) with addition of 9.5×10^{-3} mol kg^{-1} C_{60}.

at 340°C, with the maximum oxidation rate (dip in the DSC curve) observed at 388°C. Oxidation of C_{60} (Fig. 1a) starts at 370°C; the temperature of the maximum oxidation rate was not determined, because no dip was observed in the DSC curve, but it is apparently no less than 500°C. Our experimental data suggest that the theoretical temperature limits T_{lim} for C_{60} and C_{70} as high-temperature antioxidants will be in the range 340°C $\le T_{lim} \le$ 390°C for C_{70} and 370°C $\le T_{lim} \le$ 500°C for C_{60}.

Our experiments on thermal oxidative degradation of the copolymers were performed at 340°C, since the rate of oxidation of the more reactive fullerene C_{70} becomes appreciable at this temperature (Fig. 1b).

At 340°C and an oxygen pressure of 200 mm Hg, PMMA degrades completely in 10–15 min. Copolymers of MMA with 15 mol % MAAc and with 5 and 10 mol % MAAm are considerably more heat-resistant under these conditions (Fig. 2). It is interesting that the copolymer of MMA with 10 mol % MAAm, despite the lower content of the second comonomer, decomposes at a lower rate than the copolymer of MMA with 15 mol % MAAc (Fig. 2a, curves *2*, *3*). Deceleration of the degradation of the comonomers, compared to PMMA, is due to a reaction between the neighboring macromolecular units to give of six-membered rings containing anhydride (MMA–MAAc) and imide (MMA–MAAm) groups [12, 13].

The six-membered rings terminate the depolymerization process propagating along the macrochain. These rings inhibit, as shown in [7], the chain oxidation, catalyzing the molecular pathway of decomposition of hydroperoxides formed by oxidation of the polymer and thus decreasing the amount of free radicals in the reaction zone.

Fullerenes C_{60}, C_{70}, and $C_{60} + C_{70}$ (80 : 20) inhibit the thermal oxidative degradation of the MMA–15 mol % MAAc copolymer at 340°C; the inhibiting effect of the individual fullerenes and their mixture is the same (Fig. 2b). Fullerene C_{60} inhibits the thermal oxidative degradation of MMA–MAAm copolymers (Figs. 2c, 2d); in the case of the copolymer with a higher (10 mol %) MAAm content, there is a short induction period in the kinetic curve (Fig. 2d, curve *2*). The stronger stabilizing effect may be due to the formation of the six-membered imide ring, which probably decelerates the depolymerization more effectively than does the anhydride ring.

CONCLUSIONS

(1) In an oxygen atmosphere at 340°C, copolymers of methyl methacrylate with methacrylic acid and with methacrylamide degrade considerably more slowly than poly(methyl methacrylate).

(2) Fullerenes C_{60} and C_{70} and a crude mixture of these fullerenes decelerate the thermal oxidative degradation of the above copolymers.

Abstract—State reference samples were developed for determining the content of mercaptan sulfur in petroleum products, and a method for metrological certification of these samples by the certified measurement procedure was approbated.

One of the major tasks in assessment of the quality of petroleum products is to determine the content of the mercaptan sulfur (MS) because mercaptans cause corrosion and impair the strength of metals and other materials contacting them under conditions of production, application, and storage [1, 2].

The MS in petroleum products is mainly determined by potentiometric titration with an ammonia solution of silver nitrate, using a silver sulfide indicator electrode [3].

For metrological provision of procedures used to determine the MS content in petroleum products by analytical monitoring laboratories of petrochemical and oil-refining industry, state reference samples of MS content in petroleum products (MS SRSs) are required.

There are no samples of this kind in Russia today. Such samples, however, are demanded by fuel- and energy-producing enterprises for internal and external checkout in the assessment of the quality of petroleum products. This fact stimulated the development and production of MS SRS.

The goal of this study was to develop and metrologically certify the first batches of MS SRS.

EXPERIMENTAL

State reference samples SM-0.001-EK, SM-0.003-EK, SM-0.005-EK, SM-0.01-EK, and SM-0.03-EK with the rated MS content of 0.001, 0.003, 0.005, 0.010, and 0.030 wt %, respectively, were prepared by dissolution of an accurately weighed portion of phenylmethanethiol (Merck, Germany). As matrix material we used isooctane or decane (Merck, Germany).

An ammonia solution of copper(II) sulfate was prepared as described in [4]. A 3.9-g portion of copper(II) sulfate hydrate was dissolved in 700 ml of distilled water in a 1000-ml volumetric flask, a 25% ammonia solution was added until the precipitate of the basic copper(II) salt dissolved completely, after which an additional 50 ml of 25% ammonia was introduced, and the solution was brought to the mark with distilled water. The concentration of the ammonia solution of copper(II) sulfate was determined with a reference solution of sodium thiosulfate, which, in turn, was standardazied with a Grade 1 SRS of potassium bichromate (SRS 2215–81).

The certification of MS SRSs was performed by the measurement procedure[1] (MP) for determining MS in petroleum products [4]. According to this MP, a sample of MS SRS was weighed in a weighing bottle and quantitatively transferred into a 100-ml separatory funnel, for which purpose the weighing bottle was washed no less than three times with 2–3-ml portions of toluene. Then the titrant, ammonia solution of copper(II) sulfate, was added to the separatory funnel from a 2-ml Class 2 buret (scale division 0.01 ml) in the amount of 90% relative to the calculated amount required for the titration. The mixture was shaken

[1] Improved by the Ekros Research and Production Association; the procedure is hereinafter designated as EK 03-2003-NP; certified by the Ural Research Institute of Metrology, Federal State Unitary Enterprise (Certificate no. 253.12.02.129/2003).

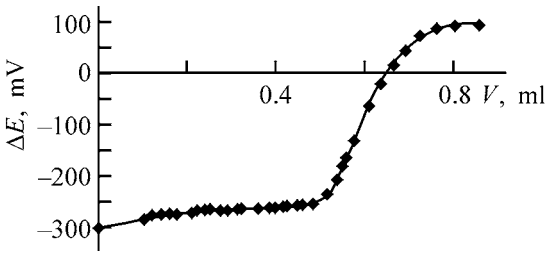
with a PE-6410 agitation device (Ekros Research and Production Association) for 5 min. Then sodium chloride was added in portions in the amount required for complete phase separation in the separatory funnel, and titration was performed until the aqueous phase acquired a light blue tint not disappearing after vigorous shaking for 5 min.

MS in MS SRSs was determined by potentiometric titration [3] on an I-160M ion meter with a standard silver chloride (ESr-10 103) and the indicated silver sulfide (ESS-01) electrodes.

In the development of MS SRSs, we used a mixing procedure for their preparation. It involved preparation of the SRS material from the starting materials by their dissolution. First, we chose the matrix and substance materials ensuring the required MS content. Among the starting materials for preparing SRSs, we chose those with which the composition and structure of SRSs did not change after mixing [5].

Additional requirements to the matrix material were as follows: inertness to the material of vials (polyethylene terephthalate) used for MS SRS storage; availability and low cost of the chemicals. It is known that permanent components of light petroleum products are paraffin, naphthenic, and aromatic hydrocarbons [1]. From the viewpoint of these requirements, paraffin hydrocarbons seem to be the most suitable as the matrix material for MS SRSs.



Potentiometric titration curve of an SM-0.001-EK SRS sample: (ΔE) Potential difference and (V) titrant (ammonia solution of silver nitrate) volume.

Among thiols, we chose phenylmethanethiol, as it has a relatively high boiling point (bp 194°C) and hence is relatively low-volatile; also, it meets the requirements formulated in [5]. Furthermore, the molecular weight of phenylmethanethiol is fairly high, which allows more accurate weighing in preparation of MS SRSs; it is also unlimitedly soluble in the available saturated hydrocarbons (e.g., isooctane, decane).

To prepare batches of reference samples, we developed a procedure ensuring preparation of SRSs with the metrological characteristics falling within the prescribed limits [6] (Table 1).

The first batches of MS SRSs were certified according to MP EK 03-2003-NP. Measurements were performed for all the rated values of the MS weight percentage. The experimental results obtained in certification of the MS SRSs are given in Table 2.

Taking into account the destination of the MS SRSs, we determined MS in these samples according to GOST (State Standard) R 52 030–2003 [3] by potentiometric titration with an ammonia solution of silver nitrate (see figure). Comparison of the results of MS determination in MS SRSs by the certified MP and by the procedure prescribed by GOST R 52 030–2003 (Table 2) shows that they are virtually identical.

Our next task was to assess the stability of MS SRSs. The stability of MS SRSs was determined according to the methodical instructions [7] by estimation of how the weight fraction of mercaptan sulfur in the samples $d_n = X_i - X_0$ and instability error $U_n = \alpha d_n + (1 - \alpha)U_{n-1}$ (where X_i is the current result of measuring the weight fraction of MS in MS SRS; X_0, control result; α, coefficient chosen in the range from 0.1 to 0.3 depending on the ratio $\sigma(\Delta)/\Delta X$ [7]) vary in storage. The weight fraction of MS in the samples was determined by the certified MP EK 03-2003-NP.

According to the methodological instructions [7], the number of measurements is chosen depending on the $\sigma(\Delta)/\Delta X$ ratio. Table 2 shows that this ratio is less than 0.5 for all the samples, i.e., the minimum number of measurements for estimating the instability error is four.

Taking into account this fact and expecting that the samples would be stable for no less than 2 years, we performed measurements at 6-month intervals. For the monitoring, we chose the samples with the lowest, highest, and medium rated weight percentage of MS: SM-0.001-EK, SM-0.005-EK, and SM-0.03-EK. The samples were stored under normal climatic conditions:

		SM-0.001-EK			
0	0.00101	0	0	0	0
6	0.00100	10^{-5}	3×10^{-6}	0	3×10^{-6}
12	0.00101	0	0	2.1×10^{-6}	2.1×10^{-6}
18	0.00099	2×10^{-5}	6×10^{-6}	1.5×10^{-6}	7.5×10^{-6}
24	0.00101	0	0	5.3×10^{-6}	5.3×10^{-6}
		SM-0.005-EK			
0	0.00502	0	0	0	0
6	0.00502	0	0	0	0
12	0.00498	2×10^{-5}	6×10^{-6}	0	6×10^{-6}
18	0.00499	10^{-5}	3×10^{-6}	4.2×10^{-6}	7.2×10^{-6}
24	0.00498	2×10^{-5}	6×10^{-6}	5×10^{-6}	1.1×10^{-5}
		SM-0.03-EK			
0	0.03005	0	0	0	0
6	0.03002	3×10^{-5}	9×10^{-6}	0	9×10^{-6}
12	0.02997	8×10^{-5}	2.4×10^{-5}	6.3×10^{-6}	3×10^{-5}
18	0.02998	7×10^{-5}	2.1×10^{-6}	2.1×10^{-5}	2.3×10^{-5}
24	0.02997	8×10^{-5}	2.4×10^{-5}	1.6×10^{-5}	4×10^{-5}

temperature of 25 ± 10°C, relative humidity of ≤80% at 25°C, and atmospheric pressure of 100 ± 4 kPa.

The results obtained in assessing the stability of MS SRSs are listed in Table 3. These results show that the highest values of U_n for all the samples tested (7.5×10^{-6}, 1.1×10^{-5}, and 4×10^{-5}) do not exceed 2/3 of the certification errors (6.7×10^{-5}, 1.7×10^{-4}, and 6×10^{-4}, respectively), which, according to [7], indicates that the samples are stable for at least 24 months.

As noted above, the other MS SRSs developed are similar solutions of phenylmethanethiol in isooctane or decane with intermediate MS weight fractions. Therefore, there is good reason to believe that the SM-0.003-EK and SM-0.01-EK samples will also be stable for no less than 24 months. Thus, by now we can warrant that the shelf life of the MS SRSs developed is 2 years.

The SRSs developed successfully passed the metrological expertise at the Ural Research Institute of Metrology, were approved by the Scientific and Technical Committee of the RF Committee for Standards (Gosstandart), and were included in the State Register of approved reference samples (Table 1).

CONCLUSION

The procedures for preparation and certification of state reference samples with rated mercaptan sul-

fur content in petroleum products (SM-0.001-EK, SM-0.003-EK, SM-0.005-EK, SM-0.01-EK, and SM-0.03-EK; rated mercaptan sulfur content 0.001, 0.003, 0.005, 0.010, and 0.030 wt %, respectively) were developed. The first batches of separate types of the samples were obtained, and their metrological characteristics were determined. The admissible relative errors for these samples do not exceed ±10, ±5, ±5, ±3, and ±3%, respectively.

Surface Tension and Density of a Sodium Hydroxide Melt

B. V. Patrov and V. P. Yurkinskii

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received October 3, 2004

Abstract—The surface tension and density of a sodium hydroxide melt were determined experimentally in a wide temperature range.

A study of the surface tension of a sodium hydroxide melt is of theoretical and practical importance, because sodium hydroxide can be used as a component of a flux for brazing of zinc and zinc–aluminum alloys [1]. The surface tension to the adhesion ratio in Young's equation can be used to judge the wettability of the solid surface with a liquid. Data on the density of sodium hydroxide density in the temperature range from 620 to 730 K are available in the literature [2, 3].

The surface tension of a sodium hydroxide melt was measured by the method of the maximum pressure in a gas bubble [4], which is the most appropriate for corrosive media. The experiments were performed as follows. A corundum vessel sealed hermetically with a ceramic lid was placed in the furnace. A platinum–platinum-rhodium thermocouple for monitoring the temperature and a pipe for supply of argon to provide an inert atmosphere were introduced through the openings in the lid.

After the prescribed temperature was attained, a glassy-graphite crucible with sodium hydroxide (chemically pure grade) was lowered into the vessel. Prior to being used, it was vacuum-treated at 873–923 K for 4 h to remove water. After melting of sodium hydroxide, the melt was kept to equalize the temperature throughout the bulk of the melt. Then, a platinum capillary, through with argon passed, was moved down, until the lower end of the capillary touched the surface of the melt. This instant was indicated by a micromanometer as the rise in the level of the manometric liquid (ethanol). The formation of a gas bubble was accompanied by an increase in pressure. After the maximum pressure P_{max} was attained, the gas bubble detached from the capillary, and a pressure drop was indicated by the manometer.

The error in determining the surface tension was estimated to be ±2%.

The surface tension was calculated with account of the asphericity of the gas bubble by Cantor's formula:

$$\sigma = \frac{gP_{max}}{2}\left(1 - \frac{2}{3}\frac{\rho r}{P_{max}} - \frac{1}{3}\frac{\rho^2 r^2}{P_{max}^2}\right), \qquad (1)$$

where g is the gravity or the conversion coefficient from pressure (cm of water column) and radius (cm) to surface tension (mJ m^{-2}); r, radius of the capillary (0.1784 cm); and ρ, the density of the melt, determined experimentally by submerging the capillary in the melt.

The difference between the increased pressure P and P_{max} in contact with the surface of the liquid, $\Delta P = P - P_{max}$ (cm of water column) was determined by submerging the capillary to different depths Δh (cm): $\Delta P\rho_w = \Delta h\rho$. The density of the melt was calculated using the equation:

$$\rho = \frac{\Delta P}{\Delta h}\rho_w. \qquad (2)$$

The error in determining the density by this method was 2%.

Preliminary experiments yielded a satisfactory agreement between the experimental values of the surface tension and published values for chloride, carbonate, and nitrate melts [4], which confirms the reliability of the procedures used in measurements and salt preparation.

The experimental results averaged over two or three measurements at 673–1073 K are listed in the table. It can be seen that the surface tension and

Surface tension and density of sodium hydroxide

T, K	σ, mJ m^{-2}	ρ, kg m^{-3}
673	150.2	1710
723	148.1	1684
773	145.8	1662
823	143.9	1633
873	142.0	1610
923	140.1	1591
973	138.0	1563
1023	136.2	1538
1073	133.8	1513

density decrease with increasing temperature. This decrease is linear and is described by the equations:

$$\sigma = A - BT, \quad (3)$$

$$\rho = A - BT. \quad (4)$$

The parameters A and B were determined by the least-squares method. In Eq. (3), they were found to be 1771.1 and 0.0402, respectively, at a confidence interval of 0.99963 and variance of 0.16068. Consequently, the temperature dependence of the surface tension (mJ m^{-2}) is described by the equation

$$\sigma = 177.1 - 0.0402T. \quad (5)$$

The parameters A and B in Eq. (4) are 2038.16 and 0.489, respectively, at a confidence interval of 0.99957 and variance of 2.10291, i.e., the temperature dependence of the density (kg m^{-3}) is described by the equation

$$\rho = 2038.16 - 0.489T. \quad (6)$$

A comparison of the densities of sodium hydroxide at 673 and 723 K with the published values [3] ρ_{673} = 1746 and ρ_{723} = 1723 kg m^{-3} demonstrated a disagreement of 2%, which does not exceed the error of density measurements. The agreement between the temperature coefficient of density, obtained in this study (0.489), and the value of 0.4784 from [3] can be considered satisfactory.

CONCLUSION

The temperature dependence of the surface tension and density of sodium hydroxide is linear and can be described by Eqs. (5) and (6).

Specific Features of Iodometric Methods for Determining the Content of Sodium Sulfite in Fixing–Bleaching Photographic Solutions

V. N. Kiryushov and L. I. Skvortsova

Institute of Solid Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

Received July 9, 2004

Abstract—The conditions of oxidation of thiocyanate ions and thiocarbamide with iodine in aqueous solutions are discussed. The range of the pH values of the solutions, in which thiocyanate ions do not interfere with the iodometric determination of sodium sulfite in fixing–bleaching photographic solutions and the expenditure of iodine for oxidation of thiocarbamide can be taken into account correctly, is revealed.

Iodometric methods are widely used for determining the content of sodium sulfite in fixing solutions that contain, in addition to sodium sulfite, only a single component reacting with I_2, sodium or ammonium thiosulfate. The working principles of these methods were published in monographs [1, 2], manuals of the analytical chemistry of fixing solutions [3, 4], and a review [5].

Sulfite ions are commonly determined by the direct and back iodometry. In either method, two aliquots of a fixing solution being analyzed are titrated. In one of these, the total volume V of the standard I_2 solution spent for oxidation of sulfite and thiosulfate ions is determined, and in the other, V_1, the volume of the I_2 solution spent for oxidation of thiosulfate ions is found. In the second aliquot, sulfite ions are masked with formalin [1–5] or are precipitated in the form of a sparingly soluble salt $SrSO_3$ [5, 6]. The volume V_2 of the iodine solution spent for oxidation of sulfite ions is found from the difference $V_2 = V - V_1$.

Variants of iodometric procedures differ in the volumes of aliquots of a fixer and a masking formalin solution and in the acidity of the medium in titration of the sum of sulfite and thiosulfate ions. Being the most accurate, the back iodometry can be recommended for performing an arbitrary analysis. According to the current OST (All-Union Standard) 19-1–83, a direct volumetric method can be used to determine the content of Na_2SO_3 in fixing solutions.

In the last two decades, fixing–bleaching solutions have found wide use in color photography. Unlike other fixers, they contain, in addition to sodium sulfite and sodium thiosulfate, either of the two components that can be oxidized with I_2, potassium thiocyanate KSCN or thiocarbamide $(NH_2)_2CS$ (TC). The TC content in such a fixing solution can be varied within 2–6 g l^{-1}, and potassium thiocyanate is added in an amount of 10 g l^{-1}.

A method for determining Na_2SO_3 has been suggested for only a single composition of the fixing–bleaching solution, containing 6 g l^{-1} TC [6]. The general pattern of how the reaction of TC and thiocyanate ions with iodine affects the determination of the sulfite ion are not discussed here. Therefore, it is unclear whether or not this method can be used for determining Na_2SO_3 in other fixing–bleaching solutions.

The aim of this study was to discuss the mechanism of reactions of TC and thiocyanate ions with I_2 and to provide, on this basis, recommendations for determination of Na_2SO_3 in any type of fixing–bleaching solutions.

The mechanism of oxidation of thiocyanate ions by I_2 has been widely discussed [7, 8]. It was established that this mechanism depends on the pH value of the aqueous medium. In alkaline solutions with pH > 8, thiocyanate ions are oxidized in quantitative yield by the reaction [7, 8]:

$$KSCN + 4I_2 + 4H_2O \rightarrow H_2SO_4 + 6HI + KI + ICN. \quad (1)$$

Reaction (1) is the basis for quantitative iodometric analysis of thiocyanate-containing compounds.

Results of determination of the known content of Na_2SO_3, c_0, in fixing–bleaching photographic solutions by direct titration in accordance with OST 19-1–83 (c_1) and by back titration with (c_2) and without (c_3) acidification of the aliquot of the fixing solution (n = 5, P = 0.95)

Interfering substance, g l^{-1}	c_0, g l^{-1}	$c_1 \pm \sigma$, g l^{-1}	S_r	$c_2 \pm \sigma$, g l^{-1}	S_r	$c_3 \pm \sigma$, g l^{-1}	S_r
KSCN, 10	2.16	2.3 ± 0.3	0.11	2.2 ± 0.1	0.04	3.3 ± 0.3	0.07
TC:							
2	2.08	1.9 ± 0.3	0.12	2.02 ± 0.12	0.05	4.2 ± 0.4	0.09
6	9.73	–	–	9.5 ± 0.3	0.02	16.4 ± 0.8	0.03

In weakly acidic solutions, at pH ≤ 5.0, thiocyanate ions do not react with I_2 [7], whereas at pH 5–8, the reaction product ICN partly reacts with I^- ions to give I_2:

$$ICN + HI \rightarrow I_2 + HCN. \quad (2)$$

The higher the solution acidity, the larger fraction of ICN is involved in the reaction to give I_2, which makes indeterminate the titrant volume spent for oxidation of sulfite ions. In [7], no products of oxidation of thiocyanate ions were found in a solution with pH < 5.0. Apparently, SCN ions will not interfere with iodometric determination of Na_2SO_3 in its titration in solutions with pH < 5. The fixing–bleaching solutions have pH 7–9 and their acidification with acetic acid to pH 3.5 is admissible. In more acidic solutions, thiosulfate ions react with H^+ ions to give S or SO_2, and, therefore, the results of analysis will be erroneous.

The mechanism of TC oxidation by iodine was discussed in [9, 10]. As in the case of thiocyanate ions, this mechanism is dependent on the solution pH. In an alkaline medium with pH > 8, TC is oxidized to carbamide by the reaction [9]:

$$(NH_2)_2CS + 4I_2 + 10NaOH \rightarrow (NH_2)_2CO + Na_2SO_4 + 8NaI + 5H_2O. \quad (3)$$

In weakly acidic and acid solutions, TC reacts with iodine in quantitative yield to form a salt of formamidine disulfide [10]:

$$2(NH_2)_2CS + I_2 + H_2SO_4 \rightarrow (NHNH_2)_2C_2S_2 \cdot H_2SO_4 + 2HI. \quad (4)$$

Thus, it is impossible to suppress the reaction of TC oxidation by varying the acidity of the medium in iodometric determination of Na_2SO_3 in the presence of TC. However, the volume of the iodine solution, V_3, spent for this process can be determined with a high accuracy. For example, if the same acidity of the medium (pH 3.5–5.0) is created in aliquots of a fixing–bleaching solution taken for determining either the total content of SO_3^{2-} and $S_2O_3^{2-}$ ions or that of only $S_2O_3^{2-}$ ions, then the volume of the I_2 solution spent for TC oxidation will be the same in both titrations. Therefore, the volume of the I_2 solution spent for oxidation of sulfite ions can be calculated from the difference of these titrations.

Indeed, the total volume of the I_2 solution spent for oxidation of the three components ($S_2O_3^{2-}$, SO_3^{2-}, and TC) can be written as $V_1 + V_2 + V_3$, and the volume spent for titration of an aliquot with masked sulfite ions, as the sum $V_1 + V_3$. Then the expenditure of I_2 for titration of Na_2SO_3 is the difference of volumes $V_1 + V_2 + V_3 - V_1 - V_3 = V_2$. Thus, the acidification of both the aliquots of a fixing solution to pH 3.5–5.0 in direct and back iodometry should eliminate the effect of thiocyanate ions and TC on the results obtained in determining of Na_2SO_3 in all types of fixing–bleaching solutions.

EXPERIMENTAL

To verify the correctness of this conclusion, different types of fixing–bleaching solutions containing 2 and 6 g l^{-1} TC or 10 g l^{-1} KSCN were analyzed by back iodometry. In one series of analyses, a 1-cm^3 aliquot of a fixing solution in which the sulfite ion was masked with formalin was acidified with 10% acetic acid (5 cm^3). In another series, an aliquot of a fixing solution, intended for determining the total volume of the standard iodine solution, was also acidified. The aliquots were treated with an excess amount (10–15 cm^3) of a 0.1 N iodine solution, which was then titrated with a 0.1 N solution of $Na_2S_2O_3$ in the presence of a starch solution as indicator. Simultaneously, some fixing solutions were analyzed for the content of Na_2SO_3 by direct iodometry in accordance with OST 19-1–83. In this method, the aliquots of a fixing solution were acidified with 10% acetic acid (10 cm^3). The compositions of the fixing solutions were reported in [6] and can be found in reference books on photography. The true content of Na_2SO_3 in a fixing solution prepared was calculated from the weight of the portion of this reagent, determined with high accuracy. The results of these determinations are listed in the table.

The data in the table show that use of the traditional back iodometry to find the total content of $S_2O_3^{2-}$ and SO_3^{2-} ions without preliminary acidification of the aliquot of a fixing solution yields erroneous results for the content of sodium sulfite (c_3) in all types of fixing–bleaching solutions containing thiocarbamide or potassium thiocyanate.

By contrast, the results obtained in determining the Na_2SO_3 content in accordance with OST 19-1–83 (c_1) and by back iodometry with acidification of all aliquots of fixing solutions (c_2) are well reproducible and correct, because the true value c_0 lies within the range of variation of the average values obtained by these methods.

CONCLUSIONS

(1) Thiocarbamide and salts containing thiocyanate ions interfere with iodometric determination of sodium sulfite in fixing–bleaching photographic solutions, because they are oxidized by iodine, together with the substance to be analyzed. The influence of thiocyanate ions can be eliminated by acidification of the solution being analyzed to pH 3.5–5.0. In such a medium, thiocyanate ions do not react with iodine.

(2) At pH 3.5–5.0, thiocarbamide is oxidized by iodine by the known reaction. The effect of this reaction can be taken into account when determining the total content of $S_2O_3^{2-}$ + SO_3^{2-} + $(NH_2)_2SC$ ions and that of only $S_2O_3^{2-}$ + $(NH_2)_2SC$ ions in the aliquots of fixing solutions acidified to these pH values.

(3) The determination in accordance with OST 19-1–83 meets these requirements, and, therefore, the content of sodium sulfite is correctly determined by this method.

(4) Back titration, in which the solution to be analyzed is acidified to pH 3.5–5.0 prior to the titration of the sum of $S_2O_3^{2-}$ + SO_3^{2-} ions, also yields correct results.

BRIEF COMMUNICATIONS

A Procedure for Preparing *N*-Hydroxyethyl-Substituted Succinimide and Phthalimide

R. A. Gasanov and M. A. Allakhverdiev

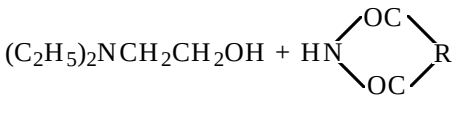
Institute of Chemistry of Additives, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

Received May 13, 2004

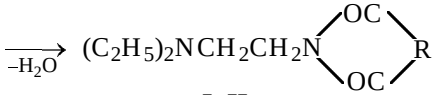
Abstract—Conditions of synthesis of *N*-hydroxyethyl-substituted succinimide and phthalimide by reactions of dicarboxylic acid imides with aminoethanol were optimized.

Synthesis of *N*-hydroxyethyl-substituted succinimide and phthalimide has been the subject of numerous papers [1, 2]. *N*-(Alkoxyethyl)succinimides are used as SO_2 absorbents [3], and *N*-(2-hydroxyethyl)-phthalimide, as a synthetic precursor of *N*-vinylphthalimide, a monomer for preparing polymers with a high softening point (200°C) [4].

Condensation of 2-(diethylamino)ethanol with succinimide and phthalimide at 360°C yielded *N*-[2-(diethylamino)ethyl]succinimide **I** and *N*-[2-(diethylamino)ethyl]phthalimide **II** [1, 2]. The subsequent reactions of **I** and **II** with aminoethanol yielded *N*-hydroxyethyl-substituted succinimide **III** and phthalimide **IV**:



$\xrightarrow[-H_2O]{}$

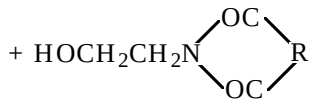


I, **II**

I, **II** + $H_2NCH_2CH_2OH$

$\xrightarrow[-H_2O]{}$ $(C_2H_5)_2NCH_2CH_2NH_2$

+ $HOCH_2CH_2N$



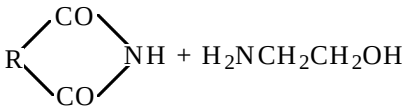
III, **IV**

where R = $(CH_2)_2$ (**I**, **III**), *o*-C_6H_4 (**II**, **IV**).

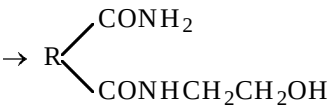
EXPERIMENTAL

We have developed a single-step procedure for preparing *N*-hydroxyethyl-substituted succinimide **III** and phthalimide **IV** by the reaction of aminoethanol with succinimide and phthalimide.

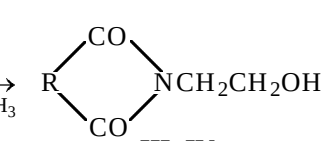
Freshly distilled aminoethanol (31 g) was added dropwise to an equimolar amount of phthalimide (73 g) or succinimide (49 g). The mixture warmed up and foamed owing to evolution of ammonia. Then the mixture was heated on a bath with Wood's alloy to 200–250°C. After the gas evolution ceased, the heating was stopped. In the case of **IV**, the mixture was poured into cold water. The crystalline precipitate was filtered off, dried, and twice recrystallized from benzene. Colorless crystals of **IV** were obtained in 87% yield (83 g); mp 127–128°C. In the case of **III**, the reaction mixture was cooled and vacuum-distilled; the fraction boiling at 178 (5 mm Hg) or 215°C (6 mm Hg) was crystallzed from hot benzene. The crystals of **III** were filtered off and dried; yield of colorless crystals of **III** 82% (58 g), mp 58°C:



$\rightarrow$



$\xrightarrow[-NH_3]{}$



III, **IV**

The structures of **III** and **IV** were confirmed by IR and ^1H and ^{13}C NMR spectroscopy.

The IR spectra were recorded on a Specord M 80-IR spectrometer (liquid films and mulls in mineral

1070-4272/04/7712-2034 © 2004 MAIK "Nauka/Interperiodica"

oil) in the range 4000–600 cm^{-1}, using KBr and NaCl prisms. In the IR spectra of imides **III** and **IV**, we observed high-frequency absorption bands at 3600–3500 cm^{-1}, characterizing the free OH group. The bands at 1780–1710 cm^{-1} corresponded to the C=O stretching vibrations.

The ^{1}H NMR spectra were recorded on a Bruker spectrometer (300 MHz). The NMR spectra of **III** and **IV** contain, respectively, the signals of two methylene groups of the succinimide ring at 4.8–4.9 ppm and of the aromatic ring at 7.8–7.87 ppm. A broad singlet at 3.98–4.1 ppm is due to the hydroxy group. The methylene groups of the aminoethanol moiety give signals at 3.78–3.80 ppm. In the ^{13}C NMR spectra, the signals of the C=O groups are observed at 168–180 ppm.

CONCLUSION

A procedure was developed for preparing *N*-(2-hydroxyethyl)phthalimide and *N*-(2-hydroxyethyl)succinimide by the reaction of the corresponding imides with aminoethanol (yield 82–87%).

BRIEF COMMUNICATIONS

Preparative Synthesis of (*Z*)-5-Decenyl Acetate

Zh. A. Chobanyan

Institute of Organic Chemistry, National Academy of Sciences of the Republic of Armenia, Yerevan, Armenia

Received July 14, 2004

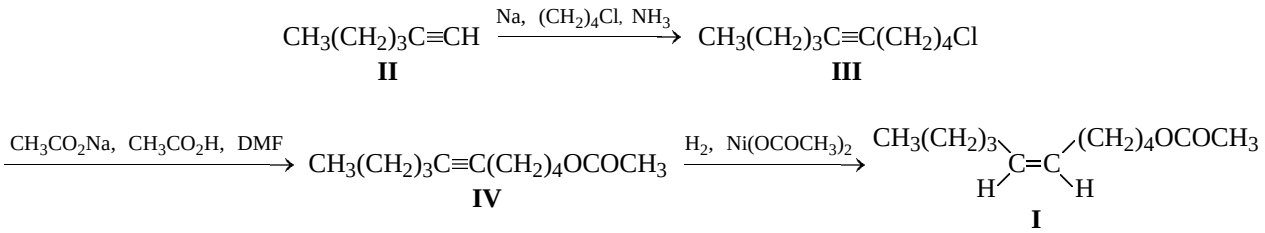
Abstract—A procedure was developed for preparative synthesis of (*Z*)-5-decenyl acetate, the sex hormone of *Agrotis Segetum.*

The use of pheromones for plant protection from pests became possible after preparation of synthetic analogs of these natural compounds. Since that time, the chemistry of synthetic pheromones has been receiving a considerable attention [1].

Agrotis Segetum is a pest damaging various cereals under natural conditions and in storehouses. The principal component of its pheromone is (*Z*)-5-decenyl acetate **I**.

Procedures have been developed for preparing **I** using the Wittig reaction to obtain the (*Z*)-alkene moiety [2–4], by selective ozonolysis of (*Z,Z*)-1,6-cyclooctadiene [5], and by metal interchange with di(1-hexenyl)mercury [6]. Medarde *et al*. [7] reported a general procedure for preparing components of *Agrotis Segetum* pheromone from 1,4-butanediol [7]. The above procedures are multistep, difficult in implementation, and time-consuming; they involve formation of undesirable by-products, and the yield of the target products is low. We have developed a new procedure for preparing pheromones of this type, which is free of the above drawbacks.

The procedure suggested starts from butylacetylene **II** and follows the $C_6 + C_4$ scheme. In the first step, sodium butylacetylenide reacts with 1-iodo-4-chlorobutane in liquid ammonia at –50 to –60°C (under these conditions, iodochloroalkanes react selectively, with only the iodine atom substituted) to form 1-chloro-5-decyne **III**. This compound is treated with sodium acetate in refluxing dimethylformamide (DMF). The resulting 5-decynyl acetate **IV** is hydrogenated in a flow of hydrogen in the presence of nickel acetate treated with ethylenediamine and sodium borohydride; the reaction gives (*Z*)-5-decenyl acetate **I**, overall yield 44%.



II **III** **IV** **I**

The process efficiency and yield of **I** essentially depend on the reaction temperature. At temperatures above –50°C, side reactions occur (dehydrochlorination, disubstitution), and below –60°C, the yield of **I** does not change further.

In the synthesis of 1-chloro-5-decyne **III** and 5-decynyl acetate **IV**, we took the reactants in an equimolar ratio, since an excess of any of the reactants had no appreciable effect on the product yield. The hydrogenation of 5-decynyl acetate **IV** to (*Z*)-5-decenyl acetate was performed according to [8].

According to GLC, the final product **I** contained the *Z* isomer only, which is confirmed by the IR data (presence of a medium-intensity band in the region of

1070-4272/04/7712-2036 © 2004 MAIK "Nauka/Interperiodica"

730 cm^{-1}; absence of a band at 980 cm^{-1}, characteristic of the *E* configuration) and by a characteristic multiplet of the (*Z*)-CH=CH protons in the ^1H NMR spectrum at 5.1–5.35 ppm (J = 11.5 Hz).

EXPERIMENTAL

The ^1H NMR spectra were recorded on a Varian Mercury-300 spectrometer (300 MHz) in $CDCl_3$, internal reference TMS, and the IR spectra, on a UR-20 spectrometer (thin films). The GLC analysis was performed on a Chrom-5 chromatograph equipped with a flame ionization detector and 25 000 × 0.2-mm glass capillary column coated with SE-30, carrier gas nitrogen, flow rate 30 ml min^{-1}.

1-Chloro-5-decyne III. Alkyne **II** (12.8 g) was added over a period of 15 min at –60°C to sodium amide prepared from 3.45 g of Na and 0.5 l of liquid ammonia; the mixture was stirred for 3 h. Then 32.8 g of 1-iodo-4-chlorobutane was added dropwise over a period of 2 h. The mixture was stirred for an additional 2 h and allowed to warm up. After evaporation of ammonia (15 h), 200 ml of anhydrous diethyl ether was added to the residue, and the mixture was refluxed with stirring for 3 h. After cooling, dilute HCl (pH 3) was added, and the mixture was extracted with diethyl ether (3 × 50 ml). The combined ether extracts were washed with a $Na_2S_2O_3$ solution and dried over magnesium sulfate. Distillation gave 18.1 g (70%) of **III** [9], bp 75–76°C (2 mm Hg), n_d^{20} = 1.4610.

5-Decynyl acetate IV. Chloroalkyne **III** (3.45 g) was added to a mixture of 1.64 g of sodium acetate and 10 ml of acetic acid in 50 ml of anhydrous DMF. The mixture was stirred at the boiling point for 10 h, the solvent was distilled off, 15 ml of water was added to the residue, and the mixture was extracted with diethyl ether (3 × 50 ml). The extract was washed with water to pH 7 and dried over magnesium sulfate. The solvent was removed. Vacuum distillation gave 3.2 g (82%) of **IV**, bp 92°C (2 mm Hg), n_d^{20} = 1.4460. IR spectrum, ν, cm^{-1}: 1745, 2250. ^1H NMR spectrum, δ, ppm: 0.9 t (3H, CH_3CH_2, J = 7 Hz), 1.4–1.7 m (8H, CH_2), 1.9–2.15 m (4H, $CH_2C{\equiv}CCH_2$), 1.85 s (3H, $COCH_3$), 4.1 t (2H, OCH_2, J = 6.8 Hz).

(*Z*)-5-Decenyl acetate I. A 0.32-g portion of $Ni(OAc)_2 \cdot 4H_2O$ in 10 ml of absolute ethanol was bubbled with hydrogen, after which 1.4 ml of a 1 M alcoholic solution of sodium borohydride was added in three portions. To the resulting black solution, we added 0.18 g of anhydrous ethylenediamine and 1.5 g of decynyl acetate **IV**; the mixture was stirred at 20°C in a flow of hydrogen. After the hydrogenation was complete, the catalyst was filtered off, the filtrate was evaporated, and the precipitate was diluted with 20 ml of water and extracted with diethyl ether (3 × 50 ml). The extract was washed with 10 ml of water and dried over magnesium sulfate; the solvent was distilled off. Yield of **I** 1.2 g (81%), bp 100–101°C (7 mm Hg), n_d^{20} = 1.4400. IR spectrum, ν, cm^{-1}: 730 m, 1150 s, 1245 s, 1370 m, 1390 m, 1465 m, 1658 w, 1745 vs, 3015 m. ^1H NMR spectrum, δ, ppm: 0.89 t (3H, CH_3CH_2, J = 7.1 Hz), 1.3–1.45 m (8H, CH_2), 1.95–2.25 m (4H, $CH_2CH{=}CHCH_2$), 1.96 s (3H, $COCH_3$), 4.01 t (2H, OCH_2, J = 6.8 Hz), 5.1–5.35 m (2H, CH=CH, J = 11.5 Hz).

Professor Adam Vladislavovich Rakovskii (To 125th Anniversary of His Birthday)

A.V. Rakovskii, a corresponding member of the Academy of Sciences of the USSR and a professor of Moscow State University, performed a wide variety of experimental studies and made a major contribution to the formation of physical chemistry as an independent educational discipline and to the development of chemical education in Russia.

Adam Vladislavovich Rakovskii was born on December 23, 1879, at Mezhirech'e village of Sedletskaya Province (now in the Republic of Poland) into the family of a teacher. In 1896, he finished a classical gymnasium at the town of Bela in the same province and entered the natural department of the physicomathematical faculty at Moscow University. Rakovskii expressed the strongest interest in chemistry beginning from the first years of his education. At that time, chemical sciences were for the most part taught at the University by professor N.D. Zelinskii (1861–1952, academician of the Academy of Sciences of the USSR since 1929); V.F. Luginin (1834–1911), founder of a thermochemical laboratory at the University; and A.P. Sabaneev (1842–1923). I.A. Kablukov (1857–1942, honorary member of the Academy of Sciences of the USSR since 1932), a known physical chemist, was elected extraordinary professor of Moscow University only in May 1903.

In 1903, Rakovskii graduated from the University with a first-degree diploma and, on Zelinskii's recommendation, was taken on the staff of the Central chemical laboratory of the Ministry of Finance as a junior laboratory assistant. The main task of the laboratory was to monitor the quality of alcoholic drinks, in connection with the state monopoly on this kind of products, and also to control the work of provincial laboratories and to improve methods for rectification of ethanol. Most of the staff members of the laboratory were graduates from Moscow University, the operation of the laboratory was supervised by Zelinskii.

Already by the end of Rakovskii's education at the University his scientific interests were mainly focused on physical chemistry, even though no separate discipline of this kind existed at Moscow University in those years. When being an undergraduate, Rakovskii worked at the thermochemical laboratory;

he is the author of an unpublished manuscript "Heats of Combustion and Formation of Organic Substances in the Context of the Structural Theory" (Moscow, 1902) [1]. During his work at the laboratory of the Ministry of Finance, Rakovskii could, in addition to discharging his duties, prepare for publication his first study "Kinetics of Consecutive First-Order Reactions" (1907) [2]. In 1907–1910, the scientist published the results of seven more physicochemical studies. These included "Specific Heats of Solutions in Water and Ethanol" (1909) and "Purification and Rectification of Ethanol" (1909). In 1911–1914, a set of 11 publications concerned with the adsorption of water and aqueous solutions by starch appeared in *Zhurnal Russkogo Fiziko-khimicheskoro Obshchestva* (Journal of the Russian Physicochemical Society). The results of these studies were summarized in Rakovskii's master's dissertation "To the Theory of Adsorption" (1913), defended at Kiev University in 1914. Based on the results of his experiments, Rakovskii, in particular, concluded that the adsorption of water vapor by solid colloids occurs continuously and irreversibly. The irreversibility of the adsorption process is manifested in that there exists a hysteresis of the water content in the colloid. This set of publications devoted to adsorption was analyzed in detail by

1070-4272/04/7712-2038 © 2004 MAIK "Nauka/Interperiodica"

Ya.I. Gerasimov and A.V. Kiselev in the collection of works [2]. The authors highly appreciated Rakovskii's studies in the field of adsorption and thermodynamics of irreversible processes.

After the degree of master of science was conferred on Rakovskii, he became a privatdocent at the chair of chemistry of Moscow University and started to deliver lectures on chemical thermodynamics and application of mathematics to chemistry. Because of the beginning of World War I, Rakovskii took active part, as a staff member of the Ministry of Finance, in the equipment of plants for manufacture of the necessary medicines. In 1917, he was appointed head of the Central chemical laboratory of the Ministry of Finance and supervisor of chemical plants affiliated with this Ministry (beginning in 1918, People's Commissariat of Finance).

In 1919–1932, Rakovskii headed the laboratory of inorganic chemistry at the Institute of Pure Chemical Reagents, in whose organization he was directly involved. Beginning in 1920, the scientist started to pay increasing attention to Moscow University, without terminating his work at industrial research institutes. In 1920–1928, Rakovskii was a professor at the chair of inorganic chemistry of Moscow University; in 1928–1930, he headed this chair; and from 1930 till the end of his life, he headed the chair of physical chemistry of Moscow State University. From 1933 to 1937, he simultaneously occupied the positions of dean of the chemical faculty and director of the Institute of Chemistry at Moscow State University. Rakovskii was a talented and many-sided teacher.

During the period from 1919 to 1933, Rakovskii and co-workers carried out, mainly at the Institute of Pure Chemical Reagents, quite a number studies. He published in *Trudy Instituta* (Coll. of Works of the Institute), *Zhurnal Prikladnoi Khimii* (Journal of Applied Chemistry), *Zhurnal Obshchei Khimii* (Journal of General Chemistry), and other editions results of 33 studies. These include important investigations concerned with equilibria in water–salt systems, development of standards and standard procedures for testing of chemical reagents (including acids and alcohols), and a set of studies devoted to heteropolyacids and heteropolycompounds. All investigations performed by Rakovskii and his pupils are distinguished by extraordinary thoroughness in experimental work and assessment of the results obtained. Rakovskii made a major contribution to the organization of manufacture of various high-purity preparations. During several years, he was a consultant at Gintsvetmet and Giredment institutes. A collection of thermodynamic works carried out by staff members of the Gintsvetmet institute was published under Rakovskii's editorship (1935).

Rakovskii's services in organization of the higher chemical education in our country were great, he was actively involved in composition of curricula and programs of chemical higher-school institutions and paid primary attention to teaching of physics and mathematics to students of chemical specialities. Rakovskii was permanently concerned with problems of publication of educational literature in the field of inorganic and physical chemistry and chemical thermodynamics. Originally, his lectures from various courses were published as lithographic editions (1926–1935). In 1933, Rakovskii published (together with E.F. Krauze and A.V. Bogomolov) *Kurs obshchei i neorganicheskoi khimii* (Course of General and Inorganic Chemistry) (420 pp.). In 1938, he published a fundamental work *Vvedenie v fizicheskuyu khimiyu* (Introduction to Physical Chemistry) (679 pp.). The book comprised an extended and supplemented course of lectures delivered by the author at Moscow State University; it was widely used by postgraduate students and research workers. In 1939 was published a more concise *Kurs fizicheskoi khimii* (Course of Physical Chemistry) (544 pp.), recommended as a textbook for students of chemical specialities.

Rakovskii paid a considerable attention to translation of foreign publications into Russian; quite a number of textbooks and monographs were published under his editorship and with his supplements, which were rather significant in some cases. The book by A. Smith *Introduction to Inorganic Chemistry* was published in three editions in Russian translation under editorship and with supplements by Rakovskii (1928–1931). Rakovskii published a special supplement *Khimicheskaya kinetika i kataliz* (Chemical Kinetics and Catalysis) (1931, 84 pp.) to the Russian translation of A.P. van Eyken's *Foundations of Physical Chemistry* (*Osnovnye nachala fizicheskoi khimii*, 1929, 343 pp.). J.R. Partington's course of chemical thermodynamics was seriously reshaped [3]. This was the first experience of publication of a course of chemical thermodynamics in Russia; the translation was done by Rakovskii's closest associate Ya.I. Gerasimov (1903–1983, corresponding member of the Academy of Sciences of the USSR since 1953). The book simultaneously served as reference and strongly affected the development and level of the thermodynamic research in our country. Of considerable interest is Rakovskii's foreword to the Russian translation of the book by I.D. Van der Waals and F. Konstamm *Course of Thermostatics* (*Kurs termostatiki*;

1936, part I, 452 pp.; part II, 439 pp.) in which, in particular, editor's standpoint concerning important problems of the theory of solutions was presented.

Rakovskii's scientific activities were honored by his election a corresponding member of the Academy of Sciences of the USSR in 1933.

Adam Vlasdislavovich Rakovskii died of long and severe illness on June 7, 1941. He gave more than quarter of a century of his life to Moscow University, being one of the leading professors of the chemical faculty. Warmest recollections of Rakovskii, a brilliant pedagogue and talented scientist, were published by his closest pupils and co-workers Ya.I. Gerasimov, A.V. Kiselev, A.V. Frost, M.M. Popov, D.N. Tarasenkov, and others [2, 4, 5]. Rakovskii's accomplishments in organization of the chair of physical chemistry and, simultaneously, of the laboratory of chemical thermodynamics of Moscow State University (1930) are described in G.F. Voronin's essay devoted to the life and activities of Ya.I. Gerasimov who headed the laboratory of chemical thermodynamics for more than 35 years (since 1943) and the chair of physical chemistry of Moscow University for more than 30 years (since 1952) [6]. The collection of works [2] contains a full list of Rakovskii's scientific publications.

A. G. Morachevskii

Russian Journal of Applied Chemistry, Vol. 77, No. 12, 2004, pp. 2041–2042. Translated from Zhurnal Prikladnoi Khimii, Vol. 77, No. 12, 2004, pp. 2066–2067.

Zelenin, K.N., Nozdrachev, A.D., and Polyakov, E.L., *Nobelevskie premii po khimii za 100 let* (Nobel Prizes in Chemistry in 100 Years), St. Petersburg: Gumanistika, 2003, 873 pp.

In accordance with the will of Alfred Nobel (1833–1896), a Swedish engineer, chemist, and industrialist, international prizes have been annually awarded since 1901 for outstanding discoveries and achievements in physics, chemistry, physiology, or medicine; for creating the most important literary works, and for making a major contribution to friendship between peoples and consolidation of peace. Beginning in 1969, prizes in economic sciences in memory of Alfred Nobel are also awarded.

The changes in the political life of Russia in the last decade of the XX century affected the attitude of State structures toward the activities of the Nobel Committee and toward how these prestigious scientific prizes are awarded. In 1992, the encyclopedia *Nobel Prize Laureates*, published in the United States in 1987, was translated into Russian. The two volumes of this encyclopedia (vol. 1, 740 pp.; vol. 2, 854 pp.; Moscow: Progress) contain 564 articles with biographies of scientists, writers, and public and political figures, as well as information about institutions awarded Nobel Prizes in 1901–1986. This was the first fundamental publication in Russian about Nobel Laureates. It should be noted that the encyclopedia *Nobel Prize Laureates* is published abroad every five years. Following the encyclopedia, a number of publications devoted to A. Nobel's life and to the activities of the Nobel Prize Committee appeared in Russian. To these belong a Russian translation from English of R. Sulman's book *Alfred Nobel's Will. History of Nobel Prizes* (Moscow: Mir, 1993, 142 pp.) and translation from French of O. de Rudder's book *Alfred Nobel* (Rostov-on-Don: Feniks, 1997, 320 pp.). Of considerable interest is A.M. Blokh's monograph *Sovetskii Soyuz v inter'ere Nobelevskikh premii. Fakty. Dokumenty, Razmyshleniya, Kommentarii* (The Soviet Union in the Context of Nobel Prizes. Facts. Documents. Reflection, Comments), edited by A.I. Melua (St. Petersburg: Gumanistika, 2001, 608 pp.), which contains an exceedingly valuable documentary evidence. The author of the monograph, a known Russian Scientist, has been extensively and effectively working in the field of history of science. Among the books devoted to Nobel-related issues ("Nobelistics"), one more very well-compiled bibliographic publication: *Lektsii i rechi laureatov Nobelevskikh premii v russkikh perevodakh: 1901–2002. Bibliographicheskii ukazatel'* (Lectures and speeches by Nobel prize laureates in Russian translation: 1901–2002. Bibliographic Index), (St. Petersburg: Bibl. Akad. Nauk, 2003, 168 pp.) should be mentioned.

The book by Zelenin, Nozdrachev, and E.L. Polakov should be referred to reference books of mostly compiled nature. It contains evidence about laureates of 94 prizes in chemistry, awarded from 1901 till 2002. In the last century, Nobel prizes in chemistry were not awarded, for various reasons, only in 1916, 1917, 1919, 1924, 1933, 1940–1942. The book comprises an introduction, five chapters, and a supplement. The brief introduction (pp. 7–10) contains evidence about Alfred Nobel's family and possible reasons for the appearance of such a will. The first chapter (pp. 14–45) includes a rather detailed description of Alfred Nobel's life and activities. In the second chapter (pp. 46–61), the working mechanism of the Nobel Committee for Chemistry is described. The prerogative right to chose a laureate is vested in the Swedish Royal Academy of Sciences. Nominations can be made by Swedish and foreign members of the Swedish Royal Academy of Sciences, members of the Nobel Committee for Chemistry, professors of chemistry at universities and technological institutes of Sweden, Denmark, Finland, Island, and Norway, Nobel Laureates in Chemistry, professors of the Karolinska Institute in Stockholm, heads of chairs of a small number of other universities by choice of the Swedish Royal Academy of Sciences, and individual scientists by invitation of the Nobel Committee. Those invited personally as nominators should not discuss their decision with colleagues and nominees themselves. The information about the work of the Nobel Committee and about all the nominators and nominees becomes publicly accessible only in 50 years.

1070-4272/04/7712-2041 © 2004 MAIK "Nauka/Interperiodica"

The third chapter of the reference book by K.N. Zelenin and co-authors (pp. 62–100) considers the distribution of Nobel Prizes among the main fields of modern chemistry and different countries in 100 years. Particularly significant in the last 50 years is the share of works of chemical-biological nature, devoted to a study of the chemism of vital processes and of the functioning of living systems.

The first Nobel Prize in Chemistry was awarded in 1901 to one of the founders of modern physical chemistry, J.H. van't Hoff (1852–1911) (Netherlands), "in recognition of the extraordinary services he has rendered by the discovery of the laws of chemical dynamics and osmotic pressure in solutions." During the period from 1901 till 1950, the obviously leading position among the recipients of Nobel Prizes in Chemistry was occupied by German chemists (19 Nobel laureates). The Nobel Prize winners from Germany include such known chemists as A. von Baeyer (1835–1917), W. Ostwald (1853–1932), F. Haber (1868–1934), W. Nernst (1864–1941), and O. Hahn (1879–1968). Considerably smaller was the number of laureates from the United States (7), UK (7), and France (6). The situation changed fundamentally in the second half of the XX century. During the period from 1951 till 2000, Nobel Prizes in chemistry were awarded to 42 scientists from the United States, 16 scientists from the UK, and 8 from Germany. Among the American recipients of Nobel Prizes in chemistry were G.T. Seaborg (1912–1999) (together with E.M. McMillan) in 1951 "for their discoveries in the chemistry of the transuranium elements" and L. Pauling (1901–1994) in 1954 "for his research into the nature of the chemical bond and its application to the elucidation of the structure of complex substances." A recipient of a Nobel Prize in chemistry among Russian scientists was, in 1956, academician N. Semenov (1896–1986) [together with C.N. Hinshelwood (1887–1967)] "for their researches into the mechanism of chemical reactions." Here are primarily meant the works of these two scientists in the field of theory of chain reactions.

The fourth chapter (pp. 101–725) occupies the central position in the reference book under discussion. It contains scientific-biographical evidence about all the Nobel Prize laureates in chemistry. Each article of the chapter includes materials about a prize, the essence of the discovery, and the formulation of the Nobel Committee; discusses the importance of the discovery for the development of the related field of chemistry; and presents biographic evidence about the laureates. The volume and content of the biographical evidence are virtually the same as those in the two-volume encyclopedia mentioned above. The fifth chapter (pp. 726–738) describes the nationality, age, education, and working places of the Nobel Prize laureates in chemistry.

The supplement (pp. 739–865) contains, in particular, information about all scientists nominated for the Nobel Prize in chemistry in 1901–1950. Among the nominated Russian scientists were D.I. Mendeleev (in 1905, 1906, and 1907), P.I. Walden (1914), creator of the chromatographic method for separation and analysis of mixtures M.S. Tsvet (1918), outstanding microbiologist S.N. Vinogradskii (1921), and academician A.N. Frumkin (1946). One of the most outstanding chemists of the first half of the XX century, academician V.N. Ipat'ev, who was deprived of the Soviet citizenship in 1936 and worked in the United States, was nominated in 1938, 1941, 1948, 1949, and 1950. Unfortunately, he was not awarded the well-deserved Nobel prize. The possible reasons were analyzed by Yu.I. Solov'ev (*Vestnik Ross. Akad. Nauk*, 1997, vol. 67, no. 7, pp. 627–631).

The book by K.N. Zelenin, A.D. Nozdrachev, and E.L. Polyakov is of interest for a wide audience of readers; it is very well published and presents photographs of the laureates and other illustrative materials, but its edition of 500 copies is obviously insufficient for our country. Fundamental reference books of this kind are to be available at libraries of all higher- and secondary school institutions engaged in training of specialists in chemistry and chemical technology. Such books are to be accessible to teachers of chemistry and chemical disciplines of any level.

A. G. Morachevskii

Russian Journal of Applied Chemistry, Vol. 77, No. 12, 2004, p. 2043–2044. Translated from Zhurnal Prikladnoi Khimii, Vol. 77, No. 12, 2004, p. 2068.

BOOK REVIEWS

Naboichenko, S.S., Myamchenkov, S.V., and Karelov, S.V., *Mysh'yak v tsvetnoi metallurgii* (Arsenic in Nonferrous Metallurgy), Naboichenko, S.S., Ed., Yekaterinburg: Ural'sk. Otd. Ross. Akad. Nauk, 2004, 240 pp.

A certain amount of arsenic is contained in the form of various compounds in the majority of ores of heavy metals. As a rule, arsenic compounds are concentrated in the course of ore dressing or metallurgical processing of raw materials in various dumps, wastes, and wastewater. The existing methods for removal of arsenic from the production cycle are frequently far from satisfying the modern requirements to integrated use of raw materials and environment protection.

The book comprises an introduction, six chapters, and a bibliographic list. In the brief introduction (pp. 3 and 4), the authors emphasize that the integrated solution of the problem of utilization of arsenic in metallurgical processes includes a number of separate problems: expansion of its application fields, removal from technological processes, detoxication of arsenic-containing wastes, and purification of wastewater and technological gases to remove arsenic. The monograph being reviewed is devoted to finding ways to solve these problems.

The first chapter (pp. 5–53) contains general evidence concerning arsenic and its compounds and minerals. Also considered are the production and application fields of arsenic and its compounds, their hazard classes and toxicology.

The second chapter (pp. 54–111) summarizes technological evidence concerning the ways of removal of arsenic from the production cycle in processing of various ores and concentrates. In particular, the behavior of arsenic in manufacture of copper from oxidized and sulfide ores, in fire and electrolytic refining of copper, production of vitriol, manufacture of nickel and cobalt from various raw materials, processing of flotation zinc concentrates, and metallurgy of gold is considered.

The third chapter (pp. 112–118) very briefly discusses the published evidence concerning gas purification to remove arsenic. The fourth chapter (pp. 119–188) considers possible methods for purification of wastewater of varied nature to remove arsenic compounds. Quite a number of techniques are described: purification with manganese dioxide (pyrolusite), purification with compounds of calcium and iron(III), phosphate purification, precipitation of arsenic sulfides and sorption with sulfide minerals, use of inorganic and polymeric sorbents, extraction of arsenic compounds from acid solutions with tributyl phosphate, and electrolytic purification.

The fifth chapter (pp. 189–213) is devoted to processing of solid arsenic-containing wastes (dusts, sublimates formed in pyrometallurgy, products obtained in purification of gases to remove arsenic, precipitates formed in purification of wastewater, etc.). In view of the widely varying chemical composition of the solid products, their processing may present a highly complicated technological problem. The authors consider possible hydrometallurgical, pyrometalurgical, and combined methods. In the authors' opinion, the most promising, with account of the ecological requirements, are hydrometalurgical techniques. However, no versatile technology for processing of arsenic-containing metallurgical dusts has been developed yet.

The sixth chapter (pp. 214–24), which closes the monograph, discusses the important problem of burial of arsenic-containing wastes. According to the available published data, arsenic-containing substances constitute more than 97% of the whole amount of toxic wastes of nonferrous metallurgy. This means that transition to ecologically safer technologies for manufacture of nonferrous metals is impossible without finding a method for utilization of arsenic. At present, high-purity arsenic is manufactured in Russia in elimination of arsenic-containing chemical warfare, which will satisfy the demand for this element for many years to come. Recovery of arsenic from technological

1070-4272/04/7712-2043 © 2004 MAIK "Nauka/Interperiodica"

wastes of nonferrous metallurgy is economically unfeasible. The authors discuss possible variants of burial of arsenic compounds. The most appropriate way is to convert these compounds into a form that would rule out any possibility of contamination of the atmosphere and water reservoirs.

The bibliographic list (pp. 225–239) contains references to 309 studies of mostly domestic authors. The bibliographic descriptions of journal articles give their titles, which improves the information value of the bibliographic list. The monograph by S.S. Naboichenko and co-authors has a clearly pronounced technological orientation, its style of presentation makes it understandable for an exceedingly wide audience of engineers and technical workers at plants of nonferrous metallurgy. The book contains a vast body of reference data and a large number of examples of industrial nature; it is well published.

Russian Journal of Applied Chemistry, Vol. 77, No. 12, 2004, pp. 2045–2046. Translated from Zhurnal Prikladnoi Khimii, Vol. 77, No. 12, 2004, pp. 2069–2070.

INFORMATION

XIII Russian Conference on Physical Chemistry and Electrochemistry of Molten and Solid Solutions

On September 27 through October 1, 2004, in Yekaterinburg was held XIII Russian conference on physical chemistry and electrochemistry of molten and solid solutions. The organizers of the conference included: Scientific Council for electrochemistry, Russian Academy of Sciences; Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences; and Russian Foundation for Basic Research. Two hundred and seventy reports were submitted to the conference, extended abstracts of these reports are grouped in two volumes. The first of these (284 pp.) includes materials of 170 reports devoted to physical chemistry and electrochemistry of molten electrolytes, and the second volume (141 pp.), abstracts of reports concerned with solid electrolytes. In each volume, materials of plenary sessions and key reports delivered at sections are given separately.

More than 60% of all the reports were delivered by staff members of research institutes and higher-school institutions of Yekaterinburg. The leading position was occupied by the Institute of High-Temperature Electrochemistry (IVTE), Ural Division, Russian Academy of Sciences. Founded in 1958, the Institute of Electrochemistry (since 1992, Institute of High-Temperature Electrochemistry) has become a prominent reasearch center specialized in physical chemistry and electrochemistry of inorganic substances in the molten and solid state, molten and solid electrolytes. The investigations performed at IVTE are known worldwide. Large-scale investigations of high-temperature systems are also being conducted in Yekaterinburg at the Ural State Technical University and at the Institute of Metallurgy, Ural Division, Russian Academy of Sciences. A large number of reports were presented by staff members of Russia's research centers traditionally conducting investigations in the field of high-temperature electrochemistry. To these belong, in particular, the following: Institute of Chemistry and Technology of Rare Elements and Mineral Resources, Kola Scientific Center, Russian Academy of Sciences (Apatity); Kabardino-Balkar State University (Nalchik); Daghestan State University and Daghestan Scientific Center, Russian Academy of Sciences (Makhachkala); North-Caucasian State Technical University (Stavropol); Vyatka State University (Kirov). Among the authors or co-authors of quite a number of reports were scientists from Great Britain, Hungary, Italy, Netherlands, United States, France, Czech Republic, Japan, and also from Kazakhstan and Ukraine.

Opening the conference, the chairman of the Organizing Committee V.A. Khohlov (Yekaterinburg) emphasized that high-end technologies employing molten and solid electrolytes will play a steadily increasing role in solution and implementation of basic practical problems governing the technical progress in the XXI century: manufacture of new materials with prescribed properties; electrochemical power engineering ensuring direct and the most efficient interconversion of chemical and electrochemical kinds of energy; and deep processing of natural raw materials and those of technological origin, including regeneration of the nuclear fuel and processing of the radioactive waste.

Among the plenary and key sectional reports devoted to physical chemistry and electrochemistry of molten salts, the following can be mentioned. V.Ya. Kudyakov with a large group of co-authors (Yekaterinburg) analyzed the involvement of IVTE, in cooperation with other institutions, in the State program "The Strategy of development of nuclear power engineering in Russia till the middle of the XXI century." The report submitted by N.N. Batalov (Yekaterinburg) was devoted to achievements and difficulties in the development of chemical power cells with molten electrolytes. Kh.B. Kushkhov (Nalchik) considered the problem of manufacture of rare-earth metals, their alloys, and other formulations with the use of ionic melts. V.N. Prusakov discussed in his report the prospects for application of fluoride melts in regeneration of irradiated nuclear fuel. A.I. Afinogenov and co-authors (Yekaterinburg) demonstrated the possibility of using ionic-electronic melts as a medium for obtaining thermodiffusion coatings and powdered alloys. P.V. Polyakov discussed in detail in his report the tendencies in the development of the aluminum industry. Yu.P. Zaikov and co-authors (Yekaterinburg) considered the topical and rather promising problem of development of nonconsumable anodes for manu-

1070-4272/04/7712-2045 © 2004 MAIK "Nauka/Interperiodica"

facture of aluminum by electrolysis. In the authors' opinion, it is necessary to create new electrolytes with a melting point not higher than 800°C and solubility of alumina in the electrolyte not lower than 3–5 wt %.

O.I. Rebrin (Yekaterinburg) noted the broad informational opportunities furnished by the galvanostatic method of investigation of electrode processes with the use of modern equipment. A number of reports by O.M. Shabanov and co-authors were devoted to investigations of the influence exerted by strong electric fields on the physical properties of molten salts.

Sectional and poster reports devoted to investigations in the field of physical chemistry and electrochemistry of molten salts are grouped in the book of abstracts as follows: I. Theory and properties of molten electrolytes (43 reports); II. Phase equilibria (5); III. Interphase phenomena (6); IV. Electrochemical thermodynamics (6); V. Kinetics of electrode processes (42); VI. Reactions in melts (46); and VII. Processes and apparatus (12).

Quite a number of problems of current interest were analyzed in reports containing results of theoretical and experimental studies of thermodynamic, structural, and transport properties of solid electrolytes. A.B. Yaroslavtsev and co-authors (Moscow) reported new data on the ionic mobility and phase transitions in complex phosphates of polyvalent elements. A.K. Ivanov-Shits (Moscow) reviewed results of molecular-dynamic calculations of structural, thermodynamic, and kinetic characteristics of a number of ionic crystals and main classes of solid electrolytes with both cationic and anionic conduction. The report by S.I. Somov (Yekaterinburg) analyzed the practical application of solid electrolytes: in chemical power cells, in ionistors and capacitors, and in sensors for chemical analysis of gaseous and liquid media in the laboratory and technological practice. E.I. Burmakin (Yekaterinburg) reported results obtained in synthesis and studies of the crystal-chemical and transport properties of electrolytes with high conductivity by cations of alkali metals, which belong to the so-called skeleton structures. Complex oxygen-containing anions form a rigid three-dimensional skeleton whose voids accommodate highly mobile alkaline cations. The report by A.K. Demin (Yekaterinburg) was devoted to electrochemical power engineering based on solid oxide conductors. L.D. Yushina (Yekaterinburg) considered problems and promises of the solid-state chemotronics. A number of reports were devoted to solid electrolytes with protonic conduction.

The conference demonstrated that, despite all the difficulties encountered in the last 15 years by virtually all research groups in Russia, investigations in the field of physical chemistry and electrochemistry of molten salts and solid electrolytes are being performed at a sufficiently high level and cover quite a number of promising areas of research. Exchange of scientific information is performed on the regular basis. The coordination center of these investigations is the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences.

A. G. Morachevskii
